1,2,3,4-Dibenzylidene-D-sorbitol

BY JOHN K. WOLFE, RAYMOND M. HANN AND C. S. HUDSON

In 1890 Meunier[1] reported that two dibenzylidene-D-sorbitols could be obtained by the condensing action of strong mineral acids on a mixture of benzaldehyde and sirupy D-sorbitol. One of these diacetals was a colorless powder (m. p. 162°) which was insoluble even in boiling water; the second one was soluble in boiling water and deposited from the cooled aqueous solution in the form of a gel, which could be dried to a powder melting at 200°. The present communication outlines the experimental procedures necessary to obtain the latter compound in pure condition and describes the reactions which lead to the definitive conclusion that its structure is that of 1,2,3,4-dibenzylidene-D-sorbitol. Under the experimental conditions which were employed, we did not encounter the compound reported as melting at 162°.

Initial efforts to obtain a dibenzylidene-D-sorbitol by condensation of *two* molecular equivalents of benzaldehyde with one equivalent of D-sorbitol through the influence of various concentrations of hydrochloric acid yielded a mixture of tribenzylidene-D-sorbitol and a gel which could not be readily separated into its components. However, when only *one* equivalent of benzaldehyde was employed and the condensing agent was 4 *N* hydrochloric acid, no formation of tribenzylidene-sorbitol was observed and the resulting condensate contained a small amount of the 2,4-monobenzylidene-D-sorbitol described by Vargha,[2] together with a second product which could be converted in high yield (88%) to a crystalline dibenzoyl-dibenzylidene-D-sorbitol. This pure recrystallized dibenzoate, upon debenzoylation in chloroform solution with sodium methylate, yielded a gel which could be dried to a cryptocrystalline powder analyzing correctly for a dibenzylidene-hexitol and showing a melting point of 219–221° (cor.) and a specific rotation $[\alpha]^{20}D$ of +21.6° in pyridine. A second portion of the crude dibenzylidene-D-sorbitol was converted to a crystalline diacetyl-dibenzylidene-D-sorbitol, and the latter compound, upon deacetylation, regenerated dibenzylidene-D-sorbitol agreeing in melting point and rotation with that obtained from the dibenzoate. The diacetal that was obtained from the crystalline diacetate was in turn converted in high yield (95%) to dibenzoyl-dibenzylidene-D-sorbitol which was identical with the dibenzoate previously mentioned. These interconversions leave no doubt that the dibenzylidene-D-sorbitol of m. p. 219–221° is a single chemical entity and not a mixture of isomers. The problem of establishing its structure was first studied through its reaction with lead tetraacetate in glacial acetic acid solution. It was observed that one molecular equivalent of lead tetraacetate was reduced in three hours and that an additional four molecular equivalents were slowly consumed over a period of twelve days; these results suggested that a glycol group was oxidized in the

(1) Meunier, *Ann. chim. phys.*, [6] **22**, 412 (1891).

(2) Vargha, *Ber.*, **68**, 23, 1337 (1935).

initial stage of the reaction and that the primary oxidation products were then slowly attacked by the reagents and further oxidized. A second oxidation was therefore interrupted at the end of four hours, and the oxidation products isolated at once; they proved to be formaldehyde and an aldehydo-dibenzylidene-pentose (isolated as a crystalline methyl hemiacetal). These results limited the structure of the dibenzylidene-D-sorbitol to 1,2,3,4-dibenzylidene-D-sorbitol or 3,4,5,6-dibenzylidene-D-sorbitol. Decision between these two structures depended upon whether the aldehydo-dibenzylidene-pentose was aldehydo-2,3,4,5-dibenzylidene-L-xylose or aldehydo-2,3,4,5-dibenzylidene-D-arabinose. The methyl hemiacetal was therefore subjected to acid hydrolysis; the resulting pentose sugar proved to be L-xylose as shown by its melting point, final rotation and mutarotation rate; the L-xylose was further characterized by conversion to its phenylosazone and phenylosazone triacetate, which were found to be enantiomorphs of the corresponding derivatives of D-xylose. The identity of the pentose with L-xylose is a definite proof that the aldehydo-dibenzylidene-pentose, obtained by oxidation of dibenzylidene-D-sorbitol, is aldehydo-2,3,4,5-dibenzylidene-L-xylose and this fact limits the structure of the dibenzylidene-hexitol to that of 1,2,3,4-dibenzylidene-D-sorbitol. Supporting evidence for this structure was obtained by the observation that dibenzylidene-D-sorbitol, upon reaction with two equivalents of triphenylmethyl chloride under mild conditions, yielded a mono-trityl derivative, a result which indicated that a single primary hydroxyl group was present in the diacetal. Attention has previously[3] been directed to the difficulty of assigning a definitive structural and stereochemical formula to a dibenzylidene-hexitol. Although Vargha[2] has demonstrated that monobenzylidene-D-sorbitol is 2,4-monobenzylidene-D-sorbitol, we have not succeeded in condensing it with further amounts of benzaldehyde to yield the dibenzylidene-D-sorbitol melting at 219–221° (cor.), and it is possible at the present time, therefore, to designate the latter compound only as 1,2,3,4-dibenzylidene-D-sorbitol.

We express our appreciation to Dr. A. T. Ness for performing the microchemical analyses and to Dr. C. P. Saylor, of the National Bureau of Standards, for assistance in the microscopic examination of 1,2,3,4-dibenzylidene-D-sorbitol, which showed the substance to be cryptocrystalline.

Experimental

5,6-Dibenzoyl-1,2,3,4-dibenzylidene-D-sorbitol.—To a solution of 10.0 g. of crystalline D-sorbitol in a mixture of 10 cc. of water and 5 cc. of concentrated hydrochloric acid, 5 cc. of benzaldehyde (1.1 molecular equivalents) was added; the reaction mixture, upon agitation at room temperature, formed a homogeneous solution which set to a gel after one hour. The next day the mass was broken into small pieces, transferred to a Büchner funnel, washed successively with water and ether, and dried; the dry powder was pulverized and leached with 100 cc. of boiling water and the undissolved solid was separated by filtration and dried to constant weight. The yield was 7.1 g. (70% based on the benzaldehyde used). The substance was dissolved in 35 cc. of pyridine and after addition of 15 cc. of benzoyl chloride the mixture was allowed to stand overnight at room temperature; the next day 200 g. of ice was added and the gummy precipitate of dibenzoate which formed, crystallized slowly. The compound deposited from its solution in 10 parts of alcohol in the form of long silky needles, which melted at 195–196° (cor.) and exhibited a specific rotation[4] of $-41.5°$ (c, 0.69) in chloroform.

Anal. Calcd. for $C_{34}H_{30}O_8$: C, 72.06; H, 5.34; C_6H_5CO, 37.1. Found: C, 72.14; H, 5.28; C_6H_5CO, 36.4.

1,2,3,4-Dibenzylidene-D-sorbitol.—A solution of 91.0 g. of 5,6-dibenzoyl-1,2,3,4-dibenzylidene-D-sorbitol in 700 cc. of chloroform was cooled in ice and 50 cc. of 0.1 N sodium methylate in methanol solution was added. After eighteen hours the gel which had formed was dried *in vacuo* at 65° to remove the chloroform and methyl benzoate, and the residual powder was washed with water and dried. The yield was 57.0 g. (99%). The compound melted at 219–221° (cor.) and showed a specific rotation of $+21.6°$ (c, 1.04) in pyridine. The substance was soluble in warm ethyl alcohol, methyl alcohol, acetone, and acetic acid, but the solutions on cooling deposited gels. The homogeneity of the material was demonstrated, however, by repeated solution and recovery from 65 parts of alcohol; the material recovered after three such treatments, agreed in melting point and rotation with the original sample and also with 1,2,3,4-dibenzylidene-D-sorbitol obtained by the deacetylation of the crystalline 5,6-diacetyl-1,2,3,4-dibenzylidene-D-sorbitol that is described in the following paragraph.

Examination of the substance under the petrographic microscope by Dr. C. P. Saylor of the National Bureau of Standards revealed that little or no birefringence was detectable in mounts prepared with aqueous media, presumably because of extensive scattering of light by dust of the compound covering the surface of the crystals. However, mounts in liquids of higher refractive index (methyl phthalate, aniline) allowed observation of the high birefringence characteristic of the compound. Since there were complex changes of optical crystallographic direction within the crystal units, the compound may be designated as cryptocrystalline.

(4) All of the crystalline compounds described in the experimental part were recrystallized to constant melting point and specific rotation, $[\alpha]^{20}D$; c is the concentration in grams in 100 cc. of solution; the tube length was 4 dm.

Anal. Calcd. for $C_{20}H_{22}O_6$: C, 67.04; H, 6.19. Found: C, 67.08; H, 6.23.

5,6-Diacetyl-1,2,3,4-dibenzylidene-D-sorbitol.— A solution of 2.0 g. of 1,2,3,4-dibenzylidene-D-sorbitol (obtained by debenzoylation of 5,6-dibenzoyl-1,2,3,4-D-sorbitol) in a mixture of 5 cc. of pyridine and 5 cc. of acetic anhydride was heated on the steam-bath for one hour and then cooled and poured upon crushed ice. The yield of 2.35 g. (95%) of diacetate was recrystallized from 15 parts of acetone and it deposited in prisms which melted at 202–205° (cor.) and rotated +4.1° (*c*, 0.95) in chloroform. Upon deacetylation with sodium methylate, 1,2,3,4-dibenzylidene-D-sorbitol, agreeing in rotation and melting point with the compound prepared from the dibenzoate, was obtained in a 93% yield.

Anal. Calcd. for $C_{24}H_{26}O_8$: C, 65.15; H, 5.92; CH_3CO, 19.4. Found: C, 65.25; H, 5.94; CH_3CO, 19.2.

5,6-Dibenzoyl-1,2,3,4-tetraacetyl-D-sorbitol.—A solution of 1.25 g. of 5,6-dibenzoyl-1,2,3,4-dibenzylidene-D-sorbitol in 50 cc. of an acid acetylating solution (prepared by adding 1 cc. of concentrated sulfuric acid dropwise to an ice-cold mixture of 35 cc. of acetic anhydride and 15 cc. of acetic acid) was allowed to stand at 20° for twenty-four hours. The reaction mixture was poured upon crushed ice and the thick sirup which precipitated was washed several times with water and dissolved in warm alcohol. As the solution cooled it deposited 5,6-dibenzoyl-1,2,3,4-tetraacetyl-D-sorbitol (0.95 g., 73%) in the form of prisms. After two recrystallizations from 6 parts of alcohol, the substance melted at 96–97° (cor.) and showed a specific rotation of +14.4° (*c*, 0.48) in chloroform.

Anal. Calcd. for $C_{24}H_{26}O_8$: C, 60.21; H, 5.42; sapn. titer, 10.7 cc. of 0.1 *N* alkali for 100 mg. Found: C, 60.34; H, 5.43; sapn. titer, 10.5 cc. of 0.1 *N* alkali for 100 mg.

5,6-Ditosyl-1,2,3,4-dibenzylidene-D-sorbitol.—Five grams of 1,2,3,4-dibenzylidene-D-sorbitol was dissolved in 15 cc. of absolute pyridine on the steam-bath and the solution was then cooled to 0° to form a gel; to this gel an ice-cold solution of 6.0 g. of *p*-toluenesulfonyl chloride in 10 cc. of pyridine was added and the reaction mixture was agitated vigorously at 0° for three hours and then allowed to stand at 15° for a further eighteen hours. The solution was then poured over crushed ice and the precipitated ditosylate (7.9 g., 84%) was recrystallized from a mixture of 10 parts of alcohol and 4.5 parts of acetone. The compound crystallized in cotton-like needles, which showed a specific rotation of +1.2° (*c*, 0.6) in acetone. The melting point of the compound varied with the rate of heating; when the bath was heated at a rate of 1° in three minutes, it melted at 155–156°, at a rate of 2° in one minute the melting point was 159–160° (cor.). When the tosylation was conducted at a temperature higher than 15°, the mixture of products which was obtained gave a strong Beilstein test for halogen, indicating that some substitution of chlorine had occurred.

Anal. Calcd. for $C_{34}H_{34}O_{10}S_2$: C, 61.24; H, 5.14. Found: C, 61.12; H, 5.29.

6-Trityl-1,2,3,4-dibenzylidene-D-sorbitol.—A solution of 2.0 g. of 1,2,3,4-dibenzylidene-D-sorbitol and 3.4 g. (2.2 molecular equivalents) of triphenylmethyl chloride in 15 cc. of pyridine was allowed to stand at room temperature for seventy-two hours. The mixture was poured into 100 cc. of ice water and the supernatant liquor, which contained crystalline triphenylcarbinol, was decanted from the insoluble gummy trityl derivative. The latter material was suspended in 50 cc. of cold alcohol and in the course of one week it crystallized in a yield of 3.3 g. (96%). This product was recrystallized twice from 10 parts of ethyl acetate and formed elongated prisms which melted slowly over a range of 110–115° (cor.) to a clear oil, then solidified in the form of needles and remelted at 182–183° (cor.). This behavior is exhibited only by material freshly crystallized from ethyl acetate; after drying at 50° overnight, the transition to the needle form is complete and only the higher melting point is observed; apparently the substance is dimorphic. The needles gave a specific rotation of +16.8° (*c*, 0.6) in ethyl acetate.

Anal. Calcd. for $C_{42}H_{38}O_7$: C, 76.61; H, 5.96. Found: C, 76.54; H, 6.01.

5-Acetyl-6-trityl-1,2,3,4-dibenzylidene-D-sorbitol.—This compound was obtained in quantitative yield by the action of acetic anhydride and pyridine on 6-trityl-1,2,3,4-dibenzylidene-D-sorbitol. It deposited from its solution in 80 parts of alcohol in long needles which melted at 117–119° (cor.) to a clear oil, then resolidified in the form of plates and remelted at 186–187° (cor.). The lower melting form showed no change on preservation at room temperature for several months. It exhibited specific rotations of −41.8° (*c*, 0.6) in ethyl acetate and −46.5° (*c*, 0.4) in chloroform.

Anal. Calcd. for $C_{42}H_{38}O_7$: C, 76.61; H, 5.96; CH_3CO, 6.58. Found: C, 76.54; H, 6.01; CH_3CO, 6.25.

Lead Tetraacetate Oxidation of 1,2,3,4-Dibenzylidene-D-sorbitol.—A sample of 0.1198 g. of 1,2,3,4-dibenzylidene-D-sorbitol was dissolved in 20 cc. of glacial acetic acid, and after the addition of 16.22 cc. of 0.0904 *M* lead tetraacetate (2.2 molecular equivalents) in glacial acetic acid, the volume was adjusted to 50 cc. with glacial acetic acid. Analysis of 5-cc. aliquots at the expiration of fifteen and thirty minutes, one, three and nineteen hours showed that 0.43, 0.63, 0.79, 0.97 and 1.15 molecular equivalents of oxidant had been consumed. In a second experiment, 5.5 molecular equivalents of lead tetraacetate were added and it was observed that 1.0 equivalent was reduced in a period of three hours and a further 4.0 equivalents was reduced very slowly over a period of twelve days. The rapid reaction was due to the oxidation of the glycol grouping at carbons five and six (see the following section) and the slower one occurred presumably as a result of a slow hydrolysis of the benzylidene groups and subsequent oxidation of the hydrolysis products. The final consumption of lead tetraacetate (5.0 molecular equivalents) agreed with that expected for such a series of reactions.

Isolation of Aldehydo-2,3,4,5-dibenzylidene-L-xylose Methyl Hemiacetal.—A suspension of 21.5 g. of 1,2,3,4-dibenzylidene-D-sorbitol and 40 g. of pulverized lead tetraacetate (1.1 molecular equivalents) in 400 cc. of glacial acetic acid was agitated vigorously for four hours with occasional cooling to maintain the temperature below 25°; the amorphous reaction product was separated by filtration, pulverized and dried over potassium hydroxide until free of acetic acid. The product (21.2 g.), which was

sufficiently pure for synthetic operations, was dissolved in a warm mixture of 100 cc. of methyl alcohol and 100 cc. of chloroform and as the solution cooled it deposited the methyl hemiacetal of aldehydo-2,3,4,5-dibenzylidene-L-xylose in the form of needles. The compound, after recrystallization to constant rotation from 80 parts of a 1:1 mixture of methyl alcohol and chloroform, melted at 187–188° (cor.) and exhibited a rotation of +40.4° (*c*, 0.46) in pyridine. The yield of hemiacetal was 15.0 g. (70%).

Anal. Calcd. for $C_{20}H_{22}O_6$: C, 67.03; H, 6.19; OCH_3, 8.65. Found: C, 67.05; H, 6.38; OCH_3, 8.38.

Identification of Formaldehyde as an Oxidation Product.—The acetic acid filtrate from the oxidation mixture was refluxed while a gentle current of carbon dioxide was passed through it; the gas was led through an efficient condenser and into 100 cc. of ice-cold water. At the end of six hours, an aliquot of the aqueous solution was tested with dimethyl-dihydroresorcinol; the characteristic formaldimethone which formed, melted at 189–190° (cor.) and no depression of the melting point was observed upon admixture with authentic formaldimethone.

Aldehydo-2,3,4,5-dibenzylidene-L-xylose.—A sample of the methyl hemiacetal of aldehydo-2,3,4,5-dibenzylidene-L-xylose was sublimed in a vacuum at 140–145° and the sublimate, which was partially crystalline, was recrystallized from 5 parts of dioxane. The compound was obtained in the form of small needles which melted at 186–187° (cor.) and showed a rotation of −33.4° (*c*, 0.52) in pyridine.

Anal. Calcd. for $C_{19}H_{18}O_5$: C, 69.93; H, 5.56. Found: C, 69.84; H, 5.66.

Aldehydo-2,3,4,5-dibenzylidene-L-xylose Oxime.—A suspension of 1.0 g. of aldehydo-2,3,4,5-dibenzylidene-L-xylose in a solution containing 25 cc. of methanol, 5 cc. of water, 1.0 g. of hydroxylamine hydrochloride and 1.0 g. of fused sodium acetate was refluxed for twenty minutes, during which period complete solution occurred; the crystalline product, which deposited as the solution cooled, was recrystallized from 240 parts of alcohol and yielded 0.9 g. (86%) of oxime in the form of colorless needles which melted with decomposition at 239–240° (cor.) and gave a rotation of −108.9° (*c*, 0.41) in pyridine.

Anal. Calcd. for $C_{19}H_{19}NO_5$: C, 66.85; H, 5.61; N, 4.10. Found: C, 66.86; H, 5.57; N, 4.28.

L-Xylose from Aldehydo-2,3,4,5-dibenzylidene-L-xylose Methyl Hemiacetal.—A suspension of 10.6 g. of 1,2,3,4-dibenzylidene-L-xylose methyl hemiacetal in a mixture of 280 cc. of methyl alcohol, 15 cc. of water and 3 cc. of concentrated hydrochloric acid was refluxed for one hour, during which time complete solution occurred and a strong odor of benzaldehyde developed. The solution, following the removal of the hydrochloric acid by silver carbonate in the usual manner, was concentrated *in vacuo* to a sirup, presumably a mixture of α- and β-methyl-L-xylosides. The sirup, which resisted crystallization, was dissolved in 100 cc. of 1% sulfuric acid and hydrolyzed for two hours on the steam-bath. The acid was neutralized with barium hydroxide and the neutral solution concentrated *in vacuo* to a sirup, which deposited crystalline L-xylose upon treatment with 3 cc. of glacial acetic acid. The yield was 1.7 g. (40%). The pentose melted at 143–145° (cor.) and gave an extrapolated initial rotation of −92° and an equilibrium value of −19.4° (*c*, 0.88) in aqueous solution. Its mutarotation rate at 20° was 20.2 × 10^{-3}, which agrees with the known rate for D-xylose. Vargha[2] records a melting point of 144° and initial and equilibrium rotations of −79.3° and −18.6°, respectively, for the L-xylose which he prepared by the lead tetraacetate oxidation of 2,4-benzylidene-D-sorbitol. Isbell[5] reports an initial rotation of +94.8° and an equilibrium rotation of +18.3° for a 4.4% aqueous solution of D-xylose.

Anal. Calcd. for $C_5H_{10}O_5$: C, 40.00; H, 6.71. Found: C, 39.86; H, 6.57.

D,L-Xylose.—A mixture of 100 mg. each of D-xylose and L-xylose was dissolved in 2 cc. of warm methanol and diluted with 5 cc. of glacial acetic acid. The D,L-xylose (110 mg., 55%) obtained was optically inactive in aqueous solution and melted at 128–130° (cor.) in good agreement with the value of 129–131° recorded by Fischer[6] for D,L-xylose.

Racemic Xylose Phenylosazone.—A mixture of 0.5 g. of L-xylose, 1.5 cc. of phenylhydrazine, 1.0 cc. of acetic acid and 5 cc. of water was heated on the steam-bath for one hour. The L-xylose phenylosazone (yield, 0.8 g.; 74%) was recrystallized from aqueous acetone and obtained as fine yellow needles melting at 161–163° (cor.). Reichstein, Grüssner and Oppenauer[7] reported a melting point of 160–162° (cor.) for D-xylose phenylosazone. A mixture of 100 mg. each of D- and L-xylose phenylosazones was dissolved in 10 cc. of warm acetone; the precipitate (171 mg.; 85%), which formed on cooling the solution, was recrystallized from 10 cc. of acetone and obtained as fine needles which decomposed at 207° (cor.) and were devoid of optical activity in pyridine solution. These properties are in substantial agreement with those reported by Fischer[6] for the racemic xylose phenylosazone which he obtained from D,L-xylose and also from the oxidation of xylitol.

Anal. Calcd. for $C_{17}H_{20}O_3N_2$: C, 62.18; H, 6.14. Found: C, 62.30; H, 6.13.

L-Xylose Phenylosazone Triacetate.—This compound was obtained in a yield of 0.672 g. (97%) by acetylation of L-xylose phenylosazone (0.5 g.) in a mixture of 3 cc. of pyridine and 2 cc. of acetic anhydride. The substance was recrystallized by solution in 12 parts of alcohol and the gradual addition of 8 parts of water. It was obtained in fine yellow needles which melted at 116–117° (cor.) and rotated +44.3° (*c*, 0.34) in chloroform. Percival and Percival[8] reported a melting point of 116–117° and a specific rotation $[\alpha]^{16}D$ of −46° for the D-form. We find a melting point of 116–117° (cor.) and a specific rotation $[\alpha]^{20}D$ of −44.2° (*c*, 0.47) for D-xylose phenylosazone triacetate.

Racemic Xylose Phenylosazone Triacetate.—A mixture of 100 mg. each of the D- and L-forms of xylose phenylosazone triacetate was dissolved in 2 cc. of warm alcohol; upon addition of 1 cc. of water the racemate deposited from the solution in the form of fine yellow needles. The yield was 165 mg. (82%). The recrystallized compound was

devoid of optical activity in chloroform solution; it melted at 131–132° (cor.), which is much higher than the melting point of its components, from which fact it is evident that the crystalline substance is a true racemate.

Summary

D-Sorbitol, in solution with 4 *N* hydrochloric acid and *one* molecular equivalent of benzaldehyde, condenses to yield principally a cryptocrystalline dibenzylidene-D-sorbitol melting at 219–221°. The latter substance, upon oxidation with lead tetraacetate in glacial acetic acid, produces formaldehyde and aldehydo-2,3,4,5-dibenzylidene-L-xylose, which is conveniently isolated as a crystalline methyl hemiacetal. This hemiacetal is converted by acid hydrolysis to L-xylose, which was isolated as the crystalline sugar and further characterized by preparation of L-xylose phenylosazone; the latter compound combines with D-xylose phenylosazone to yield the long known racemic xylose phenylosazone. Also, L-xylose phenylosazone triacetate forms a true racemate with D-xylose phenylosazone triacetate.

The work constitutes a definitive proof that the structure of dibenzylidene-D-sorbitol is that of 1,2,3,4-dibenzylidene-D-sorbitol.

The Action of Alkali on Cyclohexenecarbonals[1]

BY H. E. FRENCH AND D. M. GALLAGHER

Although the cyclohexenecarbonals possess alpha hydrogens, one might reasonably expect reactions like those of the aromatic series toward alkaline reagents, because of the steric effect of the large radical attached to the alpha carbon. In order to test this supposition, we have investigated the reactions with several 3-cyclohexenecarbonals, particularly the 3,4,6-trimethyl derivative. Concentrated aqueous solutions of sodium or potassium hydroxide acted on this aldehyde forming a tripolymer. Similar tripolymers of cyclohexanecarbonal and of 3-cyclohexenecarbonal had previously been prepared by the action of mineral acids.[2] Saturated aqueous solutions of barium hydroxide gave very small yields of the polymer, most of the aldehyde being recovered. A cold 10% solution of potassium hydroxide in methyl alcohol was also without action on the aldehyde. At 70°, using a methyl alcohol–water solution, reaction took place with the formation of the corresponding acid and the alcohol. The acid had previously been prepared from ethyl crotonate and 2,3-dimethylbutadiene.[3] The structure of the alcohol was shown by its synthesis from the aldehyde using aluminum *iso*propoxide, and by carbon and hydrogen analyses of the naphthyl urethan.

Under similar conditions, 3,4-dimethyl-6-phenyl-3-cyclohexenecarbonal, 6-methyl-3-cyclohexenecarbonal, and 3-cyclohexenecarbonal were found to give the Cannizzaro reaction. In all cases the acids formed were known compounds[4] but the alcohols had not previously been reported. These were identified by their syntheses from the aldehydes using aluminum isopropoxide, and analyses of their phenyl or naphthyl urethans. Yields of the pure acids were of the order of 80%. Varying amounts of polymerization products were obtained if the temperature of reaction was much in excess of 70°.

Freshly distilled 6-methyl-3-cyclohexenecarbonal gave but a trace of reaction in the usual reaction time, while aldehyde used after long standing, or through which air had been bubbled, readily entered into the reaction. This is in accord with the observation that peroxide is a catalyst for the Cannizzaro reaction.[5]

Each of the aldehydes was dissolved in aqueous methyl alcohol and heated to approximately 70° with potassium hydroxide and formalin solution. Diols, in yields of from 50 to 60% of the pure redistilled or recrystallized compounds, were obtained in all cases. The formation of these compounds presumably follows the course indicated by the equation

The molecular weight of 3,4,6-trimethyl-3-cyclohexene-1,1-dicarbonol in camphor and in dioxane was found to be 184 and 183.5, respectively, and in the Grignard machine was found to possess two active hydrogens. Each of the diols combined with two molecules of phenyl isocyanate to yield crystalline urethans. The ring unsaturation of the 3-cyclohexene-1,1-dicarbonol was reduced, and on oxidation the known cyclohexane-1,1-dioic acid was obtained.[6]

Experimental

The cyclohexenecarbonals were prepared by the Diels–Alder condensation, and their properties corresponded to those given in the literature for the pure compounds.

3,4,6-Trimethyl-3-cyclohexenecarbonal with Alkali.—Twelve and one-half grams of the aldehyde was allowed to stand for twenty-four hours at room temperature with a solution of 20 g. of potassium hydroxide in 12.5 cc. of water. An insoluble oil was then separated from the aqueous layer and washed with water. In the course of a month this oily material partly solidified. The pasty mass was filtered with suction and was washed with ethyl alcohol. The white solid thus obtained was found to be soluble in benzene and in acetone, and insoluble in ethyl alcohol and in ether; white, powdery material from acetone; m. p. 132–134°; molecular weight in benzene, 482; molecular weight of the original aldehyde, 152; yield of polymer, 2 g.

A solution containing 20 g. of the aldehyde in 20 cc. of ether was shaken for forty-eight hours at room temperature with 20 cc. of a saturated solution of barium hydroxide in water. Practically all of the aldehyde was recovered from the ether solution as the bisulfite compound, together with a trace of an oily material, presumably a polymer of the aldehyde.

A solution of 10 g. of the aldehyde in 20 cc. of methyl alcohol was shaken for three days at room temperature with 10 cc. of a 10% solution of potassium hydroxide in methyl alcohol. Eight and a half grams of the aldehyde was recovered.

The Cannizzaro Reaction.—The following procedure is typical for the Cannizzaro reactions using the various aldehydes. A solution of 9 g. of potassium hydroxide in 5.5 cc. of water was added rapidly to 8.5 g. of the aldehyde in 11 cc. of methyl alcohol, with mechanical stirring at 65–75° for two hours. At temperatures much in excess of 75°, considerable polymerization occurred. Addition of an equal volume of water caused the separation of a second layer, which was extracted with ether. After drying, the ether and methyl alcohol were removed on the water-bath. Vacuum distillation of the residue gave the carbinols as colorless liquids which readily formed urethans with α naphthyl isocyanate. In each case the identity of the carbinol was demonstrated by its synthesis from the aldehyde with aluminum isopropoxide and a comparison of the urethans. The acids were obtained from the alkaline solutions remaining after the ether extraction, in yields which were generally of the order of 78%. Melting points of the acids were found to correspond to those given in the literature for those compounds.

3,4-Dimethyl-6-phenyl-3-cyclohexenecarbonol.—Naphthyl urethan; white crystals from petroleum ether; m. p. 110–111°.

Anal. Calcd. for $C_{26}H_{27}O_2N$: C, 81.03; H, 7.01. Found: C, 80.84; H, 7.32.

6-Methyl-3-cyclohexenecarbonol.—Phenyl urethan; white crystals; m. p. 83°. *Anal.* Calcd. for $C_{15}H_{19}O_2N$: N, 5.71. Found: N, 5.86.

3-Cyclohexenecarbonol.—Naphthyl urethan; white crystals from petroleum ether; m. p. 106°.

Anal. Calcd. for $C_{18}H_{19}O_2N$: C, 76.86; H, 6.76. Found: C, 76.92; H, 6.94.

3,4,6-Trimethyl-3-cyclohexenecarbonol.—Naphthyl urethan; white crystals from petroleum ether; m. p. 112°.

Anal. Calcd. for $C_{21}H_{25}O_2N$: C, 78.01; H, 7.74. Found: C, 78.35; H, 8.05.

The Cross Cannizzaro Reaction.—The following represents a typical reaction for these aldehydes. A mixture of 8 g. of the aldehyde, 10 cc. of methyl alcohol, and 5 cc. of formalin in a 3-neck flask equipped with dropping funnel, motor stirrer, and reflux condenser was heated to 70°, and maintained at that temperature while a solution of 8.4 g. of potassium hydroxide in 6 cc. of water was added. The mixture was heated at 70° for forty minutes, then refluxed for one hour. The reaction mixture was cooled, diluted with an equal volume of water, and extracted with ether. From this ether solution the diol was obtained. The unsubstituted and the monomethyl substituted compounds were obtained as oils which solidified after vacuum distillation and standing for several hours in an ice chest. The others were obtained as crystalline compounds, and were recrystallized from petroleum ether. The diols were obtained in yields of 50–60% of the pure compounds. In each case the diol combined with two molecules of phenyl isocyanate, yielding crystalline urethans which were recrystallized from dilute alcohol.

3,4,6-Trimethyl-3-cyclohexene-1,1-dicarbonol.—White crystals; m. p. 86.5°; molecular weight in camphor, 184; in dioxane, 183.5; calcd. for $C_{11}H_{20}O_2$, 184; active hydrogens, 1.91; urethan, m. p. 121.5–123°.

Anal. Calcd. for $C_{25}H_{30}O_4N_2$: C, 71.09; H, 7.10. Found: C, 71.01; H, 7.34.

3,4-Dimethyl-6-phenyl-3-cyclohexene-1,1-dicarbonol.—White crystals; m. p. 131.5°; phenyl urethan, m. p. 166°.

Anal. Calcd. for $C_{30}H_{32}O_4N_2$: C, 74.36; H, 6.61. Found: C, 74.22; H, 6.85.

6-Methyl-3-cyclohexene-1,1-dicarbonol.—White crystals; m. p. 45°; phenyl urethan, m. p. 150°.

Anal. Calcd. for $C_{23}H_{26}O_4N_2$: C, 70.05; H, 6.59; N, 7.10. Found: C, 70.28; H, 6.53; N, 7.06.

(6) Wightman, *J. Chem. Soc.*, 2541 (1926).

3-Cyclohexene-1,1-dicarbonol.—White crystals; m. p. 92.5°; phenyl urethan, m. p. 118.5°.

Anal. Calcd. for $C_{22}H_{24}O_4N_2$: C, 69.45; H, 6.36. Found: C, 69.29; H, 6.57. Active hydrogens in the diol, 1.81.

Hydrogenation of 3,4,6-Trimethyl-3-cyclohexene-1,1-dicarbonol.—The compound was reduced at 2500 lb. pressure at 150°, using Raney nickel, to the known cyclohexane-1,1-dicarbonol, m. p. 95–96°.[7]

Oxidation of Cyclohexane-1,1-dicarbonol.—Oxidation with potassium permanganate in neutral and in alkaline solutions, using water and water–acetone solvents, gave only uncrystallizable oils. Nitric acid oxidation gave a small yield of a solid acid which was not identified.

1.7 g. of the diol was dissolved in 10 cc. of pyridine. A solution of 5.5 g. of potassium permanganate in 110 cc. of water was added with stirring, at a temperature of 0°. The mixture was stirred for eight hours at that temperature and allowed to warm slowly to room temperature. The excess permanganate was discharged with 1 cc. of ethyl alcohol. After filtering, the solution was concentrated on a water-bath to 10 cc. using vacuum. Hydrochloric acid was added and the solution placed in the ice chest. A yield of 0.8 g. of the known cyclohexane-1,1-dioic acid was obtained.

(7) Franke and Sigmund, *Monatsh.*, **46**, 61 (1925).

Summary

1. The action of alkaline solutions on certain cyclohexenecarbonals has been studied.

2. These aldehydes were found to undergo the Cannizzaro reaction, and to react with formaldehyde to yield cyclohexene-1,1-dicarbonols.

Sulfanilamido Derivatives of Nitrogen Bases from California Petroleum[1]

BY LESLIE M. SCHENCK[2] AND HENRY R. HENZE

Bobranski[3] and Winterbottom[4] have reported syntheses in the sulfanilamidoquinoline series; however, no alkylation in the quinoline nucleus higher than methyl was included. Since detailed pharmacological tests of their compounds have not been published, it was considered of interest to prepare sulfanilamido derivatives of a series of alkylated quinoline homologs encountered in nitrogen bases extracted from California petroleum. Since quinolines substituted in positions 2, 3 and 8 occur in appreciable quantity among the complex petroleum base fractions, this series was selected for investigation. The compounds prepared in this work are sulfanilamido and acetylated sulfanilamido derivatives of 5-amino-2,3,8-trimethylquinoline, and of the hitherto unreported 5-amino-8-ethyl-2,3-dimethylquinoline and 5-amino-2,3-dimethyl-8-*n*-propylquinoline.

Through the courtesy and coöperation of Parke, Davis and Company, the 2,3,8-trimethyl and 2,3-dimethyl-8-*n*-propylquinoline sulfanilamido derivatives have received preliminary testing for possible pharmacological activity. No activity was found in mice infected with experimental Type I pneumococcus, *Staph. aureus* or *Strep. viridans*. The slight activity toward hemolytic streptococci indicates that the activity of sulfanilamide is lowered by substitution of the quinoline heterocycle at the N^1 position. Certainly the compounds here reported do not have the desirable properties obtained with other heterocycles such as pyridine, thiazole and pyrimidine.

Two of the new compounds reported herein have received preliminary testing for antimalarial activity (through the courtesy of Parke, Davis and Company). It is of interest to note the activity against avian malaria of 5-sulfanilamido-2,3,8-trimethylquinoline in the *blood*, whereas larger doses of this material are inactive in the tissue.

	Stage tested	Dose, mg.	Result
5-Sulfanilamido-2,3,8-trimethylquinoline	Blood	50	Active
	Tissue	100	Inactive
5-(N^4-Acetylsulfanilamido)-2,3-dimethyl-8-*n*-propylquinoline	Blood	50	Inactive

Experimental

2,3,8-Trimethyl-5-nitroquinoline.—Fourteen grams of 2,3,8-trimethylquinoline,[5] isolated from petroleum nitrogen bases, was converted to 2,3,8-trimethyl-5-nitroquinoline in accordance with Burger and Modlin.[6] There was obtained 13 g. of purified product, crystallizing from petroleum ether as pale yellow needles melting at 124° (cor.).

(6) Burger and Modlin, *ibid.*, **62**, 1079 (1940).

2,3,8-Trimethyl-5-aminoquinoline.—Burger and Modlin[6] report the preparation of this compound by reduction of the corresponding nitro derivative with stannous chloride and 17% hydrochloric acid. When their method was tried upon larger quantities of 2,3,8-trimethyl-5-nitroquinoline, the isolation was found unsatisfactory, and it was necessary to steam distil the amine from the reduction mixture and to recover it from the large volume of distillate by ether extraction.

As an alternate method, promising less difficulties in isolation and purification of the desired intermediate, 12.5 g. of 2,3,8-trimethyl-5-nitroquinoline (0.058 mole) was hydrogenated over Raney nickel catalyst at 70° and 1000 lb./sq. in. pressure for thirty minutes, employing ethyl alcohol as the solvent. The catalyst was removed by filtration, the solvent diluted with water and the precipitated amine crystallized from dilute ethyl alcohol to give a quantitative yield of 2,3,8-trimethyl-5-aminoquinoline melting at 110–111° (cor.) identical with that prepared by the more laborious method of Burger and Modlin.

5-(N_4-Acetylsulfanilamido)-2,3,8-trimethylquinoline.—The amine (0.059 mole) was dissolved in 100 cc. of pyridine which had been dried by prolonged contact with potassium hydroxide pellets. To the solution was added 18 g. (0.077 mole) of acetylsulfanilyl chloride which had been purified by crystallization from acetone–benzene and thoroughly dried through vacuum desiccation over calcium chloride. Heat was immediately developed, and the solution was agitated until all the acid chloride was in solution. At this point, the reaction mixture was heated three hours on the steam-bath, a calcium chloride tube being employed to protect against atmospheric moisture.

The crude 5-(N^4-acetylsulfanilamido)-2,3,8-trimethylquinoline was precipitated by pouring its pyridine solution into 500 cc. of ice water. Separating first as a highly discolored oil, the product soon solidified and was removed by filtration. One-half the product was purified by repeated treatment with Norite in boiling ethyl alcohol. The purified compound, prepared in 47% yield, crystallized from this solvent as hair-like needles melting undecomposed at 260.5–261.5° (cor.).

Anal. Calcd. for $C_{20}H_{21}N_3O_3S$: N, 10.95. Found: N, 10.78.

5-Sulfanilamido-2,3,8-trimethylquinoline.—One-half of the crude 5-(N^4-acetylsulfanilamido)-2,3,8-trimethylquinoline described above was dissolved in 100 cc. of 4 *N* hydrochloric acid and hydrolyzed by refluxing thirty minutes. After cooling, the acid solution was neutralized with ammonium hydroxide and the product removed by filtration. Purification was effected by three crystallizations from ethyl alcohol, Norite being employed during the initial process. The final product, realized in 58% yield, was in the form of fine colorless needles melting without decomposition at 225.5–226° (cor.).

Anal. Calcd. for $C_{18}H_{19}N_3O_2S$: N, 12.31. Found: N, 12.26.

8-Ethyl-2,3-dimethyl-5-nitroquinoline.—Six grams of 8-ethyl-2,3-dimethylquinoline[7] (0.032 mole) was added slowly to 60 cc. of fuming nitric acid (sp. gr. 1.49) and heated on the steam-bath for five hours. Upon neutralization of the diluted acid with sodium carbonate, the nitrated base was recovered by filtration and crystallized in 83% yield from ethyl alcohol as fine needles melting undecomposed at 107–109° (cor.).

Anal. Calcd. for $C_{13}H_{14}N_2O_2$: C, 67.81; H, 6.13. Found: C, 67.88; H, 6.37.

5-Amino-8-ethyl-2,3-dimethylquinoline.—Six grams of the nitro compound was hydrogenated under the identical conditions used in the reduction of the trimethyl analog to yield 5 g. (94%) of amine which crystallized from ligroin as irregular shaped needles melting at 101–102° (cor.).

Anal. Calcd. for $C_{13}H_{16}N_2$: N, 13.99. Found: N, 13.97.

5-(N^4-Acetylsulfanilamido)-8-ethyl-2,3-dimethylquinoline.—In the manner previously described, 5 g. of 5-amino-8-ethyl-2,3-dimethylquinoline was dissolved in 50 cc. of dry pyridine and heated with acetylsulfanilyl chloride for three hours on the steam-bath. The product was recovered from the pyridine by dilution with water, and crystallized only after prolonged standing. The crude material was divided into two equal portions, one of which was purified. Unlike its 2,3,8-lower homolog, 5-(N^4-acetylsulfanilamido)-8-ethyl-2,3-dimethylquinoline is extremely soluble in alcohol. Since no suitable solvent for recrystallization was found, purification was achieved by repeatedly dissolving the discolored compound in boiling ethyl alcohol, treating with Norite, and precipitating the colorless acetyl derivative by addition of water. Only 1 g. (20%) of pure material, melting at 244–245° (cor.), was obtained.

Anal. Calcd. for $C_{21}H_{23}N_3O_3S$: N, 10.57; S, 8.07. Found: N, 10.74; S, 8.20.

5-Sulfanilamido-8-ethyl-2,3-dimethylquinoline.—The second portion of the crude product referred to above was hydrolyzed as in the previous case by thirty minutes of refluxing with 60 cc. of 6 *N* hydrochloric acid. The product, precipitated by the addition of ammonium hydroxide, was purified to the constant melting point of 241–242° (cor.) by recrystallization from ethyl alcohol, from which solvent it crystallizes in fine needles.

Anal. Calcd. for $C_{19}H_{21}N_3O_2S$: N, 11.83. Found: N, 11.81.

2,3-Dimethyl-5-nitro-8-*n*-propylquinoline.—Fifteen grams (0.075 mole) of 2,3-dimethyl-8-*n*-propylquinoline[8] was nitrated by heating at steam-bath temperature with 150 cc. of nitric acid (sp. gr. 1.49) for three hours. The nitro derivative, precipitated by neutralizing the diluted solution with sodium carbonate, was recrystallized from petroleum ether in 93% yield. A small sample was further purified to a constant melting point of 97–99° (cor.).

Anal. Calcd. for $C_{14}H_{16}N_2O_2$: N, 11.47. Found: N, 11.51.

5-Amino-2,3-dimethyl-8-*n*-propylquinoline.—Reduction was realized in 95% yield by hydrogenating the nitro compound (17 g.) over Raney nickel at 70–100° and 1000 lb./sq. in. pressure. Following crystallization from petroleum ether, the amine melted at 90–92° (cor.).

Anal. Calcd. for $C_{14}H_{18}N_2$: N, 13.08. Found: N, 13.15.

(7) Key and Bailey, THIS JOURNAL, **60**, 3028 (1938).

(8) Axe and Bailey, *ibid.*, **60**, 3028 (1938).

5-(N^4-Acetylsulfanilamido)-2,3-dimethyl-8-*n*-propylquinoline.—Fourteen grams of 5-amino-2,3-dimethyl-8-*n*-propylquinoline (0.065 mole) reacted with 22 g. of acetylsulfanilyl chloride (0.094 mole) in 140 cc. of dry pyridine for three hours. The product, recovered by dilution with water, separated as an oil which did not crystallize upon standing. The aqueous layer was decanted, and the tarry product divided into two fractions of approximate equality. By repeatedly dissolving one portion of the oil in ethyl alcohol, refluxing with Norite, and precipitating the product with water, the acetyl derivative was obtained (in 15% yield) and melted at 208–209° (cor.).

Anal. Calcd. for $C_{22}H_{25}N_3O_3S$: N, 10.21. Found: N, 10.26.

5-Sulfanilamido-2,3-dimethyl-8-*n*-propylquinoline.—The residual oil referred to above was refluxed for one hour with 150 cc. of 4 *N* hydrochloric acid. Following neutralization with ammonium hydroxide, the hydrolysis product was filtered and crystallized from ethyl alcohol with the aid of Norite as fine needles in 70% yield; melting point 237–238° (cor.).

Anal. Calcd. for $C_{20}H_{23}N_3O_2S$: N, 11.38; S, 8.66. Found: N, 11.46; S, 8.48.

Summary

The preparation of a series of sulfanilamido derivatives of nitrogen bases from California petroleum has been described. Preliminary pharmacological tests of these 2,3,8-trialkyl-5-sulfanilamidoquinolines show them to be practically inactive as sulfa drugs, indicating that such substitution of the quinoline nucleus for hydrogen of the amide group reduces the therapeutic effectiveness of sulfanilamide. One of the compounds exhibits some activity against avian malaria at the blood stage.

Azoyl Derivatives of Sugars and Separation by Chromatographic Adsorption[1]

BY GEORGE H. COLEMAN, ALFORD G. FARNHAM AND AARON MILLER

Reich[2] has reported the chromatographic separation of the *p*-phenylazobenzoyl esters of α-D-glucose and β-D-fructose on both alumina and silica as adsorbents.

The present work was undertaken to determine the applicability of the chromatographic adsorption method to similar derivatives of other sugars with the thought of applying the procedure to mixtures such as "hydrol."

p-Phenylazobenzoyl derivatives were prepared from the following sugars by the method described in the experimental part: α-D-glucose, β-D-glucose β-D-fructose, α-D-galactose, α-lactose, trehalose, sucrose, β-cellobiose, β-gentiobiose, β-maltose, D-xylose and melezitose. The compounds were analyzed for percentage azoyl and the specific rotations were measured in chloroform solution using both sodium and cadmium vapor lamps.

Several pairs of the sugar esters were separated by the chromatographic adsorption method. The following pairs of azoates were separated using Magnesol[3] as adsorbent with Dicalite as a filter aid: α-lactose and α-D-galactose, trehalose and β-D-glucose, α-lactose and sucrose, α-D-glucose and β-D-fructose, β-maltose and α-D-glucose, sucrose and α-D-glucose. On silicic acid[4] as adsorbent α-D-glucose and β-D-fructose, α-D-galactose and β-D-fructose, sucrose and β-D-fructose, α-D-glucose and melezitose were separated. Several other pairs of derivatives did not give satisfactory separation under the conditions employed.

Experimental

Preparation of Azoyl Derivatives.—The *p*-phenylazobenzoyl or "azoyl" derivatives were prepared by allowing the sugars to react in pyridine solution at 0° with *p*-phenylazobenzoyl chloride over a period of eight to twenty days. The mole ratio of azoyl chloride to sugar was about eight to one for monosaccharides and twelve to one for disaccharides. At the end of this time the excess acid chloride was decomposed by adding methanol. The products were precipitated by pouring the reaction mixture into water. The precipitate, after drying, was purified by dissolving in chloroform and reprecipitating by pouring into alcohol. The monosaccharide derivatives were recrystallized, the glucose derivatives from dioxane and the galactose and fructose derivatives from mixtures of chloroform and carbon tetrachloride. The disaccharide esters were purified by several reprecipitations.

Specific Rotations.—The specific rotations were measured at 25° in chloroform solution at a concentration of 0.5 g. per 100 ml. of solvent using a water-jacketed 2-decimeter tube. Two light sources were used, the sodium and cadmium vapor lamps, giving, respectively, the readings for the sodium D line and the cadmium 6438 Å. line.

(3) "Magnesol" is a hydrous magnesium silicate manufactured by the Magnesol Co.

(4) Merck Reagent Silicic Acid.

The cadmium lamp gave more satisfactory readings, especially at higher concentrations. Physical constants are listed in Table I.

TABLE I

SPECIFIC DATA ON AZOYL DERIVATIVES

Sugar azoate	M. p., °C.[a]	$[\alpha]^{25}D$	$[\alpha]^{25}_{6438}$	% Azoyl
α-D-Glucose	234–236	+282°	+226°	85.14
β-D-Glucose	204–206	+111	+ 86	86.00
β-D-Fructose	128–130	−511	−394	82.64
α-D-Galactose	224–226	+504	+399	85.77
α-Lactose	218–220	+355	+274	83.32
Trehalose	123–125	+276	+217	82.89
Sucrose	125–126	+ 43	+ 35	82.92
β-Cellobiose	206–208		+101	82.00
β-Gentiobiose	159–161		+ 28	82.03
D-Xylose	146–148	+285	+225	84.83
β-Maltose	242–244	− 30	− 22	78.50
	253–255			80.20
Melezitose	135–137	+110	+ 81	

Calculated per cent of azoyl:

Hexose pentaazoate = 85.66
Hexose tetraazoate = 82.61
Pentose tetraazoate = 85.13
Pentose triazoate = 81.01
Disaccharide octaazoate = 83.35
Disaccharide heptaazoate = 81.37

[a] The melting points were determined between cover glasses using a Fisher Johns apparatus.

Some of these constants may be revised when perfectly pure derivatives unmixed with isomers are prepared. In certain cases complete azoylation and purification of the product was difficult by the methods used. Since the primary interest in the present work was to determine the value of these derivatives in the separation of sugars, extended study was not given to methods of preparation and purification. The work is being continued and special attention given to modification of the method of preparation and the characterization of the pure compounds.

Analysis for Percentage of Azoyl.—The derivatives were analyzed by hydrolyzing the esters and weighing the free *p*-phenylazobenzoic acid formed. The azoyl derivative was dissolved in 20 ml. of dioxane, and 15 ml. of methanol containing about 12 mg. of sodium methylate was added. The mixture was refluxed for thirty minutes and then 3 ml. of sodium hydroxide (6 *N*) and 30 ml. of water were added. Refluxing was continued for another half hour and the solution was diluted to about 200 ml. with water and 125–150 ml. removed by distillation. The residual solution was filtered, cooled, and made slightly acid with dilute hydrochloric acid. After cooling for some time to allow complete precipitation, the solid acid was collected in a crucible with sintered glass bottom, dried and weighed.

Chromatographic Adsorption.—For chromatographic adsorption a column (23 mm. by 30 cm.) was packed by suspending the solid adsorbent in petroleum ether containing about 10% of benzene and filtering under a pressure of 10 cm. of mercury. A solvent mixture of equal volumes of chloroform, benzene and petroleum ether was passed down the column followed by a solution of the azoyl derivatives. The solution contained 120 mg. of each of a pair of sugar azoates dissolved in 35–50 ml. of chloroform to which were then added corresponding volumes of benzene and petroleum ether. The solutions were all filtered through the column under a nitrogen pressure of 10 cm. of mercury and the column was not allowed to run dry, as this caused channeling.

After adding all of the solution of sugar derivatives the chromatogram was developed using a solvent mixture of the same composition as the solution. When development was complete the column was allowed to run partially dry, the adsorbent was removed, and the bands were separated. Elution of the adsorbed materials was accomplished by extracting the adsorbent layers with hot chloroform containing a small amount of methanol. The solvent was evaporated from the eluted materials, which were then transferred in chloroform to volumetric flasks. The optical rotations were measured and the weights determined by evaporating aliquot portions of the solutions.

Typical Chromatographic Adsorption Separations

α-D-Glucose and Sucrose Azoates.—From 100 mg. of each derivative was obtained an upper band of 106.7 mg. $[\alpha]^{25}_{6438}$ +47° as compared to +35° for the pure sucrose derivative; calcd. sucrose azoate, 93.8%. The lower band of 88.1 mg. had a specific rotation of $[\alpha]^{25}_{6438}$ +212° as compared to +225° for the pure α-D-glucose derivative; calcd. α-D-glucose azoate, 93.2%.

β-D-Fructose and α-D-Galactose Azoates.—From 120 mg. of each derivative was obtained an upper band of 128 mg. $[\alpha]^{25}_{6438}$ −340° as compared to −394° for the pure fructose derivative; calcd. fructose azoate, 93.2%. The lower band contained 104 mg.; $[\alpha]^{25}_{6438}$ +413° as compared to +399° for the pure galactose derivative; calcd. galactose azoate, 101.6%.

α-Lactose and Sucrose Azoates.—From 120 mg. of each azoate was obtained an upper band of 144.5 mg., $[\alpha]^{25}_{6438}$ +206° as compared to +274° for the pure lactose derivative; calcd. lactose azoate, 71.6%. The lower band contained 89.2 mg., $[\alpha]^{25}_{6438}$ +36° as compared to +35° for the pure sucrose derivative; calcd. sucrose azoate, 99.4%.

α-D-Glucose and Melezitose Azoates.—From 55 mg. of each derivative was obtained an upper band of 52.5 mg., $[\alpha]^{25}D$ + 115° as compared to +110° for the pure melezitose azoate; calcd. melezitose azoate, 82.8%. The lower band of 50.5 mg. had a specific rotation of $[\alpha]^{25}D$ + 261° as compared to + 282° for the pure α-D-glucose azoate; calcd. α-D-glucose azoate, 89.3%.

Summary

1. The *p*-phenylazobenzoyl esters of several sugars have been prepared. These derivatives were analyzed for percentage azoyl and the specific rotations measured in chloroform solution.

2. Several pairs of these sugar esters have been separated by the chromatographic adsorption method using silicic acid and mixtures of Magnesol and Dicalite as adsorbents. This included the separation of two monosaccharides, a monosaccharide and disaccharide, two disaccharides, and the separation of a monosaccharide and trisaccharide.

Synthesis of 2-Alkylaminoethanols from Ethanolamine

BY ARTHUR C. COPE AND EVELYN M. HANCOCK

Certain disadvantages are inherent in the methods which are available for the preparation of 2-alkylaminoethanols, $RNHCH_2CH_2OH$. The reaction of primary amines with ethylene oxide[1] and with ethylene chlorohydrin[2] produces a mixture of mono and dialkylaminoethanols. The reaction of ethanolamine with alkyl halides[3] may lead to either secondary or tertiary amino compounds. The method described by Goldberg and W. F. Whitmore,[4] in which an alkyl aniline is converted into a dialkylaminoethanol with ethylene oxide, and then cleaved to a monoalkylaminoethanol by nitrosation and hydrolysis, leads to pure products but involves several steps.

We have investigated the preparation of 2-alkylaminoethanols by the reduction of mixtures of ethanolamine with ketones and aldehydes.

The catalytic reduction of mixtures of ethanolamine with various ketones proved to be a remarkably successful method for the preparation of 2-alkylaminoethanols containing secondary alkyl groups. Of the aminoalcohols listed in Table I, seventeen were prepared in this manner, from ketones containing three to ten carbon atoms. The yields in many cases are nearly quantitative. The 2-alkylaminoethanols are produced in a state of exceptional purity, as indicated by constant boiling points and refractive indexes, and uniform agreement between calculated and observed molecular refractions.

Adams platinum oxide-platinum catalyst was used in preparing all of the aminoalcohols. Most of the reductions were exothermic and proceeded rapidly without heating in alcohol solution, the rates of the various reductions corresponding to the reactivity of the ketones. The reductions were much slower in acetic acid, and still slower when palladinized charcoal was used as the catalyst. Raney nickel and copper chromite proved to be suitable catalysts at elevated temperatures and pressures.

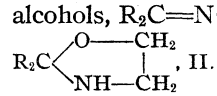
(4) Goldberg and W. F. Whitmore, THIS JOURNAL, **59**, 2280 (1937).

Five 2-*primary* alkylaminoethanols were prepared in a similar manner in 60 to 90% yield by reducing mixtures of aldehydes with ethanolamine. By-products were formed from the aldehydes, but they could be removed by distillation, or by dissolving the amino-alcohols in dilute hydrochloric acid and extracting with ether or benzene.

Skita[5] has prepared a number of amines (different in type from the aminoalcohols herein described) by the reduction of aldehydes and ketones in the presence of ammonia and amines, or by the reduction of the alkylidene amines (Schiff bases) which are the intermediates. We have isolated the products formed by the reaction of four ketones with ethanolamine and found that in three cases the compounds formed by elimination of water are not alkylidene aminoalcohols, $R_2C{=}NCH_2CH_2OH$, I, but oxazolidines,



, II.

By refluxing a benzene solution of cyclohexanone and ethanolamine under a constant water separator until the separation of water became very slow, an anhydro compound was formed in about 90% yield. It is very readily hydrolyzed back to ethanolamine and cyclohexanone. Catalytic reduction converts the anhydro compound into 2-cyclohexylaminoethanol. The low boiling point of the anhydro compound [89–90° (16 mm.)] compared to that of 2-cyclohexylaminoethanol [122–123.5 (13 mm.)] suggests a more fundamental change in structure on reduction than simple saturation of a double bond.[6] The molecular refraction of the anhydro compound (39.55) is in much better agreement with the value calculated for the oxazolidine (40.00) than the calculated value for the alkylidene aminoalcohol (41.48). A similar easily hydrolyzed anhydro compound regarded as an oxazolidine was formed from methyl amyl ketone and ethanolamine; b. p. 88–90° (7 mm.), in contrast to the b. p. of 115–116° (10 mm.) observed for its reduction product, 2-(2-heptylamino)-ethanol; M_D found 46.86, calculated for the oxazolidine 46.82, for the alkylidene aminoalcohol 48.30.

[a] Previously prepared by Matthes (ref. 1). [b] Matthes (ref. 1) reports m. p. 98°. M. p. of the picrolonate 211–213°, in fairly good agreement with the value of 218° reported by Matthes. [c] Reported by Goldberg (ref. 4) as having b. p. 214–216°; refractive index (conditions unspecified) 1.4508; sp. gr. 0.8814; picrate m. p. 57–58°. [d] Reported by Bain and Pollard (ref. 1), whose physical constants are in good agreement with ours. Our sample solidified on standing, m. p. 40–41°. Physical constants were determined on the supercooled liquid. [e] Solidified on standing, m. p. 30–32°. Physical constants were determined on the supercooled liquid. [f] We are indebted to Mr. C. S. Miller and Mr. J. P. Lutz for semi-micro Kjeldahl analyses.

The reaction of methyl propyl ketone and ethanolamine also gave an anhydro compound with physical properties indicating an oxazolidine structure; b. p. 62–62.5° (16 mm.) compared to 98–99° (15 mm.) for its reduction product; M_D found 37.06, calculated for the oxazolidine 37.58, for the alkylidene aminoalcohol 39.06. The refractive index of this compound increased rapidly on standing for a few hours from an initial value of 1.4400 to a final value of 1.4502, which remained practically constant for two months. Redistillation reconverted the material into the form with the original refractive index, which again increased to 1.4502 on standing. These data are interpreted as meaning that this particular anhydro compound exists as an oxazolidine (II) in fairly mobile equilibrium with an alkylidene aminoalcohol (I). The freshly distilled material is the lower boiling oxazolidine, which reaches an equilibrium with I on standing. The conversion is apparently not complete, for the molecular refraction of the material at equilibrium is 37.81, a value too low for structure I.

The condensation of diisobutyl ketone with ethanolamine produced an anhydro compound which boiled only slightly lower than its reduction product [110–111° (8 mm.)] compared to [113–114 (7 mm.)], and had a molecular refraction (57.21) closer to the value for the alkylidene aminoalcohol (57.54) than the oxazolidine (56.06). Presumably it is largely or completely in the form of the alkylidene aminoalcohol.

It is of interest to note that the three anhydro compounds which appear to exist predominantly in the form of oxazolidines are derived from the three reactive, relatively unhindered ketones. Presumably the first step in the reaction is the formation of an addition product, $R_2C(OH)NHCH_2CH_2OH$. Whether the oxazolidines are formed directly from these intermediates by the elimina-

tion of water, or whether the reaction takes the course of dehydration to an alkylidene aminoalcohol followed by an intramolecular addition to give the oxazolidines, the presence of large branched alkyl groups would be expected to retard or prevent their formation.

Knorr and Matthes[7] have prepared anhydro compounds from aldehydes and ethanolamine, and considered that their low boiling points and ease of hydrolysis proved them to be oxazolidines. Knorr and Rössler[8] obtained anhydro compounds formulated as oxazolidines from the reaction of ethanolamine with acetyl acetone and acetoacetic ester. They did not obtain pure products from either acetone or acetophenone. Oxazolidines derived from ketones and ethanolamine are mentioned as intermediates in the patent literature,[9] but were not isolated.

Experimental Part

Most of the ketones and all of the aldehydes listed in Table I were obtained from commercial sources and purified by distillation before use. Methyl heptyl ketone was prepared from caprylyl chloride and methyl zinc iodide; dibutyl ketone from valeronitrile and butylmagnesium bromide; methyl octyl ketone from ethyl *n*-heptylacetoacetate; 2,2,6-trimethylcyclohexanone by reducing isophorone in the presence of palladinized charcoal.

Preparation of 2-*s*-Alkylaminoethanols.—Details of the preparation of 2-(2-octylamino)-ethanol may be cited to illustrate the method used for the 2-*s*-alkylaminoethanols listed in Table I, with one exception. Platinum oxide catalyst (0.5 g.) was placed in a one-liter bottle containing 50 cc. of absolute alcohol and reduced to platinum by shaking in an atmosphere of hydrogen. Ethanolamine (61 g., 1 mole) was dissolved in 100 cc. of absolute alcohol and methyl hexyl ketone (166 g., 1.3 mole) was added. The mixture became warm from the heat of reaction. The solution was rinsed into the bottle containing the platinum catalyst with 50 cc. of alcohol and reduced by shaking with hydrogen at one to two atmospheres pressure for seven hours. The reduction was rapid and exothermic. The catalyst was removed by filtration and the bottle and catalyst rinsed with 75 cc. of benzene. The benzene and alcohol were removed from the filtrate by distillation at atmospheric pressure, and the residue was distilled in vacuum through a Widmer column. The excess ketone was recovered as a fore-run. There was practically no distillation residue.

Mixtures of ethanolamine with all of the methyl ketones except acetophenone reduced rapidly, preparations of one-half to one mole requiring three to ten hours for completion. The cyclic ketones, except *l*-menthone, gave equally rapid reductions. The reduction was slightly slower in the case of diethyl ketone, but went to completion without heating. The mixtures of ethanolamine and acetophenone, dipropyl ketone, dibutyl ketone and *l*-menthone were heated to 50 to 60°, and complete reduction of one-half mole quantities required 20 to 30 hours. No reduction occurred with diisobutyl ketone under these conditions. An excess of ketone was used in each reduction in order to eliminate the possibility that the products might be contaminated with ethanolamine. It is noteworthy that no dialkylaminoethanols were formed through further reaction of the monoalkylaminoethanols with the ketones present in excess.

The following facts concerning the reductions were established during the development of the procedure illustrated above. It is advantageous to reduce the catalyst separately before adding the mixture of ethanolamine and carbonyl compound, in order to avoid a long induction period which otherwise occurs before the catalyst reduces. Palladinized charcoal[10] is a much less effective catalyst for the reduction. Thus a half-mole preparation of 2-*s*-butylaminoethanol required a total of 3 g. of palladinized charcoal added in three portions and thirty-one hours for complete reduction at 60°. A number of reductions were carried out in acetic acid (2 moles per mole of ethanolamine). With platinum catalyst under these conditions the reductions required twenty to thirty hours at 60°, while palladium gave even slower reductions. The yields were also 10 to 20% lower than those obtained by the above procedure, due to the loss of the aminoalcohols which occurred because of their solubility in water when they were liberated from their acetate salts by treatment with alkali. Raney nickel and copper chromite are satisfactory catalysts for the reductions either in alcohol solution or without a solvent. Thus the reduction of 28 g. of methyl ethyl ketone and 18 g. of ethanolamine in the presence of 3 g. of Raney nickel at 150° and 1000 to 2000 lb. hydrogen pressure gave 27.2 g. (86%) of 2-*s*-butylaminoethanol. A similar reduction in the presence of 1 g. of copper–barium chromite[11] at 160° gave 28.5 g. (88%) of the aminoalcohol.

Preparation of 2-*primary*-Alkylaminoethanols.—The method described in detail above was followed, except that the alcohol solution of ethanolamine was cooled in ice while the aldehyde (15% molar excess) was added slowly, in order to avoid polymerization. One attempt to prepare 2-butylaminoethanol in acetic acid solution was unsuccessful due to extensive polymerization of the aldehyde under these conditions.

The picrates described in Table I were prepared by heating to boiling alcohol solutions of the aminoalcohols with equivalent quantities of picric acid, followed by cooling. Water was added if necessary. They were recrystallized from alcohol or alcohol and water.

Condensation of Ketones with Ethanolamine. Spiro-[cyclohexane-1,2′-oxazolidine].—A mixture of 30.5 g. of ethanolamine, 63.7 g. of cyclohexanone and 100 cc. of benzene was refluxed under a constant water separator[12] for thirty minutes, while 9.4 cc. of water collected. The benzene was removed in vacuum and the residue distilled in vacuum through a Widmer column. The yield of spiro-[cyclohexane-1,2′-oxazolidine] was 66.8 g. (94%); b. p.

89–90° (16 mm.); $n^{25}D$ 1.4803; d^{25}_{25} 1.0178; MD calcd. 40.00, found 39.55.[13]

Anal. Calcd. for $C_8H_{15}ON$: N, 9.92. Found: N, 9.81.

Reduction of 28.2 g. of the oxazolidine in 40 cc. of alcohol with the platinum from 0.3 g. of platinum oxide gave 26.3 g. (92%) of 2-cyclohexylaminoethanol.

2-Methyl-2-amyloxazolidine.—Ethanolamine (30.5 g.), methyl amyl ketone (74 g.) and 100 cc. of benzene were refluxed under a water separator. After thirty-five minutes 9.2 cc. of water had collected. Distillation gave 50 g. (64%) of the oxazolidine; b. p. 88–90° (7 mm.); $n^{25}D$ 1.4501; d^{25}_{25} 0.9047; MD calcd. 46.82, found 46.86.

Anal. Calcd. for $C_9H_{19}ON$: N, 8.92. Found: N, 9.16.

2-Methyl-2-propyloxazolidine.—Ethanolamine (30.5 g.), methyl propyl ketone (56 g.) and 100 cc. of benzene were refluxed under a water separator for one hour, when 9.0 cc. of water had collected. Distillation gave 49.5 g. (85%) of the oxazolidine; b. p. 62–62.5° (16 mm.); $n^{25}D$ 1.4400; d^{25}_{25} 0.9215; MD calcd. 37.58, found 37.06.

Anal. Calcd. for $C_7H_{15}ON$: N, 10.84. Found: N, 11.01.

The refractive index of this oxazolidine increased noticeably on the refractometer. After one day its refractive index was 1.4502, after two months, 1.4510. The density remained constant; d^{25}_{25} 0.9216. Redistillation converted the sample without appreciable loss into material with $n^{25}D$ of 1.4400, which again increased to 1.4502 after standing for one day.

In a quantitative reduction with platinum catalyst 2.50 g. of this oxazolidine took up 99.3% of one molecular equivalent of hydrogen. Distillation gave 2.0 g. of 2-(2-pentylamino)-ethanol, identified by its physical properties and the melting point of its picrate.

2-[4-(2,6-Dimethylheptylidene)-amino]-ethanol.—A mixture of 30.6 g. of ethanolamine, 92 g. of diisobutyl ketone and 150 cc. of benzene was refluxed under a constant water separator for thirteen hours, during which time 12.4 cc. of water collected. The mixture was not homogeneous at the beginning of the reaction, but was at the end. The water which collected in the separator contained some ethanolamine. After the benzene had been removed in vacuum, the residue was distilled through a Widmer column. The yield of the alkylidene aminoalcohol was 52 g. (56%); b. p. 110–111° (8 mm.); $n^{25}D$ 1.4568; d^{25}_{25} 0.8844; MD calcd. 57.54, found 57.21.

Anal. Calcd. for $C_{11}H_{23}ON$: N, 7.56. Found: N, 7.66.

Reduction of 29.6 g. of the above anhydro compound with platinum catalyst in alcohol solution gave 28 g. (94%) of 2-[4-(2,6-dimethylheptyl)-amino]-ethanol (Table I).

All of the above anhydro compounds were very readily hydrolyzed. Samples which were freshly distilled or stored in sealed containers had a distinct amine-like odor, but after exposure to moist air for a few minutes the odor of the ketones appeared.

Methyl hexyl ketone and acetophenone were also condensed with ethanolamine in benzene solution. A molecular equivalent of water was formed in both cases, but the condensation products did not have constant boiling points and appeared to polymerize slightly on distillation in vacuum.

In order to determine whether condensation products could be prepared from ketones and 2-alkylaminoethanols, 32.8 g. of 2-(2-pentylamino)-ethanol, 28 g. of methyl propyl ketone, 1.5 g. of acetic acid and 50 cc. of benzene were refluxed under a constant water separator for 48 hours. Although 1.4 cc. of water collected, on distillation 29 g. (88%) of the aminoalcohol was recovered.

Summary

The reduction of mixtures of ethanolamine with ketones and with aldehydes provides a convenient synthesis for 2-alkylaminoethanols. Nearly quantitative yields of 2-*s*-alkylaminoethanols are obtained from ketones and ethanolamine.

The substances which are presumably intermediates in this synthesis were isolated in four cases by condensing four ketones with ethanolamine. The condensation products obtained from cyclohexanone and methyl amyl ketone had physical properties which indicated that they were not alkylidene aminoalcohols (I) but oxazolidines (II). The product obtained from methyl propyl ketone and ethanolamine had the properties of an oxazolidine when distilled, but rapidly changed in refractive index on standing, probably because of ring-chain tautomerism and the establishment of an equilibrium between I and II. The condensation product obtained from diisobutyl ketone and ethanolamine had physical properties indicating that it was largely in the alkylidene aminoalcohol form.

BRYN MAWR, PENNSYLVANIA RECEIVED MARCH 5, 1942

(13) The following atomic refractions were used in obtaining calculated molecular refractions: nitrogen in the oxazolidines, 2.50 as in secondary amines; Eisenlohr, *Z. phys. Chem.*, **79**, 134 (1912). Double bond-nitrogen in the Schiff bases, 4.10 as in alkylidene amines; von Auwers, *ibid.*, **147**, 436 (1930). Other values (C, 2.42; H, 1.10; O, 1.64) are the usual Eisenlohr values; *ibid.*, **75**, 605 (1910). "Optical depression" is frequently observed in (unsaturated) heterocyclic compounds [see Brühl, *ibid.*, **79**, 38 (1912); von Auwers, *Ber.*, **57**, 461 (1924)]. Consequently it is probable that the low molecular refractions observed for spiro[cyclohexane-1,2'-oxazolidine] (deviation −0.45) and 2-methyl-2-propyl-oxazolidine (−0.52) are characteristic of the oxazolidine ring system, while the agreement of calculated and found values for 2-methyl-2-amyl-oxazolidine (deviation +0.04) is fortuitous and may indicate the presence of some of the corresponding Schiff base.

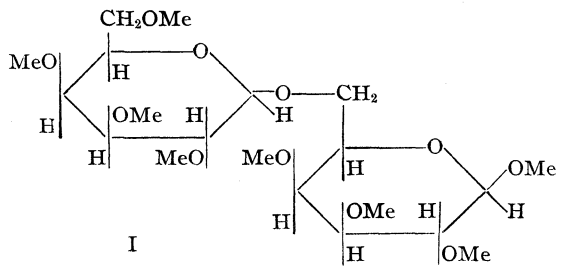
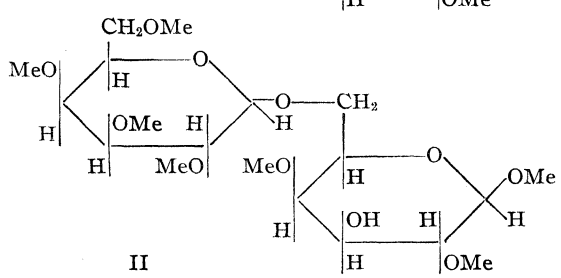
The Constitution of Arabo-galactan. III. The Location of the Arabinose Component

BY E. V. WHITE

It has been shown that the water-soluble gum[1] of the western larch, *Larix occidentalis*, yields the glycosides of 2,4-dimethyl-*d*-galactose, 2,3,4-trimethyl-*d*-galactose, 2,3,4,6-tetramethyl-*d*-galactose, and 2,3,5-trimethyl-*l*-arabinose in the approximate molecular ratio 3:1:2:1 upon alcoholysis of the methyl ether derivative.[2] Furthermore, by partial methanolysis of arabo-galactan methyl ether,[3] two methylated disaccharides have been obtained in crystalline form. These are, respectively, octamethyl-6-*d*-galactosidogalactose (I)and heptamethyl-6-*d*-galactosidogalactose (II).[3a]





Apparently the terminal galactose anhydride units of the polysaccharide are engaged by oxygen linkage through the 1 position to the 6 position of adjacent galactose residues and the question arises as to the mode of union of the terminal arabofuranose unit.

As is well known, the furanopentosides are considerably more susceptible to acid hydrolysis than are the corresponding derivatives of the pyranopentoses and especially the pyranohexoses, although, under similar conditions, the rate of hydrolysis is a function of the particular saccharide under consideration. Advantage has been taken of this phenomenon in the investigation of certain oligosaccharides,[4a,b] xylan[5] and arabic acid.[6] Hirst and co-workers[7] report its successful application to arabo-galactan but do not give details of the experiment.

The relative rates of hydrolysis of the galactopyranosides as compared with those of the corresponding arabofuranosides under similar conditions are not known, although it is indicated indirectly that the difference is not as large as might be expected. Thus, since the methyl arabopyranosides are hydrolyzed about 1.5 times as rapidly as the methyl galactopyranosides[8] and since the only known methyl arabofuranoside is hydrolyzed about 10 times as rapidly as the corresponding pyranoside,[9] it is to be expected that the arabofuranosides would hydrolyze about 15 times as rapidly as the galactopyranosides. In the case of arabo-galactan, therefore, wherein six molecules of galactose are associated with one residue of arabofuranose, hydrolysis of the furanopentose unit should be accompanied theoretically by concomitant hydrolysis of 0.4 unit of galactose.

The strictly preferential hydrolysis of the arabofuranose component of arabo-galactan is thus a matter of some difficulty. However, after mild treatment, any substantial change in the ratio of the components isolated upon alcoholysis of a partially hydrolyzed, fully methylated material as compared with those obtained upon similar treatment of the methyl ether derivative would indicate the method of linkage of the pentose unit.

With these considerations in mind, a quantity of arabo-galactan was separated from larch sawdust and divided into two portions. One of these was subjected to partial hydrolysis. Samples of the hydrolyzing solution were removed at intervals and analyzed for residual polysaccharide. The non-hydrolyzed pentose fraction of the latter was then determined by the Tollens method. The

TABLE I

PARTIAL HYDROLYSIS OF ARABO-GALACTAN

Acidity, 0.020 N H_2SO_4; temp., 90°

Time, hours	% Residual polysaccharide	% Arabinose in residual polysaccharide
0	100	13.6
7	94.2	9.91
16	90.0	7.24
23	88.4	6.16

results obtained, given in Table I, are represented graphically in Fig. 1.

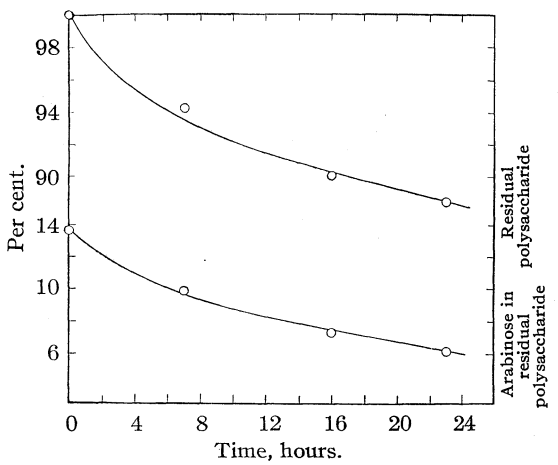

Fig. 1.—The hydrolysis of arabo-galactan (acidity, 0.02 N H_2SO_4; temp., 90°).

Hydrolysis of the gum obviously proceeds with gradual decrease in the pentose fraction of the residual polysaccharide and apparently tends toward a final value. Furthermore, within the range investigated, the decrease in yield of residual polysaccharide parallels approximately the loss of pentose, indicating that simultaneous galactose fission was relatively slight under the conditions employed.[10] No attempt was made to completely remove the arabinose component lest prolonged treatment promote undue galactose hydrolysis. The hydrolyzate, therefore, is to be regarded as a mixture of unchanged arabo-galactan and arabinose-free arabo-galactan together with some more extensively hydrolyzed material. The partially hydrolyzed product was methylated with dimethyl sulfate and alkali and subjected to simultaneous complete hydrolysis and glycoside formation with methanolic hydrogen chloride. The resulting sirup was distilled fractionally and the yield of the components compared with those obtained from the second portion of arabo-galactan which was methylated directly and subjected to alcoholysis.

An analysis of the results obtained is given in Table II as taken from Tables III and IV, respectively.

An examination of this table shows a sharp decrease in the amount of dimethyl-galactoside obtained from the glycosidic sirup of the partially hydrolyzed, fully methylated product as compared with that obtained from the ether of the original polysaccharide. Correspondingly, an increase is noted in the yield of trimethyl-galactoside. When correction is made in the glycosidic sirup for those components resulting from unchanged arabo-galactan in the partially hydrolyzed product, a substantially equimolecular ratio is obtained for the di-, tri- and tetramethyl-galactoside components[7] derived from methylated, arabinose-free arabo-galactan. The conclusion is reached, therefore, that the arabinose fraction of the polysaccharide is joined by oxygen linkage to an already di-linked galactose residue and that the new hydroxyl group formed by hydrolysis of the furanopentose residue and substituted in subsequent methylation contributes to the increased proportion of the trimethylated component in the glycosidic sirup from the partially hydrolyzed, fully methylated product.

The location of the new hydroxyl group, and therefore of the arabinose residue, was revealed by an examination of the trimethyl galactoside component of the glycosidic sirup. Thus, while arabo-galactan methyl ether yields only 2,3,4-trimethyl-methyl-galactoside as trimethyl component upon methanolysis, the partially hydrolyzed, methylated and hydrolyzed material provides a trimethyl galactoside fraction which furnishes 2,3,4-trimethyl-galactose and 2,4,6-trimethyl-galactose. The latter evidently originates through methylation of a hydroxyl group in the 6-position of a galactose residue formed during partial hydrolysis by removal of the arabinose unit. The same galactose residue normally occurs in the alcoholysis products of arabo-galactan methyl ether as 2,4-dimethyl-methyl-galactoside. In the original arabo-galactan, therefore, the arabinose

(10) After twenty-three hours of treatment, arabinose removed by hydrolysis = 13.6 − (6.16 × 88.4/100) = 8.2%; residual galactan = (88.4 − 5.4) = 83.0%; hydrolysis ratio galactose : arabinose = $\left(\frac{8.2}{13.6} \div \frac{86.4 - 83.0}{86.4} \times \frac{180}{160}\right)$ = 13.6:1. The experimental value approximates the theoretical hydrolysis ratio 15:1 and indicates 4.5% galactose fission under conditions hydrolyzing 62% of the arabinose component. Similar calculations made after sixteen and seven hours of hydrolysis yield the ratios 13.8:1 and 16.2:1, respectively. However, these evaluations of hydrolysis ratio must be regarded as approximations since galactan hydrolysis may occur leaving an alcohol insoluble residue without formation of galactose.

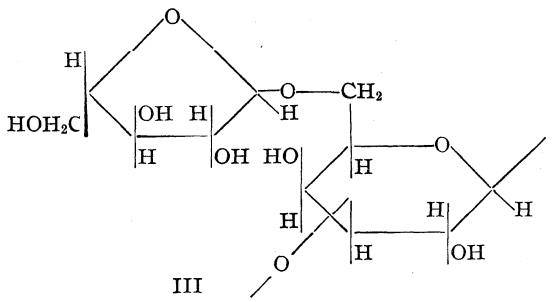
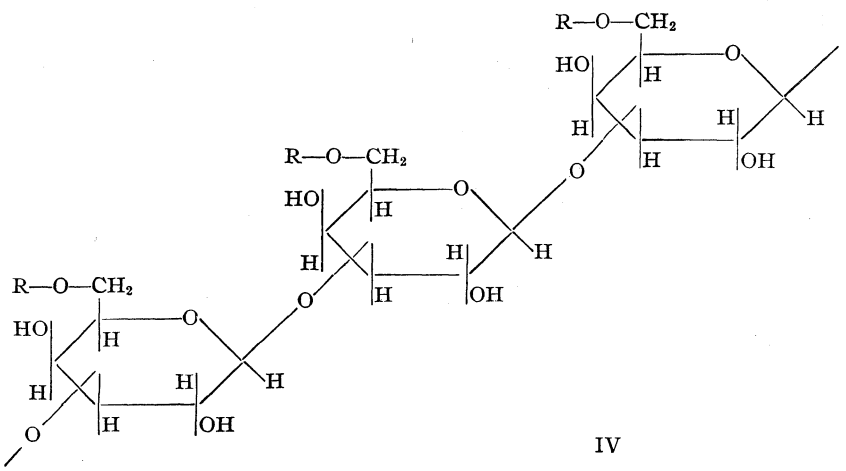
fraction occurs as a 1-6 linked arabofuranosido-galactan III.



III

A consideration of these facts, together with the knowledge that octamethyl- and heptamethyl-6-*d*-galactosidogalactose have been isolated through partial methanolysis of arabo-galactan methyl ether, furnishes direct information concerning six monosaccharide units of the polysaccharide wherein six galactose residues are associated with one unit of arabinose. The remaining galactose anhydride occurs as the 2,4-dimethyl derivative in arabo-galactan methyl ether and is thus tri-linked in the original polysaccharide. The exact location of this unit is not known, although the problem resolves itself into two possibilities. Thus, the tri-linked residue may be situated in the main chain of the branched structure previously indicated,[3] whereupon the constitution of the polysaccharide is represented by a "backbone" or main chain of 1-3 linked galactose anhydride units IV each substituted in the 6 position by the radical R. The repeating unit of arabo-galactan then becomes one of three main chain units bearing the radicals R, respectively, *l*-arabinose, *d*-galactose, and 6-*d*-galactosidogalactose. In the event, however, that the final tri-linked galactose anhydride is not part of the main chain but that one or more such units are engaged in side-chain linkage, a portion or all of the radicals R become of polysaccharide character and the nature of the main chain linkage is unknown. This phase of the investigation is now being extended.



IV

Experimental

Extraction and Purification of Arabo-galactan.—Larch sawdust was extracted with water and the extract, purified by filtration through norite and Super-Cel, fractionally precipitated with ethyl alcohol.[2] The precipitate thus obtained was dissolved in water, evaporated under reduced pressure at 50° to remove residual alcohol, and divided into Parts A and B, respectively. Part A was fully methylated under nitrogen with dimethyl sulfate and alkali, as described previously.[3] Part B was subjected to partial hydrolysis.

Partial Hydrolysis of Arabo-galactan.—A number of preliminary experiments indicated that hydrolysis of arabo-galactan took place rapidly when the gum was heated in sulfuric acid solutions of greater concentration than 0.05 *N*. In more dilute solutions hydrolysis proceeded progressively slower until in 0.01 *N* acid solution only slight change was noted over long periods of time. Accordingly, Part B (72.6 g. of solid) of the arabo-galactan extract was heated at 90° on the water-bath in 750 cc. of 0.02 *N* sulfuric acid.

Samples of the hydrolyzing solution were removed at intervals, cooled, and a 25-cc. portion precipitated into excess rapidly stirred ethyl alcohol. The precipitate was washed with fresh alcohol to remove residual monosaccharide, dissolved in water, and made up to 100 cc. volume. Aliquot portions of this solution were then analyzed for total solid and for furfural distilled by the Tollens method. The results are given in Table I and are illustrated graphically in Fig. 1.

Methylation of Partially Hydrolyzed Arabo-galactan.—The hydrolyzing solution of arabo-galactan after twenty-three hours of treatment was cooled (635 cc.) and precipitated into excess rapidly stirred ethyl alcohol. The precipitate was removed from the supernatant liquor (C), washed with fresh alcohol, dissolved in water, and evaporated to a thin sirup. The latter was methylated at 25° under nitrogen using 300 cc. of methyl sulfate and 900 cc. of 30% sodium hydroxide. The reagents were added dropwise and simultaneously over a period of five hours. Acetone (200 cc.) was added over the interval to reduce foaming. After complete hydrolysis of the methyl sulfate the partially methylated product separated from the inorganic reaction components. The latter were removed and the residue remethylated under similar conditions. After four methylations, retreatment effected no increase in methoxyl content of the product, which was isolated by extraction of the methylation liquors with chloroform. The extract, dried over magnesium sulfate, decolorized with norite and filtered, was evaporated to a sirup and precipitated into excess rapidly stirred petroleum ether (30–60°). The precipitate, taken up in ether, filtered and evaporated to dryness, yielded a friable glassy solid of light yellow color; yield, 57 g. (Found: MeO, 44.7.).

Isolation and Identification of Arabinose.—The supernatant alcoholic liquor (C) was neutralized with barium carbonate, decolorized with norite, and evaporated to small volume. The resulting solution was precipitated into excess alcohol and a small quantity (1.5 g.) of residual gum removed. The solution, containing 5.6 g. of arabinose by the Tollens method, evaporated to a sirup and taken up in fresh alcohol, crystallized, yielding crude arabinose identified as the benzyl-phenylhydrazone: m. p. 174°.

Methanolysis of Fully Methylated, Partially Hydrolyzed, Arabo-galactan and of Arabo-galactan Methyl Ether.—Fifty-six grams of fully methylated, partially hydrolyzed arabo-galactan was dissolved in 360 cc. of anhydrous pure methyl alcohol containing 2% of dry hydrogen chloride. After reaction in sealed tubes[4] maintained at 115° for five and one-half hours, excess acidity was neutralized with silver carbonate. The filtered solution was decolorized with norite, evaporated to a sirup, and taken up in anhydrous ether. Filtration of the solution and evaporation of solvent gave a sirupy mixture of variously methoxylated glycosidic components; yield, 62.0 g. A similar experiment performed on the methyl ether of non-hydrolyzed arabogalactan (66.0 g.) gave a similar glycosidic sirup; yield, 75.2 g.

Examination of the Glycosidic Sirups.—The sirup obtained upon methanolysis of arabo-galactan methyl ether was distilled fractionally under high vacuum, yielding the portions indicated in Table III. No attempt was made to separate trimethyl-methyl-arabinoside from tetramethyl-methyl-galactoside, although the separation of these components from trimethyl-methyl-galactoside and the latter from dimethyl-methyl-galactoside was relatively complete. In calculation of the components, the arabinoside fraction was determined upon the basis of the 6:1 molecular ratio of galactose to arabinose in arabo-galactan, while the small intermediate portions and the trimethyl fraction were apportioned on the basis of methoxyl content.

TABLE III

FRACTIONAL DISTILLATION OF THE GLYCOSIDIC SIRUP FROM ARABO-GALACTAN METHYL ETHER

			Components			
Distillate	Grams	OMe	*a*	*b*	*c*	*d*
Fraction I	28.3	61.3	9.6	18.7		
Fraction II	3.2	55.0		2.4	0.8	
Fraction III	12.2	51.5			10.9	1.3
Fraction IV	5.8	43.4			0.8	5.0
Fraction V	25.2	41.9				25.2
Total	74.7		9.6	21.1	12.5	31.5

[a] Trimethyl-methyl-arabinoside. [b] Tetramethyl-methyl-galactoside. [c] Trimethyl-methyl-galactoside. [d] Dimethyl-methyl-galactoside.

A similar fractional distillation was performed upon the glycosidic sirup resulting from methanolysis of the partially hydrolyzed, fully methylated material. The results obtained are listed in Table IV, wherein calculation of fraction composition was again determined as previously. In this case, the arabinose component is based upon unchanged arabo-galactan in the partially hydrolyzed product as determined from the arabinose content thereof.

TABLE IV

FRACTIONAL DISTILLATION OF THE GLYCOSIDIC SIRUP FROM PARTIALLY HYDROLYZED, FULLY METHYLATED ARABO-GALACTAN

			Components			
Distillate	Grams	OMe	*a*	*b*	*c*	*d*
Fraction I	23.2	61.5	3.6	19.6		
Fraction II	2.9	54.5		0.6	2.3	
Fraction III	12.9	51.6			11.8	1.1
Fraction IV	6.7	43.8			1.2	5.5
Fraction V	15.5	41.9				15.5
Total	61.2		3.6	20.2	15.3	22.1

[a] Trimethyl-methyl-arabinoside. [b] Tetramethyl-methyl-galactoside. [c] Trimethyl-methyl-galactoside. [d] Dimethyl-methyl-galactoside.

Separation of 2,4,6-Trimethyl-galactose from 2,3,4-Trimethyl-galactose.—The distilled fraction containing the major portion of trimethylgalactoside, Fraction III, Table IV, was hydrolyzed (5.0 g.) in 50 cc. *N* sulfuric acid on the boiling water-bath for twelve hours. The product was isolated in the usual manner and distilled under high vacuum [b. p. 150° (0.1 mm.)] yielding trimethyl galactose as a sirup; yield, 4.8 g. (Found: OMe, 41.8. Calcd. for $C_9H_{18}O_6$: OMe, 41.9).

A partial separation of 2,3,4-trimethyl-galactose from 2,4,6-trimethyl-galactose can be achieved through fractional crystallization of the corresponding anilides from ether–alcohol solution. A more satisfactory method was developed through the preferential reaction of the 2,3,4-

trimethyl derivative with triphenylchloromethane. Accordingly, 2.5 g. of the sirup was treated with 3.0 g. of triphenylchloromethane in 12 cc. of pyridine solution at room temperature for two days. The reaction mixture was then triturated with a small quantity of water to dissolve pyridine hydrochloride and the solution poured into an excess of rapidly stirred ice-water. The insoluble trityl derivative settled out as a gum along with residual reactant. After standing in the icebox with occasional stirring, the solution (A) was decanted from the granular residue. The latter, washed with fresh ice-water, dissolved in acetone, dried over magnesium sulfate, decolorized with norite, filtered and evaporated to a thin sirup, deposited crystals of triphenylcarbinol. The mother liquor, upon evaporation to a sirup (0.9 g.) and treatment with aniline (0.4 g.) in absolute ethanol under reflux for three hours, crystallized upon removal of solvent. Recrystallization from absolute ethanol gave the anilide of 2,3,4-trimethyl-6-trityl-galactose; yield, 0.7 g., m. p. 152°. (Found: OMe, 17.1. Calcd. for $C_{34}H_{37}O_5N$; OMe, 17.2).

The solution (A) containing unreacted 2,4,6-trimethyl-galactose was neutralized with silver carbonate and filtered. Silver ion was removed with hydrogen sulfide, and, after filtering, decolorizing with norite, and evaporating excess solvent, a sirupy residue was obtained; yield, 1.0 g. (Found: OMe, 52.2. Calcd. for $C_9H_{18}O_6$: MeO, 52.5).

The sirup, upon treatment with aniline (0.5 g.) in the usual manner crystallized upon removal of solvent. Recrystallization from ether–alcohol solution gave 2,4,6-trimethyl-galactose anilide; yield, 0.9 g., m. p. 178°.[11] (Found: OMe, 31.4. Calcd. for $C_{15}H_{24}O_5N$: OMe, 31.4.)

Summary

1. Fractional distillation of the glycosidic sirup obtained upon methanolysis of arabo-galactan methyl ether yields three main fractions. These are, respectively, dimethyl-methyl-galactoside, trimethyl-methyl-galactoside, and a mixture of tetramethyl-methyl-galactoside and trimethyl-methyl-arabinoside.

2. Based upon the 6:1 molecular ratio of galactose to arabinose in the original polysaccharide, the molecular ratio of the glycosidic components is 3:1:2:1, respectively.

3. The arabinose component of arabo-galactan is joined to a tri-linked galactose residue.

4. The position of such linkage is through the 1 position of the arabinose component to the 6 position of the galactose residue.

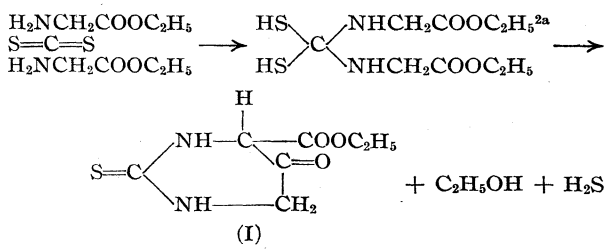
2-Thio-5-keto-4-carbethoxy-1,3-dihydropyrimidine and Related Compounds

BY JOHN H. YOE AND GEORGE R. BOYD, JR.

Sheppard and Brigham[1] described the preparation of a heterocyclic compound which gave a deep purple colored precipitate in the presence of silver ions and suggested that it might be used as a sensitive reagent for silver. Recently Yoe and Overholser[2] have employed this compound for the colorimetric determination of silver.

The compound, 2-thio-5-keto-4-carbethoxy-1,3-dihydropyrimidine, was prepared by the action of carbon disulfide on the ethyl ester of glycine. An intermediate product was formed, diethylaminoacetate dithiocarbamate, which upon further treatment with carbon disulfide eliminated hydrogen sulfide and ethyl alcohol, closing the ring and forming the desired product. The reaction as outlined by Sheppard and Brigham[1] is as follows



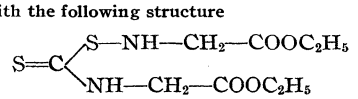
(I)

M. L. Huggins prefers to regard the structure (I) not as a closed heterocyclic ring, but as a chain which is chelated through a hydrogen bridge,[3] thus

(1) S. E. Sheppard and H. R. Brigham, THIS JOURNAL, **58**, 1046 (1936).

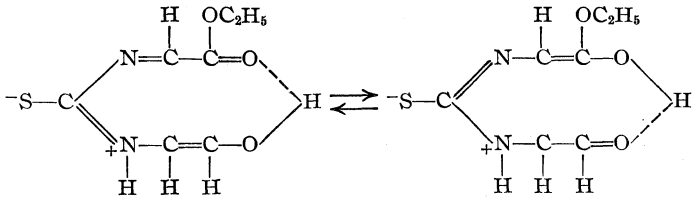
(2) J. H. Yoe and L. G. Overholser, *Ind. Eng. Chem., Anal. Ed.*, **14**, 148 (1942).

(2a) Sheppard and Brigham wrote the formula of this intermediate product with the following structure



Consideration of the arrangement of the electrons about the atoms, however, suggests that the structure first given is more likely.

(3) Private communication to the authors from Dr. S. E. Sheppard, Eastman Kodak Company.



The compound prepared in this manner is an orange solid which is very soluble in aniline, phenol, thymol, and hot ethylenechlorohydrin. It is soluble in hot acetophenone and slightly soluble in acetone, acetic acid, and hot benzene. It is insoluble in carbon tetrachloride, ligroin, and water. Its melting point is 276–280°.

In an attempt to confirm the structure of this silver reagent, Sheppard and Brigham[1] attempted to synthesize it by the condensation of thiourea with α,γ-dichloracetoacetate, but obtained only "a red oil which could not be crystallized."

First attempts to synthesize the compound in this Laboratory were made according to the published directions of Sheppard and Brigham,[1] but as the reaction gives only very small yields (on the order of 1%) and since only small amounts of ethyl glycinate were used, it was impossible to isolate any crystalline material by this means.

In a private communication to the authors, Sheppard and Brigham revised their procedure slightly, saying that it gave somewhat higher yields than their older one. Both procedures required the use of absolute alcohol, but it has been found in this Laboratory that the presence of a small amount (1%) of water in the alcohol is essential for the preparation of the cyclic compound.

Preparation of 2-Thio-5-keto-4-carbethoxy-1,3-dihydropyrimidine.—The best method of synthesis was found to be as follows: 50 g. of ethyl glycinate hydrochloride was suspended in 25 ml. of water in a separatory funnel and 30 ml. of a 40% solution of sodium hydroxide was added while shaking and cooling under running water. This was saturated with anhydrous potassium carbonate and then extracted with ether, using four 25-ml. portions. The extract was allowed to dry over anhydrous potassium carbonate for twenty-four hours. At the end of this time, the potassium carbonate was filtered off and washed twice with ether that had been dried over sodium. The filtrate was cooled in ice.

Eight milliliters of carbon disulfide was added to the ether solution of ethyl glycinate while stirring and cooling in ice. The diethylaminoacetate dithiocarbamate settled out as an oil and froze to a white solid upon further cooling. The ether was decanted and poured on 50 ml. of 99% alcohol at once (the intermediate product changed into a red oil upon prolonged contact with the air); 2 ml. of carbon disulfide was added and the solution was refluxed for forty-eight hours.[4] At the end of this time, the solution was quite dark in color. When the solution was cooled in ice and stirred, a large amount of precipitate appeared and was filtered off. The solution from this precipitation was evaporated to about one-half of its original volume; an orange red precipitate settled out, and this was filtered off and recrystallized from ethylene chlorohydrin. The compound so formed melted at 275° and gave a very intense purple color when a 0.025% solution in acetone was treated with silver nitrate solution. The amount of the orange compound thus obtained was about 0.3 g.

Following the same procedure except for the use of absolutely dry reagents (absolute alcohol was prepared by distilling alcohol dried over lime from sodium methylate and ethyl phthalate; carbon disulfide dried over "Drierite") and with the reactions carried out in an atmosphere of nitrogen, a yellow compound was obtained. This compound was purified by recrystallizing from dioxane. The melting point was 181° and the compound gave a red color reaction with silver.

If more than 1% of water is present in the alcohol, the yield of (I) is decreased; only about 150 mg. was obtained using alcohol containing 1.5% of water.

Additional Compounds

Since the above procedures for the synthesis of the silver reagent gave, at best, only very poor yields of the desired product, several related compounds were prepared in an attempt to find some compound which would be comparable in sensitivity toward silver, but which could be more easily prepared. The starting material in every case was diaminoacetone which was synthesized from citric acid by the method of Kalischer[5] as improved by Koessler and Hanke.[6]

The diamine, in the form of its dihydrochloride, can be purified by recrystallizing from water. *Anal.* Calcd. for $C_3H_8ON_2 \cdot 2HCl$: N, 17.39. Found: N (Dumas), 17.24; (Kjeldahl), 17.31.

Diaminoacetone is quite reactive and can be coupled with several reagents to give cyclic compounds. These were investigated as possible sensitive reagents for silver.

Van Alphen[7] has shown that diamines react with carbon disulfide forming cyclic compounds, and so it was thought that diaminoacetone should react with carbon disulfide according to the scheme.

(4) S. E. Sheppard reports that the yield of 2-thio-5-keto-4-carbethoxy-1,3-dihydropyrimidine may be greatly increased by adding hydrogen peroxide in aqueous solution just before refluxing the alcoholic solution of diethylaminoacetate dithiocarbamate. In one experiment in which 20 ml. of 2.5% aqueous solution of hydrogen peroxide was added to 80 ml. of an alcoholic solution of the dithiocarbamate (obtained from 13 g. of ethylglycinate hydrochloride) before refluxing, a 12.6% yield of the purified orange compound was obtained. This is about a ten-fold increase in the yield previously obtained. Stronger solutions of hydrogen peroxide and also sodium peroxide are now being tried. Private communication from Dr. S. E. Sheppard.

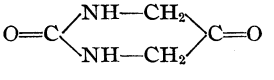
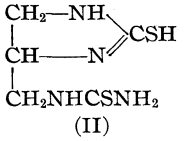
Diaminoacetone dihydrochloride was dissolved in hot alcohol and hot alcoholic sodium hydroxide then added in sufficient quantity to neutralize all hydrochloric acid. An equivalent amount of carbon disulfide was then poured into the solution, causing a vigorous reaction. A brown precipitate formed immediately, which was filtered off and dried at 110°. This compound gives a white precipitate with silver ions which decomposes into silver sulfide upon standing.[8] The compound decomposes without melting at about 150°.

Chloroformic ester was added to a hot alkaline solution of diaminoacetone, yielding a white precipitate which Rügheimer and Mischel[9] say is probably a derivative of urea having the formula

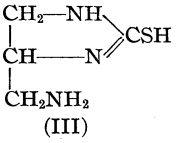


This compound gives a white precipitate with silver ions.

According to Pyman[10] two products are obtained when diaminoacetone is treated with potassium thiocyanate



(II)



(III)

Diaminoacetone dihydrochloride was heated on a water-bath for ninety minutes with the theoretical amount of potassium thiocyanate causing the formation of a white precipitate. The two products were separated by heating with water in which most of the precipitate dissolved leaving only a small residue. This residue, which melts at 212° with decomposition, is only very slightly soluble in acetone and alcohol. In acid solution, however, it gives a yellow precipitate with silver ions. This seems to be compound (II).

If the aqueous solution is allowed to crystallize, another compound is obtained which darkens at 240° but does not melt even when heated to 350°. This compound gives a white precipitate with silver and presumably is compound (III).

It is apparent from the reactions of the various compounds with silver ions that those with simpler structures give white or light colored precipitates and that only compound (I) gives a highly colored precipitate and hence is the most sensitive reagent for silver.

Rhodanine, which is closely related to these compounds, behaves in an analogous manner. Thus, Feigl[11] found that the condensation product of rhodanine with *p*-dimethylaminobenzaldehyde gave a more highly colored precipitate with silver ions than did rhodanine itself.

Acknowledgment.—Our thanks are expressed to Professors Robert E. Lutz and Alfred Burger for helpful suggestions during the course of this investigation.

Summary

2-Thio-5-keto-4-carbethoxy-1,3-dihydropyrimidine has been prepared by a modification of the Sheppard and Brigham method. Several related compounds have also been made. The reactions of these compounds with silver ions have been studied; only the former is a sensitive reagent for silver.

(8) Sheppard and Brigham[1] also prepared this compound by another method and report this reaction with silver.

Adsorption of Organic Compounds. I. Adsorption of Ampholytes on an Activated Charcoal*

BY VERNON H. CHELDELIN AND ROGER J. WILLIAMS

During recent years charcoal adsorption has become an important operation in the purification of materials of biological importance. It has been especially useful in the concentration and isolation of several of the water-soluble vitamins, the wound hormone traumatin[1] and the amino acid methionine.[2]

Amino acids as a class might be expected to be adsorbed considerably less than the parent carboxylic acids, due to their salt forming properties and high water solubilities. A few experiments by Phelps and Peters[3] and Bartell and Miller[4] indicate that glycine and alanine are not adsorbed at all on Norite or sugar charcoal, and that aspartic acid and glutamic acid are only slightly adsorbed, with a maximum near the isoelectric point. Ito[5] observed marked adsorption of the

basic amino acids lysine, histidine and arginine. Wunderly[6] obtained adsorption isotherms for phenylalanine, leucine, alanine, serine and aspartic acid on animal and sugar charcoals.

Further information regarding the charcoal adsorption of organic ampholytes is lacking. It was therefore decided to begin a systematic study of the problem by obtaining adsorption isotherms for thirty-three amino acids, vitamins and related compounds on one charcoal, with emphasis upon discovering differences in adsorption produced by constitutive differences within the molecules of the different adsorbates.

Experimental

Adsorbent.—The adsorbent used in the present investigation was Darco G-60, a commercial grade lignite charcoal which is in general a very effective adsorbent.[6a] Its ash content (practically all non-leachable) is 4% and the charcoal was used as received since information was first desired with respect to an adsorbent which finds common laboratory and commercial use. Adsorption studies using other charcoals will be discussed in another communication.

Method of Measuring Concentrations.—Measurements of all amino acid solutions and some of the others were made by the interferometric method.[7] The instrument used was of the Zeiss portable water type and was calibrated for each adsorbate by obtaining readings of several solutions of known concentrations. After adsorption and centrifuging, readings were made and the residual concentrations were calculated by comparison with the standards. The inorganic constituents of the charcoal were not leached away by this procedure, so that it was possible to detect concentration changes as small as 10 mg. per liter.

The lower concentrations of calcium pantothenate, β-alanine, biotin, pyridoxin and thiamin after adsorption were determined by microbiological assay methods developed in this Laboratory.[8,9]

Duplicate determinations were made for each experimental point. The number of duplicate experiments ranged from three to ten for each substance tested, averaging five or six.

Procedure.—Samples of the adsorbent were weighed into 50-cc. Erlenmeyer flasks. To these were added the desired volumes of various concentrations of a given solution. The amounts varied from 25 ml. to 2 liters per gram of carbon, depending upon the solute used. The flasks were stoppered and shaken for thirty minutes, after which the solutions were centrifuged, decanted and their concentrations determined in the interferometer.

Experiments were run at room temperature, which was usually about 25° but at times rose to 35°. Other workers[10] have found little change in adsorption over this temperature range.

Preliminary experiments with asparagine showed that adsorption was essentially complete in a very few minutes. This is in line with general experience in so far as adsorption is a reversible process.

The substances tested were adsorbed from pure solutions with no special effort being made in most instances to control their *p*H, since ampholytes in solution tend to maintain *p*H values near their isoelectric points. Comparison of the *p*H values of many amino acid solutions before and after adsorption revealed relatively little change in *p*H (Table I). In the cases of pantothenic acid and biotin dilute solutions of aspartic acid (0.0025 *M*) were added to buffer the systems near the isoelectric points of these substances.

Treatment of Adsorption Data.—Any attempt to reduce adsorption behavior to a simple mathematical expression usually results in the adoption of the well-known Freundlich equation.[11] In almost all cases in the present study the Freundlich equation was found applicable. The Langmuir equation[12] has been found in our work to be less useful.

Data and Results

The data obtained for each adsorbate are listed in Table II. The values of $1/n$ and k were determined from adsorption isotherms (not shown) derived from the experimental data.

It may be observed from Table II that, contrary to previous reports,[3,4] glycine and alanine are definitely adsorbed, although only slightly. The amounts adsorbed are less than for the parent carboxylic acids, but increase with increasing members of a homologous series. This is in accordance with adsorption experience in general.

The introduction of an amino group into the carboxylic acid molecule more than doubles the values of $1/n$ in the Freundlich equation. The

[a] The per cent. average deviation is the average of the deviations obtained at all concentrations. [b] 50 mg. carbon per cc. solution in the first two cases, 20 mg. per cc. in the last three. [c] 20 mg. carbon per cc. solution for the five highest concentration levels, 40 mg. per cc. for the lower five. [d] 20 mg. carbon per cc. solution at the highest concentration, 10 mg. per cc. in the others. [e] In this case the logarithmic plot is not a straight line. The value of $1/n$ increases with dilution. [f] Duplicate determinations made nine months later with a different sample of charcoal. [g] This value does not fit in well with generalizations presented later, but is only very approximate due to experimental difficulties involved in obtaining sufficient data regarding a compound of such low solubility. In several similar cases the $1/n$ values increased with dilution.

higher homologous alpha amino acids have somewhat lower $1/n$ values compared to the lower members and branched chain amino acids seem to have higher $1/n$ values than the corresponding straight chain acids. The position of the amino group appears to be important, for β-alanine has a lower $1/n$ value than either α-alanine or α-aminobutyric acid.

The introduction of additional functional groups causes at most a slight rise in the $1/n$ value. The effect of these additional groups on the *amount* of adsorption is in the opposite direction, however, as was the case with the monoamino monocarboxylic acids mentioned above.

Striking differences exist between aromatic and

aliphatic compounds, both in the values of $1/n$ and in the amounts adsorbed.

While the difference in $1/n$ for the representative carboxylic acids (acetic, benzoic) is not large, the difference becomes much greater when amino groups are introduced; for whereas among aliphatic acids the $1/n$ values are increased by the presence of polar groups, the effect of these groups when placed on the aromatic nucleus is to *lower* the $1/n$ values. The difference in $1/n$ for alanine and phenylalanine is most striking, and illustrates the influence of the benzene nucleus on adsorption.

The relation between the amounts of adsorption and the trend in $1/n$ values is opposite in aromatic compounds to that found among the aliphatic compounds.

The adsorption data for various nutrilites is as varied as might be expected on the basis of the structures of the nutrilites themselves.

Calcium pantothenate, β-alanine, thiamin hydrochloride and inositol are all non-aromatic compounds with several polar groups. Their $1/n$ values are high (above 0.6) in accordance with the previous discussion. The aromatic compounds nicotinic and *p*-aminobenzoic acids and pyridoxin hydrochloride have low $1/n$ values (below 0.4). Biotin, the structure of which is unknown, on this basis would be expected to be non-aromatic ($1/n = 0.69$), provided of course that the extrapolated curve is valid over the extremely wide range for which as yet no experimental data are available.

It is worthy of note that the adsorption data for several of the nutrilites follow the Freundlich equation through extremely wide concentration ranges. By using microbiological tests it has been possible in some cases to measure adsorption from solutions far more dilute than has hitherto been possible in dealing with organic compounds. The application of the Freundlich equation through a wide range is somewhat contrary to results obtained with certain other substances studied within a much narrower range.

Summary

1. Adsorption isotherms have been obtained for thirty-three amino acids, vitamins and related substances using Darco G-60 as the adsorbent. The experimental data fit the equation commonly known as the Freundlich adsorption isotherm.

2. Several generalizations have been evolved from the data which show certain trends (based upon structure) in adsorption and in the $1/n$ values of the Freundlich equation. The presence and position of polar groups and the presence or absence of aromatic nuclei are important factors.

Studies on High Molecular Weight Aliphatic Amines and their Salts. VII. The Systems Octylamine–, Dodecylamine– and Octadecylamine–Water

BY A. W. RALSTON, CHARLES W. HOERR AND EVERETT J. HOFFMAN

Previous studies upon the behavior of aliphatic amines in water have been concerned only with amines of low molecular weight, and the literature pertaining to the higher homologs in water is confined to statements regarding their solubility. Preceding papers of this series have reported some aspects of the behavior of the hydrochlorides and acetates of primary aliphatic amines containing from 8 to 18 carbon atoms in the paraffin chain. This paper reports the behavior of octyl-, dodecyl- and octadecylamines in water. Since these three amines represent a cross-section of the series of normal primary aliphatic amines, a comparison of their water systems illustrates the effect of increased length of the alkyl chain upon such systems.

The applicability of the phase rule to colloidal systems has been demonstrated with respect to soap phases by McBain and his co-workers.[1] While they have shown that the phase rule can be applied in its usual form without the introduction of any new variable, they point out several of the assumptions and interpretations which must necessarily be made to fit the phase rule to some of the phenomena encountered in colloid chemistry. Of course, the original Gibbs deduction of the phase rule specifically excludes the effects of surface and boundary forces which are so important in connection with colloidal behavior; hence, in some cases certain observations must be omitted

(1) McBain, Vold and Vold, THIS JOURNAL, **60**, 1866 (1938).

or ignored. In other cases relative importances must be determined before an interpretation can be made. For example, no absolute meaning can be attached to the definitions of homogeneity and heterogeneity, since in dealing with colloids the degree of dispersion of the various phases has considerable bearing on their behavior.

Further complexities in the application of the phase rule to colloidal systems, aside from the confusion of the terminology, arise from the experimental difficulties encountered in dealing with these systems. The problem of establishing and maintaining equilibrium conditions is often an obstacle presented by the nature of the substances under observation. At certain temperatures the liquid phases may possess a very high viscosity, or the solid phases may exist in gelatinous or mesomorphic states. Hence, there is a problem of maintaining intimate admixture of the phases to bring about an equilibrium between them. In some cases, too rapid cooling may introduce a false phase which may not disappear for such a length of time that it would appear to be a true equilibrium phase. While these metastable phases have a given place in the phase diagram, they are misleading in the investigation of the stable phases. Thus it is essential, in studying a given phase, to demonstrate that equilibrium can be attained from higher and lower temperatures, and from higher and lower concentrations.

Procedure

Preparation of Materials.—Caprylonitrile, lauronitrile and stearonitrile were prepared by the action of ammonia upon the respective acids.[2] The caprylonitrile and lauronitrile ($n^{25}D$ 1.4184 and 1.4342, respectively) were purified by vacuum distillation,[3] and the stearonitrile (m. p. 42.0–43.0°) was crystallized from 95% ethanol. These nitriles were hydrogenated to the corresponding amines, which were then purified by fractional distillation *in vacuo*.[4] The amines used in this investigation had the following boiling points: octylamine, 46.5° (4 mm.); dodecylamine, 81.4° (1 mm.); and octadecylamine, 153.2° (1 mm.). Their freezing points, determined by the cooling curve method (*vide infra*), were −1.0, 28.0 and 52.5°, respectively. Titration with standard hydrochloric acid solution using methyl red as the indicator, in all cases yielded values exceeding 99.95% amine. These compounds were exposed to the atmosphere as little as possible in order to minimize absorption of carbon dioxide.

The water used in most of these experiments was distilled from an alkaline potassium permanganate solution in an all-Pyrex glass still, and was used in making up the amine samples directly after cooling without access to the air. Its specific conductance was 0.8×10^{-6} mho at 25°. The carbon dioxide content, therefore, was at a minimum. For the cooling curve measurements, boiled distilled water was used.

Experimental.—Five methods of investigation were followed. In every case, each amine–water sample prepared was first heated until it became a homogeneous liquid, or, in the ranges of concentrations where the systems do not become homogeneous at ordinary temperatures, until both components were liquefied and could be intimately mixed by shaking or stirring. This precaution has been stressed as a most desirable prerequisite in dealing with colloidal substances.[1]

The first experimental procedure was a synthetic method in which weighed amounts of the two components were sealed in glass tubes. After preliminary heating, the samples were suspended in a constant temperature water-bath and shaken regularly. The temperature of the bath was changed 0.1 to 0.2° about every half hour and the samples were observed visually to determine what phases were present. Since the various phases were arrived at both from higher and lower temperatures, and since the observed transition temperatures obtained in this manner could be duplicated within ±0.1°, it was considered that equilibrium had been attained.

The second method was an analytical procedure. Various compositions of amines and water (of approximately 50 g. total weight) were prepared in tightly stoppered flasks and, after preliminary heating, were placed in a constant temperature water-bath at several given temperatures. The flasks were shaken intermittently for two to three hours to allow the samples to attain equilibrium. Preliminary experimentation indicated that equilibrium was reached well within this time. After this interval, the separate phases were removed by means of a pipet and analyzed for amine content by titration with standard hydrochloric acid solution using methyl red as the indicator. The results obtained by this method showed that the analyses of samples existing in given phases at given temperatures gave calculated compositions of amine which agreed within 0.1% of those predicted by the synthetic method.

Cooling curves were run on amine–water mixtures in the following manner: an amine–water sample (10 g.), after being prepared in a tightly stoppered flask and heated to liquefaction, was transferred to a transparent Dewar flask (100 ml.) fitted with a rubber stopper through which were inserted a glass stirrer and a glass thermocouple well. This flask was swept with nitrogen before the introduction of the sample, and the stirrer was sealed at its insertion through the stopper with stopcock lubricant to minimize diffusion of carbon dioxide into the sample. Iron–constantan thermocouples were employed, and the reference junction was immersed in melting ice kept in a silvered Dewar flask (2 l.). Ice and water were used as the cooling bath for the amine–water samples above 0°, and acetone and solid carbon dioxide were used below this temperature. The thermal analyses thus obtained, for the most part, gave transition temperatures which agreed within ±0.1° of those obtained from the visual observations. However, in the cases in which samples containing the most highly hydrated forms of the two higher amines went through

(2) Ralston, Harwood and Pool, THIS JOURNAL, **59**, 986 (1937).

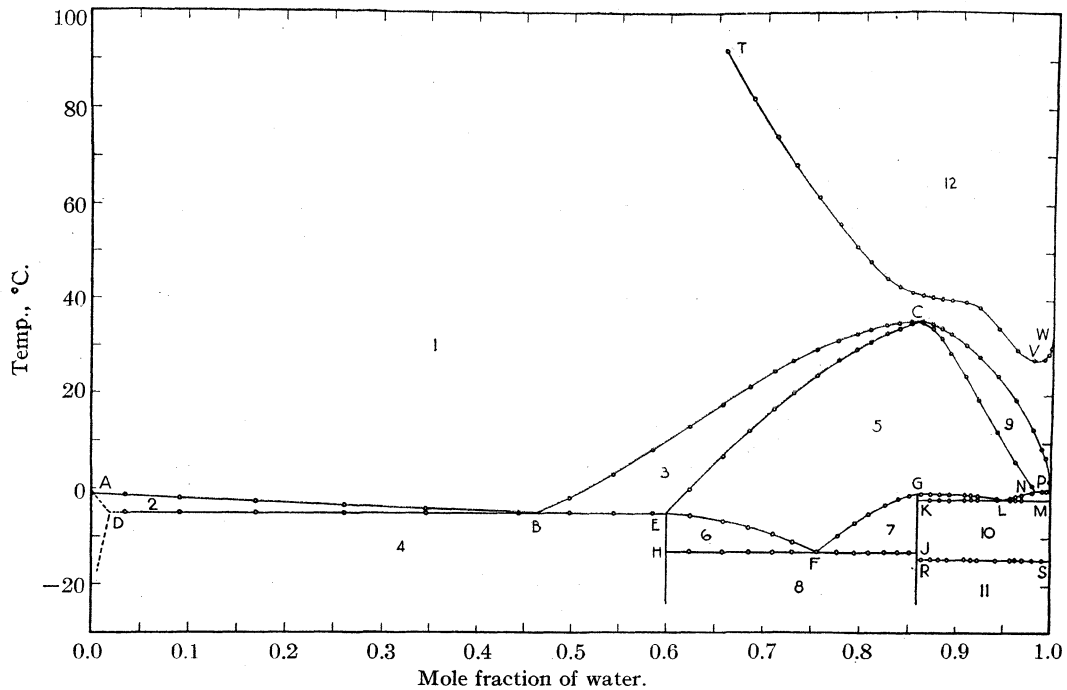

Fig. 1.—Transition temperatures of the system octylamine–water.

mesomorphic changes before crystallization, the cooling curves gave less accurate results because of the slower rate of heat transfer within the samples and the slow rate of formation of the crystalline phases.

Several of the transitions, chiefly the lowering of the freezing point of water by solution of the amines, were determined with a Beckmann thermometer in the usual manner. The transition temperatures obtained by this method agreed well within 0.1° of those obtained by the above procedures.

Finally, microscopic examinations with polarized light were made on a number of samples of varying composition in order to determine more definitely what phases were present. The samples were placed on ordinary glass slides and inclosed with thin glass cover slips sealed with paraffin. Observations were made chiefly at room temperature. However, some samples were heated gently over a small flame and were examined as they cooled. These observations verified the existence of the various phases in their given order as previously found by gross examination. Further observations of the order of appearance of certain phases were made by cooling the stage of the microscope below room temperature by means of a small piece of solid carbon dioxide.

Since transition temperatures could, in general, be duplicated to ±0.1°, and since the agreement of the results obtained by the various experimental procedures was also within ±0.1°, the transitions shown in the phase diagrams presented in this paper are probably accurate to ±0.2°.

Experimental Results

Octylamine–Water.—The temperature–composition relations of octylamine and water are shown graphically in Fig. 1. On this diagram, point A represents the freezing point of octylamine (−1.0°). Area 1 is isotropic solution. Two hydrates are formed, one having a composition of $(C_8H_{17}NH_2)_2 \cdot 3H_2O$ and the other $C_8H_{17}NH_2 \cdot 6H_2O$. The sesquihydrate exists as a crystalline solid below −5.0°, and above this temperature it breaks down to a mixture of hexahydrate and solution (area 3). The hexahydrate changes from a crystalline solid to a mesomorphic state at −14.5° (R). Between this temperature and −0.4° (G) it exists as a firm semi-solid of the smectic type of liquid crystal. From −0.4° (G) to its melting point, 34.6° (C), it exists as a nematic type of liquid crystal.

The portion of the diagram ABCED represents the equilibrium between octylamine and its hexahydrate. Octylamine precipitates from the isotropic solution (area 1) along AB and the hydrate precipitates along BC, giving a eutectic at B. Thus area 2 consists of a two-phase mixture of solid amine and solution, and area 3 of mesomorphic hydrate and solution. Below DBE (area 4) the system consists of a heterogeneous mixture of crystals. Microscopic examination of solutions at temperatures just below BC with polarized light shows the presence of inverted focal conics, indicating that the hydrate molecules are beginning to aggregate in liquid crystalline arrangements as the system cools below BC.

Examination of samples in area 5 shows a microscopically homogeneous fluid of a viscosity such that it will barely flow under its own weight at the lower temperatures, but of lower viscosity as the temperature is increased. Under polarized light, samples in this region reveal delicate thread-like lines of light, showing the presence of molecular layers in the liquid. The samples in this region can be considered to be one phase in accordance with the phase rule, analogous to the solid solutions of mixtures of metallic elements. In this case, however, instead of being a crystalline solid, the system consists of a highly dispersed mixture of amine and hydrated amine molecules in a mesomorphic state.

Octylamine sesquihydrate crystallizes from the isotropic solid solution (area 5) along EF while one of the forms of the hexahydrate precipitates out along FG, giving a eutectoid at F. Below HFJ (area 8) the system consists of a heterogeneous mixture of crystals.

The equilibria between the several forms of octylamine hexahydrate and water are in the concentration range of 0.857 to 1.0 mole fraction of water. The equilibrium between the nematic form of the hexahydrate and water is not shown clearly in the diagram. The eutectic between them (P) is located near 0.9996 mole fraction of water. Investigations in this neighborhood were considered relatively inaccurate since it was impossible to prevent contamination of such necessarily small amounts of amine with some carbon dioxide. However, measurement of the lowering of the freezing point of water along NP indicated that 0.0004 mole fraction of amine was in solution. The nematic octylamine hexahydrate precipitates from the isotropic solution (area 1) along CP, giving a two-phase mixture in area 9. On crossing CN, the microscopically homogeneous solid solution (area 5) is obtained.

On further cooling of the solid solution, smectic hexahydrate precipitates along GL, while water freezes along LN, giving a eutectoid at L. Thus below KLM (area 10) the system consists of a heterogeneous mixture of mesomorphic hydrate and ice. Since the crystalline hexahydrate forms at $-14.5°$, the system consists of a mixture of ice and hydrate crystals in area 11.

On being heated above TVW, the isotropic solution separates into two conjugate solutions, the layer of lower density being rich in amine, and the more dense one being water-rich. Analysis of the amine-rich layer by titration showed that the amount of octylamine at any given temperature was of the composition corresponding to that temperature on TV. The composition of the water-rich layer could not be determined accurately by analysis because small amounts of amine remained as a suspension of microscopic droplets in the water-rich layer.

Dodecylamine–Water.—The temperature–composition relations of dodecylamine and water are shown graphically in Fig. 2. On this diagram A represents the freezing point of dodecylamine (28.0°). Area 1 is isotropic solution. Three hydrates are formed, one having a composition of $(C_{12}H_{25}NH_2)_3 \cdot 2H_2O$, another $C_{12}H_{25}NH_2 \cdot 2H_2O$ and the third $C_{12}H_{25}NH_2 \cdot 4H_2O$. The lowest hydrate exists as a crystalline solid below 24.4° (F), while above this temperature it breaks down to a mixture of higher hydrate and solution. The dihydrate exists as crystalline solid below 15.4° (H), while between this temperature and 35.5° it exists as a smectic type of liquid crystal. At 35.5° the mesomorphic hydrate begins to liquefy, while at 36.5° (C) this mixture of hydrate and solution changes to isotropic solution. The dodecylamine tetrahydrate exists as crystalline solid below 14.0° (R), while above this temperature it exists as a smectic type of liquid crystal, changing to a form of the nematic type at 34.2° (P) and to another form of the latter type at 38.0° (O). At 48.0° (M) the tetrahydrate decomposes.

The equilibrium between dodecylamine and its dihydrate is similar to that between octylamine and its hexahydrate. Dodecylamine precipitates out of the isotropic solution (area 1) along AB, while the dihydrate freezes out along BC, giving a eutectic at B. Thus areas 2 and 3 consist of two phase mixtures, solid amine and solution, and solid dihydrate and solution, respectively. Below EBF (area 4) the system consists of a heterogeneous mixture of crystals of dodecylamine and its dihydrate.

Area 5 of this diagram is similar to area 5 of the octylamine–water system. Again the solid solution consists of a microscopically homogeneous mesomorphic mixture of amine and amine hydrate. As samples in this area are cooled, the lower hydrate precipitates out along FG and dihydrate freezes out along GH, giving a eutectoid at G. Below JGK (area 6) the system consists of a heterogeneous mixture of crystals of the two hydrates.

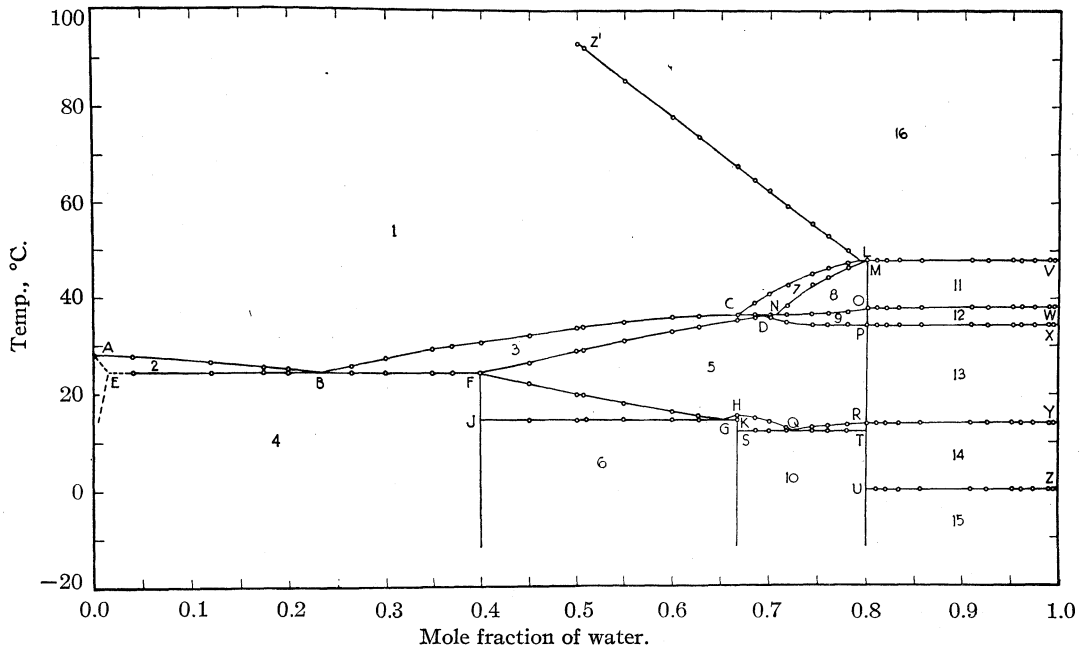

Fig. 2.—Transition temperatures of the system dodecylamine–water.

As the isotropic solution above CL is cooled, dodecylamine tetrahydrate freezes out, giving a two phase mixture of solid hydrate and solution in area 7. Below NM this mixture changes to a solid solution similar to that in area 5, while along NO the tetrahydrate transforms to another mesomorphic form giving a two phase mixture (area 9). On cooling this mixture, solid solution (area 5) is obtained.

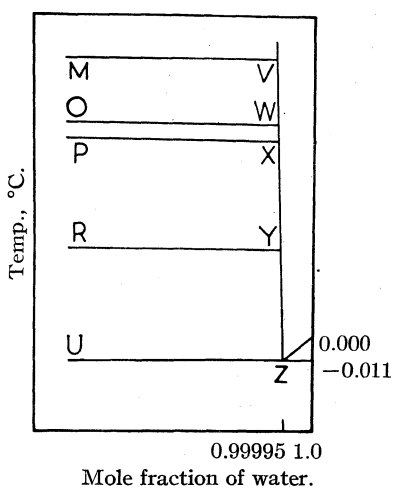

Fig. 3.—Diagram of eutectic between dodecylamine tetrahydrate and water (not drawn to scale).

Along HQ crystalline dodecylamine dihydrate freezes from the solid solution, while crystalline tetrahydrate appears along QR, giving a eutectoid at Q. Below SQT (area 10) the system consists of a mixture of these crystalline hydrates.

Beyond 0.8 mole fraction of water (MOPRTU), Fig. 2 shows the practically independent behavior of the various forms of dodecylamine tetrahydrate and of water. Measurements of the freezing point of water (along UZ) indicated that the eutectic between the tetrahydrate and water lies in the neighborhood of 0.99995 mole fraction of water. Hence, the isothermals (LMV, OW, PX, RY and UZ) intersect a curve (VWXYZ) representing the solubility of dodecylamine tetrahydrate in water. This region is illustrated by the enlarged diagram in Fig. 3. Thus, beyond 0.99995 mole fraction of water above Z to 0.0°, the system exists as isotropic solution.

In the part of the diagram between Z'LMOPRTU and VWXYZ in the temperature range investigated the system exists in all regions as two phases. In areas 11, 12 and 13 one of the phases is solution, and the other is the appropriate mesomorphic form of tetrahydrate (*vide supra*). In area 14 one of the phases is crystalline tetrahydrate, and the other is solution. In area 15 one phase is crystalline tetrahydrate, and the other is ice. Above LMV the system exists as two conjugate solutions similar to those occurring in the octylamine–water system (area 12, Fig. 1). The lines LMV, OW, PX and RY are isothermals. Their depression with increasing concentration is

well within the experimental accuracy of their measurement.

The portion of the diagram in the neighborhood of area 12 is a region of formation of a fibrous, curd-like solid of hydrated amine. This is a metastable compound which is frequently obtained on cooling the two phase mixture of mesomorphic tetrahydrate and solution, and is never obtained on heating the system. It is not found in the octylamine– and octadecylamine–water systems. If samples in which this metastable product is obtained are held at room temperature, transformation to the smectic form of the tetrahydrate and solution takes place slowly. The metastable compound, in some cases, has remained for several months.

In Fig. 4 are shown photomicrographs of the crystalline forms of dodecylamine and of its three hydrates, together with the appearance of the metastable curd-like compound.

Octadecylamine–Water.—The temperature–composition relations of octadecylamine and water are shown graphically in Fig. 5. On this diagram A represents the freezing point of octadecylamine (52.5°). Area 1 is isotropic solution. Two hydrates are formed, one having a composition $(C_{18}H_{37}NH_2)_3 \cdot H_2O$, and the other $C_{18}H_{37}NH_2 \cdot 2H_2O$. The lower hydrate exists as crystalline solid below 50.5°, while above this temperature it breaks down to a mixture of dihydrate and solution. The dihydrate exists as crystalline solid below 43.3°, while above this temperature it transforms to a smectic state. At 64.0° the dihydrate decomposes.

In Fig. 5 octadecylamine crystallizes from the isotropic solution (area 1) along AB, while the dihydrate precipitates along BC, giving a eutectic at B. Thus areas 2 and 3 consist of two-phase mixtures of solid amine and solid dihydrate, respectively, and solution. Below EBF (area 4) the system consists of a heterogeneous mixture of crystals.

Samples in area 5 are solid solutions microscopically indistinguishable from the corresponding phase of the other amines (area 5, Figs. 1 and 2). On cooling this solid solution, the lower octadecylamine hydrate freezes out along FG and the dihydrate along GH, giving a eutectoid at G. Below JGK (area 6) the system consists of a mixture of the two crystalline hydrates.

The part of the diagram beyond 0.667 mole fraction of water (DHKL) represents the behavior of the several forms of the dihydrate with water. As in the case of dodecylamine tetrahydrate, there is a eutectic between the octadecylamine dihydrate and water similar to that shown in Fig. 3. As far as was determined, the solubility of this dihydrate in water must be less than 1.8×10^{-6} g./liter, since this amount must be in solution to lower the freezing point of water 0.001°. However, no such depression was observed by measurement with a Beckmann thermometer. Hence, the eutectic in this case is beyond 0.999991 mole fraction of water. No further attempt was made to determine more accurately the location of the solubility curve through MNP in Fig. 5.

Between DHKL and MNP the octadecyla-

Discussion

Qualitatively the three systems investigated are similar. All three amines form hydrates; the higher the molecular weight, the lower the degree of hydration. Microscopic examinations indicated that hydrates of the lower amines tend to form more nearly perfect crystals than hydrates of the higher amines. As would be expected, the lower amines and their hydrates are considerably more soluble in water than the higher homologs. Of the systems investigated, that of octylamine–water is the only one in which there is an isotropic liquid region across the whole range of concentrations.

The amine hydrates found, with the exception of the lowest hydrate of each amine, pass through one or more mesomorphic states before their melting or decomposition points are reached. The hydrates of the lower members of the series tend toward the nematic type of liquid crystal, while those of the higher members tend toward the smectic type.

In the case of octylamine, the hexahydrate is relatively unstable, the water of hydration being very loosely bound to the amine molecules.

This is shown by the relative flattening of the curve as the melting point of the hydrate is approached from higher and lower concentrations, indicating that considerable change in the water content of the hydrate is necessary to change the melting point to any great extent. Since the addition of an impurity (in this case one of the decomposition products) tends to cause lowering of the melting point of a given compound, and since the lowering is greater with greater compound stability, the relative instability of this hydrate is indicated. The decomposition of the other amine hydrates is evidence of their instability.

The fibrous, curd-like, metastable compound formed only in the dodecylamine system suggests the behavior of dodecylamine hydrochloride in water.[5] In the latter system, also, a similar fibrous, curd-like, metastable compound was found on rapid cooling of systems containing large amounts of water. This behavior is not observed in the case of the octadecylamine hydrochloride–water system, and likewise it is absent in the present case of octadecylamine–water.

In each of the three diagrams presented the dotted lines at the left of the figures show the existence of a small region of solid solution of amine and amine hydrate. While these areas were indicated, their exact location was not verified by direct measurement.

With the interpretations and limitations which have been placed upon the mesomorphic states, and since equilibrium conditions have been evidenced by the agreement of the transition temperatures obtained by several different experimental methods, the applicability of the phase rule to these colloidal systems has been demonstrated. The equilibria between the amines and their respective hydrates are similar to phase diagrams for ordinary crystalloidal compounds. In the case of the higher amine hydrates, their insolubility and their mesomorphic changes account for the numerous isothermals which are present in their diagrams.

The authors are indebted to Drs. J. A. Wilkinson and H. A. Wilhelm of Iowa State College for their assistance and helpful suggestions during the course of this investigation.

Summary

1. The systems octylamine–water, dodecylamine–water and octadecylamine–water have been investigated.

2. The phase rule has been applied to these systems.

3. The following hydrates have been found: $(C_8H_{17}NH_2)_2 \cdot 3H_2O$ (dec. −5.0°); $C_8H_{17}NH_2 \cdot 6H_2O$ (m. p. 35.6°); $(C_{12}H_{25}NH_2)_3 \cdot 2H_2O$ (dec. 24.4°); $C_{12}H_{25}NH_2 \cdot 2H_2O$ (m. p. 36.5°); $C_{12}H_{25}NH_2 \cdot 4H_2O$ (dec. 48.0°); $(C_{18}H_{37}NH_2)_3 \cdot H_2O$ (dec. 50.5°); and $C_{18}H_{37}NH_2 \cdot 2H_2O$ (dec. 64.0°).

Plumbic Acetate–Anhydrous Acetic Acid Solutions

BY ARTHUR W. DAVIDSON, W. CLARENCE LANNING AND SR. M. MAXINE ZELLER

It is well known that whenever a comparison is made between two hydroxides of the same metal, the one in which the metal is in the lower state of oxidation is the more basic and the more soluble in water. A partial qualitative explanation of this fact may be based upon the distribution of electrons about the metal atom.[1] Evidence of an analogous relationship in non-aqueous systems has hitherto been limited to observations on the solubilities of sulfates in sulfuric acid.[2]

The fact that plumbic acetate (lead tetraacetate), unlike most plumbic salts, is stable at ordinary temperatures and may, in fact, be prepared rather readily, affords an opportunity for a comparison of the solubilities of the two acetates of lead in anhydrous acetic acid, solutions of plumbous acetate in this medium having already been studied.[3] Hutchinson and Pollard,[4] who were the first to make an extensive study of the properties of plumbic acetate, reported that it is

not acted upon at ordinary temperatures by concentrated sulfuric acid, and it was confirmed in this Laboratory that plumbic acetate in acetic acid solution, unlike the plumbous salt, does not take part in rapid metathetic reactions (except with water); the compound behaves in this respect like a non-electrolyte. It seemed of interest, therefore, to compare the electrical conductivities of the two solutions.[5,6] Another property of the acetates which might be expected to vary greatly with the valence state of the lead is the tendency to form addition compounds with alkali acetates. Griswold and Olson[7] found the solubility of plumbous acetate in acetic acid to be increased in the presence of sodium acetate, although they were unable to obtain an addition compound of the two acetates in the solid state; Lehrman and Leifer,[8] however, showed the existence of potassium acetatoplumbites analogous to the hydroxoplumbites of the aqueous system.

In the present work, the solubility of plumbic acetate in acetic acid over a range of temperatures has been determined, the conductances at 30° of both plumbous and plumbic acetates have been measured, and the effect of sodium acetate upon the solubility of the plumbic compound has been studied. The results, in every case, were in accord with the hypothesis that plumbic acetate is an extremely weak electrolyte in this solvent.

Method

Preparation of Materials.—Anhydrous acetic acid, and sodium and plumbous acetates, were prepared as described in previous papers from this Laboratory. Plumbic acetate was prepared by crystallization from a solution made by adding red lead to hot glacial acetic acid, as described by Hutchinson and Pollard[4b]; their method was slightly modified, however, in that the product was recrystallized from anhydrous acetic acid and was dried over phosphorus pentoxide in a current of dry air. The product was analyzed by treatment with water to give lead dioxide and acetic acid; the precipitate was filtered off and weighed, while the filtrate was titrated with sodium hydroxide solution. A typical analysis gave: PbO_2, 54.00%; $(CH_3CO)_2O$, 46.07% (calculated for $Pb(C_2H_3O_2)_4$: PbO_2, 53.95; $(CH_3CO)_2O$, 46.05%).[9]

Solubility of Plumbic Acetate in Acetic Acid.—The solubility at various temperatures was determined both by synthetic and by analytic methods. In the former method, equilibrium temperatures were determined for samples of known composition as described in previous papers. The chief source of error in these determinations lay in the difficulty of preventing hydrolysis of the plumbic acetate by atmospheric moisture. Because of the extraordinary sensitiveness of the dry salt to hydrolysis, samples which had been moistened with acetic acid and subsequently analyzed were used in many of the determinations. It may be of interest to mention that the atmospheric humidity was an important factor in determining whether or not the dry salt could be handled successfully. When the humidity was high, even the briefest exposure to the atmosphere brought about appreciable discoloration, whereas at low humidity several samples could be removed successively from the same weighing bottle without discoloration of the residue. At several temperatures, also, mixtures containing an excess of solid salt were allowed to come to equilibrium, from both higher and lower temperatures, in a constant temperature bath. Samples of the liquid phase were drawn off, weighed, and analyzed for plumbic acetate content. Points obtained by both methods fall upon the same smooth curve.

Conductance Measurements.—These were all made at 30°, by means of a Leeds and Northrup bridge, an audio oscillator as a source of alternating current, and a type A Washburn cell; the conventional method was suitably modified for the measurement of low conductances. The specific conductivity of the acetic acid used was 3.8×10^{-8} reciprocal ohm, which is within the range of variation of the values given in the literature.

Solutions were made up by weight in stoppered 50-ml. flasks; each such solution was diluted several times with known weights of acetic acid, and the conductance measured after each dilution. In the case of plumbic acetate, the conductivity of the solutions differed so little from that of pure solvent that only specific conductivities have been reported. For plumbous acetate, which was found to approximate a weak binary electrolyte in behavior, the molar conductances were calculated.[10] Since the conductance of the solvent would probably be greatly decreased in acetate solutions, because of the common ion effect,[11] no solvent correction was applied.

Solubility of Plumbic Acetate in Sodium Acetate Solutions.—The method used for these determinations was the same as that described in a previous paper[12] for a similar study on zinc acetate. Acetic acid solutions were prepared containing six different concentrations of sodium acetate, and the solubility of plumbic acetate in each of these solutions, over a limited range of temperature (22 to 46°), was determined just as in the binary solutions. From these solubility curves data were obtained, by interpolation, to show the isothermal variation of solubility of plumbic acetate with sodium acetate concentration.

(5) Conductance data for solutions of plumbous acetate in 99.4% acetic acid are given by Schall and Meltzer, *Z. Elektrochem.*, **28**, 474 (1922). Molar conductances observed by them for this medium, however, are very much higher than for the anhydrous acid.

(6) A determination of the conductance of plumbous acetate in pure acetic acid at a single concentration is reported by Kolthoff and Willman, THIS JOURNAL, **56**, 1014 (1934).

(7) Griswold and Olson, *ibid.*, **59**, 1894 (1937).

(8) Lehrman and Leifer, *ibid.*, **60**, 142 (1938).

(9) Since the completion of the experimental work here described, an improved method of preparation of lead tetraacetate, similar to the above, has been described by Bailar, in "Inorganic Syntheses," Vol. I, McGraw-Hill Book Co., Inc., New York, N. Y., 1939, p. 47.

(10) In this calculation, the molar concentration was taken as the molality multiplied by 1.039, the density of acetic acid at 30°. Since the highest concentration used was less than 0.1 molar, no significant error was introduced by this simplification.

(11) Kolthoff and Willman, THIS JOURNAL, **56**, 1007 (1934).

(12) Davidson and McAllister, *ibid.*, **52**, 519 (1930).

Results

1. Solubility of Plumbic Acetate in Acetic Acid.—In the following table, S denotes the mole percentage of plumbic acetate, and T the corresponding equilibrium temperature. The synthetic method was used except as otherwise noted. The data are presented graphically in Fig. 1.

TABLE I

PLUMBIC ACETATE—ACETIC ACID

S	T	S	T
Solid phase $HC_2H_3O_2$		Solid phase $Pb(C_2H_3O_2)_4$ (cont.)	
0	16.60		
0.088	16.52		
.193	16.45	0.638[a]	37.0
.280	16.40	.798[a]	45.0
		1.03	53.0
Solid phase $Pb(C_2H_3O_2)_4$		1.29	59.8
		1.64	68.4
0.354	18.2	1.96	74.6
.427	25.2	2.55	82.3
.512[a]	29.9	3.31	90.7
.582	33.5	3.74	94.4

[a] These data were obtained by the analysis of solutions saturated at the given temperature.

Since analysis by the method already described had already shown that crystallization from acetic acid at ordinary temperatures yielded pure unsolvated plumbic acetate, and since there was no indication of a break in the curve except at the eutectic point, no further analysis of solid phases was necessary.

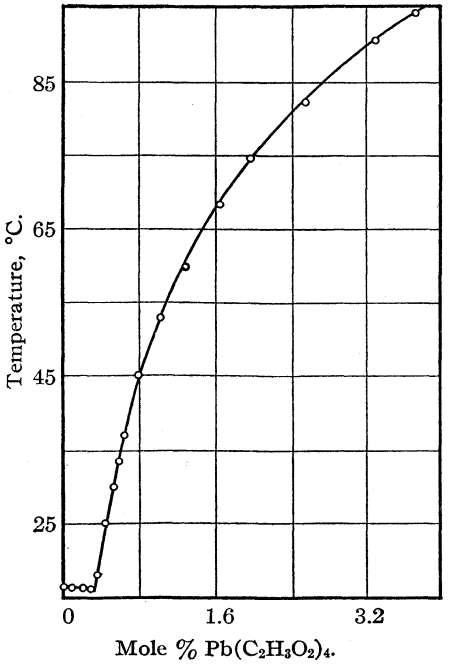

Fig. 1.—Solubility of plumbic acetate in acetic acid.

The solubility of plumbic acetate in anhydrous acetic acid at 25° is found by interpolation to be 0.43 mole %, or 0.072 molal; this is in marked contrast to the solubility of the plumbous salt (hemisolvate) at the same temperature, 16.75 mole %, or 3.35 molal. By a very short extrapolation, the solubility of the plumbic compound at 17° is found to be 0.34 mole %, or 0.057 molal; the latter figure may be compared with Hutchinson and Pollard's[4b] value of 0.062 molal, which, however, applies to the solubility in "glacial" (not anhydrous) acetic acid.

2. Conductance Data.—Specific conductivities, κ, of solutions of plumbic acetate of molality m are shown in Table II, and of plumbous acetate in Table III. Here c is the concentration in moles of solute per liter of solution, Λ the molar conductance. The data for plumbous acetate are shown in a log c–log Λ plot in Fig. 2.

TABLE II

CONDUCTANCE OF PLUMBIC ACETATE SOLUTIONS AT 30°

m	$\kappa \times 10^8$
0	3.80
0.00593	3.80
.0186	4.05
.0262	4.82
.0616	5.56

TABLE III

CONDUCTANCE OF PLUMBOUS ACETATE SOLUTIONS AT 30°

c	$\kappa \times 10^7$	Λ
0.00195	0.556	0.0286
.00626	.880	.0141
.00705	.937	.0133
.0181	1.76	.00973
.0284	2.62	.00921
.0432	3.83	.00887
.0822	8.03	.00977
.0866	8.80	.0102

It is evident from the data of Table II that the specific conductivities of plumbic acetate solutions differ so little from that of the pure solvent that any attempt to calculate molar conductances

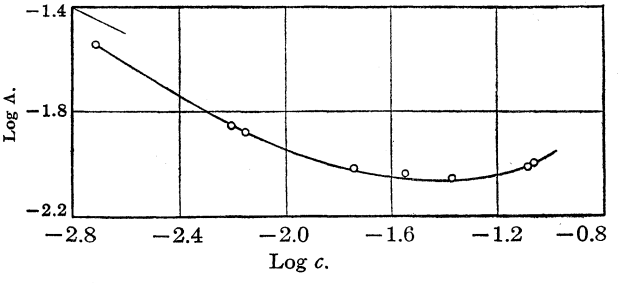

Fig. 2.—Molar conductance of solutions of plumbous acetate in acetic acid.

would have been meaningless. In Table III, the value of Λ is found to go through a minimum (at about 0.04 molar), as is usual in this solvent[13] and in others of low dielectric constant. The molar conductance of a 0.02 molar solution obtained from these data by interpolation is 0.00942; Kolthoff and Willman[11] found the value of 0.00855 for a similar solution at 25°.

3. Solubility of Plumbic Acetate in Sodium Acetate Solutions.—In Table IV, the mole fraction of sodium acetate in the binary solvent is represented by R, while S denotes the mole percentage of plumbic acetate in the ternary solution in equilibrium with solid plumbic acetate at the temperature T.

TABLE IV

SOLUBILITY OF PLUMBIC ACETATE IN SODIUM ACETATE SOLUTIONS

S	T	S	T	S	T
$R = 0.003$		$R = 0.007$		$R = 0.015$	
0.390	24.1	0.404	25.2	0.394	25.7
.417	26.2	.425	27.3	.445	28.3

$R = 0.025$		$R = 0.050$		$R = 0.07$[a]	
0.321	22.5	0.266	23.1	0.339	32.1
.446	32.7	.294	26.3	.368	34.3
.507	36.2	.356	31.9	.379	36.3
.597	41.3	.451	37.8	.429	40.5
.634	43.2	.471	39.0	.461	42.8

[a] This mole fraction is barely below the solubility of sodium acetate (7.06%) in acetic acid at 25°. Hence, in the ternary solutions, $NaC_2H_3O_2 \cdot 2HC_2H_3O_2$ appeared as solid phase at temperatures in the neighborhood of 25°.

Samples of the solid phase from several different solutions were filtered off, dried between porous tiles, and analyzed. The percentages of lead dioxide were found to vary only between 53.6 and 53.9%; hence the solid phase was undoubtedly unsolvated plumbic acetate.

The data of Table IV were plotted in a series of curves, not reproduced here, none of which showed any discontinuity of slope. From these curves were obtained, by interpolation, the isothermal data shown in Table V, where R and S have the same significance as in Table IV.

Thus, contrary to the statement of Schall and Meltzer,[5] the solubility of plumbic acetate is not increased by the presence of sodium acetate, but

(13) Weidner, Hutchison and Chandlee, THIS JOURNAL, **60**, 2877 (1938).

TABLE V

SOLUBILITY OF PLUMBIC ACETATE IN SODIUM ACETATE–ACETIC ACID SOLUTIONS AT 30°

decreases markedly with increasing concentration of the sodium salt.

Discussion

A comparison of the behavior of plumbous and plumbic acetates in acetic acid brings out the following differences.

1. The plumbic compound forms no solvate, and its solubility is little more than one-fortieth as great as that of the plumbous salt. This variation corresponds to the difference between plumbous and plumbic oxides in water; the solubility of the former, at 25°, is about 0.0002 mole per 1000 g. of water,[14] while that of the latter is so small (less than 1×10^{-6} mole per 1000 g.)[15] that it has never been accurately determined.

2. As was pointed out by Kolthoff and Willman,[6] plumbous acetate is a much poorer conductor in acetic acid than are the acetates of the alkali metals; the lead salt must be regarded as being but very slightly dissociated. The course of the log Λ–log c curve, with its slope of $-1/2$ at the lowest concentrations measured (as indicated by the straight line in Fig. 2), is characteristic of the behavior of electrolytes in solutions of low dielectric constant,[13,16] while the minimum molar conductance at a concentration of 0.04 molar, and the increase in Λ with increasing concentration beyond this point, may be attributed to the formation of triple ions.[17] In the case of plumbic acetate, however, the increase in specific conductance brought about by its addition to acetic acid is so small that this solute appears to be altogether non-ionic in character.

3. Although no compound of sodium and plumbous acetates has as yet been isolated from acetic acid solutions, it has been shown[7] that the solubility of plumbous acetate increases with in-

creasing concentration of sodium acetate. In the case of plumbic acetate, the solubility is *decreased* by the addition of the sodium salt. There is no evidence for the existence of compounds corresponding to the plumbates of the aqueous system. The absence of amphoteric properties of plumbic acetate would, by itself, be difficult to reconcile with the generally analogous behavior of corresponding compounds of the water and the acetic acid systems. In view of the other facts here presented, however, the decrease in solubility of plumbic acetate in the presence of sodium acetate appears merely as an instance of the "salting out" of a non-electrolyte.

Summary

1. The solubility of plumbic acetate in acetic acid over a wide range of temperature was determined. No solvate was isolated.

2. The conductivities of solutions of plumbous and plumbic acetates in acetic acid at 30°, over a range of concentrations, were measured. The former was found to behave as a typical weak base, the latter as a non-electrolyte.

3. The solubility of plumbic acetate was found to decrease with increasing concentration of sodium acetate. There was no evidence of amphoteric behavior.

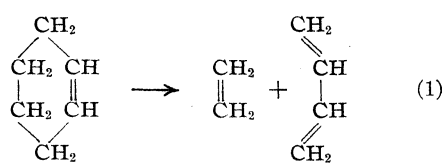
The Decomposition of Cyclohexene Oxide and 1,4-Cyclohexadiene from the Standpoint of the Principle of Least Motion[1]

BY FRANCIS OWEN RICE AND ADRIAN L. STALLBAUMER

(I) **Cyclohexene Oxide.**—In this paper we propose to discuss the homogeneous thermal decomposition of organic compounds in the gaseous state, more particularly with reference to two compounds which we have investigated experimentally. The principle of least motion which we use to interpret our results has been discussed in a recent paper.[2a]

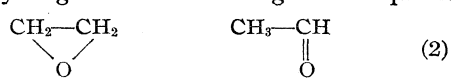
Before taking up in detail the decomposition of cyclohexene oxide, we should like to point out that under certain conditions[2b] cyclohexene decomposes according to the following equation, in which ethylene and butadiene are the sole products



(1)

This decomposition illustrates the value of the principle of least motion because this reaction obviously requires less motion of the constituent atoms and involves less disturbance of the electronic system than any other thermodynamically possible reaction that can be written.

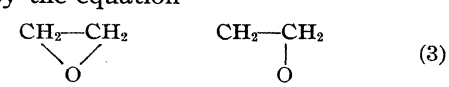
A second reaction that we wish to discuss in this connection is the decomposition of ethylene oxide.[3] The decomposition is obviously complicated yielding methane and carbon monoxide as the final products presumably produced from the decomposition of acetaldehyde which appears as an intermediate product. We exclude a direct migration of a hydrogen atom according to the equation



(2)

both from the principle of least motion (attack of a hydrogen atom on a shielded carbon atom) and also on the experimental basis that ethylene oxide produces free radicals (Paneth effect) under conditions[4] where acetaldehyde is stable. Accordingly we are forced to assume that the change of ethylene oxide into acetaldehyde is not a single step reaction merely involving the migration of a hydrogen atom.

The first step of the decomposition of ethylene oxide may occur in two ways. The first way represented by the equation



(3)

seems unlikely because migration of a hydrogen atom to the exposed end carbon atom could read-

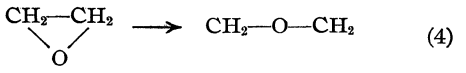
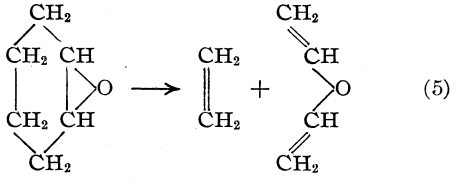
ily occur and acetaldehyde would form in the same way that ethylene forms from diazoethane.[4a] The second possible method of decomposition may be represented by the equation



(4)

and is, we believe, followed by a radical chain decomposition leading to the formation of acetaldehyde. The radical $CH_2—O—CH_2$ cannot isomerize to any molecule unless the constituent atoms undergo a very large amount of motion indeed.

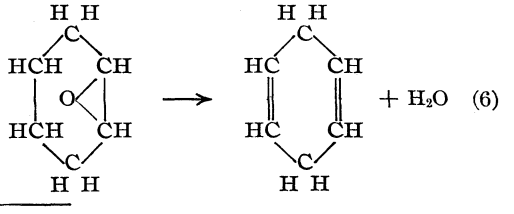
We are now prepared to discuss the thermal decomposition of cyclohexene oxide. If we assume that the decomposition occurs by rupture of a carbon–carbon bond in a manner similar to that shown in Eq. 4, we may expect the production of ethylene and divinyl ether according to the equation



(5)

Actually no divinyl ether was found in the decomposition so that we may assume that incorporating the two carbon atoms of ethylene oxide into a six-membered ring somewhat strengthens the bond between them.

On the other hand, if the carbon–oxygen bond breaks in a manner similar to that shown for ethylene oxide in Eq. 3, we may expect that this will be followed by exceedingly rapid isomerization to cyclohexanone. Our experiments show that there is indeed extensive formation of cyclohexanone. However, this decomposition is accompanied by another because we find in the products appreciable quantities of water, acetylene, butadiene and a hydrocarbon which we believe is 1,4-cyclohexadiene. The appearance of these products would seem to indicate that the following reaction occurs



(6)

(4a) Rice and Glasebrook, THIS JOURNAL, **56**, 741 (1934).

The occurrence of small amounts of water and a C_6 diolefin would not appear to be unreasonable in spite of the relatively large hydrogen–oxygen distances in cyclohexene oxide since these distances become smaller during the normal vibrations of the molecule. The partial decomposition of 1,4-cyclohexadiene into acetylene and butadiene is exactly parallel to the decomposition of cyclohexene into ethylene and butadiene shown in Eq. 1.

Experimental

The cyclohexene oxide was prepared according to a method given in "Organic Syntheses."[5] A second sample was prepared by oxidizing cyclohexene with perbenzoic acid in chloroform solution.[6] The only point requiring special notice in this preparation is that after both reactants have been added, the homogeneous solution must not be allowed to rise above 0° and must be stirred for about ten hours. This is because the reaction is slow and exothermic and, even if kept in an ice-bath, stirring is necessary to prevent local heating. The pyrolytic apparatus used was essentially the same as that described in a preceding article.[2b] The cyclohexene oxide was passed through a quartz tube at a known temperature, the condensable products were caught in traps and the permanent gases were collected over saturated aqueous zinc sulfate solution after leaving the glycerol pump. Podbielniak distillations supplemented by gas analysis enabled us to make a satisfactory analysis of the products and obtain a weight balance. Table I shows the results of three experiments in which cyclohexene oxide was decomposed.

TABLE I

THERMAL DECOMPOSITION OF CYCLOHEXENE OXIDE

	I	II	III
Moles used	1.00	1.15	0.95
Decomposed, %	25	6	27.6
Press., mm.	10	10	6
Temperature, °C.	780	630	735
Contact time, sec.	0.030	0.038	0.048
Water recovered, g.	2.0	1.3	3.6
"1,4-Cyclohexadiene," g.		1.1	4.9
Cyclohexanone, g.			22.3
Butadiene, moles	0.016	0.001	0.005
Acetylene	.015	.003	.016

The cyclohexanone was identified by its boiling point, refractive index and conversion into the oxime. We did not make a satisfactory identification of the material, which we assumed to be 1,4-cyclohexadiene. However, this material had two double bonds, boiled at 88°, was liquid at −80° and its refractive index was $n^{20}D$ 1.4680. The hydrocarbon, 1,4-cyclohexadiene, does not seem to have been very well characterized and its boiling point is variously reported[7] from 84–89° (760 mm.) and $n^{20}D$ 1.47±0.003.

(7) Egloff, "Physical Constants of Hydrocarbons," Reinhold Publishing Corp., New York, N. Y., 1940, Vol. 2, p. 407.

(II) **1,3-Cyclohexadiene.**—We studied this compound because we hoped it would throw light on the decomposition of ethane which yields ethylene and hydrogen according to the equation

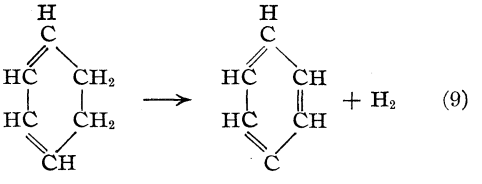
$$C_2H_6 \longrightarrow CH_2{=}CH_2 + H_2 \qquad (7)$$

This may occur by the direct separation of molecular hydrogen in a single elementary act or it may occur by the primary separation into two methyl radicals according to the equation

$$C_2H_6 \longrightarrow 2CH_3 \qquad (8)$$

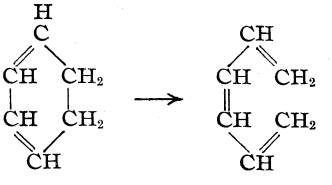
followed by a radical chain.

It seemed at the commencement of this investigation that we could distinguish between these two possibilities in the case of 1,3-cyclohexadiene because the final product would be different depending upon whether the process represented by Eq. 7 or that of Eq. 8 was followed. The process analogous to Eq. 7 would be



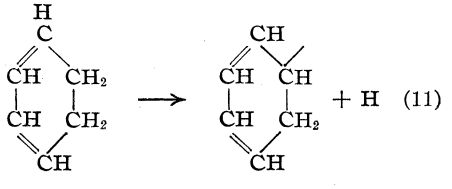
(9)

in which the separation of hydrogen occurs in a single elementary act; on the other hand, the process analogous to Eq. 8 is



(10)

Actually the experimental results showed that benzene and hydrogen are the only products and that there is no 1,3,5-hexatriene formed. However, after further consideration we concluded that our experiment is not after all decisive, and the reaction shown by Eq. 9 may not be the separation of a hydrogen molecule in a single elementary act. This is because the separation of a hydrogen atom from 1,3-cyclohexadiene according to the equation



(11)

results in a large gain of resonance energy in the ring so that the C–H bond may be as weak or even weaker than a C–C bond. Consequently reaction 9 may also occur by a hydrogen atom chain in a manner similar to that postulated for ethane.

It is not even necessary to assume the initial separation of a hydrogen atom as shown in Eq. 11 because a trace of free radicals produced by impurities or initiated at the wall could start a hydrogen atom chain.

Experimental

Six moles of a commercial sample of *o*-cyclohexanediol was acetylated according to standard procedure and 4.4 moles of diacetate [b. p. 240° (760 mm.) and 133° (33 mm.)] were obtained; the yield was 73%. The decomposition of the diacetate to 1,3-cyclohexadiene and acetic acid was performed in the apparatus previously described in which 820 g. (4.1 moles) was pyrolyzed at 750° and 6 mm., the time of the run being six hours; a 50% yield was obtained.

In Table II we show the results of a preliminary experiment on the decomposition of cyclohexane diacetate in which we made an over-all balance and established the fact that hydrogen is formed to the extent of less than 5% and that the main product is 1,3-cyclohexadiene.

TABLE II

PYROLYSIS OF CYCLOHEXANE DIACETATE AND 1,3-CYCLOHEXADIENE

	Cyclohexane diacetate	1,3-Cyclohexadiene

Cyclohexadiene	0.45	...
Benzene	Trace	0.70

In Table II we also give the results of the pyrolysis of 1,3-cyclohexadiene. We performed the experiment at high temperature because we wanted to attain 100% decomposition and thus avoid the difficulty of separating the products from undecomposed substrate; since we anticipated that all the possible products would be very stable we felt that in this particular experiment the procedure would not lead to difficulties due to decomposition of the products. Furthermore, we performed the experiment at a rather low pressure in an attempt to avoid as far as possible the initiation of chain decompositions by the adventitious formation of traces of free radicals. As will be seen in the table we ob-

tained a 70% yield of benzene and 53% of hydrogen. Since 15% of methane was formed it is evident that some sort of secondary chain reaction accompanies the main decomposition into benzene and hydrogen in spite of the low pressure. In these circumstances we feel that we cannot neglect the possibility that 1,3-cyclohexadiene may have been formed by a chain reaction in which a hydrogen atom is one of the chain carriers.

Summary

1. We have discussed the thermal decomposition of organic compounds from the standpoint of the principle of least motion and have pointed out that organic decompositions may consist of a comparatively few elementary (*i. e.*, single step) reactions.

2. On heating cyclohexene oxide the main change is a rearrangement to cyclohexanone. This is accompanied by a decomposition of the cyclohexene oxide into water and a hydrocarbon, probably 1,4-cyclohexadiene.

3. 1,3-Cyclohexadiene decomposes into benzene and hydrogen.

Reproducible Contact Angles on Reproducible Metal Surfaces. II. Interfacial Contact Angles between Water and Organic Liquids on Surfaces of Silver and Gold

BY F. E. BARTELL AND PAUL H. CARDWELL

The angle formed at the line of contact of two liquids, such as water and an organic liquid, against a solid phase is generally referred to as an *interfacial contact angle.* Reliable data pertaining to interfacial contact angles could be of much importance, but such data as do exist are for the most part of questionable value, for seldom do data presented by different investigators show good agreement.

One difficulty which besets the investigator is that, for a given system, he may obtain different and *apparently* stable angles anywhere between two fairly wide limits. The limits of variation are the values of the angles which have usually been referred to as "advancing" and "receding" contact angles. This same variation exists also with contact angles of solid–liquid–air systems and has been discussed in an earlier paper.[1]

In the majority of investigations the fact that the two liquids of a solid–liquid–liquid system possess at least limited miscibility has been largely disregarded. Furthermore, it appears that no one has given much consideration to the possibility that adsorption of the dissolved material might occur at either or both of the solid–liquid interfaces, nor to the fact that highly condensed and firmly held layers might be formed which could not easily be removed and which, by their presence, would cause considerable alteration of interfacial tension.

In the present investigation it has been quite conclusively demonstrated that all of the factors mentioned above must be taken into consideration. In addition it has been shown that time must be allowed for any given system to attain equilibrium. Moreover, in case the experimental procedure is such as to bring about a slight displacement of the liquid–liquid interface at the line of contact with the solid, there then exists a tendency for a comparatively great readjustment of conditions at and near the line of intersection of the interfaces. Such readjustment would involve partial or total removal or deposition of condensed layers as well as both adsorption and desorption processes and might require considerable time before the reattainment of equilibrium.

The solid surfaces selected for study in the present investigation were silver and gold surfaces formed by vaporization and subsequent condensation on Pyrex tips.[1] The liquids were "conductivity" water and purified isoamyl alcohol, *n*-butyl acetate, benzene, α-bromonaphthalene and heptane. The interfacial contact angles were formed with each of these different organic liquids against water on the solids. To save time in attaining equilibrium conditions each pair of liquids (*i. e.*, water and each of the organic liquids) used in this research were mutually saturated before use and it is to be understood that when reference is made to one of the liquids it refers to that liquid as being saturated with the other liquid of the pair.

(1) Bartell and Cardwell, THIS JOURNAL, **64**, 494 (1942).

The apparatus used for the formation of the interfacial contact angles was described in an earlier paper.[1] This apparatus made possible the formation of water drops on metal surfaces immersed in organic liquid as well as of organic liquid drops on metal surfaces immersed in water. In recording contact angles *the convention has been observed of expressing the value as that obtained when measured through the water phase.*

The results obtained in this investigation have shown that for a given solid–liquid–liquid drop system there exist two definite, stable, closely reproducible, contact angles.

Stable Solid–Organic Liquid–Water Contact Angles.—In order to obtain a stable and reproducible contact angle with a drop of water on a solid immersed in an organic liquid, one must form the drop on a solid which was in a fresh and clean condition when it was immersed in the organic liquid and which had been allowed to remain for a sufficient time in the organic liquid before the water drop was formed. If left undisturbed after its formation, the water drop will spontaneously adjust itself so as to reach the *stable* water advancing angle provided the drop as initially formed had an initial advancing angle greater in value than the value of the *stable* water advancing angle. In case the water drop as initially formed had an advancing angle smaller in value than that of the *stable* water advancing angle, no movement of the drop will occur spontaneously until the system has stood awhile longer and the volume of the drop has been expanded by addition of water to such an extent that the contact angle becomes greater than the stable water advancing angle. The drop will then adjust itself so as to form the *stable water advancing* angle. This stable angle does not change with time nor with further addition of water to the drop.

If, after one obtains a *stable water advancing* (solid–organic liquid–water drop) contact angle, one progressively withdraws liquid from the water drop, causing it to decrease in volume, the angle will progressively decrease until finally a definite and *stable water receding* angle is obtained. The value of this angle remains constant even though the volume of the drop is materially altered by withdrawal of liquid and even though the line of contact of solid–liquid–liquid drop is caused to move inward to a considerable extent. This angle we have designated as the *stable water receding contact angle.*

The values obtained for stable angles of water drops are presented in Table I. The stable water advancing angles for each of the organic liquid–water systems have practically identical values for a given metal. For silver this value is approximately 128° and for gold approximately 117°. Earlier investigators have found a similar constancy of interfacial angles for corresponding systems with other solids.[2] The stable water receding angles for the different organic liquid systems on a given metal were not identical and, moreover, in each case they were considerably different from the stable advancing angle.

TABLE I

STABLE SOLID–ORGANIC LIQUID–WATER DROP CONTACT ANGLES

Organic liquid	Water angle on silver Advancing	Receding	Water angle on gold Advancing	Receding
Isoamyl alcohol	127	72	117	61
n-Butyl acetate	129	68	116	57
Benzene	129	58	116.5	45
α-Bromo-naphthalene	127	65	118	55
Heptane	127	58	116.5	45

TABLE II

STABLE SOLID–WATER–ORGANIC LIQUID DROP CONTACT ANGLES

Organic liquid	Water angle on silver Advancing	Receding	Water angle on gold Advancing	Receding
Isoamyl alcohol	126	71	117	59
n-Butyl acetate	129	68	115.5	57
Benzene	129	57	116	45
α-Bromo-naphthalene	126	65	116	55
Heptane	127	57	115.5	45

In the formation of stable interfacial contact angles by organic liquid drops on solids immersed in water the instructions for the formation of stable angles with drops of water can be used. For the use with the organic liquid drops the terms advancing and receding must be interchanged, however, since an advancing (*i. e.*, expanding) organic liquid drop produces a receding water angle. It must be kept in mind also that a spontaneous movement of the organic liquid drop, while giving a smaller angle through the organic liquid phase, will give a larger angle through the water phase which is the phase through which the contact angle measurements must be made.

The results obtained with organic liquid drops are given in Table II. It will be noted that for the different organic liquids on a given metal the water advancing angles were all practically iden-

(2) Bartell and Bartell, THIS JOURNAL, **56**, 2205 (1934).

tical. The angles obtained for silver were, as before, somewhat larger than those obtained for gold. The water receding contact angle values were considerably smaller than the water advancing angle values and were not identical for all the different organic liquids. As was the case also for the water drop measurements, with the non-polar liquids benzene and heptane the receding angle values were the same for a given solid while with the heteropolar organic liquids the receding angle values varied according to the solubility of the organic liquids in water, the greater the solubility the larger the stable receding angle.

A comparison of the data of Tables I and II obtained by the two methods, the one using the water drop and the other using the organic liquid drop, shows that all the corresponding values for the two methods of operation agree within the limit of two degrees. Each value reported in the tables or in the text is the average of at least twenty measurements. The maximum deviation for individual measurements was $\pm 1.5°$, but the deviation of many of the measurements was not more than $\pm 0.5°$. Maximum deviation occurred in the measurement of angles having maximum difference in advancing and receding angle values.

Initial Solid–Liquid–Liquid Contact Angles.—When a water drop was formed upon a new and clean metal surface immediately after immersion of the metal in one of the organic liquids, the water advancing contact angle thus initially obtained was not the same as the stable water advancing angle. On the other hand, when a drop of one of the organic liquids was formed upon a new and clean metal surface immediately after immersion of the metal in water the water receding contact angle thus initially obtained was in all cases, except that of isoamyl alcohol, the same as the corresponding stable angle. Values obtained from measurements made on drops formed within two minutes after immersion of the metal are shown in Table III and are designated *initial angles*.

TABLE III

INITIAL INTERFACIAL CONTACT ANGLES

	Solid–organic liquid–water drop Water advancing angle on		Solid–water–organic liquid drop Water receding angle on	
Organic liquid	Silver	Gold	Silver	Gold
Isoamyl alcohol	107	83	79	65
n-Butyl acetate	111	88	69	58
Benzene	180	95	57	45
α-Bromo-naphthalene	151	108	65	55
Heptane	180	107	58	45

These initial angles were closely reproducible when identical methods of procedure were used, but they were not in all cases stable angles since some of them changed upon standing or upon addition of liquid.

Theory of Condensed Liquid Layers on Solids.—The experiments on stable interfacial angles and on initial interfacial angles demonstrate clearly that there are two, and only two, stable contact angles for any one of these solid–liquid–liquid systems. One stable angle, the water receding angle, can be obtained (except for the liquid systems containing isoamyl alcohol which has the highest solubility in water of any of the organic liquids used) immediately after the mutually saturated immiscible liquids are brought into contact with the solid surface. The other stable angle, the water advancing angle, can be obtained only after these liquids have been allowed to stand in contact with the surface for an optimum period of time which is different for different systems. This indicates that alteration of surface properties at the solid–liquid interfaces must occur before *stable* water advancing interfacial angles can be obtained.

In the case of the stable receding angles, which are obtained immediately, the interface is moving over an area previously occupied by water. In the case of the advancing angles, where the stable advancing angle cannot be obtained immediately, the interface is moving over an area previously occupied by organic liquid. It seems probable that the organic liquids produce on the metals highly condensed and firmly held layers which take time for their formation, whereas water produces no such layers on the metals. The organic liquids used, with the exception of alpha bromonaphthalene which forms small angles, do not form contact angles when placed upon silver or gold in air. The work of adhesion of silver or gold against one of these liquids is greater than the work of cohesion of the liquid. As a result of the attraction of the liquid molecules to the solid phase, the liquid immediately adjacent to the solid apparently tends to become denser and to form, in effect, a condensed layer. The force of attraction may extend through a distance representing a number of molecular diameters. Water, which forms a fairly large contact angle both on silver and gold in air, apparently does not tend to form condensed layers on these metals since the work of adhesion of water against the metals is less than the work of cohesion of water.

Condensed layers formed on solids by the non-angle-forming liquids appear to be tenaciously held and not quickly removed from the solid surface by water. The time that elapsed between the measurements of the initial water advancing angles of Table III and the stable water advancing angles of Table I, shown in Table IV, appears to

TABLE IV

TIME NECESSARY FOR TRANSFORMATION OF INITIAL ADVANCING ANGLES TO STABLE ADVANCING ANGLES FOR SYSTEM SOLID–ORGANIC LIQUID–WATER DROP

Liquid–liquid system	Silver, hours	Gold, hours
Isoamyl alcohol–water	2	1
n-Butyl acetate–water	4	1
Benzene–water	>72	11
α-Bromonaphthalene–water	12	2
Heptane–water	12	2

be approximately the length of time which was necessary for formation of the fully condensed organic liquid layers on the solid plus the time (*i. e.*, in those cases in which the initial contact angles are larger than the stable contact angles) for the water to partially remove this condensed organic liquid so as to give the stable water advancing contact angle. The shortest time was required for isoamyl alcohol (slightly less than one hour with gold) and the longest time was required for benzene (over 72 hours with silver). The water drop in the silver–benzene–water system had not broken through the benzene layer at the end of seventy-two hours as was evidenced by the fact that at the end of that time the contact angle was still approximately 180°. The value of 129° reported in Table I for the stable water advancing angle of the silver–benzene–water system was obtained on a silver surface which had been immersed in benzene no longer than half a minute before the water drop was formed.

The time required for producing stable interfacial water advancing angles formed by receding drops of organic liquids upon the metal surfaces immersed in water was much shorter than the time required for producing the corresponding angles by means of advancing water drops. In general it was found that the systems which required the shortest time to give the stable water advancing angle when the water drop was used required the longest time to give the stable water advancing angle when a corresponding organic liquid drop was used. Drops of heptane, α-bromonaphthalene and benzene on silver gave stable angle values if the organic liquid drops were receded within a few seconds, while with drops of *n*-butyl acetate and isoamyl alcohol it was necessary to let the drops stand for a period of about one minute. If the drops of benzene and heptane were allowed to stand on the solid for an hour or more before being withdrawn, the water advancing contact angles thus obtained approached 180°. As with the water drop system, if the benzene was allowed to remain in contact with the metal too long before the water was advanced over it, the water did not sufficiently remove the firmly held organic liquid layer, at least within any reasonable period of time, to give the stable advancing interfacial contact angles.

Adsorption Effects.—Some adsorption of water from the organic liquid phase at the solid–organic liquid interface probably occurs, but in the systems studied such adsorption is probably less than the adsorption of organic liquid from the water phase at the solid–water interface. Any effect due to adsorption appears to be of much smaller magnitude than the effects due to condensed layers, but the exceptional effects obtained with isoamyl alcohol may be due to its greater solubility in water and the consequently greater amount of this solute available for adsorption at the water–solid interface.

"Hysteresis" of Contact Angles.—The causes for the "hysteresis" of contact angles, that effect responsible for the existence of a definite advancing and a definite receding angle, have been obscure.[3] A rational explanation of the "hysteresis" of contact angles can be made if it is assumed that formation of condensed layers does occur, and if, in addition, consideration is given to the fact that there is adsorption from the fluid phases in contact with the solid. The changes brought about at the various solid–liquid interfaces by adsorption and by the formation of condensed liquid layers would be sufficient to provide very different conditions at the line of contact of the phases when the water is caused to advance and when it is caused to recede. These different conditions account for the existence of stable advancing and stable receding angles. It is probable that both the advancing and the receding angles are equilibrium angles for the system as it exists at the moment of measurement, and that there is no single "equilibrium" angle for any system unless the system is so arranged that the

(3) Adam, "The Physics and Chemistry of Surfaces," Oxford Univ. Press, New York, N. Y., 1938, 2nd ed., p. 180.

same conditions prevail whether the water is advancing or receding.

During the course of this work it was demonstrated that for many systems one can obtain receding angles which have the same value as the advancing angles (including the stable advancing angles). This can be accomplished by permitting the solid to stand in contact with the organic liquid for a comparatively long period of time before forming the water drop, then by immediately receding the drop after its formation. It seems probable that the advancing angles (including the stable advancing angles) thus obtained are formed by water drops advancing over a condensed organic liquid layer, and that the receding angles are formed by water drops withdrawn before the water has an opportunity to remove the condensed organic liquid layer. If the water drop is allowed to stand it begins to remove the condensed layer and not only is the receding angle then obtained different from the advancing angle, but a new advancing angle, immediately reformed over the area that had been under the drop, is not the same as the advancing angle previously obtained.

With metal surfaces and other solid surfaces less inert chemically than gold and silver other complicating factors are introduced which affect the magnitude of contact angles and of interfacial contact angles. Studies carried out in this Laboratory on antimony, bismuth and cadmium have shown that for these more active substances still further factors must be considered in explaining differences between advancing and receding angles. The results of the work on antimony, bismuth and cadmium will be presented in a later paper.

Summary

1. With the sessile drop apparatus described in a previous paper interfacial contact angles were measured for water drops on silver and on gold immersed in organic liquids and for organic liquid drops on these solids immersed in water.

2. For each of the solid–organic liquid–water systems it was possible to produce two stable and reproducible interfacial contact angles. These two angles have been designated as "stable advancing" and "stable receding" interfacial contact angles.

3. The stable advancing and stable receding interfacial contact angles given by water drops on silver and on gold immersed in organic liquids were the same (*i. e.*, within the limits of experimental error, 2° or less) as the corresponding angles obtained by using organic liquid drops on the solids in water.

4. The values of the stable advancing interfacial contact angles were found to be approximately the same for all the different organic liquids on a given metal, silver or gold. For silver this value was 128° and for gold 117°.

5. The stable receding interfacial contact angles were smaller than the stable advancing interfacial contact angles of the same system. For the non-polar organic liquids (benzene and heptane) the stable receding angles were practically of the same value against a given solid. For silver this value was 57.5° and for gold 45°. For the heteropolar organic liquids on silver and gold the stable receding contact angle values of the different liquids were not the same for a given solid but varied according to the solubility of the organic liquids in water. The greater the solubility of the organic liquids in water the larger were the stable receding angles.

6. The existence of two different stable interfacial contact angles for a given system has been explained by the theory that the solid surfaces, or interfaces, contiguous to the fluid phases become altered through adsorption from the fluids or by formation of condensed layers of fluid upon the surfaces. The experimental evidence obtained supports this view.

7. When a given system could be so acted upon by special manipulation that conditions at the interfaces were the same whether the water was advancing or receding, the water advancing angle was the same as the water receding angle.

Magnetism and the Third Law of Thermodynamics. The Heat Capacity of Manganous Fluoride from 13 to 320°K.

BY J. W. STOUT AND H. E. ADAMS

The multiple electronic states present in paramagnetic compounds cause at sufficiently low temperatures a contribution to the heat capacity due to the changing population of the magnetic ions among the various states. Calorimetric investigation yields information about the number and separation in energy of the electronic states in the solid. For example, from low temperature heat capacity measurements on $NiSO_4 \cdot 7H_2O$[1] it has been possible to infer the magnetic energy spectrum in the solid. At high temperatures the random distribution of the magnetic ions among the various states gives rise to a magnetic contribution to the entropy. In order to apply the third law of thermodynamics to the calculation of entropies from low temperature heat capacity measurements, it is necessary to correct for any magnetic entropy remaining at the lowest temperature of measurement. The investigation of the thermal behavior of typical paramagnetic salts contributes to our knowledge of and ability to allow for such magnetic entropy.

The measurements of Bizette and Belling[2] and of de Haas, Schultz and Koolhaas[3] show that the magnetic susceptibility of anhydrous manganous fluoride exhibits a sharp maximum at 72°K. At the temperatures of liquid hydrogen the susceptibility varies with the field strength and there is a small remanent magnetization when the field is removed. We have measured the low temperature heat capacity of manganous fluoride in order to investigate the calorimetric phenomena associated with the behavior of the susceptibility curve as well as to obtain, through the application of the third law of thermodynamics, the entropy at 298°K. for use in thermodynamic calculations.

Apparatus.—The calorimeter consisted of a cylindrical copper can 5.1 cm. in diameter and 10.2 cm. long. An open copper tube, 1.27 cm. i. d., extended axially along the center of the calorimeter. The resistance thermometer made a snug fit inside this tube. A chamber of volume 11 cc. in the top of the calorimeter was connected to a reflux tube in thermal contact with the shield and the liquid hydrogen and nitrogen reservoirs. The portion of the reflux tube between the calorimeter and the surrounding shield consisted of a nickel–silver tube, 6.5 cm. long, 0.32 cm. o. d. and 0.010 cm. in wall thickness. The reflux tube and chamber were used to cool the calorimeter before the start of measurements. The volume of the sample chamber in the calorimeter was 169.5 cc. The sample was introduced through a nickel–silver tube, 0.63 cm. i. d., opening into the bottom of the sample chamber. After the introduction of the sample a copper cap with a small pinhole was soldered on the filling tube. The air was removed from the sample chamber and helium gas at one atmosphere pressure introduced through the pinhole which was then closed with solder. The outside of the calorimeter was gold plated in order to reduce the radiation loss and to prevent tarnishing. The weight of the empty calorimeter was 126.8 g. and of the resistance thermometer 46.6 g.

The calorimeter was mounted in the cryostat which has been described by Blue and Hicks.[4] The inside of the shield surrounding the calorimeter was covered with aluminum foil to decrease the heat radiated to the calorimeter and the lead wires were heat stationed at the top of the shield. A copper–constantan difference thermocouple read the temperature difference between the shield and the calorimeter and another couple measured the difference between the top and bottom of the shield. The current in the shield heaters was manually controlled so as to keep the shield always at the same temperature as the calorimeter. The readings of the difference couples were recorded and corrections have been applied when necessary for the small heat interchange between the shield and calorimeter when the conditions were not completely adiabatic. The maximum correction for non-adiabaticity between 25 and 310°K. was 0.2% of the measured heat capacity. Below 25°K. the shield was not kept at exactly the same temperature as the calorimeter and the corrections for heat interchange were made as in the Nernst-type apparatus. Above 200°K., where radiation is important, the adiabatic apparatus permits a more accurate determination of heat capacities than does the Nernst-type apparatus since the heat interchange can be made very small and corrected for accurately. Furthermore, the temperature difference between the outside radiating surface of the calorimeter and the surrounding shield is measured directly and no assumptions as to the temperature distribution throughout the calorimeter during energy input are necessary. This is particularly important when the thermometer-heater is on the inside of the calorimeter, as in the present case.

Energy was introduced and the temperatures measured by means of the platinum–rhodium resistance thermometer of laboratory designation R222. The calibration of the thermometer has been described by Blue and Hicks.[4] During the present measurements the thermometer was

checked at the ice point and at the triple point of hydrogen and found to agree with the original calibration to within 0.01°. The leads to the resistance thermometer (No. 30 B. and S. gage D. S. C. copper) were wrapped once around the calorimeter. Each of the four lead wires was connected to a corresponding lead from the heat station on the shield by one inch of No. 40 B. and S. gage copper wire so as to minimize the heat conduction. Electrical measurements were made with a Leeds and Northrup Wenner potentiometer.

The method of measurement and the corrections applied to the heat capacities, other than those discussed above, followed the standard practice[5] in low temperature calorimetry. The ice point was taken as 273.16°K. The temperatures calculated from the resistance thermometer calibration of Blue and Hicks[4] were corrected for the change in the choice of the ice point. The defined calorie, 4.1833 international joules, was used throughout.

Material.—The manganous fluoride used for the heat capacity measurements was prepared by the method described by Kurtenacker, Finger and Hey.[6] Manganous carbonate was precipitated from a solution of analytical reagent manganous sulfate by means of a solution of sodium carbonate containing sufficient sodium bicarbonate to prevent the formation of basic carbonates. Only about 90% of the available manganese was precipitated as the carbonate in order to avoid precipitating any magnesium which was a probable impurity in the original manganous sulfate. The manganous carbonate, after being washed free of soluble impurities, was added to a 50% solution of hydrofluoric acid contained in a platinum dish. A fine precipitate of pink manganous fluoride was obtained. In order to remove all the volatile impurities from the precipitated manganous fluoride it was necessary to heat the sample at 250° for five hours. During the heating the manganous fluoride was kept in an atmosphere of carbon dioxide in order to prevent reaction with the oxygen of the air. When the resulting material was examined under a microscope individual crystals could not be distinguished but from the extinction of polarized light it was estimated that the crystals were between 10^{-5} and 10^{-6} cm. in size. A sample of the manganous fluoride was analysed for manganese by Professor G. G. Marvin of this Laboratory. He obtained 58.9% Mn; calcd. for MnF_2 59.11%. Two of the heat capacity points just below the ice-point are about 0.3% high. If this is due to the fusion of ice it would correspond to 0.01% by weight of water in the sample. The presence of this amount of water would produce a negligible effect upon the observed heat capacities so no correction has been made for it.

The Heat Capacity of Manganous Fluoride.—The calorimeter contained 1.7604 moles (163.593 g. *in vacuo*) of manganous fluoride. The heat capacity measurements are presented in Table I and represented graphically in Fig. 1. In Table I Series I and II are exploratory runs. The measurements of Series III extend from 13°K. to above the maximum in the heat capacity curve. In the neighborhood of the maximum the temperature increments were made small in order to determine the shape of the curve. Series IV consists of measurements with small temperature increments extending through the region of the maximum. Immediately before the start of Series IV the calorimeter was cooled from above 80°K. to 65.86°K. The good agreement with the points of Series III shows that there was no supercooling of the heat effect associated with the maximum in the curve. At no time during the measurements was there evidence of thermal hysteresis or slowness in the attainment of equilibrium. Series V and VI extend the measurements to room temperatures. The point in Series VII was measured after the completion of

The heat capacity measurements listed in Table I are values of $\Delta H/\Delta T$ and when ΔT and the curvature of the heat capacity–temperature curve are large, as is the case with some of the measurements in Series II, may differ appreciably from the differential heat capacity. The values in Table II represent the true differential heat capacity.

The heat capacity curve of manganous fluoride rises smoothly to a maximum of about 10.0 cal. deg.$^{-1}$ mole^{-1} at 66.5°K. and then falls rapidly, but not discontinuously, on the high temperature side of the maximum. The measurements indicate that the maximum is rounded at the top, that is, there is no discontinuity in the slope of the heat capacity curve. Measurements of the rate of warming under a small temperature head qualitatively confirmed the shape of the curve given by the short heat capacity measurements. The maximum in the magnetic susceptibility curve[2,3] is at 72°K.

Two measurements were made of the total energy necessary to heat the sample from 61.00 to 76.50°K. In Table III these values are compared with those obtained from the heat capacity measurements. Corrections have been applied in order to convert the different measurements to a common temperature interval for comparison.

TABLE III

CHANGE OF HEAT CONTENT OF MANGANOUS FLUORIDE BETWEEN 61.00° AND 76.50°K.

Measurement	Temp. interval, °K.	H (76.50) − H (61.00), cal. mole^{-1}
Integral heat no. 1	61.34–76.67	121.76
Integral heat no. 2	60.97–76.26	121.79
$\Sigma C_p \Delta T$, Series II	60.46–77.17	121.72
$\Sigma C_p \Delta T$, Series III	61.12–77.64	121.61
	Accepted value	121.8

The entropy was evaluated by graphical integration of $\int C_p \, d \ln T$. The calculation is summarized in Table IV. In making the entropy extrapolation to the absolute zero the function 3/4 D (119.6°K.) per mole of manganous fluoride, which gave the best representation of the lowest temperature heat capacity data, was used. D is the Debye function.

15–298.16°K., graphical integration	22.03
S at 298.16°K.	22.25 ± 0.10 cal. deg.$^{-1}$ mole^{-1}

Discussion.—The ground state of the free Mn^{++} ion is, according to Hund,[7] a ^6S. The magnetic susceptibility measurements as well as theoretical considerations[8] show that in solid manganous salts at high temperatures the magnetic ions are randomly distributed among the six states per ion. As the temperature is lowered the distribution of the magnetic ions among the states changes until at the absolute zero they are all in a completely ordered arrangement of zero entropy. The maximum in the heat capacity curve of manganous fluoride as well as the anomalous behavior of the magnetic susceptibility[2,3] of this substance is associated with the loss of the magnetic entropy. The dotted line in Fig. 1 is an estimate of the "normal" heat capacity curve due to the crystalline vibrations. The entropy contributed by that portion of the measured heat capacity lying above this curve is 1.2 cal. deg.$^{-1}$ mole^{-1}. This is to be compared with R ln 6 = 3.56 cal. deg.$^{-1}$ mole^{-1} which is the total amount of magnetic entropy present at high temperatures which must be acquired as the temperature increases from the absolute zero. It is apparent that a large portion of the magnetic entropy must be acquired in regions of temperature other than that in which there is the evident anomaly in the heat capacity curve. It seems most probable that there is a gradual increase in the magnetic entropy at temperatures above the region of the maximum so that the magnetic contribution to the heat capacity cannot be distinguished from that due to the crystalline vibrations. A similar conclusion was drawn in the case of anhydrous copper sulfate[9] which also exhibits a maximum in its heat capacity curve. Another possibility, which we believe to be very unlikely, is that even at 13°K. there remains a large amount of magnetic entropy which would be lost at lower temperatures.

The maximum in the heat capacity curve is much sharper and narrower than would be the case if the energy states available to each magnetic ion were independent of the situation of its neighbors as is the case in $NiSO_4 \cdot 7H_2O$.[1] The name antiferromagnetism has been given to such a cooperative phenomenon which occurs frequently at low temperatures in concentrated paramagnetic salts. Van Vleck[10] has proposed a theory of antiferromagnetism which is formally similar to the Weiss theory of ferromagnetism. The theory predicts that the magnetic heat capacity would rise gradually to a maximum and then drop discontinuously to zero. At the temperature of the maximum the complete magnetic entropy of R ln 6 would have been acquired. These predictions are not in agreement with our results.

Summary

The heat capacity of manganous fluoride has been measured from 13 to 320°K. There is a maximum in the heat capacity curve, due to the changing distribution of the magnetic manganous ions among the available energy states, at 66.5°K. Short heat capacity measurements were taken in the region of the maximum in order to define accurately the shape of the curve. Measurements were also made of the total heat absorbed between 61.00 and 76.50°K.

The entropy of manganous fluoride calculated from the heat capacity measurements is 22.25 cal. deg.$^{-1}$ mole^{-1} at 298.16°K.

The Distribution of Acetyl Groups in a Technical Acetone-Soluble Cellulose Acetate[1]

BY THOMAS S. GARDNER[2] AND C. B. PURVES

The *p*-toluenesulfonyl (tosyl) esters of primary, as opposed to secondary, alcoholic groups in carbohydrates are quantitatively converted to the corresponding halides by heating with sodium iodide dissolved in a suitable solvent.[3] This analytical method made it possible to determine the molar amount of unsubstituted primary hydroxyl group in the sixth positions of acetone-soluble cellulose acetate, to estimate the corresponding rate of tosylation under standard conditions and to obtain, by difference, the total amount of secondary alcoholic groups distributed in the second and third positions of the anhydroglucose residues.[4] More recent work with a partly ethylated cellulose showed that hydroxyl groups in the second position were tosylated very much more rapidly than those in the third and that a mathematical analysis of their combined tosylation rate plot gave the molar amount of each.[5] The improved experimental and mathematical methods developed in this ethylcellulose study have now been applied to the high grade, commercial acetone-soluble cellulose acetate II used in the previous work.[4]

Experimental

Materials.—Acetyl analysis of the cellulose acetate by a modification of a standard method,[6] as yet unpublished, gave values of 39.73, 39.72, 39.79, 39.60%, corresponding to an average substitution of 2.44. The substitution value of 2.33 formerly accepted as correct for du Pont sample II was accordingly too low.[7] All samples were dried before use or before analysis over phosphorus pentoxide *in vacuo* at 65°.

High grade pyridine was dried over barium oxide and redistilled shortly before use. Commercial *p*-toluenesulfonyl chloride was purified by washing the benzene solution with cold water, drying and decolorizing with carbon. After recovery, the acid chloride was recrystallized from ether–petroleum ether until the colorless product melted at 69°.

The acetonylacetone was freshly distilled under diminished pressure and the sodium iodide was a carefully dried C. P. specimen.

Rate of Tosylation.—The experiment was carried out as formerly[4] but on a four-fold scale. The mixture of 80 g. of the cellulose acetate (1 mole hydroxyl) and 424 g. of tosyl chloride (13.1 moles), dissolved in a total of 1420 ml. of pyridine, was contained in a large, glass stoppered bottle kept in the dark at 20 ± 0.5°. Discoloration of the solution set in very slowly. From time to time a 30 to 50 ml. sample was withdrawn in a glass dipper and the tosylated product was isolated and prepared for analysis as previously described.[4] The first samples were colorless and fibrous but those withdrawn after one week, when replacement of tosyl by chlorine began to be apparent (Notes *e*, *f*, *g*, Table I) had a little color and gave light brown solutions in acetone.

Sulfur analyses were conveniently carried out on the semi-micro scale by a recently published method.[8] Acetyl was determined by the modified technique, in which the carefully shredded sample was heated in alcoholic sodium methylate before the mixture was acidified with excess *p*-toluenesulfonic acid and acetyl was recovered in the form of methyl acetate by distillation. The analyses in Table I, columns 3 and 4, are the mean of closely concordant duplicates and obvious simultaneous equations made it possible to calculate the moles of acetyl present at each stage of the tosylation. The data (column 5) show that the acetyl substitution did not change during the first five days from the original value of 2.44 and the reliability and accuracy of the analytical methods were thereby confirmed. After seven days, when the presence of combined chlorine rendered the acetyl values high, an acetyl content of 2.44 was assumed and the total substitution was calculated from the sulfur and halogen values (Table I, notes *f* and *g*). The last sample isolated (eighty days) was a light brown fibrous material that was soluble in pyridine, acetonylacetone and acetone. Tests for nitrogen were negative. The assumption that this sample had the usual acetyl substitution of 2.44 was justified because on this basis the 1.65% of chlorine and 3.89% of sulfur gave a combined acetyl, chloro and tosyl substitution of 2.99 where theory was 3.00. A Staudinger viscosity determination made with this sample dissolved in glacial acetic acid at 25 ± 0.1°, gave an η_{sp}/c value of 54.8. This value checked very well with those of 53.3 and 52.5 previously found for a 6-chlorotosyl acetate and for the original cellulose acetate II.[4,9] The absence of degradation during prolonged tosylation and the consistency of the acetyl analyses justified the calculation of the molar tosyl substitution (column 6) from the observed sulfur content (column 4) and the average acetyl substitution of 2.44 (column 5).

[a] Calcd. from columns (3) and (4) by means of simultaneous equations. [b] Calcd. from % iodine and acetyl substitution of 2.44. [c] Calcd. by $(0.56 - 0.198) = Z_S = Z_A + Z_B$; $\log 0.139/(0.139 - Z_A) = 2.16\,t$; $\log 0.223/(0.223 - Z_B) = 0.106\,t$. [d] Column 11 was obtained by subtracting a constant iodine substitution of 0.198 (average value) from column 6. [e] Replacement of tosyl by chlorine gives high acetyl values. [f] % Cl = 0.93, giving 0.434 mole of tosyl and 0.087 mole of chlorine, and if acetyl is 2.44; total = 2.961 moles. [g] % Cl = 1.65, giving 0.400 mole of tosyl, and 0.153 mole of chlorine, and if acetyl is 2.44 moles; total = 2.993 moles.

Chlorine in later tosylated acetates was determined by heating 20–30 mg. samples under reflux for two hours with 100 ml. of 95% ethanol containing 2 g. of chloride-free sodium hydroxide (made from metallic sodium). Nitrite-free, 6 *N* nitric acid was used to acidify the mixture before the halogen was estimated by the Volhard method[10] with nitrobenzene to coagulate the silver chloride.

Iodination.—The dry, tosylated sample, 1 g., sodium iodide, 2 g., and acetonylacetone, 75 ml., were heated together to 120°, when solution was complete in all cases. After two hours at that temperature, which was again shown to be sufficient[4,5] for maximum iodination, the solution was cooled, poured into 1 liter of ice water, allowed to stand for one hour and filtered. The residue was washed with distilled water, dried and purified by reprecipitation from aqueous acetone. A final drying at 65° *in vacuo* over phosphorus pentoxide preceded the analyses for sulfur and for iodine. Iodine analyses were carried out as described in the work on ethylcellulose.[5]

The assumption that iodination replaced a portion of the tosyl groups by iodine without altering the original acetyl substitution was checked by calculating the per cent. of sulfur in the iodinated specimens from the observed iodine content (Table I, column 7) and an assumed acetyl substitution of 2.44. Calculated sulfur values (column 9) agreed well with the observed ones (column 8) except with the first four samples, in which the sulfur content was too small to be estimated accurately. The corresponding data for the molar substitution of iodine (column 10) were therefore accepted as reliable. All attempts to iodinate later specimens containing chlorine gave dark colored products which were not amenable to purification and were not further examined.

Results

The molar amount of tosyl groups replaced by iodine (Z) corresponded to the primary hydroxyl groups that had been esterified at any given time. Reference to Table I, column 10, shows that a total of 0.198 mole of hydroxyl was originally present in the sixth position of the cellulose acetate and that all were tosylated within two hours. The total agreed excellently with the earlier value of 0.197 mole,[4] and, as the cellulose acetate averaged 0.56 mole per glucose unit, about 35% of the hydroxyl groups were primary. The earlier work showed that the amount lay between one-third and one-half. Substitution in the first order rate

equation, $\log 0.198/(0.198 - Z) = kt$, of the data in columns 2 and 10 gave values for k of (21.4), 23.2, 21.9 and 25.0 corresponding to (0.25), 0.50, 0.75 and 1.00 hour, respectively. The average rate constant for the last three samples was 23.4 when reckoned in days and decimal logarithms. Calculation by the method of least squares, using the same time intervals, gave 24.9 when most weight was given to the hour interval. No advantage was gained by assuming a second order rather than a first order equation for the tosylation.

Subtraction of 0.198 from 0.56 gave 0.362 as the total moles of hydroxyl group in the second and third positions of the cellulose acetate. Subtraction of the data in column 10 from those in column 6 gave the amount of tosylation, Z_S, in both of these secondary positions at various times. Points corresponding to the function $\log 0.362/(0.362 - Z_S)$ were plotted against time t (in days) and those within the limits 0.71 to 3.08 days inclusive were found to lie about a straight line whose position was determined by the method of least squares[5] (Fig. 1). The conclusion was that the amount of tosylation, Z_B, of 0.223 mole of the secondary hydroxyl groups at any time was given by the equation

$$\log 0.223/(0.223 - Z_B) = 0.106\, t \qquad (1)$$

The remaining 0.139 mole was esterified at a faster rate. If Z_A represented the amount of this more rapid tosylation at any time, $Z_A + Z_B = Z_S$. By the use of Eq. 1, the amount of Z_B was calculated for times between 0.125 and 0.5 days and was subtracted from Z_S (column 11). The values of Z_A so obtained were found to fit the following first order rate equation

$$\log 0.139(0.139 - Z_A) = 2.16\, t \qquad (2)$$

In order to check the data, the sums $Z_A + Z_B$, as calculated from Eqs. 1 and 2, were tabulated in Table I, column 12. The agreement with the observed values of Z_S (column 11) was always within 0.02 mole, and usually within 0.01 mole, until the replacement of tosyl by chlorine became appreciable from sample 23 onward. It is interesting to note that no such replacement complicated the equally prolonged tosylation of the ethylcellulose.[5]

Discussion

The above work was an experimental duplicate of that on the ethylcellulose, when it was demonstrated that hydroxyl groups in the sixth, second and third positions of the anhydroglucose units were tosylated at rates in the approximate ratio of 15:2.3:0.07. Rates for acetone-soluble cellulose acetate were 23.4 for the sixth position with 2.16 and 0.106 for the two kinds of hydroxyl groups occupying the other two positions. Comparison with ethylcellulose values justified the conclusion that the faster rate (2.16) was characteristic of the second position in the acetyl cellulose and the slower one (0.106) pertained to the third. There was no reason to expect that the rates for ethylcellulose and acetyl cellulose would be absolutely the same in magnitude, because steric and other effects caused by the different substituents would not necessarily be the same in the two cases. These effects, however, could hardly be large enough to obliterate or reverse a ratio of rates, one of which was twenty or thirty times the other. It therefore appeared that the deacetylation of cellulose triacetate to the acetone-soluble condition removed 0.223 mole of acetyl from the third position and only 0.139 mole from the second, which was more than twenty times as reactive in tosylation. While it is possible that the reactivities displayed toward acetylation and deacetylation may be reversed, it seems probable that the original "triacetate" contained a few unacetylated hydroxyl groups in the sluggishly reacting position three. Further experiments are required to decide between the alternative explanations.

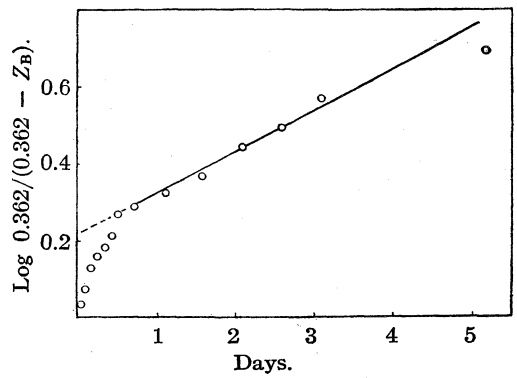

Fig. 1.—Logarithmic plot of rate of tosylation of 0.362 mole of secondary hydroxyl group. Solid line is calculated relationship $\log 0.223/(0.223 - Z_B) = 0.106$ day.

If secondary hydroxyl groups in the acetone-soluble cellulose acetate were distributed in random order but with uniform average density along the length of the macromolecules, the probability of a particular glucose residue containing a completely unsubstituted 2,3 glycol group was 0.139 ×

0.223 or 0.031.[11] If the hydroxyl groups occurred in sharply localized patches along the macromolecule, the probability of a glycol grouping was obviously 0.139 and if deacetylation in one position tended to preclude deacetylation in the other, the probability was 0.139 + 0.223 − 1 or zero.[5]

The oxidation of the cellulose acetate with lead tetraacetate was carried out as before[5] and the results (Table II) showed that 0.0071 to 0.0079, or almost zero, moles of glycol were actually present. This confirmation of the earlier low value of 0.0067 to 0.01 mole[11] supports the inference that the number of 2,3 glycol groups in acetone soluble cellulose acetate, as well as in the partly ethylated cellulose,[5] is depressed by factors still unknown. It also suggests that the partial deacetylation of the triacetate was carried out in a practically homogeneous system and that the loss of acetyl from one of the two secondary alcoholic positions had a marked tendency to stabilize the adjacent group in the same anhydroglucose residue.

(11) Cramer, Hockett and Purves, THIS JOURNAL, **61**, 3463 (1939).

Summary

1. A technical cellulose acetate, averaging 2.44 acetyl and 0.56 hydroxyl groups per glucose residue, was esterified by *p*-toluenesulfonyl chloride. Analyses of samples removed at intervals showed that 0.198 mole of hydroxyl groups was present in the sixth or primary positions of the original cellulose acetate.

2. The data in (1) give, by difference, a value of 0.362 mole of total secondary hydroxyl in the cellulose acetate and mathematical analyses of the rate of esterification showed that there was a first order, fairly rapid tosylation of 0.139 mole of hydroxyl, on which was superimposed a slow tosylation of 0.223 mole. The 0.139 mole was assigned to the second position and the 0.223 mole to the third by analogy with previous experience on an ethylated cellulose.

3. The first order rate constants for the tosylation of unsubstituted hydroxyl groups in the cellulose acetate were found to be in the ratio of 2.16 for the second, 0.106 for the third and 23.4 for the sixth position.

4. Lead tetraacetate oxidation of the cellulose acetate indicated that 7.4×10^{-3} mole of unsubstituted 2,3 glycol was present per glucose residue. The amount calculated for a random distribution of hydroxyl groups in the two positions was 3.1×10^{-2} mole and for localized concentrations of hydroxyl, 13.9×10^{-2} mole. If deacetylation in either the second or third position of cellulose triacetate stabilized the adjacent acetyl group, the probability of 2,3 glycol groups in the resulting acetone-soluble acetate was zero.

The Preparation of Several Deuterium Derivatives of Pyrrole

BY FOIL A. MILLER[1]

In the course of some studies on the vibrational spectrum of pyrrole[2] it became necessary to prepare several of the symmetrically substituted deuterium derivatives. Inasmuch as the methods of preparing these compounds add some interesting facts to our knowledge of pyrrole chemistry, and since other workers may have occasion to prepare deuteropyrroles, it seems worth while to describe the preparations in some detail.

Very little earlier research has been reported on this subject. Pyrrole-N-*d* has been prepared by Redlich and Stricks[3] and by Bonino and Manzoni-Ansidei.[4] The extent of exchange between pyrrole and heavy water has been determined by Koizumi and Titani.[5] They conclude that at *p*H $\geqq$ 2 only one hydrogen exchanges, but that at *p*H $\leqq$ 1 all five hydrogens exchange rapidly. However, no attempt was made to prepare and isolate an isotopically pure product. This paper reports the application of Koizumi and Titani's findings to the preparation of 8 ml. quantities of pyrrole-N-*d*, *sym*-pyrrole-d_4, and pyrrole-d_5. Spectroscopic evidence is offered as convincing proof for the course of the exchanges.

Experimental

Pyrrole-N-*d*. 1. Preparation from Potassium Pyrrole.—This is the method used by both Redlich and Stricks and by Bonino and Manzoni-Ansidei. It was deemed necessary to repeat the work, however, because the Raman spectra of the two samples differed considerably,[3,4] and because pyrrole-N-*d* was needed for purposes of comparison in a later experiment.

The reactions involved are

$$2C_4H_4NH + 2K \longrightarrow 2C_4H_4NK + H_2$$
$$C_4H_4NK + D_2O \longrightarrow C_4H_4ND + KOD$$

Clean potassium was added slowly in slight excess to 10 ml. of freshly-distilled pyrrole[6] dissolved in 80 ml. of toluene. The mixture was warmed and later refluxed in a water-free atmosphere until the precipitate became white. Most of the excess potassium was removed mechanically. The solid was filtered off on a sintered glass funnel in a gas box, washed with ether which was sufficiently dry to give a blue color with sodium and benzophenone, and dried; yield of potassium pyrrole, 80%. The solid was suspended in 40 ml. of dry ether, and heavy water (99.6%) was added dropwise with continued shaking until a second layer of liquid was formed. Five and one-half ml. of heavy water was used, which is about 2.5 times the theoretical amount. The ether-pyrrole-N-*d* solution was filtered through a sintered glass funnel and removed from the gas box, and the ether was evaporated with a stream of dry nitrogen. The pyrrole-N-*d* was dried over sodium carbonate and distilled four times in succession at low pressure in an all-glass apparatus; yield on the second reaction, 70%.

This synthesis, while extremely wasteful of heavy water and pyrrole, is useful because one knows that the deuterium atom introduced into the molecule has bonded to the nitrogen atom of the ring.

Pyrrole-N-*d*. 2. Preparation by Exchange.—Koizumi and Titani suggest that the one hydrogen which exchanges in solutions of *p*H $\geqq$ 2 is the N-hydrogen. It was necessary to confirm this, however, for it was hoped that the suggestion could be applied later to the preparation of *sym*-pyrrole-d_4. One can test the suggestion by carrying out an exchange between pyrrole and neutral heavy water. Comparison of the Raman spectrum of the resulting compound with that of the pyrrole-N-*d* prepared from potassium pyrrole will show whether the exchange proceeds on the nitrogen atom alone. An experiment of this kind has been performed.

Four 2.5-ml. samples of freshly-distilled pyrrole were shaken for one hour with 2-ml. portions of heavy water (99.6%) in 6-ml. cylindrically-shaped separatory funnels. Each portion of the heavy water was used with each of the pyrrole samples in turn. The exchange was continued until calculation indicated that the deuterium content was at least 99% of the total exchangeable hydrogen. The united product was dried over sodium carbonate and distilled as before. Practically no pyrrole was lost.

The Raman spectrum of this product agreed exactly with that of the pyrrole-N-*d* prepared from potassium pyrrole. Hence exchange between pyrrole and neutral water involves only the N-hydrogen.

Pyrrole-d_5.—Koizumi and Titani[5c] have pointed out that *p*H 1 is optimum for exchanging

(6) The pyrrole was obtained through the kindness of Dr. Saul R. Buc, formerly of this Department. It had been prepared from ammonium mucate according to the method of Blicke and Powers [*Ind. Eng. Chem.*, **19**, 1334 (1927)].

all five hydrogens of pyrrole. At pH > 1.5, all the hydrogens do not exchange; at pH < 1, acid-induced decomposition of the pyrrole becomes serious. Pyrrole-d_5 was prepared by an exchange between pyrrole and heavy water at this optimum pH.

Adjusting the heavy water to pH 1 without contaminating it with light hydrogen required special methods. Deuterium chloride was made from heavy water and thionyl chloride, using the apparatus of Langseth and Klit.[7] The deuterium chloride was bubbled into heavy water to which had been added a trace of dry methyl violet, until the color of the solution matched that of a comparison solution of ordinary hydrochloric acid whose pH had been adjusted to 1.0. Trials with ordinary water and hydrogen chloride showed that the pH could readily be adjusted in this manner to 1.0 ± 0.2 unit, which is sufficiently close. The procedure for exchange was similar to that for pyrrole-N-*d*. Because decomposition of the pyrrole resulted in the formation of a scum, and because the liquids did not separate as nicely as in the former case, the separatory funnels were rotated rather slowly in a large centrifuge to hasten the separation. The product was dried and distilled as before. About 1 ml. of pyrrole was lost during the exchange.

Symmetrical Pyrrole-d_4.—This compound was prepared from pyrrole-d_5 by an exchange with neutral water. It has already been shown that under these conditions only the N-deuterium will be involved. The procedure for carrying out the exchange and purifying the product was identical with that for pyrrole-N-*d*. There was practically no loss of material.

(7) A. Langseth and A. Klit, *Kgl. Danske Videnskab Selskab, Math. fys. Medd.*, **15**, No. 13, p. 7 (1937).

Spectroscopic Results.—It is well known that C–H stretching frequencies in aromatic rings are in the 3000–3100 cm.$^{-1}$ region, while the corresponding C–D frequencies are found at 2200–2300 cm.$^{-1}$. The N–H stretching frequency in liquid pyrrole occurs at 3400 cm.$^{-1}$, and the N–D at 2530 cm.$^{-1}$. Thus the vibrational spectrum offers a good criterion for the isotopic purity of the products. Each of the deuteropyrroles has been studied by the Raman effect.[2] In every case valence frequencies were found only in the expected regions; even on long exposure there was no trace of lines due to an improper isotope. This is thought to mean that the isotopic purity was at least 99%. It also offers convincing proof that exchange between pyrrole and water at pH 1 involves all five of the pyrrole hydrogens, but that at pH 7 only the N-hydrogen is involved.

Acknowledgment is made for a grant-in-aid from the Hynson, Westcott and Dunning Fund. The author also wishes to thank the Chemical Foundation, Incorporated, for a fellowship for graduate study.

Summary

Simple and efficient methods of preparing pyrrole-N-*d*, *sym*-pyrrole-d_4, and pyrrole-d_5 are described. It is confirmed that exchange between pyrrole and water at pH 1 involves all five of the pyrrole hydrogens. In neutral solution only the N-hydrogen exchanges.

Conductivity Studies.[1] III. The Limiting Equivalent Conductances of Potassium Chloride in Water at Temperatures between 15 and 40°

BY NORMAN C. C. LI[2] AND HSING FANG[3]

The determination of the electrical conductivity of electrolytes has been the subject of many investigations. A search of the recent extensive literature in this field shows that many investigators study conductivity as a function of concentration at some particular temperature or conductivity as a function of temperature at some particular concentrations, and only few study the variation of the limiting equivalent conductances with temperature.

Since aqueous solutions of potassium chloride have been used as standard solutions for determining cell constants, extensive conductivity studies on these are desirable. Recently Jones and Bradshaw[4] and Bremner and Thompson[5] studied the variation in conductance of "demal"

potassium chloride solutions and Clews[6] applied the Debye–Hückel–Onsager equation to data on 0.1, 0.01 and 0.001 N potassium chloride solutions at different temperatures. Except at 18 and 25°, however, there are no precise values of the limiting equivalent conductance, Λ_0, of potassium chloride in water. It was the purpose of this investigation to study the electrical conductances of potassium chloride solutions over a wide range of concentrations and temperatures in order to determine the temperature coefficient of Λ_0. In the paper following this one, certain transference data will be used together with the conductance data reported in this paper to calculate the limiting equivalent conductances of several univalent ions at different temperatures.

Experimental

The Wheatstone bridge and accessory apparatus used in conductivity determinations have been described.[1] The temperatures investigated were 15, 20, 22, 25, 30 and 40°. For each temperature the bath was adjusted and the temperature variation observed by a Beckmann thermometer which had been compared against a standard thermometer. The temperature variation was 0.005°. The standard solutions for the determination of cell constants were the 0.1 and 0.01 demal solutions defined and measured by Jones and Bradshaw[4] at 0, 18 and 25°. The measured specific conductance was corrected in each case for the conductivity of the water used, amounting to about 1.2×10^{-6} at 25°. The potassium chloride was of Merck reagent quality and was further purified by repeated recrystallization from conductivity water, dried and fused. Solutions were prepared by direct weighing of both solute (or concentrated stock solution) and solvent, the balance used for weighing the dry salt being sensitive to 0.01 mg. with a 50-g. load and that for the solvent sensitive to 0.1 mg. The weights were carefully calibrated on each balance and all weighings were corrected to vacuum, taking the density of the air to be 0.0012 g./ml. and the density of potassium chloride to be 1.987.

Since the salt solutions were made up by weight and the concentrations used in the theory are on a volume basis (moles per liter, C), it was necessary to know the density of the solutions. It was found that the density of the aqueous solutions of potassium chloride was a linear function of the concentration up to the highest concentration used, and obeyed the equation

$$d = d_0 + bf_{KCl} \qquad (1)$$

where d is the density of a solution of f_{KCl} weight per cent. concentration in potassium chloride and d_0 is the density of pure water, both at the same temperature. The values of the density coefficients at 20, 22, 25, 30 and 40° were calculated from the density data in the "International Critical Tables." These were confirmed by the experimental determination of the density of the potassium chloride solutions at 25 and 30°. The density values for 15° are not given, but were calculated by the equation:

$$d = 1.00661 + 0.0000407\,t - 7.95 \times 10^{-6}t^2 + 4.83 \times 10^{-8}t^3$$

the equation obtained from an analysis of the data given in "I. C. T." for 1% potassium chloride solutions. The equations for density at different temperatures are listed

$$\begin{aligned} d_{15} &= 0.99913 + 0.00646f \\ d_{20} &= .99823 + .00640f \\ d_{22} &= .99780 + .00637f \\ d_{25} &= .99707 + .00635f \\ d_{30} &= .99567 + .00631f \\ d_{40} &= .99225 + .00622f \end{aligned}$$

The solutions were kept in seasoned and steamed Pyrex glass-stoppered bottles. In determining the resistance of a given solution, each cell was rinsed with four or five portions of the solution and allowed to stand, filled with the same solution, for fifteen to thirty minutes. The cell was then refilled with a fresh portion of the solution and immersed in the thermostat until temperature equilibrium was reached. The leads were placed in position and the bridge balanced. The leads were then shifted to the next cell and the bridge rebalanced.

Results

Table I gives the results of measurements on the potassium chloride solutions at different temperatures. The third column gives the equivalent conductances calculated from the Shedlovsky–Onsager equation

$$\Lambda_0 = \frac{\Lambda + \beta\sqrt{C}}{1 - \alpha\sqrt{C}} - BC$$

The fourth column lists the values of Λ_0'

$$\Lambda' = \frac{\Lambda + \beta\sqrt{C}}{1 - \alpha\sqrt{C}}$$

In order to calculate the theoretical coefficients α and β, we made use of the viscosity data given in "I. C. T." and the dielectric constant data of

(6) Clews, *Proc. Roy. Phys. Soc.* (London), **46**, 764 (1934).

Drake, Pierce and Dow[7] and substituted them in the equations[8]

$$\alpha = 8.147 \times 10^5/(DT)^{3/2} \quad \beta = 81.86/(DT)^{1/2}\eta \quad (2)$$

where D and η are the dielectric constant and viscosity of the medium at temperature T. These constants are collected in Table II for reference.

Graphs corresponding to the data in Table I for the various temperatures are shown in Fig. 1, where the values of Λ are plotted against $\sqrt{C}$ and Λ_0' plotted against C. The values of Λ_0 and B

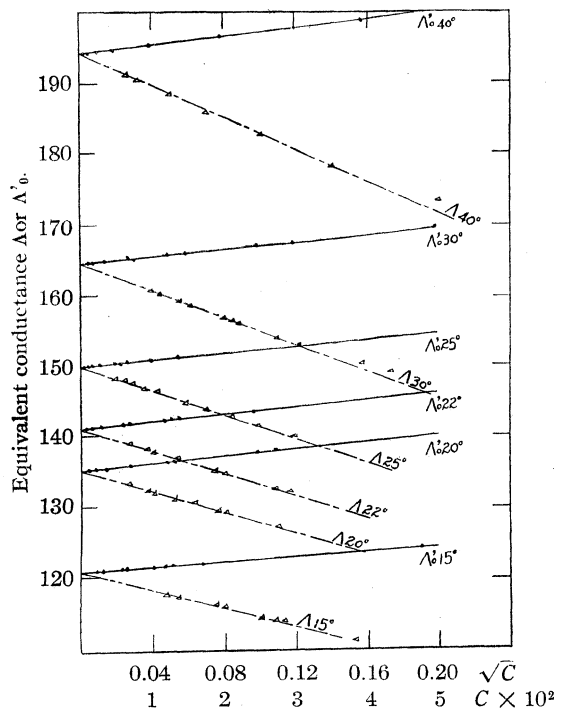

Fig. 1.—Variation of equivalent conductance with concentration.

patrick[10] is 149.86, with which our value of 149.84 is in good agreement. Figure 2 brings out the relationship between Λ_0 and temperature.

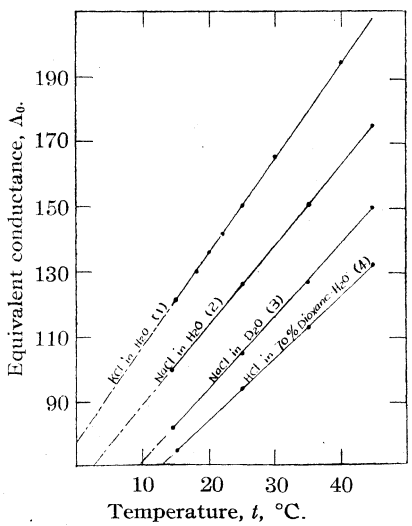

Fig. 2.—Variation of conductance at infinite dilution with temperature.

The relationship in Curve I can be expressed by the empirical equation $\Lambda_0 = 75.94 + 2.956\,t$. It is also interesting to note that the relationship between B and temperature is linear and can be expressed by the equation $B = 46.9 + 1.92\,t$.

Curves 2, 3 and 4 in Fig. 2 are plots taken from data by Brescia, LaMer and Nachod[11] and Owen and Waters[12] and the limiting conductances can be expressed by the equations

NaCl in H_2O	$\Lambda_0 = 64.08 + 2.462\,t$
NaCl in D_2O	$50 + 2.2\,t$
HCl in 70% dioxane	$45.9 + 1.91\,t$

It was shown by Owen and Waters[12] that viscosity and equivalent conductance in a given solvent at various temperatures are simply related by an equation $\Lambda_0\eta_0^s = r$. Figure 3 gives such a plot between log Λ_0 and log η_0 and the constants s and r are found to be 0.872 and 3.039, respectively.

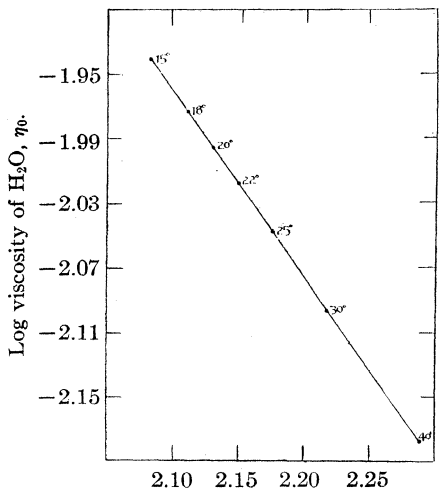

Fig. 3.—Variation of conductance at infinite dilution with viscosity of medium.

Summary

1. The equivalent conductances of potassium chloride solutions have been measured at 15, 20, 22, 25, 30 and 40° in the concentration range 0.0004 to 0.1 N. The experimental data follow closely the Onsager limiting slope at high dilutions. At other concentrations only one empirical constant B is needed.

2. The temperature dependence of the limiting conductance is linear between 15 and 40°. The variation with viscosity can be expressed by $\Lambda_0\eta_0^s = r$, s being less than 1.

The Thermodynamic Theory of Electrocapillarity[1]

BY DAVID C. GRAHAME AND ROBERT B. WHITNEY

The Gibbs adsorption theorem (Gibbs' equation 508) is a relationship between the change in the interfacial tension between two phases, the change in chemical potential of the components of the phases, the change in the superficial density of entropy in the system and the amounts of the various independent components adsorbed at the interface.[1a] When some of the components of the system are electrically charged particles, as in an electrocapillary system, the Gibbs equation cannot be applied directly in its original form for reasons which will be pointed out below. In the study of electrocapillary phenomena it is desirable to have a thermodynamic equation analogous to the Gibbs adsorption theorem. The Lippmann equation[2] is a special case of such an equation.

Many discussions of this problem have focussed attention on the "potential-determining" ion, as though the causal agent producing the potential difference between the phases at equilibrium were the ions of the metal in the non-metallic phase (often present in amounts so small as to be meaningless except in a statistical sense) instead of the external apparatus by means of which the potential difference is fixed. The difficulties of this line of approach led Koenig[3] to give up the hope of extending the Gibbs equilibrium treatment and to regard the polarized electrode as a system in which equilibrium does not subsist between the phases. He assumed, instead, that n the interface there exists a barrier impermeable to charged particles. On this basis Koenig has derived a general equation of electrocapillarity for the ideal polarized electrode and has applied it to the deduction of equations referring to special experimental conditions which may be realized in the laboratory. It is the purpose of this paper to show that the equations developed by Koenig are not peculiar to the type of system which he postulates but may be derived for a polarized electrode *at equilibrium* with respect to the distribution of its charged components and *not* possessed of a barrier impermeable to charged particles. It appears to the present authors that real systems are best characterized in this manner and may be made to approach the postulated ideal condition of equilibrium as closely as the physical perfection of the experimental apparatus will permit. In addition, we shall show that the equations here developed have a wider scope and a slightly different significance from those of identical form given by Koenig.

Qualitative Considerations.—Consider a system composed of a metal in contact with an electrolytic solution and provided with some external means whereby the potential difference between the phases may be altered at will. It need not concern us that the absolute magnitude of the potential difference must remain unknown. We exclude from consideration all cases in which the system just postulated is not at equilibrium as regards ordinary chemical action or as regards the distribution of charged particles between the phases. In a system at equilibrium there will be no net transfer of charge from one phase to the other, and therefore there will be no current flowing through the external circuit by which the superimposed potential is applied. From a practical standpoint the systems we are considering form three classes of electrodes, ideal polarized electrodes, ideal non-polarizable electrodes and partially polarizable electrodes. We distinguish these three classes by the magnitude of the continuous current which flows through the external circuit when the potential difference between the phases is *altered* slightly from its value in the original (equilibrium) state. In an ideal polarized electrode no continuous current flows; in an ideal non-polarizable electrode a continuous current flows, limited only by the ohmic resistance of the system, whereas in a partially polarizable electrode a continuous current flows, but of magnitude less than that predicted by Ohm's law (if polarization e. m. f.'s are ignored). These distinctions are practical rather than thermodynamic criteria of polarizability, since Ohm's law and the concepts associated with that law are not a part of thermodynamics. Indeed, the distinction between ideal non-polarizable electrodes and partially polarizable electrodes appears to have no meaning

for thermodynamics, and the concept will not be used in the thermodynamic treatment which follows. The distinction between ideal polarized electrodes and the two types of electrodes just mentioned (regarded as a single class) may be made on the basis of the amounts of the charged components present in the two phases at equilibrium, as will presently appear.

When the potential difference across the phases of an electrode at equilibrium is altered slightly, there is a momentary surge of current through the external system as a result of a readjustment of the composition of the electrical double layer at the interface, but this readjustment takes place very quickly and in no way obscures the slow readjustment which may be observed as a continuous flow of current in a partially polarizable or non-polarizable electrode.

Although the two ideal types of electrode cannot be attained in practice, it is possible to prepare electrodes which approach ideal conditions almost as closely as desired. Thus a large reversible electrode is practically non-polarizable under favorable conditions, and a system composed of mercury in contact with aqueous potassium chloride is, to all intents and purposes, ideally polarized over a considerable range of superimposed potentials. The same system becomes partially polarizable when the potential difference between the phases is such that the concentration of mercurous ions in the aqueous phase is not negligible at equilibrium.

It will be recognized that *at equilibrium* the concentration of the so-called potential-determining ion in the non-metallic phase varies with the applied potential difference between the phases. In an ideal polarized electrode this concentration is necessarily extremely small in one of the two phases, for if it were not so, a change in the potential difference between the phases would result in a finite current flow during the relatively long period of time required for the system to attain a new state of equilibrium. Since any ion in the system might be regarded as a potential-determining ion, it follows that in an ideal polarized electrode the concentration of every charged species must be negligibly small in one of the two bulk phases. It is this circumstance which makes it unnecessary to postulate a barrier impermeable to charged particles in an ideal polarized electrode.

From the standpoint of thermodynamics it is desirable to *define* the ideal polarized electrode as one in which each charged species is present in appreciable amounts in only one of the two bulk phases. This definition is equivalent to the practical definition first given. An electrode at equilibrium and containing one or more charged components at finite concentrations in both phases would be classed as a non-polarized electrode. It should not be inferred from this nomenclature that the electrode is necessarily non-polarizable, however.

On the Application of the Gibbs' Adsorption Theorem to Systems in which Charged Substances Are Regarded as Independent Components.—The Gibbs' adsorption theorem, in its original form, applies to systems in which all components are regarded as neutral substances. (Any actual system may be so regarded, of course, provided the system as a whole remains electrically neutral.) It would appear reasonable to rewrite the equation, substituting electrochemical potentials for chemical potentials,[4] and to assume that the rewritten equation would apply to systems in which charged components are regarded as independent components. Such an assumption would not be strictly correct, however, as we now proceed to show.

The physical system treated by Gibbs is chosen as an internal part of a larger system of the same kind in order to eliminate from the discussion phase boundaries other than the one specifically under consideration. This is an important characteristic of the derivation not easily dispensed with if thermodynamic rigor is to be maintained. Such a system must remain electrically neutral as a result of the fact that any excess charge will accumulate on the external surfaces of the conducting system.[5] In a system constrained to remain electroneutral, the principal charged components[6] cannot be added or removed independently of one another. One of these components is not an independent component, yet the system cannot be regarded as formed from its independent

(4) For an uncharged component, the electrochemical potential may be regarded as identical with the chemical potential.

(5) It is debatable whether or not one may consider infinitesimal deviations from electrical neutrality in the interior of a conducting system. We avoid this question, and at the same time simplify our treatment, by restricting the allowable variations to those which can be carried out without destroying the electrical neutrality of the system as a whole. Since actual systems do remain electroneutral, the applicability of our final equations is not thereby impaired.

(6) By principal charged components we mean those substances which must be added to make up the system under consideration. Electrolytes which dissociate into two or more ionic species we regard as mixtures of these substances. Water is regarded as a single substance. Metals are regarded as mixtures of ions and electrons, each of which is a principal component.

components only. One of the principal charged components may be singled out and called a dependent component, yet its presence must be taken into account, either explicitly or implicitly, in any equation relating to the energy content of the system.

In the derivation of the adsorption theorem in its original form the chemical potentials enter as a substitution for the quantity $\partial E/\partial n_i$ where E is the energy of the system (regarded as a function of the entropy and the number of moles of the *independent* components) and n_i is the number of moles of the component X_i. In the particular kind of system we are now considering, it is not valid to write $\partial E/\partial n_i = \bar{\mu}_i$,[7] where $\bar{\mu}_i$ is the electrochemical potential, because the addition of a charged component necessitates the addition or removal of another charged component, regarded as a dependent component. It is this fact which makes it incorrect simply to write $\bar{\mu}_i$ for μ_i in the Gibbs' adsorption theorem.

Derivation of the General Equations of Electrocapillarity.—If we choose to regard the electrons of the metallic phase as the dependent component whose amount varies with the addition or removal of charged components in such a way that electrical neutrality is always preserved, we may write

$$\partial E/\partial n_i = \bar{\mu}_i + z_i\bar{\mu}_e \qquad (1)$$

where z_i is the "valence" (including sign) of X_i, and $\bar{\mu}_e$ is the electrochemical potential of the electrons in the system.

The derivation of the adsorption theorem can be carried through in the usual manner without substituting any new symbol for the quantity $\partial E/\partial n_i$. Then Gibbs' equation 508 becomes

$$d\sigma + S_s dT = -\sum^{c}\Gamma_i d\left(\frac{\partial E}{\partial n_i}\right) \qquad (2)$$

In this equation σ is the interfacial tension of the interface under consideration, Γ_i is the excess of the component X_i, in moles per unit area, over that which would be present in the system if the density of X_i in each phase remained constant (at its value in the internal parts of the bulk phases) right up to a mathematical surface drawn parallel to, but not necessarily coincident with, the physical interface. The physical interface is assumed to be effectively plane, by which it is meant that its radius of curvature is very large relative to the thickness of the region of discontinuity at the interface. S_s is the superficial density of entropy (entropy per unit area) defined in a manner analogous to the Γ's. T is the (absolute) temperature. The summation is carried out over the c *independent* components. If charged substances are regarded as independent components, c will be less by one than the number of principal components.

Equation 2 is valid for any two-phase system at equilibrium, subject only to the usual limitations with regard to gravitational and electric fields, strains in solids, etc.[1a] If we agree to adopt the conventions appropriate to Eq. 1, we may write

$$d\sigma + S_s dT = -\sum^{c}\Gamma_i d\bar{\mu}_i - \sum^{c}\Gamma_i z_i d\bar{\mu}_e \qquad (3)$$

It may be noted in passing that this equation may be obtained somewhat more readily, if not so rigorously, by overlooking the requirement of electrical neutrality imposed upon the system by its physical arrangement. In that case the adsorption equation would be written

$$d\sigma + S_s dT = -\sum^{c+1}\Gamma_i d\mu_i$$

where the $c + 1$ components include the electrons. Expanding this equation, and noting that *when* the system is electrically neutral $\sum^{c}\Gamma_i z_i = \Gamma_e$, we obtain

$$\begin{aligned} d\sigma + S_s dT &= -\sum^{c}\Gamma_i d\bar{\mu}_i - \Gamma_e d\bar{\mu}_e \\ &= -\sum^{c}\Gamma_i d\bar{\mu}_i - \sum^{c}\Gamma_i z_i d\bar{\mu}_e \end{aligned}$$

In these equations, as elsewhere, the subscript e refers to the electrons.

We may express electrochemical potentials in terms of chemical potentials and electrical potentials by the substitution[7]

$$d\bar{\mu}_i = d\mu_i + z_i F d\varphi_i \qquad (4)$$

where F is the faraday and $d\varphi_i$ is the change in the electrical potential of the phase in which the chemical potential, μ_i, is reckoned. Equation 4 is valid for electrons, as for ions. It is also valid for uncharged substances, since for these latter, $z_i = 0$. Substitution of Eq. 4 into Eq. 3 gives

$$\begin{aligned} d\sigma + S_s dT = &-\sum^{c}\Gamma_i d\mu_i - \sum^{c}\Gamma_i z_i d\mu_e - F\sum^{\alpha}\Gamma_i z_i d\varphi^\alpha - \\ &F\sum^{\beta}\Gamma_i z_i d\varphi^\beta + F\sum^{\alpha}\Gamma_i z_i d\varphi^\alpha + F\sum^{\beta}\Gamma_i z_i d\varphi^\alpha \qquad (5) \\ = &-\sum^{c}\Gamma_i d\mu_i - F\sum^{\beta}\Gamma_i z_i d(\varphi^\beta - \varphi^\alpha) - \sum^{c}\Gamma_i z_i d\mu_e \qquad (6) \end{aligned}$$

In these equations we have divided the summations containing φ's into two parts according to the phase in which the chemical potential of each

(7) E. A. Guggenheim, "Modern Thermodynamics," Methuen and Co., London, 1933, p. 133.

particular component has been reckoned. The symbols α and β over the signs of summation signify that the summation is to include those independent components whose chemical potentials have been reckoned in the metallic and non-metallic phases, respectively. φ^α and φ^β are the electrical potentials of these phases. It will be noted that in a system at equilibrium the electrochemical potential of every component is the same in the two phases, and it will therefore make no difference in which phase a component is reckoned. But it will usually be more convenient to measure the *chemical* potential in one phase rather than in the other, and this consideration will generally indicate the phase in which a given component may most conveniently be reckoned. Equations 5 and 6 have been written on the assumption that the electrons will be regarded as a component of the metallic phase. This is a matter of convenience rather than of thermodynamic necessity.

Equation 6 may be regarded as a general equation of electrocapillarity. It is applicable to polarized and non-polarized electrodes alike. In order to apply it more conveniently to ideal polarized electrodes we may define a quantity ϵ^β by the equation

$$\epsilon^\beta = F\sum^{\beta}\Gamma_i z_i \qquad (7)$$

Because of the electrical neutrality of the system as a whole we may write

$$\sum^{c}\Gamma_i z_i = \Gamma_e \qquad (8)$$

Substitution of Eqs. 7 and 8 into Eq. 6 yields the simplest form of the general equation, when this is to be used in connection with ideal polarized electrodes, as follows

$$d\sigma + S_s dT = -\epsilon^\beta d(\varphi^\beta - \varphi^\alpha) - \sum^{c+1}\Gamma_i d\mu_i \qquad (9)$$

Like Eq. 6, this equation applies to any electrode at equilibrium. It is restricted only by the requirement that the physical interface be essentially plane, as defined above. This restriction limits the possible variation of $\varphi^\beta - \varphi^\alpha$ and of the μ's to values such that the pressures within the two phases are (nearly) equal. Since this is also the requirement that the interfacial tension be measurable by the usual methods, the equations may be applied to any system for which the interfacial tension is measurable.[8]

(8) Our equations are valid for a system in which the interface is not essentially plane if the position of the dividing surface, with reference to which the Γ's are reckoned, is sensibly coincident with the physical interface. This point is discussed in detail by Gibbs, ref. 1a.

It is particularly to be noted that the position of the surface of reference, with respect to which S_s and the Γ's are reckoned, is not specified in the foregoing treatment but may be taken as any surface parallel to the (essentially plane) interface. This makes it possible to set any one of the Γ's equal to zero, whereby the position of the surface of reference is fixed. The component for which Γ is set equal to zero may be called the reference component. If it is desired to place the surface of reference as nearly coincident with the physical interface as possible, the reference component must be chosen as that component which may most reasonably be assumed not to undergo concentration or dilution at the physical interface. From the standpoint of thermodynamics alone, it is a matter of indifference which component is selected as a reference component except in certain very unusual cases discussed by Gibbs, ref. 1a, p. 234.

In an *ideal polarized electrode* the value of ϵ^β will be independent of the position of the surface of reference. This results from the fact that every charged component is to be found in only one of the bulk phases, and since the interior of each phase is electrically neutral, the *excess* of charge is uninfluenced by changes in the assumed volume of each such neutral phase.

For an ideal polarized electrode the quantity ϵ^β is nearly identical with what is commonly called the surface charge density, but it happens that the thermodynamically significant quantity is ϵ^β and not the surface charge density, as that term is commonly understood. For example, it is ϵ^β which is actually measured in experiments which purport to measure the surface charge density.[9,10] If physical interfaces are as sharply defined as is generally believed, the practical difference between these quantities is wholly negligible, but it is important from the standpoint of thermodynamics to realize that the quantities are not identical. The differential capacity of an ideal polarized electrode is identical with the quantity $\partial\epsilon^\beta/\partial(\varphi^\beta - \varphi^\alpha)$.[10] Thus it appears that the experimentally observable properties of an ideal polarized electrode form a self-consistent system independent of any concepts relating to the "true" surface charge density. It will be noted that the concept of a "true" surface charge density is analogous to the concept of a

"true" degree of dissociation of an electrolyte.[11]

At constant temperature and composition, Eq. 9 reduces to the familiar Lippmann equation

$$d\sigma = -\epsilon^{\beta} d(\varphi^{\beta} - \varphi^{\alpha}) \qquad (10)$$

When the composition of the phases remains constant, $d(\varphi^{\beta} - \varphi^{\alpha})$ is an experimentally observable quantity. At the potential of the electrocapillary maximum, $\epsilon^{\beta} = 0$.

Equation 9 gives rise to a number of other useful equations related to the electrocapillary properties of an ideal polarized electrode. These have been worked out in detail by Koenig[3] from an equation substantially identical with our Eq. 9. The only change in these further equations which our treatment requires is in the manner of interpreting ϵ^{β} and in the location of the surface of reference, which latter is arbitrary in our treatment. Since the form of the equations is not changed by these considerations, we have not thought it necessary to repeat the equations here. It should be pointed out to prospective users, however, that Koenig has defined his Γ's and μ's in terms of equivalents rather than in moles.

It is found experimentally that the Lippmann equation is sometimes obeyed with considerable accuracy even when the system under investigation is far removed from a state of equilibrium.[10] This circumstance is doubtless to be attributed to the fact that the properties of an interface are affected chiefly by the composition of the phases in the immediate neighborhood of the interface. Since this part of the system readily reaches a steady state only slightly different from an equilibrium state, it is understandable that the observable properties should be essentially those of a system at equilibrium.

Application of the General Equation to the Non-polarized Electrode.—At constant temperature, the only variation of a non-polarized electrode consistent with the condition of equilibrium is a simultaneous variation of composition and $\varphi^{\beta} - \varphi^{\alpha}$. The most important case of a system of this kind is the system formed by a pure metal in equilibrium with a solution of one of its simple salts (a salt which dissociates into two ionic species only). If we let the subscripts $_o$, $_+$ and $_-$ designate, respectively, quantities related to the solvent, the cation and the anion of the salt, then from Eq. 4, by equating $d\bar{\mu}^{\alpha}_{+}$ and $d\bar{\mu}^{\beta}_{+}$

$$z_+ F d(\varphi^{\beta} - \varphi^{\alpha}) = -d\mu^{\beta}_{+} \qquad (11)$$

The superscripts on the chemical and electrochemical potentials designate the phase in which the chemical potential of the component is to be reckoned. Substitution of Eq. 11 into Eq. 6 gives

$$d\sigma = -\Gamma_+ d\mu^{\beta}_{+} - \Gamma_- d\mu^{\beta}_{-} - \Gamma_o d\mu_o + \Gamma_+ d\mu^{\beta}_{+} + \frac{z_-}{z_+}\Gamma_- d\mu^{\beta}_{+} \qquad (12)$$

$$= -\frac{f}{z_+}\Gamma_- d\mu - \Gamma_o d\mu_o \qquad (13)$$

The symbol μ, without subscript, denotes the chemical potential of the salt, which is equal to $(z_+\mu_- - z_-\mu_+)/f$ where f is the largest common factor of z_+ and $-z_-$. In deriving Eq. 12 the cation was arbitrarily regarded as a component of the non-metallic phase. The same final result would have been obtained if it had been regarded as a component of the metallic phase. Equation 13 can also be derived very readily from the Gibbs adsorption theorem in its usual form by regarding the metal, the salt and the solvent as the three independent components of the system.

It has not been customary in the past to measure interfacial tensions of non-polarized systems under conditions suitable for the application of Eq. 13. However, there seems to be no reason why such measurements could not be carried out with mercury as the metallic phase and aqueous mercurous nitrate, for example, as the electrolyte. Taking the solvent as the reference component, one could readily calculate Γ_- at various concentrations of electrolyte, and also, by equation 8, $z_+\Gamma_+ - \Gamma_e$. It does not appear to be possible, however, to evaluate Γ_+ and Γ_e separately.

Summary

The thermodynamic equations of electrocapillarity have been derived with no assumptions other than that of equilibrium between the phases. It is shown that the interpretation of the equations so obtained is slightly different from what had previously been supposed. A general electrocapillary equation has been derived for a non-polarized electrode, and it is shown how this may be applied to experimentally obtainable data.

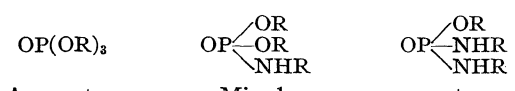
The Aquo Ammono Phosphoric Acids. III. The N-Substituted Derivatives of Phosphoryl and Thiophosphoryl Triamide as Hydrogen Bonding Agents

BY L. F. AUDRIETH AND A. D. F. TOY

Introduction

The alkyl and aryl esters of phosphoric acid have found extensive application as solvents, and as plasticizers for various polymeric substances. They are most effective for those polymeric materials which contain active acceptor atoms, such as the polyamides, the phenol-formaldehyde resins, the urea-formaldehyde resins, and the vinyl polymers. Hydrogen bonding is considered to play a very important role in this particular application, for it is assumed that the oxygen atoms in the phosphoric acid esters serve as the donor atoms in bonding to active hydrogen atoms. Copley, Zellhoefer and Marvel[1,2] have shown that the extraordinary solubility of CH_2Cl_2 in a series of phosphoric acid esters, such as $(C_2H_5O)_3PO$, $(C_3H_7O)_3PO$, $(C_4H_9O)_3PO$, $(C_6H_5O)_3PO$, $(o\text{-}C_6H_4O\text{-}CH_3)_3PO$, and $(CH_3OCH_2CH_2O)_3PO$, may be explained on the basis of hydrogen bond theory. The high heat of mixing of triethyl phosphate with chloroform also indicates that loose compound formation through a hydrogen bond occurs.[3]

The present investigation was undertaken in order to determine if the nitrogen analogs of phosphoric acid might not also be capable of acting as potential hydrogen bonding agents. The N-alkyl and N-aryl substituted derivatives of phosphoryl triamide, $OP(NH_2)_3$, may be looked upon as the nitrogen analogs of the esters of phosphoric acid. Compounds in which one or two of the -OR groups are replaced by an amine radical may be regarded as the mixed aquo ammono phosphoric acid esters. With this concept in mind, the close relationship between the aquo phosphoric acid esters and the N-substituted phosphoryl triamides should be evident.



$OP(NHR)_3$ or $OP(NR_2)_3$

Ammono esters[4]

Theoretically, the ammono phosphoric acid esters should be capable of acting as hydrogen bonding agents because of the presence of both oxygen and nitrogen atoms which may be capable of acting as donor atoms. Donor molecules (hydrogen bonding agents) have been found to exhibit extraordinarily high solubility in such solvents as chloroform, which contains an acceptor hydrogen atom. On the other hand, solubility of these same materials in solvents such as carbon tetrachloride is considerably less, despite the fact that the structures of chloroform and carbon tetrachloride are quite similar. This difference has been ascribed to the absence of an active hydrogen atom in carbon tetrachloride. This does not mean that such donor compounds are abnormally soluble in all hydrogen containing solvents. The hydrogen atom must possess some lability. Petroleum ether, for instance, exhibits no tendency to act as an acceptor solvent since the hydrogen atoms are non-labile. However, these considerations should not be taken as absolute criteria since a substance, because of its structure, may still exhibit considerable solubility or insolubility in typical non-polar solvents. Consequently the relation of structure to potential hydrogen bonding ability is a factor which should not be overlooked. It has already been shown by the authors[5] that phenyl di-(morpholido)-phosphate is extraordinarily soluble in many solvents, including water, while the diphenyl morpholido-phosphate is insoluble in water, but nevertheless very soluble in organic solvents. In order to determine the effect of structure upon hydrogen bonding ability, a series of N-substituted phosphoryl triamides were prepared and these together with related compounds were investigated for their solubility in chloroform and in carbon tetrachloride. A number of N-substituted thiophosphoryl triamides, derivatives of the thio ammono phosphoric acid, $SP(NH_2)_3$, were also prepared to determine specifically the effect of replacing oxygen by sulfur.

In the course of this work standard methods for the preparation of N-substituted phosphoryl

triamides were investigated, but none found to be satisfactory. These compounds previously had been prepared from phosphoryl chloride and the corresponding amines, (a) in the presence of sodium hydroxide,[6] (b) by direct reaction in the cold and subsequent heating,[7,8] and (c) at higher temperatures under pressure in a closed tube,[9] or (d) in the presence of diluents.[10] The new and recommended procedure involves interaction of the phosphoryl chloride-pyridine complex with the amine in chloroform solution.

Experimental

A. Preparation of N-Substituted Phosphoryl Triamides.—To 15.4 g. (0.1 mole) of phosphoryl chloride dissolved in 200 cc. of chloroform in a 500-cc. 3-neck flask there was added slowly with stirring 23.7 g. (0.3 mole) of pyridine. The temperature of reaction was maintained at 0 ± 1° by means of an ice–salt-bath. The addition of the first few cc. of pyridine had to be slow since a great deal of heat was generated. After this initial reaction the rest of the pyridine could be added rapidly (ten minutes). This solution was then transferred to a dropping funnel and added slowly (thirty to forty minutes) to 0.6 mole of amine dissolved in 200 cc. of chloroform in a 1-liter 3-neck flask cooled to 0 ± 2° by an ice–salt-bath. The resulting product was heated on the steam-bath and refluxed for two hours to ensure complete reaction. If, upon cooling, a chloroform insoluble amine hydrochloride formed, it was removed by filtration and the residue was washed with chloroform. The combined filtrates were distilled over a steam-bath to remove most of the solvent, the last portions having been eliminated by heating over a very low free flame at a pressure of 3–4 mm. The residue was washed first with dilute hydrochloric acid and then with water until the washings gave no chloride test. The desired product was then recrystallized from a proper solvent. Any amine hydrochloride residue was also washed with water, for in this way an additional quantity of the water insoluble product was often recovered. Specific preparative details are given in Table I.

In the recommended procedure a ratio of $POCl_3$:Amine:C_5H_5N = 1:6:3 was used. In similar reactions pyridine acts not only to moderate the reaction, but also serves to take up the hydrogen chloride which is formed. If the latter function is also served in the present case, then the use of six moles amine to one of phosphoryl chloride represents a needless hundred per cent. excess of amine. An experiment was therefore carried out using a $POCl_3$:Amine:C_5H_5N ratio of 1:3:3. The other conditions of the reaction were kept identical with those given above. Specifically, 15.4 g. (0.1 mole) of phosphoryl chloride, 23.7 g. (0.3 mole) pyridine, and 28 g. (0.3 mole) of aniline were used. The yield of phosphoryl trianilide was 10.5 g. (32.3%) as compared to a yield of 82% when a $POCl_3$:$C_6H_5NH_2$:C_5H_5N ratio of 1:6:3 was used. This seems to indicate that the presence of pyridine serves largely to moderate the reaction and not react to take up the hydrogen chloride to form pyridine hydrochloride. It should also be pointed out that phosphoryl chloride actually forms pyridinium complexes[13] of the type $[POCl_2 \cdot Py]^+Cl^-$, and that these complexes undergo solvolysis much more smoothly than the acid chloride by itself or in some inert solvent.

B. Preparation of the N-Substituted Thiophosphoryl Triamides.—The method first employed by Michaelis and Steinkopf[14] was used for the preparation of the N-substituted thiophosphoryl triamides. The general procedure involved the addition of one mole of thiophosphoryl chloride to six moles of amine at 5 ± 5°. The resultant mixture was heated on a steam-bath for twelve hours. It was then cooled and washed free of amine hydrochloride with water. The water insoluble portion was recrystallized from a proper solvent. In the case of the thiophosphoryl trimorpholide which is slightly soluble in water, the reaction product was extracted with chloroform to separate the desired compound from morpholine hydrochloride.

The chloroform extract was then evaporated and the residue washed with a small quantity of ice-water to remove the last traces of morpholine hydrochloride. The N-substituted thiophosphoryl triamides are listed in Table II.

C. Solubility Determinations.—The solubilities of all compounds in chloroform and carbon tetrachloride at 25° were determined. Only in the case of the morpholine derivatives were quantitative solubilities in water also determined. The solubility data are given in Tables III and IV.

Discussion

The marked differences in the solubility of the N-substituted phosphoryl triamides in chloroform and in carbon tetrachloride may be ascribed to hydrogen bonding. This difference is especially striking in the case of the morpholine derivatives where not only are there oxygen atoms in peripheral positions in the ring, but also nitrogen atoms devoid of hydrogen atoms. While the derivatives of aniline and of amines of similar structure also are much more soluble in chloroform than in carbon tetrachloride, the solubility in chloroform is low in every case. This low solubility may be due to the fact that the nitrogen is located next to a phenyl ring which permits the pair of free electrons on the nitrogen to resonate with the electrons in the double bonds of the phenyl ring. The availability of the nitrogen as a donor atom is thus decreased. This hypothesis is substantiated by the observation that elimination of resonance (a) by reduction of the ring, as in the case of the cyclohexylamine derivatives, and (b) by separating the nitrogen from the phenyl group with a CH_2 group, as in the case of the benzylamine derivative, brings about a great increase in solubility in chloroform. The presence of an ether oxygen atom attached to the ring, as in the case of the *p*-phenetidine derivative, increases the solubility in chloroform presumably because the extra oxygen serves as another donor of electrons, that is, a point where hydrogen bonding may occur. However, this increase is not of the same order of magnitude as that observed in the case of the morpholine derivatives where the oxygen atom is in the ring. It may be that this difference is also due to the fact that the electrons in the oxygen next to the phenyl ring are in resonance with the electrons in the double bonds of the ring.

Our observations demonstrate clearly that the oxygen atom connected directly to the phosphorus atom also possesses some donor characteristics. The N-substituted thiophosphoryl triamides are in every case less soluble in chloroform than the corresponding phosphoryl compounds.

Summary

A number of phosphoryl and thiophosphoryl triamides have been prepared and their solubilities in chloroform, carbon tetrachloride, and water have been determined. The solubility data indicate that these substances are good hydrogen bonding agents and that the oxygen and the nitrogen atoms in these compounds are capable of acting as donor atoms in solvents such as chloroform which contains an active hydrogen atom.

The Solubility of Propylene Vapor in Water as Affected by Typical Detergents

BY JAMES W. McBAIN AND A. M. SOLDATE

It has been shown[1,2] that potassium oleate added to water greatly increases the amount of hydrocarbon which can dissolve. The solubilized hydrocarbons are incorporated in or upon the colloidal particles or micelles of the soap, thus lowering the vapor pressure of the hydrocarbon and leaving the freezing point of the soap solution unaffected.

These observations are now extended to a series of typical detergents, surface active agents, and other substances in order to determine whether such solubilization always occurs with detergents, and to contrast it with the effects of salts and mixed solvents. The result is to show that all the detergents tested exhibit this property, whereas salts such as a carbonate, pyrophosphate, or a Calgon do not; and much larger quantities of an organic solvent must be added to produce a comparable effect.

Experimental

Propylene was used in all experiments following the procedure already described.[1] Although evacuation was carried out in each case for half an hour in a Cenco Hyvac pump, the evacuation was necessarily incomplete.[3] All data refer to solutions at 25°.

Since it was not always convenient to arrange for the same equilibrium pressure, it was assumed that Henry's law could be used within the range 500 to 700 mm. pressure. Hence all the data are expressed in terms of grams of propylene dissolved per gram of water per mm. pressure for this range.

The Data

The observations are collected in Table I, which gives the amount of detergent, salt, or other substance added expressed as per cent. (meaning, however, grams per 100 cc. of solvent), and the values of x/m, multiplied by 10^5, and a comment as to the effect noted.

Discussion

The chief result is to show that all the detergents exhibit solubilizing action for propylene in water, as well as for otherwise insoluble dye.

TABLE I

THE SOLUBILITY OF PROPYLENE IN AQUEOUS SOLUTIONS[a] AT 25° IN GRAMS × 10^{-5} OF PROPYLENE PER GRAM OF WATER PER MM. PRESSURE FOR THE RANGE 500–700 MM.

[a] For a description of the active agent in materials here designated only by trade names, see *Ind. Eng. Chem.*, **31**, 66 (1939); **33**, 16, 740 (1941).

This is strikingly emphasized by the contrasting behavior between the detergent, sodium deoxycholate, and the closely similar non-detergent, sodium dehydrocholate. Whereas the former doubled the solubility of propylene in water, the latter salts out three-quarters of what would otherwise dissolve in the water alone. Frazer, Stewart and Schulman have stated[4] that bile salts form no complexes with paraffin, but this is evidently not true in solution; therefore, the solubilized paraffin may be of some significance in experiments on digestive processes.

(4) Frazer, Stewart and Schulman, *Nature*, **149**, 167 (1942).

Salts, as such, have a definite salting out effect, although the present method is usually too insensitive to show the influence of only a few per cent. of either salt or detergent. A small amount of electrolyte may have an enormous effect upon the viscosity of such a detergent as potassium oleate without altering its solubilizing power very noticeably. 15% detergent usually increases the solubility many fold, the highest value in Table I being 18.7 for potassium oleate. Even this is only a small fraction of the amount of propylene which would dissolve in equal weight of a similar pure organic solvent.

In contradistinction to the detergents, the addition of 15% of a good organic solvent has a comparatively negligible result. Thus 15% diethyl carbitol increases the solubility of propylene by only 10% of that of water alone. This again illustrates the difference between solubilizing by detergents which can be appreciable with only a few tenths of a per cent., whereas in hydrotropy with the addition of a good miscible solvent, very high concentrations are required to get a comparable result. The difference is that in the mixed solvent the added molecules are separate and are submerged in the excess of first solvent whereas with the detergent or colloidal electrolyte the solute is segregated in colloidal particles, which themselves incorporate the solubilized material.

Summary

A further study of the effect of added substances upon the solubility of propylene in water is to show that all the detergents tested greatly increase the amount of propylene dissolved, in spite of any salting out action which they may otherwise possess. This solubilizing effect is shown by anion active, cation active, and non-electrolytic detergents.

The Effect of Temperature and Solvent Type on the Intrinsic Viscosity of High Polymer Solutions

BY T. ALFREY, A. BARTOVICS AND H. MARK[1]

According to hydrodynamics, the specific viscosity of a Newtonian liquid containing a small amount of dissolved material should depend in first approximation only upon the volume concentration and the shapes of the suspended particles. By suitable application of such hydrodynamical considerations to solutions of long chain molecules, it is possible in a rough fashion to derive the Staudinger–Kraemer equation, denoting proportionality between specific or intrinsic viscosity and molecular weight. It is an experimental fact, however, that the proportionality constant, K_m, is dependent not only upon the type of polymer concerned, but also upon the temperature and the nature of the solvent. Even in the dilute range, where specific viscosity is linear with concentration, these variations are often quite considerable. This paper tries to treat such variations in a systematic fashion, and to advance for them an explanation which is based upon changes in the average geometrical shape of the particles. A relationship between intermolecular and intramolecular agglomeration tendency is presented.

(1) This paper was presented in October, 1941, at the meeting of the Society of Rheology in New York City.

Theoretical Considerations.—According to Burk,[1a] Eyring,[2] Flory,[3] Guth,[4] Huggins,[5] Kuhn,[6] Mark,[7] and Meyer,[8] a long chain hydrocarbon molecule in solution takes on a somewhat kinked or curled shape, intermediate between a tightly rolled up mass and the rigid linear configuration assumed by Staudinger.[9] Presumably all possible degrees of curling are represented, owing to the internal Brownian movement of the flexible chains, but the configurations of intermediate extension predominate statistically. The average or effec-

tive value of any shape-dependent molecular property (such as hydrodynamical influences) may be obtained by summing this property over all configurational states, after each state has been given a proper weight factor. If the long chain molecule is surrounded by a continuous, energetically indifferent solvent, then the weight factor for a particular configuration is determined only by internal parameters—potential energy function for restricted rotation, prohibition of segment interpenetration, etc. The mean value of any molecular property in such ani ndifferent (and perhaps hypothetical) solvent might be called the "unbiased" statistical mean for the property.

If the solvent is energetically unfavorable, so that the dissolving of the high polymer is an endothermic process, then the polymer segments will attract each other in solution and squeeze out the solvent between them. The curling forces in such a case will be similar to those postulated in the Mack[10] theory of rubber elasticity. Those molecular configurations which involve many contacts of the molecule with itself will be weighted more heavily than in an indifferent solvent, and the mean value of any molecular property will represent a more curled and contracted shape than the unbiased mean. On the other hand, if a solvent is energetically more favorable than the indifferent solvent as previously defined, then in solution the long chain molecule will be surrounded by a solvated hull which tends to prevent polymer–polymer contacts. Uncurled configurations will be favored, and the mean value of any property will represent a more extended shape than the unbiased mean. Since an extended or uncurled configuration is associated with a high intrinsic viscosity, and *vice versa*, the first prediction as to effect of solvent type upon viscosity is the following.

Other conditions being equal, a given high polymeric material made up of flexible molecules will exhibit a high intrinsic viscosity in an energetically favorable solvent, and a low intrinsic viscosity in an energetically unfavorable solvent. This of course holds only for very diluted systems. At higher concentrations (around or above 5% by weight) an energetically unfavorable solvent will favor polymer–polymer contacts between different chains and hence lead to the danger of gelation, while an energetically favorable solvent will stand a higher concentration of the polymer and yet give a fluid, stable solution. Solvents are often classified as "good" or "bad" on the basis of the viscosity of concentrated solutions.

If a good solvent is mixed with a precipitating agent, the resulting mixture can be expected to be energetically less favorable to a long chain molecule than is the pure solvent. A dilute solution of high polymer in a solvent–non-solvent mixture should, therefore, exhibit a lower intrinsic viscosity than a solution of the same polymer in the pure solvent. It will be shown that a series of high polymer solutions of given polymer concentration, in mixtures of increasing non-solvent content, shows a regular decrease in specific viscosity until the precipitation point is reached.

We have interpreted variations in the intrinsic viscosity of a given high polymeric material as being due to changes in the degree of *intramolecular* agglomeration. If this interpretation is correct, there should be also a close connection between the intrinsic viscosity of a high polymer solution and the degree of *intermolecular* agglomeration. Exactly the same solvent characteristics which determine the mean geometrical properties of an isolated long chain molecule should also determine the amount of association of different solute molecules into aggregates. When a non-solvent is added to a high polymer solution, the point at which precipitation begins represents a certain definite agglomeration tendency for chain segments of different molecules. To a first approximation, therefore, it should represent a certain definite mean value for any shape-dependent *internal* property. That solvent composition which is critical from the standpoint of solubility should correspond to a certain intrinsic viscosity, no matter what the solvent and what the non-solvent. One would therefore conclude the following: The intrinsic viscosities of a series of solutions of a given polymer in solvent–non-solvent mixtures of increasing non-solvent content, should decrease to a final value at the limit of solubility. This final value should be in first approximation the same in all solvent–non-solvent systems.

All of these effects should be more pronounced for polymer molecules of high flexibility than for more rigid chains. A paraffin chain should exhibit greater shape changes than a cellulose derivative.

The effect of temperature upon intrinsic viscosity should depend strongly upon the nature of the solvent. In a poor solvent, the effective molecular shape is more compact and curled than the un-

(10) E. Mack, *J. Phys. Chem.*, **41**, 221 (1937).

biased statistical mean. An increase of temperature should increase the relative importance of entropy factors over energetic factors, and result in an uncurling of the molecule. In such a solvent, a temperature increase should result in an increase of intrinsic viscosity. In a very good solvent, the energetic weighting factors favor the more extended configurations; here a temperature increase should result in a downward approach to the unbiased statistical mean shape. In a very good solvent, therefore, a temperature increase should cause a decrease in intrinsic viscosity. There should be an intermediate case in which the intrinsic viscosity is independent of temperature over a limited range.

The above use of the "unbiased statistical mean" as the shape which is approached as the temperature increases is an oversimplification, since this value itself includes energetic weighting factors, arising from the internal potentials of the molecule. If we consider only the forces which depend upon the solvent, we can make the prediction: In a very good solvent, the intrinsic viscosity of a dilute solution of a flexible polymer should decrease with temperature; in a poor solvent, it should increase.

Experimental

Polystyrene, rubber, and cellulose acetate were used in this investigation. The polystyrene had a weight average molecular weight of 165,000, calculated from viscosity data and using a K_m value of 1.1×10^{-4}. The rubber was smoked crepe, with a weight average molecular weight of 223,000, based upon a K_m value of 2.7×10^{-4}. The cellulose acetate was a fraction with a molecular weight of 35,000, which had been obtained by Harris and Sookne from a sample of commercial cellulose acetate having a weight average molecular weight around 90,000.

Solutions of polystyrene at a concentration of 0.2% by volume in the following solvent–non-solvent systems were investigated: Methyl ethyl ketone–methanol, toluene–acetone, toluene–methanol, toluene–isoamyl alcohol. Figure 1 shows the variation of specific viscosity with non-solvent content. In each case, the specific viscosity decreases as the mixed solvent becomes less favorable until the coagulation point is reached. For all the solvent–non-solvent systems investigated, the specific viscosity at the solubility limit is in the same range.

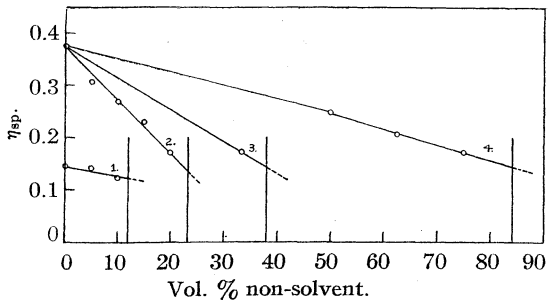

Fig. 1.—Variation of specific viscosity of 0.2% polystyrene solutions with non-solvent content: (1) methyl ethyl ketone–methanol; (2) toluene–methanol; (3) toluene–isoamyl alcohol; (4) toluene–acetone.

Solutions of rubber at a concentration of 0.0468% by volume in the following solvent–non-solvent systems were investigated: toluene–methanol, toluene–acetone, carbon tetrachloride–methanol, carbon tetrachloride–acetone. Figure 2 shows the variation of specific viscosity of these solutions with composition of the mixed solvent. Rubber behaves in the same general way as polystyrene.

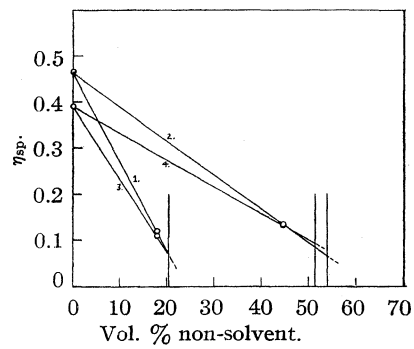

Fig. 2.—Variation of specific viscosity of 0.0468% rubber solutions with non-solvent content: (1) carbon tetrachloride–methanol; (2) carbon tetrachloride–acetone; (3) toluene–methanol; (4) toluene–acetone.

Solutions of cellulose acetate at 0.2% by volume in the following solvent–non-solvent systems were investigated: methylcellosolve–methanol, acetone–methanol, acetone–toluene. The specific viscosities of all solutions were about 0.33. The nature of the solvent medium apparently had no marked effect upon the shape of the cellulose acetate molecule in solution. It is to be expected that the cellulose chain is much less flexible than the rubber and polystyrene molecules.

Effect of Temperature.—Viscosities of many of the solutions were determined at two different temperatures, 25 and 60°. Table I shows the relation between the specific viscosity at 60°

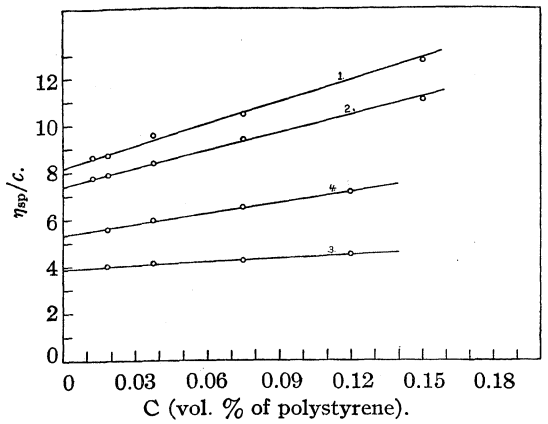

Fig. 3.—Relation between η_{sp}/c and c for polystyrene solutions: (1) toluene, 20°; (2) toluene, 80°; (3) 20% methanol, 80% toluene, 20°; (4) 20% methanol, 80% toluene, 60°.

and that at 25°, as a function of solvent composition, for several systems. In the pure solvents, specific viscosity decreases with temperature, while in the mixtures containing much non-solvent, specific viscosity increases with temperature.

TABLE I

η_{sp} AS A FUNCTION OF TEMPERATURE

Sample	Temperature, °C. 25	60
Rubber in		
Toluene	0.390	0.373
Carbon tetrachloride	.466	.430
Toluene–14% methanol	.205	.243
Polystyrene in		
Toluene	.370	.350
Toluene–10% methanol	.320	.317
Toluene–20% methanol	.160	.185
Toluene–10% amyl alcohol	.336	.340
Toluene–33% amyl alcohol	.170	.210

Effect of Concentration.—The effect of concentration on specific viscosity (in the dilute range) was investigated in both "good" and "poor" solvents, and at different temperatures. A sharp molecular weight fraction of polystyrene (mol. wt. 730,000) was used in this part of the investigation.

If η_{sp} is given by a power series in concentration, there will be a range in which all terms but the first can be neglected ($\eta_{sp} = ac$). Experimentally this range turns out to be very small in the case of a high molecular weight sample. Deviations from the simple linear relation are found at concentrations well below 0.05% by volume. For a somewhat wider range, the first two terms will serve to give the viscosity ($\eta_{sp} = ac + bc^2$). Experimentally, this range proves to be fairly wide, even for high molecular weight samples. When η_{sp}/c is plotted against c, the slope of the straight line gives the second coefficient, b, and the ordinate intercept gives the first coefficient, a. In Fig. 3, (η_{sp}/c) is plotted against c for polystyrene in toluene, and in a mixture of 80% toluene and 20% methanol. In this way is seen the effect of temperature and solvent type upon both virial coefficients. The presence of the non-solvent not only reduces the linear coefficient (which reflects the shape of individual molecules), but also reduces to an even greater degree the second coefficient (which is determined by the *degree of interaction* among different molecules).

An increase in temperature shifts the whole curve downward in the case of toluene, and upward in the case of the toluene–methanol mixture. In the toluene–methanol mixture, the interaction term, b, is least important at the lowest temperature.

It may be significant that Flory[11] has reported a similar situation in regard to the osmotic pressure–concentration relationship for high polymer solutions. The osmotic pressure is more nearly linear with concentration in "poor" solvents than in "good" solvents.

Summary

1. The specific viscosity of a dilute solution of polystyrene or rubber is strongly dependent upon the nature of the solvent; the specific viscosity is high in a good solvent, and low in a poor solvent or a solvent–non-solvent mixture. This has been interpreted as being due to changes in mean molecular shape. The specific viscosities of cellulose acetate solutions are not so sensitive to the nature of the solvent.

2. The extrapolated specific viscosity at the limit of solubility is in the same range for several different solvent–non-solvent systems.

3. The effect of a temperature increase is to lower the specific viscosity of rubber or polystyrene solutions in a good solvent, but to increase the specific viscosity in a mixture of solvent and non-solvent.

4. The specific viscosity of a dilute polystyrene solution is more nearly linear with concentration in a toluene–methanol mixture than in pure methanol. The quadratic term b in the equation ($\eta_{sp} = ac + bc^2$) is reduced relatively more than the linear term a by the presence of the non-solvent.

Oxidation Processes. XIV.[1] The Effect of Silver on the Autoxidation of Some Photographic Developing Agents

BY A. WEISSBERGER AND D. S. THOMAS, JR.

The Ostwald-Abegg theory[2] of photographic development suggested that the developing agent reduces silver ions which are in solution. The silver ions may be added to the developer (physical development) or may come from the silver halide of the emulsion which dissolves as development proceeds (chemical development). The reduction comes to a standstill, for thermodynamic reasons, wherever a certain supersaturation of the silver atoms is reached in the emulsion. Silver specks, however, which are formed by the exposure of the silver halide to light act as crystallization nuclei. In their neighborhood the supersaturation is broken and the reduction continues. This theory obviously applies only to developers which form reversible oxidation–reduction systems and fails to explain the action of the common organic, sulfite-containing, developers. Piper[3] suggested a catalytic action of the latent image on the reduction process itself, and Sheppard,[4] and Volmer[5] explained the mechanism of this catalysis. Sheppard studied the effect of certain compounds on the induction period of development and suggested that the developing agent forms a complex with the silver halide which, in the presence of metallic silver, decomposes into silver and the oxidized developing agent. Volmer passed air through *N* carbonate alkaline solutions of a number of developing agents and found that the resulting discoloration was accelerated by the addition of colloidal silver. His results are shown in Table I. The figures state the number of seconds after which solutions without silver and solutions which contained 0.5 g. of colloidal silver in 5 ml. had about identical colors.

Taking the formation of color as a measure of the oxidation and drawing the analogy between oxidation by air and by silver ion, Volmer suggested that a similar catalysis is essential in photographic development. Such a catalysis would, like the quinone catalysis,[6,7,8] affect the reactivity of the developing agent directly. It would be unspecific with respect to the oxidizing agent, while the mechanism suggested by Sheppard[4] is specific for the reduction of metal salts. Likewise specific for metal ions is the mechanism suggested by James,[9] according to which the reduction of the silver ions is accelerated when the latter are deformed through adsorption to silver or because they are located at the interface of silver and silver halide. To complete this brief account[10] it may be mentioned that the unexposed grains are, according to Sheppard,[11] protected by an adsorption layer of gelatin which becomes permeable for the developing agents when silver nuclei are formed in the exposure. According to Schwarz and Urbach,[12] the protection of the unexposed grains of the common emulsions against reduction consists in an adsorbed electrical barrier. This is, according to James, the more effective the higher the charge of the active species of the developing agent, while it does not function against neutral molecules of the *p*-phenylenediamine type.

In view of their importance for the theory of development, Volmer's experiments were repeated with a volumetric control of the oxygen absorption. This appeared advisable because a change in the rapidity of discoloration of a developer through the addition of colloidal silver may or may not indicate that the silver affects the autoxidation itself, *i. e.*, the reaction of the developing agent with oxygen. The formation of the colored reaction products takes place in later phases of the reaction, and it may well be that the silver accelerates the discoloration without speeding up the autoxidation proper. Moreover, it may be questioned whether the effect recorded by Volmer is big enough to be significant for photographic

TABLE I

VOLMER'S RESULTS[a]

	Pyrocatechol	Metol	Hydroquinone	Glycine	*p*-Aminophenol	Amidol[b]	Eikonogen
With silver	60	30	40	30	20	30	30
Without silver	160	60	100	80	120	140	60

[a] Metol = N-methyl-*p*-aminophenol; Glycine = N-*p*-hydroxyphenylaminoacetic acid; Amidol = 3,4-Diaminophenol; Eikonogen = 1-Amino-2-hydroxynaphthalene-6-sulfonate.

[b] Aqueous solution without addition of carbonate.

development, unless the size of the observed catalysis was depressed by the experimental technique used.

Materials[12a] and Methods

Hydroquinone was recrystallized from water; catechol from benzene.

p-Aminophenol was sublimed in a high vacuum (0.003–0.004 mm.); m. p. 189°. *p*-Aminophenol oxalate was recrystallized twice from water, containing about 1% of oxalic acid, decolorizing with Nuchar. The filtered crystals were washed with water, alcohol, and ether; m. p. 224° dec. *p*-Methylaminophenol was precipitated from a concentrated aqueous solution of the sulfate by sodium carbonate, filtered and dried. It was then distilled *in vacuo* [140° (3 mm.)], recrystallized twice from benzene and washed with petroleum ether; m. p. 86–87°. *p*-Methylaminophenol sulfate was recrystallized from slightly acidulated water. No difference was found in the autoxidation between the free bases and the salts.

p-Hydroxyphenylaminoacetic acid (photographic glycin) was dissolved in aqueous carbonate, filtered from insoluble impurities, precipitated with acetic acid and washed with water and alcohol. *p*-Phenylenediamine was distilled *in vacuo* and kept as a solid cake, m. p. 140–141°, the surface of which was discarded in taking samples for measurements. *p*-Aminodimethylaniline sulfate was precipitated from an alcoholic solution of the freshly distilled free base with the theoretical amount of sulfuric acid, recrystallized from 50% methyl alcohol, and washed with methyl alcohol and ether. 2,4-Diaminophenol sulfate (amidol) was precipitated from an aqueous solution of the hydrochloride by sulfuric acid, recrystallized from water containing about 1% of sulfuric acid and washed with water, alcohol and ether.

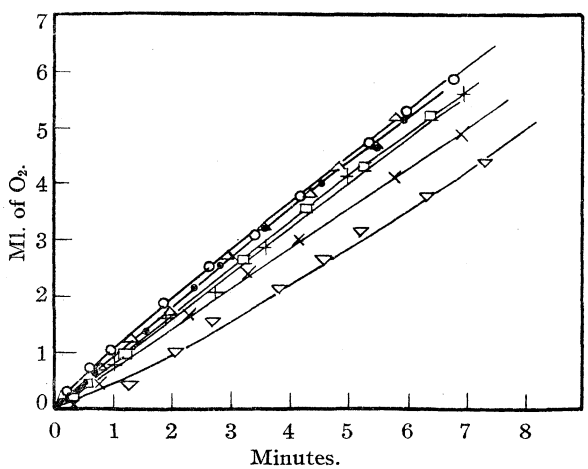

Fig. 1.—2 millimoles of hydroquinone in 50 ml. of 0.1 *N* barbital buffer, *p*H 8.06, with various shaking rates in oscillations per minute: ○, 330 o.p.m.; △, 300; ●, 270; □, 240; +, 210; ×, 195; ▽, 180.

The silver was prepared by reduction of silver nitrate with formaldehyde as described by Volmer.[5]

The buffers were made up with potassium phosphate, carbonate, borate, diethyl barbiturate, or hydroxide. Twenty-five milliliters of 0.2 molar standard solutions was adjusted to the desired *p*H by addition of nitric acid or potassium hydroxide. The type of buffer and the *p*H are indicated with the experimental results. The hydrogen-ion concentrations were measured with a glass electrode. For solutions of a *p*H above 9 a special electrode[12b] was used to reduce errors caused by cations. These were further diminished by using potassium salts exclusively. The measurements were made on duplicates of the solutions actually oxidized.

The apparatus for measuring the reaction rates was that described in the preceding papers of this series.[13] The reactions were run at 20.0 ± 0.02°, the volumes given for the oxygen absorptions were measured over water at this temperature and reduced to 760 mm.; the G. M. V. for these conditions is 24.6 l. Before the start of the reaction, the buffer was in the bottom part of the reaction vessel, the developing agent in slightly acidulated solution in the top chamber. The silver was added to the buffer, and, in the experiments in presence of halogen ion, this was also added to the buffer. In the experiments with addition of permanganate, the vessel with two top chambers[6] was used.

Results and Discussions

A critical factor in autoxidations of high velocity is the supply of oxygen to the reaction mixtures. Unless this is fast enough to maintain a constant oxygen concentration in the solutions, it may become the limiting factor of the oxygen absorption. The capacity of an apparatus similar to the one used at present was tested by Weissberger, Mainz and Strasser[13] in the autoxidation of benzoin. With this reaction no observations were made in the very beginning of the absorption, and it appeared desirable to characterize the capacity of the present apparatus more completely. This is done in the experiments recorded in Fig. 1. At shaking rates of 270 oscillations per minute and

(12a) For the preparations we are indebted to Mr. E. C. Armstrong and Dr. John M. Snell†.

(12b) National Technical Laboratories, Berkeley, California.

(13) Weissberger, Mainz and Strasser, *Ber.*, **62**, 1942 (1929).

higher, and absorption rates of 1 ml. per minute and lower, equilibrium between the gaseous (oxygen) and liquid phases is established. The critical shaking rates are somewhat higher with the new than with the old apparatus. Most likely the difference is due to the fact that in the older apparatus vigorous splashing of the solutions occurred at lower rates than in the new one. For reactions of high rates, the shaking mechanisms should cause jerky, rather than smooth, movements. In the experiments described in this paper, shaking rates of 280 o. p. m. were maintained. Hence, it will demonstrate a catalytic effect if the addition of silver raises the rate of the oxygen absorption from values up to 1 ml./min. to higher values. Rates, however, which are higher than 1 ml. oxygen/min. will suffer a depression by a lack of saturation of the liquid phase which is the more serious the higher the rate.

An insufficient saturation of the liquid phase with oxygen appears to be responsible for results published recently by Green and Branch.[14] These authors claim that the rate of the autoxidation of hydroquinone is proportional to the *3/2 power* of the hydroxyl-ion concentration, and, on the basis of this result, draw conclusions about the mechanism of the reaction. The same rate law had been found by LaMer and Rideal,[15] while it is contradicted by the results of Euler and Brunius[16] and of Reinders and Dingemans,[17] who found that the autoxidation rate is proportional to the square of the hydroxyl-ion concentration. James, Snell and Weissberger[7] have confirmed this quadratic dependency. Green and Branch worked with solutions containing about 10 m. mole of hydroquinone and observed only the beginning of the autoxidation over a range where the uptake of oxygen per minute could be treated as constant. Plotting log (ml. O_2/min.) against *p*H, they obtained a straight line with the slope 3/2. James, Snell and Weissberger, using 0.5 m. mole of hydroquinone for each run, followed the course of the oxygen absorption until it had slowed down considerably. They calculated the rate constants according to the first-order law, using as final volume absorbed the theoretical one of the reaction

$$C_6H_4(OH)_2 + O_2 \longrightarrow C_6H_4O_2 + H_2O_2$$

When the logarithm of the rate constant was plotted against *p*H, a linear dependency was obtained with the slope 1.98. Following this procedure, with measurements made over a wider range of *p*H (6.95–8.21), the values of Fig. 2 marked by 0 were obtained. The straight line is drawn with a slope of 2.00, thus confirming the result of Euler and Brunius, Reinders and Dingemans, and James, Snell and Weissberger.

It might be contended that the use of the theoretical final volume in the calculation of the rate constants is arbitrary, although ample reasons exist for the validity of the above equation.[6,7] To avoid this contention, the values of ml. O_2/min. for each measured point of a number of experiments were plotted against the time, and the initial rates in ml. O_2/min. were determined by extrapolation to time = 0. When these initial rates were plotted against *p*H, the values marked by X in Fig. 2 were obtained, which confirm that *the autoxidation rate of hydroquinone increases with the square of the hydroxyl-ion concentration.* The latter method of evaluation of the results is free from any assumption about the final volume and corresponds to that used by Green and Branch. The difference in the determination of the initial rates is necessitated by the fact that only 1/20 of the amount of hydroquinone used by Green and Branch was used in the present experiments in order to keep well within the limits of capacity of the apparatus.

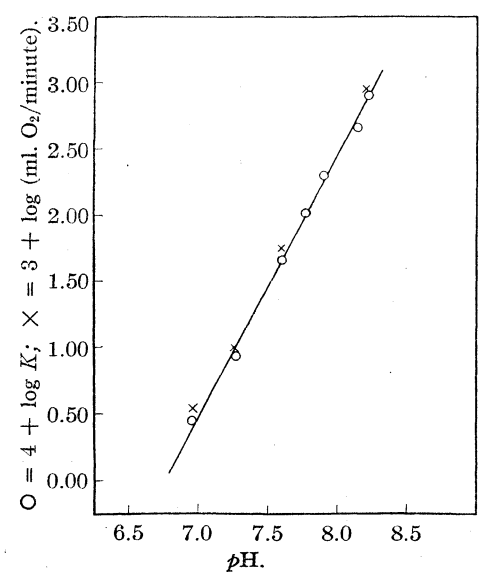

Fig. 2.—Dependency of rate of hydroquinone autoxidation on *p*H.

Experiments in the absence of silver with the concentrations and alkalinity used by Volmer proceeded at rates which were too high to maintain

constant oxygen concentrations in the solutions. It may be mentioned, however, that in such experiments with catechol, metol, amidol and glycine no great increase in the rate of the oxygen absorption could be observed when silver was added. If it was the capacity of the apparatus which limited the effect in our experiments, the same might apply to Volmer's because the oxygen supply in our experiments was probably not less efficient than in those of this author. In order to obtain more exact data, buffered solutions containing 0.5 m. mole of the developing agents in 50 ml. were used. The *p*H's were so chosen that the absorption rates kept within the limits given above, and oxygen was used instead of air to keep the gas phase constant throughout the reactions. With each compound two experiments were made at the same *p*H, one of them with and the other without the addition of silver in a large excess (1.8 g. for each run).

When silver is added to the reaction mixtures containing hydroquinone (Figs. 3 and 4), the absorption of oxygen is accelerated only little in spite of the large excess of the metal and only in the beginning of the reactions. After an uptake of about 0.4 mole of oxygen per mole of hydroquinone, the absorption of the silver-containing solutions sinks below those of the corresponding silver-free systems, and the curves show that the silver decreases the total amount of absorbed oxygen. One might suspect that this deficit is caused by the presence of silver oxide which oxidizes part of the developing agent. However, analyses, for which we thank Mr. Ballard of these Laboratories, showed that the silver contained less than 0.4% of oxide. This can account for an oxidation of not more than 10% of the develop-

ing agent. The total absorption of oxygen by hydroquinone, however, may upon addition of silver drop as much as 25%, and that by other developing agents, *e. g.*, metol and *p*-aminophenol, even more than 50%.

A silver-catalyzed evolution of oxygen from peroxide (formed according to the above equation), is likely to contribute to the deficit. The catalytic action of silver on the decomposition of peroxide is well known.[18] Table II illustrates the extent of this catalysis under the conditions of our experiments. It gives the times at which one half of the total oxygen evolution had taken place when solutions of 1 m.mole of hydrogen peroxide in 50 ml. of the various buffers were shaken at 20.0° with and without addition of 1.8 g. of silver. It is evident that hydrogen peroxide formed in the autoxidation will, in the presence of silver, decompose rapidly, and the liberation of oxygen contributes toward the deficit in the observed oxygen absorption.

11.8	70	
11.7		0.1
7.9		1.4
7.6	21×10^3	

Moreover, the reaction of hydrogen peroxide with the developing agent itself is catalyzed by silver. This is shown by the following experiments. One m.mole of hydrogen peroxide and 0.5 m.mole of hydroquinone in 50 ml. of 0.1 molar dipotassium phosphate of *p*H 7.5 were kept under nitrogen for twenty minutes. During this time, the volume of the gas phase did not change measurably. Then 20 ml. of 0.25 molar permanganate solution was added, and an evolution of 19.2 ml. of oxygen indicated that 78% of the peroxide was still present. In two corresponding experiments, but with addition of 2 g. of silver, the gas phase increased during the keeping period of twenty minutes by 0.6 and 1.2 ml., respectively, by the silver-catalyzed decomposition of the peroxide. In the absence of hydroquinone under otherwise identical conditions, this decomposition yields 5.5 ml. of oxygen. The reduction in the evolution of oxygen in the presence of hydroquinone is caused by a reaction of the hydroquinone with the hydrogen peroxide, which is catalyzed by the silver; when permanganate solution was added to the solutions which had evolved 0.6 and 1.2 ml., no further evolution occurred, showing that the peroxide had been used up completely. The observation that the deficit in the total oxygen absorption of the developing agents, which is caused by the presence of silver, varies with the different developing agents shows that the silver-catalyzed reaction between peroxide and developing agent takes place to a considerable degree. In the absence of silver, most of the peroxide appears to react with the quinonoid oxidation products of the developing agents.[6,7]

Oxidation by silver oxide contaminating the silver will produce oxidation products of the developing agents and thus accelerate the autoxidation of those compounds which are subject to quinone catalysis.[6,7] This acceleration is, however, not caused by a catalytic action of the silver. On the other hand, the consumption of developing agent by the silver oxide and by the silver-catalyzed reaction with hydrogen peroxide diminishes the amount of autoxidizable material, and, therefore, the rate of the oxygen absorption. This apparent rate of autoxidation is likewise diminished by the liberation of oxygen in the silver-catalyzed decomposition of hydrogen peroxide.

In Figs. 3–5, the absorption of oxygen is plotted against the time for pairs of experiments with

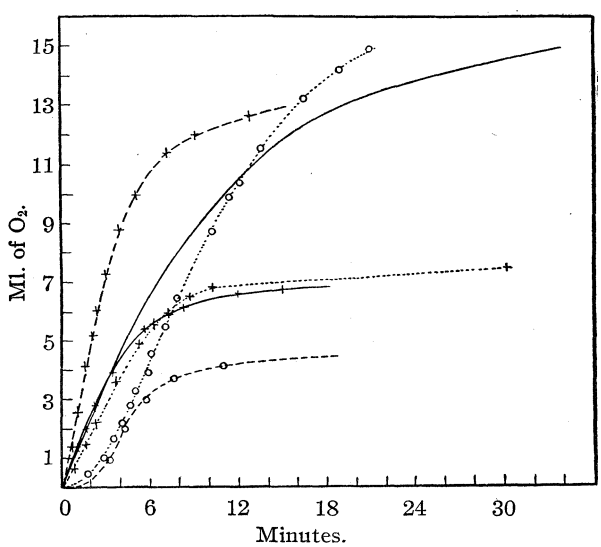

Fig. 5.—Reactions without silver, experimental points marked O; reactions with silver, experimental points marked +.

	Compound	*p*H	Buffer

and without silver. In view of the badly defined end-points of many of the reactions, the calculation of rate constants does not afford an advantage for the interpretation of these data. The discussion will, therefore, be based upon an inspection of the curves themselves. The figures show that the silver accelerates the initial oxygen absorption of hydroquinone, catechol, *p*-aminophenol and glycine. The absence of an observable induction period with hydroquinone[7] and catechol[19] makes it unlikely that with these compounds the acceleration can be attributed to the elimination of an induction period. The latter effect is unmistakable in the cases of *p*-aminophenol and glycine, where it causes at least part of the observed speeding-up of the oxygen absorption. With metol and amidol no absolute acceleration of the oxygen absorption was observed on addition of silver. However, considering the above-mentioned simultaneous reactions as they are evidenced by the deficit in the total oxygen absorption, silver may cause some acceleration in the autoxidation of metol, while hardly any influence of the silver can be observed with amidol at *p*H 5.57. The total absence of an effect with amidol may be due to the low *p*H of the measurement. With all the other systems, the silver causes some small acceleration. It has not been studied whether the effect is limited to silver or whether it can likewise be caused by other metals. The latter is rather probable,[6] but the effect is not general for fine powders as such, because the addition of purified diatomaceous earth had no effect at all.

The *p*H of our experiments with catechol, *p*-aminophenol, glycine and amidol included regions in which these developing agents can be used in practical development. With hydroquinone and metol the *p*H for the measurements had to be lower in order to keep the rates within the capacity of our apparatus. However, observations at different *p*H leave little doubt that at higher *p*H the influence of the silver would not show a significant increase. Hence, *no silver catalysis which is likely to be of importance for photographic development is observed in the autoxidation of the above-mentioned developing agents.* The acceleration of the rate of the darkening of these developing agents beyond that of their autoxidation in the presence of silver must be caused by an effect of the metal on other reactions than the autoxidation proper. The colored compounds are formed by polymerization of the oxidized developing agents, and the silver-catalyzed oxidation of the developing agents by hydrogen peroxide may explain a certain amount of the darkening in Volmer's experiments. Moreover, the reaction of the hydrogen peroxide with quinonoid oxidation products of the developing agents in the absence of silver may be responsible for a decreased formation of dark products if the metal is not present.

Volmer did not include in his investigation *p*-phenylenediamine or its derivatives. It is these compounds, however, which show a marked effect of silver on their autoxidation. This is demonstrated in Figs. 4 and 5. With *p*-phenylenediamine the acceleration is about 10^2 fold; with *p*-aminodimethylaniline it is less, but still pronounced. The curve of the silver-catalyzed autoxidation of *p*-phenylenediamine at *p*H 13.05 has a marked and reproducible inflection after an absorption of about $^1/_2$ equivalent of oxygen. In the beginning of the reaction, the concentration of hydrogen peroxide builds up, while that of the oxidized compound sinks, and conditions can be reached where the liberation of oxygen from peroxide just compensates for the absorption of oxygen by the developing agent. In certain other cases even a temporary increase in the oxygen volume was observed. The fact that a considerable catalytic action of the silver is limited to a certain type of the developing agents shows that neither an adsorption of oxygen to the silver nor the intermediary formation of silver oxide[20] gives a sufficient explanation for this catalysis. Such a mechanism might, however, be considered in connection with the small acceleration of the oxygen uptake by the developing agents of the types of hydroquinone and aminophenol. The lack of a silver catalysis with hydroquinone agrees with the results of Perry, Ballard and Sheppard[21] who, disproving observations of Rabinowitsch,[22] showed that this compound is not adsorbed to silver to any measurable extent. It would be interesting to see whether *p*-phenylenediamine is adsorbed to a higher degree.

The systems described above differ from developing emulsions by the absence of halogen ion. Addition of chloride ion depressed the effect of the

silver on *p*-phenylenediamine. With the other developing agents it eliminated the effect of the silver on the total oxygen absorption, showing that the halogen ion interferes with the silver catalysis of the decomposition of hydrogen peroxide and of the oxidation of the developing agents by hydrogen peroxide. The effect of halogen ion on the shortening of the induction period, *e. g.*, of metol, is much less pronounced.

According to the present results, a catalytic effect of silver in photographic development of the type suggested by Volmer, *i. e.*, a catalysis which directly affects the reactivity of the developing agents is most unlikely with developing agents of the types of dioxybenzene and aminophenol. It may possibly play some role in development with *p*-phenylenediamine and its derivatives. For the discrimination between exposed and unexposed grains in general, however, the other mechanisms indicated in the introductory remarks should be responsible.

Summary

1. The oxygen absorption of hydroquinone at various rates of shaking was investigated to check the conditions under which the concentration of oxygen in the liquid phase remains constant.

2. In agreement with results in earlier papers of this series and in disagreement with Green and Branch, it was shown that the rate of autoxidation of hydroquinone between *p*H 7 and 8.2 increases with the square of the hydroxyl-ion concentration.

3. Silver accelerates the autoxidation of hydroquinone, catechol, *p*-aminophenol, and glycine only to a very small degree. With these developing agents, therefore, the catalysis suggested by Volmer is most unlikely to be of significance for photographic development.

4. The autoxidation of *p*-phenylenediamine and *p*-dimethylaminoaniline shows a more considerable catalysis by silver.

5. The addition of silver strongly diminishes the total amount of oxygen which is absorbed by the developing agents in alkaline solutions. This is chiefly caused by a catalytic effect of the silver on reactions of peroxide formed in the autoxidation.

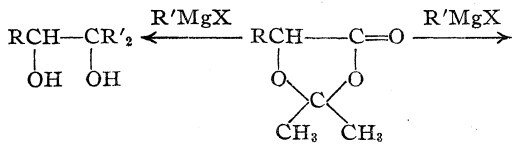
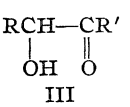
Reductive Cleavage of Dioxolones by the Grignard Reagent

BY REYNOLD C. FUSON AND A. I. RACHLIN

Dioxolones, acetone derivatives of α-hydroxy acids (I), are known to react with the Grignard reagent to form glycols (II).[1] It seemed probable that if the reagent had a very highly branched radical, acyloins (III) might be produced.

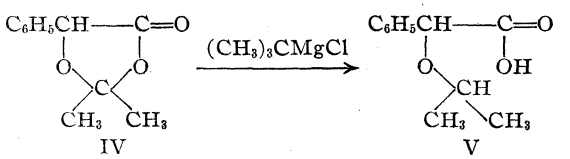


II I



III

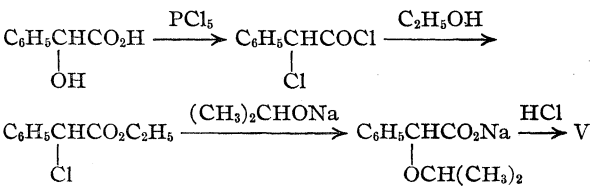
In an attempt to obtain the latter type of compound, the acetone derivative of mandelic acid (IV) was treated with *t*-butylmagnesium chloride. The product was not the acyloin, however, but α-isopropoxymandelic acid (V). Isobutylene was evolved.



IV V

The reaction is a hydrogenolysis of the dioxolone ring and appears to be new in type. Moreover, it has no parallel among the reactions between the Grignard reagent and esters or lactones.

The structure of the product was established by synthesis. The following series of reactions was employed



It has been found that the reaction is general for acetone derivatives of α-hydroxy acids. The iso-

(1) Freudenberg, Todd and Seidler, *Ann.*, **501**, 210 (1933).

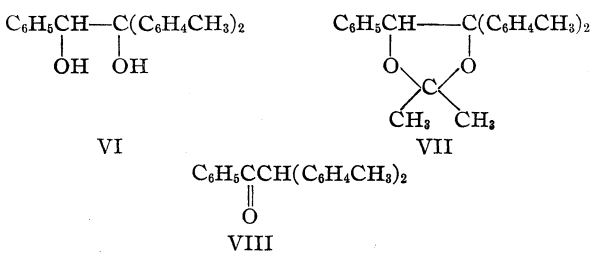
propyl ethers of mandelic, *p*-methylmandelic, *p*-bromomandelic, α-mesitylglycolic, lactic and α-hydroxyisobutyric acids have been prepared by this method in yields of 57, 66, 71, 80, 20 and 50%, respectively. All these acids are new compounds.

Unsuccessful attempts were made to produce the cleavage with the binary mixture (Mg + MgI_2),[2] aluminum isopropoxide, the zinc–copper couple and hydrogen in the presence of platinum. Hydrogen with copper chromite has been reported[3] to convert dioxolones into a mixture of compounds none of which is analogous to the product described here.

Attempts to effect the reduction of the acetone derivative of mandelic acid by use of other alkyl Grignard reagents were unsuccessful, indicating that the reaction may be peculiar to *t*-butylmagnesium halides.

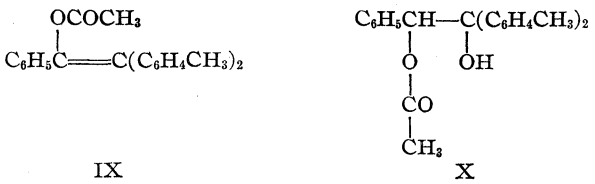
No evidence of reduction was observed in reactions involving aryl Grignard reagents. Normal addition was the principal reaction, with steric hindrance playing an interesting role. For example, phenylmagnesium bromide gave a 66% yield of triphenylethylene glycol as reported by Freudenberg, Todd and Seidler.[1]

Mesitylmagnesium bromide produced an intractable oil. On the other hand, *o*-tolylmagnesium bromide converted the dioxolone into the glycol (VI). Small amounts of the corresponding dioxolane (VII) and the ketone (VIII), formed from the glycol by dehydration, were also isolated.



VI VII VIII

The glycol (VI) was transformed readily into the ketone (VIII) by acids. Treatment of the glycol with acetic anhydride in the presence of a mineral acid produced an acetate (IX) obtained by similar treatment of the ketone (VIII). On the other hand, acetic anhydride in pyridine produced a different acetate (X), which was readily dehydrated to the other acetate (IX) by acetyl chloride. The glycol had two active hydrogen atoms.

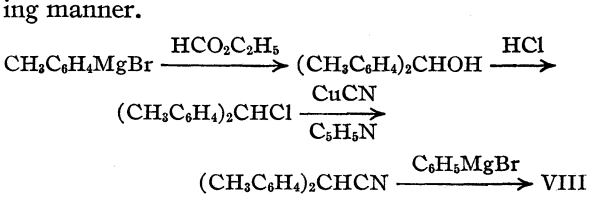


IX X

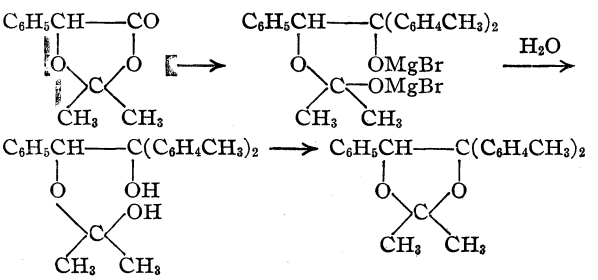
An attempt to synthesize the glycol by treating methyl mandelate with *o*-tolylmagnesium bromide resulted in the formation of an oil. A similar experience was reported by Roger and McKay[4] who used the ethyl ester.

The structure of the dioxolane (VII), an acetal, is based on the analysis, the transformation to the ketone (VIII) in the presence of acid and the synthesis by condensing the glycol (VI) with acetone. The dioxolane had no active hydrogen atom. When it was treated with acetic anhydride and acid, the acetate (IX) was formed.

The ketone (VIII) was synthesized in the following manner.



The formation of the dioxolane may be explained by assuming that the behavior of the original dioxolone toward *o*-tolylmagnesium bromide resembles that of lactones. The transformation may be represented as



Experimental

The dioxolones were made by condensing acetone with the appropriate α-hydroxy acids by means of concentrated sulfuric acid. The method, essentially that of Audrieth and Sveda,[5] was modified in order to give a pure product. The following directions for making acetonemandelic acid illustrate the general procedure.

A solution of 304 g. of mandelic acid in 880 cc. of dry acetone was cooled to −10° in an ice–salt-bath. The solution was stirred vigorously while 196 g. of concentrated sulfuric acid was added. The addition was made over a period of one hour and the unused acid was neutralized by

[a] Described by Audrieth and Sveda.[5] [b] "Mes" is used to represent mesityl. [c] Described by Oeda.[3] [d] The reaction mixture was poured into benzene. The benzene layer was treated with diethylamine to neutralize the acid, dried over magnesium sulfate and distilled. [e] $n^{20}D$ 1.4065.

pouring the reaction mixture into an ice-cold solution of 400 g. of anhydrous sodium carbonate in 3500 cc. of water. The curdy white product was collected on a suction filter and sucked dry. Purification was effected by washing the solid with four 250-cc. portions of ether. The ether solution was dried over calcium chloride and the solvent was removed by distillation. Removal of the last traces of ether *in vacuo* caused the acetone compound to solidify in a white mass. The hard cake was pulverized and used without further purification.

The physical constants, yields and analytical data for this and similar compounds are given in Table I.

The Action of *t*-Butylmagnesium Chloride on Dioxolones.—The procedure, illustrated for the reaction of *t*-butylmagnesium chloride on acetone-mandelic acid, was the same in all cases.

t-Butylmagnesium chloride was made by adding 55.8 g. of *t*-butyl chloride to a mixture of 14.4 g. of magnesium and 150 cc. of ether. To this well-stirred solution was added 38.4 g. of acetone-mandelic acid dissolved in 100 cc. of ether. The time of addition was one-half hour. The solution was stirred and refluxed for an additional hour before decomposition with 200 cc. of concentrated hydrochloric acid and 1000 g. of ice. After separation of the layers, the aqueous part was extracted with 200 cc. of ether. The combined ethereal solution was extracted repeatedly with 10% potassium bicarbonate. Acidification of the alkaline solution with hydrochloric acid caused the α-isopropoxymandelic acid to precipitate as an oil. The oil solidified when the mixture was allowed to stand for a few hours; yield, 22 g., 57% of theoretical.

One experiment was devoted to the examination of the gaseous by-product. By means of a stream of nitrogen the gas was forced through a series of wash bottles containing the following solutions in order: 64 g. of bromine in 200 cc. of carbon tetrachloride (0°); 10 g. of bromine in 100 cc. of carbon tetrachloride (0°); 25 cc. of sodium sulfite in 300 cc. of water; an empty trap at dry-ice temperature. The reaction was carried out as described above, using the Grignard reagent made from 24 g. of magnesium, 92 g. of *t*-butyl chloride, 250 cc. of ether and a solution of 76.8 g. of acetone-mandelic acid in 200 cc. of ether. The solution was refluxed a total of two hours, after the addition of the acetone compound. No other effort was made to drive the gas out of the ether. The carbon tetrachloride solutions were combined, washed with sodium sulfite solution, water and distilled. There was produced 20 g. (24%) of pure dibromoisobutane; b. p. 146–147°; $n^{20}D$ 1.508. The absence of a condensate in the dry-ice trap indicated that no saturated hydrocarbon was formed. The reaction mixture was worked up as described above and yielded 34 g. (45%) of isopropoxymandelic acid; m. p. 57–58°.

The physical constants, yields and analyses of the isopropoxy acid and their *p*-phenylphenacyl esters are given in Table II.

Synthesis of α-Isopropoxymandelic Acid.—Phenylchloroacetyl chloride was made, according to the directions of Bischoff and Walden,[7] by heating mandelic acid with phosphorus pentachloride at 140°. This compound was converted to ethyl phenylchloroacetate, reported by Findlay and Turner,[8] by heating it with absolute ethanol. A sodium isopropoxide solution, prepared by dissolving 8 g. of sodium in 120 cc. of dry isopropyl alcohol, was refluxed on a steam-bath while 30 g. of phenyl chloroacetate was added. The mixture was heated for four hours, cooled and filtered. The solid was dissolved in water and the solution acidified with hydrochloric acid. The oily product was isolated by extraction with ether, drying the ethereal extract with calcium chloride and removing the solvent by distillation. Treatment of the residual oil with low-boiling petroleum ether caused the separation of 14 g. of white acid; m. p. 41–55°. Several recrystallizations from low-boiling petroleum ether resulted in a pure product melting at 58–59°—alone or when mixed with the compound obtained by the other method.

The Reaction of *o*-Tolylmagnesium Bromide with Acetone-mandelic Acid.—To an *o*-tolylmagnesium bromide solution, prepared from 342 g. of *o*-bromotoluene and 48 g. of magnesium in 500 cc. of ether, was added, with vigorous stirring over a period of one hour, a solution of 96 g. of acetone-mandelic acid in 300 cc. of ether. The solution was stirred and refluxed for an additional three hours after which it was cooled and decomposed with 400 cc. of concentrated hydrochloric acid and 1500 cc. of ice. The ether was distilled from the organic layer and the residue was subjected to steam distillation in order to remove the toluene. The residue was dissolved in ether and repeatedly extracted with 10% potassium bicarbonate

[a] The *p*-phenylphenacyl esters were made from *p*-phenylphenacyl bromide according to the method described in Shriner and Fuson, "Identification of Organic Compounds," 2nd Edition, John Wiley and Sons, New York, N. Y., 1940, p. 132. [b] R is used to represent isopropyl. [c] The product was a clear uncrystallizable oil. [d] "Mes" is used to represent mesityl. [e] $n^{20}D$ 1.4158. [f] $n^{20}D$ 1.4196.

solution. Acidification of the alkaline solution with hydrochloric acid produced 3 g. of mandelic acid.

The ether was distilled from the organic layer after it was washed with water and dried over calcium chloride. The residue was treated with 150 cc. of methanol and cooled in an ice-bath. A solid product (39 g.) melting at 118–132° was removed by filtration. Concentration of the mother liquor followed by cooling and filtration produced 3 g. of a solid (VIII), m. p. 100–102°. The pure compound, recrystallized from methanol, melted at 104–106°.

Anal. Calcd. for $C_{22}H_{20}O$: C, 87.96; H, 6.71. Found: C. 88.25; H, 6.88.

The crude solid melting at 118–132° was washed with 200 cc. of low-boiling petroleum ether. The insoluble residue (VI) weighed 30.5 g. and melted at 139–141°. After recrystallization from methanol, it melted at 146°.

Anal. Calcd. for $C_{22}H_{22}O_2$: C, 82.99; H, 6.99. Found: C, 83.23; H, 7.19.

A Zerewitinoff determination showed the presence of two active hydrogen atoms in the molecule.

The wash solution was evaporated to an oily residue. Treatment of the oil with methanol produced 8.5 g. of a solid (VII), melting at 104–106°. The dioxolane, recrystallized from methanol, melted at 108–109°.

Anal. Calcd. for $C_{25}H_{26}O_2$: C, 83.76; H, 7.31. Found: C, 83.97; H, 7.69.

A Zerewitinoff determination showed the absence of active hydrogen.

The Condensation of 1-Phenyl-2,2-di-*o*-tolylethylene Glycol (VI) with Acetone.—To a solution of 0.6 g. of the glycol in 10 cc. of anhydrous acetone was added 0.4 cc. of concentrated sulfuric acid and 1 g. of anhydrous sodium sulfate. The reaction flask was allowed to stand with occasional shaking for twenty-four hours. The solution was filtered and the solvent was removed by a stream of air. The residue, dissolved in ether, was washed with 10% potassium bicarbonate solution and water, dried over calcium chloride and evaporated to an oil. Treatment of the oil with methanol caused the separation of a solid; m. p. 104–106°. The compound was recrystallized from methanol and melted at 108–109° alone or mixed with other samples of the dioxolane. The yield of pure product was 0.4 g.

Reaction of 1-Phenyl-2,2-di-*o*-tolylethylene Glycol with Acetic Anhydride and Pyridine.—Five grams of the glycol was dissolved in 50 cc. of a 20% solution of acetic anhydride in pyridine. The solution was heated on a steam-bath for twelve hours. About 35 cc. of the solvent was removed by distillation and the residue was added to 100 cc. of water. The solution was digested for fifteen minutes, cooled and extracted with ether. The ethereal solution was dried over calcium chloride and concentrated to an oil. Treatment with methanol produced 4 g. of a solid (X), which melted at 153–155°. The acetate, recrystallized from methanol, melted at 158–160°.

Anal. Calcd. for $C_{24}H_{24}O_3$: C, 79.97; H, 6.71. Found: C, 80.01; H, 6.81.

The compound had one active hydrogen atom.

Reaction of 1-Phenyl-2,2-di-*o*-tolyl Ethylene Glycol with Acetic Anhydride and Hydrochloric Acid.—Three grams of the glycol was refluxed for eighteen hours with 30 cc. of acetic anhydride and 3 drops of concentrated hydrochloric acid. The reaction mixture was poured into 100 cc. of water and digested for fifteen minutes, cooled and extracted with ether. The ethereal solution was dried over calcium chloride and evaporated to an oil. Treatment of the oil with methanol produced 2.5 g. of a white solid (IX) which melted at 133–135°. The acetate, recrystallized from methanol, melted at 138.5–140°.

Anal. Calcd. for $C_{24}H_{22}O_2$: C, 84.20; H, 6.48. Found: C, 84.09; H, 6.53.

The Reaction of Acetyl Chloride with the Acetate (X).—Two grams of the acetate (X) was heated at the refluxing temperature for four hours with 20 cc. of acetyl chloride. The reaction mixture was poured on ice and allowed to come to room temperature. The organic matter was extracted with ether. The ethereal solution was washed with 10% potassium bicarbonate solution and water and then dried over calcium chloride. The solvent was removed and the residue was taken up in hot methanol. Cooling caused the precipitation of 1.2 g. of a compound

melting at 135–136°. Recrystallized from methanol, it melted at 138.5–140° alone or mixed with the acetate (IX).

Reaction of the Dioxolane (VII) with Acetic Anhydride and *p*-Toluenesulfonic Acid.—Two grams of the dioxolane was heated at the refluxing temperature for four hours with 20 cc. of acetic anhydride and a few crystals of *p*-toluenesulfonic acid. The reaction mixture was worked up in the usual manner; yield, 1.5 g. of a white compound melting at 129–132°. Recrystallization from methanol gave a melting point of 138.5–140° alone or mixed with other samples of the acetate (IX).

Transformation of 1-Phenyl-2,2-di-*o*-tolylethylene Glycol and the Dioxolane in Acid Solution.—One gram of the compound was dissolved in 4 cc. of methanol and three drops of concentrated hydrochloric acid. The solution was refluxed for twelve hours and the solvent was removed by distillation. The residue was 0.75 g. of a solid identified as ω,ω-di-*o*-tolylacetophenone (VIII).

Treatment of the dioxolane (VII) with hydriodic acid, 30% sulfuric acid, phosphoric acid or *p*-toluenesulfonic acid gave practically quantitative conversion to ω,ω-di-*o*-tolylacetophenone. Treatment of the 1-phenyl-2,2-di-*o*-tolylethylene glycol with hydrochloric acid or *p*-toluenesulfonic acid gave similar results.

Reaction of ω,ω-Di-*o*-tolylacetophenone with Acetic Anhydride and Pyridine.—Two grams of the compound was heated at the refluxing temperature for twelve hours with 4 cc. of pyridine and 16 cc. of acetic anhydride. The reaction mixture was worked in the usual fashion; yield, 1.5 g. of the acetate (IX); m. p. 133–135°; the pure compound melted at 138.5–140°.

Synthesis of Di-*o*-tolylcarbinol.—A solution of *o*-tolylmagnesium bromide was prepared from 171 g. of *o*-bromotoluene, 24 g. of magnesium and 250 cc. of ether. To this solution was added 33.4 g. of ethyl formate. The solution was refluxed and stirred for seven hours before it was cooled and decomposed with hydrochloric acid and ice. It was necessary to add 250 cc. of benzene to the mixture in order to dissolve all the organic matter. The organic layer was separated, dried over calcium chloride and evaporated; yield, 70 g. (73%); m. p. 115–119°[9].

Synthesis of Di-*o*-tolylchloromethane.—The di-*o*-tolylcarbinol was converted, without further purification, into di-*o*-tolylchloromethane by the method of Reid[10]; yield, 94%.

Synthesis of Di-*o*-tolylacetonitrile.—A mixture of 23.1 g. of di-*o*-tolylchloromethane, 10.7 g. of cuprous cyanide and 20 cc. of dry pyridine was heated for twenty-four hours at 200–215°. Ground glass equipment, protected from moisture by a calcium chloride tube, was used. The dark mass was cooled and poured into dilute aqueous ammonia. The organic matter was extracted with ether. It was necessary to remove some dark solid material by filtration. The ethereal solution was washed successively with dilute ammonia, water, dilute hydrochloric acid and finally with water. The solution was dried with calcium chloride and evaporated to dryness. The residue was recrystallized from 95% ethanol; m. p. 107–109°; yield, 12 g. (54%). The pure compound, recrystallized from 95% ethanol, melted at 114–115°.

Anal. Calcd. for $C_{16}H_{15}N$: C, 86.83; H, 6.83. Found: C, 87.17; H, 6.91.

Synthesis of ω,ω-Di-*o*-tolylacetophenone.—A solution of phenylmagnesium bromide, made from 14.1 g. of bromobenzene, 1.94 g. of magnesium and 35 cc. of ether, was added to a well-stirred solution of 4.5 g. of di-*o*-tolylacetonitrile in 75 cc. of ether. The solution was stirred and refluxed for twenty-four hours, after which it was cooled and decomposed with hydrochloric acid and ice. The organic layer was separated and discarded. The aqueous layer was digested on a steam-bath for two hours. Cooling to room temperature produced an oil which soon solidified; yield, 4 g.; m. p. 100–102°. Recrystallized from methanol, the product melted at 104–106° alone or mixed with other samples of (VIII).

Summary

Dioxolones, acetone derivatives of α-hydroxy acids, react with *t*-butylmagnesium chloride to yield the corresponding α-isopropoxy acids. The reaction is a hydrogenolysis of the dioxolane ring and appears to be new in type.

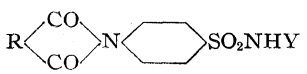
Dicarboxylic Acid Derivatives of Sulfonamides[1]

BY MAURICE L. MOORE AND CHARLES S. MILLER

In continuing our studies of the possible chemotherapeutic activity of sulfonamide compounds,[2] it was found that certain of the derivatives from dicarboxylic acids possessed interesting activity as intestinal antiseptics. We undertook to prepare a large series of these compounds, some of which have been studied as intestinal antiseptics.[3] One of these, succinylsulfathiazole,[4,5] has shown unusually marked activity for this purpose. In this paper we describe the preparation and properties of these compounds and discuss some of the results obtained from the reactions involved in their preparation.

The condensation of succinic, maleic and phthalic anhydrides with the various sulfonamides, using anhydrous alcohol or dioxane as a solvent according to the method previously described for the sulfanilamide and sulfanilhydroxamide derivatives,[2b,c] occurred in the ratio of 1:1, giving monobasic acids of the general formula I. Condensa-

I



II

tion of succinic anhydride with sulfanilamide in the presence of pyridine had been found to give the anil II.[2c] Recently, Shapiro and Bergmann[6] have found that in the condensation of sulfapyridine with succinic and phthalic anhydrides temperatures below 100° give acid amides I while temperatures above 100° give the anils II. They found that with maleic anhydride the acid amide was the sole reaction product, even at 190°. However, neither Shapiro and Bergmann nor we had obtained any of the diamides III in condensations with anhydrides.

III

The oxalic and malonic acid derivatives of sulfathiazole, sulfadiazine and sulfaguanidine were made by refluxing the sulfonamide with an excess of the ethyl ester of the appropriate acid and hydrolyzing the ester amides IV thus formed with

IV

alkali to give the corresponding acid amides. The ester amides were obtained in yields above 80%, although, in most cases there was isolated a small quantity of by-product which appeared to be the diamide. Esters of higher acids, such as ethyl glutarate and sebacate, did not condense with sulfathiazole even when heated at 160–170° for two hours.

The higher acid derivatives, *i. e.*, from glutaric, adipic and sebacic acids, were made by heating the sulfonamide with the acid itself at a temperature between 150–170° for one to two hours. Succinylsulfathiazole (compound no. 8) was also prepared in this manner and the reaction studied in some detail. It appears that with an equimolar mixture of the components, or with as much as 5 or 10% excess of the acid, the reaction proceeded with the formation of the anil and about 5–7% of the diamide. Hydrolysis of the anil with 5–10% sodium hydroxide solution gave the acid amide which was removed from the diamide by solubility in cold bicarbonate solution. Similar results have been obtained by carrying out the condensation in refluxing "Carbitol."

Condensation of adipic acid with sulfapyridine, sulfathiazole and sulfaguanidine, followed by treatment with alkali, led to the isolation of the acid amides and the diamides, with a larger portion of the product being the diamides. However, with glutaric and sebacic acids, the diamides were the principal product from the condensation with sulfathiazole.

Attempts to condense *p*-succinimidobenzenesulfonyl chloride with 2-aminothiazole led to some interesting observations. With two equivalents of 2-aminothiazole, in pyridine or acetone as a sol-

vent, the acid amide was obtained in about a 1:1 ratio with an unidentified product. Similar results were obtained with 1 equivalent of 2-aminothiazole in sodium carbonate solution.

Experimental

1. Anhydride Condensations.—Five hundred grams (1.96 moles) of sulfathiazole was added to 5000 cc. of anhydrous alcohol and heated to refluxing with mechanical stirring. When refluxing occurred, 250 g. (2.5 moles, 25% excess) of succinic anhydride was added and the mixture refluxed for forty-five minutes. During this period, all of the materials had gone into solution and toward the end of the reaction a solid began to crystallize out, which after standing overnight was obtained in a yield of 90%. Yields equally as good were obtained by using only 5 or 10% excess of succinic anhydride. Purification was effected by recrystallizing 104 g. of the crude material from a refluxing solution of 400 cc. of alcohol and 300 cc. of water. The yield was 89 g. (77%), melting at 192–195°, with decomposition.

Dioxane was used as the solvent for the condensation of succinic anhydride with 2-sulfanilamido-5-ethyl-4-thiazolone, sulfadiazine and sulfanilylsulfathiazole.

2. Ester Condensations.—Twenty grams (0.078 mole) of sulfathiazole was added to 60 g. (0.375 mole) of ethyl malonate and heated under reflux at a temperature of 130–150° for two hours. After cooling the reaction mixture to room temperature, the solid product was filtered and washed thoroughly with dilute hydrochloric acid and water. A yield of 24.7 g. (85%) of the ester amide IV, compound no. 6, was obtained and after purification by recrystallizing from dilute alcohol, it melted at 193–194.5° with decomposition.

A similar yield was obtained when only two equivalents of the ethyl malonate was used under the same experimental conditions. However, in this experiment, a small quantity of material was obtained which was insoluble in dilute alcohol. On crystallization from methyl "Cellosolve" and water, this product melted at 233–236° with decomposition. A mixed melting point with acetylsulfathiazole, m. p. 256–257°, was 225–226° followed by decomposition. Reactions and analysis suggest that the product was the diamide, **malonamide-4,4'-bis-(2-benzenesulfonamidothiazole).**

Anal. Calcd. for $C_{21}H_{18}O_6N_6S_4$: N, 14.53. Found: N, 14.00.

An 86% yield of ester amide was obtained by condensing sulfathiazole with two equivalents of ethyl oxalate under the above conditions and no diamide was isolated.

Hydrolysis of the ethyl malonylsulfathiazole to the acid amide was accomplished by heating 14 g. of the material in 150 cc. of 2.5% sodium hydroxide solution at 85–95° for one-half hour. The solution was decolorized with charcoal (Darco) and the product precipitated from the solution by neutralization with dilute hydrochloric acid. A yield of 10 g. (77%) was obtained and after several recrystallizations from dilute alcohol the malonylsulfathiazole decomposed in the range of 240–250°, without definitely melting.

3. Acid Condensations.—(A) Ten grams (0.0392 mole) of sulfathiazole and 4.6 g. (0.0392 mole) of succinic acid were mixed in a flask and heated in a sand-bath to a temperature of 150–160° for one hour, with occasional stirring. At the end of the hour, the reaction melt began to solidify, while stirring, as a granular solid. The material was treated with a boiling solution of 90% acetic acid and an insoluble product filtered. The yield was 0.9 g. and melted at 277–279° with decomposition after purification by dissolving in dilute ammonia and precipitating with dilute hydrochloric acid. The product was soluble in dilute ammonia and alkali but insoluble in cold sodium bicarbonate solution. This corresponded to the diamide III, **succinamido-4,4'-bis-(2-benzenesulfonamidothiazole).**

Anal. Calcd. for $C_{22}H_{20}O_6N_6S_4$: N, 14.19. Found: N, 14.13.

The hot acetic acid filtrate from the above was allowed to cool overnight and a white crystalline solid was obtained. The yield of the product was 5.6 g. and it melted at 266–267° after recrystallization from anhydrous methyl "Cellosolve." It was soluble in dilute ammonia and alkali but insoluble in cold sodium bicarbonate solution. This corresponded to the anil II, **2-(4'-succinimidobenzenesulfonamido)-thiazole.**

Anal. Calcd. for $C_9H_{11}O_4N_3S_2$: N, 12.46. Found: N, 12.30.

A sample of the anil was converted into the acid amide, succinylsulfathiazole, by dissolving in a warm 2.5% sodium hydroxide solution and precipitating with dilute hydrochloric acid. The product was readily soluble in cold sodium bicarbonate solution with the evolution of carbon dioxide and it melted at 140° with decomposition. After several crystallizations from dilute alcohol the product melted at 185–187° with decomposition.

A sample of the diamide was dissolved in 5% sodium hydroxide solution, refluxed for a few minutes and after cooling to room temperature the solution was carefully neutralized with dilute hydrochloric acid giving sulfathiazole; m. p. 196°. A mixed sample with authentic sulfathiazole, m. p. 199–200°, melted at 199–200°.

(B) Ten grams of sulfathiazole and 4.6 g. of succinic acid were heated together under the same conditions as described above. The solid obtained from the reaction mixture was dissolved in dilute ammonia, the solution decolorized with charcoal (Darco), and precipitated by the careful addition of a slight excess of dilute hydrochloric acid. A yield of 9.9 g. of an unidentified product (A) was obtained which melted at 194.5–195.5° after four recrystallizations from methyl "Cellosolve" and water. It was insoluble in cold bicarbonate solution. *Anal.* Found: N, 14.63. The identity of this compound is being investigated.

Four grams of the above compound was dissolved in 50 cc. of 5% sodium hydroxide solution and heated at about 90° for ten minutes. The acid amide, succinylsulfathiazole, melting at 129–133° with decomposition, was isolated by precipitation with dilute hydrochloric acid and after several recrystallizations from dilute alcohol melted at 185–187°.

(C) Sulfathiazole, 100 g. (0.392 mole), and 48.8 g. (0.411 mole) of succinic acid were mixed in a liter flask and heated

[a] Most of these compounds actually decomposed with effervescence instead of melting. In some cases these decomposition ranges were difficult to recheck. [b] The analyses were carried out in these laboratories by Mr. John R. Taylor. [c] All samples were dried in the Abderhalden dryer for at least one hour before analyzing. [d] Shapiro and Bergmann [*J. Org. Chem.*, **6**, 774 (1941)] reported a melting point of 145° for the succinyl derivative and 208° for the maleyl derivative without mentioning their decomposition. [e] A sample of this compound decomposed at 191–194° after standing for seven months. *Anal.* Found: N, 11.94. [f] Recrystallized from water. [g] Purified by dissolving in dilute ammonia and precipitating with dilute hydrochloric acid. [h] Hygroscopic; takes up water during weighing. [i] The first samples of this compound decomposed at 184–186°. *Anal.* Found: N, 11.60. After standing for six months the same samples decomposed at 192–195°. All subsequent samples prepared by the anhydride condensation have decomposed at the higher range. [j] *Anal.* before drying. Calcd. for $C_{13}H_{13}O_5N_3S_2 \cdot H_2O$: N, 11.26. Found: N, 11.21. [k] This compound is unstable in solution and is subject to hydrolysis. [l] The anhydride condensation was carried out in dioxane as the solvent. [m] A sample of this compound was heated at the melting point until no further decomposition occurred. After recrystallizing from water it melted at 260–261°. Mixed with an authentic sample of N^4-acetylsulfanilylguanidine, m. p. 266–267°, it melted at 260–262°. [n] *Anal.* before drying. Calcd. for $C_{11}H_{12}O_5N_4S \cdot H_2O$: N, 16.97. Found: N, 17.00. [o] Melted to a clear liquid. [p] Recrystallized from methyl "Cellosolve" and water. [q] Solidified after melting at this temperature and remelted at 270°. [r] We are indebted to Dr. T. M. Immediata for the preparation of these compounds. [s] Recrystallized from acetone and water. [t] Recrystallized from dioxane and water. [u] Charred instead of melting.

in an oil-bath to approximately 165° for one hour with stirring. At the end of this time, the reaction melt had begun to solidify and the flame was removed from the oil-bath. With the flask still in the oil-bath, 380 cc. of 10% sodium hydroxide solution was cautiously added and after stirring for about fifteen minutes all of the solid had dissolved. After cooling to room temperature, the alkali solution was poured into a mixture of 88 cc. of concentrated hydrochloric acid and 960 cc. of water giving 130 g. of crude product (melting at 129–135° with decomposition), which was removed by filtration and purified by dissolving in a solution of 1000 cc. of ethanol and 200 cc. of water, decolorizing with charcoal (16 g. of Norite) and filtering with the aid of 16 g. of Filter-cel. Crystallization was completed by the addition of 504 cc. of water and 40 cc. of concentrated hydrochloric acid. The yield of succinylsulfathiazole was 87.5 g., which after further crystallization from dilute alcohol melted at 138–140°.

The diamide formed was removed by the Norite and Filter-cel and was isolated by treating with dilute alkali, filtering and precipitating with dilute hydrochloric acid. A yield of 6–9 g. was obtained.

(D) One hundred grams of sulfathiazole and 48.8 g. of succinic acid were heated together in 100 cc. of diethyl "Carbitol" under the same conditions as described in (C) above, for two hours. During the heating all of the materials went into solution and at the end of one and one-half hours a solid began to precipitate. After standing overnight, the product was filtered, dissolved in 400 cc. of 10% sodium hydroxide and precipitated with dilute hydrochloric acid. A yield of 81.9 g. (59%) of succinylsulfathiazole was obtained after recrystallization from dilute alcohol. Eight grams of crude diamide was recovered from the Norite and Filter-cel.

(E) Ten grams (0.0467 mole) of sulfaguanidine was mixed with 6.7 g. (0.0467 mole) of adipic acid and heated at 140–150° for one hour. After standing overnight, the solid was treated with 60 cc. of 10% sodium carbonate solution and the insoluble product filtered. A yield of 8 g. was obtained, melting at 234–240° with decomposition. After having been washed with dilute ammonia, hydrochloric acid and water and recrystallized from methyl "Cellosolve," the product melted at 268–269° with decomposition. It corresponded to the diamide, **adipamido-4,4′-bis-(benzenesulfonylguanidine)**.

Anal. Calcd. for $C_{20}H_{26}O_6N_8S_2$: N, 20.82. Found: N, 20.51.

The carbonate soluble filtrate was neutralized with dilute hydrochloric acid and a yield of 2.8 g. of adipoylsulfaguanidine was obtained, melting at 132–133° after recrystallization from dilute alcohol.

Similar results were obtained by the condensation of adipic acid with sulfapyridine and sulfathiazole.

(F) Ten grams (0.0392 mole) of sulfathiazole was mixed with 7.9 g. (0.0392 mole) of sebacic acid and heated to 150–170° for one and one-half hours. The cooled solid reaction mixture was treated with 200 cc. of 5% sodium hydroxide solution, decolorized with charcoal (Darco) and precipitated with dilute hydrochloric acid. The crude product (14 g.) was extracted thoroughly with saturated sodium bicarbonate solution, leaving 7.5 g. of insoluble material which was thoroughly washed with dilute hydrochloric acid and water and crystallized from dilute methyl "Cellosolve" containing a small amount of sodium bicarbonate. Purification by further crystallization from dilute methyl "Cellosolve" gave the diamide, **sebacamido-4,4′-bis-(2-benzenesulfonamidothiazole)**, melting at 245–246°.

Anal. Calcd. for $C_{28}H_{32}O_6N_6S_4$: N, 12.42. Found: N, 12.31.

Acidification of the sodium bicarbonate solution gave unreacted sebacic acid, m. p. 133°.

Glutaramido-4,4′-bis-(2-benzenesulfonamidothiazole), melting at 251–254° with decomposition after crystallization from dilute methyl "Cellosolve," was obtained in the same manner from glutaric acid and sulfathiazole.

Anal. Calcd. for $C_{23}H_{22}O_6N_6S_4$: N, 13.84. Found: N, 13.56.

Succinimidobenzenesulfonyl chloride was prepared by the method reported by Adams, Long and Jeanes.[7] However, the compound was purified by two recrystallizations from acetone and water, melting at 189–195° with decomposition.

Anal. Calcd. for $C_{10}H_8O_4NSCl$: N, 5.12. Found: N, 5.10.

Condensation of Succinimidobenzenesulfonyl Chloride with 2-Aminothiazole.—Twenty grams (0.2 mole) of 2-aminothiazole was dissolved in 75 cc. of anhydrous pyridine and 27.4 g. (0.1 mole) of succinimidobenzenesulfonyl chloride was added slowly with stirring. After the addition, the solution was heated on the steam-bath for one-half hour and the pyridine was then removed by distillation under reduced pressure. The residue was triturated with 50 cc. of cold water and the brown insoluble solid (4 g.) was filtered. After purification by several recrystallizations from dioxane and water the solid melted at 250.5–251.5° with decomposition. It was insoluble in cold sodium bicarbonate solution.

Anal. Found: N, 14.85.

The aqueous filtrate from above was acidified with concentrated hydrochloric acid and after chilling for several days 6.8 g. of succinylsulfathiazole was obtained, melting at 180–184°. It was soluble in cold sodium bicarbonate solution with evolution of carbon dioxide.

Condensations with two equivalents of 2-aminothiazole in acetone or one equivalent of 2-aminothiazole in sodium carbonate solution gave similar results.

Summary

A series of dicarboxylic acid derivatives of sulfonamides has been prepared for study as intestinal antiseptics.

Succinic, maleic and phthalic anhydrides condensed with the sulfonamides to give the monobasic acid amides I. Ethyl oxalate and ethyl malonate condensed with sulfathiazole, sulfadiazine and sulfaguanidine to give the ester amides IV, which were easily hydrolyzed by alkali to give the acid amides I, and a small amount of the diamides III. Esters of higher acids, such as ethyl glutarate, adipate and sebacate did not con-

(7) Adams, Long and Jeanes, THIS JOURNAL, **61**, 2316 (1939).

dense with sulfathiazole even when heated at 160–170° for two hours.

Succinic acid condensed with the sulfonamides, when heated at a temperature of 150–170° for one to two hours, to give the anils II and 5–7% of the diamides IV. Hydrolysis of the anils II with 5–10% alkali gave the corresponding acid amides I. Condensation of glutaric, adipic and sebacic acids with the sulfonamides led to the isolation of the acid amides I and diamides III, in varying proportions.

p-Succinimidobenzenesulfonyl chloride condensed with 2-aminothiazole, under varying conditions, to give N^4-succinylsulfathiazole and an unidentified product.

The Condensation of Some Secondary Aliphatic Alcohols with Benzene in the Presence of Aluminum Chloride

BY R. C. HUSTON AND I. A. KAYE[1]

Previous work in this Laboratory has shown that *t*-aliphatic alcohols condense with benzene and phenol in the presence of aluminum chloride to give the expected *t*-alkylbenzenes.[1a-3] Secondary aliphatic alcohols have been condensed with benzene too, but the nature of the products was not determined.[1a] The purpose of the present investigation was to extend the study of the condensation of secondary aliphatic alcohols with benzene, using aluminum chloride as catalyst, and to determine the nature of the products obtained.

s-Propyl, butyl, amyl, hexyl and nine of the *s*-heptyl alcohols were condensed with benzene. That isopropyl and *s*-butyl alcohols gave the expected hydrocarbons, cumene and *s*-butylbenzene, was shown by their monoacetamino derivatives whose melting points agreed with those in the literature.[4] The other monoalkylbenzenes were nitrated yielding the *p*-nitro derivatives which were then reduced to the amines. Phenols were prepared from the latter through the diazonium salts. The α-naphthylurethans of the phenols were then prepared. By comparison with the melting points of the α-naphthyl-urethans of known *t*-alkylphenols[2,3] and by mixed melting point determinations with these compounds, it was established that 2-methylbutanol-3, 2-methylpentanol-3, 2-methyl-hexanol-3 and 3-methylhexanol-4 gave the *t*-alkylbenzenes, 2-methyl-2-phenylbutane, 2-methyl-2-phenylpentane, 2-methyl-2-phenylhexane and 3-methyl-3-phenylhexane.

The *p*-hydroxy derivatives and their α-naphthylurethans of 2-phenylpentane, 3-phenylpentane, 2-phenylhexane, 3-phenylhexane, 3-methyl-2-phenylpentane, 2-methyl-4-phenylpentane, 2,2-dimethyl-3-phenylbutane, 2-phenylheptane, 3-phenylheptane, 4-phenylheptane, 2-methyl-4-phenylhexane, 2-methyl-5-phenylhexane, 3-methyl-2-phenylhexane, and 2,2-dimethyl-3-phenylpentane were synthesized. The condensation of pinacolyl alcohol with benzene gave an alkylbenzene which was converted into a phenol identical with synthesized 2,2-dimethyl-3-*p*-hydroxyphenylbutane. The other alcohols, pentanol-2, pentanol-3, hexanol-2, hexanol-3, 3-methylpentanol-2, 2-methylpentanol-4, heptanol-2, heptanol-3, heptanol-4,2-methylhexanol-4, 2-methylhexanol-5, 3-methylhexanol-2 and 2,2-dimethylpentanol-3 undoubtedly gave mixtures of monoalkylbenzenes such as might be formed by the splitting out of water and the condensation of the resulting olefin in either of the two possible positions. This formation of mixtures in the condensation of the *s*-amyl alcohols with benzene and phenol and in the condensation of the secondary hexylphenols has been observed by others[5,6,7] and it is quite possible that the same phenomenon occurs with the higher homologs. The formation of tertiary products in the condensation of *s*-aliphatic alcohols with methyl groups adjacent to the carbinol group has also been reported.[5,6,7]

Alcohols listed in Table I were prepared by the Grignard method. Some of their physical constants were redetermined. Other alcohols used showed constants which agreed with those in the literature.

Condensation of the Secondary Aliphatic Alcohols with Benzene.—All condensations were carried out in the same manner. One-half mole of the alcohol, dissolved in 50 ml. of benzene, was added dropwise and with vigorous stirring to a suspension of 50 g. of anhydrous aluminum chloride in 400 ml. of ice-cold anhydrous, thiophene-free benzene. Dry hydrogen chloride gas was bubbled through the reaction mixture at the same time at a rate such that the bubbles could just be counted. The reaction mixture was stirred one hour after the addition of the alcohol and then permitted to stand eight hours at room temperature.

In the case of the straight-chain alcohols, refluxing the reaction mixture eight hours longer, while bubbling in hydrogen chloride gas, was found to improve the yields. This practice was omitted in the condensation of the branched alcohols, since poorer yields were obtained.

The reaction mixture was then poured on ice; hydrochloric acid was added, and the benzene layer was separated and washed once with water, twice with a dilute sodium bicarbonate solution and once more with water. After drying over anhydrous sodium sulfate, the benzene was removed *in vacuo*. The residual liquid was distilled at atmospheric pressure using a ten-inch Vigreux column.

Derivatives of the Monoalkylbenzenes.—Acetamino derivatives were prepared by the method of Ipatieff and Schmerling.[4] The *p*-nitroalkylbenzenes, *p*-aminoalkylbenzenes and *p*-hydroxyalkylbenzenes were prepared by the methods given in Fisher's test.[8] α-Naphthylurethans were prepared by the method of French and Wirtel.[9]

Synthesis of the *s*-Alkylbenzenes.—These compounds were prepared by a modification of the method of Klages.[10] The alkyl Grignard reagent was treated with acetophenone or its homologs. The tertiary alcohol formed was not isolated but converted directly into an olefin by refluxing, using a Dean–Stark moisture trap[11] to collect the water which was eliminated. The product was then distilled and

reduced to the hydrocarbon by dissolving 0.25 mole in 375 ml. of absolute ethanol. Forty grams of sodium was added to the boiling solution in small portions over a period of time. Water was added when all the sodium had dissolved and the mixture was extracted three times with ether. The combined ether extracts were washed free of alcohol, dried over anhydrous sodium sulfate and the ether removed by distillation. The residue was shaken thoroughly with a saturated aqueous potassium permanganate solution and the excess permanganate reduced by the addition of solid sodium bisulfite. The alkylbenzene was then extracted with ether and distilled at atmospheric pressure after drying and removing the ether. The product was then converted into the *p*-hydroxyphenylalkane (see Table III, C) through the *p*-nitro and amino derivatives. The α-naphthylurethan of the phenol was then prepared.

TABLE V

α-NAPHTHYLURETHANS OF THE SYNTHESIZED *p*-HYDROXYPHENYLALKANES

TABLE VI

MONOALKYLBENZENES FROM *s*-ALCOHOLS WITHOUT REARRANGEMENT

Alcohol condensed with benzene	M. p. of derivatives, °C. Monoacetamino	Diacetamino	Pure compound alkylbenzene	M. p. of derivatives, °C. Monoacetamino	Diacetamino
Isopropyl	105	213–214	Cumene	106[5]	216[5]
s-Butyl	126	...	2-Phenylbutane	126[5]	...

	p-Hydroxyphenol	Phenol	M. p. of Phenol
Pinacolyl	122[a]	2,2-Dimethyl-3-*p*-hydroxyphenylbutane	120–121[b]

[a,b] Melting point of mixture of *a* and *b* showed no depression.

Table VI indicates definitely that propanol-2 condenses with benzene to form only cumene, and butanol-2 forms only 2-phenylbutane. The only other case of apparent simple replacement of the hydroxyl with phenyl was found in the condensation of 2,2-dimethylbutanol-3 with benzene. The alkylbenzene gave, upon nitration, reduction and diazotization, a phenol which was proved by mixed melting point and melting points of derivatives to be identical with 2,2-dimethyl-3-*p*-hydroxyphenylbutane. This is especially noteworthy in view of the fact that it has been found in this Laboratory[7] that pinacolyl alcohol reacts with phenol in the presence of aluminum chloride at 50° to give 2,3-dimethyl-2-*p*-hydroxyphenylbutane.

Of the remaining alcohols listed (Table II), none showed simple replacement of the hydroxyl with the phenol group. The α-naphthylurethan from the condensation of 3-methylpentanol-2 gave a melting point (not sharp) intermediate between that of the α-naphthylurethan of 3-methyl-2-*p*-hydroxyphenylpentane (Table V) and of 3-methyl-3-*p*-hydroxyphenylpentane, while the α-naphthylurethan from 3-methylhexanol-2 melted between that of 3-methyl-2-*p*-hydroxyphenylhexane and of 3-methyl-3-*p*-hydroxyphenylhexane.[2]

The other four alcohols in which the hydroxyl is on a carbon adjacent to one carrying tertiary hydrogen gave products identical with those obtained from tertiary alcohols. 2-Methylbutanol-3 gave an alkylbenzene which was converted into 2-methyl-2-*p*-hydroxyphenylbutane.[1a] 2-Methylhexanol-3 gave 2-methyl-2-*p*-hydroxyphenylhexane,[2] and 3-methylhexanol-4 gave 3-methyl-3-*p*-hydroxyphenylhexane.[2] Identification was accomplished by mixed melting points of the α-naphthylurethans.[12] Probability of the admixture of some secondary alkylbenzene in the condensation products was indicated by the repeated crystallizations which were necessary in order to obtain the α-naphthylurethans in the pure state.

All straight chained alcohols and those in which branching occurs on carbons not adjacent to the alcoholic group give mixtures of condensation products which may be accounted for by assuming the elimination of water and the reaction of the mixture of alkenes with benzene. Both 2-methylhexanol-4 and 2-methylhexanol-5 gave urethan mixtures melting at 119–121°. This is between

(12) The earlier publication reported a m. p. of 110–111° for the α-naphthylurethan of 2-methyl-2-*p*-hydroxyphenylhexane and 82.3° for the α-naphthylurethan of 3-methyl-3-*p*-hydroxyphenylhexane. The melting points of these derivatives, as prepared by the authors from the phenols prepared by Huston and Hedrick, were found to be 125° and 101°, respectively.

the melting points of the α-naphthylurethans of 2-methyl-5-*p*-hydroxyphenylhexane and of 2-methyl-4-*p*-hydroxyphenylhexane.

Unlike 2,2-dimethylbutanol-3, 2,2-dimethylpentanol-3 apparently forms a mixture of condensation products. The melting point of the α-naphthylurethan mixture is 114–115°. This is well below that of the α-naphthylurethan of 2,3-dimethyl-3-*p*-hydroxyphenylpentane[2] (124–125°) or of 2,3-dimethyl-2-*p*-hydroxyphenylpentane[2] (122–123°) but is quite near that of 2,2-dimethyl-3-*p*-hydroxyphenylpentane. This leads to the suggestion that the mixture is the result of the reaction of 2,2-dimethylpentene-3 with benzene and not of methyl migration.

Summary

1. The *s*-propyl, butyl, amyl, hexyl and nine of the *s*-heptyl alcohols were condensed with benzene in the presence of aluminum chloride.

2. The alkylbenzenes obtained in the condensations were converted to the corresponding *p*-hydroxy compounds through the *p*-nitro and *p*-amino derivatives. α-Naphthylurethans of the *p*-hydroxy compounds were also prepared as well as acetamino derivatives of some of the alkylbenzenes.

3. A number of pure *s*-alkylbenzenes and *s*-alkylphenols were synthesized and their α-naphthylurethans prepared.

4. By comparison of the melting points of the acetamino derivatives of the alkylbenzenes with those in the literature and of the melting points of the phenols and of the α-naphthylurethans with those synthesized and with those of *t*-alkylphenols, the following facts have been established: (a) Isopropyl, *s*-butyl and pinacolyl alcohols gave the corresponding *s*-alkylbenzenes in pure form. (b) 2-Methylbutanol-3, 2-methylpentanol-3, 2-methylhexanol-3 and 3-methylhexanol-4 gave tert-alkylbenzenes. (c) The straight chain alcohols, those having a branched methyl group remote from the carbinol group, and 2,2-dimethylpentanol-3 gave mixtures of monoalkylbenzenes. (d) 3-Methylpentanol-2 and 3-methylhexanol-2 also gave mixtures consisting, probably, of the *s* and *t*-alkylbenzenes.

Solid 10,12-Octadecadienoic Acid-1. A New Conjugated Linoleic Acid Melting at 57°

BY J. D. VON MIKUSCH

When linoleic and linolenic acids or their glycerides are treated with an excess of alcoholic potash for prolonged periods of time, a rearrangement of the double bonds into the conjugated position has been found to take place.[1] In the case of linolenic acid, a solid isomer, pseudoeleostearic acid, is formed, which was identified by Kass and Burr[2] as 10,12,14-octadecatrienoic acid-1. Linoleic acid, on the other hand, was found by Moore[1] (pp. 145, 147) to give rise "to a product which remains liquid at room temperature." On alcoholic-potash isomerization of maize oil containing linoleic but no linolenic acid, "no solid acids were formed" (ref. 1, p. 143).

Burr and collaborators, however, disclose an isomerization of linoleic acid to crystalline forms as a result of treatment with sodium butylate,[3] and give absorption spectrum, diene number and extinction coefficient for a solid 10,12-linoleic acid.[4] They also describe a solid 10,12-linoleyl alcohol.[5]

As a result of extensive studies in this Laboratory[6] a commercial conjugating process has been developed in which oils and fatty acids are isomerized with caustic soda in aqueous medium (patents pending). When oils containing a large proportion of linolenic acid, for instance linseed oil, are subjected to this process, the melting point or titer of their free fatty acids rises, indicating the formation of solid products. The fatty acids of oils containing little or no linolenic acid but a large proportion of linoleic acid experience a drop in titer.[7] From this it appears that linoleic acid does not yield solid isomerization products to any appreciable extent under the conditions

(7) Titer of linseed fatty acids: 18° before, 23.1° after isomerization; of soybean fatty acids: 22° before, 12.5° after isomerization.

of the commercial process. In order to verify this, the fatty acids of walnut oil were freed from the bulk of their solid constituents by storing and pressing at 0–3°. When the resulting liquid fraction was isomerized, the conjugated fatty acid product was liquid at room temperature and remained liquid on renewed cold storage at 0–3°.

In contrast herewith, it was found that a sample of dehydrated castor oil ("isoline"), the fatty acids of which remain liquid at 3°, produces a fatty acid mixture upon isomerization which sets to a semi-solid mass at 3°, and from which a considerable quantity of a solid acid separates even at room temperatures. The fatty acids of dehydrated castor oil have previously been found to contain 26% or less of 9,11-linoleic acid, the remainder being largely non-conjugated, *i. e.*, 9,12-linoleic acid.[8]

The diene value of dehydrated castor oil increases considerably during the caustic treatment, and the solid fatty acid formed, m. p. 57°, methyl ester m. p. 25°, is conjugated as shown by its analysis. It is found to be not identical with Mangold's[9] solid 9,11-linoleic acid. Another solid conjugated linoleic acid, m. p. 56°, which was obtained by Smit[10] by the debromination of tetrabromostearic acid, m. p. 124° and believed to be also a 9,11-isomer, was not available; but no bromide melting at 124° was formed by the new acid.

Oxidation with permanganate, both in alkaline and neutral solution, served to characterize the new acid as 10,12-octadecadienoic acid-1 and it may, therefore, be concluded that it resulted from the isomerization of the 9,12-linoleic acid present in dehydrated castor oil. Since other oils containing 9,12-linoleic acid, such as soybean or walnut, do not yield a solid fatty acid under similar treatment, it may be further concluded that the linoleic acid present in dehydrated castor oil, or at least a portion of it, is not identical with ordinary linoleic acid but a stereoisomer thereof.

Only one of the four theoretically possible 10,12-linoleic acids has in the past been identified. It was found by Böeseken and collaborators[11,12] in the products of partial hydrogenation of both alpha- and beta-eleostearic acids and their esters and had a melting point of 28.5°. The melting point of the 10,12-linoleic acid referred to by Burr, *et al.*,[2–5] has not been reported.

Experimental

The fatty acid product obtained from the commercial isomerization of dehydrated castor oil ("Isoline") with caustic soda in an aqueous medium was refrigerated at 3° for forty-eight hours. Repeated filtration and pressing on a suction funnel yielded a dry cake weighing more than 20% of the original total fatty acids.

Two recrystallizations from petroleum ether gave snow-white crystals, m. p. 55–56°, which, with Wijs solution, showed the color of free iodine characteristic for conjugated double bonds,[13] Wijs I. V., 130; diene value, −88.5 (Ellis–Jones).

Two recrystallizations of the purified product from ether, in which it is less soluble at low temperatures than stearic acid, and two from 95% alcohol yielded crystals melting at 56.3–57.7° (cor.), which became tacky when left exposed to air, showing sensitivity to oxidation. The final crop formed a clear solution in a little warm petroleum ether but, in ample excess, this solvent precipitated a white cloud indicating the presence of oxidized fatty acids. The dilute solution was, therefore, filtered with charcoal and cold stored. Before each of the following determinations, a sample of the resulting acid suspension in petroleum ether was removed, filtered, and dried under carbon dioxide; properties, melting point 55.7–57.5° (cor.); partial iodine value (modified Wijs, 2 min. on ice)[14] 89.91, 89.80 (calcd. 90.52); total iodine value (Woburn Method, 0.32 *N* iodine bromide solution, 1 hr., 20°)[15] 186.7 (calcd. 181.0); acid value 199.6 (calcd., 200.06); from this: mol. wt. 281.1 (calcd. 280.436); refractive index, $n^{60}D$ 1.4689; $n^{70}D$ 1.4656[16]; density by pycnometer, d^{70}_4 0.86857; molar refraction (Lorenz–Lorentz) 89.36,[16] calcd. (acc. to Eisenlohr) 85.93, exaltation, +3.43.[17]

The white lead soap, precipitated quantitatively from the hot aqueous potassium soap solution, was practically insoluble in cold benzene (6°), but 100 ml. of boiling benzene dissolved approximately 3 g. After one crystalliza-

(16) The author is indebted to H. E. Riley for determining the refractive indices listed, and suggesting improvements in the preparation of the manuscript. Mr. Riley also points out in a private communication that the specific refraction of the new acid is 0.31853, compared to a value of 0.31772 for 9,11-linoleic acid calculated from the data cited by Smit and Böeseken.

(17) Böeseken, *et al.*,[11] report a molar refraction of 88.9 for 9,11-linoleic acid, m. p. 52.2°, but from this value incorrectly derive an exaltation of +3.4, although Smit (ref. 10, p. 545) correctly states the calculated molar refraction to be 85.9, showing an exaltation of +3.0. If the values for $n^{77}D$ 1.4624 and sp. gr. at 77° 0.8659 as reported identically by Böeseken, *et al.*, and Smit[10] are used together with the calculated molecular weight for octadecadienoic acid using 1941 atomic weights, m. wt. 280.4, a molar refraction of 89.1 results giving an exaltation of +3.2. This is seen to be close to the present value for the 10,12-isomer.

tion from boiling benzene, the lead soap melted indistinctly at 115°.

Mangold's acid was prepared in the usual manner by the dry distillation of ricinelaidic acid.[3,11] The yield after one recrystallization from 95% alcohol was 17.4%, m. p. 52°. A mixture of this with the new acid melted at 48 to 51°, or lower than either acid alone.

Methyl Ester.—Twenty-four grams of a sample of the new acid which had been recrystallized only once from petroleum ether was refluxed with twice its weight of anhydrous methyl alcohol for three and one-half hours while passing hydrogen chloride gas into the solution. Recrystallization of the product from methyl alcohol gave 12.2 g. of white scales melting at 25°; the remaining brown oil was not further investigated; (9,11-linoleic methyl ester, m. p. 29.8°, according to Böeseken, *et al.*[11]). The bulk of the dried scales distilled at 207–208° (uncor.) at 9 mm. The distillate solidified sharply at 23–23.5°; total iodine value (Woburn, 1 hr. 20°)[15] 173.4; 173.4 (calcd. 172.4); partial iodine value (mod. Wijs, 2 min., ice)[14] 86.6; 86.1 (calcd. 86.2); Woburn diene value (by diff.) compare[15] 87.0 (calcd. 86.2).

Bromination of the new acid in cold petroleum ether with one mole of bromine and storing of the solution at 3° for forty-eight hours did not lead to solid products. After adding a second mole of bromine and allowing to stand in diffuse daylight at room temperature for two days, the color of free bromine had disappeared and a white solid had settled out, m. p. 104–113°. Extensive fractional crystallizations from 95% alcohol resulted in two portions, melting at 149.5–150.5° and 104–105° (cor.), respectively; acid values 95.8 and 94.7 resp. (calcd. 93.5 for tetrabromide).

Mild oxidation with alkaline potassium permanganate of 15 g. of the once recrystallized acid yielded a cake of hydroxy acids from which 0.1 g. of soluble substance was extracted with petroleum ether. Extraction of the remaining cake with warm ether yielded 4.8 g. of a viscous, almost water-white liquid which did not solidify after several days at 3°; acid value 178.6 (calcd. for dihydroxystearic acid, 178.4).

The remaining hydroxy acids were extracted successively with hot chloroform and boiling alcohol. These extracts on cooling yielded 0.3 and 0.9 g., respectively, of white precipitates, identical although of different purity, melting at 177–182° and 186–189°, recrystallized, 187–188.5° (cor.); acid value 159.9 and 156.6 (calcd. for tetrahydroxy stearic acid 161.0).

Ether extraction of the aqueous solution remaining after the separation of the hydroxy acids yielded 2.5 g. of an oil which on extraction with boiling water yielded crystals, melting after one recrystallization at 127–129.5°. They showed no depression with sebacic acid; acid value 580 (calcd. for sebacic acid 554.8). Other oxidation products, in evidence, were not further investigated.

Destructive Oxidation of Methyl Ester.—Following in general the procedure of Armstrong and Hilditch,[18] 8 g. of the recrystallized and distilled methyl ester was oxidized with 75 g. of powdered potassium permanganate in 250 ml. of boiling acetone. The ether-soluble oxidation products were dry-distilled at atmospheric pressure. When the distillate, which had the odor of caproic acid, was redistilled, the two main fractions collected passed over at 193–201° and 201–205.5°, respectively, and had equivalent weights by titration of 106.1 and 110.3 (caproic acid, mol. wt., 116.2; b. p. 202°).

The residue was boiled with alcoholic potassium hydroxide, acidified with dilute sulfuric acid, and the acidified solution extracted three times with ether. After evaporation, a white solid, contaminated with a yellow oil, remained. The solid was soluble in boiling water, which on cooling yielded 1.4 g. of white crystals, m. p. after four recrystallizations from boiling water 130.5–132.5°, acid value 542, which gave no depression with genuine sebacic acid.

Summary

A new solid conjugated isomer of linoleic acid, melting at 57°, was isolated from the isomerization products obtained from dehydrated castor oil in a commercial conjugating process using aqueous alkali. It is identified as 10,12-octadecadienoic acid-1 by its oxidation products.

The exaltation of the new acid compares with that of 9,11-octadecadienoic acid-1, which has been recalculated from data listed in the literature.

Properties of the acid and some of its derivatives are given.

Since other oils containing linoleic acid do not yield the new solid isomer upon identical treatment, it is concluded that it is formed from a stereoisomer of 9,12-linoleic acid in dehydrated castor oil which is not identical with ordinary linoleic acid.

Furfuryl Formate

BY W. R. EDWARDS, JR., AND LESLIE H. REEVES[1]

Furfuryl formate does not appear to have been prepared previously. Tobie[2] attempted this by mixing furfuryl alcohol with formic acid, whereupon the mixture became hot and a violent explosion resulted. The present authors succeeded in preparing it by employing the reaction of furfuryl alcohol with acetyl formate[3] at a moderate temperature: after unsuccessful attempts (1) by treatment of furfuryl alcohol with formic acid at temperatures from 0 to 25°, (2) by refluxing these materials in low-boiling organic solvents, (3) by treatment of furfuryl chloride with sodium formate, (4) by alcoholysis, using *n*-heptyl formate and furfuryl alcohol, distilling slowly at atmospheric pressure, and (5) by treatment of furfuryl alcohol with formamide at 100 to 120°.

Preparation of Acetyl Formate.—Following Béhal,[4] three moles of formic acid and four moles of acetic anhydride were mixed and heated at 50° for one hour. Because of the difficulty of protecting a vacuum pump from the quantity of corrosive fumes evolved, Béhal's method of separation of the product was modified conveniently by employing an aspirator, distilling at 45 mm., and collecting distillates at 43–46° and 42–43.5°, respectively, before and after washing with petroleum ether.

Furfuryl Formate.—To a mixture of 2.5 moles of furfuryl alcohol[5] and 0.75 mole of sodium formate in a flask with a mercury-seal stirrer, 3.4 moles of acetyl formate was added dropwise. The flask was cooled with tap water during the addition, and then immersed in a water-bath at 60° for five hours. Stirring was continuous during addition and subsequent heating. The resultant mixture was separated by addition of water, in which the ester was nearly insoluble. The ester layer was withdrawn, shaken with saturated aqueous sodium bicarbonate, separated again, and dried over anhydrous sodium sulfate. It was then distilled four times at 16 mm., using a 45-cm. Widmer column; yield 138 g. (44%) of an almost constant-boiling product.

With another batch, a second water washing was employed after the first distillation; only one additional distillation was then required. The product appeared to be equal in quality to the first batch, but the yield was lower.

Anal. Calcd. for $C_6H_6O_3$: C, 57.12; H, 4.80; mol. wt., 126.0. Found: C, 57.41; H, 5.07; mol. wt. (Cottrell), 127.4.

Saponification of the ester with aqueous sodium hydroxide yielded furfuryl alcohol (identified by the melting point of its α-naphthyl urethan) and the salt of formic acid (identified by Duclaux constant determinations).

The high carbon content, and the fact that the boiling point was higher than might have been predicted from a study of the data on other furfuryl esters, suggest some contamination of the product by furfuryl alcohol, a difficult substance to eliminate completely. It may be observed, however, that Zanetti[6] has suggested that the accepted boiling point of furfuryl acetate may be several degrees too low. If this is true, the boiling point of the formate occupies a more nearly regular position in the series.

Furfuryl formate is a colorless liquid with a pleasant odor; b. p. 66.2–66.5° (16 mm.), 166.3° (with some coloration) (760 mm.); d^{25}_4 1.1584; d^0_4 1.1830; $n^{25}D$ 1.4662. The sample obtained as described did not crystallize at −68°. Sealed in a glass tube, it turned faintly yellow on standing two months; exposed to air, it darkened rapidly. One hundred grams of water at 25° dissolved 1.31 g. of the ester. It was infinitely soluble in ether, benzene and ethanol. It dissolved 34% of its own weight of nitrocellulose (viscosity, 1/2 second), forming a viscous, greenish paste; and 25% of its own weight of cellulose acetate (Celanese satin), forming a viscous, transparent, colorless paste.

Attempted Oxidation.—The oxidation of furfuryl formate should be of interest, since the formyl group might be expected to undergo elimination during the process, simultaneously influencing the nature of the reaction of the remainder of the molecule. In an initial attempt to investigate this, furfuryl formate (0.45 mole) was added dropwise to 1.35 moles of hydrogen peroxide (30% aqueous solution) containing a trace of ferrous sulfate. The mixture was stirred vigorously for one hour at room temperature, and then for two hours at 50°; at the end of this time, no odor of the ester could be detected. Formic acid (36% of the theoretical) and furfural (18% of the theoretical) were identified among the diverse products of the reaction; identification of other products was incomplete.

Preparation and Properties of a Resin.—Recent work[7] on the use of synthetic resins for the removal of chlorides and sulfates from aqueous solutions included the observation that several resins prepared from either furfural or furfuryl alcohol, usually by condensation with a diamine, possessed widely varying efficiencies. The present authors prepared, washed, dried and sub-divided a resin by an essentially similar procedure, using furfuryl formate, *m*-phenylenediamine, and hydrochloric acid. The initial reaction was vigorous but not violent. The resultant resin was black and very hard. One gram of it was shaken for three hours at 31° with 250 cc. of water containing 500 p. p. m. of sulfuric acid. There was no decrease in the sulfate ion concentration of the solution.

(4) Béhal, *Compt. rend.*, **128**, 1460 (1899).

(5) The authors wish to thank Dr. F. N. Peters and the Quaker Oats Company for a gift of the furfuryl alcohol used in these experiments.

(6) Zanetti, THIS JOURNAL, **47**, 535 (1925).

(7) Schwartz, Edwards and Boudreaux, *Ind. Eng. Chem.*, **32**, 1462 (1940).

Growth-promoting Action.—Initial tests by Dr. C. F. Moreland on tomato leaves showed furfuryl formate to be ineffective in giving an epinastic response. On this tentative basis, it appears probable that the formate does not possess the growth-promoting power which Traub[8] reported as a conspicuous characteristic of furfuryl acetate and a number of other furan derivatives.

Attempted Preparation of Furfuryl Oxalate.—(1) Oxalic acid and furfuryl alcohol were mixed, ether was added, and the mixture was refluxed with stirring for eight hours; there was no reaction. (2) Furfuryl acetate (0.75 mole) and oxalic acid (0.67 mole) were heated together at 70°, with stirring, for five hours; there was no apparent reaction. The temperature was then raised. At about 85–90° there was an explosion which scattered a black tarry material over a circle of ten feet radius.

(8) Traub, *Proc. Am. Soc. Hort. Sci.*, **35**, 438 (1937).

Summary

Furfuryl formate has been prepared in fair yield by the reaction between furfuryl alcohol and acetyl formate at 60°. Its properties have been ascertained and some of its reactions have received preliminary study. Attempts to prepare furfuryl oxalate were unsuccessful.

Organoboron–Nitrogen Compounds. II. The Reaction of Boron Chloride with *p*-Toluidine

BY CORLISS R. KINNEY AND MARTIN J. KOLBEZEN

In an earlier paper the results of a study of the salt of aniline and boron chloride ($C_6H_5NH_2BCl_3$) were described[1] which indicated that several types of organoboron–nitrogen compounds could be made from such salts or addition compounds by the elimination of the halogen acid. In order to determine the extensiveness of these reactions the behavior of *p*-toluidine and boron chloride was studied and is described in the experimental part.

Experimental Part

The Salt of *p*-Toluidine and Boron Chloride, $CH_3C_6H_4NH_2BCl_3$.—A 500-ml. two-necked flask equipped with a mercury-sealed stirrer and a dropping funnel was used. Into the flask, 114 g. of sodium dried benzene was introduced and 13.9 g. (0.118 mole) of boron chloride was distilled into the benzene. The flask was cooled with snow and 9.7 g. (0.0906 mole) of *p*-toluidine dissolved in 127 g. of dry benzene was dropped in slowly and with stirring. With the dilute solutions used the precipitate redissolved immediately but, toward the end, 180 g. more benzene was added and the cooling bath removed in order that the product be kept in solution. When more concentrated solutions were used, the addition compound separated as a white powder which could not be purified readily.

When all of the *p*-toluidine had been added, the stirrer and dropping funnel were removed and the clear solution vacuum distilled. The pressure was about 370 mm. A fine stream of dry carbon dioxide was admitted to minimize bumping. When about one-half of the benzene had been removed, the distillation was stopped and the crystals which had formed filtered out. The filtrate was concentrated to about 50 ml. and a second crop of crystals obtained. The product weighed 19.4 g., a yield of 95.4%. Considering the material left in the 50 ml. of mother liquor, the reaction must proceed quantitatively.

The product was decomposed rapidly by the moisture in the air. Filtrations were made using a Büchner funnel into which was fitted a rubber stopper carrying a tube connected with a source of dry air. The melting point was 159–160° with evolution of hydrogen chloride. Also, when dissolved in dry boiling benzene, hydrogen chloride was evolved and the product obtained on cooling had a melting point of 147–149°. The salt is quite insoluble in cold benzene or other anhydrous solvent and further attempts at recrystallization were unsuccessful. The solubility was determined to be 0.896 g. per 100 ml. of dry benzene at 27°.

Anal.[1] Calcd. for $CH_3C_6H_4NH_2BCl_3$: B, 4.83; Cl, 47.48. Found: B, 4.87, 4.81, 4.83; Cl, 47.32, 47.32, 47.14.

On heating the salt to its melting point or in boiling benzene, hydrogen chloride was evolved with no evidence of boron chloride. The number of equivalents of hydrogen chloride was determined by heating 0.0059 mole with boiling benzene. A current of dry carbon dioxide was used to remove the hydrogen chloride which on titration required 0.0124 equivalent of base. The chloride ion was determined gravimetrically and 0.0120 mole was found, which demonstrated that the acid was entirely hydrogen chloride within a small error because, if boron trichloride had been liberated, three equivalents of hydrogen chloride and one of boric acid would have been produced. Similar quantitative results were obtained when the salt was heated dry.

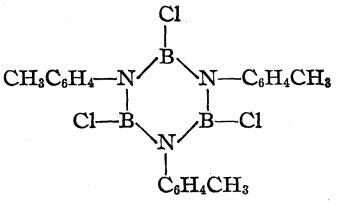
Tri-*p*-tolyltrichlorotriboron-nitride ($CH_3C_6H_4NBCl)_3$.—The clear colorless benzene solution obtained by refluxing the addition compound until no more hydrogen chloride was evolved was concentrated and allowed to cool. From the solution a colorless compound slowly crystallized,

(1) Jones and Kinney, THIS JOURNAL, **61**, 1378 (1939).

usually taking two or three days for complete crystallization. The crystals were proved to contain benzene of crystallization by removing the benzene and making the dinitro derivative. On standing in air the crystals became opaque and eventually fell to a powder. The melting point was 308–309° with slight softening at 304°. The substance darkened on melting and if heated for some time turned black, indicating extensive decomposition.

Anal. Calcd. for $(CH_3C_6H_4NBCl)_3 \cdot C_6H_6$: B, 6.10; Cl, 20.00; C_6H_6, 14.66; mol. wt., 532. Found: B, 6.15, 6.02, 6.10; Cl, 20.09, 19.81, 20.07; C_6H_6, 15.55; mol. wt. in freezing benzene, 505–492, 526–556, 512–524.

This is clearly the benzene addition product of the trimer which may be assigned the cyclic structure



The compound decomposes slowly in air giving off hydrogen chloride fumes, but appears to be quite stable when kept under dry benzene. It is quite insoluble in cold anhydrous solvents such as benzene, carbon tetrachloride, ethyl acetate or ether. It reacts slowly with cold water and rapidly with hot forming *p*-toluidine hydrochloride and presumably boric acid. With 95% alcohol or moist ether the compound dissolves rapidly and heat is liberated. In an attempt to hydrolyze the compound to a trihydroxy derivative corresponding to that obtained with the phenyl homolog,[1] a dry benzene solution was mixed with moist benzene. However, only *p*-toluidine hydrochloride and boric acid could be isolated.

Boric Tri-*p*-toluidide $(CH_3C_6H_4NH)_3B$.—To 8.9 g. of boron chloride dissolved in 85 g. of dry benzene and cooled in a freezing mixture, 41.7 g. of *p*-toluidine dissolved in 83 g. of benzene was added slowly while the mixture was stirred constantly. The amount of toluidine was 2.5 g. less than the calculated to account for the loss of boron chloride in the early stages of the reaction. When the addition was complete, the cooling bath was replaced by an oil-bath and the reaction mixture refluxed with constant stirring for three hours. The temperature of the oil-bath was 110°.

The mixture was filtered hot using suction. The precipitate of toluidine hydrochloride was returned to the reaction flask and extracted with 200 ml. of boiling benzene for ten minutes. The benzene was filtered and combined with the first filtrate. The residue gave no test for boron, but did give tests for nitrogen and chlorine. The melting point was 240.5° and was not lowered by admixture with *p*-toluidine hydrochloride (m. p. 241°).

The combined filtrates were distilled to a volume of 40 ml. On cooling fine colorless needles formed which were filtered, washed with dry benzene, and dried in a current of dry air; the yield was 35%. More of the product was obtained from the mother liquor, but this was impure and was not easily purified.

The substance was recrystallized readily from dry benzene, crystallization occurring suddenly. The melting point was 165–166°. On cooling and remelting, the melting point was not lowered, indicating that no decomposition had occurred.

Anal. Calcd. for $(CH_3C_6H_4NH)_3B$: B, 3.29. Found: B, 3.28, 3.29.

The compound was hydrolyzed easily and was not stable in air. Even in a desiccator over calcium chloride, the odor of toluidine soon became apparent. However, the compound could be kept apparently indefinitely when covered with dry benzene.

The compound reacted readily with dry hydrogen chloride in a benzene solution, forming a solid product. No boron chloride or other boron compound was carried out in sufficient quantities to give the characteristic green flame of boron when ignited. The solid product, in part, reacted violently with water and part dissolved more slowly. No method was found for purifying the product. However, when it was heated with boiling benzene, hydrogen chloride was evolved, the boron containing material passed into solution, and the solid remaining was identified as *p*-toluidine hydrochloride melting at 241°. From the benzene extract, the trimer, tri-*p*-tolyltrichlorotriboron-nitride, was obtained. All of these observations indicate that the product was a mixture of the addition compound, $CH_3C_6H_4NH_2BCl_3$, and *p*-toluidine hydrochloride.

Summary

The reactions of *p*-toluidine with boron trichloride have been investigated. The addition salt $CH_3C_6H_4NH_2BCl_3$ was prepared. Upon heating it evolved hydrogen chloride and formed a trimer which was named tri-*p*-tolyltrichlorotriboron-nitride and was assigned a cyclic structure. By heating the salt with an excess of *p*-toluidine, boric tri-*p*-toluidide $(CH_3C_6H_4NH)_3B$ was obtained. By treating boric tri-*p*-toluidide with excess dry hydrogen chloride the reaction was reversed.

Electrophoresis of Crotoxin*

BY CHOH HAO LI AND H. FRAENKEL-CONRAT

The crystalline protein (crotoxin), isolated by Slotta and Fraenkel-Conrat[1] from rattlesnake venom, has been shown to behave as a homogeneous substance in ultracentrifuge and diffusion studies.[2] The electrophoretic behavior of this beautifully crystalline substance will now be reported.

Experimental

Approximately 150 mg. of crystalline crotoxin was prepared from the crude venom[2a] and crystallized twice according to the method described previously.[1] The electrophoretic experiments were carried out in the Tiselius apparatus[3] at 1.5°.

Fig. 1.—Electrophoretic patterns of crotoxin solutions in buffers of different *p*H and ionic strength 0.10 at 1.5° after the current has been put on for 2.0, 1.5 or 6 hours: (a) is the base line for the electrophoretic patterns.

The electrophoretic patterns were recorded by the method described by Longsworth.[4] Buffers were prepared according to Clark[5] and brought to ionic strength 0.10 by the addition of sodium chloride. The *p*H of the solution was obtained with the aid of a glass electrode–vacuum tube assembly at room temperature. No corrections were made for 1.5°. The conductance was measured with the usual Wheatstone bridge type of circuit and a Washburn conductivity cell at 1.5°. The mobility was calculated from the descending boundary as recommended by Longsworth and MacInnes[6] and was determined in the manner described in a previous paper.[7]

Results

The first experiment was conducted in a phosphate buffer of *p*H 7.20 with 1.0% crotoxin solution. The boundaries appeared very sharp and there was no indication of the appearance of other components after the current had been on for two hours in a field gradient of 6.40 volts per cm. (see Fig. 1b). Studies in solutions of other *p*H also indicate that the crystalline crotoxin is an electrophoretically homogeneous protein. Fig. 1[8] presents a few typical patterns obtained in *p*H 7.20, 7.00, 6.23 and 4.40 buffer solutions. Each experiment was made in a field gradient approximately 6 volts per cm.

It is to be noted that here, as in the case of other proteins, the ascending boundary is always sharper than the descending one. This anomaly is currently attributed to variations of the electric field strength in the boundary.[9] When the current is reversed and the descending boundary becomes a rising one, this boundary should gradually become sharper. This is the case for the crotoxin solutions. Figure 2A shows a series of photographs taken after electrolysis for one and two hours at 6.26 volts per cm. with a 0.5% crotoxin solution

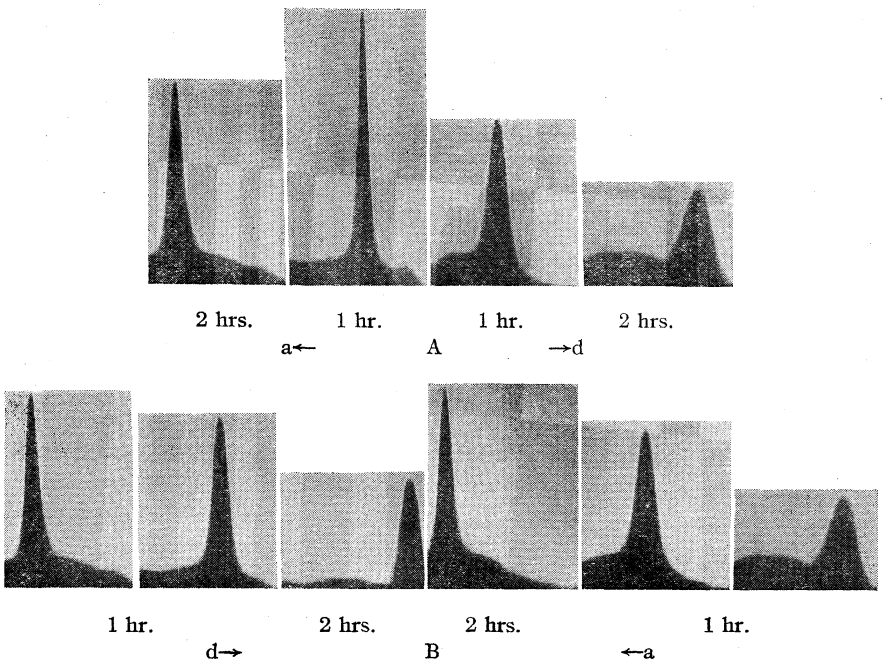

Fig. 2.—Electrophoretic patterns of a crotoxin solution illustrating no "reversible boundary spreading" phenomena in *p*H 7.00 phosphate buffer of ionic strength 0.10 at 1.5°.

in a *p*H 7.00 phosphate buffer of ionic strength 0.10. After the current was reversed, the descending pattern became much sharper while the rising one showed spreading as indicated in Fig. 2B. These observations are particularly interesting, for certain proteins always give rise to a phenomenon of "reversible boundary spreading" which, as first discovered by Tiselius and Horsfall,[10] indicates that "an initial sharp boundary will become diffuse as the electrolysis proceeds but if the direction of the amount is reversed will progressively recover most of its initial sharpness."[11] Some authors[11] believe that this phenomenon is due to the inhomogeneity of the protein and others[12] express the view that it is a property of pure proteins. Here, we have a case which does not show the phenomenon of "reversible boundary spreading" as illustrated in Fig. 2, nor was it observed in any other experiment with crotoxin.

Table I summarizes the mobility determinations in different *p*H solutions of ionic strength 0.10. A plot of *p*H against mobility is found in Fig. 3. The isoelectric point is located from the straight line which is drawn through the points made in acetate buffers of *p*H 3.91, 4.23, 4.40 and 4.90. This seems to be justified, for phosphate ions have been shown[13] to alter the electrophoretic mobility of a protein as compared with that made in a monovalent salt buffer. Thus, the isoelectric point of crotoxin is found to be 4.71 and the $d\mu/dpH_0$ value is 4.65×10^{-5} in a solution of ionic strength 0.10.

TABLE I

ELECTROPHORETIC MOBILITY OF CROTOXIN IN DIFFERENT *p*H OF IONIC STRENGTH 0.10 AT 1.5°

*p*H	Buffer salt	Protein concn.	μ_d (10^5)
7.20	Phosphate	1.0	−4.97
7.00	Phosphate	0.4	−4.51
6.23	Phosphate	.5	−2.80
4.90	Acetate	.3	−0.57

Summary[14]

1. Crotoxin, the crystalline neurotoxin isolated from rattlesnake venom, has been shown to be a homogeneous substance in electrophoresis experiments.

2. Crotoxin solutions do not exhibit the phenomenon of "reversible boundary spreading" to a detectable extent, in contradistinction to all other proteins studied.

3. The isoelectric point of crotoxin has been determined and the $d\mu/dpH_0$ value.

(14) The authors are indebted to Dr. L. G. Longsworth for his suggestions during the preparation of the manuscript.

Ionization and Dissociation by Electron Impact: Normal Butane, Isobutane, and Ethane

BY D. P. STEVENSON[1] AND J. A. HIPPLE, JR.

Introduction

Mass spectrometer studies of the dissociation products resulting from electron bombardment of gases at low pressures have provided many interesting and instructive results. In particular, the work on the lower hydrocarbons, methane,[2] ethane,[3] ethylene,[4,5] propane,[6] propylene[6] and allene[6] has yielded considerable data on energies and unimolecular reactions of the ions CH_4^+, $C_2H_6^+$, etc., not obtainable in any other way. It was felt that the extension of such studies to one of the simplest isomeric pairs, *n*- and *i*-butane, would be helpful in deciding or at least defining questions of interpretation raised by the work on the simpler molecules. Furthermore, the continually growing interest in the application of the mass spectrometer to problems in the analysis of hydrocarbon mixtures makes necessary a knowledge of the complete mass spectra, so that the limitations of this analytical tool can be discussed. With this latter point in mind we have extended the results of the previously published investigation of ethane.[3]

Experimental

Inasmuch as the apparatus is to be described in detail by one of the authors (J. A. H.) in a separate publication, we will give but a cursory discussion of the pertinent details here.

The 180° tube (~16 cm. radius) and accessories are supported within a water-cooled spherical solenoid. The strength of the magnetic field used throughout this investigation was ~1000 Oersteds, corresponding to 130 volts accelerating potential to bring $m/e = 100$ into focus. The positive ion accelerating voltage is supplied by a 1200 volt electronic power source. The electrons are obtained from an oxide coated platinum cathode, their accelerating potential being controlled by means of a wire wound drum potentiometer. An electrometer tube amplifier and sensitive galvanometer are used to measure the positive ion current. The resolving power of the tube with the wide slits used is 1:150 as indicated by the extent to which the mercury isotopes are resolved.

The gases are admitted to the ionization chamber through a glass capillary leak. A separate pumping lead to the arm of the tube containing the cathode chamber assures the complete removal of any pyrolysis products formed on the filament.

The samples of the two butanes were obtained from the Gulf Research Laboratories, while the ethane was taken from a sample given to us by the Standard Oil Co. of Indiana.

Preliminary examinations of the mass spectra of the butanes were made using an automatic recorder. The peaks corresponding to the various masses were all quite symmetrical, and were spaced in exact accord with the inverse relationship between m/e and accelerating voltage. No satellites or shoulders were observed for any of the masses. The measurements reported in this paper were all manually recorded. The symmetry of the peaks indicated that the current at the top of the maxima could be taken as a measure of the total current due to the corresponding ion. The linear variations of the positive ion current with the density of the electron beam and with the pressure in the ionization chamber indicate that only the products of primary reactions were observed. The total electron emission from the cathode ran from 5 to 15 μ amp., while the intensity of the bombarding beams lay between 0.1 and 3 μ amp.

Results

The results of this investigation may be divided, for convenience, into two parts: (A) the variation of the mass spectra of the molecules with the electron energy, V^-, for V^- large with respect to the critical potentials; and (B) the determination

of the critical potentials for the more abundant ions in the mass spectra.

A. The relative abundances of some of the principal ions in the spectrum of ethane are given for round values of V^- in Table I. The dots in this and subsequent tables indicate no measurements were made. The data of Hipple[3] for 100 volt electrons are included for comparison. Since the earlier work was carried out with a tube whose focusing properties are independent of the initial velocity of the ions[7] in contrast to our tube in which the initial velocities of the ions enter into the focusing, the agreement is very satisfactory.

Tables II and III summarize the behavior of the spectra of the butanes. No corrections were made for the presence of C^{13} in its natural abundance, 1.1%. Thus the spectra as given correspond to the mass numbers (m/e), rather than to the formulas. Since the correction is small and the relative currents due to the masses are of analytical interest, the uncorrected values have been tabulated.

Careful comparison of the ratios of the currents due to masses 44 and 43 and masses 30 and 29 showed that the butane samples were free of propane and ethane. The exact correspondence of the ratio 44/43 to that calculated for

$$\left(\frac{C^{13}C_2^{12}H_7^+}{C_3^{12}H_7^+}\right) \text{ and of } \frac{30}{29} \text{ to } \left(\frac{C^{13}C^{12}H_5^+}{C_2^{12}H_5^+}\right)$$

(7) W. Bleakney and J. A. Hipple, *Phys. Rev.*, **53**, 521 (1938).

indicated that neither of the butanes gives the ions $C_3H_8^+$ or $C_2H_6^+$. This point will be returned to later.

The currents of masses 29^+ and 28^+ could conceivably be due in part to $C_4H_{10}^{++}$ and $C_4H_8^{++}$. We searched very carefully, but were unable to find currents due to masses 29.5 or 28.5 ($C^{13}C_3^{12}H_{10}^{++}$ or $C^{13}C_3^{12}H_8^{++}$), hence concluded that the ions $C_4H_{10}^{++}$, $C_4H_9^{++}$ and $C_4H_8^{++}$ are absent from the butane spectra.

B. The method used to derive the critical or appearance potential, $A(X^+)$, from the initial portions of the ionization efficiency curves has been discussed by Smith[2] (see below). Argon was used to correct the voltage scale for the contact potential of the cathode. Its ionization potential, $I^Z(A) = 15.69$ e. v. was taken from the tables of Bacher and Goudsmit.[8]

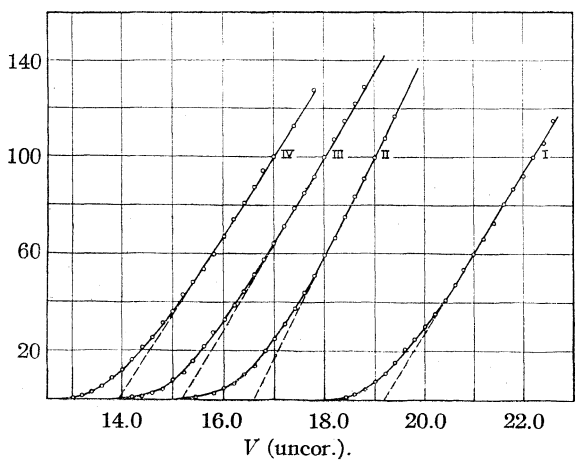

Fig. 1.—Ionization efficiency curves for the processes I, $A \rightarrow A^+$; II, $C_2H_6 \rightarrow C_2H_5^+$; III, $C_2H_6 \rightarrow C_2H_6^+$ and IV, i-$C_4H_{10} \rightarrow C_4H_{10}^+$. Vertical scale is arbitrary and different for each curve.

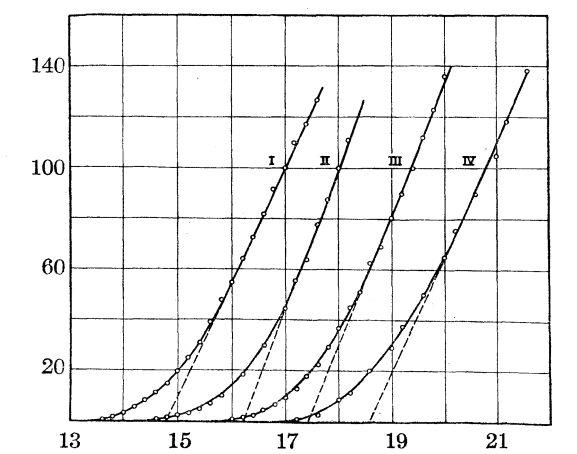

Fig. 2.—Ionization efficiency curves for the processes I, i-$C_4H_{10} \rightarrow C_3H_7^+$; II, n-$C_4H_{10} \rightarrow C_2H_5^+$; III, i-$C_4H_{10} \rightarrow C_3H_5^+$ and IV, n-$C_4H_{10} \rightarrow C_2H_3^+$. Vertical scale is arbitrary and different for each curve.

In Table IV the results of our investigation of ethane are compared with the earlier results of Hipple.[3] The agreement between the results given by such very different instruments is excellent.[8a]

TABLE IV

Ion	A (ion) [This Research], e. v.	A (ion) [Hipple[3]], e. v.
$C_2H_6^+$	11.59 ± 0.1	11.6 ± 0.1
$C_2H_5^+$	12.84 ± 0.1	12.7 ± 0.2
$C_2H_4^+$	12.09 ± 0.1	12.1 ± 0.1
$C_2H_3^+$	15.1 ± 0.2	15.2 ± 0.3

The appearance potentials of those ions in the spectra of the butanes, which were investigated, are given in Table V. Typical examples of the ionization efficiency curves from which the appearance potentials were determined are given in Figs. 1 and 2.

TABLE V

APPEARANCE POTENTIALS FOR n- AND i-BUTANE (ELECTRON VOLTS)

ion = R^+	$A_6(R^+)$ n-C_4H_{10}	i-C_4H_{10}	Probable process
$C_4H_{10}^+$	10.34 ± 0.1	10.34 ± 0.1	$C_4H_{10}^+ + \epsilon^-$
$C_4H_9^+$	12.0 ± 0.3	11.5 ± 0.3	$^xC_4H_9^+ + H + \epsilon^-$

$C_2H_3^+$	14.1 ± 0.3	14.6 ± 0.3	$^xC_2H_3^+ + ? + \epsilon^-$
CH_3^+	>20	20 ± 2	$CH_3^+ + C_3H_7^+ + 2\epsilon^-$

^{x} Ambiguity with respect to the structure of the positive ion; see text.

The method employed in determining the critical potentials given in Tables IV and V is not completely satisfactory. Considerable personal factors may be involved in the choice of the initial break (V_B^-) of the ionization efficiency curve, $I^+(V^-)$. Furthermore, greatest weight is given to measurements of least accuracy, that is, those near the appearance potential. For these reasons

(8) R. F. Bacher and S. Goudsmit, "Atomic Energy States," McGraw-Hill Book Co., New York, N. Y., 1932.

(8a) The reason that our value of $A(C_2H_5^+)$ is higher than Hipple's lies in the fact that we corrected our ionization efficiency curve for mass 29 for the contribution by the ion $C^{13}C^{12}H_4^+$. This correction was suggested by Dr. O. Beeck and Mr. Eltenton of the Shell Development Co. in a letter to one of the authors. The value of $A(29^+)$ derived from the uncorrected ionization efficiency curve is in exact agreement with Hipple's value. It may be noted that the correction is entirely insignificant for similar processes in the butanes.

we examined the curves, $I^+(V^-)$, for various processes in ethane, the butanes, argon and neon very carefully in the hope that some other characteristic, subject to a more objective determination, could be used in estimating the appearance potentials.

The observation that all the ionization efficiency curves, $I^+(V^-)$, are linear over the range ~7% to ~65% of their maximum values, suggested that the intercept of the extrapolated linear portion with the V^- axis ($I^+ = 0$), V_L^-, might be used in making estimates of the appearance potentials. It was found that for the process, $R \rightarrow R^+ + \epsilon^-$, in eight atoms or molecules[9] $V_L^- - V_B^- = 1.06_5$ volts. The mean deviation was ± 0.06 volt and the maximum deviation was 0.12 volt from the average, which are well within the uncertainty of the individual measurements. Thus the linear intercepts, V_L^-, can be used in place of the initial breaks, V_B^-, in determining the appearance potentials of the parent ions.

For more complex processes, such as those involving the rupture of a C–C or a C–H bond, the difference $V_L^- - V_B^-$ is also constant but greater than for simple ionization. Eleven reactions of the types, $R—CH_3 \rightarrow R^+ + CH_3$ or $R—H \rightarrow R^+ + H$, have $V_L^- - V_B^- = 1.54 \pm 0.09$ volts. In a recent article one of the authors[10] applied differences between the V_B^-'s for such reactions to the estimation of C–H and C–C bond strengths. The use of V_L^-'s gives the same results. If one wishes to compare the appearance potentials of the reactions $R_1—R_2 \rightarrow R_1—R_2^+ + \epsilon$ and $R_1—R_2 \rightarrow R_1^+ + R_2 + \epsilon^-$, the apparent difference given by the V_L^-'s is ~0.5 volt greater than that given by the V_B^-'s.

The still more complex processes, such as the formation of $C_2H_3^+$ from ethane, normal or isobutane, have $V_L^- - V_B^- = 2.3 \pm 0.2$ volts. The various phenomena discussed here are illustrated in Figs. 1 and 2.

Discussion

Ignoring the questions concerning the suitability of the method used to correct the voltage scale, we may associate the appearance potentials of the parent ions, $C_2H_6^+$, i-$C_4H_{10}^+$ and n-$C_4H_{10}^+$ with their vertical ionization potentials.[11] It has been pointed out by Mulliken[12] that the lowest ionization potential in ethane is probably that of removing an electron from the C–C bonding orbital [$\sigma + \sigma$] and that I_{vert} [$\sigma + \sigma$] is undoubtedly greater than $I_{adiabatic}$ [$\sigma + \sigma$]. The reason for the inequality $I_{vert} > I_{ad}$ lies in the fact that the removal of a bonding electron will cause an increase in the equilibrium separations of the atoms. In ethylene a comparison of the appearance potential of $C_2H_4^+$ (10.8 e. v.)$^{-1}$ with the spectroscopic ionization potential $I_{ad}(C_2H_4) = 10.41$ e. v.[13] suggests that in ethane the inequality is at least 0.4 e. v. Thus, one might estimate $I_{ad}(C_2H_6) \leq 11.6 - 0.4 = 11.2$ e. v. The electron removed in ionizing a butane probably comes from the same type of orbital as in ethane. Since the electron deficiency is much less in the ions $C_4H_{10}^+$ than in $C_2H_6^+$ it is likely that $I_{vert} \sim I_{ad}$, and thus from Table V, $I_{ad}(C_4H_{10}) \leq 10.34 \pm 0.1$ e. v.

If we take the strength of the first C–H bond in ethane as 4.2 e. v.[10] and the appearance potential, $A(C_2H_5^+) = 12.7$ e. v. given in Table IV as the heat of the reaction $C_2H_6 \rightarrow C_2H_5^+ + H$, we find $I_{ad}(C_2H_5) = 8.5$ e. v. If the linear intercepts discussed above were used to estimate the appearance potentials, this value would be increased by 0.5 e. v. to $I_{ad}(C_2H_5) = 9.0$ e. v. It is clear that a reliable direct measurement of $I_{ad}(C_2H_5)$ would be extremely valuable in determining the relative merits of the two possible modes of calibrating the voltage scale.

The relative reactivities of C–H bonds are in the order primary < secondary < tertiary. The lower value of $A(C_4H_9^+)$ in isobutane than in n-butane is probably due in part to this. The greater number of C–C acceptor bonds for hyper conjugation[14] in the t-$C_4H_9^+$ ion (3) than in the s-$C_4H_9^+$ ion (2) probably results in greater stability for the former. Thus one might expect $I_{ad}(t\text{-}C_4H_9) < I_{ad}(s\text{-}C_4H_9)$. If one guesses that the inequality signs in the reactivity sequence correspond to ~0.1 e. v.[15] and that the strength of a primary C–H bond is 4.2 e. v.,[10] we get

$$D[s\text{-}C_4H_9\text{-}H] = 4.2 - 0.1 = 4.1 \text{ e. v.}$$
$$D[t\text{-}C_4H_9\text{-}H] = 4.2 - 0.2 = 4.0 \text{ e. v.}$$

Combining these estimates with the corresponding appearance potentials from Table V, we find

(9) Neon, argon, ethane, n- and i-butane, propane, propylene and isobutene.

$I_{ad}(s\text{-}C_4H_9) = 7.9$ e. v. and $I_{ad}(t\text{-}C_4H_9) = 7.5$ e. v. Due to the low precision of the appearance potentials of $C_4H_9^+$ from the butanes great weight cannot be given to these estimates of $I_{ad}(C_4H_9)$.

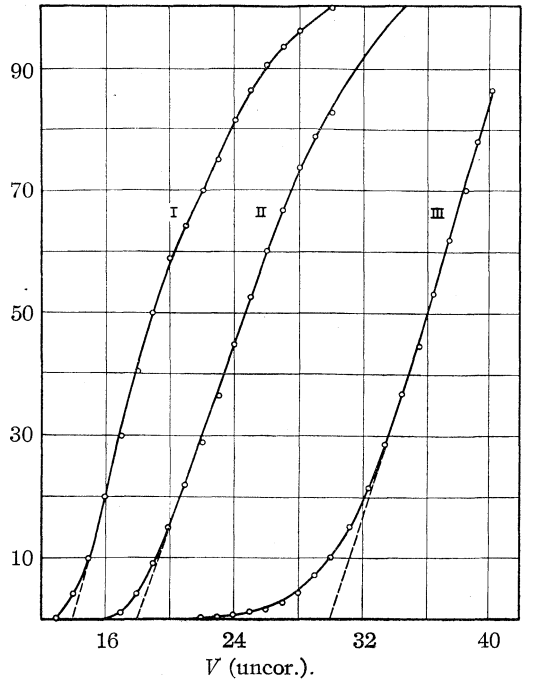

Fig. 3.—Ionization efficiency curves for I, $i\text{-}C_4H_{10} \rightarrow i\text{-}C_4H_{10}^+$; II, $i\text{-}C_4H_{10} \rightarrow C_3H_5^+$; and III, $i\text{-}C_4H_{10} \rightarrow CH_3^+$. Vertical scale is different for each curve. Maximum values are I, 121; II, 123; and III, 180. Compare with Table III.

It seems reasonable to assume that no molecular rearrangement accompanies the formation of $C_3H_7^+$ from either butane. Then, since isobutane is 0.07 e. v.[16] more stable than normal butane one concludes from the values of $A(C_3H_7^+)$ given in Table V that $s\text{-}C_3H_7^+$ is 0.3 e. v. lower in energy than $n\text{-}C_3H_7^+$. If a secondary C–H bond is 0.1 e. v. weaker than a primary C–H bond, we can write, $I_{ad}(s\text{-}C_3H_7) + 0.2$ e. v. $= I_{ad}(n\text{-}C_3H_7)$.

The high value of the appearance potential of CH_3^+ in both butanes is probably to be attributed to the simultaneous formation of $C_3H_7^+$. If the vertical ionization of C_4H_{10} to $C_4H_{10}^{++}$ results in the doubly charged ion being formed in a state above the dissociation limit this result is explained. Our failure to observe any $C^{13}C_3^{12}H_{10}^{++}$ ions is in accord with this explanation. The marked second break in $I^+(V^-)$ for the CH_3^+ at ~28 volts indicates that a second state of $C_4H_{10}^{++}$ is involved. Since the maxima corresponding to the ions CH_3^+ and $C_3H_7^+$ in the mass spectra are quite symmetrical there is no indication that a fraction of these ions is formed with excessive kinetic energy. We may thus conclude that the second reaction giving rise to CH_3^+ involves electronic excitation and not simply an antibonding state of C_3H_7—CH_3^{++}. The ionization efficiency curve for CH_3^+ is compared with those of $i\text{-}C_4H_{10}^+$ and $s\text{-}C_3H_5^+$ in Fig. 3.

From its structure, one would not expect isobutane to give rise to the ion $C_2H_5^+$. The fact that $C_2H_5^+$ is observed indicates that rearrangements can occur in the ions $C_nH_{2n+2}^+$ in the short time between their formation and dissociation. The value of $A(C_2H_5^+) = 12.0$ e. v. in isobutane indicates that C_2H_5 is the accompanying product, since any other products would require at least 2 volts more energy. The ~0.7 e. v. difference between $A(C_2H_5^+)$ from isobutane and normal butane can probably be associated with the activation energy of the isomerization $i\text{-}C_4H_{10}^+ \rightarrow n\text{-}C_4H_{10}^+$.

The magnitude of the appearance potentials of the ions $C_2H_4^+$ and $C_3H_6^+$ in the spectra of ethane and the butanes indicates that the formation of these ions is accompanied by the formation of stable molecules.[3,6] Two mechanisms are possible for these reactions. The one suggested by Delfosse and Bleakney[6] involves the assumption that the atoms or groups which form the stable un-ionized accompanying product are originally bound to the same carbon atom. This suggests an ethylidine structure for the ions $C_2H_4^+$ and $C_3H_6^+$. The other possible mechanism would involve the groups forming the stable un-ionized molecule coming from adjacent carbon atoms, and suggests that the ions $C_2H_4^+$ and $C_3H_6^+$ are olefinic molecular ions.

One might expect the resonance between the equivalent structures

$$H_2C\text{—}C^+H_2 \qquad H_2C^+\text{—}CH_2$$

in the olefinic molecular ions to stabilize them with respect to the isomeric ethylidene ions by at least 0.5 e. v. If this is true, the appearance potentials given in Tables IV and V for $C_2H_4^+$ and $C_3H_6^+$ indicate that the second mechanism is the more probable one.

From Rossini's review article[16] we can write

$$C_2H_6 = C_2H_4 + H_2 \qquad \Delta H^0_{298.1} = 1.42 \text{ e. v.} \quad (1)$$

$$n\text{-}C_4H_{10} = C_2H_4 + C_2H_6 \qquad \Delta H^0_{298.1} = 0.96 \text{ e. v.} \quad (2)$$

$$i\text{-}C_4H_{10} = C_3H_6 + CH_4 \qquad \Delta H^0_{298.1} = 0.80 \text{ e. v.} \quad (3)$$

$$n\text{-}C_4H_{10} = C_3H_6 + CH_4 \qquad \Delta H^0_{298.1} = 0.73 \text{ e. v.} \quad (4)$$

(16) F. D. Rossini, *Chem. Rev.*, **27**, 1 (1940) (1 kcal. = 0.04338 e. v.).

Treating the appearance potentials, $A(C_2H_4^+)$ and $A(C_3H_6^+)$ as heats of reaction, we find

$$C_2H_6: I_{ad}(C_2H_4) = 12.09 - 1.42 = 10.67 \text{ e. v.} \quad (1')$$
$$n\text{-}C_4H_{10}: I_{ad}(C_2H_4) = 11.49 - 0.96 = 10.53 \text{ e. v.} \quad (2')$$
$$i\text{-}C_4H_{10}: I_{ad}(C_3H_6) = 10.74 - 0.80 = 9.94 \text{ e. v.} \quad (3')$$
$$n\text{-}C_4H_{10}: I_{ad}(C_3H_6) = 10.94 - 0.73 = 10.21 \text{ e. v.} \quad (4')$$

Equations (1′) and (2′) compare very favorably with Price's[13] directly measured $I_{ad}(C_2H_4) = 10.41$ e. v. Delfosse and Bleakney[6] found C_3H_6; $A(C_3H_6^+) = 10.0$ e. v.[17] with which Eqs. (3′) and (4′) are to be compared. The essential agreement between the directly observed $I_{ad}(C_2H_4)$ and $I_{ad}(C_3H_6)$ with the indirect calculations (1′ to 4′) suggests that olefinic molecular ions rather than ethylidinic ions are formed in these reactions.

The mechanism suggested by Delfosse and Bleakney was suggested by the observations of Delfosse and Hipple[5] that in the reactions $C_2H_4 \rightarrow H_2^+ + \ldots$ the hydrogens forming the H_2^+ are originally attached to the same carbon atom. Kusch, Hustrulid and Tate[4] have shown that this reaction of ethylene is considerably more complex than the reactions like $C_2H_6 \rightarrow C_2H_4^+ + H_2$. In this connection it will be noted that the reactions $C_4H_{10} \rightarrow C_3H_8^+$ or $C_2H_6^+$ do not occur.

The ~0.7 e. v. difference between $A(C_2H_4^+)$ in normal butane and in isobutane may be attributed to an activation energy of isomerization as was done in the discussion of the formation of $C_2H_5^+$ from isobutane. On the other hand, it might be that the "same atom mechanism" operates in the dissociation of isobutane and the 0.7 e. v. is the difference in energy between the ethylene and the ethylidene ions.

Attempts to interpret the appearance potentials of the ions $C_3H_5^+$ and $C_2H_3^+$ from the butanes are impeded not only by the ambiguity with respect to the structures of these ions but also by the fact that several sets of un-ionized products of roughly the same energy are possible. The magnitudes of the appearance potentials are indicative of a minimum decrease in the number of bonds.

If we combine Eq. 2 given above with $A(C_2H_3^+)$ in ethane, Table IV, we get

$$n\text{-}C_4H_{10} = C_2H_3^+ + C_2H_4 + H_2 + H \quad A \sim 16.1 \text{ e. v.} \quad (5)$$

Kusch, Hustrulid and Tate[4] found $A(C_2H_3^+)$ in ethylene to be 14.1 e. v., thus we can write

$$n\text{-}C_4H_{10} = C_2H_6 + C_2H_3^+ + H \quad A \sim 15.1 \text{ e. v.} \quad (5')$$

These values are considerably greater than our observed $n\text{-}C_4H_{10}$; $A(C_2H_3^+) = 14.1$ e. v. Similar difficulties exist in attempted interpretations of the observed values of $A(C_3H_5^+)$.

The ionization efficiency curves for the ion $C_2H_3^+$ from both butanes indicate a second break ~4–4.5 e. v. above the initial break. Since this is just the order of the strength of C–C and C–H bonds, one can infer that the accompanying un-ionized products are more dissociated for electron energies greater than 18 e. v. than for electrons with energies between 14–18 e. v.

An examination of the distribution of the ions in the mass spectra of the two butanes (Tables II and III) immediately reveals certain limitations to the applicability of the mass spectrometer to hydrocarbon analysis. The excessively large fragmentation to ions in the C_3 and C_2 mass regions will reduce considerably the accuracy with which C_3 and C_2 hydrocarbons can be determined in the presence of butanes. Although this is particularly true with respect to C_3 and C_2 unsaturates, it is also true for propane and ethane. The large relative abundances of the ions $C_3H_7^+$ and $C_2H_5^+$ give rise to considerable quantities of masses 44 and 30 through the ions $C^{13}C_2^{12}H_7^+$ and $C^{13}C^{12}H_5^+$. Since the natural abundance of C^{13} is 1.1%, the relative current of mass 44 will be ~3.3% of mass 43 and of mass 30 will be 2.2% of mass 29. For concentrations of propane and ethane of the order of 2–3% or less, the corrections will be of the order of the quantity to be measured which is always unsatisfactory. In contrast to this less pleasant aspect it should be noted that extremely small traces of the butanes can be determined with ease in the presence of large concentrations of lower hydrocarbons. This is possible because at the low pressures involved there is no building up of heavier ions by recombination.

The relatively small abundances of the ions $C_4H_8^+$—C_4^+ to which the butanes give rise, will make possible the determination of C_4 unsaturates with reasonable precision.

It is interesting to note that a definite similarity exists between the unimolecular dissociation reactions of the ions $C_nH_{2n+2}^+$ and the thermal reactions of the hydrocarbons. The carbon–carbon bond in the ethane ion shows but little tendency to break; less than 10% of its spectrum lies in the C_1 region. The butanes on the other hand have only ~10% of their spectra in the parent C_4 region. A direct comparison of the ions in the mass spectra with the pyrolysis products

(17) One of the authors (D. P. S.) has found, C_3H_6; $A(C_3H_6^+) = 9.7$ e. v.

of hydrocarbons or hydrocarbon free radicals[18] cannot be made because none of the ions in the mass spectra result from collisions after the initial ionization. Thus the characteristic chain reactions are absent.

Summary

The variation of the relative abundances of the ionic dissociation products formed by electron impact in ethane, normal and isobutane are reported as a function of the energy of the bombarding electrons. The critical potentials of a number of the processes have been measured, and their significance is discussed. Certain limitations of the mass spectrometer as an analytical tool are also discussed.

The Mechanism of the Catalytic Conversion of Para-hydrogen on Nickel, Platinum and Palladium

BY A. FARKAS AND L. FARKAS

The catalytic conversion of para-hydrogen on metals was explained by the dissociation of the hydrogen molecules on the surface of the catalyst.[1] This mechanism was later extended to the ortho–para conversion of deuterium and to the reaction $H_2 + D_2 = 2HD$.[2]

It seemed to receive confirmation when it was found that the rate of ortho–para conversion on palladium was very nearly equal to the rate of the diffusion of hydrogen through palladium.[3] From these experiments the conclusion was drawn that in the conversion and in the diffusion process the rate determining step is the dissociation of the hydrogen molecules on the surface of the catalyst.

Roberts questioned the correctness of the suggested mechanism[4] on the basis of his own experiments.[5] In these he was able to show that a clean tungsten surface will take up hydrogen molecules with great speed, that the molecules will be dissociated and that the atoms form a very stable layer on the surface of the tungsten. As this layer will give off atoms or molecules only at a very high temperature it was suggested that it is more reasonable to assume that the ortho–para conversion of hydrogen involves a reaction between the atomic layer and the molecules adsorbed or impinging on this layer. A direct proof for this view was brought forward by Eley and Rideal,[6] who showed that on an evaporated tungsten layer which has been in contact with hydrogen, the rate of the para-hydrogen conversion and the rate of exchange of atoms between molecular deuterium and the hydrogen in the tungsten layer are about equal.

The object of the present paper was the examination of the mechanism of the para-hydrogen conversion on typical hydrogenation catalysts such as nickel, palladium and platinum.

Experimental

The reaction vessel was either a bulb or a cylindrical vessel having a volume of 700 to 1100 cc. The pressure in the reaction system was measured by a Pirani gage. The entrance of vapors of grease or mercury into the reaction vessel or into the Pirani gage was prevented by traps cooled by liquid air. The gases were introduced into the reaction vessel by means of locks having a volume of 0.1 to 0.2 cc.

The reaction vessel was equipped with an electrically heated wire. The catalyst was prepared by heating the wire to a temperature at which the evaporation of the metal begins and thus an invisible layer of high activity is formed on the inner surface of the reaction vessel. The active layer thus prepared was, on the average, not more than one or two atoms deep, since the whole of the wire when completely evaporated would have formed a layer about one hundred atoms deep and actually only a small fraction of the wire, certainly not more than one per cent., was evaporated.

The concentration of para-hydrogen and of deuterium was determined according to the micro-thermal conductivity method.[2,7]

Nickel.—In the first series of experiments a reaction vessel of 730 cc. volume and having an inner surface of 390 sq. cm. was used. This vessel was provided with a nickel wire 11 cm. long, 0.1 mm. in diameter.

Table I shows the dependence of the half-life time of the para-hydrogen conversion on pressure in the presence of an evaporated nickel film.

5.2	1.6
10	2.6
26	3.2
76	4.2
26	2.9
Apparent order of reaction.	0.65

In two other series (Expts. 2 and 3), on the same catalyst, but in a less active stage, the order of 0.7 was found in the pressure region 3.4×10^{-3} to 3.4×10^{-2} mm.

In Expt. 4, on a fresh catalyst the para-hydrogen conversion was found to be complete in five minutes. Then (Expt. 5) a sample of pure deuterium was admitted into the reaction vessel at a pressure of 0.013 mm. and the deuterium content of the sample was determined after a four-minute contact with the catalyst. Then after evacuation with a mercury diffusion pump to a pressure of 10^{-6} mm., fresh deuterium was admitted and analyzed and this procedure repeated twice more with deuterium and four times with hydrogen (Expt. 6). In the experiments with hydrogen the pressure was 0.0095 mm. The results obtained are given in Table II. It will be seen that there

TABLE II

	Fourth sample[a]	10

[a] Time of contact nine minutes.

is reversible exchange between the hydrogen adsorbed on the catalyst and the molecular deuterium; *i. e.*, the deuterium introduced by exchange into the catalyst can be recovered by exchange with hydrogen. Furthermore, the extent of the exchange observed indicates that the amount of hydrogen in the catalyst is comparable to the amount of hydrogen (or deuterium) present in the gaseous phase.

By heating the reaction vessel the catalyst was deactivated and neither the conversion of para-hydrogen nor the exchange reaction took place.

The amount of exchangeable hydrogen in the catalyst can be determined by adding up the amount of exchanged hydrogen in a number of consecutive experiments.

Before Expts. 10 and 11 were performed, a fresh deuterium layer was produced on the catalyst by exchange with a great excess of deuterium. In Expt. 10 the catalyst was brought into contact five times with fresh hydrogen samples each time, at a pressure of 0.006 mm. for five minutes, after which period the deuterium content of the gas was determined. In Expt. 11 the pressure was 0.0057 mm., the contact time two minutes and the exchange was repeated six times. The results are given in Table III.

TABLE III

TEMPERATURE 20°

	Expt. 10 %D in sample	Expt. 11 %D in sample
First sample	33	16.4
Second sample	18	12
Third sample	11	8.4
Fourth sample	7	5.9
Fifth sample	4	5.3
Sixth sample	.	3.7

Taking the amount of gas present in each experiment in the reaction vessel as unity, the sum of exchanged hydrogen, a, is 0.73 in Expt. 10 and 0.52 in Expt. 11. If the amount of exchangeable deuterium is allowed for that which remains in the catalyst layer after the first five or six exchanges, the above figures can be corrected to 0.8 and 0.6, respectively.

Assuming that in equilibrium the concentration of deuterium is equal in the gas and in the catalyst layer the half-life time of the exchange calculated for Expts. 10 and 11 is 2.4 minutes.

Immediately after Expt. 11 the rate of the para-hydrogen conversion was measured at a pressure of 0.006 mm. and a half-life time of two minutes was found. Thus on the nickel catalyst the conversion of para-hydrogen and the exchange reaction proceed at practically identical rates in agreement with the findings of Eley and Rideal on a tungsten catalyst.

In a second series of experiments a Pyrex reaction vessel of cylindrical form (volume 750 cc., surface 550 sq. cm.) was used, equipped with a 34-cm. long nickel wire 0.1 mm. in diameter. This reaction vessel was placed in an electric oven so that it could be baked out at higher temperatures and maintained at any desired temperature.

The first experiments in this reaction were carried out at 64° and again it was found that at pressures of $7–10 \times 10^{-3}$ mm., the para-hydrogen conversion and the exchange reaction proceeded at similar speed, the half-life times being 2.5 and four minutes, respectively. The amount of exchangeable hydrogen was 0.82 if the gas present in the reaction vessel at 0.01 mm. and 64° was taken as unity (Expts. 39 and 40).

As it is known that hydrogen atoms are exchanged between molecular hydrogen and ethylene in the presence of a catalyst,[8] it was tested whether such an exchange reaction takes place between ethylene and the hydrogen layer. This test was performed by bringing hydrogen into contact with a layer containing about 50% deuterium before and after it had been in contact with ethylene or by saturating the layer with deuterium and continuing the saturation after having exposed the layer to ethylene.

The results of this test (Expts. 41 to 44 at 64°, and Expts. 56 to 59 at 30°) are summarized in Table IV. In Expt. 41 a catalyst layer containing 48% deuterium produced a deuterium content of 17.6% in a hydrogen sample which had been in contact with the catalyst for four minutes. After this experiment a new layer with 49% deuterium was exposed to ethylene and then to a sample of hydrogen. In Expts. 56–57 a hydrogen layer was treated four times with fresh samples of deuterium. After each treatment the loss in the deuterium content of the samples was smaller, showing that the deuterium content of the catalyst layer was increasing. When, however, ethylene

	.0093	D_2	3	54

was brought into contact with the deuterated catalyst, the loss in the deuterium content of the deuterium applied subsequently was nearly as large as the loss in the very first treatment in Expt. 56.

Both series of experiments show clearly that fresh exchangeable hydrogen appears on the catalyst layer after the contact with ethylene, indicating that either the hydrogen layer is capable of exchanging with ethylene or that the ethylene is taken up and retained by the catalyst in a form which can subsequently exchange with molecular deuterium. This point requires further investigation but it was proved by special experiments that no measurable amounts of hydrogen are displaced from the catalyst and evolved when the hydrogen layer is brought into contact with ethylene.

Palladium.—In the next series of experiments a reaction vessel having a volume of 1150 cc. and an inner surface of 520 sq. cm., equipped with a palladium wire 10 cm. long, 0.1 mm. in diameter, was used.

The results of Expts. 14 and 15, which were carried out in the same manner as Expts. 5 and 6, are given in Table V. In Expt. 14 deuterium samples and in Expt. 15 hydrogen samples were brought into contact with the catalyst, the pressure being 0.0073 and 0.0082 mm., respectively. Before and after these experiments, the half-life time of the para-hydrogen conversion was found to be fifteen seconds at the reaction temperature of 25°.

TABLE V

Reaction time in min.	Change in D-content in %	Reaction time in min.	Change in D-content in %
Expt. 14		Expt. 15	
1	−53	2	33.7
2	−31.5	2	19.6
2	−21.8	2	9.8
2	−13.0	2	6.5
2	− 9.8	10	5.4
2	− 8.7	20	5.8
90	−16.3	1	2.5
		1	1.4

If the exchange reaction had proceeded at the same speed as the para-hydrogen conversion, equilibrium would have been established in about two minutes. It will be noted, however, that, in the last run, after a reaction time of ninety minutes, the amount of exchange was higher than in the previous run after a reaction time of two minutes. This shows that there is a certain amount of slowly exchangeable hydrogen on the catalyst. The half-life time calculated with $a = 1.5$ varies between twenty and sixty seconds for the first four runs in Expt. 14, while for the first four runs in Expt. 15 half-life times of fifty-five to one hundred and twenty-five seconds are obtained. In Expt. 15, $a = 1$.

The results of all experiments with palladium layers are summarized in Table VI and it will be seen that the para-hydrogen conversion is up to fifteen times faster than the exchange reaction and that the amount of exchangeable hydrogen is in no direct relation to the rate of the conversion reaction.

Discussion

The described experiments with nickel, palladium and platinum catalysts indicate, in accordance with Roberts' conclusions and Eley and Rideal's findings on tungsten, the following points:

1. There is a hydrogen layer on these metals which is not removed by pumping at room temperature and which can exchange atoms readily with molecular hydrogen, and in the case of nickel with ethylene as well.

2. The rate of this exchange reaction with molecular hydrogen is on nickel equal to the rate of the conversion of para-hydrogen, but it is smaller on palladium and on platinum than that of the para-hydrogen conversion.

The explanation of the findings on nickel is that either the mechanisms of the exchange and conversion reactions are the same or the rate determining steps in these two reactions are the same.

Before discussing the various possible reaction mechanisms, the number of exchangeable hydrogen atoms in the stable hydrogen layer will be calculated. This number will be of some importance as it can be taken as the number of the active centers and will indicate that fraction of the catalyst's area which is active.

The difference between the number of exchangeable hydrogen atoms and the number of the hydrogen atoms in the layer on the catalyst is significant. While it is possible to determine the amount of hydrogen in the layer by adsorption measurements, all of these "chemisorbed" hydrogen atoms are not necessarily exchangeable and the whole surface covered by chemisorbed hydrogen is not necessarily catalytically active.

In Expt. 10 the volume of the reaction vessel was 730 cc., its surface 390 sq. cm., the hydrogen pressure 0.006 mm., $a = 0.77$ and the temperature 20°. From these data the number of the hydrogen atoms in the reaction vessel is 2.90×10^{17} and the number of the exchangeable atoms in the layer is 2.22×10^{17}.

If each hydrogen atom is attached to a different nickel atom, 2.22×10^{17} is the number of active centers on the nickel catalyst. The total area of the active catalytic layer is obtained by multiplying the number of active centers by the area covered by each nickel atom. For an unoriented nickel layer the area covered by one nickel atom can be taken as 6.7×10^{-16} sq. cm., being the arithmetic mean of the areas 5.32, 6.15 and 8.7×10^{-16} sq. cm., in the (111), (100) and (110) planes, respectively[9]; thus the total area of 148 sq. cm. As the apparent area of the glass vessel was 390 sq. cm. and the catalyst layer was on the average not deeper than a few atoms it follows that at least one-tenth of the nickel atoms evaporated was catalytically active.

The figure of 2.22×10^{17} corresponds to 5.7×10^{14} active centers per sq. cm. of apparent catalytic area. In other experiments values of the same order were obtained ranging from 1.6 to 16×10^{14} per sq. cm.

These results have significance if considered together with recent experiments of Beeck, Smith and Wheeler.[9] These authors have found that oriented nickel films of definite crystal structure and reproducible activity for the hydrogenation of ethylene can be prepared by evaporation in an indifferent gas atmosphere at a few millimeters pressure, and that the active regions of the catalyst coincide with a homogeneous, definite crystal lattice, rather than with extra-lattice atoms and related atomic combinations. They have also measured the adsorption of hydrogen on fresh nickel layers up to a thickness of several thousand atoms and have found that an instantaneous, irreversible adsorption, "chemisorption," takes place in agreement with Roberts' results on tungsten.[5] The chemisorption observed in this case is probably closely related to the chemisorption type A described by Brunauer and Emmett[10] on iron.

There are two different types of reactions which might be operative in the exchange and conversion reactions:

1. Reaction between the stable layer of hydrogen on the catalyst and gas molecules impinging thereon.

2. Reaction between the stable layer of hydrogen on the catalyst and hydrogen adsorbed on places adjacent to those occupied by the stable layer.

According to Roberts and Beeck, Wheeler and Smith, and also to Brunauer and Emmett, the stable layer consists of chemisorbed atoms, but we have no definite information about the hydrogen in the second layer. The hydrogen may be present in the second layer either in the form of more or less deformed molecules or in the form of atoms which can recombine and leave the catalyst in contradistinction to chemisorbed atoms.

The apparent order of a reaction of the first type should be one since the concentration of the hydrogen in the stable layer is independent of the pressure and the number of molecules impinging is proportional to the pressure. Furthermore, one would expect that the collision efficiency of a reaction of this type such as

$$p\text{-}H_2 + H_{ads} = o\text{-}H_2 + H_{ads} \qquad (1)$$

would be much smaller than that of the homogenous reaction

$$p\text{-}H_2 + H = o\text{-}H_2 + H \qquad (2)$$

(9) Beeck, Smith and Wheeler, *Proc. Roy. Soc.* (London), **A177**, 62 (1940).

(10) Brunauer and Emmett, THIS JOURNAL, **62**, 1752 (1940); **59**, 1553 (1937); **57**, 1631 (1935).

because in the latter case the hydrogen atom is free and the molecule can approach the atom in the direction of the line joining the nuclei and thus encounter the least energy of activation.[11]

Actually, the observed order of reaction (Table I) is definitely below unity and the calculated collision efficiencies for reaction 1 are of the same order as, and in some cases ten to twenty times higher than, the collision efficiencies for reaction 2. For these reasons one might rule out the reaction of type 1 as highly improbable.

On the other hand, it is not possible to decide between the two alternatives of reaction type 2; *i. e.*, whether the reaction with the stable layer involves adsorbed molecules or adsorbed atoms. A close investigation of the conversion of para-hydrogen and of the exchange reaction on palladium and platinum might help to decide between the two mechanisms if it would be possible to ascertain whether the difference in the rates of conversion and exchange is real and not only apparent owing to the existence of centers of various catalytic activity. A renewed comparison of the para-hydrogen conversion on palladium with the diffusion of hydrogen into the metal may also contribute to the solution of the above problem.

In case it is definitely proved that the exchange and para-hydrogen conversion involve adsorbed molecules rather than adsorbed atoms, all conclusions drawn from the assumption that the rate of the para-hydrogen conversion is governed by the rate of dissociation of the molecules, will need revision.

For example, the repeatedly observed parallelism between the rate of the para-hydrogen conversion and the rate of the hydrogenation of ethylene on the same catalyst[12] was explained by the assumption that the dissociation of the hydrogen molecules is the rate determining step in both processes. In case the participation of atoms other than those in the stable layer in the exchange and conversion must be ruled out, another explanation will be needed. The following might be possible. In the exchange reaction between the stable layer and the adsorbed molecules the rate determining step is the adsorption and deformation of the molecules preceding the actual exchange of atoms. In fact this mechanism would not disagree with the general picture of catalytic hydrogenation according to which both hydrogen atoms of the same molecule are added simultaneously in the act of hydrogenation.[13]

If the dissociation of the hydrogen molecules takes place only in the chemisorbed layer and the recombination of the atoms in this layer is too slow to cause conversion or exchange it is not probable that a dissociation of hydrocarbons into hydrogen atoms and hydrocarbon radicals will contribute to the catalytic exchange of hydrogen atoms between hydrocarbons and molecular hydrogen as postulated by the dissociative theory.[8,14]

The exchange of hydrogen atoms between hydrocarbons and the stable hydrogen layer is possible according to the experimental results given in Table V. This possibility must be taken into account especially when dealing with exchange of hydrogen atoms between hydrocarbons.[15]

Finally, the bearing of the present experiments on two catalytic isomerization reactions will be referred to. Twigg[16] observed that in the catalytic interaction of butene-1 and deuterium the double bond migration was faster than the exchange reaction, while the isomerization was very slow in the absence of hydrogen or deuterium. A similar observation was made by Baxendale and Warhurst[17] in the catalytic hydrogenation of methyl oleate with deuterium when a considerable amount of "light" elaidic ester was formed, indicating that the *cis–trans* conversion proceeded faster than the exchange reaction. Again the isomerization was slow and soon stopped completely when no hydrogen was present.

Both observations can be explained by assuming that the isomerization is caused by an interaction with the stable layer of hydrogen. The effect of hydrogen or deuterium in accelerating the isomerization might be due to the circumstance that the hydrogen in the stable layer is gradually removed by addition to the unsaturated hydrocarbon and gaseous hydrogen is needed for replacing the used-up layer. Since each hydrogen or deuterium atom will cause a number of isomerization processes before it is removed the isomerization will appear to be faster than the exchange.

Summary

The catalytic conversion of para-hydrogen was

investigated at room temperature and a pressure of about 0.01 mm. on evaporated layers of nickel, palladium and platinum. It was found that there is a stable layer of hydrogen on the catalysts which is not removed by pumping at room temperature and which exchanges readily with molecular hydrogen or deuterium. The rate of this exchange is equal to the rate of the para-hydrogen conversion on nickel, but is smaller on palladium and platinum. It is shown that the amount of exchangeable hydrogen in the stable layer can be taken as an indication of the number of active centers on the catalyst. This number is 10^{14} to 10^{15} cm.$^{-2}$ and shows that a great fraction of the apparent catalytic surface is active. The various possible mechanisms for the conversion of para-hydrogen and the exchange are discussed and their bearing on other exchange, hydrogenation and isomerization reactions considered.

Fluorochlorobromomethane

BY KENNETH L. BERRY[1,2] AND JULIAN M. STURTEVANT

In connection with recent theories of optical activity,[3] an optically active pentatomic molecule would be of considerable interest. Attempts have therefore been made to resolve fluorochlorobromoethane, perhaps the most readily obtainable of the few such substances having potential optical activity. During this work several physical properties of this substance have been determined.

Swarts[4] attempted to resolve this substance by fractional crystallization of the complex it forms with salicylide, but without success. He was also unsuccessful[5] in attempts to decarboxylate optically active fluorochlorobromoacetic acid to yield the active substituted methane.

Preparation and Purification.—Ethyl chloroacetal was prepared by the addition of chlorine to vinyl acetate in alcohol solution according to the method of Filachione.[6] Bromination[7] of the chloroacetal, followed by hydrolysis, yielded chlorodibromomethane. This latter halide on treatment with antimony trifluoride and bromine gave fluorochlorobromomethane[4] in fair yield, though contaminated with considerable amounts of higher and lower boiling halides. The crude product was washed at 0° with very dilute alkali followed by water, dried over calcium chloride, and fractionated from phosphorus pentoxide through a 48-cm. vacuum-jacketed column packed with glass helices. The main fraction was collected between 36.3 and 36.8°, and was stored in sealed ampoules in the dark. Over-all yields of approximately 25% were obtained.

Anal. 0.2097 g. gave 0.4693 g. AgCl + AgBr; calcd. 0.4711 g. AgCl + AgBr.

One hundred and forty grams of material boiling at 36.3–36.8° was refractionated, and the middle cut of 65 g. was again fractionated to give a 37 g. fraction boiling at 36.11–36.18° (cor.) (756.0–756.2 mm.). This sample was used for the determination of physical properties. It remained perfectly colorless when sealed in an ampoule and stored in the dark.

Physical Properties.—The fusion curve of fluorochlorobromomethane, which was observed in an apparatus similar to that described by Skau,[8] showed the 36.11–36.18° fraction to be quite pure. The melting point was found to be −115° (cor.).

The density was determined dilatometrically from 0 to 25°, and can be represented in this range by the equation (t = °C.)

$$d_t = 1.9771 - 2.51 \times 10^{-3}t - 2.03 \times 10^{-5}t^2 + 3.3 \times 10^{-7}t^3 \quad (1)$$

A Pulfrich refractometer was employed to determine the refractive dispersion of fluorochlorobromomethane in the visible spectrum at 0.5, 10.0 and 20.0°. The data were fitted to an equation of the form recommended by Tilton[9] (λ = wave length in microns)

$$n^2 = a^2 - k\lambda^2 + \frac{m}{\lambda^2 - l^2} \quad (2)$$

The constants for this equation listed in Table I reproduce the data within the experimental accuracy from λ 0.7065 to λ 0.4047.

TABLE I

THE CONSTANTS OF EQUATION (2)

Temp., °C.	a^2	k	m	l^2
0.5	2.0083	0.00432	0.01175	0.01832
10.0	2.0041	.01828	.00873	.03954
20.0	1.9778	.00610	.01082	.02256

The Lorenz–Lorentz molecular refractivities for the sodium D line are $R_{0.5} = 19.24$, $R_{10} = 19.26$, $R_{20} = 19.31$. Using the atomic refractivities[10] of carbon, hydrogen, chlorine and bromine, one finds the atomic refractivity of fluorine at λ 0.5893 and 20° to be 0.956.

Attempted Resolution.—Three types of procedure for accomplishing the resolution of fluorochlorobromomethane suggest themselves: (a) formation of solid addition compounds with optically active substances; (b) utilization of vapor pressure differences in asymmetric solvents; and (c) selective adsorption on optically active adsorbents. Limitations of time have not permitted an extensive investigation of these procedures, though indications of positive results were obtained with the first method.

It was found that digitonin[11,12] forms an insoluble digitonide with fluorochlorobromomethane. This digitonide cannot be dried and characterized since it very readily loses its volatile component. The halide was added to an aqueous alcoholic solution of digitonin at 0°; after vigorous shaking the mixture was centrifuged, and the precipitate was then warmed to 55° under a slow stream of air to sweep the vaporized halide into a dry-ice-cooled receiver. The distillates thus obtained had rotations varying from zero to +0.15° (1-decimeter tube). The irreproductibility of the results, and the poor recovery of the very expensive digitonin make further experiments along this line seem unpromising.

The Pressure–Area–Temperature and Energy Relations of Monolayers of Octadecanenitrile

BY L. E. COPELAND AND WILLIAM D. HARKINS

1. Introduction

Until recently only three liquid phases have been known to exist in monolayers. These are (1) the liquid expanded or L_1 phase, (2) the intermediate or I phase, and (3) the liquid condensed or L_2 phase. Any one of these may exist at low pressures, and therefore may be designated as a low pressure liquid phase. Recently a new liquid LS[1,2] phase has been discovered, but is found to exist only at high film pressures, since it is formed by a transition from the liquid condensed (L_2) phase when the pressure is raised to a sufficiently high value. Except at the lowest temperatures at which this new phase is formed, the transition is of the second order, so at the transition point the molecular area is the same in the high pressure LS phase as in the low pressure L_2 phase. However, by increase of pressure the area for the LS phase may be reduced below any possible area, for the given temperature, at which the L_2 phase may exist. This new high pressure phase has been found to form in monolayers of the normal long chain paraffin alcohols, but its lower limiting molecular area is 19.98 sq. Å., since below this it transforms into the "solid" or S phase.

At the highest pressure at which a low pressure liquid alcohol monolayer is stable, its molecular area may be below that possible for the stable existence of the high pressure liquid phase. Thus at 2.85° and 14 dyne cm.$^{-1}$ the molecular area for octadecanol is 19.8 sq. Å., the lowest area

(1) W. D. Harkins and L. E. Copeland, *J. Chem. Physics*, **10**, 272 (1942).
(2) L. E. Copeland, W. D. Harkins and G. E. Boyd, *ibid.*, **10**, June (1942).

thus found for any liquid phase. The area at 0° as obtained by extrapolation would be about 19.7 sq. Å.

Reliable measurements of the molecular areas of the normal long paraffin chain acids have not been made at such low temperatures but even at 25° the L_2 film of nonadecanoic acid has a minimum value of 20.2 sq. Å., while the minimum for octadecanol is 20.53 sq. Å. Thus the data seem to indicate that at 25° the minimum area for the acid is lower than that for the alcohol. The molecular areas obtained at 25° by extrapolation to zero pressure are 22.41 sq. Å. for the alcohol and 24.41 for the acid when the molecule of each contains 18 carbon atoms. The larger area for the acid at low pressure and the nearly equal areas at high pressure are explained by the higher mean compressibility of the monolayer of the acid as compared with that of the alcohol.

The fact that the minimum molecular area for the acid is lower than that of the alcohol may be misleading if the pressure of the transformation of liquid (L_2) into the high pressure phase is not taken into account, since the transition pressure is much higher (24 dyne cm.$^{-1}$) than for the alcohol (14 dyne cm.$^{-1}$). At this latter pressure the areas are 20.53 sq. Å. for the alcohol, but 21.7 for nonadecanoic, and 21.9 for stearic, acid, so at equal pressures the acid has the higher area.

2. The Liquid Condensed Monolayer of Octadecanenitrile

Since in monolayers of the long chain alcohols and acids the polar groups are oriented toward the water, they are also brought close together, if the film is condensed. With either of these substances there is a possibility that there may be hydrogen bonding either in (1) the film itself, or (2) between polar groups in the film and molecules of water.

It is, therefore, of interest to learn the effect, upon the molecular area, which is produced by the elimination of the first possibility, that is, of hydrogen bonding in the film. This may be eliminated by the use of a long chain nitrile.

The pressure–area–temperature relations obtained with monolayers of octadecanenitrile are exhibited in Fig. 1. From this figure it is evident that the —C≡N group gives a much higher area (with a minimum of 25.82 sq. Å. at 15.1°) in the monolayer than either —CO·OH or —OH. Adam[3] explains the relations on the basis of the assumption that the nitrile group is the largest, and the hydroxyl group the smallest of the three. However, it does not seem possible that the nitrile group, with its two atoms and a carbon–nitrogen distance of only 1.15 Å., can be larger than the carbonyl group with its content of four atoms, even though one (H) of the latter is small. Therefore it seems necessary to reject Adam's hypothesis, and to seek another cause for the high area in the nitrile monolayers. Obviously if there is intramonolayer hydrogen bonding in the case of the acids and alcohols, its absence in the nitrile films would give a sufficient explanation of their higher areas. Unfortunately the existence of this type of bonding in the film itself has not been demonstrated, even in the case of the alcohols and acids.

Some investigators assume, without solving the statistical mechanics of the problem, that the dipoles in monolayers of this type always repel each other. If this were assumed the higher dipole moment of the nitriles (3.56×10^{-18}) as compared with those of the acids (1.4×10^{-18}) and the alcohols (1.7×10^{-18}) would give a sufficient cause for the higher areas exhibited by the nitriles. This problem will be considered in a later paper which considers other relations of the nitrile mono-layers.

3. The Intermediate Phase

The interesting feature revealed by Fig. 1, as related to the intermediate phase of octadecanenitrile, is that the pressure (π)–area (σ) curves are very much steeper than those exhibited by the normal long chain paraffin acids. Thus the compressibilities of the nitriles, in this phase, are very much smaller. In contrast the esters give much larger compressibilities than the acids.

At 25.8° the intermediate phase of the nitrile has a compressibility of 0.06 at areas close to that at which this phase is formed by a transition, on increase of pressure, from the liquid expanded state. As the area is reduced the compressibility falls to about 0.015. Adam and Harding[4] have obtained a maximum compressibility of the order of 0.45 for the intermediate phase of margaric nitrile, but their value is very much higher than any obtained by us at any temperature with the 18 carbon atom nitrile.

4. The Liquid Expanded Phase

The compressibilities exhibited by the liquid expanded phase of the nitriles are of the same order

(3) N. K. Adam, "The Physics and Chemistry of Surfaces," Oxford, Clarendon Press, 1938, p. 53.

(4) N. K. Adam and J. B. Harding, *Proc. Roy. Soc.* (London), **A143**, 104 (1934).

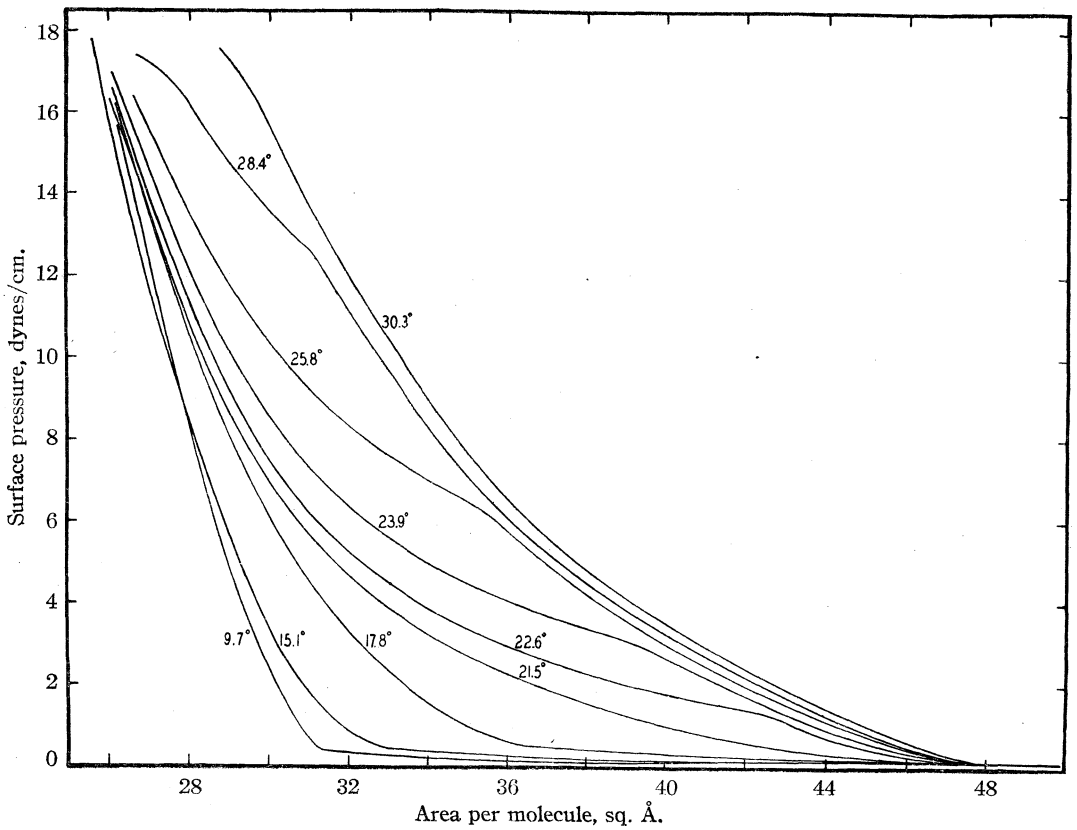

Fig. 1.—Pressure–area–temperature relations of monolayers of octadecane nitrile on water.

of magnitude as those of the acids. That the phase is of the liquid rather than of the vapor type is indicated by the areas at which the film pressures become small, and which are of the order of those to be expected when a liquid expanded film begins to vaporize. At 22.6° and 30.3° the areas are 46 and 48 sq. Å., while with pentadecylic acid, known to be in the liquid expanded state, the areas are 44 and 49 sq. Å. at 17.9 and 35.2°. In the case of myristic acid the transition occurs at 42 and 46 sq. Å. at 4° and 25°.

5. Energy of Spreading and Extension

The values of the energies of extension of the surface of clean water, which are the same as the energies of surface formation, are given in the first row of Table I. The energies of extension of the water covered by the nitrile monolayer are all higher (than those of water), except for the free energies which are lower. Any energy of spreading may be obtained from the corresponding energy of extension by subtracting the value for water. As usual there is a decrease of free energy but an increase of total energy, and of entropy, and of absorption of heat when the monolayer spreads.

TABLE I

THE ENERGIES OF THE MONOLAYER OF OCTADECANE-NITRILE IN THE VARIOUS STATES AT 20°

Energy in erg cm.$^{-2}$ and entropy in erg cm.$^{-2}$ deg.$^{-1}$

Phase	Area	Process	f	h	q	s
Clean water			72.75	116	43.2	0.148
L_1	40.0	extension	72.25	155	82.2	.282
		spreading	−0.49	38.8	39.3	.134
I	32.0	extension	69.00	170	201	.685
		spreading	−3.75	154	158	.537
L_2	28.0	extension	66.38	124	57.5	.197
		spreading	−6.37	7.9	14.3	.049

The effect of pressure and temperature upon the energy values for the monolayers, as obtained at various constant areas, are given in Table II. The values are not extremely high, as in the case of the alcohols,[1,2] but are of somewhat the same order of magnitude as those for pentadecylic acid. As is usual they are very much higher for the intermediate phase than for the expanded and condensed liquid phases.

This publication was made possible by funds granted by the Carnegie Corporation of New York. That Corporation is not, however, the author, owner-publisher or proprietor of this publication, and is not to be understood as approving

	4.0	23.52	.541	160	156

by its grant any of the statements made or views expressed therein.

Summary

1. The lowest area thus far found, in accurate work, for any *n*-long chain paraffin derivative in its monolayer on water is 19.57 sq. Å. This was obtained with *n*-octadecanol in the S-phase at 2.85°. At lower temperatures somewhat lower areas could be obtained. In solid three dimensional crystals the area of the hydrocarbon chain is 18.5 sq. Å. Nonadecanoic acid in its monolayer at 25° has been compressed to 20.2 sq. Å. At 25° the extrapolated area at zero pressure is, for the liquid condensed phase, 22.41 sq. Å. for octadecanol and 24.41 sq. Å. for stearic acid.

2. In monolayers of the alcohols and acids there is the possibility of hydrogen bonding between the polar groups in the film itself as well as with water. In monolayers of *n*-octadecane nitrile hydrogen bonding in the film itself is no longer possible, and it was found that the minimum area obtained at any temperature and pressure employed was 25.8 sq. Å. at 15.1° and 18 dyne cm.$^{-1}$, while the lowest area found by extrapolation at zero pressure was 30 sq. Å. Thus the —C≡N end group gives much less condensed films than either the —COOH or the —OH groups. Unfortunately the dipole moment of the nitrile is much higher (3.56×10^{-18}) than that of the alcohol or the acid, so there is a possibility that this produces a repulsion which accounts for the greater area. The decision as to which factor is responsible for the high area, is left to later work.

3. The hypothesis that the larger area of the nitrile is due to a large size of the —C≡N group, with its interatomic distance of only 1.15 Å., as compared with the —COOH group, is rejected.

4. The pressure–area curves for the intermediate phase are much steeper than those for the long chain acids. Thus in this phase the nitriles exhibit a much smaller compressibility.

5. The pressure–area curves for the expanded phase fall to low pressures at just those areas characteristic of the liquid expanded state, so these films are not gaseous. Thus at 22.6° and 30.3° these areas are 46 and 48 sq. Å., while with pentadecylic acid at 17.9° and 35.2° the corresponding areas are 44 and 49 sq. Å.

Ultraviolet Absorption Spectra of Nitrogenous Heterocycles. IV. Effect of *p*H and Irradiation on the Spectra of Isoguanine and 2-Hydroxy-6,8-diaminopurine

BY SR. MIRIAM MICHAEL STIMSON, O. P.

The introduction of a hydroxy group on the second carbon atom of adenine to give isoguanine and the same relative positions of the hydroxy and amino groups on the pyrimidine ring of 2-hydroxy-6,8-diaminopurine permits a study of the combination effect of tautomerism of the imidine type[1] and of the amide-imidole type.[2]

Although the spectrum of guanine was found by Holiday[3] and by Heyroth and Loofbourow[4] to be greatly affected by *p*H change, the position of the amino group on carbon 2 rather than 6 introduces the possibility that some of the variation may be positional[5] rather than a modification of the spectrum of adenine by introduction of a hydroxy group.

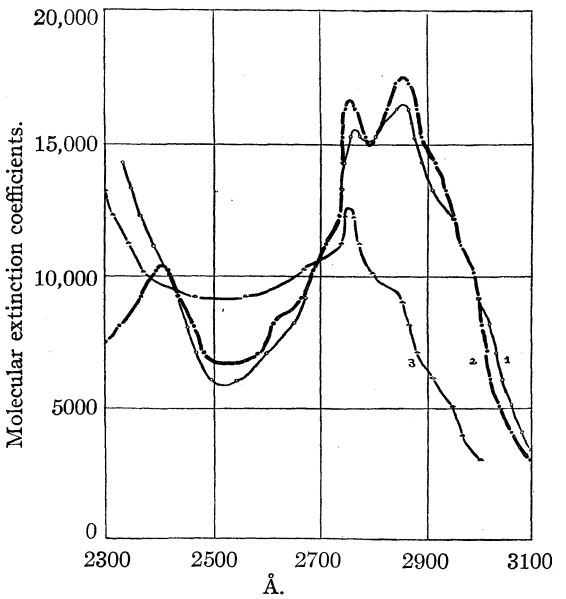

Fig. 1.—Isoguanine: 1, *p*H 3.0; 2, *p*H 7.0; 3, *p*H 11.0.

Experimental

Materials.—The isoguanine and 2-hydroxy-6,8-diaminopurine were kindly furnished by Mr. Joseph R. Spies, Bureau of Chemistry and Soils, U. S. Department of Agriculture.

Method.—The details of the techniques employed were given in Part I of this series.

Results and Discussion

Figure 1 shows the spectra of isoguanine at *p*H 3, 7, 11. The $\epsilon_{max.}$ is greatest for *p*H 7 and is considerably lower for *p*H 11.0 than for *p*H 3.0. In 6-aminopyrimidine[6] and 6-aminopurine[1] $\epsilon_{max.}$ for neutral solution is less than that for acid reaction. On the other hand, unpublished findings of Loofbourow and Stimson indicate $\epsilon_{max.}$ for cytosine to be greatest at *p*H 7.0. From this it may be concluded that the downward trend of the amino (on C 6) $\epsilon_{max.}$ with change from acid to alkaline conditions is over balanced by the high absorption of the hydroxyl group at *p*H 7.0.[2] The effect of the hydroxyl in position 6 is weaker than in 2, however, since the work of Williams, *et al.*,[6] shows 5-methyl-6-hydroxypyrimidine to absorb less at the long wave maximum in neutral solution than in either acid or alkaline reaction. Unpublished findings of Stimson and Loofbourow for hypoxanthine also show the influence of the hydroxyl on C 6 to be insufficient to raise $\epsilon_{max.}$ for neutral solutions above that for acid or alkaline solutions. Although $\lambda_{max.}$ for 6-aminopyrimidine and 6-aminopurine shifts progressively to longer wave lengths with increase in *p*H, the reverse condition is true for the compounds with the 2-hydroxy-6-amino arrangement. The introduction of the second amino group in position 8 shows in 2-hydroxy-6,8-diaminopurine, the shift of $\lambda_{max.}$ to be in the same direction as the other two 2-hydroxy-6 amino compounds although the degree is considerably less (Fig. 2). However $\epsilon_{max.}$ here again takes on the characteristics of purely amino substituted compounds, which may be attributed to overbalancing the hydroxyl absorption. The short wave maximum found by Williams, *et al.*, for 6-amino- and 6-hydroxy compounds, by Stimson and Loofbourow for 2-chloro-6-aminopyrimidine and by Uber and Winters[7] is indicated only at *p*H 7 for isoguanine and did not appear in the photographic ultraviolet for 2-hydroxy-6,8-di-

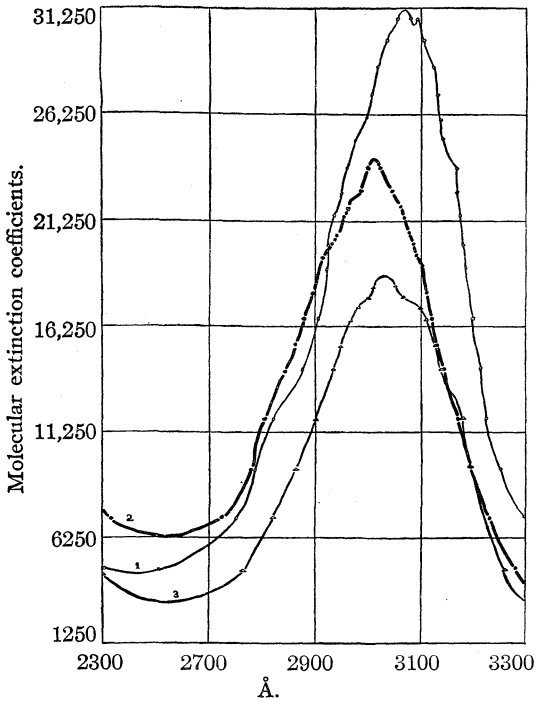

Fig. 2.—2-Hydroxy-6,8-diaminopurine: 1, *p*H 3.0; 2, *p*H 7.0; 3, *p*H 11.0.

aminopurine. In the case of isoguanine the inability to photograph the peak in acid and in alkaline solution may be due to the absorption of the buffers in the short wave end of the spectrum. This, in conjunction with any shift which might occur, could readily prevent it from being recognized under the experimental conditions.[8]

Figure 3 shows the effect of irradiation on isoguanine for as long as four hours. Unlike adenine, which is markedly stable to ultraviolet radiation isoguanine shows response of the type shown by barbituric acid.[4]

Summary

1. A comparison of 2-hydroxy-6-amino-pyrimidine and purine with 6-amino-pyrimidine and purine shows that the substitution of the hydroxyl group causes $\lambda_{max.}$ to shift to shorter wave lengths with increase in *p*H and $\epsilon_{max.}$ to rise at *p*H 7 and then to fall so that the value at *p*H 11.0 is lower than that at *p*H 3.

2. Location of the hydroxy group on C 6 in these compounds tend to increase $\epsilon_{max.}$ at neutral *p*H above that in acid or alkaline *p*H, whereas certain 2-hydroxy purines and pyrimidines have a reduced $\epsilon_{max.}$ at *p*H 7.0.

3. An additional amino group in the case of 2-hydroxy-6,8-diaminopurine shows the same general *p*H effect on $\lambda_{max.}$ but to a lesser degree, however $\epsilon_{max.}$ follows the amino substitutes.

4. Whereas adenine showed only negligible change on irradiation, isoguanine showed a decided change in extinction.

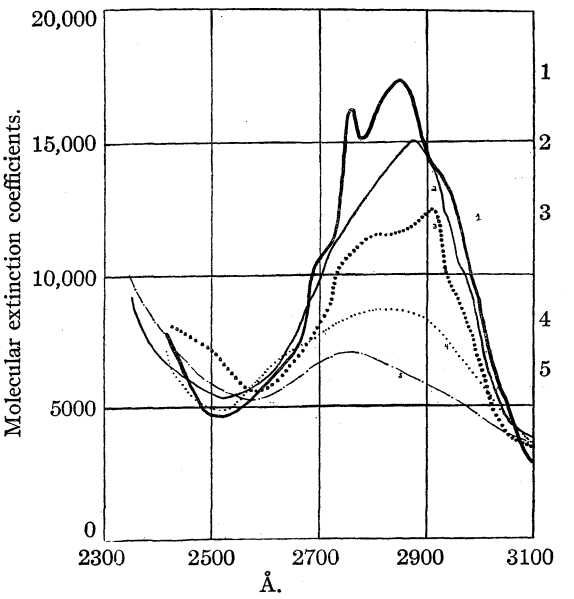

Fig. 3.—Effect of irradiation on isoguanine: 1, 15 min.; 2, 1 hr.; 3, 2 hr.; 4, 3 hr.; 5, 4 hr.

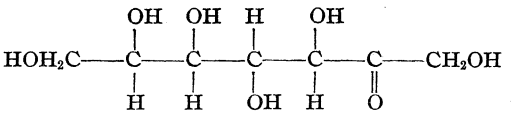
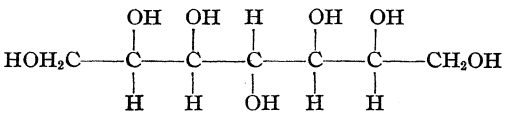
Some Studies on L-Glucoheptulose

BY W. DAYTON MACLAY, RAYMOND M. HANN AND C. S. HUDSON

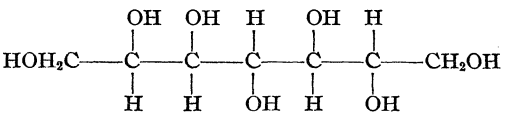
The biochemical oxidation of a number of polyatomic alcohols to ketoses by *Acetobacter suboxydans* has been reported[1] in previous publications from this Laboratory. The present article describes the preparation of L-glucoheptulose through the biochemical oxidation of D-gluco-D-gulo-heptitol[2] (α-glucoheptitol) by the procedure previously found to be successful for the oxidation of D-manno-D-gala-heptitol (perseitol) to L-galaheptulose. The L-glucoheptulose was obtained in a yield of 88%; the pure ketose melted at 172–173° (cor.) and exhibited a specific rotation $[\alpha]^{20}D$ of −67.8° in water without mutarotation; these constants agree with those reported (m. p. 173.5°; $[\alpha]^{20}D$ −67.1°) by Bertrand and Nitzberg[3] for the "α-glucoheptulose" which they obtained by the biochemical oxidation of D-gluco-D-gulo-heptitol with *Bacterium xylinum* (syn. *Acetobacter xylinum*). Austin[4] has shown that "α-glucoheptulose" is L-glucoheptulose since it is the enantiomorph of D-glucoheptulose (m. p. 171–174°; $[\alpha]^{20}D$ +67.7°) prepared by the Lobry de Bruyn rearrangement of D-gluco-D-gulo-heptose (D-α-glucoheptose). He prepared the D-glucoheptose phenylosazone that is common to D-gluco-D-gulo-heptose and D-glucoheptulose and showed that it mutarotates in absolute alcohol–pyridine solution from −5.3° to +35.0°; he pointed out that the phenylosazone of "α-glucoheptulose," which had been described by Bertrand and Nitzberg as identical with D-glucoheptose phenylosazone, must in reality have been the enantiomorphous L-glucoheptose phenylosazone. Bertrand and Nitzberg did not report its rotation; Austin did not have the L-form of glucoheptulose available for the repreparation of its phenylosazone. We have now confirmed the observation of Austin on the rotation of D-glucoheptose phenylosazone; we have also prepared the enantiomorphous L-glucoheptose phenylosazone from L-glucoheptulose and find that it mutarotates from +6.0° to −35.3° in absolute alcohol–pyridine solution, proving that the phenylosazones are enantiomorphs, as was concluded by Austin. Confirmation of the configuration of L-glucoheptulose (I) was obtained also through its reduction with hydrogen and Raney nickel to form a mixture of the inactive L-gluco-L-gulo-heptitol (syn. D-gluco-D-gulo-heptitol, α-glucoheptitol) (II) and the active L-gluco-L-ido-heptitol (syn. L-β-glucoheptitol) (III).



L-Glucoheptulose (I)



L-Gluco-L-gulo-heptitol (II)
(syn. D-Gluco-D-gulo-heptitol, α-Glucoheptitol)



L-Gluco-L-ido-heptitol (III)
(syn. L-Ido-D-gulo-heptitol, L-β-Glucoheptitol)

The alcohols were separated by conversion into their respective heptaacetates, that of L-gluco-L-gulo-heptitol crystallizing readily while that of L-gluco-L-ido-heptitol remained dissolved in the acetylating solution. The L-gluco-L-gulo-heptitol heptaacetate was optically inactive, melted at 118–119° (cor.) and gave a quantitative yield of the inactive L-gluco-L-gulo-heptitol upon deacetylation. The L-gluco-L-ido-heptitol heptaacetate was obtained as a sirup, which upon deacetylation yielded crystalline L-gluco-L-ido-heptitol, melting at 129–130° (cor.) and exhibiting a specific rotation $[\alpha]^{20}D$ of −0.8° in water. The recorded values[5] of these constants for the enantiomorphous D-gluco-D-ido-heptitol are 130–131° and +0.8°, respectively, and we also have observed a melting point of 129–130° (cor.) and a specific rotation $[\alpha]^{20}D$ of +0.7° in water on a sample of D-gluco-D-ido-heptitol prepared by the catalytic reduction of D-gluco-D-ido-heptose with hydrogen and Raney nickel. The L-gluco-L-ido-

(5) Phillipe, *Compt. rend.*, **147**, 1481 (1908).

heptitol was further characterized by conversion to its crystalline heptabenzoate and this compound was found to have the same melting point, namely, 181–182° (cor.) as authentic D-gluco-D-ido-heptitol heptabenzoate; the specific rotation of the heptabenzoate in chloroform solution (−25.3°) was equal in magnitude, but opposite in sign, to that of the D-isomer. The data from the reduction therefore confirm the accepted configuration of L-glucoheptulose (I). They are also in agreement with the results obtained by Khouvine,[6] who has shown that D-glucoheptulose is reduced by hydrogen and Raney nickel to form D-gluco-D-gulo-heptitol and D-gluco-D-ido-heptitol, although reduction with sodium amalgam yielded D-gluco-D-gulo-heptitol and a substance designated as α-D-glucoheptulitol, which Humoller, Kuman and Snyder[7] regard as mixed crystals of D-gluco-D-gulo-heptitol and a small amount of an optically active impurity of undetermined identity.

We express our appreciation to Mr. L. B. Lockwood, Dr. Evelyn B. Tilden and Dr. W. T. Haskins for assistance in parts of this work.

Experimental

L-Glucoheptulose (I) from D-Gluco-D-gulo-heptitol.—A medium for inoculating the solution employed in the biochemical oxidation was prepared as follows: a solution of 10 g. of D-gluco-D-gulo-heptitol, 1.0 g. of Difco yeast extract, 0.6 g. of potassium acid phosphate and 0.1 g. of glucose in 200 cc. of water was placed in a 500-cc. Jena glass gas-washing bottle; following sterilization, a bacterial suspension of *Acetobacter suboxydans* was added, and the bottle was placed in a 30° constant temperature room and sterile air was passed through the suspension at a rate of 200 cc. per minute; after twenty-four hours the oxidation of the alcohol to ketose was complete and the inoculum was ready for use. A solution of 400 g. of D-gluco-D-gulo-heptitol, 20 g. of Difco yeast extract, 12 g. of potassium acid phosphate, 2 g. of glucose and 0.5 g. of octadecyl alcohol in 4000 cc. of water was sterilized in a 10-liter Pyrex bottle suitably equipped with an air intake and dispersion unit. After introduction of the previously described inoculum the bottle was placed in a 30° constant temperature room and sterile air was passed through the culture at a rate of 12 liters per minute. Subsamples were analyzed for reducing value at the expiration of 24, 48, 96, 120 and 144 hours and the analyses indicated that the oxidation was 9, 28, 80, 93 and 100% complete at these periods. The solution was clarified by filtration and successive treatments with lead acetate and hydrogen sulfide, and the final filtrate was concentrated *in vacuo* at 60° to a volume of 400 cc.; the sirup was diluted with 700 cc. of warm alcohol and as the solution cooled it deposited the crystalline ketose in a yield of 349 g. (m. p. 166–167°). A second crop of 6 g. was obtained by concentrating the filtrate to a volume of 55 cc. and adding 285 cc. of warm alcohol, and the final mother liquor, upon treatment with *p*-bromophenylhydrazine, gave a yield of L-glucoheptose *p*-bromophenylosazone equivalent to 12 g. of ketose. The yield of crystalline ketose was therefore 355 g. or 88%, and the over-all yield was 367 g. or 91%. The compound was recrystallized by solution in 1 part of water and addition of 5 parts of alcohol; it formed large rhombs which melted at 172–173° (cor.) and showed a specific rotation of −67.8° (*c*, 2.5; *l*, 4) in water, without detectable mutarotation. Bertrand and Nitzberg[3] reported a melting point of 173.5° and a specific rotation of −67.1° in water for "α-glucoheptulose" and Austin[4] reported a melting point of 171–174° and a specific rotation of +67.7° in water for D-glucoheptulose.

Mr. G. L. Keenan, of the Food and Drug Administration of the Federal Security Agency, has examined the L-glucoheptulose and finds its optical-crystallographic properties to be identical with those of authentic D-glucoheptulose, as would be expected. *In ordinary light*, the powdered L-glucoheptulose consists of angular fragments, showing by the immersion method in oily organic liquids refractive indices, $n_\alpha = 1.545$, n_β indeterminate and $n_\gamma = 1.560$, both ±0.002; *in parallel polarized light* (*crossed nicols*) the birefringence is moderate and the fragments extinguished sharply with crossed nicols, only an occasional fragment being found which remains bright; *in convergent polarized light* (*crossed nicols*), a partial biaxial interference figure is only rarely observed.

A mixture of 1.0 g. each of pure L- and D-glucoheptulose was recrystallized from 15 parts of warm alcohol. The crystals which were deposited as the solution cooled melted at 150–152° (cor.) and this melting point was unchanged by further recrystallization. This D,L-glucoheptulose showed no optical rotation in aqueous solution. An optical-crystallographic examination by Mr. Keenan disclosed that the indices of refraction of the crystals were identical with those of the optically active forms of the ketose; the crystals form therefore a mixture of the D- and L-modifications rather than a true racemate.

L-Glucoheptose Phenylosazone.—A solution of 10.0 g. of L-glucoheptulose in a mixture of 25 cc. of phenylhydrazine 12.5 cc. of acetic acid and 100 cc. of water was heated on the steam-bath for two hours. The osazone, which separated as an oil as the reaction progressed, crystallized readily as the suspension was cooled. The yield was 18.1 g. (98%). The compound was recrystallized from 25 parts

(7) Humoller, Kuman and Snyder, THIS JOURNAL, **61**, 3370 (1939).

of boiling alcohol in the form of yellow needles which melted with decomposition at 181–182° (cor.). The specific rotation was determined in a mixture of 2 parts of pyridine and 3 parts of absolute alcohol and, as shown in the following summary, it was equal in magnitude, but opposite in sign to that of a sample of authentic D-gluco-heptose phenylosazone.

A mixture of 1.0 g. of each of the enantiomorphous osazones was dissolved by refluxing in 250 cc. of alcohol and, upon cooling, the solution deposited yellow needles which melted at 176–177° (cor.). This melting point was not changed by recrystallization from alcohol and a pyridine–alcohol solution of the recrystallized product showed no rotation. Since the melting point of the compound is lower than that of its components it may be designated at the present time only as D,L-glucoheptose phenylosazone.

Anal. Calcd. for $C_{19}H_{24}O_5N_4$: C, 58.75; H, 6.23. Found: (for L-form) C, 58.78; H, 6.14; (for D,L-form) C, 58.13; H, 6.18.

Reduction of L-Glucoheptulose.—A solution of 50.0 g. of L-glucoheptulose in 250 cc. of water was heated for six hours at 100° under a pressure of 2500 pounds (167 atm.) of hydrogen in the presence of 10.0 g. of Raney nickel. Following removal of the catalyst, the solution was concentrated *in vacuo* at 60° to a thick sirup, which was thinned with 25 cc. of water and then mixed with 300 cc. of warm alcohol. As the solution cooled it deposited 47.5 g. of a mixture of plates and needles (m. p. 116–119°) and an additional 2.6 g. of crystalline material (m. p. 116°) was obtained from the mother liquor. The total yield was therefore 50.1 g. (99%). It was found impractical to separate the mixture of crystalline heptitols by fractional crystallization, and accordingly, 45.0 g. of the mixed alcohols was acetylated by heating for two hours on the steam-bath with 180 cc. of acetic anhydride and 11.3 g. of fused sodium acetate. The acetylation mixture was poured upon crushed ice and the precipitated L-gluco-L-gulo-heptitol heptaacetate (41 g., 38%) was removed by filtration. The acetate, after recrystallization from 4 parts of alcohol, melted at 118–119° (cor.) and this melting point was not depressed upon admixture with authentic L-gluco-L-gulo-heptitol heptaacetate. A chloroform solution of the substance showed no optical activity. Upon deacetylation the heptaacetate gave a quantitative yield of L-gluco-L-gulo-heptitol.

Anal. Calcd. for $C_{21}H_{30}O_{14}$: C, 49.79; H, 5.97; CH_3CO, 59.5. Found: C, 49.68; H, 5.89; CH_3CO, 59.2.

The dilute acetic acid mother liquor remaining, after removal of the crystalline L-gluco-L-gulo-heptitol heptaacetate, was neutralized with sodium bicarbonate and extracted with chloroform. The washed extract was concentrated to a dry sirup (59.5 g., 55%) which was dissolved in 500 cc. of absolute methanol and deacetylated with barium methylate in the usual manner. The solution was freed of barium ion by balancing out with sulfuric acid, and after concentration to a sirup was dissolved in 100 cc. of boiling methanol. The alcoholic solution upon cooling deposited L-gluco-L-ido-heptitol in a yield of 21.8 g. (48%). The substance was recrystallized by solution in 0.5 part of water and the addition of 10 parts of warm methanol; it formed plates which melted at 129–130° (cor.) and showed a specific rotation $[\alpha]^{20}D$ of −0.8° (*c*, 4.0; *l*, 4) in water. Pure D-gluco-D-ido-heptitol, prepared by the catalytic reduction of D-gluco-D-ido-heptose, melted at 129–130° (cor.) and showed a specific rotation $[\alpha]^{20}D$ of +0.7° in water in agreement with the recorded value[5] (m. p. 130–131°; $[\alpha]^{20}D$ +0.8°) of Phillipe. An examination by Mr. G. L. Keenan showed that the L- and D-forms of the alcohol possessed identical optical crystallographic properties. *In ordinary light* they consist of thin quadratic plates showing refractive indices, $n_\alpha = 1.552$, n_β indeterminate and $n_\gamma = 1.561$, both ±0.002; *in parallel polarized light* (*crossed nicols*) the birefringence is weak and low order polarization colors are invariably shown; no interference figures were observed *in convergent polarized light* (*crossed nicols*).

Anal. Calcd. for $C_7H_{16}O_7$: C, 39.60; H, 7.60. Found: C, 39.66; H, 7.54.

L-Gluco-L-ido-heptitol Heptabenzoate (L-β-Glucoheptitol Heptabenzoate).—A mixture of 1.0 g. of L-gluco-L-ido-heptitol, 5 cc. of pyridine, and 6 cc. (10.5 molecular equivalents) of benzoyl chloride was heated in a boiling water-bath for two hours. The solid reaction products were dissolved in a mixture of chloroform and water and the chloroform layer was separated, washed, dried over anhydrous sodium sulfate and concentrated to a sirup; the sirup was dissolved in 475 cc. of boiling alcohol and as the solution cooled it deposited the heptabenzoate in a yield of 3.2 g. (72%). The compound was recrystallized from 150 parts of boiling alcohol and was obtained in the form of needles which melted at 181–182° (cor.) and exhibited a specific rotation $[\alpha]^{20}D$ of −25.3° (*c*, 2.0; *l*, 4) in chloroform. D-Gluco-D-ido-heptitol heptabenzoate, prepared from D-gluco-D-ido-heptitol, obtained by the catalytic reduction of D-gluco-D-ido-heptose, showed the same melting point and its rotation, +25.1°, was the same in magnitude, but opposite in sign. Phillipe[5] recorded the melting point of D-gluco-D-ido-heptitol heptabenzoate as 182°, but did not measure its rotation.

Anal. Calcd. for $C_{56}H_{44}O_{14}$: C, 71.48; H, 4.71; C_6H_5CO, 78.2. Found: C, 71.55; H, 4.65; C_6H_5CO, 77.7.

Racemic Gluco-ido-heptitol Heptabenzoate (Racemic β-Glucoheptitol Heptabenzoate).—A mixture of 0.4 g. each of D-gluco-D-ido- and L-gluco-L-ido-heptitol heptabenzoates was dissolved in 640 cc. of boiling 95% alcohol and as the solution cooled it deposited the racemate in the form of small needles. The pure compound may be recrystallized from 750 parts of alcohol; it was devoid of optical activity in chloroform solution. Its melting point of 193–194° (cor.) is considerably higher than that of its components, which shows that it is a true racemate.

Anal. Calcd. for $C_{56}H_{44}O_{14}$: C, 71.48; H, 4.71; C_6H_5CO, 78.2. Found: C, 71.54; H, 4.63; C_6H_5CO, 78.0.

Racemic Gluco-ido-heptitol (Racemic β-Glucoheptitol).—A mixture of 1.0 g. each of pure D-gluco-D-ido-heptitol and L-gluco-L-ido-heptitol was dissolved in 1 cc. of water and the aqueous solution diluted with 50 cc. of hot absolute methanol. As the solution cooled, racemic gluco-ido-heptitol was deposited in a yield of 1.85 g. (92%). The substance was recrystallized by solution in 1 part of water and the addition of 30 parts of methanol and formed small plates which melted at 114–115° (cor.) and showed no ro-

tation in an aqueous solution. An optical-crystallographic examination of the compound by Mr. Keenan showed that *in ordinary light* the refractive indices were $n_\alpha = 1.552$, n_β indeterminate and $n_\gamma = 1.555$, both ± 0.002; *in parallel polarized light* (*crossed nicols*) the birefringence is weak and low order polarization colors are usually seen; no interference figures were observed *in convergent polarized light*. The differences in these optical-crystallographic properties from those of L-gluco-L-ido-heptitol indicate that the substance which is here described is a true racemate.

Anal. Calcd. for $C_7H_{16}O_7$: C, 39.60; H, 7.60. Found: C, 39.66; H, 7.72.

Summary

L-Glucoheptulose has been prepared in high yield through the biochemical oxidation of α-glucoheptitol with *Acetobacter suboxydans*. The phenylosazone of the ketose has been shown to possess a specific rotation equal in magnitude, but opposite in sign, to that of D-glucoheptose phenylosazone. Catalytic reduction of L-glucoheptulose by hydrogen and Raney nickel produces L-gluco-L-gulo-heptitol and L-gluco-L-ido-heptitol and thus provides supporting evidence for the accepted configuration of the ketose. New substances which have been described are D,L-glucoheptulose, L-gluco-L-ido-heptitol (L-β-glucoheptitol), L-gluco-L-ido-heptitol heptabenzoate, racemic gluco-ido-heptitol heptabenzoate, and racemic gluco-ido-heptitol.

The Oxidative Degradation of L-Glucoheptulose

BY NELSON K. RICHTMYER AND C. S. HUDSON

In an earlier communication from this Laboratory[1] we reported the isolation of potassium L-galactonate in a 45% yield from the degradation of perseulose (L-galaheptulose) in alkaline solution by oxygen, according to the procedure developed by Spengler and Pfannenstiel.[2] Having available a considerable amount of L-glucoheptulose from another research,[3] we had planned to degrade it in similar fashion to potassium L-gluconate, and thus to obtain, by reduction of the lactone, the difficultly accessible L-glucose.[4] Unfortunately for our purpose the oxidation could not be controlled sufficiently to yield L-gluconic acid as the principal degradation product. Instead there was formed one of those complex mixtures of acids such as have been obtained, by a succession of enolizations and cleavages, from the oxidation of other sugars in alkaline solution by air.[5]

When the oxidation of L-glucoheptulose was carried out in the manner described previously for L-galaheptulose, the first product to be isolated was the readily crystallized potassium L-arabonate, in a yield of 31%. It was identified by its rotation[6] of +5.2° in water as compared to −5.0° for potassium D-arabonate, and by conversion to the benzimidazole derivative described by Moore and Link.[7] The remainder of the oxidation products was converted to a mixture of brucine salts. Crystallized from water, the least soluble fraction, about 14% of the theoretical yield, consisted of approximately equal amounts of the brucine salts of L-gluconic and L-erythronic acids. Brucine L-gluconate was identified by comparison of its constants with those recorded in the literature, by conversion to potassium L-gluconate rotating −11.3° in water as compared to +11.3° for potassium D-gluconate, and by conversion to 2-[L-*gluco*-pentahydroxyamyl]-benzimidazole. This last-named compound has the same melting point as the D-derivative described by Moore and Link,[8] while the rotation, −9.0° in citric acid solution, is about equal in magnitude but is opposite in sign to that recorded for its better-known antipode.

Brucine L-erythronate was identified by analy-

sis, melting point and rotation, and by conversion to the known, crystalline L-erythronolactone. The latter was characterized further by preparing from it 2-[L-*erythro*-trihydroxypropyl]-benzimidazole, which has the same melting point as 2-[D-*erythro*-trihydroxypropyl]-benzimidazole prepared from D-erythronolactone; the rotations are similar in magnitude, but are opposite in sign.

The more soluble fractions of the brucine salts contained some additional brucine L-gluconate, but carbon and hydrogen analyses indicated that the rest of the material consisted chiefly of the brucine salts of hydroxy acids containing only two or three carbon atoms.

While the oxidative degradation of L-galaheptulose to L-galactonic acid had been satisfactory in regard to yield, the degradation of L-glucoheptulose was disappointing because the principal product isolated was L-arabonic acid. However, such a two-carbon atom degradation would be very useful if the oxidation of sedoheptulose should be found to produce D-ribonic acid in considerable amount in addition to the small yield of D-altronic acid already reported.[9]

The degradation of L-glucoheptulose to L-gluconic acid derivatives, as reported above, completes a series of reactions by which D-glucose has been transformed to its mirror-image, L-glucose, as follows: D-glucose → D-gluco-D-gulo-heptose (= D-α-glucoheptose)[10] → D-gluco-D-gulo-heptitol (= L-gluco-L-gulo-heptitol = α-glucoheptitol)[10] → L-glucoheptulose[11] → L-gluconic acid → L-glucose.[12]

Experimental Part

Oxidation of L-Glucoheptulose; Isolation of Potassium L-Arabonate.—A solution of 21 g. of L-glucoheptulose (0.1 mole) in 100 cc. of water was added to 150 cc. of 2 *N* aqueous potassium hydroxide (0.3 mole) and the mixture was shaken vigorously with oxygen at 20–25°. After twenty-four hours the oxygen consumption had ceased at about 3000 cc., measured at room temperature. A product was isolated, as in the oxidation of perseulose, by concentration, precipitation with methyl alcohol, and crystallization from water by the addition of methyl alcohol. It was identified as potassium L-arabonate,[13] and was obtained in a 31% yield (average).

Anal. Calcd. for $C_5H_9O_6K$: K, 19.15. Found: K, 19.20.

A thrice recrystallized sample rotated[6] +5.2 ± 0.1° in water (*c*, 5; *l*, 4). For comparison, a specimen of potassium D-arabonate was crystallized to constant rotation and showed −5.0 ± 0.1° in water (*c*, 5; *l*, 4). Both D- and L-salts melted about 220° with decomposition. The potassium L-arabonate was characterized further by conversion to 2-[L-*arabo*-tetrahydroxybutyl]-benzimidazole by the procedure of Moore and Link.[7] This derivative melted at 235° (decomp.) and rotated +49.7 ± 0.2° in 5% citric acid solution (*c*, 2), in good agreement with the data reported by those authors.

Isolation of L-Gluconic Acid Derivatives.—After 145 g. of potassium L-arabonate had been separated from the products obtained by the oxidation of 478 g. of L-glucoheptulose, the mother liquor was acidified with hydrochloric acid until all the organic acids had been liberated. The solution was concentrated *in vacuo* to a thin sirup which was diluted with methyl alcohol and most of the potassium chloride was removed by filtration. The filtrate was concentrated to a thick sirup which was heated *in vacuo* for two hours at 70°, and the lactones and acids were extracted from the remainder of the potassium chloride with hot absolute alcohol. The alcohol was removed by distillation, and the residue was heated for several hours with 1500 cc. of water and 60 g. of calcium carbonate. Excess carbonate and any calcium oxalate were removed by filtration. Inasmuch as no crystalline calcium salt could be obtained by concentrating the aqueous solution, the calcium ions were removed by the addition of an equivalent amount of oxalic acid, as determined by analysis of an aliquot portion, and the organic acids were then converted to brucine salts in the usual manner. Upon concentration of the aqueous solution of the brucine salts, there were obtained several crops of crystals, totaling 181 g. An attempt to purify this material showed that it consisted of about equal amounts of the brucine salts of L-gluconic and L-erythronic acids which could be separated, partially, by a series of extractions and crystallizations with methyl alcohol. In this way we were able to isolate **brucine L-gluconate** in clusters of elongated, more or less rectangular, plates which were solvent-free after being dried in the air at room temperature. The rotation, −28.6° in water (*c*, 4), is higher than −25.4° in water (*c*, 4), the only value recorded previously, by Upson, Sands and Whitnah.[14] The melting point, 180° with evolution of gas, is in agreement with that of those authors, but is higher than the value 167–168° reported by Kiliani.[14]

Anal. Calcd. for $C_{29}H_{38}N_2O_{11}$: C, 58.97; H, 6.49. Found: C, 59.36; H, 6.59.

A portion of the brucine L-gluconate was converted to barium L-gluconate by treatment with barium hydroxide in the usual manner. Although barium L-gluconate has been obtained in crystalline form by Kiliani,[14] our product was amorphous. By reacting with an equivalent amount of potassium sulfate, the barium salt was converted to a crystalline potassium salt. **Potassium L-gluconate,** twice recrystallized from water by the addition of methyl alcohol, separated in clusters of flattened, acicular prisms. It melted about 185° with decomposition, and rotated −11.3 ± 0.2° in water (*c*, 4; *l*, 4).

Anal. Calcd. for $C_6H_{11}O_7K$: K, 16.69. Found: K, 16.82, 16.62.

(10) Fischer, *Ann.*, **270**, 64 (1892).
(11) Bertrand and Nitzberg, *Compt. rend.*, **186**, 925 (1928).
(12) Fischer, ref. 4.
(13) First prepared by Kiliani, *Ber.*, **21**, 3009 (1888); neither m. p. nor rotation was reported.
(14) Upson, Sands and Whitnah, THIS JOURNAL, **50**, 519 (1928). *cf.* Kiliani, *Ber.*, **55**, 100 (1922); **58**, 2349 (1925).

Potassium D-gluconate, prepared for comparison and thrice recrystallized as similar acicular prisms, melted at 185° (decomp.), and rotated +11.3 ± 0.2° in water (*c*, 4; *l*, 4). This value is higher than the value +10.3° reported by May, Weisberg and Herrick[15] but lower than the +13.0° reported by Nilkantum.[16]

Final identification of L-gluconic acid was obtained by converting it to **2-[L-*gluco*-pentahydroxyamyl]-benzimidazole** by the procedure of Moore and Link.[7] This compound, after four recrystallizations as colorless needles from water, melted about 215° with decomposition, and rotated −9.0 ± 0.2° in 5% citric acid solution (*c*, 2; *l*, 4). Although optical enantiomorphs should have equal and opposite rotations, according to the classical views of stereochemistry,[17] this rotation is slightly lower in magnitude than the value +9.6° reported by Moore and Link, and +9.5 ± 0.2° as confirmed by our own measurements for the D-antipode; this is due perhaps to the presence of a very small amount of the dextrorotatory (+49.7°), rather insoluble L-*arabo*-benzimidazole which might accompany the L-*gluco* derivative as an impurity.

Anal. Calcd. for $C_{12}H_{16}N_2O_5$: C, 53.72; H, 6.02. Found: C, 53.72; H, 6.04.

Isolation of L-Erythronic Acid Derivatives.—Besides brucine L-gluconate we were able to isolate, from the less soluble brucine salts, **brucine L-erythronate.** This salt crystallized from methyl alcohol as small, colorless prisms with many faces. The air-dried product contained about 0.9% of water which it lost in a desiccator but regained upon subsequent exposure to the air. It melted about 210° with vigorous decomposition. The rotation, on a solvent-free basis, was −31.6° in water (*c*, 4), or slightly higher than the value −28.4° in water (*c*, 4) reported by Ruff.[18]

Anal. Calcd. for $C_{27}H_{34}N_2O_9$: C, 61.12; H, 6.46. Found, on sample dried at 100° *in vacuo:* C, 61.08; H, 6.42.

The conversion of brucine L-erythronate to **L-erythronolactone** was accomplished by standard procedures. The lactone crystallized from ethyl acetate as elongated, flattened prisms, which appeared to consist of bundles of tough, flexible needles. The m. p. 102–103° and the rotation +73.0° in water (*c*, 4) are in agreement with the data of Glattfeld and Forbrich.[19]

Benzimidazole derivatives were prepared from both D- and L-erythronolactones by the procedure of Moore and Link.[7] The compounds were recrystallized from 12 parts of hot water, as colorless, prismatic needles melting at 177–178°. A thrice-recrystallized sample of **2-[D-*erythro*-trihydroxypropyl]-benzimidazole** rotated +9.0 ± 0.2° in 5% citric acid solution (*c*, 2; *l*, 4), and the twice recrystallized **2-[L-*erythro*-trihydroxypropyl]-benzimidazole** rotated −8.3 ± 0.2° under identical conditions. The L-form may be contaminated with a very small amount of the L-*arabo*-benzimidazole which would lower the rotation.

Anal. Calcd. for $C_{10}H_{12}N_2O_3$: C, 57.68; H, 5.81. Found: (D-form) C, 57.73; H, 5.76; (L-form) C, 57.58; H, 5.78.

One of the authors (N. K. R.) desires to thank the Chemical Foundation of New York for a Research Associateship. The authors express their indebtedness to Dr. W. Dayton Maclay and Dr. Raymond M. Hann for their generous gift of L-glucoheptulose, and to Dr. Arthur T. Ness for carrying out the micro-analyses.

Summary

1. L-Glucoheptulose has been degraded in alkaline solution by oxygen to potassium L-arabonate in a 31% yield. Smaller amounts of L-gluconic and L-erythronic acids were isolated and identified by means of their salts and other derivatives.

2. The D- and L-forms of 2-[*erythro*-trihydroxypropyl]-benzimidazole have been described.

3. The transformation of D-glucose to L-glucose has now been completed by the step involving the degradation of L-glucoheptulose to L-gluconic acid.

A Benzimidazole Rule for the Determination of Configuration of the Aldonic Acids and Related Compounds

BY NELSON K. RICHTMYER AND C. S. HUDSON

During the course of a recent investigation[1] in which several 2-[*aldo*-polyhydroxyalkyl]-benzimidazoles were prepared for the identification of aldonic acids, as recommended by Moore and Link,[2] a certain correlation was noticed between the sign of rotation and the configuration of the compound. This correlation may be stated in the form of a "benzimidazole rule" as follows: *whenever the hydroxyl group on the second (or alpha) carbon atom of an aldonic acid is written on the right in the conventional projection formula, the rotation of the derived benzimidazole is positive, and conversely, when the hydroxyl group is written on the left, the rotation of the benzimidazole derivative is negative.*

In Table I are recorded the specific and molecular rotations in either aqueous citric or hydrochloric acid, or both, of the known benzimidazoles derived from the optically active aldonic acids. Of these, the D-*ribo*, the D-*glucomethylo*, the L-*galacto*, and the D-*gluco*-L-*gala*-*octo* derivatives are described for the first time; the D-*arabo*, the D-*galacto* and the D-*gluco* derivatives have been prepared and recrystallized to constant rotation the better to compare the D- and L-forms of these substances. All twenty-three compounds, or all nineteen if we include only one member of a D and L pair, are in agreement with the rule stated above. From the laws of probability we should expect this rule to hold for other benzimidazoles of this class which may be prepared in the future.[2a] Consequently, this benzimidazole rule, like the well-known phenylhydrazide[3] and amide[4] rules, may be used to determine the configuration of the hydroxyl group on the carbon atom adjacent to the carboxyl group of an aldonic acid.

If the benzimidazole derivatives listed in Table I are arranged according to the configurations of the hydroxyl groups on the second and third carbon atoms, certain additional correlations will be noted. When these hydroxyl groups are in a *cis* relationship, as in compounds 1, 2, 5, 6, 9, 15, 17, 18, 19 and 20, the molecular rotations are of relatively low magnitude, the highest being +7350 in the case of the L-*mannomethylo* derivative. When the hydroxyl groups in question are in a *trans* relationship, the compounds may be separated further into two classes. The members of the one class, with the hydroxyl groups on the second, third and fourth carbon atoms in a + − − or − + + sequence (arabonic configuration), as in compounds 3, 4, 10, 11, 12, 22 and 23, have relatively high molecular rotations, between 11,750 and 14,750. The members of the other class, with the same three hydroxyl groups in a + − + or − + − sequence (xylonic configuration), seem to show no regularity in their molecular rotations, the values ranging from +1900 for the D-*glucomethylo* to +15,450 for the D-*xylo* derivative. As new benzimidazoles are prepared in the future for characterization and determination of configuration of other aldonic acids, additional regularities or irregularities in their rotations may become evident.

One of the authors (N. K. R.) desires to thank the Chemical Foundation of New York for a Research Associateship. The authors also express their indebtedness to Dr. Arthur T. Ness for carrying out the microanalyses.

Summary

1. The "benzimidazole rule" may be stated as follows: whenever the hydroxyl group on the second (or alpha) carbon atom of an aldonic acid is written on the right in the conventional projection formula, the rotation of the derived benzimidazole is positive and, conversely, when the hydroxyl group is written on the left, the rotation of

(2) Moore and Link, *J. Biol. Chem.*, **133**, 300 (1940); *J. Org. Chem.*, **5**, 637 (1940).

(2a) Note added June 10, 1942.—Dimler and Link [*J. Biol. Chem.*, **143**, 557 (1942)] have reported the rotation of the benzimidazole derivative of L-lactic acid ("sarco" lactic acid, with the configuration $CH_3-\underset{H}{\overset{OH}{C}}-COOH$) to be −33.4° in ethyl alcohol, and the rotation of the D-antipode to be +33.4° in the same solvent. Inasmuch as the L-derivative has a rotation of −14.7° in 5% aqueous citric acid [Moore, Dimler and Link, *Ind. Eng. Chem., Anal. Ed.*, **13**, 160 (1941)] the data for these derivatives of the simplest optically active α-hydroxy acid are in accord with the benzimidazole rule.

23	D-Gluco-L-gala-octo[r,s]	−			−44.7	−14,700

[a] A plus sign indicates that the hydroxyl group on the second carbon atom is on the right, and a minus sign indicates that the hydroxyl group is on the left, when the aldonic acid is written in the usual vertical projection formula. [b] The specific rotations reported by the present authors, either here or in a preceding paper (ref. *c*), were measured in a 4-dm. tube; the values are considered accurate to ±0.2°. Concentrations were 2 g. per 100 cc. of solution unless otherwise noted. The rotations reported by Moore and Link (ref. *h*) were observed at 25°. [c] Richtmyer and Hudson, THIS JOURNAL, **64,** 1609 (1942). [d] The rotations observed in the cases of the L-*erythro* and L-*gluco* benzimidazoles were slightly lower than the corresponding values in the D-series; this is due, probably, to the presence of a trace of a high dextrorotating, less soluble impurity (see ref. *c*). [e] This compound was prepared first by Moore and Link (ref. *h*, p. 307). The rotation was reported as −51°; no analysis was given. *Anal.* Calcd. for $C_{11}H_{14}N_2O_4$: C, 55.45; H, 5.92. The Structure of Di-*o*-nitrobenzylidene-dulcitol (1,3:4,6-Di-*o*-nitrobenzylidene-dulcitol)

BY RAYMOND M. HANN, W. T. HASKINS AND C. S. HUDSON

Tanasescu and Macovski[1] have assigned the structure of a 1,2:5,6-di-*o*-nitrobenzylidene-dulcitol to a substance which they obtained by condensing *o*-nitrobenzaldehyde and dulcitol through the agency of 75% sulfuric acid. They stated that the behavior exhibited by dulcitol in forming this supposed 1,2:5,6-diacetal was a general property of this hexitol and in their communication they assigned 1,2:5,6-diacetal structures to the dimethylene-dulcitol of Weber and Tollens[2] and the dibenzylidene-dulcitol of Emil Fischer,[3] although the original investigators did not designate 1,2:5,6 or any other structure for the diacetals which were described by them. No evidence justifying the assignment of a definitive structure to any of these diacetals appears in the experimental work reported by Tanasescu and Macovski. Recently it has been established that Fischer's dibenzylidene-dulcitol is 1,3:4,6-dibenzylidene-dulcitol[4] and that the dimethylene-dulcitol of Weber and Tollens is 1,3:4,6-dimethylene-dulcitol.[5] In the present paper we present conclusive evidence that the di-*o*-nitrobenzylidene-dulcitol of Tanasescu and Macovski possesses an analogous structure and is therefore 1,3:4,6-di-*o*-nitrobenzylidene-dulcitol and not 1,2:5,6-di-*o*-nitrobenzylidene-dulcitol as was assumed by its discoverers.

The di-*o*-nitrobenzylidene-dulcitol which was employed in the investigation was prepared by the method of Tanasescu and Macovski and melted at 261–262° (cor.) in substantial agreement with the melting point of 256–258° (presumably uncor.) reported by them. It formed a dibenzoate which melted at 320–321° (cor.); the melting point recorded for the dibenzoate by them was 310° (presumably uncor.). The diacetal was tested for the presence of contiguous hydroxyl groups by oxidation with lead tetraacetate in glacial acetic acid. It was concluded that they were absent, because of the slight consumption of oxidant (only 0.043 of a molecular equivalent in twenty-two hours); thus hydrolysis of the diacetal appears to be necessary before oxidation can proceed. If the compound possessed the structure proposed by Tanasescu and Macovski it would contain a glycol grouping at positions 3 and 4 and it should consume one molecular equivalent of lead tetraacetate upon oxidation. The acetal linkages therefore cannot be at positions 1,2 and 5,6 of the hexitol. Definitive proof of their location at positions 1,3 and 4,6 was obtained when it was found that dibenzoyl-di-*o*-nitrobenzylidene-dulcitol, upon simultaneous hydrolysis and acetylation in a 2% sulfuric acid acetylating mixture, formed the known 2,5-dibenzoyl-1,3,4,6-tetraacetyl-dulcitol. Previous experience has indicated that this reaction proceeds with the substitution of acetyl groups on those hydroxyl groups which are concerned in the acetal formation as evidenced by the formation of 2,5-dibenzoyl-1,3,4,6-tetraacetyl-dulcitol from 2,5-dibenzoyl-1,3:4,6-dibenzylidene-dulcitol[4] and of 1,6-dibenzoyl-2,3,4,5-tetraacetyl-dulcitol from 1,6-dibenzoyl-2,3,4,5-dibenzylidene-dulcitol.[6] Acyl migration of benzoyl groups has not been observed in the transformation of a dibenzoylated hexitol diacetal into a dibenzoyltetraacetyl-hexitol by this reagent. The isolation of the same dibenzoyl-tetraacetyl-dulcitol from the dibenzoate of di-*o*-nitrobenzylidene-dulcitol and from 2,5-dibenzoyl-1,3:4,6-dibenzylidene-dulcitol may thus be accepted as strong evidence that the acetal linkages in di-*o*-nitrobenzylidene-dulcitol are at positions 1,3 and 4,6 of the dulcitol moiety.

We express our appreciation to the Atlas Powder Company for furnishing a supply of dulcitol.

Experimental

1,3:4,6-Di-*o*-nitrobenzylidene-dulcitol.—This compound was prepared from dulcitol and *o*-nitrobenzaldehyde by the procedure described by Tanasescu and Macovski.[1] It was recrystallized from 40 parts of acetic acid or dioxane and formed yellow needles which melted at 261–262° (cor.). Tanasescu and Macovski recorded a melting point of 256–258°. The yield of product from 5 g. of dulcitol was 12.0 g. (98%).

Anal. Calcd. for $C_{20}H_{20}O_{10}N_2$: C, 53.57; H, 4.50; N, 6.25. Found: C, 53.51; H, 4.47; N, 6.17.

Failure of Lead Tetraacetate to Oxidize 1,3:4,6-Di-*o*-nitrobenzylidene-dulcitol.—To a solution of 0.1605 g. of the di-*o*-nitrobenzylidene-dulcitol in 80 cc. of glacial acetic acid, 12 cc. of 0.09108 *N* lead tetraacetate–glacial acetic acid solution (3.05 molecular equivalents) was added and the volume was adjusted to 100 cc. with glacial acetic acid. Analysis of 5-cc. aliquots at the expiration of fifteen minutes, one hour, and twenty-two hours, at 20°, showed that 0.016, 0.016 and 0.043 molecular equivalents of oxidant had been consumed; this slight reducing action was presumably due to a slow hydrolysis of the diacetal. A 1,2:5,6-di-*o*-nitrobenzylidene-dulcitol should reduce one molecular equivalent of lead tetraacetate; the failure of the substance to reduce lead tetraacetate indicated that it does not contain a glycol grouping, and therefore cannot possess the 1,2:5,6-diacetal structure proposed by Tanasescu and Macovski.

2,5-Dibenzoyl-1,3:4,6-di-*o*-nitrozylidene-dulcitol.—A solution of 1.0 g. of the di-*o*-nitrobenzylidene-dulcitol in 20 cc. of pyridine was cooled in an ice-bath and after the addition of 5.0 g. of benzoyl chloride, the reaction mixture was allowed to stand at room temperature (25°) for seventy-two hours. The dibenzoate, which precipitated in quantitative yield from the mixture upon the addition of water, was recrystallized from 15 parts of pyridine; it formed yellow prisms which were devoid of optical activity in pyridine solution and melted at 320–321° (cor.) on an electrically heated microscope stage. Tanasescu and Macovski recorded a melting point of 310° for the compound.

Anal. Calcd. for $C_{34}H_{28}O_{12}N_2$: C, 62.19; H, 4.30. Found: C, 62.16; H, 4.19.

2,5-Diacetyl-1,3:4,6-di-*o*-nitrobenzylidene-dulcitol.—The diacetate was obtained in quantitative yield by the acetylation of the di-*o*-nitrobenzylidene-dulcitol in pyridine solution with acetic anhydride. The substance was practically insoluble in boiling alcohol or chloroform, but could be recrystallized from 200 parts of acetic anhydride; it formed small needles which melted at 320–321° (cor.) on an electrically heated microscope stage.

Anal. Calcd. for $C_{24}H_{24}O_{12}N_2$: C, 54.13; H, 4.54; CH_3CO, 16.2. Found: C, 54.00; H, 4.66; CH_3CO, 16.0.

2,5-Ditosyl-1,3:4,6-di-*o*-nitrobenzylidene-dulcitol.—A solution of 1.0 g. of the di-*o*-nitrobenzylidene-dulcitol and 1.5 g. of *p*-toluenesulfonyl chloride in 25 cc. of pyridine was refluxed for two hours; the 1.0 g. of precipitate which formed on cooling the solution was separated by filtration and recrystallized from 50 parts of acetic anhydride to constant physical properties. The ditosylate formed light yellow needles which decomposed at 221–222° (cor.) and were optically inactive in pyridine.

Anal. Calcd. for $C_{34}H_{32}O_{14}S_2N_2$: C, 53.96; H, 4.26; S, 8.47. Found: C, 54.15; H, 4.31; S, 8.32.

2,5-Dibenzoyl-1,3,4,6-tetraacetyl-dulcitol from 2,5-Dibenzoyl-1,3:4,6-di-*o*-nitrobenzylidene-dulcitol.—A suspension of 2.0 g. of the dibenzoyl-di-*o*-nitrobenzylidene-dulcitol in 50 cc. of an acid acetylating solution, prepared by adding 1 cc. of concentrated sulfuric acid dropwise to an ice-cold mixture of 35 cc. of acetic anhydride and 15 cc. of acetic acid, was agitated until the suspended solid dissolved completely (two and one-half hours) and the solution was allowed to stand at 20° overnight. The mixture was then poured into 300 cc. of ice-cold water and the crystalline precipitate (1.0 g., 59%) which formed was separated by filtration and recrystallized twice from 25 parts of alcohol. It then showed a melting point of 157–158° (cor.), and a mixed melting point with authentic 2,5-dibenzoyl-1,3,4,6-tetraacetyl-dulcitol[4] showed no depression. The conversion of the dibenzoate of the di-*o*-nitrobenzylidene-dulcitol of Tanasescu and Macovski to 2,5-dibenzoyl-1,3,4,6-tetraacetyl-dulcitol is a definitive proof that the acetal linkages in the former compound are at positions 1,3 and 4,6 of the dulcitol molecule and not at the 1,2 and 5,6 positions as assumed by these investigators.

Anal. Calcd. for $C_{28}H_{30}O_{12}$: C, 60.21; H, 5.41. Found: C, 60.32; H, 5.49.

Summary

The di-*o*-nitrobenzylidene-dulcitol described by Tanasescu and Macovski is not oxidized by lead tetraacetate in glacial acetic acid and therefore cannot possess the structure of 1,2:5,6-di-*o*-nitrobenzylidene-dulcitol arbitrarily assigned to it by its discoverers. Its crystalline dibenzoate is converted to the known 2,5-dibenzoyl-1,3,4,6-tetraacetyl-dulcitol by treatment with an acid acetylating mixture, a fact which proves that the acetal linkages are at positions 1,3 and 4,6 of the dulcitol molecule. The compound of Tanasescu and Macovski is therefore 1,3:4,6-di-*o*-nitrobenzylidene-dulcitol and its structure is analogous to that of the diacetals which dulcitol forms with benzaldehyde and formaldehyde.

Isolation of a Copper Bearing Protein from Cow's Milk

BY WILLIAM L. DILLS AND J. M. NELSON

The presence of traces of copper in plant and animal tissues is attracting more and more attention. Not only is it being recognized as essential for the formation of hemin iron in animals[1] but it also has been found to play a role in the form of copper proteins as oxidases in plants.[2] Recently Saha and Guha[3] report the presence in animal tissues of a non-hemin iron associated with copper in the form of a copper–iron nucleoprotein complex.

Cow's milk contains from 0.09 to 0.17 mg. of inherent copper per liter.[4] Since the copper in milk appears not to be combined with the fat, it has been suggested that it probably occurs combined with the protein.[5] In the present study, a protein has been isolated from milk containing around 15% nitrogen and 0.19% copper. Dialysis experiments showed the copper in this protein to be non-ionic in form. Due to lack of sufficient material it was not possible to establish definitely that the protein isolated was absolutely pure, although comparing its copper content with those of other copper bearing proteins listed below suggests that it might have been mainly a single chemical substance. No attempt was made in the present study to see whether the milk copper protein was related in any way to the haemocuprein in blood.

Copper protein	Source	Copper, %
Laccase[6]	Juice of the lac-tree	0.15
Ascorbic acid oxidase[7]	Crook-neck squash	.15
Tyrosinase[8]	Lactarius piperatus	.23
Tyrosinase[2]	Common mushroom	.30
Tyrosinase[10]	Potato	.20
Haemocyanins[11]	Certain invertebrates	0.19–0.26
Haemocuprein[9]	Blood	0.34

No reactions were found in which the milk copper protein showed enzymatic activity. The authors are inclined to the opinion that this non-enzymatic activity cannot be attributed to denaturation during its isolation, although no definite proof for this conclusion can be offered. Other enzymes present in the milk, such as peroxidase, continued to accompany, in the active form, the milk copper-protein during several steps in the isolation process, without being inactivated. This conclusion is also favored by the fact that the process of isolating the milk protein was quite similar to those employed in the isolation of other copper proteins in their native condition. The isolation of tyrosinase from mushrooms and from potatoes, and ascorbic acid oxidase from squash, may be mentioned as examples.

It has been reported that milk shows a loss of antiscorbutic activity on standing.[12] Since ascorbic acid oxidase is a copper protein,[7] it was deemed worth while to test the milk copper protein for ascorbic acid oxidase activity. The result, however, proved to be negative. Likewise the milk copper protein showed no polyphenolase activity.

Experimental

Raw (unpasteurized) skimmed milk was used for the isolation of the copper bearing protein. Twenty-four to thirty-six hours had elapsed from the time the milk had been taken from the cow up to the time it was used. Forty liters of this milk contained before treatment about 1200 g. of solids, and this quantity of solid matter contained 4 mg. of copper.

The 40 liters of milk was made 0.3 saturated with ammonium sulfate by adding the salt gradually with stirring. The resulting mixture was allowed to stand overnight in a cool place. The clear supernatant liquid, formed on standing, was siphoned off and the remaining wet solids suspended in muslin bags and allowed to drain overnight. The liquid thus obtained, together with that obtained by siphoning, amounted to 33 liters (solution A), and contained 200 g. of solids (dry weight basis) exclusive of salts. The *p*H of the liquid was 6.6 and the 200 g. of solids contained 2 mg. of copper.

Solution A was made 0.7 saturated with ammonium sulfate, permitted to stand overnight, filtered and the filtrate discarded. The precipitate was dissolved in 4 liters of 0.1 *M* Na_2HPO_4, *p*H 8, yielding a clear reddish-yellow solution B. Solution B was next subjected to successive fractional precipitations with 0.2, 0.3, 0.4, 0.5 and 0.7 saturation with ammonium sulfate, dissolving the precipitates, formed in each precipitation, in 0.1 *M* Na_2HPO_4.

(12) Tauber, *Proc. Soc. Exptl. Biol. Med.*, **35**, 422 (1931).

In this way solutions C, D, E, F, and G, described in Table I, were obtained.

TABLE I

Soln.	Satn. amt. of $(NH_4)_2SO_4$ used	Vol., cc.	Color	Solids exclusive of salts, g.	Mg Cu	% Cu
C	0.2	295	Tan, turbid	17.0	0.12	0.0007
D	.3	370	Tan, turbid	56.2	.37	.0007
E	.4	520	Clear deep red	28.2	.24	.0008
F	.5	1340	Clear light red	73.0	1.00	.0014
G	.7	425	Colorless	17.0	0.10	.0006

Solution F, containing the highest percentage of copper, was selected for obtaining the copper protein in still higher state of purity. It was subjected to more fractional precipitation by means of varying concentrations of ammonium sulfate, following much the same procedure as that followed in obtaining the solutions described in Table I. The solutions thus obtained are described in Table II.

TABLE II

Soln.	Satn. amt. of $(NH_4)_2SO_4$ used	Vol., cc.	Color	Solids exclusive of salts, g.	Mg Cu	% Cu
H	0.6	1365	Deep red	68.60	0.64	0.0013
I	.7	510	Light red	3.10	.18	.0056
J	Saturated	320	Colorless	0.84	.10	.0120

Solution J, containing the highest percentage of copper, was selected for further purification of the copper protein. For this purpose 3 cc. of a 2.5% basic lead acetate solution was added to the 320 cc. of solution J. This operation was followed immediately by the addition of 30 cc. of cold acetone (cooled with solid carbon dioxide). The precipitate formed was removed by centrifugation and discarded since it contained no copper. To the remaining liquid 3 cc. more of the basic lead acetate solution was added followed by the addition of 30 cc. of cold acetone, the resulting precipitate removed by centrifugation and discarded. To the clear supernatant liquid, 30 cc. more of cold acetone was added and the precipitate M which was formed was separated by means of the centrifuge. Precipitate M, containing most of the copper, was suspended in 50 cc. of 0.1 *M* disodium phosphate, and allowed to stand for an hour, with intermittent stirring. Lead phosphate separated, was removed in the centrifuge, and the clear liquid thus obtained was dialyzed until free of phosphate. This dialyzed solution, M1, contained 0.23 g. of solids having 0.07 mg. or 0.03% of copper.

Further purification of the material contained in solution M1 was accomplished by adsorption to alumina at *p*H 6.8, followed by elution with 0.1 *M* disodium phosphate. After elution with 0.1 *M* disodium phosphate and dialysis, the resulting solution (solution O) was found to contain 0.14 g. of solids containing 0.06 mg. or 0.043% of copper.

Solution O was then treated dropwise with 2.5% basic lead acetate solution (about 2 cc.) at *p*H 7.5 until no further precipitate formed. The precipitate (P) was removed by centrifugation, and the clear supernatant liquid, containing no copper, discarded. The precipitate P was then suspended in 40 cc. of 0.1 *M* disodium phosphate and allowed to stand for three hours with intermittent stirring. The lead phosphate which had formed was removed in the centrifuge and the clear liquid dialyzed, yielding solution P1. The latter contained 0.04 g. of solids, containing 0.034 mg. or 0.085% of copper.

The contents of solution P1 were then subjected to adsorption to alumina followed by elution by means of 0.1 *M* disodium phosphate. The clear solution thus obtained was then dialyzed for four days at 0° yielding a solution Q, which contained 0.0088 g. of solids (dry basis). This solid matter, on analysis, was found to contain 0.017 mg. or 0.19% of copper and 15% of nitrogen.

Determination of Copper.—The method used for the copper determinations was that of Warburg as modified by Warburg and Krebs.[13]

Determination of Nitrogen.—Two samples from solution Q, one equivalent to 2 and the other to 2.8 mg. of solids, were analyzed for nitrogen by the micro-Kjeldahl method. Both determinations gave values for nitrogen content equal to 15%.

To ensure no contamination by extraneous copper, all the samples used for copper determinations were dialyzed against distilled water which had been redistilled in glass vessels.

Dry weights of the solids were determined by the method described by Lutz and Nelson.[14]

The Copper in the Protein Is Non-ionic.—A freshly prepared milk protein fraction, containing in solution 540 mg. of solids (dry basis), which in turn had a copper content of 0.0185%, was divided into two equal portions, (I) and (II). To one aliquot, (I), was added 0.05 mg. of copper ion($CuSO_4$) thereby bringing the copper in its solid matter (the latter determined by evaporating a given amount of the solution) up to 0.037%. The two solutions, (I) and (II), were dialyzed separately at 0° for six days, at *p*H 6.5. At the end of each of the first three days, the solutions were removed from the dialyzing bags, and samples taken for copper determinations. The remaining solutions were again placed in fresh bags[15] and the dialysis

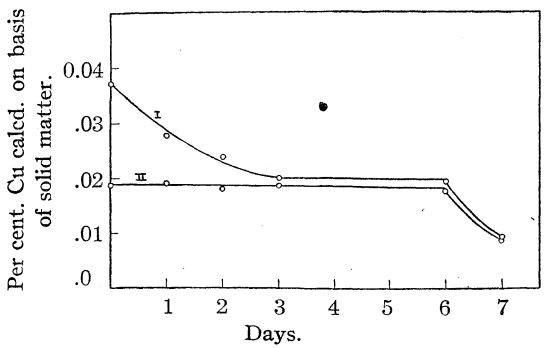

Fig. 1.

continued. As shown in Fig. 1, at the end of the three days of dialysis, the copper content of the solids in solution (I) had dropped to practically the same value (0.018%) as that of solution (II). On the other hand, the copper content of the solids in (II) remained at the original value (0.018%). In other words, the added ionic copper in solution (I) was lost in the dialysis while the copper belonging to the milk protein was not. From the end of the

(13) Warburg and Krebs, *Biochem. Z.*, **190**, 143 (1927).

(14) Lutz and Nelson, *J. Biol. Chem.*, **107**, 169 (1934).

(15) Visking sausage casing, made by the Visking Corporation, Chicago, was used in all dialyses.

third day up to the end of the sixth day of the dialysis, both solutions (I) and (II) lost no copper. Since most copper proteins lose copper in dilute acid solutions,[16] at the end of the sixth day both solutions were made *p*H 3.5 with hydrochloric acid, and under these conditions the copper belonging to the milk protein was lost in the dialysis.

The authors wish to express their thanks to the Borden Company for their generous supply of milk which made this study possible.

(16) Kubowitz, *Biochem. Z.*, **299**, 32 (1938).

Summary

A procedure is described for isolation of a copper bearing protein from cow's milk.

The copper in the protein is non-ionic and cannot be removed by dialysis at *p*H 6.5.

Up to the present, no chemical reactions have been found which are catalyzed by this milk protein.

Abnormal Grignard Reactions. XIV.[1] Sterically Hindered Aliphatic Carbonyl Compounds. IV. Methyl Triethylcarbinyl Ketone and its Bromomagnesium Enolate

BY FRANK C. WHITMORE AND C. E. LEWIS[2]

An attempt to prepare 2-methyl-3,3-diethyl-2-pentanol by the reaction of methylmagnesium bromide with triethylacetyl chloride was unsuccessful. The action of the Grignard reagent with the acid chloride caused the evolution of one-half mole of methane for each mole of Grignard reagent used. The liquid products were methyl triethylcarbinyl ketone and bis-triethylacetyl-methane.

$$\underset{\text{I}}{Et_3CCOCl} + MeMgBr \longrightarrow \underset{\text{II}}{Et_3CCOCH_3} + MgBrCl \quad (1)$$

$$\underset{\text{II}}{} + MeMgBr \longrightarrow \underset{\text{III}}{Et_3CCOCH_2MgBr} + CH_4 \quad (2)$$

$$\underset{\text{III}}{} + \underset{\text{I}}{} \longrightarrow \underset{\text{IV}}{Et_3CCOCH_2COCEt_3} \quad (3)$$

Such a series of reactions is not new. Methyl-*t*-butylneopentylacetyl chloride[3] and dineopentylacetyl chloride[4] have both been found to give good yields of the corresponding methyl ketones with methylmagnesium bromide. These ketones give bromomagnesium enolates which react as true Grignard reagents.[3,4,5] Fuson and co-workers[6] had earlier shown that mesityl alkyl ketones give halomagnesium enolates which also react as true Grignard reagents.

Methyl triethylcarbinyl ketone gave 94% enolization and no addition when run in the Grignard machine[7] with methylmagnesium bromide. Thus, it is the lowest molecular weight ketone known which gives only enolization with the methyl Grignard reagent. The bromomagnesium enolate of methyl triethylcarbinyl ketone acts as a true Grignard reagent. Treatment of the enolate with carbon dioxide and formaldehyde gave the corresponding beta-keto acid and beta-ketol, respectively.

The few reactions studied indicate that the carbonyl of methyl triethylcarbinyl ketone is almost as sterically hindered as that of methyl methyl-*t*-butylneopentylcarbinyl ketone,[3] methyl dineopentylcarbinyl ketone[4] and acetomesitylene.[6] This is interesting when it is remembered that the reactions of pinacolone indicate only slight steric influence on the carbonyl. Thus, the remarkable difference in steric influence of the methyl and ethyl groups is clearly demonstrated.

We thank R. S. George of this Laboratory for his help on this paper.

Experimental

The Grignard reagents for this work were prepared in the usual manner. All fractionations were done with the usual type of column[8] having 12–18 theoretical plates. The triethylacetyl chloride was prepared by standard reactions as follows:

$$EtCO_2Pr \xrightarrow{EtMgBr} Et_3COH \xrightarrow{HCl} Et_3CCl \xrightarrow{Mg} Et_3CMgCl \xrightarrow{CO_2} Et_3CCO_2H \xrightarrow{SOCl_2} Et_3CCOCl$$

The chloride had b. p. 98° (65 mm.); $n^{20}D$ 1.4438.

Action of Methylmagnesium Bromide with Triethylacetyl Chloride (I).—To a solution of 157 g., 0.95 mole, of triethylacetyl chloride in ether was added 2 moles of 1.52 molar methylmagnesium bromide. About 0.5 mole of gas was evolved per mole of Grignard reagent added. The material was worked up as usual. Fractionation gave 45.6 g., 0.32 mole, or 34% of methyl triethylcarbinyl ketone (II), b. p. 90° (60 mm.), $n^{20}D$ 1.4318–9, and 39.9 g., 0.15 mole, or 32% of bis-triethylacetyl-methane (IV), b. p. 135–6° (8 mm.), $n^{20}D$ 1.4769–70. The *2,4-dinitrophenylhydrazone* and the *oxime* of the *monoketone*, both of which were prepared with difficulty, melted at 93–94.5° and 97–101°, respectively. The diketone gave a chelate copper derivative with ammoniacal cupric acetate. The derivative was a brilliant purple compound with m. p. 143–144°. The monoketone gave 94% enolization and no addition when run in the Grignard machine with methylmagnesium bromide.[7]

3-Keto-4,4-diethylhexan-1-ol.—To 16 g., 0.65 gram-atom, of magnesium in 200 cc. of dry ether was added 70 g., 0.65 mole, of ethyl bromide. When the reaction was completed 80 g., 0.56 mole, of methyl triethylcarbinyl ketone was added. The reaction mixture was stirred for twenty-four hours. Formaldehyde gas was then passed into the reaction flask until an excess had been added. The reaction mixture became viscous as the reaction proceeded, and heating was necessary to keep it fluid enough for adequate stirring. The material was worked up as usual. Fractionation gave 37.7 g., 0.22 mole, or 34% of 3-keto-4,4-diethylhexan-1-ol, b. p. 86° (2 mm.), $n^{20}D$ 1.4554–8; alpha-naphthylurethan, m. p. 120–122°. *Mol. wt.* Calcd. for $C_{10}H_{20}O_2$: mol. wt., 172. Found: mol. wt. (cryoscopic), 171.

3-Keto-4,4-diethylhexanoic Acid.—To 0.07 mole of ethylmagnesium bromide was added 10 g., 0.07 mole, of methyl triethylcarbinyl ketone. The reaction mixture was stirred three hours. Gas was evolved during the reaction. An excess of carbon dioxide gas was passed into the reaction mixture with continuous stirring. The material was worked up as usual. The oil layer was extracted with dilute sodium carbonate. The alkaline extract was acidified with sulfuric acid and the solid beta-keto acid was filtered off. The yield was 2.5 g., 0.014 mole, or 21%. The acid, m. p. 63–65°, decomposed on heating to give carbon dioxide and methyl triethylcarbinyl ketone.

Anal. Calcd. for $C_{10}H_{18}O_3$: neut. equiv., 186. Found: neut. equiv., 183, 185, 190.

Summary

1. The presence of three ethyl groups on the carbon adjacent to a carbonyl group has been found to have a pronounced influence on the reactions of the carbonyl.

2. The reaction of methyl triethylcarbinyl ketone with a Grignard reagent gives an enolate which reacts as a true Grignard reagent.

3. Methyl triethylcarbinyl ketone is the lowest molecular weight aliphatic ketone found to give only enolization with the methyl Grignard reagent.

Grignard Reactions. XV.[1] Sterically Hindered Aliphatic Carbonyl Compounds. V. Enolization Studies. I

BY FRANK C. WHITMORE AND L. P. BLOCK[2]

Methylmagnesium halides have long been used as reagents for the determination of active hydrogen in organic compounds. Early work on such determinations has been reviewed by Courtot,[3] who pointed out that the method is applicable to the study of keto-enol tautomerism.

Kohler and co-workers[4] devised a new type of apparatus with which one can determine the amount of gas evolved with the methylmagnesium halide, and also measure the amount of reagent used in the reaction.

Enolization studies until recently have been confined almost entirely to ketones containing an aromatic group. The reason for this is probably because hindered ketones which would contain conjugated double bonds in the enol form almost invariably give enolization.[5] Thus acetomesitylene and related compounds[6] have been studied rather extensively.

A definite correlation between the branching in aliphatic ketones and the amount of enolization given with the methyl Grignard reagent is not yet entirely clear. The literature indicates that such ketones show little tendency to give enolization with simple Grignard reagents. However, several new aliphatic sterically hindered ketones[7] prepared in this Laboratory give as high as 100%

enolization and no addition with the methyl Grignard reagent.

The present work was undertaken to extend the studies on enolization of branched aliphatic ketones with the methyl Grignard reagent. The compounds studied are not sufficiently branched to prevent the addition reaction entirely. The results of the studies are given in Table I.

The Grignard machine used in this work is essentially the same as the one used by Kohler.[4] The amount of enolization was calculated from the amount of gas evolved by the action of methylmagnesium chloride with the carbonyl compound. The excess methylmagnesium chloride present was determined by observing the amount of gas evolved on the addition of water to the reaction flask. The amount of addition reaction was taken as the difference between the number of moles of methylmagnesium chloride added and the total moles of gas evolved by the enolization reaction and by the decomposition of the excess reagent. This is based on the assumption that the amount of condensation is negligible. The reaction flask was always heated to ensure optimum reaction conditions. The apparatus was enclosed in a case to protect it from changes in temperature caused by air currents. The usual corrections were made for the gas evolved due to the presence of moisture in the reaction flask.

TABLE I

Compound	Percentage Enolization	Addition
Methyl isopropyl ketone	0	100
Ethyl isopropyl ketone	0	100
Methyl *t*-butyl ketone	5	86
Ethyl *t*-butyl ketone	9	86
Pentamethylacetone	0	49
Methyl pinacolyl ketone	48	47
Ethyl pinacolyl ketone	62	33
Methyl *s*-butyl ketone	32	..
Propyl *s*-butyl ketone	53	40
2,2-Dimethyl-4-ethyl-3-hexanone	5	19
2,2,4,6,6-Pentamethyl-3,5-heptadione	27/2	129/2

From the above measurements it can be seen that the amount of enolization and addition is dependent upon the steric influence of the groups around the carbonyl. This was first pointed out by Conant and Blatt.[8] The carbonyls of methyl and ethyl isopropyl ketones are not sufficiently hindered to retard the normal addition reaction and allow time for the competing enolization reaction. It is interesting to note that although pentamethylacetone gave only 49% addition, no enolization took place. This recalls the failure of phenyl dineopentylcarbinyl ketone to give any enolate.[7b] All of the other ketones investigated gave both enolization and addition.

The steric influence of the ethyl group is shown to be much greater than that of the methyl group. The carbonyls of 2,2-dimethyl-4-ethyl-3-hexanone and 2,2,4,6,6-pentamethyl-3,5-heptadione are sterically hindered to such an extent that the sums of the enolization and addition reactions are 24% and 78%, respectively, of the calculated amount assuming complete reaction. It is thus apparent that steric hindrance in carbonyl compounds may retard, and in some cases prevent, either enolization or addition or both.

We thank R. S. George of this Laboratory for his help.

Experimental

The procedure used in making the enolization measurements has been described above. The compounds run in the Grignard machine were prepared by conventional procedures. The compounds, their physical properties and the method of preparation are given very briefly.

Methyl isopropyl ketone: dichromate oxidation of methylisopropylcarbinol; b. p. 92° (740 mm.) and $n^{20}D$ 1.3886.

Ethyl isopropyl ketone: dichromate oxidation of ethylisopropylcarbinol; b. p. 111–113° (740 mm.) and $n^{20}D$ 1.3975.

Methyl *t*-butyl ketone: reaction of acetyl chloride with *t*-butylmagnesium chloride; b. p. 103.5° (735 mm.) and $n^{20}D$ 1.3974.

Ethyl *t*-butyl ketone: oxidation of olefins; b. p. 124.5° (730 mm.) and $n^{20}D$ 1.4049.

Pentamethylacetone: diisopropyl ketone by reaction with sodamide and dimethyl sulfate; b. p. 135° (735 mm.) and $n^{20}D$ 1.4074.

Methyl pinacolyl ketone: ozonolysis of 3,4,5,5-tetramethyl-2-hexene; b. p. 144° (740 mm.).

Ethyl pinacolyl ketone: reaction of methyl-*t*-butylacetyl chloride with ethylmagnesium bromide; b. p. 87° (50 mm.) and $n^{20}D$ 1.4221.

Methyl *s*-butyl ketone: dichromate oxidation of methyl-*s*-butylcarbinol; b. p. 115.5° (733 mm.) and $n^{20}D$ 1.3988.

Propyl *s*-butyl ketone: dichromate oxidation of propyl-*s*-butylcarbinol; b. p. 154° (73 mm.) and $n^{20}D$ 1.4132.

2,2-Dimethyl-4-ethyl-3-hexanone: dichromate oxidation of 2,2-dimethyl-4-ethyl-3-hexanol; b. p. 120° (150 mm.) and $n^{20}D$ 1.4240.

2,2,4,6,6-Pentamethyl-3,5-heptadione: oxidation of triisobutylene; b. p. 91° (16 mm.) and $n^{20}D$ 1.4320.

Summary

1. Eleven aliphatic ketones have been analyzed in the Grignard machine with methylmagnesium chloride.

(8) Conant and Blatt, THIS JOURNAL, **51**, 1227 (1929).

2. Pentamethylacetone gave no enolization and 49% addition with the methyl Grignard reagent.

3. It has been confirmed that steric hindrance around the carbonyl retards both the enolization and addition reactions. Thus 2,2-dimethyl-4-ethyl-3-hexanone gave 5% enolization and 19% addition with the methyl Grignard reagent.

Carboxylation. III. The Peroxide-catalyzed Reaction of Oxalyl Chloride with the Side-chains of Aralkyl Hydrocarbons. A Preliminary Study of the Relative Reactivity of Free Radicals

BY M. S. KHARASCH, STEPHEN S. KANE[1] AND HERBERT C. BROWN

It has been suggested that the photochemical carboxylation[2] of the paraffin hydrocarbons with oxalyl chloride proceeds in the following manner.

Primary process

$$(A)\quad (COCl)_2 \xrightarrow{h\nu} 2\cdot COCl$$

and/or

$$(A')\quad (COCl)_2 \xrightarrow{h\nu} \cdot COCOCl + Cl\cdot$$

Secondary processes

$$(B)\quad \cdot COCl \longrightarrow CO + Cl\cdot$$

and/or

$$(B')\quad \cdot COCOCl \longrightarrow 2CO + Cl\cdot$$
$$(C)\quad RH + Cl\cdot \longrightarrow R\cdot + HCl$$
$$(D)\quad R\cdot + (COCl)_2 \longrightarrow RCOCl + \cdot COCl$$
$$(E)\quad \cdot COCl \longrightarrow CO + Cl\cdot$$

The experimental evidence upon which this mechanism is based has already been discussed.[3]

Study of the carboxylation of a number of representative hydrocarbons indicates that this reaction is general for the paraffins, the cycloparaffins and their halogen derivatives. However, attempts to extend this photochemical reaction to the carboxylation of the side chains of representative aralkyl hydrocarbons have thus far met with little success.

This observation can be interpreted in either of two ways: (1) the aromatic hydrocarbons containing side-chains are opaque to the radiation necessary for the chain-initiating step, which is the photolysis of the oxalyl chloride (A); or (2) the aralkyl free radicals which are formed (C) require a relatively high energy of activation to break the carbon-to-carbon bond in oxalyl chloride (D).

Considerable support for the belief that the first of these interpretations is of importance in the photochemical carboxylation reaction was furnished by a study of the carboxylation of cyclohexane in the presence of various diluents. Carbon tetrachloride, chloroform, and similar inert diluents exert but small effects upon the rate of carboxylation of cyclohexane. The slight decrease observed, approximately 20%, can easily be accounted for by decreased concentration of the reactants. On the other hand, the presence of comparable quantities of benzene in the reaction mixture causes a five-fold drop in the rate. It is evident, therefore, that in the *photochemical* carboxylation of the aralkyl hydrocarbons, the poor yields are largely due to the effect of the aromatic nucleus upon the radiation required to initiate the carboxylation reaction.

It is noteworthy, however, that this interpretation does not eliminate the second of the two possibilities mentioned above: namely, that the low degree of reactivity[4] of the aralkyl free radicals might also contribute to the sluggishness of the aralkyl hydrocarbons in the photochemical carboxylation reaction under discussion. The observation that the carboxylation reaction could be initiated thermally in the dark by the addition of several mole per cent. of an organic peroxide[3] offered a means of investigating this question.

Accordingly, a study of the peroxide-catalyzed carboxylation of a number of aralkyl hydrocarbons was undertaken. It is significant that low yields (about 5–10%) of the corresponding acid chlorides were obtained with such representative aralkyl hydrocarbons as toluene, *m*-xylene, and mesitylene. In these reactions, the inhibitory ef-

(1) This paper is part of a dissertation submitted by Stephen S. Kane to the Faculty of the Division of Physical Sciences of the University of Chicago in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

(2) The authors have adopted the term carboxylation to describe the introduction of the chloroformyl (—COCl) group; see the first paper of this series (reference in footnote 3).

(3) Kharasch and Brown, THIS JOURNAL, **64**, 329 (1942).

(4) That is, low compared with the highly reactive normal alkyl free radicals.

fect exerted by the nucleus in the photochemical reaction is absent, since cyclohexane readily participates in the peroxide-catalyzed carboxylation reaction in the presence of as much as 50 mole per cent. of benzene. Therefore, the authors are led to the conclusion that the low reactivity of the aralkyl free radicals (resulting in comparatively short chain lengths) must be an important factor in the low conversions noted in the reaction of oxalyl chloride with aralkyl hydrocarbons. In other words, the reaction of the comparatively inactive aralkyl free radicals with oxalyl chloride (D) is so slow that the free radicals have greatly increased opportunity to disappear by participation in side reactions.[5]

An interesting question which is raised by these considerations is that of the relative reactivity of free radicals. If the organic free radicals differ markedly in chemical reactivity (as the results of the carboxylation studies indicate), it would be of considerable interest then to obtain information concerning their relative reactivity. This paper describes some preliminary experiments to establish a method for carrying out such studies.

There is at hand considerable experimental evidence to support the conclusion that the decomposition of the diacyl peroxides in solution proceeds through the formation of organic free radicals as intermediates.[6] The free radicals formed in this way may either react with the solvent or disappear by disproportionation, combination or other side reactions. The relative amount of any species of free radical which disappears by reaction with the solvent depends largely upon the nature of that solvent. Hence, by a judicious choice of solvent it should be possible to divide the free radicals into two groups which differ markedly in the extent of their attack upon the solvent in question. Obviously, these two groups could be further subdivided by the use of other solvents. In this way, a large number of organic free radicals might finally be arranged in the order of their relative activities.

As a preliminary study of the practicability of the method outlined, an investigation of the decomposition of several representative diacyl peroxides in carbon tetrachloride was undertaken.[7] Appreciable quantities of methyl, *n*-propyl and isopropyl chlorides were isolated from the reaction products of carbon tetrachloride, with diacetyl, di-*n*-butyryl and di-isobutyryl peroxides, respectively. On the other hand, no *t*-butyl or benzyl chloride could be found in the corresponding thermal decomposition products of di-trimethylacetyl or di-phenylacetyl peroxides in carbon tetrachloride. These results are interpreted, in accordance with the argument previously outlined, to mean that the methyl, *n*-propyl and isopropyl free radicals are of a higher order of reactivity than the benzyl or *t*-butyl free radicals. To the group of more active free radicals phenyl may be added, since dibenzoyl peroxide decomposes in carbon tetrachloride solution to form phenyl chloride and hexachloroethane[8]; triphenylmethyl, which crystallizes unchanged from carbon tetrachloride solution,[9] evidently belongs to the less reactive class.

These results are summarized in Table I.

TABLE I

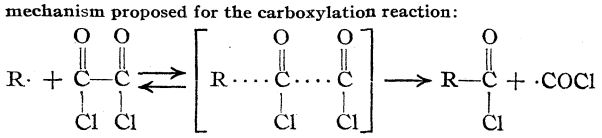
PRELIMINARY RESULTS ON A RELATIVE REACTIVITY SERIES OF ORGANIC FREE RADICALS

	Free radical	
Class I[a] More reactive free radicals	phenyl	$C_6H_5\cdot$
	methyl	$CH_3\cdot$
	n-propyl	$CH_3CH_2CH_2\cdot$
	isopropyl	$(CH_3)_2CH\cdot$
Class II[a] Less reactive free radicals	benzyl	$C_6H_5CH_2\cdot$
	t-butyl	$(CH_3)_3C\cdot$
	triphenylmethyl	$(C_6H_5)_3C\cdot$

[a] The arrangement of the free radicals within each of the two groups has not yet been verified experimentally.

It is perhaps too early to draw any theoretical

(5) This reactivity of the free radical must be intimately connected with the energy required for the formation of the activated complex, as indicated in the following equation, which is a more detailed representation of the processes involved in step D of the mechanism proposed for the carboxylation reaction:



That is, a free radical of "high" reactivity must require considerably less energy for the formation of the activated complex (shown in brackets above) than a free radical of "low" reactivity.

(6) Hey and Waters, *Chem. Rev.*, **21**, 169 (1937).

(7) Selection of carbon tetrachloride as the solvent in these preliminary experiments was dictated by a number of observations made at various times in this Laboratory that the decomposition of peroxides in this substance proceeds smoothly in accordance with the following equations:

$$(RCOO)_2 \longrightarrow 2R\cdot + 2CO_2$$
$$R\cdot + CCl_4 \longrightarrow RCl + Cl_3C\cdot$$
$$2Cl_3C\cdot \longrightarrow C_2Cl_6$$

The possibility of isolating and identifying both the organic chloride and the hexachloroethane offers a simple means of checking the results of any experiment. *Cf.* Böeseken and Gelissen, *Rec. trav. chim.*, **43**, 869 (1924); Kharasch, Kane and Brown, THIS JOURNAL, **63**, 526 (1941).

(8) Böeseken and Gelissen; unpublished work of Kharasch and Walling.

(9) Gomberg and Cone, *Ber.*, **37**, 2036 (1904).

conclusions from the chemical structures of the two groups of radicals. However, it is of considerable interest that this division of the free radicals closely follows the relative electronegativity series[10] of organic groups.[11] Thus the more reactive radicals are related to the more electronegative groups and the less reactive radicals to the less electronegative groups.

At first glance, it may appear somewhat surprising to find that the electronegativity series of organic groups, set up by a study of the hydrolytic splitting of unsymmetrical organomercurials, should correspond so closely to the arrangement of the free radicals according to their relative reactivities, as determined by the ease with which they react with carbon tetrachloride. Yet this correlation cannot be entirely fortuitous. The factors which tend to give an organic group such as phenyl or methyl a relatively high place in the electronegativity series, *i. e.*, which increase the tendency of the group to exist as a negative ion, probably also give the corresponding free radical a relatively high affinity for electrons.[12] Consequently, the free radical would fall into the more reactive class. By an obvious extension of the argument, the less electronegative groups may be identified with the less reactive free radicals. Whether other factors cause minor divergences between the two series remains to be settled by further experimentation. Until more definite information is available, however, the comprehensive classification of organic groups in the electronegativity series can probably be used as a rough indication of the relative reactivity of the organic free radicals. It is hoped to elaborate on these ideas in subsequent publications from this Laboratory.

Experimental Part

Attempt to Carboxylate the Aralkyl Hydrocarbons Photochemically.—A typical procedure utilizing toluene will be described. A mixture of 16.8 g. (0.2 mole) of toluene and 12.7 g. (0.1 mole) of oxalyl chloride was placed in an elongated flask and illuminated under the conditions previously described for the carboxylation of the paraffinic hydrocarbons.[13] After twenty hours, the reaction mixture was fractionated. Less than 0.4 g. of higher boiling material was isolated. With ammonia this material gave only a slight test for acid chloride groups. There was some indication of the presence of dibenzyl. Similar results were obtained with *m*-xylene, mesitylene, *p*-chlorotoluene, tetralin and β-methylnaphthalene. Under similar conditions, in a reaction mixture of cyclohexane and oxalyl chloride, approximately 50% of the oxalyl chloride is converted to the carboxylic acid derivative.

Photochemical Carboxylation of Cyclohexane in Presence of Diluents.—A number of reaction mixtures were made up using 0.1 mole of oxalyl chloride, 0.1 mole of cyclohexane and 0.1 mole of the diluent (benzene, carbon tetrachloride, chloroform, methylene chloride); these were illuminated for twenty hours by the standard procedure.[13] The yields of cyclohexane carboxylic acid chloride from those reaction mixtures containing the halogenated methanes as diluents were only slightly less (approximately 80%) than those obtained from reaction mixtures free from diluents. On the other hand, the yield of the acid chloride from the reaction mixture containing benzene as diluent was markedly lower—only 15% of the usual yield.

Peroxide-Catalyzed Carboxylation of the Aralkyl Hydrocarbons.—In the main, the experimental procedure was similar to that used for the peroxide-catalyzed carboxylation of the paraffin hydrocarbons.[14] A few modifications were, however, introduced. The hydrocarbon, oxalyl chloride, and dibenzoyl peroxide (3.0, 2.0, and 0.08 moles, respectively) were refluxed for twenty-four hours. The solution was then fractionated through a small column. The oxalyl chloride and most of the unreacted hydrocarbon was removed at ordinary pressure; the higher boiling material was fractionated under reduced pressure (approximately 20 mm.). Particular care was taken to separate benzoyl chloride (formed by the reaction of the peroxide on oxalyl chloride) from the acid chloride produced in the course of the reaction. The acid chloride thus obtained was identified by its boiling point, its neutral equivalent and the melting point of either the corresponding acid, or amide.

Under these experimental conditions, toluene produced an 8% yield of phenylacetyl chloride, *m*-xylene a 10% yield of 3-methylphenylacetyl chloride, mesitylene a 7% yield of 3,5-dimethylphenylacetyl chloride,[15] and *p*-chlorotoluene a 5% yield of 4-chlorophenylacetyl chloride.

No appreciable quantity of the carboxylic acid derivatives could be obtained from diphenylmethane, *p*-nitrotoluene and β-methylnaphthalene.[16]

Di-phenylacetyl Peroxide.—Phenylacetyl chloride, b. p. 99–103° (16 mm.), was prepared from phenylacetic acid and phosphorus pentachloride. The peroxide was made by slowly running 5 g. of the acid chloride into a vigor-

(10) Kharasch and Marker, THIS JOURNAL, **48**, 3131 (1926); Kharasch and Flenner, *ibid.*, **54**, 674 (1932). For leading references to the application of the electronegativity theory to the interpretation of organic reactions, see Kharasch, Reinmuth and Mayo, *J. Chem. Ed.*, **13**, 7 (1936).

(11) The term "groups" has been substituted for the original term "radicals." At the time the electronegativity series was set up, no particular significance had yet been attached to the term radical. At the present time, however, "radical" is used chiefly to refer to *neutral* organic aggregates and it seems advisable thus to restrict the use of this term.

(12) The correlation which exists between the electronegativity series and dipole moment data [Brown, THIS JOURNAL, **61**, 1483 (1939)] lends further support to the view that the position of an organic group in the electronegativity series is a measure of the affinity of the bonding carbon atom for electrons.

(13) Kharasch and Brown, *ibid.*, **64**, 331–332 (1942).

(14) Kharasch and Brown, *ibid.*, pp. 332–333.

(15) M. p. of the amide (not previously reported) is 154–154.5°. *Anal.* Calcd. for $C_{10}H_{13}ON$: N, 8.59. Found: N, 8.66.

(16) It may be recalled that these substances also failed to undergo the peroxide-catalyzed chlorination reaction with sulfuryl chloride [Kharasch and Brown, THIS JOURNAL, **61**, 2142 (1939)].

ously stirred solution of 4 g. of sodium peroxide in 100 cc. of water. The temperature was carefully maintained slightly below 5°. After thirty minutes, the granules formed were filtered off and immediately added to carefully purified carbon tetrachloride.[17] When the mixture was warmed, a vigorous reaction occurred which kept the carbon tetrachloride refluxing for several minutes. The carbon tetrachloride was then removed by distillation under ordinary pressure. The residue, 7 g., distilled from 115–200° (23 mm.). The combined distillate was washed with aqueous alkali and steam distilled. The solid obtained was identified as dibenzyl by its melting point of 52–53° (verified by the melting point of a mixture with an authentic sample). Acidification of the aqueous extract yielded a white crystalline precipitate, which, after recrystallization from water, was identified as phenylacetic acid from its m. p. of 75–76° and its neut. eq. of 140. Neither benzyl chloride nor hexachloroethane could be found in the reaction product.

Di-trimethylacetyl Peroxide.—Trimethylacetic acid was prepared by the Grignard reaction[18] and was transformed into its acid chloride by the use of benzoyl chloride.[19] The peroxide was prepared by the action of sodium peroxide on a solution of the acid chloride in ethyl ether.[20] This peroxide decomposed readily in warm carbon tetrachloride. Neither *t*-butyl chloride nor hexachloroethane could be identified in the reaction mixture.

From the less volatile constituents of the reaction product was obtained a liquid which distilled at 166–168°. It contained chlorine (28.54%) and appeared to be a C_8 derivative. Further identification was not attempted; the substance is probably formed by secondary reactions of the *t*-butyl free radicals.

Diacetyl, Di-*n*-butyryl, and Di-isobutyryl Peroxides.—These peroxides were prepared by methods similar to that described for di-trimethylacetyl peroxide. Their decomposition in hot excess carbon tetrachloride proceeded smoothly. From the reaction mixtures the corresponding alkyl chlorides[21] were isolated in yields of 10 to 20% and the presence of equivalent quantities of hexachloroethane was demonstrated.

(17) The carbon tetrachloride used in this work was washed with potassium permanganate solution, dried over Drierite, and distilled through an efficient column.

(18) "Organic Syntheses," Coll. Vol. I, p. 510.

(19) Brown, THIS JOURNAL, **60**, 1325 (1938).

(20) Procedure modified from that described by Gambayan, *Ber.*, **42**, 4008 (1909); see also Kharasch, Kane and Brown, THIS JOURNAL, **63**, 527 (1941).

(21) It is of considerable interest that *only* *n*-propyl chloride was obtained in the decomposition of *n*-butyryl peroxide and *only* isopropyl chloride was obtained from isobutyryl peroxide. This result suggests that the organic free radicals in solution do not isomerize to any appreciable extent. This point is of considerable importance for the further development of the chemistry of free radicals in liquid systems and has been discussed in detail in an earlier publication [Kharasch, Kane and Brown, *ibid.*, p. 526].

Summary

1. A number of aralkyl hydrocarbons (toluene, *m*-xylene, mesitylene, *p*-chlorotoluene) react with oxalyl chloride in the presence of dibenzoyl peroxide to form the corresponding acid chlorides. (The reaction is $RC_6H_4CH_3 + (COCl)_2 \rightarrow RC_6H_4CH_2COCl + CO + HCl$.) The conversions in the instances mentioned are low; they average 5–10% under conditions such that the carboxylation of representative paraffinic hydrocarbons is practically complete. Under the same conditions, some other aralkyl hydrocarbons (β-methylnaphthalene, diphenylmethane, *p*-nitrotoluene) are not appreciably carboxylated.

2. None of the aralkyl hydrocarbons were observed to undergo photochemical carboxylation with oxalyl chloride to any appreciable extent.

3. An important factor in the inhibition of the photochemical reaction of oxalyl chloride with the aralkyl hydrocarbons appears to be the effect of the aromatic nucleus on the radiation required for the photolysis of the oxalyl chloride, the chain-initiating step.

4. The low conversions in the peroxide-catalyzed reaction are ascribed to the comparatively low reactivity of the aralkyl free radicals, which results in a sluggish reaction of these intermediates with the oxalyl chloride.

5. Means of investigating the relative reactivity of aralkyl free radicals are discussed. Preliminary results indicate that the free radicals phenyl, methyl, *n*-propyl and isopropyl are more reactive than the benzyl, *t*-butyl and triphenylmethyl.

6. There is an interesting correspondence between the order of the free radicals when arranged according to their reactivities and the electronegativity series of organic groups. A plausible interpretation of this correspondence is advanced.

CHICAGO, ILL. RECEIVED MARCH 18, 1942

Some Mono- and Di-alkyl Ethers of Stilboestrol[1]

BY E. EMMET REID AND EDITH WILSON

For a study of the variation of the physical and pharmacological properties of the members of a series, the mono- and di-alkyl ethers of stilboestrol[2] (*trans*-4,4′-dihydroxy-α,β-diethylstilbene) seemed to be desirable. The parent compound has an intense physiological activity which can be determined readily and comparatively accurately. The dimethyl ether and several of the esters are known to have similar activity. The nonyl. The hexyl, octyl and decyl di-ethers have extremely low activity. The lower mono-ethers are 8 to 15 times as active as the corresponding di-alkylated compounds.[3] The figures given are the weights in gamma of the compounds which equal one rat unit as found by the Allan–Doisy method. The rat unit is the minimum amount of the estrogen required to produce cornification of the vaginal smear in 50% or more of a group of ten cas-

[a] The m. p. is 112–114° when it is recrystallized from aqueous alcohol and 116–117.5° from benzene–petroleum ether or from methylene chloride. *Anal.* Methoxyl calcd., 11.0; found, 10.9. [b] Sondern, Sealey and Kartsonis give 121–123°, 119–121° and 93–94° as the melting points of dimethyl, diethyl and dipropyl ethers, *Endocrinology*, **28**, 849 (1941). [c] Stilboestrol by same method 0.3 γ. [d] The mono-ethyl may have water of crystallization at times. One sample from aqueous alcohol, m. p. 105.5–107°, lost 6.0% on drying, calcd. for 1 water 5.7%, and then m. p. 99.5°.

mono-alkyl ethers appeared to be particularly interesting since, having one phenolic hydroxyl open, they might be expected to resemble the parent substance more closely than the dialkyl ethers.

We have prepared the mono- and di-ethers of stilboestrol using the normal alkyls from methyl to octadecyl. The melting points, activities and analyses are given in Table I and the melting points are plotted in Fig. 1.

In each series the estrogenic activity decreases as the alkyl increases in size, though in the mono-ethers there is not much change from amyl to

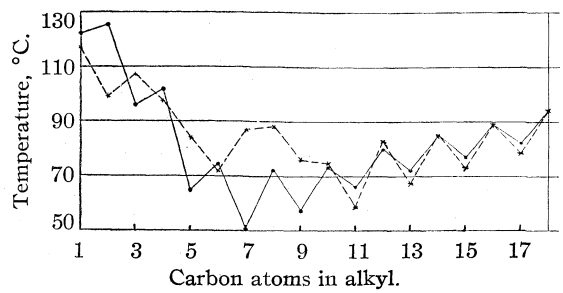

Fig. 1.—Melting points of the mono- and di-alkyl ethers of stilboestrol: —*——*—, mono-ethers; —●——●—, di-ethers.

trated female rats. The melting points of the di-ethers show regular alternation; those of the mono- do so from the decyl up.

Experimental

These ethers were prepared in the conventional manner by heating stilboestrol in alcoholic solution with alkali and the required alkyl bromide (or iodide for the methyl). The preparation of the di-ethers presented no difficulty. These (particularly the high alkyl di-ethers) are much less soluble than the corresponding mono-ethers and can be purified by two or three recrystallizations from alcohol. To get rid of traces of mono-ether, alkali was usually added in the first recrystallization. The yields were high, usually above 90%. The mono-ethers proved to be difficult to prepare. The exclusive formation of a mono-ether could not be obtained by any attempted modification of the alkylation procedure. With less than one equivalent of alkyl halide and alkali the product always contained di-ether along with unreacted stilboestrol. Although stilboestrol is soluble in 0.1 *N* aqueous alkali and the mono-ethers only in alcoholic alkali, the separation, theoretically simple, is tedious in practice. Since the solubilities change greatly with the size of the alkyl, each mono-ether required special study. In some cases the separation was repeated as many as 10 times before a satisfactory product was obtained. For the monomethyl ether 0.4 *N* potassium hydroxide in 50% alcohol was used; the higher mono-ethers required stronger alcohol.

The monomethyl ether was recrystallized from 70% ethanol and then distilled *in vacuo*, b. p. 185–195° (0.3 mm.).

Summary

1. The normal mono- and di-alkyl ethers of stilboestrol from methyl to octadecyl have been prepared.

2. Their estrogenic activities have been determined.

The Effect of Temperature on the Validity of Hudson's Rules of Isorotation

BY WALTER KAUZMANN*

Over thirty years ago, Hudson[1] proposed his "rules of isorotation" for use in calculating the optical rotatory powers of carbohydrate derivatives. Although these have since been of great use to the carbohydrate chemist in determining the structure of new derivatives, their reliability has been seriously reduced by the existence of a number of definite instances, notably but not solely in the mannose series, in which calculated rotations fail to agree at all satisfactorily with those observed. It has been felt that if the source of these discrepancies could be determined, the value of the rules as a tool in carbohydrate structure determination might be considerably enhanced. So far, the effects of different solvents and concentrations[2] and of wave length[3] on carbohydrate rotations have been studied, but the behavior of the anomalous cases with respect to these variables has not led to any clue as to the true nature of the difficulty. Previous theoretical considerations,[4] based upon the physical origin of optical rotation have led us to suspect that the real clue to the problem is to be found in temperature dependence of the rotation. In this paper we shall give the reasoning which leads to this conclusion and show by means of experimental data that there is indeed good reason to believe that this is actually the case.

In a previous paper[4] it was shown by relatively simple, essentially geometrical arguments that Hudson's rules may be expected to be valid if two conditions are fulfilled. (1) The vicinal actions between any two groups whose locations, conformations and relative orientations in a molecule are fixed must be unaffected by change in the spacial configurations of other groups in the molecule.[5] In order to state this more explicitly,

* Westinghouse Research Fellow. The experimental work in this paper was carried out at Frick Chemical Laboratory, Princeton University, Princeton, New Jersey.

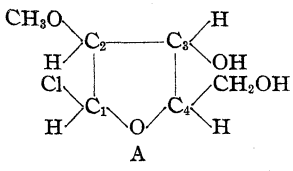
(4) E. Gorin, W. Kauzmann and J. Walter, *J. Chem. Phys.*, **7**, 327 (1939).

(5) Vicinal actions are the optical interactions between groups in a molecule, the sum total of which results in the molecule's being able to rotate the plane of polarized light. For further details, see W. Kauzmann, J. Walter and H. Eyring, *Chem. Rev.*, **26**, 339 (1940).

consider the molecule shown as A. This condition then requires that the contribution to the optical rotation due to the interactions of, say, the methoxyl on C_2 and the chlorine on C_1 shall not be influenced by the configurations of the groups about C_3 and C_4, either directly, through the "higher order perturbations" considered in reference 5, or indirectly through, for instance, solvent and steric effects[6] on the methoxyl which might depend on the orientation of the groups about C_3. (2) The second condition which must be fulfilled in order that Hudson's rules may be valid is that the framework of the molecule have a plane of symmetry, such that when the configurations about any two asymmetric centers in the compound are simultaneously reversed, all of the contributions to the optical activity resulting from the interactions of the groups about the two centers with one another change their signs but not their absolute values. Referring again to compound A, this condition means that if we change the configurations about C_1 and C_2, the new *average* conformation which the molecule assumes must be merely the mirror image of the old one as far as C_1 and C_2 by themselves are concerned. In a plane, five-membered ring with tetrahedral carbon atoms this will be automatically true; in a puckered, six-membered ring this will only be true if the various possible "chair conformations" occur in equal amounts, and similarly if "bed conformations" are also present, so that the *average* conformation of the ring will be symmetrical.



A

As far as the vicinal actions themselves are concerned, condition (1) will very probably be well satisfied in the sugars. Evidence for this has been discussed elsewhere.[7] On the other hand, the effect of steric repulsions, solvent effects and other structural factors may not be such as to allow the molecule to conform with these requirements, and it is probably here that we should seek the reason for the observed discrepancies to the rules, as well as the failure of optical superposition rules more generally.

Now let us inquire what will be the effect of an increase in the temperature on these structural factors which tend to invalidate Hudson's rules. First of all, solvent effects are known to tend to decrease with increasing temperature, so that any trouble from this source must also decrease with increasing temperature. Secondly, increasing temperatures tend more or less to equalize the frequency of occurrence of all possible conformations of a molecule. This will tend to reduce the effects of "higher order steric interactions" which tend to invalidate the rules. It will also probably tend to equalize the amounts of the two possible chair forms of a six-membered ring, and it will tend to do the same for the bed forms. In short, except for the purely optical interactions (which would probably not lead to serious discrepancies anyway), an increase in the temperature should tend to bring about those conditions which result in Hudson's rules being valid.

Experimental.—The rotations of a number of sugar derivatives were measured at different temperatures and wave lengths. Since there was nothing particularly striking about the rotatory dispersion, however, these data will not be given here. The results at three temperatures for Na D light are given in Table I for various sugar derivatives. These derivatives were supplied by Dr. E. Pacsu, of Princeton University, or were prepared by standard procedures starting with materials furnished by him. The α-methyl mannofuranoside was supplied by Dr. A. Scattergood. The author wishes to express his gratitude for these materials.

The rotations recorded in Table I have been corrected for changes in the densities of the solutions on which the measurements were made. In all cases, rotations at room temperature were taken both before and after the readings at high temperatures in order to make sure that the observed changes with temperature were reversible. Practically all of the rotations changed very nearly linearly with the temperature in the range studied here.

Discussion.—It is obvious from the data of Table I that perhaps the conformations of, and certainly the solvent effects on, many of the sugars change with temperature sufficiently to cause, in some instances, very considerable changes in the optical rotation. Thus we see that there is no real justification for applying Hudson's rules indiscriminately to data obtained at room temperature, and serious errors might be expected from such a course.

(6) By the solvent effect here is meant the difference between the rotation in a given solvent and the rotation at the same temperature in the dilute vapor or (neglecting the internal field effect given by the factor $(n^2 + 2)/3$—see ref. 5) in an inert solvent.

TABLE I

VARIATION IN THE OPTICAL ROTATIONS OF CARBOHYDRATE DERIVATIVES WITH TEMPERATURE AND SOLVENT

Substance	Solvent	Concn., g./100 ml.	$[M]^{20}D$	$[M]^{70}D$	$[M]^{80}D$
α-Glucose pentaacetate	$C_2H_2Cl_4$	5.07	394.5	394.5	394.5
β-Glucose pentaacetate	$C_2H_2Cl_4$	4.98	16	25	26.5
α-Mannose pentaacetate	$C_2H_2Cl_4$	3.12	190.5	223	230.5
β-Mannose pentaacetate	$C_2H_2Cl_4$	5.04	−97.5	−90	−88.5
α-Methyl glucoside tetraacetate	$C_2H_2Cl_4$	4.80	439	461	465.5
α-Methyl glucoside tetraacetate	C_6H_6	5.30	623	583	(578)
β-Methyl glucoside tetraacetate	$C_2H_2Cl_4$	5.17	−80	−58.5	(−55)
β-Methyl glucoside tetraacetate	C_6H_6	4.85	−83.5	−73	(−70.5)
α-Methyl mannoside tetraacetate	C_6H_6	4.94	160.5	180	182.5
α-Methyl mannoside tetraacetate	$C_2H_2Cl_4$	5.06	221	218.5	(219)
α-Methyl glucopyranoside	H_2O	5.12	302	301.5	301
β-Methyl glucopyranoside	H_2O	5.00	−64.5	−61	−60.5
α-Methyl mannopyranoside	H_2O	4.93	150.5	152.5	153
α-Methyl mannofuranoside	H_2O	5.26	212	199	196.5

In order to see if our previous theoretical considerations are valid, values of $2A$ for the pentaacetates of glucose and mannose in acetylene tetrachloride were calculated at 20, 70 and 80°. The results are given in Table II. It is apparent that by increasing the temperature from 20 to 80° the agreement with Hudson's rules is improved by nearly 50%, and since at even the highest temperature the rotations were still rapidly changing with the temperature, it is easy to believe that at sufficiently high temperatures the agreement would be very nearly complete.

In Table III the values of $2A_{OMe}$ are given as determined from the methyl glucoside tetraacetates in benzene and acetylene tetrachloride as solvents. It is apparent that as the temperature is increased, the discrepancy due to the very large solvent effects here is considerably reduced. It is also apparent from Table I that when there are large differences in the rotation of one substance in different solvents, these differences tend to be reduced at higher temperatures, in accordance with a rule previously given.[7]

In the previous paper[4] it was recalled that there is a corollary to Hudson's rules[8] which predicts that, for instance, the difference in the rotations of α-methyl glucoside and α-glucose should be the same as that between α-methyl mannoside and α-mannose. It was shown that this corollary should and does tend to be very accurate when the partial rotations being compared (here A_{OH} and A_{OMe}) are due to optically similar groups, but that when optically dissimilar groups are compared (such as CH_3—O and CH_3—CO—O)[9] no good agreement should be expected, as is indeed found to be the case (Table VI, ref. 4). In Table IV this conclusion is tested further, and it is again seen that when dissimilar groups are involved, no general improvement in the discrepancy is found at higher temperatures. Even the apparent convergence for the glucose derivatives here is only temporary, since at the higher temperatures the rotations appeared to be still changing rapidly enough so that at about 100° their differences will probably become equal and then start to diverge.

The considerable temperature effects on the rotation of α-methyl mannofuranoside in water is of significance in connection with the poor agreement found for the mannofuranosides with respect to Hudson's rules.[10]

The temperature variation of the optical rotation offers a method for evaluating the F factors introduced by Pacsu[10,11] in order to improve the agreement with observed rotations of the rotations calculated using Hudson's rules: these factors at any given temperature should be given by the difference between the limiting rotation at high temperatures (insofar as the frequency of occurrence of all conformations is actually equalized at high temperatures) and the rotations at the given temperature. Pacsu[11] originally suggested that the factors arise from new types of isomerism, perhaps involving chair and bed forms of the sugar rings. More recently Scattergood and Pacsu[11] have suggested that they arise through "different

(8) C. S. Hudson, THIS JOURNAL, **47**, 271 (1925).

(9) By optically similar groups it is meant that the electronic transitions which play a predominant role in determining the contribution to the rotatory power by these groups acting as chromophores (see ref. 5, p. 351) are similar. Thus the first excited states in hydroxyl and methoxyl groups involve predominantly the same orbitals on the oxygen atom, so the groups are similar to one another in this sense, while the first excited state in the acetyl group involves the double bond of C=O, so this group is dissimilar to hydroxyl and methoxyl.

(10) A. Scattergood and E. Pacsu, THIS JOURNAL, **62**, 903 (1940).

(11) E. Pacsu, *ibid.*, **61**, 2669 (1939).

orientation [about the C—O bond] of the hydroxyl groups in the α- and β-isomers of certain sugars." In the light of the observed large solvent effects for some substances, it does not, however, seem profitable to ascribe all of these variations to any one such physical cause.

When the temperature dependence of the rotations of β-methyl mannoside tetraacetate in benzene and in acetylene tetrachloride and of β-methyl manno-pyranoside and -furanoside in water are known, it will be possible, with the data presented here, to find out if the values of $2A$ for these compounds, too, tend to agree any better at higher temperatures with the corresponding values of the glucose derivatives, just as we have shown is the case for the pentaacetates of the two sugars.

TABLE II

(FROM DATA ON THE PENTAACETATES)

t, °C.	$2A_{OAc}$(glucose)	$2A_{OAc}$(mannose)	Discrepancy
20	378.5	288	90.5

20	519	706.5	187.5
70	519.5	656	136.5
80	(520.5)	(648.5)	(128)

TABLE IV

(FROM DATA ON SOLUTIONS IN ACETYLENE TETRACHLORIDE)

t, °C.	α-Me gluc. tetraac.-α gluc. pentaac.	$-(\beta$-Me gluc. tetraac.-β gluc. pentaac.)	α-Me mann. tetraac.-α mann. pentaac.
20	44.5	96	−30
70	66.5	83.5	−43
80	71	82	(−48)

Conclusion.—From the evidence presented here it should be clear that for many of the derivatives of the carbohydrates there is a considerable dependence of the rotation on the temperature, so that structural influences on Hudson's rules must be important in affecting their validity, and it is not at all unlikely that these structural influences lie at the root of the major part of the observed discrepancies in those rules. It would be very desirable if, when a test is being made concerning the validity of Hudson's rules in a series of compounds, measurements of the effect of the temperature on the rotations as well as the rotations themselves were made. Then, if the rotations were found to be in disagreement with the rules, the influence of the temperature in making the rules better or worse could be ascertained, and we would gain considerably more insight into the origin of the discrepancy.

It would also be very interesting to have such temperature data for the menthyl amines investigated by Read,[12] since these should show superposition in the ordinary van't Hoff sense at higher temperatures. Similarly, the recent application of superposition rules to the γ-lactones by Hudson[13] should become more exact at higher temperatures, and no division of the γ-lactones into two classes should be necessary. By working at higher temperatures, superposition rules would undoubtedly be found to apply to many new types of compounds, possibly even to some open chain compounds.

Summary

It is shown from theoretical considerations that the clue to the discrepancies observed on the application of Hudson's rules of isorotation to the calculation of the optical rotations of carbohydrates is probably to be found in the temperature variation of the optical rotation for these compounds. Experimental measurements are made which support the prediction that as the temperature is increased, the rules should with certain restrictions tend to become more and more accurate.

Complex Ions. III. A Study of Some Complex Ions in Solution by Means of the Spectrophotometer[1]

BY ROBERT K. GOULD AND W. C. VOSBURGH

A modification of Job's method[2] of continuous variations for the identification of compounds formed in solution has been described by Vosburgh and Cooper.[3] The modification made it possible to apply the method to cases in which more than one compound is formed from the same components. It was thought desirable to test the method further on a wider variety of systems, and to investigate some more systems to determine how many different complex ions are formed from the same components.

The modified method consists of making a number of mixtures of equimolar solutions of the two reactants and measuring the optical densities of the mixtures at certain pre-selected wave lengths. From the density of each mixture is subtracted the density calculated by the law of mixtures assuming no reaction. The difference, Y, is a maximum or minimum for the mixture in which the two reactants have been brought together in the proportions in which they react.

When more than one compound is formed, particular wave lengths can be selected as the most favorable for obtaining evidence of the various compounds. Different wave lengths lead to different composition values for a maximum or minimum in Y when more than one compound is formed. If Y is a maximum or minimum at the same composition for all wave lengths, the probability is that only one compound is formed. The shapes of the curves obtained when the results are plotted help in deciding whether or not more than one compound is formed.

Theoretical

In the course of this work the question arose as to the effect of a second equilibrium in the system being investigated. For example, suppose that substance A in addition to reacting with B in accordance with the equation

$$A + nB \rightleftarrows AB_n \qquad (1)$$

reacts also with the substance D

$$A + rD \rightleftarrows AD_r \qquad (2)$$

Let us suppose that D is present in the equimolar solutions of A and B so that when these are mixed in varying proportions all mixtures contain the same concentration of D, and further that this concentration is large enough to remain practically constant in spite of Reaction 2. Then the concentration of AD_r is proportional to the concentration of A and can be set equal to Lc_1. The following equations can be set up, in which c_1, c_2 and c_3 are the concentrations of A, B and AB_n, respectively, and x is the volume of solution B added to the volume $1 - x$ of solution A to give unit volume of the mixture.

$$c_1 = M(1 - x) - c_3 - Lc_1$$
$$c_2 = Mx - nc_3$$
$$c_1c_2^n = Kc_3$$

On differentiation of each of these equations, setting dc_3/dx equal to zero, and solving the six equations simultaneously, the result is that when c_3 is a maximum, $n = x/(1 - x)$. This is the same as when there is no second equilibrium corresponding to Reaction 2.

If the compound AD_r is colored, but D is colorless, the difference Y between the actual optical density of the solution and the density calculated for no reaction is given by

$$Y = l(\epsilon_1 + \epsilon_4 L)\, c_1 + \epsilon_2 c_2 + \epsilon_3 c_3 - \epsilon_1 M(1 - x)/(1 + L) - \epsilon_2 Mx - \epsilon_4 LM(1 - x)/(1 + L)$$

in which ϵ_1, ϵ_2, ϵ_3 and ϵ_4 stand for the extinction coefficients of the substances A, B, AB_n, and AD_r, respectively, and l is the length of the path of light through the solution. Differentiating and equating dc_3/dx to zero shows that Y is either a maximum or minimum when c_3 is a maximum. Consequently, when a second substance is present that enters into reaction with Reactant A, the method of continuous variations may be used without the necessity of correcting for the second reaction. It should be noted that this is true only when the concentration of the second reactant is practically constant throughout the series of mixtures. Another restriction not mentioned is that the activity coefficients, if not cancelling from the equilibrium equations, must be held constant by constant ionic strength.

(3) Vosburgh and Cooper, THIS JOURNAL, **63**, 437 (1941).

Ferric and Thiocyanate Ions.—Bent and French[4] and also Edmonds and Birnbaum[5] have shown that in dilute solutions the only compound formed from ferric and thiocyanate ions is the ion $FeCNS^{++}$. It was of interest to see whether or not the method of continuous variations would lead to the same conclusion.

Solutions containing iron(III) and thiocyanate ions, both at a concentration of 0.02 *M*, and other solutes as shown below, were prepared

Iron(III) ion solution, *M*	Thiocyanate solution, *M*
0.02 $Fe(NH_4)(SO_4)_2$	0.02 NH_4CNS
.06 H_2SO_4	.16 $(NH_4)_2SO_4$
.06 $(NH_4)_2SO_4$	

First, mixtures of the two solutions were made in the proportions of 1:1, 1:2 and 1:3 and their absorption spectra were measured by means of a Coleman Double Monochromator spectrophotometer. The slit width was 30 mμ, and by means of plungers in the sample tubes the length of the path of light through the solution was reduced to 2 mm. The spectra are shown in Fig. 1, in which the density values for the 1:1 mixture have been multiplied by 0.5 and those for the 1:2 mixture by 0.75. The curves are of the same shape and

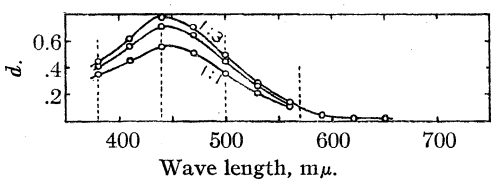

Fig. 1.—Absorption spectra of solutions containing iron(III) and thiocyanate ions in the ratios 1:1, 1:2 and 1:3. Dotted lines represent arbitrarily selected wave lengths.

are in agreement with the conclusion of Bent and French that only a single compound of low stability is formed. No particular wave lengths can be selected in accordance with the rules of Vosburgh and Cooper in this case, since the curves do not cross. A series of mixtures was therefore measured at four arbitrarily selected wave lengths. The values of *Y* as defined above were plotted against *x*, the volume of 0.02 *M* thiocyanate added to the volume $(1 - x)$ of 0.02 *M* iron(III) ion solution. The resulting curves are shown in Fig. 2. The curves all have a broad maximum in the vicinity of $x = 0.5$, indicating a compound $FeCNS^{++}$ which is considerably dissociated in solution, in agreement with Bent and French. There is no indication of the existence of any other compound under these conditions.

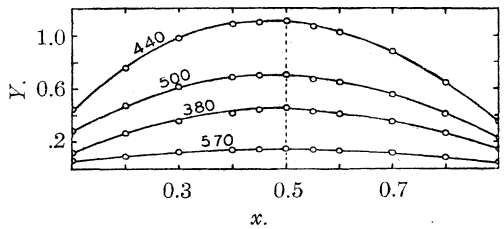

Fig. 2.—Iron(III) and thiocyanate ions; volume $(1 - x)$ of 0.02 *M* iron(III) ion solution plus *x* of 0.02 *M* thiocyanate ion solution.

It is shown in the theoretical part that the existence of a complex ion of iron and sulfate ions[6] would not affect this conclusion provided the sulfate ion concentration is held constant.

Iron(II) Ion and *o*-Phenanthroline.—Ferrari[7] has presented evidence that iron(II) ion forms only one complex ion with α,α′-dipyridyl in solution. Jaeger and van Dijk,[8] prepared solid complex sulfates with iron(II) ion and α,α′-dipyridyl in the proportions 1:1, 1:2 and 1:3. However, when it was attempted to convert these into chlorides by treatment with barium chloride, only the tridipyridyl iron(II) chloride was obtained. Vosburgh and Cooper[3] found evidence of three complex ions formed from nickel ion and *o*-phenanthroline in solution. Because of the similarity of α,α′-dipyridyl and *o*-phenanthroline, it was of interest to investigate compound formation between iron(II) ion and *o*-phenanthroline by the method of continuous variations.

A 0.004 *M* solution of ferrous ammonium sulfate was prepared by weighing the required amount of reagent grade material. A small amount of sodium bisulfite was included to prevent oxidation. A 0.004 *M* phenanthroline solution was prepared similarly from *o*-phenanthroline obtained from the G. Frederick Smith Chemical Co.

The two solutions were mixed in varying proportions, and the optical densities of the resulting solutions were measured at wave lengths 400, 500, 540 and 570 mμ with a length of path of 2 mm. The wave lengths were selected arbitrarily to cover the region of the spectrum absorbed by the iron $Fe(phen)_3^{++}$. The results are shown in Fig. 3, in which density is plotted against compo-

sition. Since the two original solutions were practically colorless, the density is equal to the difference Y. At all four wave lengths the maximum comes at composition 0.75, and each of the curves consists practically of two intersecting straight lines, indicating only one compound, $Fe(phen)_3^{+++}$, which is very stable.

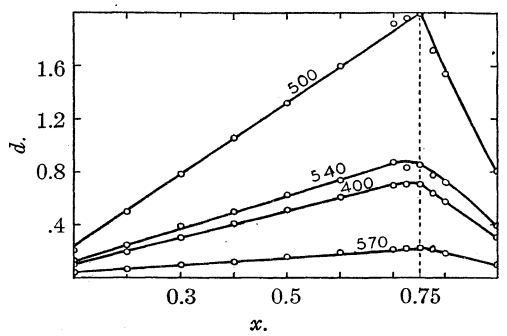

Fig. 3.—Iron(II) ion and *o*-phenanthroline; volume $(1 - x)$ of 0.004 M iron(II) sulfate solution plus x of 0.004 M *o*-phenanthroline solution.

The difference between the reaction of ferrous ion with phenanthroline and that of nickel ion is striking. There is another important difference between the ferrous phenanthroline and the three nickel phenanthroline ions: the ferrous phenanthroline ion is diamagnetic[9] while all three of the nickel phenanthroline ions are paramagnetic.[10]

The formation of a series of two or more complex ions from the same components is rather common. Bjerrum[11] has pointed out that this is to be expected theoretically, though the theory provides that in extreme cases a compound AB_n might be considerably more stable than the possible intermediate compounds. Bjerrum has investigated several series of ammines and ethylenediamine complex ions, finding in each case a series AB, AB_2, . . ., AB_n in which the stability decreases as n increases.

The ferrous phenanthroline complex ion seems to be exceptional in this respect, and the ion $Ni(CN)_4^=$ which is also diamagnetic seems to be another exception. Cambi, Cagnasso and Tremolada[12] have presented evidence from magnetic measurements that hydrated nickel cyanide, $Ni(CN)_2 \cdot nH_2O$ is in reality composed of the paramagnetic cation $Ni(H_2O)n^{++}$[7] and the diamagnetic anion $Ni(CN)_4^=$. Whether these two diamagnetic compounds are special cases or examples of a general rule can be determined by the examination of other ferrous and nickel complex ions.

Nickel and Dithio-oxalate Ions.—A highly colored complex salt formed from potassium dithio-oxalate and a nickel salt was shown by Jones and Tasker[13] to have the composition $K_2Ni(C_2O_2S_2)_2$. Cox, Wardlaw and Webster[14] showed that all atoms in the complex ion $Ni(C_2O_2S_2)_2^=$ are co-planar. According to Pauling, co-planar nickel compounds should be diamagnetic, and potassium nickel dithio-oxalate has been shown to conform.[15] Therefore, it was of interest to see if more than one complex ion formed from nickel and dithio-oxalate ions could be identified.

A 0.004 M solution of nickel sulfate was prepared by dilution of a stock solution made from reagent grade material and standardized gravimetrically. A 0.004 M solution of potassium dithio-oxalate was prepared by weight. The dithio-oxalate was obviously somewhat impure, and the concentration of the solution was somewhat lower than 0.004 M. However, it was felt that purification or standardization was unnecessary, since the main object was to see whether or not evidence could be found for more than one compound, and there was little doubt as to the formula of the known compound.

The two solutions were first mixed in the proportions of one part by volume of nickel sulfate solution to one, two, and three parts of dithio-oxalate solution. The optical densities were measured as described for the iron(III) and thiocyanate ions, and corrected to a nickel ion concentration of 0.001 M. The resulting absorption spectra are shown in Fig. 4. Since the curves do not cross in the visible region, wave lengths 440, 500 and 590 mμ were arbitrarily selected for the

measurement of the usual series of mixtures. The results of these measurements are shown in Fig. 5. The straight lines, with the points of intersection all coming at about the same composition, indicate the formation of only one compound, which is quite stable. The difference between the 1:2 and 1:3 curves of Fig. 4 might appear to indicate some dissociation of the ion $Ni(C_2O_2S_2)_2^=$, but the error in concentration of the dithio-oxalate solution is responsible for at least part of the difference.

Copper and Aminoacetate Ions.—Copper aminoacetate, $Cu(OOCCH_2NH_2)_2$, was found by Ley[16] to be little dissociated in solution and was early recognized as a chelate compound.[17] Borsook and Thimann[18] found evidence for four different compounds of copper ion and aminoacetic acid or aminoacetate ion, two in the more acid solutions, one in neutral solution and a fourth in alkaline solutions. These were formed from either 1.5 or 2 moles of aminoacetic acid per gram atom of copper. Ley[19] has recognized the possibility of the stepwise dissociation of copper aminoacetate to give the ion $Cu(OOCCH_2NH_2)^+$. Application of the method of continuous variations to the study of compound formation from copper sulfate and sodium aminoacetate showed that two compounds were formed, with ratios of copper ion to aminoacetate ion of 1:1 and 1:2, respectively.

A 0.02 M copper sulfate solution was prepared from recrystallized material and standardized by iodometric determination of the copper. A 0.02 M sodium aminoacetate solution was prepared by weighing the twice recrystallized acid and adding the equivalent quantity of standard sodium hydroxide solution.

Absorption spectra were measured of a solution 0.01 M with respect to both copper sulfate and sodium aminoacetate, and of a solution 0.004 M with respect to copper sulfate and 0.08 M with respect to sodium aminoacetate. Circular sample tubes of 16 mm. diameter were used in the spectrophotometer. The optical densities of the second solution were corrected by multiplication by 2.5, and the data for the two solutions and for 0.01 M copper sulfate solution were plotted to give Fig. 6.

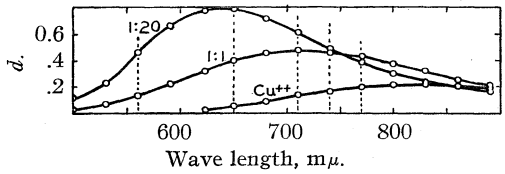

Fig. 6.—Absorption spectra of 0.01 M copper sulfate solution and solutions containing copper and aminoacetate ions in ratios of 1:1 and 1:20, with 0.01 M total copper.

The wave lengths indicated by the dotted lines in Fig. 6 were selected for use in the further investigation of the system. Measurement of a series of mixtures of the 0.02 M solutions described above at these wave lengths gave the data shown in Fig. 7. The Y-values for all of these curves were determined by the subtraction of the calculated densities for no reaction. This is wrong theoretically[3] for the curves with the maximum at $x = 0.67$. However, experience has shown that the position of the maximum is usually changed only a little when the correct subtraction is made instead of the one made in this case.

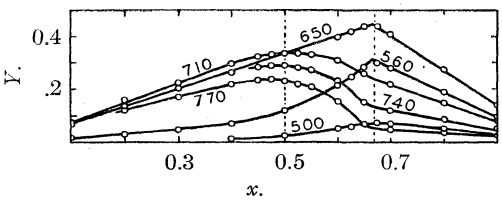

Fig. 7.—Copper and aminoacetate ions; volume $(1 - x)$ of 0.02 M copper sulfate solution plus x of 0.02 M sodium aminoacetate solution.

Figure 7 gives evidence of two compounds, the ion $Cu(OOCCH_2NH_2)^+$ postulated by Ley[19] and the neutral compound $Cu(OOCCH_2NH_2)_2$. It is interesting that the curve for wave length 650 mμ consists of two intersecting straight lines. Straight lines are generally found when only a single compound of high stability is formed. The straight line on the left for 650 mμ is the result of a coincidence, since it happens that at 650 mμ the molar extinction coefficient of the first compound is very nearly half that of the second.

(16) Ley, *Z. Elektrochem.*, **10**, 954 (1904).

(17) (a) Tschugaeff, *J. prakt. Chem.*, [2] **75**, 162 (1907); (b) Ley, *Ber.*, **42**, 354 (1909).

(19) Ley, *Z. anorg. allgem. Chem.*, **164**, 387 (1927).

At other wave lengths this is not true, and the curves for 500 and 560 mμ indicate the existence of a second compound, as do also the right-hand parts of the curves for 740 and 770 mμ. The wave length 740 mμ is the most favorable one for showing the existence of the first compound, and for this wave length the maximum in the *Y*-curve comes nearest to $x = 0.5$.

Nickel and Aminoacetate Ions.—Ley[19] has prepared a nickel aminoacetate and has found it to have the composition $Ni(OOCCH_2NH_2)_2 \cdot 2H_2O$. The method of continuous variations shows that in addition a compound is formed from three aminoacetate ions to one nickel ion. The new compound is presumably an anion in which the nickel has a coördination number of six.

A 0.2 *M* nickel sulfate solution was standardized gravimetrically. A 0.2 *M* sodium aminoacetate solution was prepared as described above in connection with the copper aminoacetate system. The two solutions were mixed in the ratios 1:1, 1:2 and 1:3, and the absorption spectra of the resulting mixtures measured in the circular sample tubes. The spectra corrected to a concentration of 0.1 *M* total nickel with the assumption of Beer's law are shown in Fig. 8. An outstanding feature

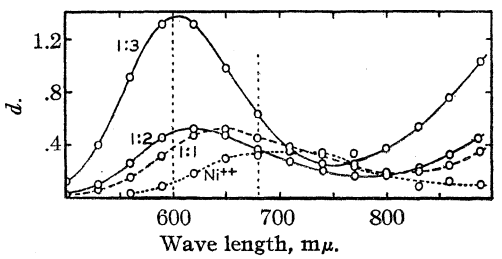

Fig. 8.—Absorption spectra of 0.1 *M* nickel sulfate solution and solutions containing nickel and aminoacetate ions in ratios of 1:1, 1:2 and 1:3, with 0.1 *M* total nickel.

of these curves is the large difference between the curve for the 1:3 ratio and the others. This curve lies above the others over so large a portion of the spectrum that it is difficult to select wave lengths that can be used to investigate the existence of other than the compound highest in aminoacetate content. In the region where the 1:1 curve is higher than the 1:3 curve, the curve for

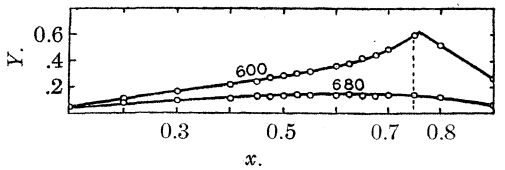

Fig. 9.—Nickel and aminoacetate ions; volume $(1 - x)$ of 0.2 *M* nickel sulfate solution plus x of 0.2 *M* sodium aminoacetate solution.

nickel ion almost coincides with the 1:1 curve, making this region useless. This system is one in which none but the compound highest in aminoacetate content can be determined with assurance. Wave length 600 mμ is favorable for showing the highest compound, and the only other that seemed worth while trying was 680 mμ. The usual series of mixtures was examined spectrophotometrically at these wave lengths and the results in Fig. 9 were obtained. At wave length 600 mμ the maximum comes slightly beyond the composition $x = 0.75$, indicating a compound of the composition $Ni(OOCCH_2NH_2)_3^-$. The curvature of the left-hand line suggests at least one other compound, and the *Y*-curve for 680 mμ has a maximum somewhere between $x = 0.5$ and $x = 0.75$, which also indicates another compound. These data give little indication of what the compound might be. Thus, it can be seen that the method of continuous variations does not always give full information about compound formation, and can be relied on for such only when conditions are favorable.

Summary

A number of systems have been examined by the method of continuous variations. In the three systems iron(III) and thiocyanate ions, iron(II) and *o*-phenanthroline, and nickel and dithio-oxalate ions, evidence was obtained for only one compound each, the compounds being already known. From copper and aminoacetate ions evidence of two compounds was obtained, with the components in ratios of 1:1 and 1:2, respectively. From nickel and aminoacetate ions evidence was obtained for a 1:3 compound and one other which could not be definitely identified.

Conductivity Studies. IV. The Limiting Ionic Mobilities of Several Univalent Ions at Temperatures between 15 and 45°

BY NORMAN C. C. LI AND WILHELM BRÜLL

Conductance data on aqueous solutions of potassium chloride at several temperatures are given in a paper preceding this one.[1] Allgood, LeRoy and Gordon[2] describe the accurate determination by moving boundary method of the transference numbers of aqueous solutions of potassium chloride at 15, 25, 35 and 45°. With these data on conductances and transference numbers at hand, we can calculate the equivalent conductances of ion constituents and the limiting ionic mobilities at different temperatures, with an accuracy of a part in several thousand.

Table I contains the assembled data on the equivalent conductances, Λ, of potassium chloride solutions and the corresponding transference numbers of the chloride ion, t_{Cl}, for 15, 25, 35 and 45°. The values of Λ are calculated from the equation

$$\Lambda = \Lambda_0' (1 - \alpha\sqrt{C}) - \beta\sqrt{C}$$

in which the theoretical coefficients α and β are calculated in the same way as described by Li and Fang[1] and Λ_0' is given by the equation

$$\Lambda_0' = \Lambda_0 + BC = \frac{\Lambda + \beta\sqrt{C}}{1 - \alpha\sqrt{C}}$$

The constants Λ_0 and B are either given in or interpolated from Table III of the preceding paper. The transference numbers as given by Allgood, LeRoy and Gordon are either the directly determined values or calculated by the equation

$$t_+^{\circ\prime} = t_+^{\circ} + AC = \frac{t_+\Lambda + {}^1/_2\beta\sqrt{C}}{\Lambda + \beta\sqrt{C}} \qquad (1)$$

where A is a disposable constant and β is the same theoretical coefficient as before, It is interesting to note that data on transference number and equivalent conductance can be treated in a similar way.

Column 4 of Table I gives the conductance of the chloride ion constituent $\lambda_{Cl} = \Lambda t_{Cl}$, and column 5 gives the values of λ_0' obtained by means of the equation

$$\lambda_0' = \lambda + {}^1/_2\beta\sqrt{C}/1 - \alpha\sqrt{C} = \lambda_0 + bC \qquad (2)$$

in which λ_0 is the limiting equivalent conductance of the ion species and b is an empirical constant.

.02	165.17	.5115	84.48	92.80
.05	158.83	.5115	81.24	94.48
		45°		
0.005	199.72	0.5131	102.48	107.48
.01	196.26	.5132	100.72	107.81
.02	191.73	.5132	98.40	108.44
.05	183.96	.5131	94.37	110.33

This equation was first given by MacInnes, Shedlovsky and Longsworth.[3] Fig. 1 shows values of λ plotted against $\sqrt{C}$ and λ_0' against C. The

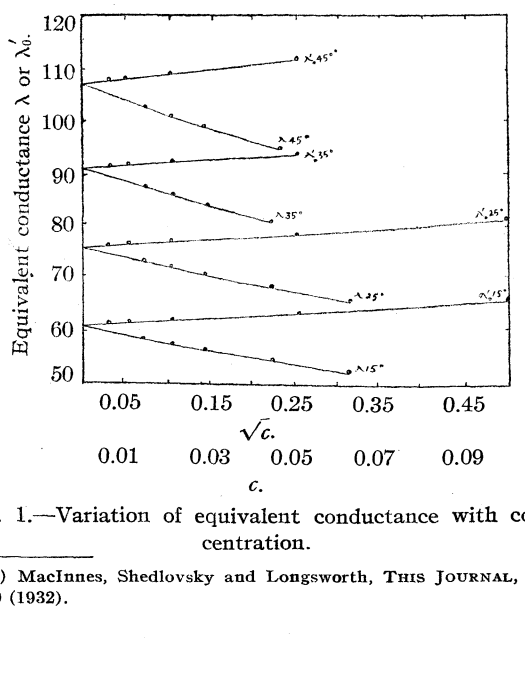

Fig. 1.—Variation of equivalent conductance with concentration.

(3) MacInnes, Shedlovsky and Longsworth, THIS JOURNAL, **54**, 2760 (1932).

values of λ_0 and b in Eq. 2 are obtained graphically and are listed in Table II.

TABLE II
LIMITING MOBILITIES OF THE CHLORIDE ION

t, °C.	b	λ_0 for Cl ion
15	40	61.30
25	48	76.34
35	56	91.68
45	64	107.16

The values of λ°_{Cl} can be calculated directly from the product of $\Lambda_{0\,KCl}$ and t°_{Cl}. Table III, columns 4 and 5 list the values of λ_0 for potassium and chloride ions, respectively, for 15, 25, 35 and 45°. The values of $\Lambda_{0\,KCl}$ are taken from Li and Fang[1] and $t^\circ_{+\,KCl}$ from Allgood, LeRoy and Gordon.[2]

TABLE III
LIMITING IONIC MOBILITIES

t, °C.	$\Lambda_{0\,KCl}$	$t^\circ_{+\,KCl}$	λ_K	λ°_{Cl}
15	120.88	0.4928	59.57	61.31
25	149.84	.4905	73.50	76.34
35	179.40	.4889	87.71	91.69
45	208.96	.4872	101.81	107.15

The values of λ°_{Cl} as seen agree very well with those listed in Table II and the very close agreements are somewhat surprising, since the transference numbers at very low concentrations are not known accurately. The relationship between λ° and temperature is linear so that the following equations can be applied

$$\lambda^\circ_{Cl} = 38.50 + 1.519t$$
$$\lambda^\circ_{K} = 38.44 + 1.407t$$

The value of λ°_{Cl} at 25° agrees with that given by MacInnes, Shedlovsky and Longsworth.[3]

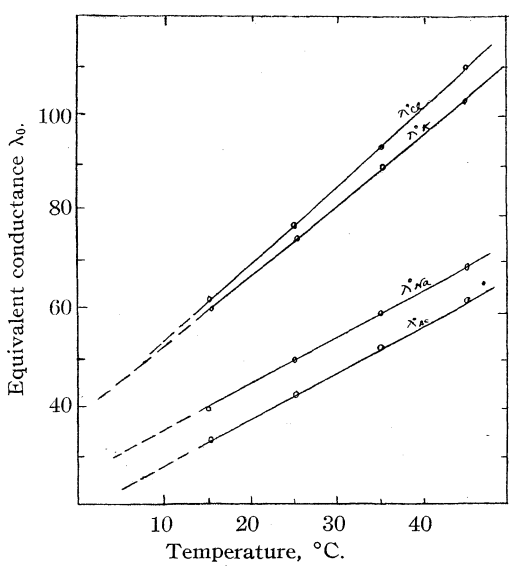

Fig. 2.—Variation of limiting ionic conductances with temperature.

From the values of λ°_K and λ°_{Cl} just given and the limiting conductances Λ_0 of sodium chloride and sodium acetate in water as given by Brescia, LaMer and Nachod,[4] the limiting ion conductances of sodium and acetate ions at different temperatures can be calculated from Kohlrausch's law of independent ion mobilities. The results obtained are shown in Table IV and in Fig. 2. The values for λ°_{Na} and λ°_{Ac} at 25° given by MacInnes, Shedlovsky and Longsworth[3] are 50.10 and 40.87, respectively, and differ considerably from the corresponding values given in Table IV, owing to the differences in the values of Λ°_{NaCl} and Λ°_{NaAc} used.

TABLE IV
LIMITING ION CONDUCTANCES AND LIMITING TRANSFERENCE NUMBERS

t, °C.	λ°_{Na}	λ°_{Ac}	t°_+ in NaCl	t°_+ in NaAc
15	39.70	32.80	0.3930	0.5476
25	49.29	42.07	.3923	.5395
35	58.57	51.65	.3898	.5314
45	67.72	61.36	.3872	.5256

The values of Λ°_{NaCl} and Λ°_{NaAc} given by Brescia, LaMer and Nachod,[5] however, are calculated from data in "International Critical Tables" and are not as accurate as the more recent values given by MacInnes, Shedlovsky and Longsworth. Using the equation

$$t^\circ_+ = \frac{\lambda^\circ_+}{\lambda^\circ_+ + \lambda^\circ_-} = \frac{\lambda^\circ_+}{\Lambda_0}$$

we have calculated the limiting transference numbers of aqueous solutions of sodium chloride and sodium acetate at the several temperatures and the results are shown in columns 3 and 4 of Table IV.

The cation transference numbers in aqueous solutions of sodium acetate are seen to decrease with rising temperature. This decrease is in accord with the well-known generalization that if the transference numbers are less than 0.5 they increase, and if greater than 0.5 they decrease with rise in temperature. The cation transference numbers in aqueous solutions of potassium and sodium chlorides, which are all less than 0.5, are seen to decrease with rising temperature and this is apparently contrary to the above generalization. Allgood, LeRoy and Gordon[2] have tentatively explained the anomaly of potassium chloride solutions as due to the hydration of the cation resulting in a different mechanism of transport for cation and anion. This difference may be-

(4) Brescia, LaMer and Nachod, THIS JOURNAL, **62**, 615 (1940).

come prominent because the anion and cation of potassium chloride have approximately the same mobility, but it is not sufficient to explain the case of sodium chloride, in which the mobilities of anion and cation are quite different. We believe that the apparent decrease in cation transference numbers in sodium chloride solutions with rise in temperature is due to the inaccurate conductivity data given in "International Critical Tables." Thus if we use the more recent value, $\Lambda_0 = 126.42$, for sodium chloride at 25°, the calculated value of t°_+ for aqueous solution of sodium chloride at 25° will be 0.3963 in agreement with the value found from direct transference data and in agreement with the above generalizations in that the limiting transference number at 25° is higher than at 15°. However, since the recent accurate conductivity data have been determined for 25° only, all the values given in Table IV for the four different temperatures are taken from the paper by Brescia, LaMer and Nachod which is based on the values given in "International Critical Tables." The older value for $\Lambda_{0\,NaCl}$ at 25° is 125.63, which is only 0.79 unit different from the new value. This illustrates the immense importance and need of obtaining accurate conductivity data at different temperatures, in order to obtain limiting ionic mobilities and limiting transference numbers with a high degree of accuracy.

Summary

Tables are given of the limiting mobilities of potassium and chloride ions at 15, 25, 35 and 45°, based on conductance data given by Li and Fang and transference data given by Allgood, LeRoy and Gordon. Approximate values for the limiting ionic mobilities of sodium and acetate as well as the limiting transference numbers in aqueous solutions of sodium chloride and sodium acetate for these temperatures are also given. The transference numbers calculated for sodium chloride solutions illustrate the necessity of obtaining accurate conductivity data not at one temperature, 25°, only, but at different temperatures.

Studies of Lead Oxides.[1] VI. The Effect of Grinding on the X-Ray Diffraction Patterns of Mixtures Containing Lead Oxides

BY GEORGE L. CLARK AND STANLEY F. KERN

Of all the variables which are known to affect the nature of materials used in the lead storage battery, grinding, especially of mixtures, has been studied the least. Leblanc and Eberius[2] report, "A hard stroke with a spatula, leaving a brown-red trail in the yellow oxide, suffices for the conversion of Y-PbO (yellow, orthorhombic) into R-PbO (red, tetragonal), while the conversion of Pb_3O_4 (black) into Pb_3O_4 (red) proceeds only under the hardest grinding and crushing on the roughest surfaces." Clark and Rowan[3] have shown that the R-PbO obtained on grinding Y-PbO is different from the normal R-PbO in that it gives an X-ray diffraction pattern identical with a distorted R-PbO formed by the vacuum decomposition of lead carbonate, basic carbonate or white lead, or lead oxide hydrate, and in that it exhibits an abnormal chemical activity toward hydrogen peroxide and an increased heat of solution in perchloric acid over that of the normal R-PbO.

It has been observed previously in this Laboratory that intense grinding of normal R-PbO caused a slight broadening of some lines on the X-ray diffraction pattern. This non-uniform broadening is indicative of distortion.

Brown, Cook and Warner[4] have reported the effect of grinding upon the apparent density of Pb_3O_4 samples obtained by oxidation of three different lead oxides.

Procedure

Seven binary mixtures involving the lead oxides were investigated using six to eight different percentage compositions of each. These mixtures were ground with a rubbing or shearing action and in identical manner in an agate mortar and samples reserved after various times of

(1) For the fifth paper of this series, see Clark and Rowan, THIS JOURNAL, **63**, 1305 (1941).

(3) Clark and Rowan, *ibid.*, **63**, 1302 (1941).

(4) O. W. Brown, S. V. Cook and J. C. Warner, *J. Phys. Chem.*, **26**, 477 (1922).

grinding for X-ray diffraction studies. In this manner, twenty to thirty patterns were obtained to describe each of the following mixtures

Y-PbO–PbO_2	$PbSO_4$–PbO_2
Y-PbO–SiO_2	R-PbO–PbI_2
R-PbO–PbO_2	Y-PbO–PbI_2
R-PbO–$PbSO_4$	

The grinding was carried out manually and in contact with the atmosphere in all cases except for a few samples of the PbO–PbO_2 system. Some of these were ground in an atmosphere of nitrogen and the rest in a vacuum. The same results could be obtained in times three times as long by grinding in the rod mill described by Clark and Rowan.[3]

Through holes bored in the sides of an air-tight box, rubber gloves were inserted and attached to the box in such a manner that these connections were also air tight. The gloves were used to operate the mortar and pestle inside the box. Nitrogen which previously had been passed through sulfuric acid and ascarite was passed through the box forming the nitrogen atmosphere used in these experiments.

For the vacuum grinding the mortar was placed in a glass jar having a flat brass cover. A rubber gasket was used between the brass cover and the glass jar to give a vacuum-tight contact. In the center of the cover was a hole fitted with a collar through which the pestle was operated. A length of rubber tubing fitting tightly around the collar and the pestle constituted the vacuum-tight connection at this point and allowed ample movement of the pestle to effect the grinding. Two smaller holes were on either side of the large central opening. One was connected to a Cenco-Hyvac pump and the other to a glass tube, one end of which was drawn into a capillary and sealed.

The sample of PbO was heated for several hours at 3 mm. pressure and 450° previous to grinding to ensure complete removal of any carbon dioxide present. A small amount of this PbO was mixed with an equal amount of PbO_2, the mixture placed in the mortar and the system evacuated within a minute after the PbO had been removed from the vacuum furnace. The sample was ground for twenty minutes and transferred to the capillary which was sealed off and used for X-ray diffraction studies.

All materials used were C. P. chemicals or made from C. P. reagents.

The X-ray diffraction patterns were registered in a cylindrical camera using a wedge-shaped sample holder for mounting the samples.[5] For the samples ground in vacuum the capillaries containing the sample were mounted directly. Radiation from a copper target X-ray tube was used throughout the investigation.

Results and Discussion

The description of some typical patterns will illustrate the phenomena observed when these mixtures were ground.

PbO–PbO_2 Mixtures.—For a mixture of 67% PbO_2 and 33% Y-PbO, after twenty minutes of grinding, the speckled lines of Y-PbO, easily observed for a mixture before grinding, are completely missing from the pattern, indicating that the Y-PbO has completely disappeared. Nor is there any evidence of R-PbO to which the yellow modification ordinarily is transformed on grinding. Other patterns were obtained from the following mixtures after they had been ground twenty minutes: 50% PbO_2–50% Y-PbO, 33% PbO_2–67% Y-PbO, 10% PbO_2–90% Y-PbO, 5% PbO_2–95% Y-PbO. *In each case both the Y-PbO and R-PbO patterns are completely missing.* On the other hand, corresponding mixtures ground with fine sand (SiO_2) as an abrasive invariably showed broad interferences of R-PbO.

The patterns of corresponding mixtures of PbO_2 and R-PbO up to a mixture of 10% PbO_2 and 90% R-PbO under the same conditions of grinding for twenty minutes disclosed only the pattern of PbO_2 with one extra line which could be attributed to $2PbCO_3 \cdot Pb(OH)_2$.

In attempting to determine what happened to the PbO on grinding, the following theories were proposed. First, the distorted (activated) PbO, formed on grinding, may have absorbed oxygen from the atmosphere and was oxidized to PbO_2. The high oxidation potential needed for such a reaction made this theory rather doubtful. Active oxygen analysis on the sample before and after grinding showed that there was no increase in active oxygen, as determined by the method of Diehl and Topf and recommended by Mrgudich and Clark.[6]

The second theory claimed that the PbO was incorporated into the PbO_2 lattice, giving either an interstitial solid solution of PbO in PbO_2 or a type of substitutional solid solution where the PbO_2 lattice remains but the ratio of oxygen to lead is less than two. The formation of an interstitial solid solution was immediately discounted as no parameter changes were observed on the PbO_2 pattern and because packing considerations would make this situation impossible.

The existence of an "oxygen-deficient" lattice of PbO_2 is well known. Clark and Rowan[1] have shown that sulfamic acid, although a very good solvent for PbO, is incapable of increasing the ratio of oxygen to lead in an oxygen-deficient lattice. However, after the ground mixture of PbO_2–PbO has been treated with sulfamic acid, an ac-

(5) G. L. Clark, "Applied X-Rays," 3rd ed., McGraw-Hill Book Co., 1940, p. 269.

(6) J. N. Mrgudich and G. L. Clark, *Ind. Eng. Chem., Anal. Ed.*, **9**, 256 (1937).

tive oxygen analysis on the residue showed that the residue was PbO_2 and therefore the PbO must have been removed. A precipitate of lead sulfate was obtained when sulfuric acid was added to the sulfamic acid extraction solution, thereby substantiating the conclusion that the divalent lead was removed from the ground mixture. In the light of these facts, there could be no appreciable incorporation of PbO into the PbO_2 lattice.

The final theory is a combination of two effects. It is known that grinding, in general, decreases the particle size of a crystalline material and in some cases introduces distortion. As mentioned previously, it has been observed in this Laboratory that R-PbO, as well as Y-PbO, when ground produces an X-ray diffraction pattern of distorted R-PbO. It is possible that grinding these mixtures decreases the particle size of the PbO and introduces such a large amount of distortion that Bragg scattering can no longer result. Thus, even a mixture of 90% PbO ground with 10% PbO_2 fails to produce the slightest diffraction evidence of PbO.

It has also been shown that this distorted PbO is highly active. In this highly distorted or activated state, some of the PbO could react rapidly with the carbon dioxide and water of the atmosphere to form a basic carbonate of lead. To substantiate this theory both R-PbO and Y-PbO were ground alone in air under the same conditions used for the mixtures, and the X-ray diffraction patterns obtained from the ground samples compared with the patterns of the basic carbonates. The patterns obtained from ground R-PbO, Y-PbO and the ground mixtures of PbO_2–PbO which contain a large percentage of R-PbO or Y-PbO always show one or more interferences characteristic of $2PbCO_3 \cdot Pb(OH)_2$ and thus indicate that this carbonate is being formed. Chemical analysis showed that the amount of carbon dioxide present in the ground samples was about 80% of that required for the complete conversion, of the PbO present, into $2PbCO_3 \cdot Pb(OH)_2$. These facts indicate that the effect of grinding on these mixtures is the activation of the PbO which then reacts with the carbon dioxide and water of the atmosphere to give $2PbCO_3 \cdot Pb(OH)_2$. However, the intensity of the diffraction interferences from this basic carbonate is far too small to account for 80% conversion of the PbO to the basic carbonate. Hence, we must conclude that either not all of the carbon dioxide in the mixture is in molecular union with the PbO or that the basic carbonate remains in a state of great dispersion and distortion. Since the diffraction interferences of the basic carbonate are very diffuse, it was more logical to accept the latter conclusion.

From these experiments, it was possible to conclude only that the absence of the PbO lines on patterns obtained from ground mixtures of PbO_2–PbO was accompanied by a large increase in carbon dioxide content of the sample. Whether the abnormal absorption or incorporation of the carbon dioxide into the mixture was a cause of the disappearance of the PbO pattern, or a result of the high activity introduced into the PbO on grinding, could not be ascertained from these experiments. To attempt to find facts favoring either explanation it was decided to grind the mixtures in an atmosphere as nearly free from carbon dioxide as possible.

The first attempt toward this goal was grinding in an atmosphere of nitrogen. The experimental procedure has been described above. X-Ray diffraction patterns taken of the samples after being ground in the nitrogen atmosphere were similar to those obtained from samples ground in air. Chemical analysis of these samples showed that they had absorbed some carbon dioxide, but to a far less degree than the samples ground in air. Although this experiment was unsuccessful in completely removing carbon dioxide from the atmosphere, it did indicate that the disappearance of the diffracting power of PbO was not primarily dependent on the amount of carbon dioxide absorbed.

Samples ground in vacuum gave X-ray patterns completely devoid of all PbO lines. Chemical analysis of the samples showed that there was less than 0.1% of carbon dioxide present in the ground sample. Hence, we are forced to conclude that the disappearance of the lines characteristic of PbO is not necessarily a function of the carbon dioxide absorbed.

Clark and Rowan[1] have shown that distorted PbO when annealed at a temperature above 300° was converted to the normal PbO. It was believed that if the PbO was present as a distinct phase annealing should restore it to the original form. A sample of PbO_2–PbO after being ground was annealed at 300° and an X-ray pattern taken of the product. The pattern showed the presence of a *large amount of the PbO* and a small amount of Pb_3O_4, as well as PbO_2, indicating that the PbO

was present in the ground sample in a form easily converted to the normal crystalline PbO.

These experiments prove that it is impracticable to place limits on the amount of PbO detectable in PbO_2 by the powder diffraction method, as too much depends upon the previous history of the sample.

R-PbO–$PbSO_4$ Mixtures.—Grinding experiments on these mixtures, followed by the X-ray method and chemical analysis, indicate that the PbO was converted into a poorly diffracting and, therefore, a highly distorted PbO.

In the unground mixture approximately 10% is the limit of detection of PbO in lead sulfate. This same limit can be said to hold for lead sulfate in PbO.

$PbSO_4$–PbO_2 Mixtures.—Grinding decreases the particle size of the lead sulfate but in no other way alters the pattern. The limit of detection of one component in the presence of the other is less than 5%.

PbO–PbI_2 Mixtures.—In direct opposition to the findings in the previous experiments it was found that grinding PbO in the presence of lead iodide does not destroy the PbO pattern. However, grinding does have an effect in that the pattern obtained from lead iodide tends to disappear. Chemical analysis of these samples before and after grinding shows no appreciable absorption of carbon dioxide on grinding.

In order to explain the apparent resistance of the PbO to reaction with carbon dioxide when ground with lead iodide, it is necessary to consider the differences between lead iodide and PbO_2. The PbO_2 lattice is made up of oxygen octahedra with a lead ion in the center of each octahedron. These octahedra are held together by shared corners and edges giving rise to strong bonding energies in each of the three directions. On the other hand, lead iodide exhibits a layer lattice composed of two layers of iodide ions to one layer of lead ions. The bonding force between the adjacent layers of iodine ions is weak and, as a result, the lead iodide crystal is easily sheared in this direction.

On grinding these mixtures, PbO_2–PbO and PbI_2–PbO, there is a tendency to set up a stress in the materials of the mixtures. In the PbO_2–PbO mixture there is a competition between the strong bonding forces between the octahedra in the PbO_2 lattice and the forces tending to keep the PbO lattice in the undistorted form as to which will yield to the applied stress. It is supposed that these forces for the latter are the weaker and, as a consequence, the PbO lattice is distorted by the stress of grinding. In the distorted form the PbO lattice is active and reacts with the carbon dioxide and moisture of the air and is partly converted into the basic carbonate. The PbO_2 seems to have more than a simple abrasive effect since silicon dioxide ground with PbO is not effective in destroying the PbO pattern or in producing a highly active oxide.

In the PbI_2–PbO mixtures the competition is between the forces of PbO and the relatively weak forces between the adjacent layers of iodide ions in the lead iodide lattice. In this case, we find that it is the bonds between these layers of iodine ions that yield to relieve the stresses introduced on grinding and thereby protect the PbO from distortion and the accompanying activation and reaction with carbon dioxide.

Summary

1. Grinding mixtures of PbO_2 with either R-PbO or Y-PbO results in the disappearance of the X-ray diffraction lines characteristic of PbO. This is not the case when PbO is ground with an abrasive like silicon dioxide. A. Active oxygen analysis on the samples before and after grinding showed that there was no increase in oxygen content in the mixture during grinding and, consequently, no oxidation of the PbO to PbO_2. B. The formation of a solid solution of PbO in PbO_2 or compound formation between them is improbable as the PbO is easily extracted from the ground mixture with sulfamic acid, no new lines indicative of compound formation are present on the pattern and, on annealing the ground sample, the PbO is restored to normal R-PbO. C. There is an abnormally high absorption of carbon dioxide by the PbO when ground with PbO_2. The absorption of carbon dioxide is not necessarily the cause of the disappearance of the PbO pattern as the PbO lines do not appear on patterns of samples ground in a vacuum and containing less than 0.1% carbon dioxide. D. The high absorption of carbon dioxide by the mixture when ground in air is further evidence of the increased activity of PbO when formed in the distorted form.

2. Lead oxide loses its diffracting power when ground with other compounds such as lead sulfate, although these are not so effective as PbO_2.

3. Grinding mixtures of lead iodide and PbO

results in the disappearance of the pattern of the lead iodide while the PbO pattern remains. The lead iodide acts as a lubricant and thereby protects the PbO from distortion. This lubricating action of the lead iodide arises from the weak forces existing between layers of iodide ions in the lead iodide crystals.

Reproducible Contact Angles on Reproducible Metal Surfaces. III. Contact Angles of Saturated Aqueous Solutions of Different Organic Liquids on Silver and Gold

BY F. E. BARTELL AND PAUL H. CARDWELL

Recent communications from this Laboratory have presented the results obtained in studies of water–air contact angles on silver and gold,[1] and of organic liquid–water interfacial contact angles on these same solids.[2] For each of these systems explanations were suggested for the "hysteresis" of the contact angles. The system solid–saturated aqueous organic liquid solution–air reported upon in this paper is even more complex than the two types of systems previously discussed, and though angles can be reproduced readily by controlled procedures, the factors which may contribute to the "hysteresis" of these contact angles are more numerous and more complex than those encountered in the other systems.

The liquids used in this investigation were "conductivity" water, isoamyl alcohol, normal butyl acetate, benzene, α-bromonaphthalene and heptane. The organic liquids were of the same high degree of purity as those previously used. The procedure for the formation and measurement of contact angles and the method for preparing reproducible surfaces of silver and gold have been described in a previous paper.[1]

Three different groups of solution contact angles were measured. Angles formed by solution drops on initially fresh and clean surfaces of silver and gold comprised the first group, angles formed by solution drops on solids which had stood in air saturated with water and organic liquid vapors comprised the second, and angles formed by air bubbles on solids in saturated aqueous organic liquid solutions comprised the third group. The contact angles reported for both drop and bubble systems are the angles measured through the aqueous solution phase.

When a drop of saturated aqueous organic liquid solution was placed upon a fresh and clean solid surface, in a cell with air saturated with water vapor alone, the angle measured immediately after formation of the drop was not reproducible. Initial air adsorption upon the metal surface was so rapid that exact duplicates could not be obtained for these initial angles. When the solution drop was left stationary on the solid for a short period of time and was then caused to advance by adding solution to increase the volume of the drop, the value of the contact angle of the advanced drop was not the same as that of the original drop. This change in the contact angle appeared to be much greater than would have been caused by further adsorption of air by the solid during the short period of time that the solution drop was allowed to stand on the solid, since after the initial rapid air adsorption the rate of air adsorption appears to decrease.[1] It was concluded that organic liquid must have evaporated from the solution drop into the air of the closed cell and subsequently have been adsorbed by the solid and that this adsorbed organic liquid caused part of the change.

Reproducible contact angles of solution drops on silver and gold surfaces could be obtained when these metal surfaces were exposed for sufficient periods of time to air saturated with the vapors of the given aqueous organic liquid solution. Values obtained for angles measured in air saturated with the vapors of the given solutions are shown in Table I. The advancing angles of Table I are the angles measured immediately after the drops were formed upon the surfaces which had been allowed to stand in contact with the vapors. The receding angles were obtained by immediately withdrawing the solution-drop once it was formed. On solids exposed to the vapors for a few seconds only, the receding angles were smaller than the

	18 hours			101	71
	7 days			101	101

advancing angles. This was probably the result of a partial removal of an incomplete adsorbed film by the solution-drop. Solids on which there was maximum adsorption of the organic liquid vapors gave advancing and receding angles which were equal or nearly equal when the drop was receded immediately. Drops allowed to stand on the solids even for short periods of time before being receded gave receding angles somewhat smaller than those of Table I, while drops allowed to stand for long periods of time gave receding angles approaching zero, which indicates that the adsorbed films of the organic liquids on the solids were gradually being removed by the solution-drops. It is of interest to note that the values of the contact angles given by solution-drops on adsorbed organic liquid films increase progressively with the hydrophobic nature of the organic liquid.

Contact angles formed by air-bubbles on surfaces immersed in saturated aqueous organic liquid solutions are given in Table II. The solution receding contact angles reported in this table were those formed as soon as the air-bubbles were advanced. The magnitude of the angles formed when the air-bubbles were withdrawn, solution advancing, depended upon the length of time the air-bubbles were left on the metal surfaces. The longer the air-bubbles were allowed to stand on the solids before being withdrawn, the larger were the solution advancing angles. The solution advancing angles reported in Table II were obtained with air-bubbles which had stood on the metal surfaces for one minute before being withdrawn.

TABLE II

CONTACT ANGLES OF SOLID–SOLUTION–AIR BUBBLE

Satd. aqueous soln. of org. liq.	Angles on silver Advancing	Angles on silver Receding	Angles on gold Advancing	Angles on gold Receding
Isoamyl alcohol	47	22	43	21
n-Butyl acetate	58	36	48	33
Benzene	65	33	61	28
α-Bromonaphthalene	73	47.5	65	40
Heptane	74	37	66	34.5

Individual angle measurements for all angles reported showed a maximum variation of ± 1° and in many cases the variation was less than ± 0.5°.

Discussion of Results

In the water drop and air bubble systems previously studied,[1] drop and bubble measurements were identical, within the limits of experimental error, when corresponding states were reproduced. In the solid–liquid–liquid systems previously reported[2] corresponding water drop and organic

liquid drop measurements were also identical, within the limits of experimental error. The contact angle values obtained for solution drops and air bubbles in the present study were not identical.

In the solid–solution–air systems the air adsorption factor, operative also in solid–water–air systems, has an effect; and at the same time the organic liquid adsorption factor, operative also in solid–liquid–liquid systems, has *two* effects. Organic liquid appears to be adsorbed on the solid surface both from saturated air and from saturated solution. The solid appears to adsorb a more complete layer from saturated air than can exist in equilibrium under a saturated solution, however, and the solution accordingly tends to remove both adsorbed air and adsorbed organic liquid. Water adsorption appears to be a negligible factor in any of the three systems. With such varied processes of adsorption and such different rates of adsorption and desorption as the measurements indicate, exactly corresponding states for drop and bubble would be very difficult, if not impossible, to achieve. Corresponding states were not achieved in the present study and the measurements on drop and bubble were, therefore, not identical.

Factors capable of causing hysteresis of contact angles were numerous and were effective to different degrees for each change of system. It was possible to obtain advancing and receding angles of the same value, however, and the method of obtaining such angles was similar to that used with the two previously described less complex systems. On solids left for long periods of time in atmospheres saturated with organic liquid, solution drops gave advancing and receding angles of the same value when the solution was immediately receded after being advanced.

It has been realized from the beginning of work on contact angles in this Laboratory that the surface tension of identical solid surfaces does not always remain strictly constant when the solid is used in different systems. For some systems it probably is so nearly constant, or changes in the tension are so nearly identical, that combinations of equations effected by cancelling surface tension values of solid can give valuable information. The work reported in all three of the papers of this series re-emphasizes, however, that conclusions drawn from all such equations and from similar equations for solid–liquid–liquid systems must be subjected to careful analysis before their validity can be considered to be established.

Summary

Measurements have been made of the contact angles of drops of saturated aqueous organic liquid solutions on silver and gold in air and of air bubbles on silver and gold in saturated aqueous organic liquid solutions.

These measurements indicate that the metal surfaces adsorb air and adsorb also organic liquid both from air and from aqueous solution. A drop of solution caused to advance by stages over a fresh metal surface gives a different angle each time it is advanced because of evaporation of organic liquid into the air and subsequent adsorption of the vapor on the exposed metal.

Because of these complex adsorption conditions identical surface states for drop and bubble systems were not achieved, and, consequently, identical angles for the two systems were not obtained.

Identical advancing and receding angles were obtained for drops caused to recede immediately after they had been advanced on metal surfaces which had previously stood in the given aqueous solution vapors for sufficient time to attain adsorption equilibrium.

The Formal Oxidation–Reduction Potentials of Thallous–Thallic Salts in Aqueous Hydrochloric Acid Solutions. Formation of Chlorothallate Complex Ions[1]

BY RICHARD H. HUGHES AND CLIFFORD S. GARNER

The oxidation–reduction potentials of thallous–thallic salts have been investigated in aqueous solutions of hydrochloric,[2] sulfuric,[2,3,4] nitric[2,5] and perchloric[6] acids. These studies have shown that the formal potentials[7] differ in the presence of various anions, suggesting the formation of anion complexes with thallic ion.

In particular, the experiments of Spencer and Abegg[2] have indicated the probable formation of one or more chloride complexes of thallic ion. However, their data are not easily interpreted for several reasons: (1) because a 0.1 N calomel half-cell was used as a reference electrode, the results were complicated by the presence of relatively large liquid junction potentials which were not taken into account; (2) since the thallous–thallic solutions were always less than 0.2 f in hydrochloric acid, considerable hydrolysis of the thallic salts must have occurred in many of their solutions; and, (3) the chloride ion concentration was not varied independently of the hydrogen ion concentration and the ionic strength.

Since it seemed desirable to have more accurate values of the formal potentials in hydrochloric acid solutions and to study the formation of chloride complexes of thallic ion, the measurement of the electromotive forces of cells of the type

$$\mathrm{Pt,}\left\{\begin{array}{ll}\mathrm{TlCl} & (c_1 f)\\ \mathrm{TlCl_3} & (c_2 f)\\ \mathrm{HCl} & (c_3 f)\\ \mathrm{HClO_4} & (c_4 f)\end{array}\right\}\mathrm{,\ HCl}\ (c_3 + c_4 f),\ \mathrm{H_2}\ (p\ \mathrm{atm.}) + \mathrm{Pt}$$

has been undertaken. Conditions of concentration were chosen such that the difficulties referred to in the above paragraph were eliminated almost entirely.

For the above cell, the formal potential, $E^{0\prime\prime}$ (for the reaction $\mathrm{Tl^I} = \mathrm{Tl^{III}} + 2e^-$) has been derived by adding to the observed potential, $E_{\mathrm{obsd.}}$, the two following quantities

$$E_{\mathrm{C}} = (RT/2F)\ln(c_2/c_1) \qquad \text{(A)}$$

to provide for equiformal concentrations of thallous and thallic salts, and

$$E_{\mathrm{H}} = (RT/F)\ln\left(\sqrt{p}/\gamma(c_3 + c_4)\right) \qquad \text{(B)}$$

to refer the values to the molal hydrogen electrode, γ being the mean ionic activity coefficient of hydrogen ions in $c_3 + c_4 f$ hydrochloric acid, and p being the partial pressure of hydrogen in atmospheres. The liquid junction potential was made negligibly small by keeping the total salt concentration $(c_1 + c_2)$ less than 1% of the total acid concentration, which was the same in both half-cells.[8] This low salt concentration also made possible the maintenance of constant ionic strength in a given series of experiments. Hydrolysis of the thallic salts was reduced to a minimum by having the acid concentration 1 f or greater.

Since thallous ion appears to have no tendency to form chloride complexes,[9] the variation of the formal potential with changes in concentration of thallic ions or chloride ions may be interpreted in terms of the formation of chloride complexes of thallic ion.

Hence, two types of experiment were planned. In one (Series 1 and 2) the ratio of thallic to thallous salt concentration, c_2/c_1, was varied, and in the other (Series 3, 4 and 5) the ratio of hydrochloric to perchloric acid concentration, c_3/c_4, was altered, in both cases $c_3 + c_4$ and all other factors being held constant in a particular series.

Experimental

Preparation and Analysis of the Solutions.—"Chemically pure" thallous nitrate was recrystallized from water solution three times, dried in an oven at 120° and stored in

(7) The "formal potential" is the potential, referred to the standard molal hydrogen electrode, when the total concentrations of the reduced and oxidized substances (without reference to their possible incomplete ionization, hydrolysis, formation of complexes, etc.) are both 1.0 f.

(8) Although there is a liquid junction between hydrochloric and hydrochloric–perchloric acid solutions in some of the cells, the junction potential is negligible, for these two acids possess at 25° closely agreeing activity coefficients and almost identical equivalent conductances over the concentration range 1 to 4 f. See, for example, Latimer, "Oxidation Potentials," Prentice-Hall, Inc., New York, N. Y., 1938, p. 323, and "International Critical Tables," Vol. VI, McGraw-Hill Book Co., New York, N. Y., 1929, p. 241.

(9) Noyes, *Z. physik. Chem.*, **9**, 603 (1892), has shown that the solubility of thallous chloride in solutions of potassium chloride or hydrochloric acid at 25° decreases substantially in accordance with the solubility product principle, at least up to 0.8 f potassium chloride solution.

a desiccator. Analysis by the iodate method using the iodine monochloride end-point[10] showed the product to be 99.5% pure. It was used without further purification.

Thallous nitrate was dissolved in water, and a slight excess of hydrochloric acid was added. The precipitated thallous chloride was washed with water until the washings gave a negative test for nitrate ion with sulfuric acid and ferrous sulfate. A portion of this thallous chloride was dissolved in water. The resulting solution was standardized by the above iodate method, using a 0.01 *N* potassium iodate solution which had been prepared by weight and checked by titration against samples of Bureau of Standards arsenious oxide. The stock solution thus prepared was 0.004032 *f* in thallous chloride. All other thallous chloride solutions were made from it by weight dilution.

To prepare a stock thallic chloride solution a suspension of thallous chloride in hydrochloric acid was heated with an excess of C. P. potassium bromate. Thallic hydroxide was then precipitated by the addition of ammonium hydroxide, and was washed until the washings failed to give a positive test for bromide or chloride ion with nitric acid and silver nitrate. The moist thallic hydroxide was suspended in water and just enough hydrochloric acid added to dissolve it. Concordant analyses, made by methods described in an earlier paper,[5] showed the resulting stock solution to be 0.02508 *f* in thallic chloride and 0.0002403 *f* in thallous chloride (this small amount of thallous chloride was always taken into account in the preparation of the cell solutions). The amount of free hydrochloric acid was negligible. Other stock thallic chloride solutions were prepared in a similar way. Both the thallous and thallic stock solutions were checked at the end of this investigation and found to have undergone no appreciable change.

The hydrochloric and perchloric acid solutions were obtained by dilution of reagent grade concentrated acids, the impurities in which were stated to be negligible. These solutions were standardized by titrating portions of a sodium hydroxide solution which had been just standardized against Bureau of Standards potassium hydrophthalate.

Tank (electrolytic) hydrogen was purified by passing it successively through concentrated solutions of sulfuric acid, potassium hydroxide and sodium plumbite, then over electrically-heated platinized asbestos.

The Cell.—The assembled cell is shown in Fig. 1. A 180-ml. electrolytic beaker served as a container (A) for the thallous-thallic mixture, in which was immersed the hydrogen half-cell and two bright platinum wire electrodes (B). In some of the early experiments one of these electrodes was cathodically polarized and the other anodically polarized in 1 *f* hydrochloric acid; our experience, unlike that of Spencer and Abegg,[2] indicated that equilibrium was more quickly attained with non-polarized electrodes. The hydrogen half-cell vessel was made from a 25 × 200 mm. test-tube equipped with a standard taper ground-glass joint (C) which prevented appreciable liquid diffusion while allowing electrolytic contact. The liquid junction was made inside this joint by diffusion. Inside this vessel was the hydrochloric acid solution into which dipped two platinized platinum-foil electrodes (D) and the hydrogen entrance tube (E). Before entering the half-cell the hydrogen from the purification train passed through a long "bubbler" trap containing hydrochloric acid of the same concentration as that used in the half-cell. A small "bubbler" trap (F) was also provided at the hydrogen outlet.

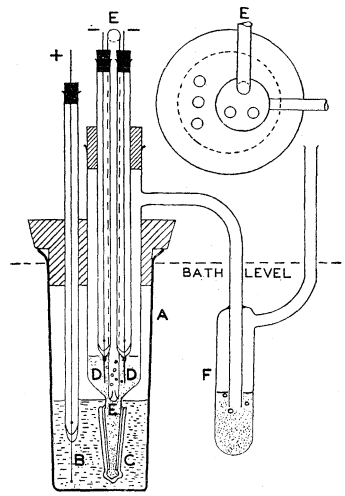

Fig. 1.—Cell for e. m. f. measurements.

All rubber stoppers and tubing were boiled in sodium hydroxide solution and rinsed well to remove sulfur.

The cell and "bubbler" traps were immersed in a kerosene-bath thermostated at the desired temperature to within ±0.05°.

Method of Potential Measurements.—A Leeds and Northrup Type K-1 potentiometer and Type R galvanometer were used for the e. m. f. measurements.[11] The Eppley standard cell used was checked several times during the investigation against a cell which had just been certified by the National Bureau of Standards.

Solutions of thallous chloride and of thallic chloride, both in 0.9952 *f* hydrochloric acid, were prepared by weight from the stock solutions, and mixed in varying proportions for the cells of Series 1 and 2. The cells of Series 3, 4 and 5 were prepared using a stock solution containing both thallous and thallic chlorides in water or in 4 or 2 *f* perchloric acid. To a given weight of one of these solutions was added a constant weight of water obtained by mixing in the desired proportion hydrochloric and perchloric acid solutions of the same concentration.

After the cells had attained thermal equilibrium (about half an hour was allowed), the potentials were measured at intervals over a period of two to fifty hours. In practically all cases equilibrium appeared to be reached within three hours, and thereafter readings were generally constant to 0.4 mv. or better. With rare exceptions, the readings taken with the duplicate electrodes in the same cell agreed to 0.1 mv. Occasionally some of the cells were agitated by hand, and this seldom produced an appreciable effect.

All volumetric apparatus, weights and thermometers employed in this research were calibrated, and all weighings were corrected to vacuum conditions. Distilled water was used in the preparation of all the solutions.

Results and Discussion

Potentials in Hydrochloric Acid Solution.—In Table I are presented the results of measurements made at 25 and 15° with cells in which perchloric acid was not present. The hydrochloric acid concentration was kept at 0.9952 f, corresponding to an ionic strength (μ) of 1.00. All concentrations have been expressed as weight formalities, f (formula weights per kilogram of water). Usually check cells were made up and measured. The values of $E_{obsd.}$ given in the table represent average values based on the number of cells indicated in the parentheses immediately following each value.[12] The values of $E^{0\prime\prime}$ were calculated as indicated earlier in this paper, the values of the activity coefficient of hydrochloric acid (given in parentheses following the concentration of the acid) being interpolated from the data of Harned and Ehlers,[13] and the partial pressure of hydrogen being computed from the corrected barometric pressure by subtraction of the vapor pressure of the acid solution at the given temperature[14] and addition of the hydrostatic head.

From the third, fourth and last columns of Table I it may be seen that the formal potential is not materially altered by changing the ratio c_2/c_1 or the formal concentration of the thallic salt one thousand-fold in the range indicated. One requirement of this constancy of $E^{0\prime\prime}$ is that there be only one thallium atom per thallic complex present in appreciable concentration.[15]

The cells of Series 1 and 2 give the average values of −0.7829 ± 0.0015 and −0.7816 ± 0.0015 volt for $E^{0\prime\prime}$ at 25 and 15°, respectively. From these values there are calculated for the cell reaction

$$Tl^+(0.9952\ f\ HCl) + 2H^+(a = 1m) = Tl^{III}\ (0.9552\ f\ HCl) + H_2(1\ atm.)$$

values of ΔF^0_{298} = 36.12 kcal., ΔH^0_{298} = 34.48 kcal., and ΔS^0_{298} = −0.0055 kcal./deg.[16]

Potentials in Mixtures of Hydrochloric and Perchloric Acid Solutions.—The measurements of Series 3, 4 and 5 were carried out with mixtures of hydrochloric and perchloric acid solutions so that the chloride ion concentration could be varied independently of hydrogen ion concentration and ionic strength. The results, together with the concentration conditions under which they were obtained, are given in Table II. Reference to columns one and six shows that the formal poten-

(12) The spread between extreme values was less than 0.5 mv. as a rule, but in a number of cases it was greater, becoming 3.7 mv. in the worst case.

(13) Harned and Ehlers, THIS JOURNAL, **55**, 2179 (1933).

(14) "International Critical Tables," Vol. III, McGraw-Hill Book Co., New York, N. Y., 1928, p. 301.

(15) If complexes of the type $Tl_xCl_y^{(y-3x)+}$ are important and stable in the solutions studied, then

$$E^{0\prime\prime} = (RT/2F)(1 - 1/x) \ln c_2 + \text{constant}$$

where x is the average number of thallium atoms per complex. For example, if x were 2, the thousand-fold variation in c_2 would have produced a change of 44 mv. in $E^{0\prime\prime}$ at 25°.

(16) From the relatively large variation in the values of $E^{0\prime\prime}$ at 15° it would appear that the entropy change is unreliable. However, by taking the temperature coefficients of the six cells involved and averaging them the value −0.00012 volt per degree was obtained, the mean deviation from the mean being 0.00002 volt per degree.

tial, $E^{0\prime\prime}$, is a function of chloride ion or perchlorate ion concentration. Since the work of Sherrill and Haas[6] has indicated that perchlorate ions have little or no tendency to form complexes with thallic ion over the range 0.5 to 1.2 f perchloric acid, this variation in $E^{0\prime\prime}$ may be interpreted in terms of the formation of complexes involving chloride and thallic ions.

Conceivably, a solution of thallic chloride in hydrochloric acid may contain complexes such as $TlCl^{++}$, $TlCl_2^{+}$, $TlCl_3$, $TlCl_4^{-}$, . . ., $TlCl_i^{(i-3)-}$, having equilibrium dissociation constants K_1, K_2, K_3, . . ., K_i, respectively. Assuming that the relatively high acid concentrations employed in these studies prevent the formation of hydrolytic complexes such as $TlOH^{++}$ and $Tl(OH)_2^{+}$, and that the concentration of free (hydrated) Tl^{+++} is very small compared to that of the complexes,[17] then

$$c_2 = (TlCl^{++}) + (TlCl_2^{+}) + \ldots + (TlCl_i^{(i-3)-}) \quad (1)$$

In terms of the dissociation constants, (1) becomes

$$c_2 = (Tl^{+++}) \sum_{i=1}^{n} (Cl^-)^i/K_i \quad (2)$$

Now, the formal potential is related to the molal thallous–thallic potential, E^0, by the equation

$$E^{0\prime\prime} = E^0 - (RT/2F) \ln (\gamma_{Tl^{+++}}/\gamma_{Tl^{+}}) + (RT/2F) \ln c_2/(Tl^{+++}) \quad (3)$$

Substitution of (2) into (3) and the collection of all terms which are constant under the conditions of Series 3, 4 or 5, leads to the following relation for the variation of $E^{0\prime\prime}$ with chloride ion concentration:

$$E^{0\prime\prime} = (RT/2F) \ln \sum_{i=1}^{n} (Cl^-)^i/K_i + \text{constant} \quad (4)$$

Within the accuracy of the results described in this paper, the sum term may be replaced by the term $(Cl^-)^y/K_y$, where y is a weighted average of the number of chlorine atoms per complex.[18] Equa-

(17) The latter assumption seems justified in view of the fact that the formal potentials in hydrochloric acid solutions are about 0.5 volt more positive than the corresponding potentials in perchloric acid solution.

(18) The condition for the replacement is that

$$(Cl^-)^y = \frac{a(Cl^-) + b(Cl^-)^2 + \ldots + n(Cl^-)^n}{ab\ldots.n}$$

where the coefficients are products of suitable dissociation constants. Consequently, the value of y is a function of chloride ion concentration as well as of the exponents, but for our experiments the change in y for a ten-fold change in (Cl^-) is less than 10%. This change in slope cannot be detected in our graphs, and for all practical purposes y is a constant.

tion (4) then becomes

$$E^{0''} = y(RT/2F) \ln(Cl^-) + \text{constant} \qquad (5)$$

Accordingly, a straight line should be obtained if $E^{0''}$ is plotted against log c_3, the slope being 2.303 $(RT/2F)y$.

In order to investigate this power dependence of $E^{0''}$ upon the chloride ion concentration, plots were made of the data from Series 3, 4 and 5, and these are given in Fig. 2. Within the experimental error the points fall on straight lines the slopes of which are almost identical. The average number of chlorine atoms per thallic complex was thus found to be 3.5 ± 0.2, indicating that chlorothallate anions exist in appreciable concentrations under the given conditions. Definite conclusions regarding the formulas of such complex ions cannot be deduced from these data, however.[19]

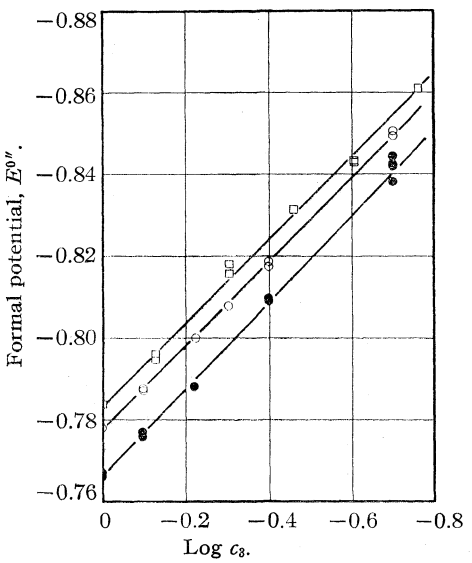

Fig. 2.—Power dependence of formal potential upon the chloride ion concentration: ●, μ = 4.01; ○, μ = 2.00; □, μ = 1.00.

In the last column of Table II are given values of $E^{0'''}$, the formal potential for the reaction

$$Tl^+ + 3.5Cl^- = TlCl_{3.5}^{0.5-} + 2e^-$$

Using the average of the values at each ionic strength, the following relation has been derived for the temperature of 25°

$$E^{0'''} = -0.7880 + 0.00508\,\mu \qquad (6)$$

Equation (6) reproduces within 1 mv. the values of $E^{0'''}$ over the range μ = 1 to μ = 4.

Equation (6) may be combined with the standard free-energy of ionization of solid thallous chloride[20] to give for the reaction

$$TlCl(s) + 2.5Cl^- = TlCl_{3.5}^{0.5-} + 2e^-$$

the formal potential, $E^{0''''}$, at 25°

$$E^{0''''} = -0.8902 + 0.00508\,\mu \qquad (7)$$

This value should replace that estimated by Latimer.[21]

Summary

1. The formal oxidation–reduction potential, $E^{0''}$, of thallous–thallic salts in 0.9952 f hydrochloric acid has been determined at 25 and 15°. $E^{0''} = -0.7829 \pm 0.0015$ volt for the reaction $Tl^I = Tl^{III} + 2e^-$ at 25° in the above acid solution and for a thousand-fold variation of thallic salt concentration. The thermodynamic constants for the reaction Tl^+ (0.9952 f HCl) + $2H^+$ (a = 1m) = Tl^{III} (0.9952 f HCl) + H_2 (1 atm.) were found to be: $\Delta F^0_{298} = 36.12$ kcal., $\Delta H^0_{298} = 34.48$ kcal., and $\Delta S^0_{298} = -0.0055$ kcal./deg.

2. Measurements have been made of the potentials in mixtures of hydrochloric and perchloric acid solutions of constant total acid concentration and constant ionic strength. The results were interpreted in terms of the formation of chlorothallate anions of the type $TlCl_4^-$ and $TlCl_6^{---}$. Most of the thallic ions are bound in the form of such complexes, there being one thallium atom and, on the average, 3.5 chlorine atoms per complex in the range of hydrochloric acid concentration from 0.1 to 1 f.

3. For the half-cell reaction $Tl^+ + 3.5Cl^- = TlCl_{3.5}^{0.5-} + 2e^-$, the formal potential at 25° was found to be given by the relation $E^{0'''} = -0.7880 + 0.00508\,\mu$, over the range of ionic strength from μ = 1 to μ = 4. The corresponding formal potential, $E^{0''''}$, for the reaction $TlCl(s) + 2.5Cl^- = TlCl_{3.5}^{0.5-} + 2e^-$ is $E^{0''''} = -0.8902 + 0.00508\,\mu$.

AUSTIN, TEXAS RECEIVED APRIL 21, 1942

(19) It has been reported that a solid with the composition $TlCl_3 \cdot 3TlCl$ may be prepared from thallous and thallic chlorides (see, for example, Spencer and Abegg, *loc. cit.*). If this solid is a compound it may be thallous hexachlorothallate, in which event $TlCl_6^{---}$ ions presumably could exist in solution as well as in the crystal lattice. Covalent complexes of this type could probably be formed by use of the 6s and 6p orbitals ($TlCl_4^-$, sp^3) or with the 6s, 6p and two 6d orbitals ($TlCl_6^{---}$, sp^3d^2); these two complexes would then resemble $SnCl_4$ and $SnCl_6^{--}$, since it is likely that the latter make use of the corresponding 5s, 5p and 5d orbitals in bond formation. There would probably be an appreciable amount of ionic character to such bonds.

(20) $TlCl(s) = Tl^+(aq.) + Cl^-(aq.)$; $\Delta F^0_{298} = 5.086$ kcal. Latimer, "Oxidation Potentials," Prentice-Hall, Inc., New York, N. Y., 1928, p. 152.

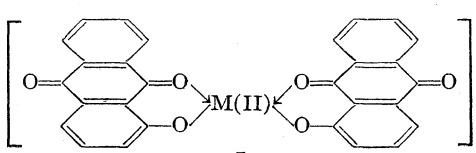
Preparation and Properties of Some Peri-Hydroxyquinone Inner Complexes[1]

BY BRADFORD P. GEYER[2] WITH GEORGE MCP. SMITH

Little work has been done on the preparation and characterization of simple inner complexes of compounds containing the C,C,C–O,OH chelating group.[3] Such inner complexes are of interest because of their structural relationship to the color lakes derived from alizarin and related substances. Because of the remarkable difference in color of these inner complexes compared to the color of the quinone and the metal ion involved, the preparation of several inner complexes of some peri-hydroxyquinones was undertaken with a view to determining, by absorption spectra, the relationship between color and structure.

1. 1-Hydroxyanthraquinone Inner Complexes.—Only three inner complexes of 1-hydroxyanthraquinone (9,10-anthracenedion-1-ol) have been described. Machemer[4] has prepared the cobalt(II) and copper(II) complexes of this quinone. Pfeiffer and co-workers[5] have made the dipyridinonickel(II) compound. We have prepared the four-coördinate cobalt(II), copper(II), magnesium, manganese(II), nickel(II), diaquonickel(II), and uranyl inner complexes of 1-hydroxyanthraquinone, with the general structure I.



I

Starting Material.—1-Hydroxyanthraquinone was prepared by a method similar to that of Roemer.[6] To 10 g. of 1-aminoanthraquinone in 500 ml. of glacial acetic acid, a cold solution of 3.5 g. of sodium nitrite in 25 ml. of 36 *N* sulfuric acid was added gradually. After forty-two hours the solution was concentrated, a large volume of cold water added, and the solid filtered off after nine hours. By treating the crude acetoxy compound with 100 ml. of 3 *N* sodium hydroxide under reflux for three hours and then acidifying with 6 *N* hydrochloric acid, 1-hydroxyanthraquinone was obtained. Sublimation of the product yielded 4.6 g. (46%) of pure yellow-orange hydroxyquinone; m. p. 193–194°. A sample of the crude 1-acetoxyanthraquinone, recrystallized from chloroform, formed pale-yellow crystals; m. p. 175–176°.

Inner Complexes: 9,10-Anthracenedion-1-olato-cobalt (II).—A cold, filtered solution of 0.25 g. of $Co(OAc)_2 \cdot 4H_2O$ in 50 ml. of methanol was added to a hot, filtered solution of 0.45 g. of 1-hydroxyanthraquinone in 200 ml. of methanol. The dark red mixture was heated under reflux for one-half hour, the solid filtered off when cool, washed with hot methanol, and dried at 100° to a brown powder.

9,10-Anthracenedion-1-olato-copper(II).—A cold solution of 0.40 g. of $Cu(OAc)_2 \cdot H_2O$ in 100 ml. of water was added to 400 ml. of a warm 95% ethanol solution of 0.90 g. of 1-hydroxyanthraquinone The solid was filtered off after twelve hours, washed with ethanol and water, and dried at 105°. It was purified by extraction with 95% ethanol for seven hours, followed by extraction with water, and dried at 105° to a bright brownish-red powder.

9,10-Anthracenedion-1-olato-magnesium.—To a warm solution of 0.90 g. of 1-hydroxyanthraquinone in 400 ml. of ethanol was added 100 ml. of a cold, water solution of 0.43 g. of $Mg(OAc)_2 \cdot 4H_2O$. Six *N* ammonium hydroxide was added dropwise until a definite precipitate persisted. After standing overnight, the excess 1-hydroxyanthraquinone was removed by decanting the reheated solution from the solid. This solid was washed with hot ethanol, followed by hot water, dried at 100°, and extracted with 95% ethanol. This inner complex is a deep red powder.

9,10-Anthracenedion-1-olato-manganese(II).—A cold solution of 0.98 g. of $Mn(OAc)_2 \cdot 4H_2O$ in 50 ml. of methanol was mixed with a warm solution of 0.90 g. of 1-hydroxyanthraquinone in 300 ml. of ethanol. The solution was concentrated under reduced pressure. After cooling, the solid formed was collected by filtration, washed with cold water and ethanol, and dried at 105°. To remove excess quinone, the solid was heated for one hour under vacuum in a drying pistol at 205°. The compound was obtained as a dark olive-brown powder.

9,10-Anthracenedion-1-olato-nickel(II).—The four-coördinate nickel complex was prepared exactly as was the cobalt compound, using identical quantities. The unsolvated complex is an orange-brown powder.

Diaquo-9,10-anthracenedion-1-olato-nickel(II).—The six-coördinate diaquo nickel complex was prepared by the method used for the copper(II) complex, using 0.50 g. of $Ni(OAc)_2 \cdot 4H_2O$, the other quantities being the same; red-violet powder.

9,10-Anthracenedion-1-olato-uranyl.—One hundred ml. of a warm methanol solution of 1.70 g. of $UO_2(OAc)_2 \cdot 2H_2O$ was added slowly to 300 ml. of a warm methanol solution of 0.90 g. of 1-hydroxyanthraquinone. After several days, the crystals were removed, washed with cold methanol, and dried at 105°. The complex was heated in the drying pistol at 204° for one hour; purple-brown crystals.

These compounds are stable at high temperatures, highly colored, insoluble in water, and in the common organic solvents at room temperature. Strong acids de-

[a] H_2O calcd.: 1:2. Found: 1:2.1; 1:1.9.

compose the complex with liberation of the quinone. The analytical data for the complexes are in Table I.

2. 1-Acetylalizarin Inner Complexes.—It has been reported[7] that alizarin, 1,2-dihydroxyanthraquinone, upon direct interaction with metal acetates, forms normal salts. Acetylation of the more active 2-hydroxy group should permit chelation through the other, or 1-hydroxy, group. As was expected, 2-acetylalizarin (2-acetoxy-9,10-anthracenedion-1-ol) did form an inner complex with copper(II) ion. The complex was similar in color and behavior to the corresponding complex of 1-hydroxyanthraquinone.

Starting Material.—2-Acetylalizarin was prepared according to Perkin[8]; m. p. 197–198°.

Inner Complex: 2-Acetoxy-9,10-anthracenedion-1-olato-copper(II).—A warm solution of 0.20 g. of $Cu(OAc)_2\cdot H_2O$ in 30 ml. of absolute alcohol was added dropwise to a warm solution of 0.56 g. of 2-acetylalizarin in 20 ml. of nitrobenzene, with stirring. After five hours, the solid was filtered off, washed with hot ethanol, then with ether, and dried. The dry powder was heated for six hours in the drying pistol at 210°, followed by extraction with chlorobenzene and reheating at 210°; red-brown powder.

3. 3-Nitroalizarin Inner Complexes.—The hydrogen bonding of peri-hydroxyquinones[9] and of *o*-nitrophenols would suggest the possibility of inner complex formation through either of the two chelating groups in 3-nitroalizarin (3-nitro-9,10-anthracenedion-1,2-diol). This proved to be the case, for a copper(II) compound, which exhibited typical inner complex behavior, was prepared from the nitro compound.

Starting Material.—Crude 3-nitroalizarin was recrystallized from glacial acetic acid; m. p. 244–245°, with decomposition.

Inner Complex: 3-Nitro-9,10-anthracenedion-2(1)-ol-1(2)-olato-copper(II).—A cold solution of 0.20 g. of $Cu(OAc)_2\cdot H_2O$ in 100 ml. of absolute alcohol was added slowly to a suspension of 0.57 g. of 3-nitroalizarin in 100 ml. of cold, absolute alcohol contained in a 3-neck flask fitted with mercury-seal stirrer, condenser with anhydrone-filled drying tube, and dropping funnel. The mixture was stirred and heated under reflux for seven hours, and while still hot was filtered. The solid was washed with cold ether, air-dried, and then heated for ninety minutes in the drying pistol at 255° to give purplish-brown microcrystals.

Absorption Spectra

The absorption of these inner complexes was measured in the visual range following the same procedure as in our earlier publication.[10] In the case of the inner complexes of 1-hydroxy-anthraquinone, absorption occurs over one narrow band in the violet and another narrow, but less intense, band in the blue-green. As in the phthiocol series of inner complexes previously described[10] the intensity of absorption is dependent upon the metal present. The absorption curves for the four-coördinate 1-hydroxyanthraquinone complexes are all similar in shape. Table I shows the wave lengths at which maximum absorption occurs and the corresponding molecular extinction coefficients.

From 370–410 mμ, the absorption of the cobalt(II), copper(II), magnesium, and nickel(II) inner complexes show the same relationships observed among the corresponding phthiocol complexes. From 470–580 mμ the absorption characteristics of the cobalt(II), copper(II), and nickel(II) complexes are again similar to the phthiocol compounds. The color of the inner complexes is caused more by the formation of the chelate ring than by the presence of a particular metal. This latter fact has been observed in all of the studies on the absorption spectra of *o*-quinone monoxime, *o*-hydroxyazo dye, and *o*-hydroxyquinone inner complexes prepared in this Laboratory.[10,11]

The absorption spectra curves for 2-acetylalizarin and 3-nitroalizarin, with those for their

copper(II) complexes, are similar in gross detail to the corresponding hydroxyanthraquinone curves.

Experimental

The experimental procedure for absorption spectra measurements[12] was the same as that described in our earlier publication.[10] The concentrations of the *n*-butanol solutions ranged from 0.00003 to 0.0002 *M*. Values of the extinction coefficients were calculated by Beer's law.

Catalytic Behavior of the Inner Complex[10]

It was found that certain of the inner complexes prepared could catalyze the chemiluminescent oxidation of luminol (3-amino-phthalhydrazide) by hydrogen peroxide. The cobalt(II) and copper(II) complexes of 1-hydroxyanthraquinone and the copper(II) complexes of 2-acetylalizarin and 3-nitroalizarin all exhibit decreasing degrees of catalytic activity, in that order. The free quinones are inactive.

The 1-hydroxyanthraquinone-cobalt(II) complex produces a bluish violet-white luminescence, lasting over three hours, but not as intense as the light produced with the cobalt(II) complex of phthiocol. The copper(II) complex produces a blue-white light of three-hour duration, but of lower intensity than either the 1-hydroxyanthraquinone cobalt(II) complex or the phthiocol copper(II) complex. Solubility and stability of the complex appear to be the governing factors in the catalysis of chemiluminescent oxidation.

(12) With H. M. Haendler.

Summary

1. The preparation and properties of the cobalt(II), copper(II), magnesium, manganese(II), nickel(II), diaquonickel(II), and uranyl inner complexes of 1-hydroxyanthraquinone, as well as the copper(II) inner complexes of 2-acetylalizarin and 3-nitroalizarin have been described.

2. The absorption spectra of these inner complexes in *n*-butanol solution have been determined in the visual region.

3. The color of the complex is due to the chelation of the quinone with the metal.

4. The cobalt(II) and copper(II) inner complexes of 1-hydroxyanthraquinone and the copper(II) inner complexes of 2-acetylalizarin and 3-nitroalizarin catalyze the chemiluminescent oxidation of luminol by hydrogen peroxide.

[CONTRIBUTION FROM THE IOWA AGRICULTURAL EXPERIMENT STATION]

The Molecular Weights of the Schardinger Alpha and Beta Dextrins[1]

BY DEXTER FRENCH AND R. E. RUNDLE

The work of Freudenberg[2] and others[3] indicates that the Schardinger dextrins are composed solely of glucose residues bonded by α-1,4-glucosidic linkages as in starch. Though these dextrins are of much lower molecular weight than starch, they are completely non-reducing. The only structure which appears to be consistent with these chemical properties is a cyclic structure.[4]

Several molecular species with the chemical properties given above are known to occur in the dextrin mixture obtained by the *B. macerans* enzymolysis of starch. The main components of the mixture have been separated and characterized by Freudenberg and Jacobi.[5] The molecular weights which these authors suggest for these species were determined by cryoscopic methods, but since these dextrins are of comparatively high molecular weight and are very difficult to free from low molecular weight impurities (solvent of crystallization and inorganic ash), the cryoscopic molecular weights can be expected to be but rough approximations.

A method better adapted to the determination of the molecular weights of high molecular weight crystalline compounds is X-ray diffraction combined with crystal density measurement. In this method low molecular weight impurities are of minor importance, and their contribution to the crystal density can be determined and corrected for with satisfactory accuracy.

By this method we have found Schardinger's

α-dextrin to contain six glucose residues per molecule and the β-dextrin to contain seven glucose residues per molecule, whereas Freudenberg and Jacobi[5] report five and six, respectively.[6] That the cryoscopic values are too low is not unexpected.

Naming of the Compounds.—The chemical properties of the α- and β-dextrins together with the molecular weights reported here leave no doubt as to the gross structure of these compounds. Their present names have no structural significance, nor have the names been standardized in usage.[7] The term amylose has been generally applied to those compounds possessing the α-1,4-glucosidic linkage of starch. The prefix *cyclo* adequately describes the distinguishing structural characteristics of this class of compounds, and the usual Greek terms can be used to identify the members of the class through the number of glucose residues in the ring. We therefore propose that Schardinger's α-dextrin be named cyclohexaamylose, and the β-dextrin be named cycloheptaamylose.

Experimental

Preparation of the Cycloamyloses.—The cycloamyloses were prepared by enzymolysis of potato starch as described by Schoch,[8] and were separated and purified by the method of Freudenberg and Jacobi.[5] The authors are indebted to Drs. T. J. Schoch and R. W. Kerr of Corn Products Refining Company for part of the material used in this investigation. Crystals of cyclohexaamylose were prepared by adding 95% ethanol to a hot, 30% aqueous solution of the cyclohexaamylose until the concentration of alcohol reached 60–80%. On cooling, crystals deposited in large, glass-clear, orthorhombic prisms. For anhydrous cyclohexaamylose $[\alpha]_D$ is 151.4 ± 0.5°. Crystals of cycloheptaamylose were prepared by evaporation of a saturated, aqueous solution at room temperature. For anhydrous cycloheptaamylose $[\alpha]_D$ is 161.9 ± 0.5°. The identity of these compounds with the α- and β-dextrins was confirmed by the formation of characteristic iodine addition products: blue-black hexagonal prisms and greenish needles from the cyclohexaamylose, and red-brown prisms from the cycloheptaamylose.

X-Ray Diffraction Patterns.—Twenty degree oscillation patterns were taken about all three axes of both crystals reported here. They were obtained using Ni filtered Cu Kα radiation and a cylindrical camera of 5-cm. radius. Reciprocal lattice goniometer patterns[9] were also made with Cu Kα radiation and a sample to film distance of $2\sqrt{3}$ cm., with the axis of rotation inclined 60° to the X-ray beam.

Cyclohexaamylose.—The density, measured by flotation in a mixture of chloroform and toluene, was 1.436 ± 0.004. The amount of volatile matter (water and/or alcohol of crystallization) amounted to 12.2 ± 0.1% of the weight of the crystals, and an ash determination showed the presence of 1.63 ± 0.02% inorganic impurity. The average value for the carbohydrate density is then 1.237 ± 0.005.

The primitive translations of the lattice, as obtained by layer line separations on oscillation patterns, are a_0 = 15.49 Å.; b_0 = 24.06 Å.; c_0 = 13.93 Å. The volume of the orthorhombic unit is 5195 cu. Å. Since the molecular weight of a glucose residue is 162.1, the number of glucose residues per unit cell is

$$\frac{5195 \times 1.237 \times 6.06 \times 10^{-1}}{162.1} = 24.02 \cong 24$$

The crystal has orthorhombic symmetry as shown by oscillation and goniometer diffraction patterns. Since the molecules are optically active only those space groups isomorphous with the point group V-222 are allowed. Many reflections from all types of planes eliminate all space groups based on any but the primitive orthorhombic lattice. The possible space groups are then V^1-$P222$, V^2-$P222_1$, V^3-$P2_12_12$, and V^4-$P2_12_12_1$. Examination of the ($h00$), ($0k0$), and ($00l$) reflections on intense oscillation and goniometer patterns reveals that all odd orders of these reflections are missing. It was possible to observe 16 orders of ($h00$), 26 orders of ($0k0$), and 14 orders of ($00l$), so that the space group is doubtless V^4-$P2_12_12_1$. This space group requires a multiple of four molecules per unit cell regardless of molecular symmetry. The number of glucose residues per molecule is then 6, 3, or 2. The latter two possibilities may be excluded on the basis of the chemical behavior of this compound and the fact that a ring of three or two glucose residues is sterically impossible. Moreover, it is quite unusual for a unit cell to contain a number of molecules greater than that required by the crystal symmetry.[10]

Cycloheptaamylose.—Crystals were obtained having a density of 1.444 ± 0.004 and a water content of 14.18 ± 0.02%. The carbohydrate density is therefore 1.240 ± 0.004. The crystals exhibit monoclinic symmetry as shown by oscillation and reciprocal lattice patterns. The unit translations determined by layer line separations are a_0 = 15.27 Å.; b_0 = 10.24 Å.; c_0 = 20.93 Å. The monoclinic angle β = 68.0° (sin β = 0.9272) was determined by direct measurement on reciprocal lattice patterns and confirmed by Laue patterns. The volume of the unit cell is

(6) O. Kratky and B. Schneidmesser [*Ber.*, **71**, 1413 (1938)], claim to have found five glucose residues per molecule of the alpha-dextrin, but their work contains a discrepancy. The possible space groups which they find for their crystal are V^3 — $P2_12_12$ and V^4 — $P2_12_12_1$. V^4 requires four asymmetric molecules per cell, and V^3 requires four asymmetric molecules or two molecules possessing a two-fold axis. They find for their unit cell two molecules of five glucose residues each, molecules which cannot possess the required symmetry.

(7) Schardinger called these compounds "crystallized amylose" and "crystallized amylopectin" [*Zentr. Bakt. Parasitenk. II*, **22**, 98 (1908)]. Pringsheim used the name "polyamylose," and referred to the individual compounds as α-tetraamylose, β-hexaamylose, etc. [*Ber.*, **47**, 2565 (1914)]. Freudenberg and Jacobi (ref. 5) refer to these compounds as α-dextrin, β-dextrin, etc., and later as pentaosan, hexaosan, etc. [K. Freudenberg and H. Boppel, *Ber.*, **73**, 609 (1940)].

(8) T. J. Schoch, Report to the Corn Industries Research Foundation (1940). This method is an adaptation of the method of E. B. Tilden and C. S. Hudson, THIS JOURNAL, **61**, 2900 (1939).

(9) The instrument used was the Clark–Gross modification of the reciprocal lattice X-ray goniometer described by W. F. deJong and J. Bouman, *Z. Krist.*, **98**, 456 (1938); **99**, 326 (1938).

(10) A. E. H. Tutton, "Crystalline Form and Chemical Constitution," The Macmillan Co., London, 1926, p. 31.

3032 cu. Å. The number of glucose residues per unit cell is then

$$\frac{3032 \times 1.240 \times 6.06 \times 10^{-1}}{162.1} = 14.05 \cong 14$$

The monoclinic space groups allowed for an optically active molecule are C_2^1-$P2$, C_2^2-$P2_1$, and C_2^3-$C2$. Many reflections of the form (hkl) with $(h + k)$ odd are present so that C_2^3-$C2$ is eliminated. Intense reciprocal lattice goniometer patterns were made rotating the crystal about the zone [100]. All reflections of the form $(0kl)$ were observed to $(\sin\theta)/\lambda = 0.56$, except the odd orders of $(0k0)$, through (090), which were absent. The space group can then be taken as C_2^2-$P2_1$. This space group requires an even number of molecules per unit cell so we must have two molecules of seven glucose residues each.

Summary

1. The molecular weights of the Schardinger α- and β-dextrins have been accurately determined by X-ray diffraction and crystal density measurements.

2. The α-dextrin contains six glucose residues per molecule and has been renamed cyclohexaamylose; the β-dextrin contains seven glucose residues and has been renamed cycloheptaamylose.

Sterols. CXLVII. Sapogenins. LXI. The Bio-reduction of Steroids

BY RUSSELL E. MARKER, R. B. WAGNER AND PAUL R. ULSHAFER

It has been postulated that Δ^5-3-hydroxysteroids arise as reduction products of Δ^4-3-ketosteroids under biological conditions.[1] Using Δ^4-dehydrotigogenone as a model substance for the bio-reduction process, we[3] have recently shown that this when administered to a dog on a biscuit diet gave diosgenin (I), smilagenin (iso-sarsasapogenin) (II) and *epi*-smilagenin (*epi*-iso-sarsasapogenin) (III). These results not only support our hypothesis, but also support the conception that cholestenone is an intermediate in the formation of coprosterol in the organism[1,5] since the products, (I), (II) and (III) correspond in nuclear structure to cholesterol, coprosterol and *epi*-coprosterol. The sapogenin derivatives having the characteristic side-chain act as effective indicators and are not subject to the suggestions of Fieser and Wolfe.[2]

We have now extended this work along the line of that of Rosenheim and Webster[4] who showed that β-sitosterol administered together with brain-powder to rats was converted into an isomeride of sitostanol which they named *copro*-sitostanol. The latter agrees in composition and properties with 24-ethylcoprostanol-3(β). Since a coprostane derivative has not been obtained directly from a Δ^5-3-hydroxysteroid by chemical action Rosenheim and Webster's experiment indicates a Δ^4-3-ketosteroid as a very probable intermediate for the formation of the *copro*-sitostanol.

Accordingly, diosgenin (I) was administered to a dog fed on a meat diet containing small portions of pig brain. The non-saponifiable fraction of the feces gave smilagenin (II) and *epi*-smilagenin (III) products which correspond to coprosterol and its epimer. This and the previous conversion support the hypothesis of Schoenheimer[5] that there is a reversible biological reaction of the type cholestenone $\rightleftarrows$ cholesterol. Δ^4-Dehydrotigogenone (IV) may be reduced by one enzyme system to smilagenin (II) and *epi*-smilagenin (III) or by another enzyme system converted to diosgenin (I). The present work indicates the reversible reaction involving the following oxidation–reduction mechanism; diosgenin (I) $\underset{[R]}{\overset{[O]}{\rightleftarrows}}$ Δ^4-dehydrotigogenone (IV) $\xrightarrow{[R]}$ smilagenin (II) and *epi*-smilagenin (III). These reactions are summarized in the accompanying chart.

Another observation in the present work is that the bio-reduction of keto-sapogenins gives hydroxy compounds of both alpha and beta configuration. This is contrary to the earlier statements[1] that reduction *in vivo* of 3-ketosteroids appears to give only alpha compounds. Tigogenone and sarsasapogenone having the cholestane and the coprostane configuration, respectively, were administered to a dog fed on a meat diet. In the case of the tigogenone the feces contained both

tigogenin and *epi*-tigogenin. Similarly, the sarsasapogenone gave both sarsasapogenin and its epimer.

We thank Parke, Davis and Company for their assistance.

Experimental Part

The Biological Conversions of Diosgenin.—A 10-kg. dog was fed daily a mixture of 150 g. of meat, 50 g. of pig-brain and 3 g. of diosgenin for three consecutive days. After these feedings the dog was maintained for three additional days on a meat diet. Its feces were collected during the entire period and immediately ground up in acetone. The residue was further extracted with ether. The solvent was removed and the residue hydrolyzed with alcoholic potassium hydroxide. The product was extracted with ether and the ethereal solution washed with water. The solvent was removed and the residue was refluxed with 30 cc. of acetic anhydride for thirty minutes. After cooling the crystalline product was filtered and washed with cold ether; m. p. and mixed m. p. with an authentic sample of diosgenin acetate, 197–200°; yield 5.2 g.

The filtrate was vacuum distilled and the residue was refluxed for thirty minutes with alcoholic potassium hydroxide. Water was added and the product extracted with ether. The solvent was removed and the residue was heated on a steam-bath for two hours with 50 cc. of pyridine and 10 g. of succinic anhydride. After cooling, ether was added and the pyridine was removed by washing the ethereal solution with dilute hydrochloric acid. The ether layer was then washed well with potassium carbonate solution. The aqueous layer was acidified and extracted with ether. The solvent was removed and the residue was refluxed with alcoholic potassium hydroxide for thirty minutes. Water was added and the product was extracted with ether. The solvent was removed and the residue was dissolved in a small amount of 95% alcohol. To this was added a solution of 15 g. of digitonin in 700 cc. of 95% ethanol. After standing for two hours in the ice-box the digitonide was filtered and washed well with alcohol. The filtrate was concentrated to about 50 cc., ether was added and the excess digitonin filtered off. The filtrate was washed well with water, the solvent was removed and the residue was crystallized from methanol, m. p. and mixed m. p. with an authentic sample of *epi*-smilagenin 217–220°; yield 0.2 g. of good material.

When refluxed with acetic anhydride it gave an acetate which was crystallized from methanol and from acetone; m. p. and mixed m. p. with an authentic sample of *epi*-smilagenin acetate, 158–160°.

Anal. Calcd. for $C_{29}H_{46}O_4$: C, 75.9; H, 10.1. Found: C, 76.0; H, 10.2.

The digitonide was decomposed with pyridine and the product thus obtained was converted to the acetate and crystallized from ether to give an additional crop of diosgenin acetate. The filtrate from this was fractionally crystallized from methanol and from acetone to give a product; m. p. and mixed m. p. with an authentic sample of smilagenin acetate, 127–130°; yield 0.1 g. of good material.

Anal. Calcd. for $C_{29}H_{46}O_4$: C, 75.9; H, 10.1. Found: C, 75.8; H, 10.0.

Sarsasapogenone.—The dog was fed meat containing 7 g. of sarsasapogenone divided into three daily feedings. Its feces were collected for six consecutive days and immediately ground up with acetone. After a thorough extraction with acetone the feces were extracted with ether. The combined extracts were evaporated and the residue was hydrolyzed with alcoholic potassium hydroxide for thirty minutes. Water was added and the product was extracted well with ether. The solvent was removed and the residue was heated on a steam-bath for two hours with 25 cc. of pyridine and 10 g. of succinic anhydride. Ether was added and the pyridine was removed by washing the ethereal solution with dilute hydrochloric acid. The succinates were removed by shaking with potassium carbonate solution. The aqueous layer was acidified, extracted with ether and the solvent removed. The residue was hydrolyzed by refluxing with alcoholic potassium hydroxide. The neutral fraction was extracted with ether and the solvent was removed; yield 2.7 g.

The residue was dissolved in alcohol and 10 g. of digitonin in 500 cc. of ethanol was added. After standing at room temperature for several hours the digitonide was filtered, washed with alcohol and dried. It was then decomposed by warming on a steam-bath for one hour with pyridine. Ether was added and the digitonin was filtered. The filtrate was washed well with water and dilute hydrochloric acid. The solvent was evaporated and the residue was crystallized from ethanol and from methanol; m. p. and mixed m. p. with an authentic sample of sarsasapogenin, 199–200°.

When refluxed with acetic anhydride it gave sarsasapogenin acetate; m. p. and mixed m. p. 126–128°.

Anal. Calcd. for $C_{29}H_{46}O_4$: C, 75.9; H, 10.1. Found: C, 75.8; H, 10.2.

The filtrate from the digitonide was evaporated to about 50 cc. Ether was added and the digitonin was filtered off. The filtrate was washed well with water and the solvent removed. The residue was crystallized from methanol; m. p. and mixed m. p. with *epi*-sarsasapogenin, 205–209°. When refluxed with acetic anhydride it gave a product which was crystallized from methanol; m. p. and mixed m. p. with *epi*-sarsasapogenin acetate, 190–195°.

Anal. Calcd. for $C_{29}H_{46}O_4$: C, 75.9; H, 10.1. Found: C, 76.0; H, 10.3.

Tigogenone.—The dog was fed a meat diet containing 7 g. of tigogenone. The feces were extracted and worked up as described above. The digitonin precipitable fraction gave a product which was crystallized from methanol; m. p. and mixed m. p. with tigogenin, 200–202°. This gave tigogenin acetate; m. p. and mixed m. p. with tigogenin acetate, 197–199°.

Anal. Calcd. for $C_{29}H_{46}O_4$: C, 75.9; H, 10.1. Found: C, 76.2; H, 10.3.

The fraction not precipitated by digitonin was crystallized from acetone; m. p. and mixed m. p. with an authentic sample of *epi*-tigogenin, 242–244°. This product gave *epi*-tigogenin acetate; m. p. and mixed m. p., 199–201°.

Anal. Calcd. for $C_{29}H_{46}O_4$: C, 75.9; H, 10.1. Found: C, 75.7; H, 10.1.

Summary

1. Diosgenin has been biologically converted to smilagenin and *epi*-smilagenin.

2. Similarly tigogenone and sarsasapogenone have been converted to the carbinols of both the alpha and beta configurations.

3. The significance of these facts has been discussed.

STATE COLLEGE, PENNA. RECEIVED MARCH 5, 1942

Sterols. CXLVIII. Sapogenins. LXII. The Structure of the Side Chain in the Dihydro-pseudosapogenins[1]

BY RUSSELL E. MARKER, D. L. TURNER AND PAUL R. ULSHAFER

When dihydro-pseudosarsasapogenin (I) was oxidized with chromic anhydride at 15–18°, two products were obtained,[2] a C-27 keto acid (II) and 16-pregnenedione-3,20 (V). The latter arises from an acid oxidation intermediate which is hydrolyzed on extraction from ethereal solution with alkali.[3] In the same manner the oxidation of dihydropseudotigogenin gives an isomeric C-27 keto acid (VIII) together with 16-*allo*-pregnenedione-3,20 (VII).

On oxidation with chromic acid the two keto-acids, like the corresponding dihydropseudosapogenins, are converted to 16-pregnenedione-3,20 (V) and 16-*allo*-pregnenedione-3,30 (VII), respectively. This suggested that the formation of the keto acids involves only the oxidation of the two hydroxyl groups at C-3 and C-27. The presence of a single carbonyl group in each acid was indicated by the analyses of the oximes and semicarbazones.[4]

Clemmensen reduction of the acid (VIII) from dihydro-pseudotigogenin removed only one oxygen to give the 3-desoxy acid (IX). Catalytic reduction of both keto acids in neutral solution gave the corresponding 3-hydroxy acids (IV), (VI), (X). In the case of the acid from dihydropseudosarsasapogenin, a mixture of the epimeric carbinols resulted, the 3(α)-carbinol being present in greater quantity. The acid of the *allo* series gave the 3(β) carbinol. Bouveault reduction of the methyl ester of the acid (II) from dihydropseudosarsasapogenin gave *epi*-dihydro-pseudosarsasapogenin (III), identified as its *bis*-*p*-nitrobenzoate.[5]

These results establish definitely that the two keto acids are mono-ketones. The reactions can best be represented as in the accompanying chart.

The various reactions of the pseudosapogenins which have been reported[2,3,6,7] from this Laboratory are all consistent with the dihydrofuran formulation of the side-chain in these substances (XI).

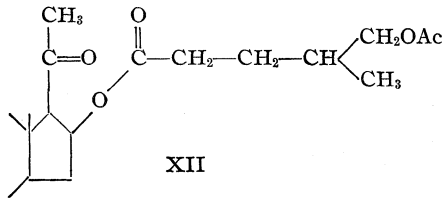
The structure of the side-chain in the oxidation products has been established as (XII).[2,3] Con-



XII

sequently the oxide bridge must be assumed to be present in dihydro-pseudosapogenins as well as in the pseudosapogenins. That the third oxygen atom is of oxide function is also indicated by the formation of diacetates from the dihydro-pseudosapogenins and by the properties of the C_{27} keto acids described in the present paper. This leads to a structure for the side-chain of dihydro-pseudosapogenins (I) which is identical with one previously assigned to the dihydrosapogenins.[8,9] The dihydrosapogenins can be oxidized to monoketo acids, anhydrotetrahydro-sarsasapogenoic acid[9] and anhydrotetrahydrotigogenoic acid,[10,11] which were assigned constitutions identical with these of the acids described in the present paper. Oxidation of the diacetates of the dihydrosapogenins at higher temperatures gave the same products which were obtained from the sapogenins: the C_{22} lactone, the sapogenoic acid, the 16-keto acid, etc.,[9,10] in extreme contrast to the behavior of the dihydro-pseudosapogenins on oxidation. This may be due to a difference of configuration at C-20 and C-22. Sterols differing only stereochemically are known to give different products of oxidation in other cases.[12]

We thank Parke, Davis and Company for their assistance.

Experimental Part

Oxidation of Dihydropseudotigogenin.—To a solution of 8 g. of dihydropseudotigogenin in 400 cc. of acetic acid at 15° was added a solution of 6.4 g. of chromic anhydride in 50 cc. of 60% acetic acid. The temperature was maintained at 10–15° for thirty minutes. The product was poured into water and then extracted with ether. The ethereal solution was washed free of acetic acid with water. The acid was then removed with 10% sodium hydroxide solution. The alkaline layer was allowed to stand for thirty minutes and then reëxtracted with ether. The C_{27} keto acid separated in the alkaline layer as an insoluble sodium salt. This was filtered and decomposed with dilute hydrochloric acid. It was taken up in ether and crystallized after evaporation to a small volume; yield about 0.8 g. It was recrystallized from ethyl acetate, m. p. 207–209°.

Anal. Calcd. for $C_{27}H_{42}O_4$: C, 75.3; H, 9.6. Found: C, 75.2; H, 9.7.

The neutral fraction from the above oxidation gave material which was crystallized from acetone, m. p. 211–213°. When mixed with 16-*allo*-pregnene-3,20-dione (m. p. 210–212°) there was no depression in melting point.

Anal. Calcd. for $C_{21}H_{30}O_2$: C, 80.2; H, 9.6. Found: C, 80.1; H, 9.7.

Semicarbazone of the Above *allo*-Keto-acid (VIII).—This was prepared in the usual manner by boiling for two hours in aqueous ethanol with semicarbazide hydrochloride and potassium acetate; recrystallized from ethanol, m. p. 210–213° dec.

Anal. Calcd. for $C_{28}H_{45}O_4N_3$ (mono-semicarbazone): C, 68.9; H, 9.3. Calcd. for $C_{29}H_{46}O_4N_6$ (bis-semicarbazone): C, 64.2; H, 8.5. Found: C, 68.9; H, 9.2.

Oxime of *allo*-Keto-acid (VIII).—This was prepared by a method similar to that used for the semicarbazone and recrystallized from methanol as colorless needles which decomposed at 232–234°.

Anal. Calcd. for $C_{27}H_{43}O_4N$: C, 72.8; H, 9.7. Found: C, 72.8; H, 9.7.

Methyl Ester of *allo*-Keto-acid (VIII).—This was prepared in ether with diazomethane and recrystallized from methanol, m. p. 138°.

Anal. Calcd. for $C_{28}H_{44}O_4$: C, 75.6; H, 10.0. Found: C, 75.3; H, 9.8.

Oxidation of *allo*-Keto-acid (VIII).—To a solution of 1.4 g. of the above keto-acid in 115 cc. of acetic acid was added a solution of 1.4 g. of chromic anhydride in 28 cc. of 80 per cent acetic acid at 28°. The mixture was allowed to stand for seventy-five minutes at 28–30°. It was poured into water and extracted with ether. The ethereal solution was washed to remove acetic acid. The acid fraction was extracted with 20% potassium hydroxide solution; it was allowed to stand for one hour and then re-extracted with ether. The united ether extracts gave crystalline material on evaporation. This was recrystallized from acetone, m. p. 212–213°. When mixed with 16-*allo*-pregnene-3,20-dione, there was no depression in melting point.

Anal. Calcd. for $C_{21}H_{30}O_2$: C, 80.2; H, 9.6. Found: C, 80.0; H, 9.5.

Oxidation of Dihydropseudosarsasapogenin (I).—This followed the procedure given for the oxidation of dihydropseudotigogenin except that the sodium salt was not sepa-

rated by filtration. The acid product was crystallized from acetone, m. p. 233–236°. When mixed with the acid previously prepared[2] there was no depression in melting point.

To a solution of 300 mg. of the acid in 70 cc. of ethanol was added a solution of 1.0 g. of semicarbazide hydrochloride in 5 cc. of water and a solution of 1.0 g. of potassium acetate in 5 cc. of water. This was refluxed for two hours. The mixture was poured into water, the product was filtered and washed with water and ether. It was recrystallized from ethanol and decomposed at 236°.

Anal. Calcd. for $C_{28}H_{45}O_4N_3$: C, 68.9; H, 9.3. Found: C, 68.7; H, 9.3.

The oxime was prepared similarly. It was recrystallized from methanol and melted at 232–234°.

Anal. Calcd. for $C_{27}H_{43}O_4N$: C, 72.8; H, 9.7. Found: C, 72.4; H, 9.6.

Methyl Ester of the Above Keto-acid (II).—This was prepared with diazomethane in ether and was recrystallized from pentane as prismatic needles, m. p. 116.5°. Upon standing for two years the ester previously described had changed in melting point from 85–87° to 112°, apparently changing crystalline form. This gave no depression with the above sample.

Anal. Calcd. for $C_{28}H_{44}O_4$: C, 75.6; H, 10.0. Found: C, 75.6; H, 10.0.

Semicarbazone of the Methyl Ester of the Above Keto Acid (II).—This was prepared in the usual manner and recrystallized from methanol. It decomposed at 225°.

Anal. Calcd. for $C_{29}H_{47}O_4N_3$: C, 69.4; H, 9.4. Found: C, 69.3; H, 9.4.

Bouveault Reduction of the Methyl Ester of (II).—Sodium (2.5 g.) was added to a solution of 2.0 g. of methyl ester in 20 cc. of absolute ethanol (dried over magnesium methylate). The mixture was boiled for one hour, then an additional 25 cc. of absolute ethanol and 2 g. of sodium was added. After boiling for two additional hours the mixture was poured into water and extracted with ether. The ethereal solution was washed with water and evaporated. The residue was a mixture difficult to separate. It was dissolved in dry pyridine and treated with an excess of *p*-nitrobenzoyl chloride. The *p*-nitrobenzoate was isolated in the usual manner and crystallized from acetone, m. p. 206–208°. Mixed with the bis-*p*-nitrobenzoate of epidihydropseudosarsasapogenin, m. p. 208–9°, the m. p. was 206–208°, yield 0.5 g.

Anal. Calcd. for $C_{41}H_{54}O_9N_2$: C, 68.5; H, 7.6. Found: C, 68.7; H, 7.4.

Clemmensen Reduction of the Keto-acid (II) from Dihydropseudosarsasapogenin.—To a refluxing solution of 1 g. of the keto acid in 250 cc. of ethanol containing 40 g. of amalgamated zinc (20-mesh) was added 70 cc. of concentrated hydrochloric acid during a period of three hours. The mixture was refluxed for an additional hour, poured into water and extracted with ether. The residue remaining after evaporation was crystallized from methanol, m. p. 81.5–82.5.

Anal. Calcd. for $C_{27}H_{44}O_3$: C, 77.8; H, 10.6. Found: C, 78.1; H, 10.7.

Catalytic Reduction of the Keto-acid (II) from Dihydropseudosarsasapogenin.—A mixture of 1.0 g. of acid and 0.5 g. of platinum oxide catalyst in 200 cc. of absolute ethanol was shaken with hydrogen at 3 atm. for two hours. The catalyst was removed and 200 cc. of ethanol was added together with a hot solution of 8.0 g. of digitonin in 500 cc. of 85% ethanol. The digitonide which separated was decomposed with pyridine in the usual manner. The 3(β)-hydroxy acid was crystallized from acetone, m. p. 189–190°.

Anal. Calcd. for $C_{27}H_{44}O_4$: C, 74.9; H, 10.25. Found: C, 74.6; H, 10.3.

The fraction which did not precipitate with digitonin was crystallized from ether, m. p. 181–183°. This is the 3(α)-hydroxy acid.

Anal. Calcd. for $C_{27}H_{44}O_4$: C, 74.9; H, 10.25. Found: C, 74.6; H, 10.3.

The **acetate** was prepared by treatment with acetic anhydride in pyridine in the usual manner. It was crystallized from methanol, m. p. 197–199°.

Anal. Calcd. for $C_{29}H_{46}O_5$: C, 73.4; H, 9.8. Found: C, 73.5; H, 9.6.

Catalytic Reduction of the Keto-acid (VIII) from Dihydropseudotigogenin.—The keto acid was reduced by the procedure given for the reduction of the acid from dihydropseudosarsasapogenin except that the digitonin separation was unnecessary. The product was crystallized from methanol, m. p. 240–241°.

It was quite insoluble in acetone, ethyl acetate and chloroform.

Anal. Calcd. for $C_{27}H_{44}O_4$: C, 74.9; H, 10.25. Found: C, 75.1; H, 10.3.

The **acetate** was prepared by refluxing with acetic anhydride. It was recrystallized from ethyl acetate, m. p. 179–181°.

Anal. Calcd. for $C_{29}H_{46}O_5$: C, 73.4; H, 9.8. Found: C, 73.7; H, 9.7.

Summary

Evidence has been presented indicating that the side chain in the dihydropseudosapogenins has the structure

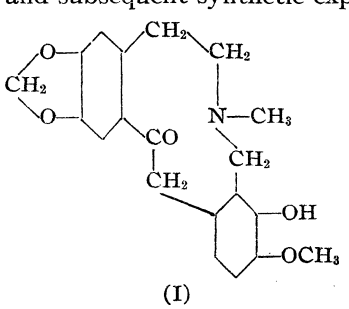
The Alkaloids of Papaveraceous Plants. XXXIV. *Hunnemannia fumariaefolia Sweet* and the Constitution of a New Alkaloid, Hunnemanine

BY RICHARD H. F. MANSKE, LÉO MARION AND ARCHIE E. LEDINGHAM

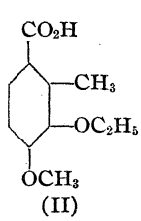
Hunnemannia is a mono-typic genus being represented only by *H. fumariaefolia Sweet*, the so-called tulip poppy. It is native to Mexico and has been successfully introduced into more temperate regions as an ornamental.

There seems to be no record of this plant having been chemically examined. Such an examination seemed to the authors particularly interesting on account of the lone position which the plant occupies in the *Papaveraceae* family.

Four alkaloids have been isolated, two of which, namely protopine and allo-cryptopine, are well-known constituents of many plants of the same family. The remaining two alkaloids appear to be new. One of these, *alkaloid F58*, is non-phenolic and is best represented by $C_{22}H_{21}O_5N$ containing two methoxyl groups. The amount available was too small for further immediate investigation. The second of the new alkaloids (F59) is now termed *hunnemanine* and its constitution has been determined. It is empirically represented by $C_{20}H_{21}O_5N$. It is a mono-hydric phenol, one methoxyl group is present, and on methylation with diazomethane it yields allo-cryptopine ($C_{21}H_{23}O_5N$). This simple observation establishes that hunnemanine is one of the two possible O-desmethyl-allo-cryptopines. That the free hydroxyl is in the sterically hindered 9-position in analogy with many other phenolic alkaloids was highly probable. On this assumption formula (I) has been adopted as a basis for degradative and subsequent synthetic experiments. The degradation of alkaloids of this nuclear type as represented by cryptopine is readily carried out by the procedure first detailed by Perkin,[1] but the yield of the final products is not always good. The O-ethyl ether of hunnemanine on subjection to the necessary series of reactions yielded two fragments. Since the isolation of one of these, 4,5-methylenedioxy-2-β-dimethylaminoethylbenzaldehyde, could give us no new information, it was not exhaustively purified. The second fragment was isolated in a pure condition and shown by a synthesis to be 2-methyl-3-ethoxy-4-methoxybenzoic acid (11), thus proving formula (I) for hunnemanine. It is pertinent to point out that this alkaloid is the first known example of a phenolic base of the protopine type. The synthesis of the above acid was effected by a very simple route but not until a variety of previous attempts had failed. Oxidation of the mono-basic acid to the known 3-ethoxy-4-methoxyphthalic acid was not practical on account of the small amount available.



(I)



(II)

The successful synthesis of the above acid was readily achieved by oxidizing the corresponding aldehyde. The synthesis of the aldehyde from 2-ethoxy-3-methoxytoluene proceeded smoothly and with good yield by Gattermann's method. It is worthy of note that in this synthesis the sole product was the desired one since the acid obtained from the crude aldehyde was pure even without recrystallization. It is to be observed in this connection that the nitration of 2,3-dimethoxybenzaldehyde gives the 6-nitro-derivative[2] almost exclusively, whereas the nitration of 2-ethoxy-3-methoxybenzaldehyde yields for the most part the 5-nitro-compound.[3] It is, of course, obvious that the synthetic and degradative acids cannot be identical unless the assigned formula is the correct one. The 2-ethoxy-3-methoxytoluene was prepared by the Clemmensen reduction of the corresponding aldehyde which was obtained by ethylating 2-hydroxy-3-methoxybenzaldehyde. For the last the authors are greatly indebted to the Monsanto Chemical Co., St. Louis, Missouri, who generously donated a liberal amount of it.

Experimental

Isolation of the Alkaloids.—The plant material for this investigation was grown in part in a local garden. The

greater portion, however, was kindly supplied by Bodger Seeds, Limited, El Monte, California, and special thanks are due to Miss Elizabeth M. Bodger of this firm who personally supervised the collecting and drying of the material. There was available a total of 12 kg. which included the roots. Nearly all of the material was collected during the early flowering stages of the plant. In the course of the chemical examination of the plant it was observed that there were present practically no alkaloids whose hydrochlorides were extractable from aqueous solution by means of chloroform. The procedure devised by one of us[4] yielded only two fractions, namely, -BS, non-phenolic bases (protopine, allo-cryptopine, and alkaloid F58) and BSE + EES, phenolic bases (hunnemanine).

Protopine and Allo-cryptopine.—The dried base, representing fraction BS, was boiled with methanol and the protopine which then crystallized was filtered off. After recrystallizing it from chloroform–methanol the protopine was obtained in brilliant colorless crystals melting at 209–210°[5] either alone or in admixture with an authentic specimen. Including a small amount obtained from the mother liquor the total yield of protopine was 0.14%.

The methanolic filtrate from the protopine was filtered with the aid of charcoal and evaporated somewhat. The crystals which then separated consisted primarily of allo-cryptopine with some protopine. The mixture was dissolved in dilute hydrochloric acid and the sparingly soluble protopine hydrochloride which then separated was filtered off. The filtrate was basified and the separated base recrystallized from chloroform–methanol. It then melted at 160° either alone or in admixture with an authentic specimen of allo-cryptopine. The yield was 0.03%.

Alkaloid F58.—The final mother liquor from which no more protopine or allo-cryptopine could be crystallized was acidified with hydrochloric acid, boiled to expel the solvents, filtered, basified with ammonia, and the liberated base extracted with ether. The washed extract was evaporated to dryness and the resin treated with an excess of oxalic acid in methanol. The sparingly soluble oxalate which then separated in orange colored plates was converted to free base by shaking with ammonia in the presence of ether. The washed ether solution left a colorless resinous base which crystallized in contact with methanol. The washed base (alkaloid F58) was recrystallized from chloroform–methanol and then consisted of aggregates of colorless fine prisms melting at 174°. It dissolved in sulfuric acid to yield an orange colored solution which changed to a dirty pink color only on heating to a high temperature. Found: C, 69.48, 69.27; H, 5.35, 5.23; N, 3.50, 3.77; OCH_3, 18.39, 18.37. Calcd. for $C_{22}H_{21}O_5N$: C, 69.65; H, 5.54; N, 3.69; OCH_3, 16.36.

Hunnemanine.—The phenolic base (BSE) precipitated by means of carbon dioxide from its solution in an excess of aqueous sodium hydroxide was dried and boiled with methanol. The cooled mixture was filtered and the crystalline solid recrystallized first from chloroform–methanol and then from a large volume of boiling methanol. Hunnemanine was thus obtained in large colorless rectangular prisms which melted at 209°. A trace of the alkaloid dissolved in sulfuric acid yielded an intensely lilac colored solution which on gentle heating changed to an olive color. Found: C, 67.95, 67.63; H, 5.93, 5.76; N, 3.51, 3.91; OCH_3, 9.19, 9.27. Calcd. for $C_{20}H_{21}O_5N$: C, 67.60; H, 5.92; N, 3.94; OCH_3, 8.73. The total yield of hunnemanine was 0.18%.

A small portion of the base was methylated by treating its suspension in methanol with an ethereal solution of diazomethane. The alkaloid dissolved as the brisk evolution of nitrogen proceeded. The non-phenolic product isolated in the usual way was recrystallized from hot methanol and then melted sharply at 160°. In admixture with allo-cryptopine it melted at the same temperature. Calcd. for $C_{21}H_{23}O_5N$: OCH_3, 16.62. Found: OCH_3, 17.46, 17.53.

Hunnemanine-O-ethyl Ether.—The ethylation of hunnemanine suspended in absolute ethanol was carried out with an ethereal solution of diazo-ethane. The yield was not quite quantitative but no difficulty was experienced in obtaining the non-phenolic base in a pure condition. When recrystallized from hot methanol it was obtained in colorless stout prisms which melted sharply at 168°. From 5 g. of the phenolic base there was obtained 4.3 g. of the ethyl ether. Calcd. for $C_{22}H_{25}O_5N$; OCH_3 + OC_2H_5 as OCH_3, 16.19. Found: OCH_3, 16.72, 16.82.

Hunnemanine-O-ethyl Ether Methosulfate.—Hunnemanine-O-ethyl ether was added to freshly distilled methyl sulfate and the mixture kept on the steam-bath for thirty minutes. The mixture was then cautiously heated over a small flame until the few remaining crystals had dissolved. The resulting thick, dark sirup was dissolved in a little boiling ethyl acetate, from which solution the methosulfate crystallized in colorless needles melting at 196°.

Tetrahydromethylhunnemanine-O-ethyl Ether.—The methosulfate dissolved in 5% sulfuric acid was reduced with sodium amalgam according to the procedure of Perkin.[1] The product consisted of a thick, light-brown, oily base.

Anhydrotetrahydromethylhunnemanine-O-ethyl Ether.—The oily tetrahydromethylhunnemanine-O-ethyl ether was refluxed for thirty minutes with acetyl chloride. After removal of the excess acetyl chloride, the oily residue was dissolved in hot water, the solution filtered, basified with strong sodium hydroxide and the precipitated base extracted with ether. The ether extract was washed with water and dried over anhydrous potassium carbonate. The oily residue from this solution did not crystallize and failed to yield a crystalline picrolonate.

Oxidation of Anhydrotetrahydromethylhunnemanine-O-ethyl Ether.—Anhydrotetrahydromethylhunnemanine-O-ethyl ether (1.29 g.) was dissolved in purified acetone (100 cc.) and the stirred and cooled (3°) solution treated with finely ground potassium permanganate (1.3 g.) added in small portions. When the oxidation had been completed, the mixture was filtered and the solid washed with acetone. The combined filtrate and washings were distilled under diminished pressure and the viscous residue dissolved in ether. The filtered ether solution was extracted repeatedly with small quantities of dilute acid (1 vol. hydrochloric acid: 3 vol. water), washed with water and extracted with two portions of dilute sodium hydroxide. The combined sodium hydroxide solutions were acidified with hydrochloric acid and the precipitated acid collected in ether.

(4) Manske, *Can. J. Research*, **8**, 210 (1933).

(5) All melting points are corrected.

The ether solution was washed with water, dried over sodium chloride and distilled. The crystalline residue after repeated recrystallization from ether–hexane was finally obtained as short white needles melting at 175°. Calcd. for $C_{11}H_{14}O_4$: C, 62.86; H, 6.67. Found: C, 62.88; H, 6.88. A further quantity of the same acid was obtained by digesting with hot water the manganese dioxide sludge which had been filtered out. The aqueous solution was evaporated down to a volume of *ca.* 25 cc. and acidified with hydrochloric acid. The chalky precipitate was filtered, dissolved in 5% sodium bicarbonate, the solution filtered and again acidified with hydrochloric acid. The precipitate was dissolved in dilute ammonia and boiled thirty minutes with a little barium chloride. The insoluble barium salt which precipitated was filtered out and the filtrate acidified and extracted with ether. The ether solution, after washing and drying, yielded an acid melting at 168° which after several recrystallizations from ether–hexane melted at 175° and was identical with that obtained as above. A mixture of this acid with a synthetic specimen of 2-methyl-3-ethoxy-4-methoxy-benzoic acid melted at 176–177°.

2-Ethoxy-3-methoxy-toluene.—A mixture of 2-ethoxy-3-methoxybenzaldehyde (50 g.), amalgamated zinc (100 g.), toluene (100 cc.) and hydrochloric acid (275 cc.) was boiled under reflux for twenty-four hours. The separated toluene solution was washed with successive portions of aqueous sodium bisulfite, the solvent distilled off, and the residue fractionated *in vacuo*. The portion boiling at 72–74° (4 mm.) weighed 20 g. and consisted substantially of 2-ethoxy-3-methoxytoluene. Calcd. for $C_{10}H_{14}O_3$: C, 72.29; H, 8.43. Found: C, 71.56; H, 8.82.

2-Methyl-3-ethoxy-4-methoxybenzaldehyde.—Aluminum chloride (25 g.) was added to a cooled solution of 2-ethoxy-3-methoxytoluene (17 g.) in dry benzene (50 cc.). To the stirred and cooled mixture was then added anhydrous hydrogen cyanide (17 g.), and a stream of dry hydrogen chloride passed in to saturation. The temperature was then raised to 40° and maintained there for two hours. After remaining at room temperature overnight, the mixture was decomposed with ice, and the aldehyde distilled in a current of steam. It was extracted from the distillate and fractionated *in vacuo*. As thus obtained 2-methyl-3-ethoxy-4-methoxybenzaldehyde was a colorless oil boiling at 121–123° (3 mm.). On cooling it formed a mass of colorless needles which when pressed out on filter paper melted at 24°. The yield was 14 g. Calcd. for $C_{11}H_{14}O_3$: C, 68.04; H, 7.21. Found: C, 68.35; H, 7.65.

The *oxime* was prepared in aqueous methanol and recrystallized from ether–hexane. It consisted of colorless pearly plates melting at 88°. Calcd. for $C_{11}H_{15}O_3N$: C, 63.15; H, 7.18; N, 6.70. Found: C, 63.36; H, 7.05; N, 7.09.

2-Methyl-3-ethoxy-4-methoxybenzoic Acid.—A suspension of the aldehyde in warm water was vigorously stirred and treated with a saturated solution of potassium permanganate until the color was permanent for five minutes. The solution was then boiled, filtered, decolorized with a little sulfur dioxide, and while still warm acidified with hydrochloric acid. The filtered, washed, and dried acid melted at 176°. It was recrystallized from hot acetone, in which it is only moderately soluble. The large brilliant highly refracting plates thus obtained melted sharply at 177°. The yield was virtually quantitative. Calcd. for $C_{11}H_{14}O_4$: C, 62.86; H, 6.67. Found: C, 63.02; H, 6.83.

Summary

Hunnemannia fumariaefolia Sweet has yielded four alkaloids, two of which, protopine and allocryptopine, are well known. A third, *alkaloid F58*, represented as $C_{22}H_{21}O_5N$, was obtained in only minute amounts. The main alkaloid now termed hunnemanine, $C_{20}H_{21}O_5N$, is phenolic, contains one methoxyl group, and on methylation yielded allo-cryptopine. O-Ethylation gave a non-phenolic base which on appropriate degradation yielded 2-methyl-3-ethoxy-4-methoxybenzoic acid, identical with a specimen synthesized for purposes of comparison. Hunnemanine is therefore 9-desmethyl-allo-cryptopine. It is the first alkaloid of the protopine type known to contain a free hydroxyl group.

Orientation Effects in the Alkylation of *m*-Xylene by Various Procedures and Reagents

BY DOROTHY NIGHTINGALE, H. D. RADFORD AND O. G. SHANHOLTZER

Investigations of the alkylation of substituted aromatic hydrocarbons by an alcohol and 70–85% sulfuric acid[1,2] have led to the belief, but apparently without definite proof in some cases, that the normal orientation effects of alkyl groups are always exerted when this procedure is used. Thus, *i*-propylbenzene has been reported to yield 1,2,4-tri*iso*propylbenzene, and the dialkylbenzenes obtained from benzene or toluene have been reported to be the *o*- and *p*-isomers. In their investigation of the action of aluminum chloride on the 1,3-dimethyl-4-butylbenzenes, Nightingale and Smith[3] assumed that the products obtained from *m*-xylene and *t*-butyl alcohol by the sulfuric acid procedure had the 1,3,4 orientation, although it was observed that the trinitro derivatives of the 1,3-dimethyl-4-*t*-butyl- and -5-*t*-butylbenzene melted at 112 and 113°, respectively, and gave only small depressions in melting points when mixed.

During further work with these compounds, the similarity in melting points and the small depressions in the mixed melting points of other derivatives of the two hydrocarbons led to the conviction either that the 1,3,4-hydrocarbon did not have this orientation, but was mainly the 1,3,5-isomer, or that a rearrangement of the 1,3,4- to the 1,3,5-isomer occurred during the preparation of the derivatives. In order to decide between these alternatives we have reinvestigated the nature of the products obtained when *m*-xylene is alkylated by *t*-butyl alcohol and 85% sulfuric acid, and it has been found that the previous work[3] was in error in that the trialkylbenzene from this reaction is a mixture consisting of approximately two parts of 1,3-dimethyl-5-*t*-butylbenzene and one part of the 1,3,4-isomer.

The study has been extended to include the trialkylbenzenes formed from *m*-xylene by alkylation with other butyl compounds in the presence of boron trifluoride or ferric chloride as catalysts. The results showed that the abnormally oriented trialkylbenzene (1,3,5) was obtained not only from 75 and 85% sulfuric acid, but with boron trifluoride and with ferric chloride, when *t*-butyl compounds were used. The abnormally oriented product with boron fluoride was unexpected, for 1,2,4-tri*iso*propylbenzene is reported from benzene, *i*-propyl alcohol and this catalyst.[4] The normally oriented trialkylbenzene (1,3,4) was obtained from *m*-xylene, *s*-butyl alcohol and either 85% sulfuric acid or boron trifluoride as the catalyst.

The structures of the hydrocarbons were established by oxidation rather than by conversion to the trinitro derivatives in order to avoid any chance that a rearrangement might occur during the preparation of the derivatives. The oxidation product of 1,3-dimethyl-5-*t*-butylbenzene (Friedel–Crafts) proved to be 5-*t*-butyl-isophthalic acid, m. p. 343°, rather than trimesic acid, and the trialkylbenzene from *m*-xylene, *t*-butyl alcohol and 85% sulfuric acid yielded a mixture of 4-*t*-butylisophthalic acid and 5-*t*-butyl isophthalic acid. The 4-*t*-butylisophthalic acid is soluble in the aqueous pyridine solution in which the oxidation was carried out, whereas the 5-isomer is only slightly soluble, and this fact made it possible to separate the mixture of acids.

To establish the identity of the 5-*t*-butylisophthalic acid, the compound was synthesized by the method of Doebner[5] from pyruvic acid, trimethylacetaldehyde and barium hydroxide. The acid so obtained melted at 343° and did not depress the melting point of the acid formed by oxidation.

The 1,3-dimethyl-4-*t*-butylbenzene was synthesized by coupling the Grignard reagent from 1,3-dimethyl-4-iodobenzene with *t*-butyl chloride.[6] Oxidation of this hydrocarbon with potassium permanganate in aqueous pyridine yielded 4-*t*-butylisophthalic acid.

The stability of the tertiary radical toward potassium permanganate is surprising. In one experiment, more than enough permanganate was used to oxidize the *t*-butyl group and the two methyl groups of the 1,3,5-hydrocarbon and the mixture was refluxed gently. The product was

(6) Smith and Perry, THIS JOURNAL, **61**, 1411 (1939).

nearly pure 5-*t*-butylisophthalic acid in almost quantitative yield. Oxidation of *p*-*t*-butyltoluene with excess permanganate likewise yielded only *p*-*t*-butylbenzoic acid.

These results do not invalidate the work of Nightingale and Smith,[3] for both 1,3-dimethyl-4-*t*-butyl- and 4-*s*-butylbenzene synthesized through the Grignard route are converted to the 5-*t*-butyl isomer by the action of aluminum chloride.

The abnormal orientation of these trialkylbenzenes made it desirable to verify the structure of the trialkylbenzene from *m*-xylene, *s*-butyl alcohol and 85% sulfuric acid or boron trifluoride. The 1,3-dimethyl-4-*s*-butylbenzene was synthesized through 2,4-dimethylacetophenone and ethylmagnesium bromide. The carbinol was dehydrated to the olefin, which was reduced with hydrogen and Raney nickel under pressure. The trialkylbenzenes were identical. This hydrocarbon could be oxidized to 4-*s*-butylisophthalic acid, but the 5-*s*-butyl isomer yielded trimesic acid.

It may or may not be significant that three of the condensing agents which lead to abnormally oriented trialkylbenzenes, sulfuric acid, aluminum chloride and ferric chloride, can also cleave a *t*-butyl group from the benzene ring.[7]

Results from the alkylation of *m*-xylene with *t*-amyl alcohol and either 85% sulfuric acid or boron trifluoride are not so clean-cut. Analyses and neutral equivalents of the acids obtained by oxidation of the trialkylbenzene fraction correspond to a *t*-amylisophthalic acid, as do their methyl esters. The fact that these compounds melt higher than 5-*t*-amylisophthalic acid and its methyl ester is difficult to explain. Mixtures of the acids with 5-*t*-amylisophthalic acid melt between the two, as do mixtures of the methyl esters. The reaction products from *t*-amyl alcohol are undoubtedly more complicated mixtures than in the case of the butyl compounds. By analogy with the reaction products from *t*-butyl alcohol the trialkylbenzenes should have the 1,3,5 orientation. *t*-Amylbenzene was unaffected by potassium permanganate in aqueous pyridine solution.

Oxidation of 1,3-dimethyl-5-*t*-amylbenzene (Friedel–Crafts) yielded 5-*t*-amylisophthalic acid, identical with 5-*t*-amylisophthalic acid synthesized by Doebner's method. Unfortunately the Grignard reagent from 1,3-dimethyl-4-iodobenzene would not couple with *t*-amyl chloride and a Fittig synthesis was likewise unsuccessful, so 4-*t*-amylisophthalic acid could not be made to complete the series.

In an effort to find solid derivatives of these alkylbenzenes which would avoid the use of nitric or sulfuric acid, the hydrocarbons were chloromethylated. The substituted benzyl chlorides were converted to the corresponding acetamides by heating with acetamide, and to the benzyl alcohols.

The reactions were useful only with 1,3-dimethyl-5-*t*-butylbenzene. The 2,4-dimethyl-6-*t* butylbenzylacetamide separated readily as a solid, and 2,4-dimethyl-6-*t*-butylbenzyl alcohol is a solid. The other amides were viscous and would not crystallize readily. The other benzyl alcohols were liquids. Careful oxidation of 2,4-dimethyl-6-*t*-butylbenzyl alcohol to the corresponding known monocarboxylic acid[8] served to establish the location of the $-CH_2Cl$ group as between the methyl and *t*-butyl radicals rather than between the two methyl groups.

Experimental[9]

Most of the trialkylbenzenes were prepared by procedures previously described.[3] The preparation of 1,3-dimethyl-4-*s*-butylbenzene has been improved by increasing the amount of *s*-butyl alcohol to 100 cc., and reducing the reaction time to seven hours. The hydrocarbons were vacuum distilled through columns packed with single turn glass helices.

The diacetamino derivative of 1,3-dimethyl-4-*t*-butylbenzene, not previously described, melts at 331°.

Anal. Calcd. for $C_{16}H_{24}O_2N_2$: N, 10.14. Found: N, 10.00.

Preparation of 1,3-Dimethyl-5-*t*-butylbenzene. (a) **With Ferric Chloride as Catalyst.**—*m*-Xylene (144 g.) and anhydrous ferric chloride (12.2 g.) were placed in a 3-necked flask cooled with an ice–salt mixture and fitted with a sealed stirrer and dropping funnel. *t*-Butyl chloride (25 g.) was added at such a rate that the temperature of the reaction mixture did not rise above −4.5°. Stirring was continued an additional four hours. The reaction mixture was decomposed as for a Friedel–Crafts reaction; yield, 29.6 g.; b. p. 88° (14 mm.).

(b) **With Boron Fluoride as Catalyst.**—*m*-Xylene (106 g.) was alkylated with *t*-butyl alcohol (74 g.) and boron fluoride (41 g.) by the method of McKenna and Sowa[4] using a 3-necked conical flask. The boron fluoride was admitted into the reaction mixture during six hours. The flask was cooled with water at the beginning of the reaction. The hydrocarbon layer was separated, washed and dried; yield, 27.5 g.; b. p. 78–79° (8 mm.).

(c) **With 75% Sulfuric Acid as Catalyst.**—The experimental conditions were those of Meyer and Bernhauer.[1]

(7) Ipatieff and Corson, THIS JOURNAL, **59**, 1417 (1937).

(8) Bauer, *Ber.*, **33**, 2562 (1900).

(9) Semimicro analyses by D. R. Smith and E. Milberger.

The *m*-xylene (184 g.) and *t*-butyl alcohol (123 g.) were placed in a 3-necked flask in a water-bath at 65–70°. A solution of concentrated sulfuric acid (1060 cc.) and water (540 cc.) was added during an hour while the reaction mixture was stirred mechanically. The hydrocarbon layer was washed, dried and distilled. The following fractions were obtained at 13 mm. after removal of *m*-xylene: (I) 24 g. up to 85°; (II) 3 g. 85–89°; (III) 8.2 g. 89–92°; (IV) 5 g. 92–97°. Fraction (III) is the trialkylbenzene.

Oxidation of 1,3-Dimethyl-5-*t*-butylbenzene.—The hydrocarbon (5 g.) from *t*-butyl chloride and aluminum chloride was dissolved in pyridine (40 cc.) and water (20 cc.) in a 3-necked flask. Finely powdered potassium permanganate (21.5 g.) was added in small portions during two hours with the temperature maintained around 80°. The mixture was heated until the purple color disappeared. The mixture was stirred mechanically during the entire period.

The manganese dioxide was separated by filtration and the filtrate acidified strongly with hydrochloric acid. The 5-*t*-butylisophthalic acid precipitated. A small amount of acid was extracted from the manganese dioxide. The combined acids (6.5 g.) were recrystallized from glacial acetic acid; m. p. 343°. Since the acid begins to sublime below the melting point, the sample was packed into the tube and the tube sealed.

Anal. Calcd. for $C_{12}H_{14}O_4$: C, 64.84; H, 6.30; neut. eq., 111. Found: C, 64.73; H, 6.49; neut. eq., 110.

The methyl ester was prepared with diazomethane, m. p. 97°.

Anal. Calcd. for $C_{14}H_{18}O_4$: C, 67.20; H, 7.20. Found: C, 67.08; H, 7.29.

Only 5-*t*-butylisophthalic acid was obtained by the oxidation of the hydrocarbons from the three alkylations described above.

Oxidation of 1,3-Dimethyl-4-*t*-butylbenzene.—A 7-g. sample of the hydrocarbon (Grignard synthesis[6]) was oxidized in aqueous pyridine solution. After separation of the manganese dioxide, most of the pyridine was distilled from the solution before acidifying; yield, 5 g.; m. p. 230°.

Anal. Calcd. for $C_{12}H_{14}O_4$: C, 64.84; H, 6.30; neut. eq., 111. Found: C, 64.77; H, 6.39; neut. eq., 112.5.

Oxidation of the Trialkylbenzene from *m*-Xylene, *t*-Butyl Alcohol and 85% Sulfuric Acid.—The hydrocarbon (10.8 g.) was oxidized with excess permanganate. The 5-*t*-butylisophthalic acid (9.7 g.) separated when the solution was acidified after removal of the manganese dioxide. The filtrate was made basic and most of the pyridine distilled off. The solution in the distilling flask was again acidified and the 4-*t*-butylisophthalic acid (5.2 g.) separated. The purified acids melted at 343° and 230°, respectively, and did not depress the melting points of authentic samples.

Synthesis of 5-*t*-Butylisophthalic Acid.—Trimethylacetaldehyde[10] (23.7 g.), pyruvic acid (50 g.), barium hydroxide (120 g.) and 1000 cc. of water were refluxed gently for one hundred hours.[5] To free the crude 5-*t*-butylisophthalic acid from oxalic acid, the solid was suspended in a little water and potassium permanganate solution added in the cold until the purple color persisted. Hydrochloric acid was added and the manganese dioxide removed with sulfur dioxide; yield, 4.1 g.; m. p. 343°.

Anal. Calcd. for $C_{12}H_{14}O_4$: C, 64.86; H, 6.30; neut. eq., 111. Found: C, 64.63; H, 6.54; neut. eq., 112.5.

Preparation of 1,3-Dimethyl-4-*s*-butylbenzene. (a) Through the Grignard Reaction.—A solution of 2,4-dimethylacetophenone (155 g.) in ether was added to the Grignard reagent from 86 g. of ethyl bromide. The complex was decomposed in the usual manner.

The crude carbinol was added to 250 g. of acetic anhydride containing ten drops of concentrated sulfuric acid. The anhydride was distilled off at a somewhat reduced pressure and the residue fractionated. The olefin distilled at 102° (1 mm.). To purify the olefin, it was heated with sodium, vacuum distilled, and again vacuum distilled from Raney nickel.

The olefin (45 g.) was reduced in methyl alcohol solution with Raney nickel at 80–90° (2000 lb.). After removal of the solvent and catalyst, the hydrocarbon was heated with sodium and fractionated; yield, 38 g.; b. p. 82° (1 mm.).

The diacetamino derivative of this hydrocarbon melted at 270° and did not depress the melting point of diacetamino-1,3-dimethyl-4-*s*-butylbenzene prepared by the sulfuric acid procedure.

(b) **With Boron Fluoride as the Catalyst.**—*m*-Xylene (106 g.) was alkylated with *s*-butyl alcohol and boron fluoride (49 g.); yield, 30 g.; b. p. 91–93° (13 mm.).

The diacetamino derivative of this hydrocarbon melted at 270° and did not depress the melting point of the derivative of the hydrocarbon from the Grignard reaction. Careful oxidation of 1,3-dimethyl-4-*s*-butylbenzene (10 g.) at 70° yielded 2 g. of 4-*s*-butylisophthalic acid; m. p. 188°.

Anal. Calcd. for $C_{12}H_{14}O_4$: C, 64.86; H, 6.30; neut. eq., 111. Found: C, 64.81; H, 6.30; neut. eq., 111.7.

Synthesis of 5-*t*-Amylisophthalic Acid.—The 2,2-dimethylbutyraldehyde was prepared by adding the Grignard reagent from 425 cc. of *t*-amyl chloride to 460 cc. of methyl formate.[10] The reaction temperature was maintained at −50° to −55°; yield, 53.7 g. (26%).

A mixture of pyruvic acid (45 g.), 2,2-dimethylbutyraldehyde (24.5 g.), barium hydroxide (106 g.) and 900 cc. of water was refluxed for one hundred hours. The acid was purified as described above; yield, 7.5 g.; m. p. 307°.

Anal. Calcd. for $C_{13}H_{16}O_4$: C, 66.10; H, 6.78; neut. eq., 118. Found: C, 66.19; H, 6.67; neut. eq., 115.

The methyl ester melted at 81°.

Anal. Calcd. for $C_{15}H_{20}O_4$: C, 68.18; H, 7.20. Found: C, 68.34; H, 7.51.

Oxidation of 4 g. of 1,3-dimethyl-5-*t*-amylbenzene (Friedel–Crafts) yielded 5-*t*-amylisophthalic acid; m. p. 307°; yield, 5 g.

The methyl ester melted at 78°.

Anal. Calcd. for $C_{13}H_{16}O_4$: C, 66.10; H, 6.78; neut. eq., 118. Found: C, 66.10; H, 7.11; neut. eq., 123.

Alkylation of *m*-Xylene with *t*-Amyl Alcohol. (a) With Boron Fluoride as Catalyst.—*m*-Xylene (200 cc.) was alkylated with *t*-amyl alcohol (200 cc.) and 30–50 g. of boron fluoride as described above. The reaction mixture was stirred for four hours. The following fractions were obtained at 16 mm. after removal of *m*-xylene: (I) 4.5

[a] Calcd. for $C_{13}H_{19}Cl$: C, 74.28; H, 9.04. [b] Calcd. for $C_{13}H_{20}O$: C, 81.25; H, 10.41.

g. 91–94°; (II) 15 g. 94–96°; (III) 15 g. 96–104°; (IV) 29 g. 100–135°; residue 15 g.

Oxidation of 4 g. of the trialkylbenzene (II) yielded 6 g. of a dicarboxylic acid, m. p. 330°, corresponding to a *t*-amylisophthalic acid.

Anal. Calcd. for $C_{13}H_{16}O_4$: C, 66.10; H, 6.78; neut. eq., 118. Found: C, 65.85; H, 6.99; neut. eq., 113.

(b) **With 85% Sulfuric Acid as Catalyst.**—This alkylation was carried out as previously described.[11] The dibenzamino derivative of the trialkylbenzene from this reaction melted at 305°. A mixture of this derivative and the dibenzamino derivative (m. p. 303°) of 1,3-dimethyl-5-*t*-amylbenzene (Friedel-Crafts) melted at 298°.

Oxidation of this hydrocarbon yielded an acid melting at 320–325°, which, mixed with the acid (m. p. 330°) from the trialkylbenzene prepared with boron fluoride, melted at 319°. The neutral equivalent was 116.

The method of oxidation of alkylbenzenes such as durene containing only methyl radicals or methyl radicals and *t*-alkyl radicals with potassium permanganate in aqueous pyridine solution has been generally successful with other compounds such as 4-methyl-2′-methoxydiphenyl ether. Yields are much higher than in aqueous solution. Bumping is avoided, for it is not necessary to boil the mixture and in some cases the temperature must be kept at 80° or lower. *t*-Butylbenzene and *t*-amylbenzene were unaffected even after long heating with excess permanganate. The ethylbenzenes gave indefinite oxidation products.

Chloromethyl Compounds and Derivatives.—The hydrocarbons were chloromethylated by the method of v. Braun and Nelles.[12] Boiling points and analytical data are summarized in Table I. Derivatives were prepared from 2,4-dimethyl-6-*t*-butylbenzyl chloride as follows:

The acetate was prepared by refluxing 4.2 g. of the chloride, 2.5 cc. of acetic anhydride, 7.5 cc. of acetic acid and 2.5 g. of potassium acetate. The mixture was poured onto ice, washed, and dried over sodium sulfate. The ether was distilled leaving the crude ester.

The crude ester (2.5 g.) was refluxed three hours with potassium hydroxide (6.6 g.) in alcohol (25 cc.) and water (35 cc.). The oily top layer solidified on cooling. The carbinol was separated by filtration and recrystallized from 28–30° petroleum ether; yield, 2.25 g.; m. p. 99°.

(11) Nightingale and Shanholtzer, *J. Org. Chem.*, **6**, 6 (1942).
(12) v. Braun and Nelles, *Ber.*, **67**, 1094 (1934).

The carbinol was oxidized to the corresponding monocarboxylic acid with potassium permanganate at 0 to 20°. The 2,4-dimethyl-6-*t*-butylbenzoic acid melted at 168°, the recorded value.[8]

2,4-Dimethyl-6-*t*-butylbenzylacetamide was prepared by heating a mixture of the chloride (2.1 g.) and acetamide (1.2 g.) in an oil-bath at 210° for thirty-five minutes. The solid was boiled with water to remove acetamide and recrystallized from a mixture of chloroform and petroleum ether; yield, 2.2 g.; m. p. 197°.

Anal. Calcd. for $C_{15}H_{23}NO$: N, 6.00. Found: N, 6.25.

Nitrations.—All efforts in this Laboratory to prepare the trinitro derivatives, by the use of the nitrating mixture previously described,[3] have been fruitless. A nitrating mixture in the ratio of 15 g. of nitric acid sp. gr. 1.5 and 30 g. of 15% fuming sulfuric acid has been satisfactory, although this mixture is not as smooth a nitrating agent as the mixture originally used. We can give no explanation for this difference.

Summary

Abnormally oriented trialkylbenzenes (1,3,5 rather than 1,3,4) are formed when *m*-xylene is alkylated with *t*-butyl alcohol in the presence of 75–85% sulfuric acid or boron trifluoride, and with *t*-butyl chloride and anhydrous ferric chloride as the catalyst.

The normally oriented trialkylbenzene (1,3,4) is formed when *m*-xylene is alkylated with *s*-butyl alcohol and either 85% sulfuric acid or boron trifluoride.

Abnormally oriented trialkylbenzenes are formed from *m*-xylene and *t*-amyl alcohol and *t*-amyl chloride under the same conditions as for the *t*-butyl compounds.

The 1,3-dimethyl-4-*t*-butyl, 5-*t*-butyl and 5-*t*-amylbenzenes can be oxidized in aqueous pyridine solution to the corresponding *t*-butyl and *t*-amyl isophthalic acids.

[CONTRIBUTION FROM THE CHEMICAL LABORATORY OF HARVARD UNIVERSITY]

The N-Methylformanilide Synthesis of Aldehydes

BY LOUIS F. FIESER AND J. ELMORE JONES

Vilsmeier and Haack[1] discovered that secondary and tertiary aromatic amines can be converted into aldehydo derivatives by the action of N-methylformanilide and phosphorus oxychloride, a reaction reminiscent of the Bischler–Napieralski synthesis of isoquinolines. In a series of patents, Kalischer, Scheyer and Keller[2] reported that the reaction is applicable to certain phenol ethers and aromatic hydrocarbons, and these claims were verified by Wood and Bost[3] to the extent of noting that β-naphthol ethyl ether and anthracene can be formylated by the method described, and detailed procedures for conducting these reactions have subsequently been published.[4]

Following the observations of Vollmann, *et al.*,[5] that pyrene-3-aldehyde can be obtained in excellent yield by the methylformanilide method, the reaction was applied in this Laboratory to a few carcinogenic and related hydrocarbons. With the use of *o*-dichlorobenzene as the solvent,[5] 3,4-benzpyrene was found to react[6] with the same degree of readiness as pyrene[5] and anthracene[4,7] and to afford the 5-aldehyde in 90% yield; 1,2-benzanthracene was converted into the 10-derivative somewhat less smoothly[7] (64%), and 1,2,5,6-dibenzanthracene failed to react.[7] In exploring other cases, we have found the reaction to be less generally applicable to aromatic hydrocarbons than claimed in the patents.[2] No trace of aldehyde could be obtained from hydrindene, α-methylnaphthalene, phenanthrene, or chrysene in condensations conducted at temperatures from 20 to 150°, and the solid hydrocarbons were recovered in good yield. 9-Methylanthracene reacted satisfactorily without added solvent, since it melts at the reaction temperature, and gave the 10-aldehyde. Acenaphthene and perinaphthane possess adequate nuclear reactivity but are highly sensitive to the action of phosphorus oxychloride and yielded only tars when condensed at 95 and 25°, respectively.

In the condensation with acenaphthene a satisfactory conversion was accomplished by controlling the temperature to 25° and allowing a reaction period of six days. The product was purified effectively if slowly by steam distillation and obtained in 85% yield. It melted at 105–107° and was identified as 3-acenaphthaldehyde (I) by oxidation to the corresponding acid.[8] Hinkel, Ayling and Beynon[9] obtained a lower melting product (87°) by the Gattermann synthesis, but the constants for the oxime and semicarbazone are comparable. 3-Acenaphthaldehyde was converted to the corresponding alcohol by hydrogenation in the presence of Adams catalyst and ferrous chloride, and it yielded 3-methylacenaphthene when heated in an autoclave with hydrazine hydrate at 200°, according to Vollmann, *et al.*[5] The aldehyde was also utilized for the synthesis of the tetracyclic hydrocarbon IV.

either catalytically or with sodium amalgam afforded the propionic acid II, and cyclization with hydrogen fluoride gave a tarry product from which the ketone was best isolated in the form of the oxime (III). Under the conditions of the Clemmensen reaction the oxime suffered hydrolysis and the ketone was reduced. The point of ring closure was established by oxidation of the ketone to the known naphthalene-1,4,5,8-tetracarboxylic acid. The hydrocarbon obtained as the end-product of the synthesis (m. p. 121.4–122°) can thus be assigned the structure of 3,4-aceperinaphthane (IV).

3-Methylacenaphthene and 3-methylpyrene were found to react smoothly with N-methylformanilide, but no satisfactory methods were found for separating the resulting mixtures of isomers.

Experimental Part[10]

9-Methyl-10-anthraldehyde.—A mixture of 9-methylanthracene[7] (m. p. 77.9–78.4°), 2.7 g. of N-methylformanilide,[11] and 2.7 g. of phosphorus oxychloride was heated with stirring on the steam-bath under protection from moisture for forty-five minutes, during which time the hydrocarbon dissolved. The cooled mixture was treated with 5.6 g. of crystalline sodium acetate in 50 cc. of water and stirred for a few minutes to decompose the excess oxychloride and any intermediate complex. The collected solid product on crystallization from acetic acid gave 1.84 g. (84%) of orange needles; m. p. 170–171.4°. After three recrystallizations from benzene–ligroin the substance melted at 171.9–172.6°.

Anal. Calcd. for $C_{16}H_{12}O$: C, 87.25; H, 5.49. Found: C, 87.34; H, 5.61.

Oxidation of the aldehyde with chromic oxide in acetic acid gave anthraquinone (mixed m. p.) in 86% yield.

The **oxime** was obtained from the aldehyde with aqueous hydroxylamine hydrochloride and alkali, with enough ethanol to effect solution; after heating at the boiling point for ten minutes, the oxime separated in deep yellow plates; m. p. 210°, dec.; (94% yield).

Anal. Calcd. for $C_{16}H_{13}ON$: C, 81.68; H, 5.57. Found: C, 81.52; H, 5.60.

The **hydrazone** was prepared by adding 0.5 g. of hydrazine hydrate to a solution of 0.5 g. of the aldehyde in 70 cc. of hot alcohol, boiling the solution for ten minutes, and adding water to saturation; on cooling 0.37 g. (69%) of orange needles separated; m. p. 175.1–175.8°. A mixture with the aldehyde showed a 10°-depression. The hydrazone is stable in the solid state but decomposes on attempted crystallization.

Anal. Calcd. for $C_{16}H_{14}N_2$: C, 82.02; H, 6.02. Found: C, 82.26; H, 6.29.

A mixture of 0.25 g. of the hydrazone with a solution of 0.05 g. of sodium in 16 cc. of absolute ethanol was shaken in a sealed tube until uniform and heated at 200–210° for twenty-four hours. The product was collected after dilution with water and neutralization with acetic acid and crystallized from ethanol, giving 0.17 g. (74%) of light yellow plates, m. p. 183–183.7°; the picrate formed dark red needles, m. p. 175.6–176.3°. The constants agree with those reported for **9,10-dimethylanthracene** (m. p. 180–181°)[12] and its picrate (m. p. 175–176°).[13]

3-Acenaphthaldehyde (I).—A mixture of 43 g. of acenaphthene, 90 cc. of N-methylformanilide, 60 cc. of phosphorus oxychloride, and 50 cc. of *o*-dichlorobenzene was shaken thoroughly to effect solution and allowed to stand at room temperature for six days, during which time the solution turned deep red and hydrogen chloride was evolved slowly. For hydrolysis, 150 g. of crystalline sodium acetate in 150 cc. of water was added slowly to prevent violent reaction, and the mixture was subjected to efficient steam distillation. The solvent was removed in about one-half hour, and the product then distilled very slowly. Filtration of the large volume of cooled distillate afforded 40.2 g. (85%) of the aldehyde; m. p. 105–107°. The best sample, purified by repeated crystallization from dilute acetic acid and sublimation at 110° (2 mm.), formed pale greenish needles; m. p. 107.4–108°.

Anal. Calcd. for $C_{13}H_{10}O$: C, 85.69; H, 5.53. Found: C, 85.95; H, 5.50.

A sample of the oxime melted at 126.8–127.9°, and the semicarbazone melted at 247.8–248.8°; Hinkel, *et al.*,[9] recorded the constants 126.5° and 234°. For oxidation, 0.3 g. of the aldehyde in 5 cc. of dioxane was treated slowly with 8 cc. of 30% hydrogen peroxide, followed by 10% sodium hydroxide. The mixture was heated on the steam-bath for ten minutes, filtered from a trace of unreacted aldehyde (0.04 g.), and acidified. Crystallization of the voluminous precipitate from acetic acid yielded 0.22 g. (78%) of **acenaphthene-3-carboxylic acid;** m. p. 219–221° (no depression with an authentic sample).[8]

3-Hydroxymethylacenaphthene.—Hydrogenation of 1.16 g. of 3-acenaphthaldehyde in 100 cc. of absolute ethanol in the presence of 25 mg. of Adams catalyst and 10 mg. of ferrous chloride proceeded to completion in one hour, and in this time a quantity of the alcohol had crystallized in colorless needles. This was dissolved by warming, and the solution was filtered and evaporated and the product crystallized from benzene, yielding 0.86 g. (73%) of needles; m. p. 153.4–154.2°. The best sample melted at 153.8–154.8°.

Anal. Calcd. for $C_{13}H_{12}O$: C, 84.75; H, 6.57. Found: C, 84.52; H, 6.66.

3-Methylacenaphthene.—A mixture of 18 g. of the aldehyde and 55 g. of hydrazine hydrate was heated in an autoclave under a nitrogen pressure of 2250 lb. at 200–210° for eight hours. The well washed reaction product on sublimation at atmospheric pressure at 100° yielded 10.4 g. (63%) of colorless blades; m. p. 95.6–95.9°. The hydrocarbon crystallized from ethanol in long, colorless needles of the same melting point (20°-depression with acenaphthene). Considerable azine was formed in the reaction and was left as a residue in the sublimation.

(10) All melting points are corrected.

3-Acenaphthalacetic Acid.—A mixture of 40.2 g. of the aldehyde, 42 g. of malonic acid, and 30 cc. of pyridine was heated on the steam-bath for eight hours and the solid product which separated was collected after cooling and dissolved in 200 cc. of 10% sodium carbonate solution by heating. The filtered solution was acidified and the pale yellow precipitate was washed thoroughly and dried for six hours at 50° (20 mm.). This material had no distinct melting point and appeared to be the **dihydrate;** yield 47.8 g. (83%).

Anal. Calcd. for $C_{15}H_{12}O_2 \cdot 2H_2O$: neut. equiv., 260. Found: 256.

Crystallization from ethanol (Norit) yielded 38.4 g. (77%) of pale yellow needles of the anhydrous acid; m. p. 250°, dec. On further purification the substance melted at 251.3–251.8° with gas evolution.

Anal. Calcd. for $C_{15}H_{12}O_2$: C, 80.33; H, 5.39; neut. equiv., 224. Found: C, 80.43; H, 5.51; neut. equiv., 219.

The acid seemed to undergo some decarboxylation on melting, but attempts to isolate a pure reaction product after vacuum distillation or treatment with copper bronze were unsuccessful.

The **methyl ester,** prepared with diazomethane, distilled at 204° at 6 mm. and crystallized from ligroin in large yellow cubes; m. p. 104.4–105.4°. A second modification was obtained by rapid cooling of the melted ester; this melted at 73–74°, solidified and remelted at the higher temperature.

Anal. Calcd. for $C_{16}H_{14}O_2$: C, 80.65; H, 5.92. Found: C, 80.34; H, 5.99.

β-3-Acenaphthylpropionic Acid (II).—A solution of 22.4 g. of the unsaturated acid in 200 cc. of 0.5 *N* sodium hydroxide was shaken with 450 g. of 2% sodium amalgam for three hours and the filtered solution was acidified. Crystallization of the precipitated material from benzene gave 21.0 g. (93%) of colorless needles, m. p. 188–190°, and repeated recrystallization raised the melting point to 191.7–192°.

Anal. Calcd. for $C_{15}H_{14}O_2$: C, 79.62; H, 6.24. Found: C, 79.44; H, 6.46.

The **methyl ester,** prepared by hydrogenation of the unsaturated ester in ethanol (Adams catalyst) formed colorless needles from methanol; m. p. 50.7–51.7°.

Anal. Calcd. for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71. Found: C, 79.92; H, 6.94.

3,4-Aceperinaphthanone-7.—A solution of 5 g. of the saturated acid in 50 g. of liquid hydrogen fluoride was poured onto ice after twenty minutes. The tarry, yellow-green product which separated solidified after about three hours and was washed thoroughly and dried at 50° (20 mm.) for three hours. Extraction with ligroin from a residual green tar and clarification with Norit gave 2.5 g. (54%) of clusters of yellow plates; m. p. 92–97°. Further purification was best accomplished through the oxime (III), which was prepared by treating a solution of the crude ketone in ethanol with the filtrate from a mixture of 13 g. of hydroxylamine hydrochloride and 14 g. of sodium carbonate which had been ground with 50 cc. of ethanol. After standing for several hours the mixture was heated to boiling, the separated solid was brought into solution with more solvent, and the solution was clarified with Norit and allowed to cool. Repeated crystallizations of the material which separated afforded 1.9 g. (40%) of colorless needles, m. p. 245–246°, dec., with darkening at 225° (even in an evacuated capillary).

Anal. Calcd. for $C_{15}H_{13}ON$: C, 80.69; H, 5.87. Found: C, 80.93; H, 5.98.

Steam distillation of a mixture of the oxime and dilute sulfuric acid yielded in the distillate 1.36 g. of the ketone (77% from the oxime, 31% from the acid). The substance crystallized from ligroin in clusters of yellow plates; m. p. 102.6–103.4°. The ketone darkened on exposure to sunlight.

Anal. Calcd. for $C_{15}H_{12}O$: C, 86.51; H, 5.80. Found: C, 86.59; H, 5.79.

The **semicarbazone** separated from a boiling solution of the components in ethanol in the form of microcrystals which turned green when introduced into a bath at 260° and melted at 268° (evacuated capillary). The substance was very sparingly soluble in the usual solvents.

Anal. Calcd. for $C_{16}H_{15}ON_3$: C, 72.43; H, 5.70. Found: C, 72.54; H, 5.86.

Oxidation of the ketone was accomplished by gradually adding 10 g. of chromic oxide in 20 cc. of 50% acetic acid to 1.5 g. of the ketone in 10 cc. of acetic acid. After the initial reaction had subsided the solution was refluxed for one hour and poured into water. The mixture was boiled to coagulate the dark brown solid, and this crude product was then dissolved in 20 cc. of 10% sodium hydroxide and refluxed with 3 g. of potassium permanganate for three hours. The mixture was poured into 100 cc. of water containing 20 cc. of concentrated sulfuric acid, sodium bisulfite was added until the manganese dioxide was dissolved, and the solution was evaporated to a volume of 75 cc. The gray product which separated was sublimed at 320° (3 mm.) and yielded 0.15 g. (7.7%) of **naphthalene-1,4,5,8-tetracarboxylic dianhydride.**[14] This was identified by the formation of the diimide and its sodium salt, by the characteristic solubility in sulfuric acid and precipitation with water, and by the analysis.

Anal. Calcd. for $C_{14}H_4O_6$: C, 62.70; H, 1.50. Found: C, 62.94; H, 1.72.

3,4-Aceperinaphthane (IV).—A mixture of 0.75 g. of the oxime, 12 cc. of 6 *N* hydrochloric acid, 6 cc. of acetic acid, 12 cc. of toluene, and 4 g. of amalgamated zinc was refluxed vigorously for six hours, after which another charge of zinc and acid was added and refluxing continued for thirty-six hours longer. The aqueous layer was extracted with ether, combined with the toluene layer, and evaporated to dryness. The residue was a greenish tar from which the hydrocarbon was obtained by sublimation at 135° (8 mm.) in the form of colorless needles. Two crystallizations from

(14) Bamberger and Philip, *Ann.*, **240**, 147 (1887); Freund and Fleischer, *ibid.*, **399**, 182 (1913).

ligroin afforded 0.2 g. (30%) of material melting at 121.4–122°.

Anal. Calcd. for $C_{15}H_{14}$: C, 92.75; H, 7.26. Found: C, 92.72; H, 7.24.

Attempts to prepare a pure picrate were unsuccessful, the best sample sintering at 121° and melting over the range 127–130°. The **trinitrobenzene derivative** crystallized from ethanol in orange needles; m. p. 147–148°.

Anal. Calcd. for $C_{21}H_{17}O_6N_3$: C, 61.91; H, 4.21. Found: C, 61.98; H, 4.50.

Other Trials.—3-Methylacenaphthene (10 g.) was condensed with N-methylformanilide under the conditions used in the reaction with acenaphthene. Steam distillation gave 8.0 g. (68%) of a mixture of aldehydes, m. p. 67–100°, but no satisfactory method of separation was found. 3-Methylpyrene[5] (9 g.) was submitted to the reaction in *o*-dichlorobenzene solution at the steam-bath temperature, and the reaction mixture when processed through the bisulfite addition product yielded 7.5 g. (73%) of a mixture of aldehydes, m. p. 98–108°, but this again proved intractable. The semicarbazone mixture did not seem favorable for fractionation and the regeneration proceeded poorly. Extensive fractionation of the aldehyde mixture from alcohol and from benzene-ligroin afforded only a small amount of possibly homogeneous orange needles; m. p. 138–140°.

Anal. Calcd. for $C_{17}H_{10}O$: C, 88.50; H, 4.99. Found: C, 88.60; H, 4.95.

Summary

The reaction of aromatic hydrocarbons with N-methylformanilide to give aldehydes is limited to substances having a particularly reactive nuclear position and not too sensitive to be destroyed by the condensing agent (phosphorus oxychloride). Acenaphthene has been formylated by this method and the product utilized for the synthesis of 3,4-aceperinaphthane.

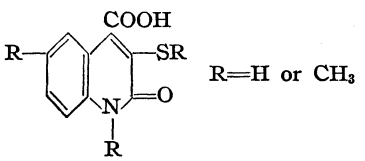
The Synthesis from Rhodanine-oxindoles of Keto and Mercapto Derivatives of Cinchoninic Acid[1]

BY RUFUS VERNON JONES[2] AND HENRY R. HENZE

Although the preparation of derivatives of keto-cinchoninic acids has been studied to a considerable extent, little attention has been directed to the synthesis of mercapto derivatives of the type



R=H or CH_3

In fact, only two examples of this type have been reported, namely, the unsubstituted keto-mercapto acid and its 1-methyl derivative, prepared, respectively, by the alkaline hydrolysis of the appropriate rhodanine-($\Delta^{5,3'}$)-oxindole.[3]

We have resynthesized these two rhodanine-oxindoles and, in addition, have prepared the 5-methyl and the 1,5-dimethyloxindole analogs, by condensation of rhodanic acid and appropriate derivatives of isatin, in order to study their conversion into keto and mercapto derivatives of cinchoninic acid. A comparison of behavior upon hydrolysis of rhodanine-($\Delta^{5,3'}$)-oxindole and its 5-methyl homolog was of special interest since it had been shown[4] that the closely related hydantoin-(5,3′)-oxindole and its 5′-methyl homolog had formed markedly different products on alkaline hydrolysis, in that the former yielded 1,2-dihydro-2-ketocinchoninic acid and the latter 5-methyloxindole.

In the present investigation, rhodanine-($\Delta^{5,3'}$)-oxindole and three methyl derivatives were hydrolyzed by alkali to form derivatives of 1,2-dihydro-2-keto-3-mercaptocinchoninic acid. The behavior of these compounds toward further hydrolysis, methylation and reduction was studied. It was found that rhodanine-($\Delta^{5,3'}$)-oxindole and its 5′-methyl homolog by treatment with one molecular proportion of potassium hydroxide are converted into mono-potassium salts of the type (A) which can be hydrolyzed to regenerate the oxindoles but cannot be methylated. With an excess of alkali, rhodanine-($\Delta^{5,3'}$)-oxindole was converted into the dipotassium salt of 1,2-dihydro-2-keto-3-mercaptocinchoninic acid, and the three methyl derivatives formed analogous dipo-

A B

tassium salts of type (B). The latter upon acidification form the corresponding 1,2-dihydro-2-keto-3-mercaptocinchoninic acid derivatives. These, in turn, when treated with dimethyl sulfate were converted into 1,2-dihydro-2-keto-3-methylmercaptocinchoninic acid analogs.

Experimental

Rhodanine-($\Delta^{5,3'}$)-1'-methyloxindole (II).—This compound was synthesized in a manner similar to rhodanine-($\Delta^{5,3'}$)-oxindole (I),[5] by heating for five hours at 140° a solution of 30 g. (0.185 mole) of 1-methylisatin,[6] 24.6 g. (0.185 mole) of rhodanine, 30 g. (0.36 mole) of fused sodium acetate, 400 cc. of glacial acetic acid and 4 cc. of acetic anhydride. Upon cooling, dark red crystalline plates separated which, after drying, weighed 51 g. (99% yield). This compound is virtually insoluble in the common organic solvents and does not melt or decompose at 300°. It yields a positive test with Feigl's reagent, (=C=C(SH)⇌=CH—C(=S)),[7] and dissolved in alkaline solution but is not reprecipitated unchanged upon acidification.

Anal. Calcd. for $C_{12}H_8N_2O_2S_2$: N, 10.14; S, 23.20. Found: N, 9.76; S, 23.31.

Rhodanine-($\Delta^{5,3'}$)-5'-methyloxindole (III).—Prepared in the same manner as the above but from 5-methylisatin, this compound possesses a copper-brown color with a metallic luster and is very sparingly soluble in ordinary organic solvents. Its physical and chemical behavior is similar to that of the 1'-isomer.

Anal. Calcd. for $C_{12}H_8N_2O_2S_2$: S, 23.20. Found: S, 22.82.

Rhodanine-($\Delta^{5,3'}$)-1',5'-dimethyloxindole (IV).—Prepared as above from 1,5-dimethylisatin[8] in 76% yield, the compound is a satin-black colored, fluffy solid with physical and chemical properties like those of the monomethyl analogs.

Anal. Calcd. for $C_{13}H_{10}NO_2S_2$: N, 9.65. Found: N, 9.83.

The same compound was obtained in 69% yield by condensing 1,5-dimethylisatin and rhodanine in ethyl alcohol solution using diethylamine as the catalyst.

Methylation of Rhodanine-($\Delta^{5,3'}$)-oxindoles.—In an attempt to convert (I) into (II), the former (0.05 mole) was mixed with dimethyl sulfate (0.05 mole) in alcoholic solution made basic with potassium hydroxide, and then was heated with an equal quantity of dimethyl sulfate for one hour. The solution was acidified and the solid which separated was purified and then melted at 216–217° with decomposition. Analysis proved the material to be **1,2-dihydro-2-keto-3-methylmercaptocinchoninic acid** (XIII), indicating that mere methylation had not occurred.

Anal. Calcd. for $C_{11}H_9NO_3S$: N, 5.95. Found: N, 5.94.

When compound I was treated with two equivalents of dimethyl sulfate in a 5% alcoholic solution, addition of 25% potassium hydroxide solution produced a red precipitate. The latter was filtered, dissolved in excess of the same alkaline solution and, upon acidification with hydrochloric acid, hydrogen sulfide was evolved. From the solution was obtained light yellow crystals melting at 345° (cor.); mixed with an authentic sample of **1,2-dihydro-2-ketocinchoninic acid** (XVII), the mixture melted unchanged.

Attempted methylation of I, suspended in methanol, by means of dimethyl sulfate and alcoholic potash for two hours at 100° was unsuccessful and I was recovered unchanged. The monopotassium salt of I was refluxed for fifteen hours with methyl iodide, but without reaction.

Likewise, no apparent change occurred when the monopotassium salt of III was suspended in dry ether and heated for several hours with dimethyl sulfate in an attempt to form IV. Even when this salt was heated for eighty hours at 100° with dimethyl sulfate, instead of methylation, hydrolysis and desulfurization produced **1,2-dihydro-2-keto-6-methylcinchoninic acid** (XVIII); m. p. 235–236° (cor.).

Anal. Calcd. for $C_{11}H_9NO_3$: N, 6.90. Found: N, 6.96.

Potassium Hydroxide on Rhodanine-($\Delta^{5,3'}$)-oxindoles.—To a well-stirred alcoholic suspension of I was added one equivalent of potassium hydroxide and the mixture was heated for one hour. The suspended, dark colored material became red and then was but slightly soluble in alcohol, ether or water. Suspended in water the salt rapidly hydrolyzed (accelerated by acid) to regenerate I. The red solid does not melt or decompose at 300°, is a monopotassium salt, and gives a positive test with the Feigl reagent.[7]

Anal. Calcd. for $C_{11}H_5KN_2O_2S_2$: N, 9.26. Found: N, 8.94.

Addition of three equivalents of potassium hydroxide to an alcoholic suspension of I caused a change of color, first to a deep red, and after a while to yellow. The mixture was boiled for one hour, cooled and filtered, yielding a canary yellow, crystalline solid. The latter is extremely soluble in water but is only slightly so in absolute alcohol or ether. The salt gave a positive Feigl test.[7] A 3% solution yields precipitates of characteristic color with many cations; these cannot be distinguished from those produced by the dipotassium salt of **1,2-dihydro-2-keto-3-mercaptocinchoninic acid** (V).

Anal. Calcd. for $C_{10}H_5K_2NO_3S$: S, 10.78. Found: S, 10.43.

A solution of this dipotassium salt in water at 0° was acidified yielding an orange colored amorphous precipitate. After drying, the product (81% yield) was recrystallized from toluene as feathery, orange crystals melting at 165–

(5) Andreasch, *Monatsh.*, **38**, 138 (1917).

(6) Heller, *Ber.*, **40**, 1300 (1907); an easier method of preparing N-methylisatin involves conversion of N-methylaniline into methylisonitrosoacetanilide and warming the latter with concentrated sulfuric acid at 40–50°.

166° (cor.). These data are in exact agreement with that reported for **1,2-dihydro-2-keto-3-mercaptocinchoninic acid**[9] (VI).

Anal. Calcd. for $C_{10}H_7NO_3S$: neut. equiv., 110.6; N, 6.33. Found: neut. equiv., 109.5; N, 6.36.

Unsuccessful attempts were made to synthesize VI from isatin (a) with thioglycolic acid in alcohol refluxed with diethylamine and (b) with thioglycolic acid heated in glacial acetic acid containing acetic anhydride and fused sodium acetate.

Boiling the dipotassium salt (V) with glacial acetic acid caused the separation of elementary sulfur and from the solution was obtained a curdy, light yellow mass. After solution in alkali, acidification yielded material (62%) melting at 345° (cor.). This material was mixed with an authentic sample of **1,2-dihydro-2-ketocinchoninic acid**[10] (XVII) and the melting point remained unchanged.

The 1-methyl, 5-methyl and 1,5-dimethyl derivatives of rhodanine-($\Delta^{5,3'}$)-oxindole appear to be more readily hydrolyzed by action of potassium hydroxide solution and are converted into the dipotassium salts of the corresponding methylated 1,2-dihydro-2-keto-3-mercaptocinchoninic acids (VII), (IX) and (XI). These salts do not appear to decompose at 300°.

Anal. Dipotassium salt from rhodanine-($\Delta^{5,3'}$)-1'-methyloxindole (VII). Calcd. for $C_{11}H_7K_2NO_3S$: N, 4.50; S, 10.29. Found: N, 4.64; S, 9.85.

This salt was converted in 79% yield by acidification into **1,2-dihydro-2-keto-3-mercapto-1-methylcinchoninic acid** (VIII), m. p. 145° (cor.) (dec.).[11]

Anal. Calcd. for $C_{11}H_9NO_3S$: N, 5.96. Found: N, 5.73.

A monopotassium salt was obtained by interaction of rhodanine-($\Delta^{5,3'}$)-5'-methyloxindole (III) and one equivalent of potassium hydroxide in alcohol. The red salt is hydrolyzed readily by hot water, regenerating the original oxindole derivative.

Anal. Calcd. for $C_{12}H_7KN_2O_2S_2$: N, 8.92; S, 20.40. Found: N, 8.87; S, 20.10.

When the oxindole derivative III is allowed to stand in the cold with alcoholic potassium hydroxide solution, or more rapidly by warming, canary yellow needle-like crystals of a dipotassium salt (IX) are obtained in 90% yield. The compound is very soluble in water, yielding a solution neutral to phenolphthalein, but is rather sparingly soluble in 95% alcohol.

Anal. Calcd. for $C_{11}H_7K_2NO_3S$: C, 42.42; H, 2.27; N, 4.50; S, 10.29. Found: C, 42.04; H, 3.01; N, 4.47; S, 10.40.

From a chilled, aqueous solution of this salt (IX), acidification caused separation (93% yield) of an orange colored solid, so finely divided as to be filtered with extreme difficulty. It is quite soluble in alcohol, acetone and ethyl acetate, but is best recrystallized from glacial acetic acid as a bright red product; m. p. 193–196° (cor.) (dec.). **1,2-Dihydro-2-keto-3-mercapto-6-methylcinchoninic acid** (X) is rather insoluble in cold water but is decomposed by continued contact with boiling water.

Anal. Calcd. for $C_{11}H_9NO_3S$: neut. equiv., 117.6; N, 5.96; S, 13.63. Found: neut. equiv. (phenolphthalein), 117.6; N, 6.01; S, 13.75.

Compound IV was heated with slightly more than two equivalents of potassium hydroxide in water (20% solution); the black compound became red in color and dissolved. Upon dilution of the solution with ethyl alcohol a yellow, crystalline dipotassium salt (XI) separated and was filtered and dried (90% yield). This salt is extremely soluble in water and is quite hygroscopic.

Anal. Calcd. for $C_{12}H_9K_2NO_3S$: N, 4.30; S, 9.85. Found: N, 4.32; S, 10.03.

This salt (XI) upon acidification formed the corresponding **1,2-dihydro-2-keto-3-mercapto-1,6-dimethylcinchoninic acid** (XII) in 87% yield. Out of toluene, the orange-brown feathery crystals melt with decomposition at 157–159° (cor.).

Anal. Calcd. for $C_{12}H_{11}NO_3S$: neut. equiv., 124.6; N, 5.62; S, 12.86. Found: neut. equiv., 125.1 (phenolphthalein); N, 5.79; S, 12.66.

In order to further characterize X, 2 g. of the latter was heated with 1.2 g. of benzyl chloride, 5 g. of sodium hydroxide and 50 cc. of alcohol until solution was complete. On cooling, sodium chloride separated and was removed by filtration. The filtrate was diluted with a large volume of water, boiled to remove much of the alcohol, again cooled, extracted with ether, and upon acidification there was precipitated **1,2-dihydro-2-keto-3-benzylmercapto-6-methylcinchoninic acid;** purified by crystallization from diluted alcohol it melts with decomposition above 200°.

Anal. Calcd. for $C_{18}H_{15}NO_3S$: N, 4.31. Found: N, 4.29.

Following the method of Johnson, Pfau and Hodge,[12] 11 g. of chloroacetic acid was dissolved in 20 cc. of water, 5 g. of X was added and the mixture was boiled for one hour. The black, suspended material was removed and dissolved in alcohol with separation of elementary sulfur. Dilution of the filtrate caused precipitation of **1,2-dihydro-2-keto-6-methylcinchoninic acid** (XVIII). The latter was recrystallized from 80% alcohol and melted with decomposition at 235–236°. The acid is insoluble in water, but is fairly soluble in alcohol, ether and glacial acetic acid.

Anal. Calcd. for $C_{11}H_9NO_3$: C, 65.02; H, 4.47; N, 6.90. Found: C, 65.21; H, 4.61; N, 6.88.

Formation of 1,2-Dihydro-2-keto-3-methylmercapto-cinchoninic Acids.—A solution of 60 g. (0.22 mole) of the yellow dipotassium salt V in 200 cc. of water was cooled to 0° and treated with 60 g. (0.475 mole) of dimethyl sulfate with subsequent addition of 20% potassium hydroxide solution as needed to maintain the mixture alkaline to litmus. A yellow precipitate was filtered and recrystallized from boiling water. The solid did not melt at 300° and yielded a negative test with the Feigl reagent.[7]

Anal. Calcd. for $C_{11}H_8KNO_3S$: S, 11.73. Found: S, 11.57.

From the dipotassium salt (IX) there was prepared a monopotassium salt which was recrystallized from 80% alcohol.

Anal. Calcd. for $C_{12}H_{10}KNO_3S$: N, 4.88; S, 11.16. Found: N, 5.00; S, 11.16.

A sample of this monopotassium salt was dissolved in water and treated with cold, dilute hydrochloric acid causing separation of a glistening yellow solid. After recrystallization from dilute alcohol, **1,2-dihydro-2-keto-3-methylmercapto-6-methylcinchoninic acid** (XV) was obtained as an orange crystalline material melting with decomposition at 221–222° (cor.).

Anal. Calcd. for $C_{12}H_{11}NO_3S$: neut. equiv., 249.3; N, 5.62. Found: neut. equiv. (phenolphthalein), 246.2; N, 5.57.

Dimethyl sulfate converted the dipotassium salt XI into a monopotassium salt which did not melt at 300° and which did not give a positive test with Feigl reagent.[7]

Anal. Calcd. for $C_{13}H_{12}KNO_3S$: N, 4.65. Found: N, 4.35.

This salt upon acidification yielded yellow, crystalline material. Recrystallized from dilute alcohol, **1,2-dihydro-2-keto-3-methylmercapto-1,6-dimethylcinchoninic acid** (XVI) melts with decomposition at 224–225° (cor.).

Anal. Calcd. for $C_{13}H_{13}NO_3S$: neut. equiv., 263.3; N, 5.32. Found: neut. equiv. (phenolphthalein), 258.0; N, 5.61.

Reduction of 1,2-Dihydro-2-keto-3-methylmercaptocinchoninic Acids.—Six grams of XIII, 5 g. of red phosphorus and 50 cc. of hydriodic acid (sp. gr. 1.7) were refluxed for seven hours at 150°. After removal of the phosphorus by filtration and most of the acid by steam distillation, the solution was made alkaline with potassium hydroxide and then faintly acidic with hydrochloric acid; upon cooling, light yellow crystals (2 g. or 41% yield) were obtained. A mixture of this material with an authentic sample of **1,2,3,4-tetrahydro-2-ketocinchoninic acid** (XIX)[13] melted at 215–216° (cor.).

Anal. Calcd. for $C_{10}H_9NO_3$: N, 7.33. Found: N, 7.16.

Three grams of XIV was heated with 25 cc. of hydriodic acid and 2 g. of red phosphorus for eight hours at 150°, a gas with mercaptan-like odor being evolved. The gum which formed could not be caused to crystallize, but did not contain sulfur.

From heating a sample of XV with concentrated hydriodic acid for ten hours at 150° there was obtained white needles of **1,2,3,4-tetrahydro-2-keto-6-methylcinchoninic acid** (XX) melting at 219–220° (cor.). This melting point was not altered by mixture with an authentic sample.[14]

Anal. Calcd. for $C_{11}H_{11}NO_3$: N, 6.86. Found: N, 6.74.

Two attempts were made to reduce 1,2-dihydro-2-keto-3-methylmercapto-1,6-dimethylcinchoninic acid (XVI) with hydriodic acid alone or with red phosphorus; in neither case was it possible to secure a crystalline product.

Summary

The preparation of ketomercaptocinchoninic acids from rhodanine-($\Delta^{5,3'}$)-oxindoles has been studied. As a result it has been possible to synthesize examples of 1,2-dihydro-2-keto-3-methylmercaptocinchoninic acids, a type not previously reported in the chemical literature.

Hydantoins Containing a Tetrahydropyranyl Substituent[1]

BY HENRY R. HENZE AND ROBERT L. McKEE

Until quite recently, the clinical utilization of hydantoin derivatives had been limited wholly to the use of ethylphenylhydantoin (Nirvanol)[2] in the treatment of convulsions of the type of St. Vitus dance. However, the sodium salt of diphenylhydantoin (Dilantin)[3] has come now to be considered as virtually a specific for control of epileptic seizures. Treatment with this substituted hydantoin does not effect a cure of epilepsy, hence the necessity for further research seeking additional anticonvulsants.

A few hydantoin derivatives containing an alkoxy substituent[4] have been prepared in this Laboratory and shown elsewhere to possess vary-

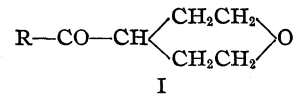
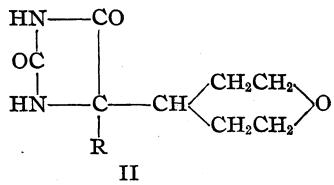
ing degrees of activity as anticonvulsants. A careful survey of the chemical literature fails to disclose evidence of the synthesis of any hydantoin possessing a cyclic ether grouping as a substituent. With these facts in mind, this research was begun with the intention to synthesize a series of cyclic keto ethers of the type (I) in which the —R grouping should be alkyl or phenyl, and, further, from these ketones to prepare a similar series of 5,5-disubstituted hydantoins of the type (II) in which the —R groupings should correspond to those of the parent ketones.



I



II

Only two examples of cyclic keto ethers (I) were known, namely, the methyl and ethyl tetrahydropyranyl ketones,[5] which were reported to be formed by action of the appropriate zinc alkyls upon the acid chloride of tetrahydropyran-4-carboxylic acid. In the present investigation, reaction of 4-cyanotetrahydropyran with appropriate Grignard reagents has been utilized in the resynthesis of these methyl and ethyl ketones, and in the initial preparation of six homologs and of the cyclohexyl and phenyl analogs. No appreciable quantity of ketone could be obtained from 4-cyanotetrahydropyran and either isopropylmagnesium bromide or *s*-butylmagnesium bromide.

Each of these ten acyl derivatives of tetrahydropyran has been converted into the corresponding hydantoin by interaction with potassium cyanide and ammonium carbonate in diluted alcohol solution. Through the courtesy of Parke, Davis and Company two of these new compounds, in the form of their sodium salts, have received preliminary pharmacological testing; 5-isoamyl-5-tetrahydropyranylhydantoin and its 5-phenyl analog were found to exhibit mild anticonvulsant activity and to be devoid of any hypnotic action.

Experimental

Ethyl 4-Cyanotetrahydropyran-4-carboxylate.—To a suspension of sodium ethylate, prepared from 31.5 g. of sodium and 450 cc. of absolute ethanol, was added 155 g. of ethyl cyanoacetate[6] followed by 97 g. of 2,2′-dichloroethyl ether. This mixture was heated under a reflux condenser for three hours and later allowed to stand for an additional twelve hours. After filtration from sodium chloride, the solution was fractionated and the material boiling 105–140° (16 mm.) was collected. Upon redistillation there was obtained 37 g. (31% yield) of ethyl 4-cyanotetrahydropyran-4-carboxylate boiling at 135° (16 mm.)[7]; $n^{20}D$ 1.4539; d^{20}_4 1.1109; y^{20} 37.4; *MR* calcd. 44.68; *MR* found 44.66; *P* calcd. 413.9; *P* found 407.9.

Anal. Calcd. for $C_9H_{13}NO_3$: C, 58.95; H, 7.15; N, 7.65. Found: C, 58.77; H, 7.29; N, 7.71.

This ester was subsequently hydrolyzed by allowing a mixture of 32 g. of ester, 10.8 g. of potassium hydroxide, 9 cc. of water and 192 cc. of methanol to stand at room temperature for fifteen hours. Carbon dioxide was passed through the solution while the latter was concentrated on a water-bath. When solid matter began to separate it was redissolved and acidified with hydrochloric acid, causing separation of the organic acid. After recrystallization from the least amount of water, **4-cyanotetrahydropyran-4-carboxylic acid** (yield quantitative) melted at 163–164° (cor.).[8]

Anal. Calcd. for $C_7H_9NO_3$: neut. equiv., 155.1; N, 9.03. Found: neut. equiv. (phenolphthalein), 156.5; N, 9.12.

Tetrahydropyran-4-nitrile.—The carboxylic acid (28.5 g.) was heated under a reflux condenser in an oil-bath at 180–200° until evolution of carbon dioxide ceased. On fractionation of the residue, the nitrile distilled at 82–83° (10 mm.)[9] and left a small amount of solid product, which on further heating at 210–220° gave an additional amount of the nitrile. The total yield was 18.4 g. or 90%; $n^{20}D$ 1.4521; d^{20}_4 1.0343; y^{20} 40.7; *MR* calcd. 29.11; *MR* found 28.99; *P* calcd. 267.9; *P* found 272.0.

Preparation of Acyl 4-Tetrahydropyrans.—The ketones were prepared by addition of a molar proportion of tetrahydropyran-4-nitrile in absolute ether to 1.2–2.0 molar proportions of an appropriate Grignard reagent; the hydrolysis could be effected equally well with cold solutions of either ammonium chloride or hydrochloric acid. The ether extracts, after drying, were fractionated through an eight-inch (21 cm.) column containing a nichrome wire spiral. The purified ketones were water-white liquids having a sweet odor, and were miscible with ethanol or ethyl ether but immiscible with water. The compounds appear to be stable on standing and readily formed semicarbazones and 2,4-dinitrophenylhydrazones.

Preparation of 5-(4-Tetrahydropyranyl)-5-substituted Hydantoins.—A given ketone, together with 1.8 molar equivalents of potassium cyanide and 3.6 molar equivalents of ammonium carbonate (U. S. P. cubes), was dissolved in about 150 cc. of 50% ethyl alcohol and heated under a reflux condenser at 58–60° for twelve hours. The solution was evaporated to about one-half its original

volume and then was acidified with hydrochloric acid causing separation of the hydantoin. In general, two recrystallizations from 20% alcohol produced crystalline white material, seemingly quite insoluble in water, but readily soluble in alkaline solution. Sodium salts of the hydantoins could be prepared readily by addition of the calculated amount of sodium ethylate to an alcoholic solution of the hydantoin and evaporation to dryness.

Summary

1. Eight new cyclic ether ketones, containing the tetrahydropyran nucleus, have been prepared.

2. The initial synthesis is reported of ten examples of a novel type of hydantoin containing a cyclic ether (tetrahydropyranyl) grouping.

Copolymerization of Alkyl Acrylates and Alkyl Maleates. Some Kinetic Studies on Copolymerization[1]

BY C. S. MARVEL AND ROBERT L. FRANK[2]

In order to learn more about copolymerization an attempt has been made to extend the method of kinetic study of the polymerization of optically active monomers[3] to mixtures of monomers. The work reported in this communication deals with copolymers of acrylates and maleates. These were selected for study because of ready availability and because it was thought that when these two monomer units entered a growing chain, they would do so in a 1:1 ratio as this seemed to be the tendency for such heteropolymers as styrene–maleic anhydride, stilbene–maleic anhydride[4] and the less closely related olefin–sulfur dioxide[5] copolymers. It was to be expected that excess acrylate units might appear in the polymer but the maleate being unable to polymerize alone should never exceed the 1:1 ratio.

The polymerization of various mixtures of *l*-monomenthyl maleate and ethyl acrylate was carried out in water-jacketed polarimeter tubes at 55° and the change in rotation was followed to determine the rate of each reaction. The change in concentration of the maleate could then be calculated by means of the equation

$$C_T = \frac{C_0(\gamma_T - \gamma_p)}{\gamma_m - \gamma_p}$$

in which C_T is the concentration of the maleate at time T (in grams per 100 cc.), C_0 is the initial concentration, and γ_m, γ_p, and γ_T are the specific rotations of the monomer, the polymer, and the solution at time T, respectively. It should be noted that what is being measured here is not necessarily the rate of polymer formation, but the rate of entrance of the maleate units into the chain.

Benzoyl peroxide was used to catalyze the polymerizations, and rather large amounts (up to 5% of the solutions) were employed in order to eliminate as much as possible the induction period and to speed up the polymerizations. Anhydrous dioxane was the solvent and the solutions contained from 6 to 16% of the combined monomers.

The entrance of maleate units into the polymer chains appears to be a zero order reaction and gives a straight line when the change in concentration ($C_0 - C_T$) is plotted against time (Fig. 1, Curve 1). This indicates that the rate should be independent of the concentration of the maleate, and this was found to be the case. When the concentration of the maleate was varied, the slope of the straight line did not change (Figs. 1 (Curve 2) and 2).

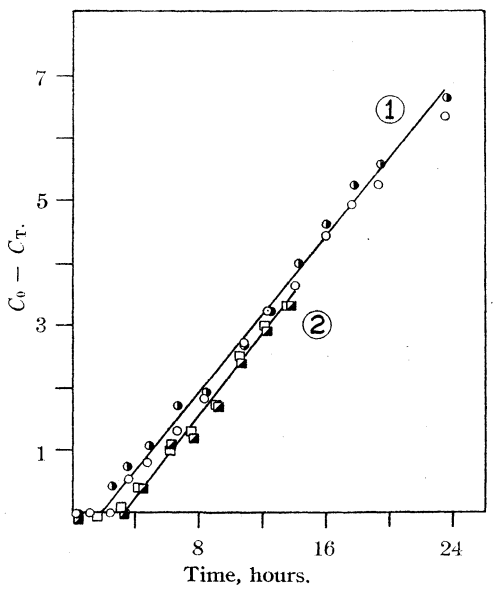

Fig. 1.—Curve 1: 0.26 molar ethyl acrylate, 0.26 molar *l*-monomenthyl maleate, 5% benzoyl peroxide; Curve 2: 0.26 molar ethyl acrylate, 0.13 molar *l*-monomenthyl maleate, 5% benzoyl peroxide.

When two equivalents of *l*-monomenthyl maleate to one of ethyl acrylate were used, it was expected that the rotation would change until half the maleate had copolymerized with the acrylate, to give a 1:1 polymer, and that the rotation would then show no further change, as indicated by the dotted line in Fig. 2. As shown by the curve obtained in Fig. 2, this was not the case. The rotation changed according to zero order kinetics until one equivalent of maleate had been used up, and then continued to decrease slowly.

(5) Frederick, Cogan and Marvel, THIS JOURNAL, **56**, 1815 (1934).

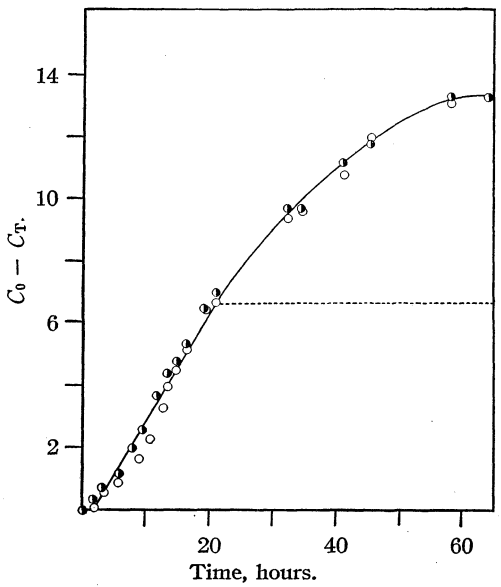

Fig. 2.—0.26 molar ethyl acrylate, 0.52 molar *l*-monomenthyl maleate, 5% benzoyl peroxide.

In order to investigate this behavior, *l*-monomenthyl maleate was heated in dioxane alone for a week to determine whether or not an ester interchange might be taking place. The rotation was unchanged at the end of this time.

The maleate was then treated with benzoyl peroxide without having any acrylate present. The rotation changed and, when the data were plotted, a first-order curve was obtained (Fig. 3). This result indicated that the maleate was polymerizing itself or that perhaps the monomer was reacting in some way with the benzoyl peroxide. In experiments using a limited amount of peroxide it was found that the latter alternative was the correct one. When less than one mole of peroxide was used for two of maleate, the rotation changed only in proportion to the amount of peroxide which would combine in this ratio. When the acrylate is present, this first order reaction is apparently superseded by the zero-order copolymerization, but takes place when the acrylate is absent. This reaction is being investigated further.

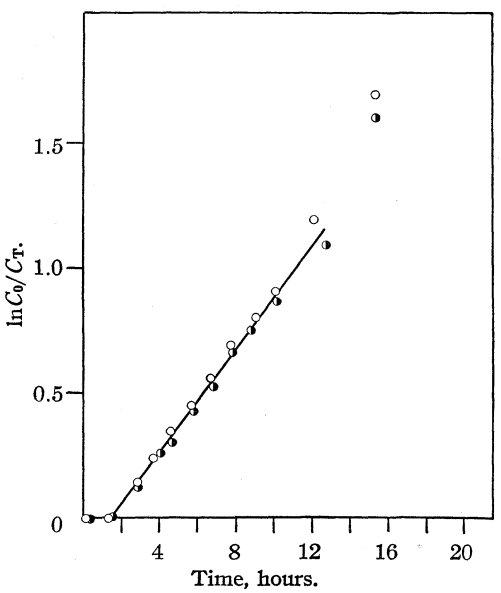

Fig. 3.—0.26 molar *l*-monomenthyl maleate, 0.21 (5%) molar benzoyl peroxide.

By doubling the concentration of acrylate and keeping the peroxide and maleate concentrations the same as in the experiments plotted in Fig. 1, it was found that the rate of reaction is independent of the acrylate concentration (Fig. 4, Curve 1).

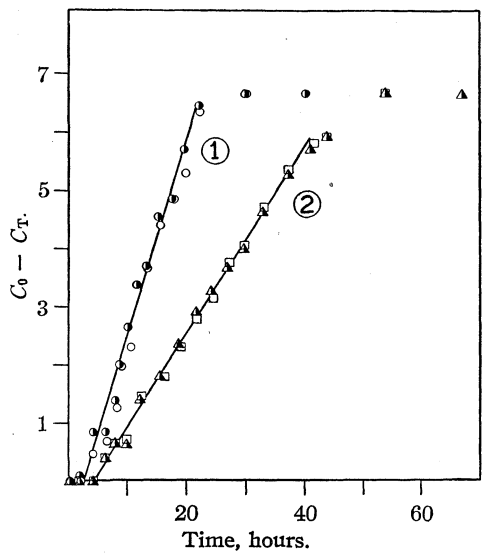

Fig. 4.—Curve 1: 0.52 molar ethyl acrylate, 0.26 molar *l*-monomenthyl maleate, 5% benzoyl peroxide; Curve 2: 0.26 molar ethyl acrylate, 0.26 molar *l*-monomenthyl maleate, 2.5% benzoyl peroxide.

When mole per mole of acrylate and maleate were used at the same concentration as in Fig. 1, and the peroxide concentration was halved, the rate of reaction was also cut in half, as illustrated in Fig. 4, Curve 2. Thus the rate of this polymerization appears to be directly proportional to peroxide concentration and not to the square root of the peroxide concentration as found by Price and Kell for *d*-*s*-butyl α-chloroacrylate.[3b]

It is possible to explain these kinetics, zero order with respect to maleate, if one makes the assumption that the reaction of *l*-monomenthyl maleate with the growing polymer chains occasionally forms a non-polymerizing product.

Polymers were isolated from the reaction mixtures containing equimolar amounts of acrylate and maleate and also from the mixtures containing two moles of maleate for one of acrylate. These polymers were found to have specific rotations of $-29.2°$ and $-39.2°$, respectively. By calculating the specific rotation of a 1:1 copolymer from the actual rotation of the reaction mixtures at the end of the reaction, a figure of $-43.2°$ is obtained, which is higher than the values found. This would indicate that the polymer chains contain less than one maleate unit for each acrylate unit, even when the maleate monomer is used in excess. This conclusion is in agreement with the analytical data obtained for the copolymers.

A second series of experiments was carried out with *l*-menthyl acrylate and ethyl maleate, in order to study the kinetics of the entrance of acrylate units into the polymer chain. These reactions, however, did not give clean-cut curves and it was impossible to ascertain whether the reactions were zero order or first order. *l*-Menthyl acrylate alone was found to polymerize according to first-order kinetics, as shown in Fig. 5. This is the expected result and similar to the polymerization of *s*-butyl α-chloroacrylate and vinyl β-phenylbutyrate.[3a]

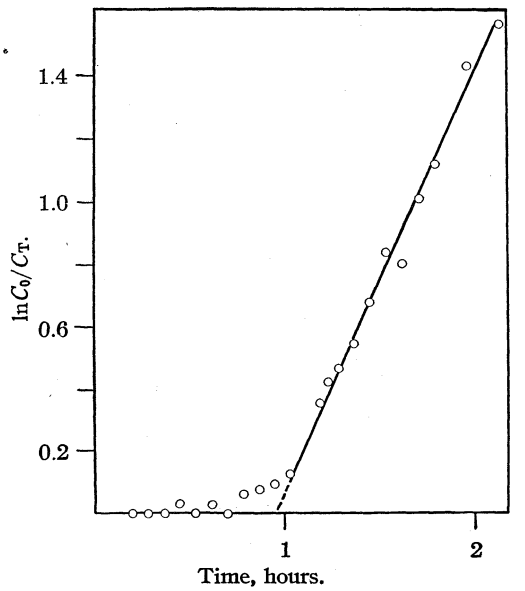

Fig. 5.—0.26 molar *l*-menthyl acrylate, 5% benzoyl peroxide.

Experimental

Kinetic Studies on Polymerization of Optically Active Esters.—Special water-jacketed 1-dm. polarimeter tubes of Pyrex glass were used for the rotation studies. These were made by the Macalaster Bicknell Company of Cambridge, Massachusetts. Between polarimeter readings these tubes were kept in a constant temperature bath at 55°. When a reading was to be taken, a tube was removed from the bath and connected by means of rubber tubing to a small centrifugal pump. Water from the bath was then circulated through the jacket.

Some difficulty was experienced in the readings at 55° because of convection currents, but by averaging a number of readings it was possible to obtain reproducible results. All the experiments were carried out in duplicate except the polymerization of *l*-menthyl acrylate.

The first experiment was made with 0.750 g. of benzoyl peroxide, 0.999 g. of *l*-monomenthyl maleate, and 0.403 g. of ethyl acrylate in 15 ml. of dry dioxane solution. The data are plotted in Fig. 1, Curve 1.

The second experiment was carried out with 0.750 g. of benzoyl peroxide, 0.499 g. of *l*-monomenthyl maleate, and 0.399 g. of ethyl acrylate in 15 ml. of dry dioxane solution. These results are plotted in Fig. 1, Curve 2.

In the third kinetic study 0.750 g. of benzoyl peroxide, 2.000 g. of *l*-monomenthyl maleate, and 0.402 g. of ethyl acrylate in 15 ml. of dry dioxane were used. These data are plotted in Fig. 2.

The reaction between peroxide and maleate alone was carried out using 0.500 g. of benzoyl peroxide and 0.667 g. of *l*-monomenthyl maleate in 10 ml. of dry dioxane solution. The results are plotted in Fig. 3.

The data represented in Curve 1 of Fig. 4 were obtained with a 15-ml. solution of dry dioxane containing 0.750 g. of benzoyl peroxide, 1.000 g. of *l*-monomenthyl maleate, and 0.787 g. of ethyl acrylate. These are represented in Fig. 4, Curve 1.

In the experiment represented by Curve 2 of Fig. 4, the reaction was carried out with a 15-ml. dry dioxane solution containing 0.375 g. of benzoyl peroxide, 1.000 g. of *l*-monomenthyl maleate, and 0.394 g. of ethyl acrylate. The results are shown in Fig. 4, Curve 2.

The final experiment, the polymerization of *l*-menthyl acrylate, was made using a 5-ml. dry dioxane solution of 0.250 g. of benzoyl peroxide and 0.277 g. of *l*-menthyl acrylate. These data are represented in Fig. 5.

The final reading in each experiment was taken after the cell had been heated overnight in order to determine the rotation of the polymer itself.

***l*-Monomenthyl Maleate.**—This was prepared by the method of Wassermann[6] and on recrystallization from petroleum ether melted at 86–87° ($[\alpha]^{28}D$ $-74.3°$, 0.1053 g. in 5 cc. of ethanol solution). The yield was 38.6%.

Ethyl Acrylate.—Röhm and Haas ethyl acrylate was distilled once through a modified Widmer column at atmospheric pressure; b. p. 98–99°.

***l*-Menthyl β-Chloropropionate.**—To 125 g. of *l*-menthol dissolved in 200 cc. of dry benzene was added 98.2 g. of β-chloropropionyl chloride. The reaction mixture became warm and hydrogen chloride was evolved. The reaction flask, fitted with a calcium chloride tube, was allowed to stand for forty-eight hours.

The reaction mixture was fractionally distilled under reduced pressure through a modified Widmer column. The main fraction distilled at 105–107° (4 mm.) and weighed

(6) Wassermann, *Ann.*, **488**, 211 (1931).

146.4 g. (77%); $n^{20}D$ 1.4642; d^{25}_4 1.011; $[\alpha]^{26}D$ +25.8° (no solvent).

Anal. Calcd. for $C_{13}H_{23}ClO_2$: C, 63.30; H, 9.39. Found: C, 63.55; H, 9.60.

l-Menthyl Acrylate.—A mixture of 30 g. of *l*-menthyl β-chloropropionate and 66 g. of quinoline was heated for three hours at a bath temperature of 170–180°. Crystalline quinoline hydrochloride separated from the reaction mixture on cooling. One hundred cubic centimeters of benzene was added and the solution was extracted with three 100-cc. portions of water and five 60-cc. portions of 50% sulfuric acid. It was then washed with ten 50-cc. portions of water, in order to remove the last traces of quinoline salts.

The dark oily solution was fractionally distilled through a modified Widmer column and 10.2 g. (39.5%) of product boiling at 64–67° (3 mm.) was obtained. This was redistilled at 78–80° (5 mm.); $n^{20}D$ 1.4628; d^{20}_4 0.927; $[\alpha]^{28}D$ −80.2° (1.002 g. in 10 cc. of dioxane solution).

Anal. Calcd. for $C_{13}H_{22}O_2$: C, 74.29; H, 10.55. Found: C, 74.53; H, 10.57.

Isolation of Polymers.—The collected washings from all the polarimeter tubes containing 1:1 ethyl acrylate and *l*-monomenthyl maleate were evaporated nearly to dryness and the viscous mixture was dissolved in 50 cc. of methanol. This was poured into 100 cc. of water and the mixture became milky. Polymer droplets adhered to the sides of the beaker and the milky supernatant liquid was poured off. This procedure was repeated and the polymer was then dried overnight at 70°. The result was a clear, light yellow, tacky plastic mass, $[\alpha]^{55}D$ −29.2° (0.0992 g. in 5 cc. of dioxane solution).

Anal. Found: C, 63.15; H, 8.39.

The contents of the two polarimeter tubes used in the experiments described in Fig. 2 (two parts maleate and one part acrylate) were washed into a beaker with dioxane. Water was added and the polymer separated as an oil which stuck to the bottom and sides of the beaker. The milky supernatant liquid was poured off. This procedure was repeated once with dioxane and once with acetone, in which the polymer was soluble. The polymer was then dried overnight at 70°, yielding a clear, amber, brittle resin (0.4 g.); $[\alpha]^{55}D$ −39.5° (0.1030 g. in 5 cc. of dioxane solution).

Anal. Found: C, 64.42, 64.48; H, 8.55, 8.57.

Summary

Some preliminary kinetic studies on mixtures of ethyl acrylate and *l*-monomenthyl maleate and of ethyl maleate and *l*-menthyl acrylate have been recorded. Evidence that *l*-monomenthyl maleate reacts with benzoyl peroxide to give a non-polymeric product has been reported.

The Synthesis of the Three Isomeric *dl*-β-Pyridylalanines

BY CARL NIEMANN, RICHARD N. LEWIS AND JOHN T. HAYS

The knowledge that the known α-amino acids containing heterocyclic ring systems are intimately associated with a number of important biological processes[1] has led us to consider the chemical and physiological properties of α-amino acids containing the pyridine nucleus, a heterocyclic ring system which, to date, has not been found in any naturally occurring α-amino acid,[2] but which is present in other compounds isolated from natural sources.[1,4] In this communication we wish to describe the synthesis of *dl*-β-(2-pyridyl)-alanine, *dl*-β-(3-pyridyl)-alanine, and *dl*-β-(4-pyridyl)-alanine, and to record some of the properties of these amino acids.

Overhoff, Boeke and Gorter,[5] starting with (2-pyridyl)-methyl chloride, prepared *dl*-β-(2-pyridyl)-alanine *via* the phthalimidomalonic ester synthesis of Sörensen.[6] The authors also reported that all attempts to prepare the amino acid from β-(2-pyridyl)-α-chloropropionic acid or from picolinaldehyde were unsuccessful. Our experiences have been similar to those described above, but we have found that *dl*-β-(2-pyridyl)-alanine can be prepared in considerably better yield than that reported by Overhoff, Boeke and Gorter[5] by substituting the benzamidomalonic ester synthesis of Redemann and Dunn[7] for the procedure of Sörensen.[6] The failure of picolinaldehyde to condense with hippuric acid[5] or with diketopiperazine in the desired fashion is not due to a lack of reac-

tivity, but rather to side reactions which lead to loss of aldehyde through tar formation. It appears that those aldehydes which undergo condensation with derivatives of glycine, to form azlactones or analogous compounds, in satisfactory yields are aldehydes in which additional stabilization is brought about by the possibility of resonance among excited structures.[8]

A comparison of the various structures that can be written for nicotinaldehyde and for picolinaldehyde[8,9] leads one to the conclusion that nicotinaldehyde has the greater resonance energy and consequently more closely resembles the aromatic aldehydes than does picolinaldehyde. One would therefore expect that nicotinaldehyde could be converted into *dl*-β-(3-pyridyl)-alanine by the Erlenmeyer procedure,[10] or modifications thereof.[11] This expectation was realized when it was found that nicotinaldehyde readily condenses with hippuric acid, diketopiperazine, hydantoin, thiohydantoin, and acetylthiohydantoin. Since the azlactone is not readily purified and the hydantoins are not readily hydrolyzed, the amino acid was prepared from the diketopiperazine-nicotinaldehyde condensation product by the method of Sasaki.[12]

The condensation of (4-pyridyl)-methyl bromide hydrobromide with benzamidomalonic ester[7] was not very satisfactory but hydrolysis of the small amount of condensation product that was obtained gave *dl*-β-(4-pyridyl)-alanine.

During this investigation we attempted to prepare the three isomeric pyridylaldehydes from the corresponding pyridine monocarboxylic acids by the method of McFadyen and Stevens.[13] In the case of nicotinic acid and picolinic acid the method proved to be satisfactory but when applied to isonicotinic acid only traces of isonicotinaldehyde were obtained. McFadyen and Stevens[13] found that *p*-nitrobenzoic acid could not be converted into *p*-nitrobenzaldehyde by their procedure although *m*-nitrobenzaldehyde was readily obtained from *m*-nitrobenzoic acid. Our observation of the difference in the behavior of nicotinic acid and isonicotinic acid in the McFadyen–Stevens reaction provides still another example of the parallel behavior of derivatives of pyridine and nitrobenzene.[9,14] The conversion of picolinic acid to picolinaldehyde by the McFadyen–Stevens reaction cannot be taken as an exception to the above generalization because with picolinic benzenesulfonhydrazide there is an excellent possibility that an intramolecular hydrogen bond is formed between the pyridine nitrogen atom and one of the nitrogen atoms present in the side chain thereby causing a decided structural modification which would preclude any direct comparison of the behavior of the alpha and gamma compounds.

A preliminary determination of the apparent dissociation constants[11] of the three isomeric *dl*-β-pyridylalanines[15] led to results which may be interpreted as follows. Considering first the zwitterionic structures, one would expect that in all of the amino acids the positively charged ammonium nitrogen atom would try to get as close as is structurally possible to the negatively charged pyridine nitrogen atom. In the case of *dl*-β-(2-pyridyl)-alanine this tendency would lead to the formation of a strong intramolecular hydrogen bond between the ammonium nitrogen atom and the pyridine nitrogen atom. It is obvious that this situation makes it difficult to add a proton to the pyridine nitrogen atom or to remove one from the ammonium nitrogen atom. Therefore one would predict that the pyridine nucleus, in all three *dl*-β-pyridylalanines, would be less basic than pyridine, and that the basicity of the pyridine nucleus would increase as the amino acid side chain is shifted progressively from the 2 to the 4 position with the greatest increment accompanying the shift from the 2 to the 3 position. The observed apparent basic dissociation constants ascribable to the pyridine nucleus are generally in accord with these predictions. Similarly the observed apparent acid dissociation constants are compatible with the idea that it is more difficult to remove a proton from the ammonium nitrogen atom in *dl*-β-(2-pyridyl)-alanine than in *dl*-β-(3-pyridyl)-alanine. However, they also show that the amino group is less basic in these amino acids than in the simple monoamino-monocarboxylic acids. The observed values for the second apparent basic dissociation constants

(15) In the case of *dl*-β-(4-pyridyl)-alanine a complete titration curve was not determined because of the small amount of amino acid available.

of *dl*-β-(2-pyridyl)-alanine and *dl*-β-(3-pyridyl)-alanine make it clear that the carboxyl group is more acidic in the case of the *dl*-β-pyridylalanines than in the case of the simple monoamino-monocarboxylic acids. This increase in acid strength as well as the decrease in basic strength of the amino group can be explained in terms of the inductive effect of the pyridine nucleus. Summing all of the above effects one finds that the values for the isoelectric points of these amino acids (*p*I = 6.6–6.8) are more acid than one would expect upon casual examination.

Experimental[16]

***dl*-β-(2-Pyridyl)-alanine.**[5]—Sodium nitrite, 4 g., in 6 ml. of water, was added dropwise, with stirring, to a well-cooled solution of 5.4 g. of (2-pyridyl)-methylamine,[17] b. p. 87–89° (2.2 mm.), in 25 ml. of concentrated hydrochloric acid. Forty grams of powdered potassium hydroxide was then added to the cold reaction mixture, the solution quickly filtered, and the filtrate extracted with ether. The ethereal solution was dried, filtered, the solvent removed by evaporation *in vacuo*, and the residue dissolved in 50 ml. of absolute ethanol. This solution was added to a warm solution of 12.1 g. of benzamidomalonic ester[7] and 1.56 g. of sodium in 76 ml. of absolute ethanol and the mixture refluxed for four hours. The ethanol was removed by evaporation *in vacuo*, the residue taken up in dilute aqueous hydrochloric acid, and the excess benzamidomalonic ester removed by extraction with ether. The aqueous phase was made alkaline, extracted with ether, the ethereal phase dried, filtered, and the solvent removed to give 5.6 g. (30%) of oily (2-pyridyl)-methylbenzamidomalonic ester. This condensation product was refluxed for eight hours with 25 ml. of 49% hydrobromic acid. The hydrolysate was diluted with 150 ml. of water, the solution cooled to 25°, and the liberated benzoic acid removed by extraction with ether. The aqueous phase was evaporated to dryness, the residue taken up in water, the solution freed of inorganic ions with the aid of silver carbonate and hydrogen sulfide, and evaporated to dryness. The residue was collected, washed with a mixture of absolute ethanol and isopropyl ether and then recrystallized from a mixture of isopropyl ether and 80% aqueous ethanol to give 1.38 g. (17%) of *dl*-β-(2-pyridyl)-alanine; m. p. 205.5–206°. Overhoff, Boeke and Gorter[5] give 216° as the melting point.

Anal. Calcd. for $C_8H_{10}O_2N_2$ (166.2): C, 57.8; H, 6.1; N, 16.9. Found: C, 58.0; H, 6.2; N, 16.8.

The addition of ninhydrin to an aqueous solution of *dl*-β-(2-pyridyl)-alanine resulted in the formation of a violet color.

Picolinic Benzenesulfonhydrazide.—Benzenesulfonyl chloride (5 ml.) was added, with stirring, to a chilled solution of 4.62 g. of picolinic hydrazide[18] in 35 ml. of pyridine.[13] The clear red solution was allowed to stand for four hours before the pyridine was removed by evaporation *in vacuo*. When the sirupy residue was stirred with a large volume of cold water a solid separated. This was washed with water, a small amount of cold ethanol, and finally with ether to give picolinic benzenesulfonhydrazide, m. p. 202–203.5°, after recrystallization from ethanol. The yield of crude product was practically quantitative.

Anal. Calcd. for $C_{12}H_{11}O_3N_3S$ (277.3): C, 52.0; H, 4.0; N, 15.2. Found: C, 52.4; H, 4.1; N, 15.1.

Picolinaldehyde.[19]—The procedure of McFadyen and Stevens[13] was modified as follows: 25 g. of picolinic benzenesulfonhydrazide, 24 g. of anhydrous sodium carbonate and 100 ml. of C. P. glycerol were heated to 160° and maintained at that temperature for two minutes. One hundred ml. of water was added to the reaction mixture, the solution saturated with sodium nitrate, filtered, and the filtrate extracted with ether in a continuous extractor for ten hours. The ethereal phase was dried, filtered, and the solvent evaporated to give 1.99 g. (20%) of picolinaldehyde. The liquid aldehyde was converted into the phenylhydrazone hydrochloride; m. p. 194.5–197°. Lénárt[19] gives a melting point of 196° for this compound. All attempts to condense the above picolinaldehyde with diketopiperazine were unsuccessful.

Nicotinic Benzenesulfonhydrazide.—The addition of 230 g. of benzenesulfonyl chloride to a suspension of 169 g. of nicotinic hydrazide[20] in 1.2 liters of technical pyridine gave 328 g. (96%) of nicotinic benzenesulfonhydrazide, m. p. 186–186.5° after recrystallization from 95% ethanol.

Anal. Calcd. for $C_{12}H_{11}O_3N_3S$ (277.3): C, 52.0; H, 4.0; N, 15.2. Found: C, 51.7; H, 4.2; N, 15.2.

Nicotinaldehyde.[21]—Nicotinic benzenesulfonhydrazide (177 g.) was decomposed, in 25-g. portions, to give 14.3 g. (22.5%) of nicotinaldehyde; b. p. 97–99° (26 mm.). The liquid aldehyde was converted into the phenylhydrazone; m. p. 157.5–158°. Harries and Lénárt[21] give a melting point of 158° for this compound.

5-(3-Pyridylmethyl)-thiohydantoin.—One gram of acetylthiohydantoin,[22] 0.53 g. of dry sodium acetate, both finely powdered, 0.67 g. of nicotinaldehyde, and 5 ml. of acetic anhydride were heated in an oil-bath at 110–115° for thirty minutes. The solid reaction product was extracted with hot water leaving 1.2 g. of a light yellow solid as a residue. This product was refluxed for six hours with 6 ml. of acetic anhydride, 6 ml. of hydriodic acid (d. 1.7) and 1.3 g. of red phosphorus. The hydrolyzate was filtered, the acetic anhydride and hydriodic acid removed by repeated evaporation, following the addition of water, and the residue dissolved in 20 ml. of ethanol. The addition of 6 *N* aqueous ammonium hydroxide to the filtered alcoholic solution precipitated an oil which solidified in contact with methanol. This product was recrystallized from aqueous ethanol to give 0.8 g. (60%) of 5-(3-pyridylmethyl)-thiohydantoin; m. p. 249–252°.

Anal. Calcd. for $C_9H_9ON_3S$ (207.2): C, 52.2; H, 4.4; N, 20.3. Found: C, 52.3; H, 4.7; N, 20.3.

Dinicotinaldiketopiperazine.—Nine grams of diketopiperazine, 27 g. of fused sodium acetate, 14.3 g. of nicotinaldehyde, and 25 ml. of acetic anhydride were heated in an oil-bath at 120–125° for five hours.[12] The solid reaction product was digested with hot water, the digest cooled, filtered, and the residue digested with hot ethanol to give 9.7 g. (50%) of crude dinicotinaldiketopiperazine. After two recrystallizations from pyridine the condensation product was obtained in the form of fine yellow needles; m. p. >300°.

Anal. Calcd. for $C_{16}H_{12}O_2N_4$ (292.3): C, 65.8; H, 4.1; N, 19.2. Found: C, 66.0; H, 4.3; N, 19.3.

***dl*-β-(3-Pyridyl)-alanine.**—A mixture of 9.7 g. of dinicotinaldiketopiperazine, 6.7 g. of red phosphorus, 67 ml. of hydriodic acid (d. 1.7), and 67 ml. of acetic anhydride was refluxed for six hours. The reaction product was filtered and the volatile acids removed by repeated evaporation, following the addition of water. The residue remaining after the final evaporation was dissolved in water and the solution freed of inorganic ions with the aid of silver carbonate and hydrogen sulfide. The solution was then evaporated to dryness and the solid residue collected with the aid of ethanol to give 7.6 g. (69%) of crude *dl*-β-(3-pyridyl)-alanine; m. p. 258–260°. The crude amino acid was recrystallized from 80% aqueous ethanol to give *dl*-β-(3-pyridyl)-alanine; pearly flakes; m. p. 262–263°.

Anal. Calcd. for $C_8H_{10}O_2N_2$ (166.2): C, 57.8; H, 6.1; N, 16.9. Found: C, 57.6; H, 6.2; N, 16.9.

dl-β-(3-Pyridyl)-alanine has a very sweet taste, gives a violet color when treated with ninhydrin, and forms a dipicrate, needles, m. p. 187–189°, after recrystallization from a dilute aqueous solution of picric acid.

Anal. Calcd. for $C_{20}H_{16}O_{16}N_8$ (624.4): C, 38.5; H, 2.6; N, 18.0. Found: C, 38.5; H, 2.7; N, 18.1.

Isonicotinic Benzenesulfonhydrazide.—A suspension of 13 g. of isonicotinic hydrazide,[22] m. p. 170.5–171.5°,[23] in 90 ml. of pyridine was treated with 18 g. of benzenesulfonyl chloride and the reaction mixture worked up as previously described to give 24.5 g. (93%) of isonicotinic benzenesulfonhydrazide; m. p. 193–194° after recrystallization from water.

Anal. Calcd. for $C_{12}H_{11}O_3N_3S$ (277.3): C, 52.0; H, 4.0; N, 15.2. Found: C, 52.2; H, 4.2; N, 15.3.

All attempts to prepare isonicotinaldehyde by decomposing the above sulfonhydrazide in the presence of glycerol and sodium carbonate, as described previously, failed in that only traces of the aldehyde were formed.

(4-Pyridyl)-carbinol Hydrochloride.[24]—A solution of 3.8 g. of (4-pyridyl)-methylamine,[17] b. p. 99–101° (24 mm.), was treated with silver nitrite according to the directions of Graf.[24] The crude carbinol hydrochloride was recrystallized from absolute ethanol to give 2.5 g. of (4-pyridyl)-carbinol hydrochloride; m. p. 167–172°.

Anal. Calcd. for C_6H_8ONCl (145.6): N, 9.6. Found: N, 9.5.

(4-Pyridyl)-methyl Bromide Hydrobromide.[25]—(4-Pyridyl)-carbinol hydrochloride (1.8 g.) was refluxed with 15 ml. of 49% hydrobromic acid, the solution evaporated to dryness, and the residue washed with absolute ethanol to give 2.8 g. of crude (4-pyridyl)-methyl bromide hydrobromide; m. p. 145–150°. The compound had a very irritating action on the skin.

Anal. Calcd. for $C_6H_7NBr_2$ (253.0): N, 5.5. Found: N, 5.8.

***dl*-β-(4-Pyridyl)-alanine.**—(4-Pyridyl)-methyl bromide hydrobromide (2.8 g.) was refluxed with a solution of sodiobenzamidomalonic ester[7] prepared by adding 0.54 g. of sodium to 5 g. of benzamidomalonic ester dissolved in 50 ml. of toluene. The reaction mixture was filtered, the filtrate extracted with 4 *N* hydrochloric acid, a slight excess of aqueous potassium hydroxide added to the aqueous phase, and the latter extracted with ether. The ethereal solution was dried, filtered, the solvent removed from the filtrate, and the residue recrystallized from aqueous ethanol to give 0.24 g. of condensation product; m. p. 106–107°.[26] The condensation product (0.24 g.) was hydrolyzed as previously described to give 0.11 g. of *dl*-β-(4-pyridyl)-alanine, m. p. 235–236°, after recrystallization from a mixture of isopropyl ether and 80% aqueous ethanol.

Anal. Calcd. for $C_8H_{10}O_2N_2$ (166.2): C, 57.8; H, 6.1; N, 16.9. Found: C, 56.9; H, 6.2; N, 17.0.

The addition of ninhydrin to an aqueous solution of *dl*-β-(4-pyridyl)-alanine resulted in the formation of a red color.

Preliminary Titration Data.—Samples of the amino acids dissolved in 10 ml. of water were titrated at 23° with 0.1 *N* hydrochloric acid and sodium hydroxide. The *p*H measurements were made with a Beckman Laboratory Model *p*H Meter equipped with external shielded electrodes. In the titration of *dl*-β-(2-pyridyl)-alanine and *dl*-β-(3-pyridyl)-alanine the mean volumetric error was less than 0.1% but in the titration of *dl*-β-(4-pyridyl)-

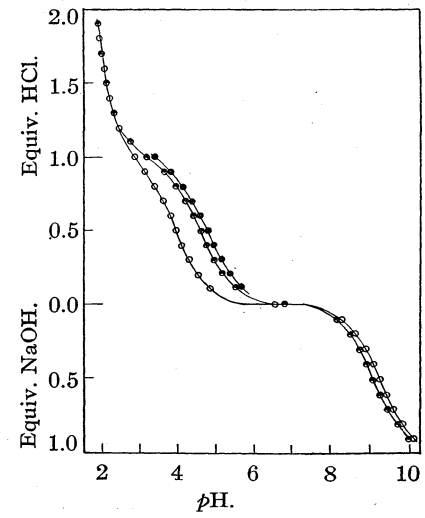

Fig. 1.—O, *dl*-β-(2-Pyridyl)-alanine, volume of solution containing 63.2 mg. of the amino acid after 1.5 equiv. of acid had been added = 17.0 ml.; ◐, *dl*-β-(3-pyridyl)-alanine, volume of solution containing 165.5 mg. of the amino acid after 1.5 equiv. of acid had been added = 27.0 ml.; ●, *dl*-β-(4-pyridyl)-alanine.

(23) Meyer and Mally[18] give a m. p. of 163°.

(24) R. Graf, *J. prakt. Chem.*, **146**, 88 (1936).

(25) All attempts to obtain (4-pyridyl)-methyl chloride directly from (4-pyridyl)-methylamine by treating the latter compound with nitrous acid in the presence of hydrochloric acid were unsuccessful.

(26) A similar yield and a comparable product was obtained when the condensation was carried out in absolute ethanol.

alanine, this error was of the order of 1%. The *p*H measurements were reproducible to within 0.02 of a *p*H unit and in the case of the base titration correction was made for the presence of sodium ion. The titration curves are given in Fig. 1 and the apparent dissociation constants, K_A, K_{B_1}, and K_{B_2}, in Table I.

TABLE I

APPARENT DISSOCIATION CONSTANTS

Amino acid	$K_{B_1} \times 10^{-10}$	$K_{B_2} \times 10^{-13}$	$K_A \times 10^{-10}$
dl-β-(2-Pyridyl)-alanine	0.89 ± 0.05	2 ± 1	6 ± 1
dl-β-(3-Pyridyl)-alanine	3.7 ± .5	5 ± 1	8 ± 1
dl-β-(4-Pyridyl)-alanine	6 ± 1		

Summary

1. The three isomeric *dl*-β-pyridylalanines have been synthesized and their apparent acid and basic dissociation constants determined. The effect of structure on acid and base strength is discussed.

2. Picolinaldehyde and nicotinaldehyde have been synthesized by the McFadyen–Stevens reaction and the applicability of this reaction to the pyridine series is discussed.

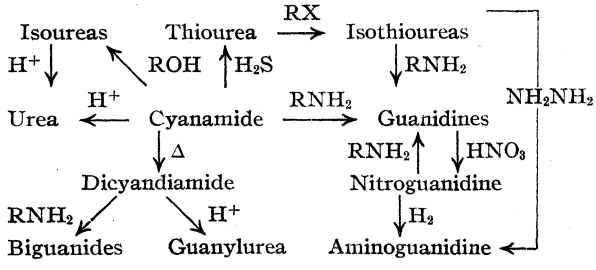
Studies in Chemotherapy. V. Sulfanilylcyanamide and Related Compounds[1]

BY PHILIP S. WINNEK, GEORGE W. ANDERSON, HARRY W. MARSON, H. ELDRIDGE FAITH AND RICHARD O. ROBLIN, JR.

Shortly after sulfanilylguanidine was described in a preceding paper of this series,[2] Marshall and co-workers[3] reported the compound independently. On the basis of a comprehensive bacteriological and pharmacological study, they suggested its use for the treatment of intestinal infections.

Guanidine is one of a large group of compounds which may be prepared from cyanamide. Because of the somewhat unusual characteristics of sulfaguanidine, it appeared to be of interest to investigate the sulfanilyl derivatives of cyanamide and a number of related compounds including a series of substituted guanidines. The following diagram illustrates some of the inter-relationships among this group of substances



Many of the same relationships have been found to exist among the sulfanilyl derivatives of these compounds (Table I). Thus, in addition to the more obvious method, sulfanilylguanidines were prepared from the sulfanilyl derivatives of cyanamide, nitroguanidine and isothioureas. Similarly, sulfanilylcyanamide was converted to the urea or isourea compounds. *p*-Nitrobenzenesulfonyl chloride and isoureas also led to the formation of sulfanilylisoureas, which in turn could be hydrolyzed to the urea derivative.[4] Other similar reactions such as the conversion of sulfanilyldicyandiamide to guanylurea and biguanide derivatives were also investigated.

Because of the alkali insolubility of many of the substituted sulfanilylguanidines (Table I), it was not possible to establish their structure directly when they were prepared through acetylsulfanilyl chloride and the substituted guanidines. For example, the sulfanilylalkylguanidines might have any of the following structures

However, the synthesis of a sample of sulfanilylbutylguanidine from N^4-acetylsulfanilylmethylisothiourea and butylamine[5] identical with the product obtained from acetyl sulfanilyl chloride and butylguanidine served to eliminate formula IV as a possibility. We have not attempted to differentiate conclusively among formulas I, II and III, because they are potentially tautomeric isomers. With the possible exception of sulfanilyl-*p*-carboxyphenylguanidine, alkali solubility would seem to favor I, since there appears to be a general tendency against the formation of III.[6]

The use of sulfaguanidine for intestinal infections is based on the fact that, while it has a reasonable degree of water solubility and therapeutic activity, it is poorly absorbed. These properties result in a high concentration in the intestinal tract without a correspondingly high level in the blood and tissues. The most important properties for compounds of this type then appear to be activity against the coliform group of organisms, degree of absorption and solubility. Given these data for a new substance, it should be possible to determine whether or not it merits further investigation. These properties for the compounds reported in this paper are recorded in Table I.[7]

It is interesting that in general the presence of a guanidyl radical resulted in low absorption. An exception to this were the alkyl guanidines, which were more completely absorbed. Other closely related compounds which lacked the guanidyl group were also absorbed.

Sulfanilylaminoguanidine was the only substance in this group which was more active *in vitro* against *B. coli* than sulfaguanidine. From the standpoint of absorption in mice and water solubility there appears to be little to choose between these two compounds. Since the preliminary results indicate that the amino derivative is bacteriostatic at higher dilutions than sulfaguanidine, it is possible that a further study of sulfanilylaminoguanidine may demonstrate it to be useful in the treatment of intestinal infections.

(7) The bacteriological and pharmacological studies were carried out in this Laboratory under the direction of Dr. W. H. Feinstone.

Experimental

A number of different procedures have been used in preparing the sulfanilyl derivatives reported in this paper. In most cases only one example of each method is described in detail. Other derivatives prepared by the same general procedure are designated in Table I. Whenever the same compound was prepared by more than one method, the identity of the different samples was established by mixed melting points as well as separate analyses.

(Method A) Sulfanilylcyanamide.—Commercial calcium cyanamide (220 g. of minimum hydrated) was stirred in 1300 cc. of water for three hours at 25–30°. To the filtrate from this mixture (about a 10% solution of $Ca(HNCN)_2$) was added with stirring, over a period of forty-five minutes, 200 g. (0.855 mole) of acetylsulfanilyl chloride at a temperature of 25–30°. The reaction mixture was kept alkaline by adding 40% sodium hydroxide solution as required. Stirring was continued for two hours, during which time a precipitate separated. After filtering the cooled mixture, the precipitate was washed with cold water and then with acetone. A yield of 162 g. (73%) of calcium acetylsulfanilyl cyanamide was obtained. Without further purification the product analyzed as follows: Ca (calcd.) 7.75%; Ca (found) 7.73%.

Thirteen grams (0.025 mole) of the acetyl derivative was refluxed with 60 cc. of 10% sodium hydroxide solution for thirty-five minutes and filtered while hot. The cooled filtrate was then made strongly acid with concentrated hydrochloric acid to separate the sulfanilyl cyanamide. It was purified by dissolving in alkali, treating with activated charcoal, filtering and precipitating with hydrochloric acid. The yield amounted to 9.8 g. (95%).

Sulfanilylcyanamide was also prepared by treating *p*-nitrobenzenesulfonyl chloride with free cyanamide in an aqueous medium in the presence of an excess of sodium hydroxide. The resulting sodium *p*-nitrobenzenesulfonylcyanamide was reduced to sulfanilylcyanamide with iron powder and 5% acetic acid.

(Method B) Sulfanilylurea.—Three grams (0.0058 mole) of calcium acetylsulfanilylcyanamide and 20 cc. of 4 *N* hydrochloric acid were warmed together on a steam-bath until solution was complete (fifteen to twenty minutes). When the solution was cooled a gummy solid separated. It was filtered off and dried. A yield of 2 g. (82%) of crude sulfanilylurea was obtained. The product was purified by repeated crystallization from water.

(Method C) Sulfanilylurea was also prepared from sulfanilylmethylisourea (see Methods D and E) by hydrolysis with concentrated hydrochloric acid on a steam-bath.[4]

(Method D) Sulfanilylmethylisourea.—14.9 g. (0.06 mole) of sodium *p*-nitrobenzenesulfonylcyanamide was added to 100 cc. of absolute methanol; most of the salt dissolved. Eight grams (0.22 mole) of hydrochloric acid gas was bubbled in from a cylinder in fifteen to twenty minutes with ice cooling. A white precipitate formed immediately. After one and one-half hours of standing in a stoppered flask at room temperature, the solid was filtered off and washed with methanol. It was then slurried with 25 cc. of water, made alkaline with ammonium hydroxide, filtered off and washed with 25 cc. of water, then with methanol. A yield of 14.4 g. (93%) of crude *p*-nitrobenzenesulfonylmethylisourea was obtained. It was purified by recrystallizing twice from methanol. Sulfanilylmethylisourea was produced in 81% yield by reduction of the purified nitro compound with iron powder in 5% acetic acid.

Sulfanilylmethylisourea was made more simply by the reaction of calcium acetylsulfanilylcyanamide with methanol and dry hydrochloric acid. Hydrolysis of the acetyl group apparently took place during the reaction, since the final compound was isolated directly from the reaction mixture.

(Method E) Sulfanilylmethylisourea was obtained also from *p*-nitrobenzenesulfonyl chloride and methylisourea hydrochloride following the general method of Cox and Raymond.[4] The nitro group was reduced as described under Method D.

(Method F) Sulfanilylmethylisothiourea was prepared from acetylsulfanilyl chloride and methylisothiourea sulfate by the general procedure described in a previous paper.[8] A mixture of 10 g. (0.035 mole) of acetylsulfanilylmethylisothiourea obtained by this procedure, 20 cc. of concentrated hydrochloric acid and 100 cc. of 95% ethanol was heated to boiling and the boiling continued for two minutes after all solid material had dissolved. The reaction mixture was then neutralized with 20% sodium hydroxide and cooled. The resulting precipitate of sulfanilylmethylisothiourea was purified by crystallization from water; yield 3.6 g. (42%).

(Method G) Sulfanilylpropylguanidine.—Fifteen grams (0.1 equiv.) of propylguanidine sulfate was suspended in 120 cc. of acetone and 10 g. (0.25 mole) of sodium hydroxide dissolved in 20 cc. of water was added. The mixture was cooled to 20°, and 25 g. (0.107 mole) of acetylsulfanilyl chloride was added gradually with stirring, while the temperature was maintained at 18–22°. After the reaction mixture had been stirred for four hours at room temperature, it was allowed to stand overnight. It was then diluted with 200 cc. of water and neutralized with acetic acid. Acetylsulfanilylpropylguanidine separated as a white solid, which was filtered off, washed with water and dried. The yield was 23 g. (78%) of crude product.

Nine grams (0.03 mole) of the crude acetyl compound was suspended in 21 cc. of 4 *N* hydrochloric acid and the mixture heated to boiling. All solid material was dissolved after five minutes and boiling was continued for three minutes. At this point a precipitate started to form. The mixture was at once diluted with two volumes of ice and the cold solution stirred for one hour with activated charcoal. The filtrate from this mixture was neutralized in the cold with 20% sodium hydroxide solution. Crude sulfanilylpropylguanidine separated as a gum which on stirring in the cold turned to a white solid. It was purified by crystallizing twice from hot water. A yield of 3 g. (40%) was obtained.

(Method H) Sulfanilylbutylguanidine.—4.1 g. (0.014 mole) of *p*-acetylsulfanilylmethylisothiourea was suspended in 20 cc. of 50% ethanol in a 3-necked flask fitted with a mercury-sealed stirrer and a reflux condenser leading through wash-bottles containing dilute hydrochloric

(8) Roblin and Winnek, THIS JOURNAL, **62**, 1999 (1940).

acid and sodium hydroxide solution; 0.86 g. (0.012 mole) of butylamine was added and the mixture warmed slowly with stirring on a steam-bath. There was a slow evolution of gas and after two hours the solid had dissolved. Heating was continued for one hour and the reaction mixture was then diluted with water and the acetylsulfanilylbutylguanidine separated as a solid; yield 3.5 g. (94%). Hydrolysis to sulfanilylbutylguanidine was accomplished by the method described under Method G except that 50% ethanol was employed as the medium.

(**Method I**) **Sulfanilylphenylguanidine.**—21.1 grams (0.07 mole) of acetylsulfanilylnitroguanidine, 13 g. (0.14 mole) of aniline, and 60 cc. of dioxane were refluxed for seven hours. All the solids had dissolved after the first half hour and the dark solution was allowed to stand overnight. Dilution with 200 cc. of water gave a sticky precipitate. The mixture was made slightly alkaline with ammonium hydroxide to dissolve any unreacted acetylsulfanilylnitroguanidine. After standing in the refrigerator for several hours, the oily material completely solidified. This was filtered off, washed with very dilute ammonia, and dried. The yield was 12.6 g. (54%). It was purified by crystallization from dilute alcohol. Deacetylation was carried out as described under Method G.

(**Method J**) **Sulfanilyl-*p*-aminophenylguanidine.**—7.5 grams (0.05 mole) of *p*-aminoacetanilide (Eastman Kodak Co., Rochester, N. Y.) was suspended in 50 cc. of water and 4 cc. of concentrated hydrochloric acid and 13 g. (0.025 mole) of calcium acetylsulfanilylcyanamide was added. A thick slurry resulted, which on heating to boiling dissolved. The mixture was refluxed for one-half hour and during the last fifteen minutes a light yellow precipitate separated. After cooling the product was filtered off, washed with water and dried. The crude acetylsulfanilyl-*p*-acetylaminophenylguanidine obtained in this manner amounted to 13 g. (67%). It was hydrolyzed as described under Method G in 54% yield.

Sulfanilyl-2-pyridylguanidine was obtained by a modification of the above method. Equivalent quantities of 2-aminopyridine hydrochloride and calcium acetylsulfanilylcyanamide were heated together at 200° for fifteen minutes. The resulting acetylsulfanilyl-2-pyridylguanidine was deacetylated by refluxing with 4 *N* hydrochloric acid. The yield of purified product was about 10%.

Sulfanilyldicyandiamide.—The acetyl derivative of this compound was obtained through the courtesy of Dr. D. W. Kaiser of this Laboratory. It was prepared by him using Method G. Sulfanilyldicyandiamide resulted from the alkaline hydrolysis of the intermediate acetyl derivative by the procedure described under Method A.

Sulfanilylguanylurea was prepared both by Method G and from the acid hydrolysis of acetylsulfanilyldicyandiamide employing the procedure described in Method B for the conversion of the cyanamide to the urea derivative. The product obtained by the latter method was somewhat difficult to purify. Only after fractional precipitation from alkaline solution was the melting point as high as that of the product obtained by Method G. Since only one product can be obtained from the dicyandiamide derivative, this method of synthesis in conjunction with the alkali solubility served to indicate the structure of sulfanilylguanylurea.

Sulfanilylbiguanides were produced by the same process that was employed for a number of the guanidines (Method G). In addition, sulfanilyl-*o*-tolylbiguanide was obtained by the reaction of acetylsulfanilyldicyandiamide and *o*-toluidine followed by hydrolysis. The conditions were the same as those described under Method I. This method helped to establish the structure of the *o*-tolyl derivative and by analogy the structure of the other sulfanilylbiguanides.

Summary

A group of sulfanilyl derivatives of cyanamide and related compounds has been prepared. The interrelationships among this group of compounds have made it possible to obtain many of them by more than one method. On the basis of this and other evidence the structure of the sulfanilyl derivatives is discussed.

The absorption, water solubility and bacteriostatic activity of these substances compared with sulfaguanidine are reported. These preliminary data suggest that sulfanilylaminoguanidine may be worth further investigation.

A Further Study of the Cyclization of Ureido Derivatives of Unsymmetrical Iminodibasic Acids Together with the Synthesis of Certain Hydantoins and Other Related Compounds[1]

BY DORIS R. SEEGER AND ANNE MACMILLAN

Observations have been reported separately to the effect that neither the acyclic ureidic derivative of phenylalanine-N-acetic acid,[2] $NH_2CON(CH_2COOH)CH(CH_2C_6H_5)COOH$, nor the corresponding phenylureide of tyrosine-N-acetic acid,[3] $C_6H_5NHCON(CH_2COOH)CH(CH_2C_6H_4OH)COOH$, has ever been obtained in pure condition. Indeed both appear to be so unstable that when formed by the hydrolysis of their esters or salts, they suffer ring closure almost instantly with the elimination of water and the formation of the corresponding hydantoin derivatives. Attention has not yet been called, however, to the fact that the dimethyl esters of such compounds also show a tendency to cyclization, in this case with the elimination of one molecule of alcohol and the formation of an acetic ester derivative of the corresponding hydantoin.[4] Even more significant is the observation that under all conditions and in the case of all of these diesters and acids only one of the two carboxyl groups enters into a reaction with the ureidic hydrogen atom, although theoretically unsymmetrical dibasic acids of this kind might be expected to form a mixture of two isomeric hydantoins, *i. e.*

(1*a*) $HOOCCH_2\overline{NCONHCOCH}CH_2C_6H_5$ and

(2*a*) $HOOC(CH_2C_6H_5)CH\overline{NCONHCOCH_2}$, or

(1*b*) $HOOCCH_2\overline{NCON(OC_6H_5)COCH}CH_2C_6H_4OH$ and

(2*b*) $HOOC(CH_2C_6H_4OH)CH\overline{NCON(C_6H_5)COCH_2}$

Actually hydantoins of the second type have never been isolated except under conditions which precluded the participation of the substituted acetic acid group in the condensation.[5]

The present investigation was undertaken in order to determine whether a phenylureide of phenylalanine-N-acetic acid, $C_6H_5NHCON(CH_2COOH)CH(CH_2C_6H_5)COOH$, would behave in the same way as the corresponding derivative of tyrosine-N-acetic acid and thus furnish additional evidence in support of the assumption that, in general, substituted acetic acid residues tend to dissociate their hydroxyl groups much more readily than unsubstituted residues. Accordingly a dimethyl ester of the above ureide was prepared by treating the free dimethyl ester of phenylalanine-N-acetic acid, dissolved in absolute ether, with phenyl isocyanate

$$\begin{matrix} & CH_2COOCH_3 & & \\ NH & & + C_6H_5NCO \longrightarrow & \\ & CH(CH_2C_6H_5)COOCH_3 & & \end{matrix}$$

$$C_6H_5NHCON\begin{matrix} CH_2COOCH_3 \\ CH(CH_2C_6H_5)COOCH_3 \end{matrix}$$

Under these conditions the product separated almost instantly in exceptionally pure condition and in quantitative amounts. Its conversion into methyl N-3-phenyl-C-5-benzylhydantoin-N-1-acetate was effected with equal ease since solution in absolute methyl alcohol containing one equivalent of sodium methoxide[6] was followed within five minutes by precipitation of the calculated quantity of the pure ester. On the other hand, the corresponding hydantoin acid

(1*c*) $HOOCCH_2\overline{NCON(C_6H_5)COCH}CH_2C_6H_5$,

was obtained by the action of aqueous hydrochloric acid upon the acyclic ester. In both cases the condensations were exactly analogous to those previously reported.

The configuration of the hydantoin (1*c*) was subsequently established by means of a separate synthesis which involved the following series of transformations

(1) $NH_2CH_2COOH + C_6H_5NCS \longrightarrow \overline{NHCSN(C_6H_5)COCH_2}$ [7]

(2) $\overline{NHCSN(C_6H_5)COCH_2} + C_6H_5CHO \longrightarrow \overline{NHCSN(C_6H_5)COC{=}CHC_6H_5}$ [8]

(3) The product, N-3-phenyl-2-thio-5-benzalhy-

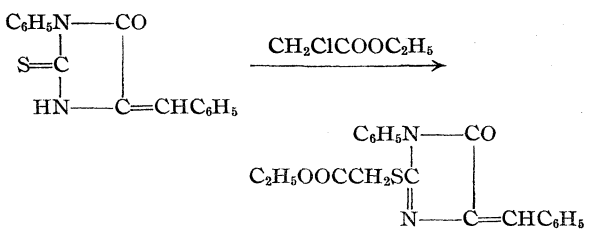
dantoin, which will be referred to again in another connection, was then converted into the corresponding oxy-compound, $\overline{NHCON(C_6H_5)COC}=CHC_6H_5$,[9] by first preparing the ethyl mercapto derivative and then hydrolyzing this in the presence of hydrochloric acid. (4) and (5) The preparation of ethyl N-3-phenylbenzalhydantoin-N-1-acetate[10] was carried out in the usual way[11] and the product then reduced and hydrolyzed simultaneously under the action of hydrogen iodide and red phosphorus.[12] The product finally obtained as a result of the above series of transformations was N-3-phenyl-5-benzylhydantoin-N-1-acetic acid. That it was identical with the compound (1*c*) previously obtained from the corresponding acyclic ureide, was established by a mixed melting point as well as by a detailed comparison of the properties of the two substances.

Supplementary work undertaken during the course of this investigation will now be outlined briefly since, although minor in character, it adds a few facts to what has been previously reported regarding the behavior of three of the substances which have been mentioned. Of these, N-3-phenyl-2-thiobenzalhydantoin[8] and ethyl N-3-phenylbenzalhydantoin-N-1-acetate[10] will be considered first.[13] The thiohydantoin has been observed, for example, to condense readily not only with ethyl chloride to form a mercapto derivative in the manner described by Wheeler and Brautlecht, but also to react almost instantly with α-halogen derivatives of esters of the fatty acids. In the case of ethyl chloroacetate, the reaction takes place as follows



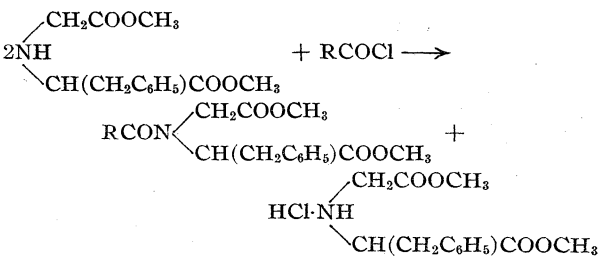
and in the presence of ethyl phenylbromoacetate or ethyl bromopropionate analogous compounds may be obtained. That all of these compounds are true mercapto derivatives was demonstrated by the fact that each, like 2-ethylmercapto-3-phenyl-5-benzalhydantoin, was converted into N-3-phenyl-2-oxybenzalhydantoin when hydrolyzed in the presence of hydrochloric acid.

A study of ethyl N-3-phenylbenzalhydantoin-N-1-acetate revealed that it reacted in a manner closely analogous to ethyl N-3-methylbenzalhydantoin-N-1-acetate when treated with bromine under certain specific conditions,[14] and that two isomeric unsaturated monobromo derivatives were formed. These appear to represent geometric modifications of a compound possessing the following structure

$$C_2H_5OOCCH_2\overline{NCON(C_6H_5)COC}=CBrC_6H_5$$

and may, therefore, be assumed to have resulted from the elimination of hydrogen bromide from a primary dibromo addition product.[15]

A third and somewhat more extended investigation was concerned with an effort to prepare N-acyl derivatives of phenylalanine-N-acetic acid, but in this case only a few positive results were obtained. The free dimethyl ester was first used as a starting point and the experiments carried out by applying Fischer's method of procedure[16]



Since the reaction takes place in an absolute ether solution, its progress can be followed by the separation of the insoluble hydrochloride. However, from among a number of different reagents employed in these experiments positive reactions were observed only in the case of three, namely, acetyl chloride, benzoyl chloride and 3,5-dinitrobenzoyl chloride. Even then only one primary product, *i. e.*

$3,5\text{-}(NO_2)_2C_6H_3CON(CH_2COOCH_3)CH(CH_2C_6H_5)COOCH_3$

could be obtained in pure crystalline condition

(9) Wheeler and Brautlecht, ref. 8, p. 451. The product, N-3-phenylbenzalhydantoin, was also prepared by condensing N-3-phenylhydantoin with benzaldehyde according to the method of Wheeler and Hoffman [*Am. Chem. J.*, **45**, 368 (1911)], a reaction which though mentioned as practical by Johnson and Brautlecht [THIS JOURNAL, **33**, 1531 (1911)], was never described in detail. The compound prepared in this way was found to be identical with that prepared by the method of Wheeler and Brautlecht.

(10) Halogen derivatives of this compound will be considered later.

(11) and (12) Compare Litzinger, THIS JOURNAL, **56**, 673, 675 (1934).

(13) Investigations concerning derivatives of these two substances were carried out, respectively, by Shirley M. Vincent and Marian L. Blanchard in connection with work that led to the B.A. degree with Honors in June, 1941.

(14) McLean and Seeger, THIS JOURNAL, **62**, 1416 (1940).

and in quantitative yields, all other products separating from their ether solution in the form of oils. Of these the acetyl derivative dissociated readily into its components since when its ether solution was treated with dry hydrogen chloride, the hydrochloride of the imino ester was precipitated quantitatively. The benzoyl derivative, on the other hand, was sufficiently stable to admit of transformation into the corresponding disodium salt. The latter formed a well defined crystalline compound which was subsequently identified by comparison with a product resulting from the application of the Schotten–Baumann reaction to phenylalanine-N-acetic acid itself. It may be added that although the latter method of acylation was applied in the case of other reagents, the only compound which was obtained in a condition sufficiently pure for analysis was *m*-nitrobenzoylphenylalanine-N-acetic acid, *m*-$NO_2C_6H_4$-$CON(CH_2COOH)CH(CH_2C_6H_5)COOH \cdot 2H_2O$.

Experimental

The phenylalanine-N-acetic acid[17] and the hydrochloride of the corresponding dimethyl ester[18] were prepared by methods previously reported. However, the yields of the latter were increased from 70% to nearly 100% by surrounding the reaction flask with an ice-bath during saturation with dry hydrogen chloride and then allowing the closed flask to remain for four days at room temperature. The product, when recrystallized from boiling acetone, melted at 144–144.5° with an evolution of gas.

Dimethyl phenylalanine-N-acetate, $NH(CH_2COOCH_3)$-$CH(CH_2C_6H_5)COOCH_3$, was prepared by treatment of the corresponding hydrochloride with an exact equivalent of aqueous sodium carbonate and extraction with ether. It boiled sharply at 182° (10 mm.).

Anal. Calcd. for $C_{13}H_{17}O_4N$: C, 62.13; H, 6.82; N, 5.58. Found: C, 62.11; H, 6.78; N, 5.73.

Dimethyl Ureidophenylalanine-N-acetate, NH_2CON-$(CH_2COOCH_3)CH(CH_2C_6H_5)COOCH_3$, was prepared by adding 0.88 g. of powdered potassium cyanate to a solution of 2 g. of the above ester hydrochloride in 5 cc. of water. The product, an oil which crystallized on stirring, consisted of a mixture of the ureide and methyl 5-benzylhydantoin-N-1-acetate,[19] the latter having formed by ring closure. Although it was impossible to effect complete separation of these two substances, a crystalline compound (m. p. 125–126°) was obtained from absolute methyl alcohol.[20]

Anal. Calcd. for $C_{14}H_{18}O_5N_2$: C, 57.12; H, 6.16; N, 9.52. Found: C, 58.80; H, 5.77; N, 9.52.

Dimethyl Phenylureidophenylalanine-N-acetate, $C_6H_5NHCON(CH_2COOCH_3)CH(CH_2C_6H_5)COOCH_3$, was obtained by adding 1.3 cc. of phenyl isocyanate, dropwise under cooling and stirring, to a solution of 2 g. of dimethyl phenylalanine-N-acetate in 200 cc. of absolute ether. The heavy white crystalline precipitate which began to form almost immediately and was complete at the end of two hours, weighed 1.7 g. and melted to a clear liquid at 124.5–125°. Additional amounts recovered from the filtrate made the yield quantitative.

Anal. Calcd. for $C_{20}H_{22}O_5N_2$: C, 64.85; H, 5.99; N, 7.56. Found: C, 64.42; H, 5.78; N, 7.83.

The ureidic ester is very soluble in methyl alcohol, acetone and chloroform; moderately soluble in ether, carbon tetrachloride and boiling water and almost insoluble in cold water. The corresponding acyclic dibasic acid was never obtained since hydrolysis of the ester in the presence of aqueous hydrochloric acid is accompanied simultaneously by ring closure.

$CH_3OOCCH_2\overline{NCON(C_6H_5)COCHCH_2C_6H_5}$, **Methyl N-3-phenyl-5-benzylhydantoin-N-1-acetate,** m. p. 97–97.5°, was obtained by dissolving 3 g. of dimethyl phenylureidophenylalanine-N-acetate in absolute alcohol which contained one equivalent of sodium methoxide (0.19 g. of sodium in 12 cc.).[21] The product precipitated immediately as fine white needles (2.21 g.) and was recrystallized from 50% methyl alcohol (1 g. in 4.4 cc. boiling). Since additional quantities could not be separated from the filtrate, the latter was evaporated to dryness and the residue dissolved in aqueous hydrochloric acid, when 0.45 g. of the corresponding hydantoin acid, m. p. 159–160°, separated, thus bringing the total yield to 98% of the theoretical.

Anal. Calcd. for $C_{19}H_{18}O_4N_2$: C, 67.44; H, 5.36; N, 8.28. Found: C, 67.50; H, 5.22; N, 8.55.

This ester is very soluble in methyl alcohol (1 g. in 0.3 cc. boiling and in 1.2 cc. at 20°) and in acetone (1 g. in 0.5 cc. boiling and in 3.5 cc. at 20°). It is extremely stable in the presence of 10% hydrochloric acid (less than 40% being hydrolyzed as a result of heating an aqueous alcohol solution for eight hours) while in the presence of alkali its hydrolysis was accompanied by the formation of decomposition products.[22]

$HOOCCH_2\overline{NCON(C_6H_5)COCHCH_2C_6H_5} \cdot 2H_2O$, **N-3-Phenyl-5-benzylhydantoin-N-1-acetic acid** (1*c*), was obtained in a number of different ways. As previously stated, it resulted from the hydrolysis of dimethyl phenylureidophenylalanine-N-acetate, since the corresponding acyclic acid, $C_6H_5NHCON(CH_2COOH)CH(CH_2C_6H_5)$-$COOH$, is unstable and suffers ring closure the moment it is liberated. The same hydantoin acid was also synthesized from phenylalanine-N-acetic acid by dissolving the latter (5 g.) in aqueous sodium bicarbonate and treating the ice-cold solution with phenyl isocyanate (4 g.) added over a period of four hours under constant stirring, after which the mixture was allowed to stand overnight at room temperature. Following the removal of a small amount of *sym*-diphenyl urea, the clear liquid was diluted to a volume of 500 cc. and treated with 20 cc. of concentrated hydrochloric acid when a heavy oil separated. The latter was transformed into fine white crystals (6.75 g.) by heating

(18) Hahn, McLean and Endicott, ref. 4, p. 1089.

(19) Hahn and Endicott, ref. 2, p. 1044.

(20) This compound on hydrolysis suffered ring closure and passed quantitatively into 5-benzylhydantoin-N-1-acetic acid. *Cf.* Hahn and Endicott, ref. 2, p. 1043.

(21) *Cf.* Bailey and Snyder, THIS JOURNAL, **37**, 391 (1915).

(22) That hydrolysis was extensive is shown by the fact that a sodium salt of phenylalanine-N-acetic acid was isolated.

the reaction mixture, and additional quantities obtained from the filtrate made the yield quantitative. The acid, crystallized from boiling water, separated in large transparent prisms which decrepitate at 95° with an evolution of a gas and on exposure to the air, slowly decompose and become opaque. Heated at 110° they lost two molecules of water rapidly, passing into the anhydrous form which melts sharply at 159.5–160°.

Anal. Calcd. for $C_{18}H_{16}O_4N_2 \cdot 2H_2O$: C, 59.99; H, 5.59; N, 7.78; H_2O, 9.91. Found: C, 59.86; H, 5.69; N, 8.20; H_2O, 9.96. Calcd. for $C_{18}H_{16}O_4N_2$: C, 66.68; H, 4.97; N, 8.64. Found: C, 66.87; H, 4.99; N, 8.80.

Since the acid is only slightly soluble in water (1 g. in 400 cc. of boiling and in 2500 cc. at 20°) while very soluble in alcohol (1 g. in 0.4 cc. of boiling and in 2 cc. at 20°), it was conveniently recrystallized from 50% alcohol. It is also very soluble in boiling methyl alcohol (1 g. in 1.8 cc.) and in cold acetone (1 g. in 1.5 cc.), glacial acetic acid and chloroform. It is readily transformed into the corresponding methyl ester when dissolved in methyl alcohol and treated with dry hydrogen chloride.

The configuration of both N-3-phenyl-5-benzylhydantoin-N-1-acetic acid and its methyl ester was finally established by means of a separate synthesis as follows.

$\overline{NHCON(C_6H_5)COC}=CHC_6H_5$, **N-3-Phenyl-5-benzalhydantoin,** m. p. 252–252.5°, was prepared by condensing N-3-phenylhydantoin[23] with benzaldehyde according to the method of Wheeler and Hoffman[24] which consisted in refluxing a mixture of 75 g. of phenylhydantoin, 52 g. of freshly distilled benzaldehyde, 78 g. of fused sodium acetate and 350 cc. of glacial acetic acid for eleven hours. The reaction mixture was then diluted with an equal volume of water, and the product, N-3-phenyl-5-benzalhydantoin[25] (91.78 g.), was freed from traces of the reactants by washing first with boiling water and then with cold alcohol.

The compound is almost insoluble in boiling water; slightly soluble in boiling alcohol (1 g. in 400 cc.) and very soluble in glacial acetic acid (1 g. in 33 cc. boiling and in 224 cc. at 20°) from which it was recrystallized.

Anal. Calcd. for $C_{16}H_{12}O_2N_2$: C, 72.71; H, 4.57; N, 10.60. Found: C, 72.85; H, 4.40; N, 10.78.

$C_2H_5OOCCH_2\overline{NCON(C_6H_5)COC}=CHC_6H_5$, **Ethyl N-3-phenyl-5-benzalhydantoin-N-1-acetate,** m. p. 88.5–89°, was obtained by treating a solution of N-3-phenyl-5-benzalhydantoin (30 g.) in 225 cc. of absolute alcohol containing 3.3 g. of sodium, with freshly distilled ethyl chloroacetate (19.5 g.) and refluxing for eighteen hours after which the precipitate (largely sodium chloride) was filtered and washed with boiling alcohol in which the ester is very soluble. Dry hydrogen chloride gas was then passed into the alkaline solution in order to precipitate phenylbenzalhydantoin (in all 6.5 g. was recovered) from any N-1 sodium salt that remained in solution. The hot filtrate from this second precipitate (volume 850 cc.) when concentrated deposited the product in theoretical amounts, calculated on the phenylbenzalhydantoin that had reacted. The ester crystallized from alcohol as white transparent plates.

Anal. Calcd. for $C_{20}H_{18}O_4N_2$: C, 68.56; H, 5.17; N, 8.00. Found: C, 68.69; H, 5.06; N, 8.22.

The product is readily soluble in alcohol (1 g. in 3 cc. boiling and in 100 cc. at 20°), cold acetone, ether and chloroform. All attempts to prepare a geometric isomer of this ester were fruitless although two modifications are theoretically possible and have been isolated in other cases.[26]

The transformation of this unsaturated ester into the corresponding saturated acid, which served to establish the configuration of the latter, was accomplished in the following way. The ester (20 g.), mixed with hydrogen iodide (54 cc., sp. g. 1.7) and red phosphorus (3.5 g.), was heated over a metal bath kept at a temperature of 140–145° until no further distillate was given off after which the excess hydrogen iodide was removed under reduced pressure. The residue was then extracted with boiling water and finally the product was extracted from the red phosphorus with boiling alcohol. The filtrate was concentrated to 100 cc. and treated with an equal volume of boiling water. On cooling it deposited 16.8 g. of the crystalline hydrate additional quantities of which were recovered from the filtrate, indicating a quantitative reaction. This acid was not only identical in all respects with that obtained from the interaction of phenylalanine-N-acetic acid and phenyl isocyanate, but it formed a methyl ester which was the same as that obtained from dimethyl phenylureidophenylalanine-N-acetate as a result of ring closure.

As stated in the introduction, two of the unsaturated hydantoins which were prepared during the course of the above investigation were made the subjects of special study. Of these the first, N-3-phenyl-2-thiobenzalhydantoin,[8] was transformed into three new mercapto derivatives and the second, ethyl N-3-phenyl-5-benzalhydantoin-N-1-acetate,[10] into two isomeric monobromo substitution products. A description of the experimental work follows.

N-3-Phenyl-2-thio-5-benzalhydantoin, prepared according to the method of Wheeler and Brautlecht,[8] was first transformed into the corresponding 2-ethylmercapto derivative[27] as a check on subsequent experiments. It was then treated with ethyl chloroacetate, ethyl phenylbromoacetate and ethyl α-bromopropionate, respectively, under exactly analogous conditions, *i. e.*, 10 g. of the hydantoin, dissolved in 75 cc. of absolute alcohol containing 1.1 equivalents of sodium, reacting with a slight excess of the reagent. In each case the transformation was either instantaneous or complete after the mixture had been heated for thirty minutes, and on cooling the product separated in almost pure condition in the form of pale yellow needles or plates. Yields varied from 86 to 96% of the theoretical value depending somewhat upon the solubility of the compound, which was recrystallized from alcohol. The melting points, solubilities in alcohol and analyses of the individual products are listed below.

(23) Prepared according to the method developed by Paal, *Ber.*, **27**, 975 (1894), and Mouneyrat, *ibid.*, **33**, 2393 (1900).

(24) Wheeler and Hoffman, *Am. Chem. J.*, **45**, 368 (1911). This reaction was mentioned as practical by Johnson and Brautlecht (ref. 9) but never described in detail.

(25) This compound, when prepared from N-3-phenyl-2-thio-5-benzalhydantoin, was reported by Wheeler and Brautlecht (ref. 8, p. 451) to melt between 242° and 243°. This melting point can be raised ten degrees by repeated recrystallizations.

Anal. Calcd. for $C_{20}H_{18}O_3N_2S$: C, 66.55; H, 4.95; N, 7.65; S, 8.75. Found: C, 66.51; H, 5.31; N, 7.72; S, 8.68.

$\overset{\frown}{N{=}CS[CH(C_6H_5)COOC_2H_5]N(C_6H_5)COC}{=}CHC_6H_5$, **Ethyl N-3-phenyl-5-benzalhydantoin-2-mercaptophenylacetate,** m. p. 156–156.5°; 1 g. in 40 cc. boiling and in 400 cc. at 20°.

Anal. Calcd. for $C_{26}H_{22}O_3N_2S$: C, 70.57; H, 5.01; N, 6.33; S, 7.25. Found: C, 70.14; H, 5.06; N, 6.55; S, 7.24.

$\overset{\frown}{N{=}CS[CH(CH_3)COOC_2H_5]N(C_6H_5)COC}{=}CHC_6H_5$, **Ethyl N-3-phenyl-5-benzalhydantoin-2-mercaptopropionate,** m. p. 111–112°; 1 g. in 7 cc. of boiling and in 150 cc. at 20°.

Anal. Calcd. for $C_{21}H_{20}O_3N_2S$: C, 66.30; H, 5.30; N, 7.36; S, 8.43. Found: C, 65.76; H, 5.07; N, 7.41; S, 8.08.

All three compounds when dissolved in alcohol and boiled for fifteen minutes with concentrated hydrochloric acid passed quantitatively into N-3-phenyl-5-benzalhydantoin,[9] their behavior being analogous to that of 2-ethylmercapto-N-3-phenyl-5-benzalhydantoin.

$C_2H_5OOCCH_2\overset{\frown}{N}CON(C_6H_5)COC{=}CBrC_6H_5$, **Ethyl N-3-phenyl-5-α-bromobenzalhydantoin-N-1-acetate,** exists in two isomeric modifications: *a*, m. p. 124–125°, and *b*, m. p. 98–100°, which were formed simultaneously when ethyl N-3-phenyl-5-benzalhydantoin-N-1-acetate,[10] dissolved in glacial acetic acid, was treated with a molecular equivalent of bromine.[28] During the process of eliminating hydrogen bromide from the reaction mixture the acetic acid was gradually displaced by carbon tetrachloride. On evaporation of the solvent, the product separated as a heavy oil which was partially resolved into its components by fractional crystallization from 60% alcohol, the ester *a* being relatively less soluble than *b*. Purification was complicated by the fact that both compounds are extremely soluble in all solvents and tend to form oily mixtures. Moreover, the substance[10] from which they were obtained is almost equally soluble.

Anal. Calcd. for $C_{20}H_{17}N_2O_4Br$: C, 55.44; H, 3.99; N, 6.53; Br, 18.61. Found: *a*, m. p. 124–125°, C, 56.30; H, 3.60; N, 6.84; Br, 18.42. Found: *b*, m. p. 98–100°, C, 55.98; H, 3.92; N, 6.98; Br, 18.89.

As stated in the introduction, dimethyl phenylalanine-N-acetate was treated successively with a number of different acyl chlorides. The procedure, which was the same in all cases, consisted in treating a solution of 2 g. of the free ester in 200 cc. of ether with one-half of a molecular equivalent of the acid chloride. In cases where a reaction took place, separation of the hydrochloride of the ester began immediately and was complete at the end of two hours; in cases where no precipitate had formed at the end of five hours, the original ester was recovered in quantitative amounts in the form of its hydrochloride by passing dry hydrogen chloride into the solution.

(28) *Cf.* McLean and Seeger, ref. 14, p. 1418.

$(NO_2)_2C_6H_3CON(CH_2COOCH_3)CH(CH_2C_6H_5)COOCH_3$, **Dimethyl 3,5-dinitrobenzoylphenylalanine-N-acetate,** m. p. 102–103°, formed in quantitative yield and crystallized from absolute alcohol in fine white needles growing in clusters.

Anal. Calcd. for $C_{20}H_{19}O_9N_3$: C, 53.91; H, 4.30; N, 9.43. Found: C, 53.57; H, 4.21; N, 9.71.

Attempts to transform this product into either the corresponding acid or salt were unsuccessful.

Dimethyl benzoylphenylalanine-N-acetate, $C_6H_5CON(CH_2COOCH_3)CH(CH_2C_6H_5)COOCH_3$, was obtained in the form of a heavy oil which refused to crystallize. That the product consisted exclusively of an ester of the benzoyl derivative was shown by the fact that an ether solution of the oil gave no precipitate when treated with dry hydrogen chloride. Moreover, when warmed with two equivalents of sodium hydroxide dissolved in aqueous alcohol, the ester passed quantitatively into the corresponding disodium salt. The latter, recrystallized from aqueous alcohol, melted at 288–289° (dec.) and was identified by means of the following synthesis.

Disodium benzoylphenylalanine-N-acetate, $C_6H_5CON(CH_2COONa)CH(CH_2C_6H_5)COONa\cdot 2H_2O$, m. p. 288–289° (dec.), was prepared by treating a solution of 5 g. of phenylalanine-N-acetic acid and two equivalents (3.8 g.) of sodium bicarbonate in 45 cc. of water with three equivalents of benzoyl chloride and six equivalents of sodium bicarbonate, the reagents being added alternately over a period of twelve hours. Concentrated hydrochloric acid was then added in excess, the precipitated gum taken up in ether and the solution extracted with the same solvent. In this way the benzoic acid and the benzoyl derivative of phenylalanine-N-acetic acid were separated from any imino dibasic acid which had failed to react (1.06 g.),[29] the latter remaining in solution as the hydrochloride. The combined ether extractions were then extracted with 10% sodium hydroxide, and the salt solution was concentrated to 10 cc. and treated with an equal volume of boiling absolute alcohol. Upon standing overnight 2.19 g. of thin, white, glistening plates separated and when absolute alcohol was added to successively concentrated filtrates, additional quantities (3.5 g.) of the same substance were obtained.[30] The salt was purified by treating its cold aqueous solution (1 g. in 2 cc.) with an equal volume of absolute alcohol.

Anal. Calcd. for $C_{18}H_{15}O_5NNa_2\cdot 2H_2O$: C, 53.09; H, 4.70; N, 3.44; Na, 11.29. Found: C, 53.01; H, 4.45; N, 3.64; Na, 11.06.

During the process of recrystallization an isomeric salt *b*, which melted sharply at 272–273° (dec.), was isolated. The latter, which appeared to be much more soluble in 50% alcohol than the compound, m. p. 288–289°, also separated as white, glistening plates. The configuration of these salts is uncertain. It may be noted also that neither on heating at 110° loses its water of crystallization, although the presence of two molecules is indicated from the results of analysis.

(29) This was identified following the hydrolysis of the hydrochloride; *cf.* Hahn and Endicott, ref. 2, p. 1041, footnote 4.

(30) In all, the yield corresponded to 86% of the theoretical as calculated upon the number of grams of imino acid which had reacted.

Anal. *b*. Calcd. for $C_{18}H_{15}O_5NNa_2 \cdot 2H_2O$: C, 53.09; H, 4.70; Na, 11.29. Found: C, 53.09; H, 4.41; Na, 11.26.

***m*-Nitrobenzoylphenylalanine-N-acetic acid,** $NO_2C_6H_4CON(CH_2COOH)CH(CH_2C_6H_5)COOH \cdot 2H_2O$, was obtained in two different crystalline modifications, one of which (*a*) melts at 90–92° and decomposes with the evolution of a gas at 105°, while the other (*b*) remains unchanged until 105° when it decrepitates with the evolution of a gas, melting at 130–131° (dec.). Both substances were formed under the conditions described above except that potassium hydroxide was used in place of the sodium bicarbonate and it was found expedient to spread the addition of the *m*-nitrobenzoyl chloride and alkali over a period of thirty-six hours. Moreover, following the addition of hydrochloric acid, a gum was precipitated which crystallized on treatment with ether, yielding 3.81 g. of the product *a* in the form of thin creamy-white, glistening plates. Additional quantities obtained from the filtrate brought the percentage yield to approximately 65% of the theoretical value. The product was recrystallized from water (1 g. soluble in 50 cc. boiling and in 100 cc. at 20°).

The product *b*, isolated in small quantities during the process of recrystallizing *a*, has the same crystalline form but is more soluble in water.

Anal. Calcd. for $C_{18}H_{16}O_7N_2 \cdot 2H_2O$: C, 52.91; H, 4.94; N, 6.88. Found: *a*, C, 52.71; H, 4.79; N, 7.19. Found: *b*, C, 52.20; H, 5.02; N, 7.25.

Summary

Both dimethyl phenylureidophenylalanine-N-acetate and the corresponding acyclic dibasic acid undergo condensation, with the elimination of one molecule of methyl alcohol and one molecule of water, respectively, to form in each case only one of the two isomeric cyclic compounds which might be expected on the basis of purely theoretical considerations. These results agree with previous observations in showing that a marked difference exists between the reactivities of the two acid complexes present in certain unsymmetrical iminodibasic acids. Moreover, the configuration of the product, which has been definitely established in each case, indicates that in all instances so far reported ring closure always takes place in the same general sense.

New derivatives of N-3-phenyl-2-thiobenzalhydantoin and of ethyl N-3-phenylbenzalhydantoin-N-1-acetate are described, together with others obtained by the action of certain acyl chlorides upon phenylalanine-N-acetic acid and its dimethyl ester.

Local Anesthetics. I. β-Monoalkylaminoethyl Esters of Alkoxybenzoic Acids[1]

BY J. STANTON PIERCE, J. M. SALSBURY AND J. M. FREDERICKSEN

The majority of the synthetic local anesthetics are alkamine esters of the type $XC_6H_4COO(CH_2)_yNR_2$ in which X usually is the primary amino group, *y* is 2 or 3, and R is an alkyl group. Goldberg and Whitmore[2] have demonstrated that the tertiary amino group, above, can be replaced advantageously by a secondary amino group. Other investigators[3] have shown that in the above type formula, X can be an alkoxy group. This investigation takes up the preparation of alkamine esters of the type $ROC_6H_4COOCH_2CH_2NHR'$.

Most of the alkoxybenzoic acids reported in this work have been made by previous investigators.[4] For this investigation the alkoxybenzoic acids not obtainable from Eastman Kodak Co. were made from the methyl or ethyl ester of the phenolic acid, according to the method of Cohen and Dudley,[4a] by the alkylation of the ester with alkyl bromide and hydrolysis of the ester.

The alkoxybenzoyl chlorides were prepared from the alkoxybenzoic acids and phosphorus pentachloride in all but one case, that of *p*-allyloxybenzoic acid, when phosphorus trichloride was used.

Most of the β-monoalkylaminoethanols were prepared by the reaction of an alkyl halide with a large excess of ethanolamine, without a solvent. Goldberg[5] recommends the use of approximately equimolar quantities of alkyl bromide and ethanolamine, in alcohol solution. This procedure was not found to be satisfactory for the formation of β-mono-*n*-butylaminoethanol, β-mono-*n*-propylaminoethanol, β-monoallylaminoethanol, and β-

mono-isopropylaminoethanol. β-Mono-isopropylaminoethanol and β-mono-*n*-dodecylaminoethanol were produced in poor yields when no solvent was used, but with dioxane as solvent (and with *n*-dodecyl iodide instead of bromide[6]), fair results were obtained. Allyl bromide reacted so vigorously with ethanolamine that it formed mainly diallylaminoethanol. Ethyl bromide gave a poor yield of β-monoethylaminoethanol when it reacted with ethanolamine. Therefore, β-monoallylaminoethanol and β-monoethylaminoethanol were prepared by the reaction of β-chloroethyl chlorocarbonate with the appropriate amine, followed by hydrolysis of the carbamate with alcoholic potash.[7]

The alkoxybenzoyl chlorides were condensed with hydrochlorides of β-monoalkylaminoethanols to form hydrochlorides of β-monoalkylaminoethyl alkoxybenzoates.

Pharmacological tests on these compounds are being made by Dr. H. B. Haag and Mr. I. L. Silverstein of the Medical College of Virginia. The results will be reported elsewhere.

Experimental

Alkoxybenzoic Acids.—In a typical experiment, 11.5 g. of sodium was dissolved in 175 ml. of absolute ethyl alcohol. To this alcoholate was added 0.5 mole of methyl- or ethyl-hydroxybenzoate and then 0.5 mole of alkyl bromide. The mixture was refluxed eight to twelve hours, cooled, and filtered from inorganic salts. About half of the alcohol was vacuum evaporated and the precipitated inorganic salt was filtered off. A solution of 1 g. of sodium hydroxide in 10 ml. of alcohol was added and the mixture was treated with 150 ml. of ether and 50 ml. of water. The ether layer and a second ether extract were combined. The ether was distilled off and the residue was vacuum distilled. The ether ester thus obtained was saponified by refluxing from 1.5 to 8 hours with aqueous sodium hydroxide or alcoholic potash. The alkaline solution was poured into from two to four volumes of water and the unchanged ester was extracted with ether. The *o*-alkoxybenzoic acids and the *m*-*n*-butoxybenzoic acid were isolated by acidification of the aqueous layer, ether extraction, and vacuum distillation. *m*-Ethoxybenzoic acid, *m*-*n*-amyloxybenzoic acid, and the *p*-alkoxybenzoic acids were isolated by acidification of the aqueous layer and filtration. The solid alkoxybenzoic acids were purified by recrystallization from ethyl alcohol and water.

Alkoxybenzoyl Chlorides.—In most cases, the alkoxybenzoyl chlorides were made by treating the corresponding alkoxybenzoic acid with 1.05 equivalents of phosphorus pentachloride and heating for one hour on a boiling water-bath. The phosphorus oxychloride formed was distilled off and the alkoxybenzoyl chloride was vacuum distilled. The alkoxybenzoyl chlorides which were decomposed by the above method were obtained in satisfactory yields by the following modification. A vacuum was applied as soon as the phosphorus pentachloride was added. When the initial vigorous reaction subsided, the phosphorus oxychloride was vacuum distilled from the reaction mixture and the alkoxybenzoyl chloride was vacuum distilled.

Phosphorus pentachloride decomposed *p*-allyloxybenzoic acid, so this compound was treated with 0.67 mole of phosphorus trichloride and was heated for two hours on a water-bath. The reaction mixture was extracted with anhydrous ether and the ether layer was filtered. The ether was removed by distillation and the *p*-allyloxybenzoyl chloride was vacuum distilled.

β-Monoalkylaminoethanols.—A typical experiment is given to illustrate the method used to form the β-monoalkylaminoethanols.

β-Mono-*n*-butylaminoethanol[8] was prepared by adding slowly 1 mole (137 g. of 93%) butyl bromide, over a period of about four hours, to 160 g. (2.54 moles) of vigorously stirred ethanolamine, in a water-bath at 50–60°. A solution of 112 g. (2 moles) of potassium hydroxide in 100 ml. of water was added and the mixture was stirred with a mechanical stirrer from five to fifteen minutes. The precipitated inorganic salt was filtered off with suction. If the filtrate did not separate into two layers, a hot concentrated solution of potassium carbonate was added until two layers were formed. The upper layer was treated in a continuous extractor with petroleum ether (preferably 65–110°) for from eight to sixteen hours. The petroleum ether was distilled off and the residue fractionated.

β-Mono-*n*-propylaminoethanol and β-mono-isobutylaminoethanol were prepared similarly. In the case of β-mono-*n*-heptylaminoethanol, it was found necessary to use several moles of ethanolamine to avoid dialkylation. β-Mono-*n*-dodecylaminoethanol was formed by heating *n*-dodecyl iodide with an excess of ethanolamine in dioxane solution for sixty hours at 102° or for sixteen hours at 140° in a sealed tube. Also, dioxane was used as solvent for the reaction of isopropyl bromide and ethanolamine. β-Mono-*n*-amylaminoethanol and the higher homologs were separated readily from excess aminoethanol by ether extraction.

The β-monoalkylaminoethanols were analyzed by titration with standard hydrochloric acid with methyl red as indicator.

Hydrochlorides of β-Monoalkylaminoethyl Alkoxybenzoates.—For the preparation of β-monoalkylaminoethyl alkoxybenzoates, an excess of hydrochloric acid was added to the amino alcohol and the solution was evaporated to dryness in a vacuum. An equimolar quantity of the alkoxybenzoyl chloride was added and the mixture was heated on a water-bath for about one hour under reduced pressure. The hydrochloride of the β-monoalkylaminoethyl alkoxybenzoate was taken up in water and this solu-

(6) Acknowledgment is made to Dr. Alfred Burger, of the Department of Chemistry of the University of Virginia, for suggesting the above change.

(7) J. S. Pierce, THIS JOURNAL, **50**, 241 (1928). Some β-monoallylaminoethanol prepared by the senior author fifteen years ago, as a possible intermediate for synthetic medicinals, had decomposed somewhat but, on vacuum distillation, yielded 85% of pure product.

(8) After most of this work was completed, β-monoethylaminoethanol and β-mono-*n*-butylaminoethanol appeared on the market.

tion was extracted with isopropyl ether or was filtered to remove acid insoluble material. The aqueous solution was made basic and was extracted with isopropyl ether. Hydrogen chloride was passed into this extract to precipitate the hydrochloride of the amino ester. Most of these compounds were purified by recrystallization. Table III lists these hydrochlorides.

Some of the β-monoalkylaminoethyl alkoxybenzoate hydrochlorides, on attempted recrystallization, came out of solution as gels. Others did not form crystalline products. Therefore, some of these products were not obtained in a pure condition. These hydrochlorides are listed below. They have the formula $ROC_6H_4COOCH_2CH_2NHR'\cdot HCl$, where R and R′ are, respectively, *p*-ethyl

[a] Yields are based on one recrystallization. [b] Recrystallized from anhydrous acetone. [c] Recrystallized from anhydrous acetone–petroleum ether (b. p. 65–110°). [d] Recrystallized from anhydrous acetone–absolute ethanol. [e] Recrystallized from anhydrous acetone–anhydrous ether.

and *n*-heptyl, *p*-*n*-butyl and *n*-dodecyl, *p*-allyl and *n*-butyl, *p*-2-octyl and *n*-butyl, *o*-ethyl and *n*-butyl,[9] *o*-*n*-butyl and ethyl, *o*-*n*-butyl and *n*-propyl, *o*-*n*-butyl and *n*-dodecyl, *o*-isopropyl and *n*-butyl, *o*-isoamyl and *n*-butyl, *m*-ethyl and *n*-butyl, *m*-*n*-butyl and *n*-propyl, *m*-*n*-butyl and isobutyl, and *m*-*n*-amyl and *n*-butyl.

Since some of the monoalkylamino esters of alkoxybenzoates have been found to have high local anesthetic action, the work is being continued in this Laboratory with alkoxycinnamates and alkoxynaphthoates to see the effect of the variation of the aromatic nucleus on the anesthetic action.

Since Donleavy and English[10] found dialkylaminoethyl alkylthiobenzoates to have anesthetic action and to have low irritation, two β-monoalkylaminoethyl alkylthiobenzoates were prepared and tested for corneal anesthesia on a rabbit's eye. *o*-*n*-Butylthiobenzoyl chloride was prepared[11] as described by Donleavy and English.[10] This acid chloride was condensed with the hydrochlorides of β-mono-*n*-butylaminoethanol and β-mono-isobutylaminoethanol, as were the alkoxybenzoyl chlorides described in this paper. The butylaminoethyl *o*-*n*-butylthiobenzoates were isolated by the usual procedure and were recrystallized from anhydrous acetone.

β-Mono-*n*-butylaminoethyl *o*-butylthiobenzoate hydrochloride, m. p. 123.5–126°, was obtained in a 50% yield. Calcd. for $C_{17}H_{28}O_2NClS$: Cl, 10.27. Found: Cl, 9.97.

β-Mono-isobutylaminoethyl *o*-butylthiobenzoate hydrochloride, m. p. 83–84°, was obtained in an 82% yield. Calcd. for $C_{17}H_{28}O_2NClS$: Cl, 10.27. Found: Cl, 10.20.

Both of these products, in 1% aqueous solution, had a slight anesthetic action on a rabbit's cornea but were irritating.

Summary

The hydrochlorides of a series of β-monoalkylaminoethyl alkoxybenzoates have been prepared and described.

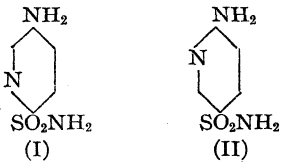
Substituted 2-Sulfonamido-5-aminopyridines

BY WILLIAM T. CALDWELL AND EDMUND C. KORNFELD[1a,1b]

Sulfanilamide and its numerous derivatives are all obtained from N-acetylsulfanilyl chloride or *p*-nitrobenzenesulfonyl chloride. In the hope of securing a group of compounds suited to comparative pharmacological studies and, of course, of obtaining products with superior therapeutic action, it seemed to us desirable to seek a new aromatic and isosteric sulfonyl chloride, *i. e.*, one which would serve as an intermediate for the preparation of a series of bactericides analogous to the many sulfanilamide derivatives already prepared.

The possible preparation of a *p*-aminopyridinesulfonamide, I or II, and its derivatives appeared



intriguing in view of the presence of the pyridine nucleus in such physiologically active substances as nicotinamide, vitamin B_6, and sulfapyridine, and also because of the solubility in water of pyridine itself. 2-Amino-5-sulfonamidopyridine II and several derivatives have been prepared and studied by investigators abroad.[2,3,4] Our work therefore centered about the isomer I, which now has been synthesized in this Laboratory. Six derivatives of this product also have been prepared according to the scheme shown in Fig. 1.

In this connection, it may be noted that 3-aminopyridine resembles aniline more closely than does either 2- or 4-aminopyridine; indeed, compounds with substituents in position 3 of the pyridine nucleus usually differ considerably in chemical behavior from isomers with these substituents in position 2 or 4. It should, therefore, be a matter of interest to compare, both chemically and pharmacologically, 2-sulfonamido-5-aminopyridine I, in which the sulfonamido group occupies the position of somewhat anomalous reactivity and the amino group is in the position characterized by closer adherence to type, with 5-sulfonamido-2-aminopyridine II where the substituent groups are interchanged. Anticipation of certain differences and even difficulties of a chemical nature has already proved to be not without foundation, as will appear from what follows.

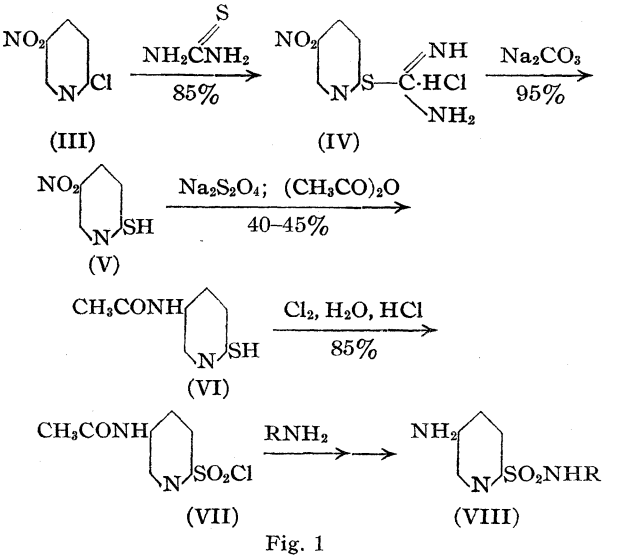


Fig. 1

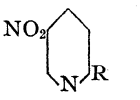
The requisite intermediate for the preparation of the substituted sulfonamides VIII could be either 5-acetaminopyridine-2-sulfonyl chloride VII or a compound containing a nitro group in the 5 position. The latter possibility was abandoned when 2-thiol-5-nitropyridine V or 5,5′-dinitro-2,2′-dipyridyl disulfide could not be oxidized to the corresponding sulfonic acid in promising yield. Confirming and extending the work of Plazek,[5] we have found that oxidation of V with nitric acid, chromic acid, or potassium permanganate in acetone leads to the formation of 5-nitro-2-pyridone IX.



IX, R = OH
X, R = NH_2
XI, R = SO_3K
XII, R = OCH_3

Treatment of (V) with ammoniacal potassium permanganate yields 2-amino-5-nitropyridine X

together with a little potassium-5-nitropyridine-2-sulfonate XI, while oxidation with chlorine results in 2-chloro-5-nitropyridine III. Oxidation of 5-nitro-2-pyridylpseudothiourea hydrochloride IV with chlorine also failed to produce the desired result. Obviously the 5-nitro group activates the 2-position to a remarkable extent. Most interesting of all, perhaps, is the fact that on treating 2-chloro-5-nitropyridine with sodium sulfite[6] in dilute methanol, 2-methoxy-5-nitropyridine XII is formed and not the desired sulfonic acid.

Therefore, to obviate the labilizing influence of the nitro group, 2-thiol-5-nitropyridine V was reductively acetylated in order to obtain 2-thiol-5-acetaminopyridine VI. This step was effected without difficulty by use of sodium hydrosulfite and acetic anhydride, and it was of particular moment to us to discover that this compound could be oxidized in excellent yield to the desired 5-acetamino-2-pyridinesulfonic acid with hydrogen peroxide (30%) in acetic acid. Nevertheless, all attempts to convert this acid to the sulfonyl chloride VII have been unsuccessful. In this connection, it is perhaps of interest to point out that King and Ware[7] were unable to obtain 4-pyridinesulfonyl chloride from 4-pyridinesulfonic acid.

Fortunately, however, 2-thiol-5-acetaminopyridine VI was found to be easily and directly convertible by the action of chlorine into the requisite intermediate, 5-acetamino-2-pyridinesulfonyl chloride VII, by the excellent method of Johnson, Sprague and Douglass.[8]

Condensations of this sulfonyl chloride with various amines have been found to be entirely analogous to those using N-acetylsulfanilyl chloride. We are reporting at this time the preparation of seven analogs of sulfanilamide and its derivatives, and the work will be continued if these show promise as therapeutic agents.

Pharmacological tests on these compounds are being made by Dr. A. E. Livingston and Dr. E. J. Fellows of the Department of Pharmacology, Temple University Medical School; the results will be published in detail elsewhere.

We wish to thank Mr. Furness Thompson of Smith, Kline and French, Inc., and Dr. James M. Sprague of Sharp and Dohme, Inc., for generous samples of some of the heterocyclic amines used in this work, and also to express our gratitude to the Temple University Committee on Research and Publication for a grant-in-aid.

Experimental[9]

2-Chloro-5-nitropyridine, III.—This compound was prepared by a method similar to that of Phillips,[10] but the synthesis had been worked out independently in this Laboratory. It is based on the original work of Tchitchibabine.[11] 2-Aminopyridine (200 g., 2.13 moles) was added with efficient mechanical agitation to 800 ml. of concd. sulfuric acid while keeping the temperature below 50° by cooling in ice. Then 120 ml. (2.53 moles) of fuming nitric acid (d. 1.49) was run in below 40°. The solution was kept at 45° with occasional cooling in ice until the temperature no longer rose spontaneously above 45°, thus indicating that the rearrangement of 2-nitraminopyridine to 2-amino-3 or 5-nitropyridine was complete (three-quarters of an hour). The reaction mixture was kept at 45° for about one hour, allowed to stand at room temperature for several hours and was then neutralized by pouring cautiously into a mixture of concd. ammonia and ice. If it is desired to isolate 2-amino-3-nitropyridine, the mixture is steam distilled until about 18 liters are collected. This distillate on cooling deposits about 20–21 g. of 2-amino-3-nitropyridine; yield, 7%. The neutralized mixture, with or without steam distillation, was cooled, filtered, and the product washed with ice water. The crude 2-amino-5-nitropyridine was then dissolved in 1500 ml. of water containing 200 ml. of concd. sulfuric acid, decolorizing carbon was added, and the mixture filtered. A concentrated solution of 140 g. of sodium nitrite was then run in drop by drop at 10–15°. Very efficient mechanical stirring was essential. The thick mixture was then heated to boiling, cooled to 0°, and the product, 5-nitro-2-pyridone, filtered, washed with water, and dried; yield, 59% based on 2-aminopyridine. This may be used without further purification to prepare 2-chloro-5-nitropyridine using phosphorus pentachloride and phosphorus oxychloride[10]; yield, 90–95%. Recrystallization from methanol, using carbon, gave a product melting at 107–108°.

2-Methoxy-5-nitropyridine, XII.—To a solution of 7.9 g. (0.05 mole) of 2-chloro-5-nitropyridine in 200 ml. of hot methanol was added a solution of 10 g. (0.079 mole) of anhydrous sodium sulfite in 150 ml. of hot water.[6] The mixture was then refluxed for three hours, filtered hot, and the filtrate cooled. White needles separated which were recrystallized from dilute methanol, m. p. 108–108.5°. A mixed melting point with a sample of 2-methoxy-5-nitropyridine prepared from the silver salt of 5-nitro-2-pyridone and methyl iodide[12] was also 108–108.5°.

5-Nitro-2-pyridylpseudothiourea Hydrochloride, IV.—This was prepared by the method of Lindwall and Surrey[13]; yield, 85%.

2-Thiol-5-nitropyridine,[13] V.—The crude 5-nitro-2-pyridylpseudothiourea hydrochloride IV from 188 g. of 2-

[a] Melts with decomposition. [b] Analyses by Carl Tiedcke. [c] Best purified by evaporating a solution of the compound in dilute ammonia. [d] Best purified by precipitation from alkaline solution by acid. [e] Dried at 150°.

chloro-5-nitropyridine III was suspended in 2 liters of water and 68 g. of sodium carbonate added with stirring. Agitation was continued for fifteen minutes, and then a solution containing 102 g. of sodium hydroxide was added to dissolve the product. The red-orange solution was then filtered to remove a small amount of 5,5′-dinitro-2,2′-dipyridyl sulfide and the filtrate acidified with concd. hydrochloric acid. The product was cooled, filtered, washed with water, and dried. The yield, based on 2-chloro-5-nitropyridine III, was 80–83%; m. p. 188–191° (d.).

2-Thiol-5-acetaminopyridine, VI.—2-Thiol-5-nitropyridine V (31.2 g., 0.2 mole) was suspended in 300 ml. of water, and 120 g. (0.69 mole) of sodium hydrosulfite was added with stirring, keeping the temperature below 50°. The mixture turned from orange to yellow, and all solids went into solution. Acetic anhydride (26 ml., 0.275 mole) was then added below 50°. The product, 2-thiol-5-acetaminopyridine, gradually separated from the warm solution. The mixture was stirred for one hour, cooled in ice, and the product filtered, washed with water, and dried; yield, 40–45% based on 2-thiol-5-nitropyridine. On recrystallization from water the bright yellow compound melted at 244–246°.

Anal. Calcd. for $C_7H_8N_2OS$: N, 16.66. Found: N, 16.78.

5,5′-Diacetamino-2,2′-dipyridyldisulfide.—2-Thiol-5-acetaminopyridine VI (0.84 g.) was dissolved in 20 ml. of warm water and a few drops of 30% hydrogen peroxide added. The white solid which separated immediately from the warm solution was cooled, filtered, washed with water, and dried; yield, 90%. Repeated crystallization from dilute ethanol gave a product melting at 240–241°.

Anal. Calcd. for $C_{14}H_{14}N_4O_2S_2$: N, 16.76. Found: N, 16.70.

5-Acetaminopyridine-2-sulfonic Acid.—To 37.5 g. (0.22 mole) of 2-thiol-5-acetaminopyridine VI suspended in 250 ml. of glacial acetic acid was added 78 ml. (0.76 mole) of 30% hydrogen peroxide keeping the temperature below 70° by cooling in ice. The solids dissolved, and the mixture became brown. When the temperature no longer rose spontaneously (one hour), the reaction mixture was allowed to stand overnight. Crystals of the sulfonic acid had deposited in 24 hours or less. These were cooled well in ice, filtered, washed with ethanol, and dried; yield, 82%. On recrystallization from water the acid melted at 302–303° (d.).

Anal. Calcd. for $C_7H_8N_2O_4S$: N, 12.96; S, 14.83; neut. equiv., 216.2. Found: N, 13.22; S, 14.75; neut. equiv., 215.3.

S-Benzylthiuronium Salt of 5-Acetaminopyridine-2-sulfonic Acid.—This compound was prepared by the method of Chambers and Watt[14]; m. p. after recrystallization from water, 93–95°.

Anal. Calcd. for $C_{15}H_{18}N_4O_4S_2 \cdot 2H_2O$: N, 14.35. Found: N, 14.37.

5-Acetamino-2-pyridone.—This was prepared to compare with 5-acetaminopyridine-2-sulfonic acid. To 1.4 g. of 5-nitro-2-pyridone in 20 ml. of water was added 6 g. of sodium hydrosulfite and then 1.3 ml. of acetic anhydride. Needles deposited on standing overnight; m. p. 232–233° after recrystallization from water.

Anal. Calcd. for $C_7H_8N_2O_2$: N, 18.41. Found: N, 18.14.

5-Acetamino-2-pyridinesulfonyl Chloride VII.—Attempts to prepare this compound from the corresponding sulfonic acid using chlorosulfonic acid, phosphorus pentachloride, thionyl chloride, sulfuryl chloride, sulfur chloride, or benzotrichloride[15] resulted only in unchanged sulfonic acid or dark, non-crystalline masses, which showed no properties of a sulfonyl chloride. The following procedure, however, gave the acid chloride in 85% yield. 2-Thiol-5-acetaminopyridine VI (60 g.) was dissolved in 450 ml. of

(13a) System based on that of Northey, *Chem. Rev.*, **27**, 85 (1940).

(14) Chambers and Watt, *J. Org. Chem.*, **6**, 376 (1941).

(15) Kranzlein and Hopff, German Patent 574,836.

cold, concd. hydrochloric acid, and then 100 ml. of ice water was added. Chlorine was bubbled into the solution, keeping the temperature below 10° throughout by external cooling. The solution became dark brown at first, and the chlorination was complete when the temperature no longer rose and when the color of the solution lightened (two and one-half hours). The solution was then diluted with 1200 g. of ice and water, keeping the temperature still below 10°. The product which separated was filtered, washed with ice water, dried *in vacuo* over phosphorus pentoxide, and recrystallized the same day from ethylene dichloride. The sulfonyl chloride should be dried and recrystallized rapidly to prevent decomposition to the sulfonic acid. An analytical sample melted at 165–166° (d.).

Anal. Calcd. for $C_7H_7ClN_2O_3S$: N, 11.94; Cl, 15.11. Found: N, 11.75; Cl, 14.97.

Substituted Acetaminopyridinesulfonamides.—2-Sulfonamido-5-acetaminopyridine was prepared by adding one part of the sulfonyl chloride to four parts of concd. ammonia (25%), and evaporating the excess ammonia on the steam-bath. The produet crystallized out on cooling; yield, 86%. The guanidine derivative was made by the method of Marshall, Bratton, White and Litchfield[16]; yield, 51%. The derivatives of the cyclic amines were prepared in 62–98% yields by adding an equivalent of 5-acetaminopyridine-2-sulfonyl chloride to the cyclic amine dissolved in dry pyridine, the weight of the latter being equal to that of the total solids. Solution took place with evolution of heat and the reactions were completed by warming at 60° for one-half to one hour. The crude derivatives obtained by pouring the dark solutions into ice water were dissolved in one equivalent of aqueous sodium hydroxide, decolorized, and reprecipitated by addition of hydrochloric acid.

Hydrolysis of the N^4-Acetyl Group.—Six of the acetyl compounds were hydrolyzed by refluxing 0.5 to 1.0 molar solutions containing 2.5 equivalents of sodium hydroxide for two and one-half to three hours. The acetyl derivative of the guanidine condensation product was hydrolyzed with 6-molar hydrochloric acid by the method of Marshall, *et al.*[16]

Summary

1. 5-Acetaminopyridine-2-sulfonyl chloride has been prepared and is available as an intermediate for the preparation of a new series of chemotherapeutic agents.

2. The preparation of seven new substituted 5-aminopyridine-2-sulfonamides and their acetyl derivatives is reported.

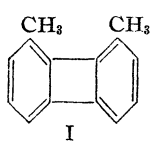
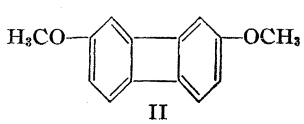
1,8-Dimethyl and 2,7-Dimethoxybiphenylene

BY WARREN C. LOTHROP

Continuing a line of investigation recently reported,[1] the present paper describes the preparation of two substituted biphenylenes. These new substances were obtained by following the procedure previously worked out for the parent substance, biphenylene, and have been assigned the structures



I



II

1,8-dimethylbiphenylene (I) and 2,7-dimethoxybiphenylene (II).

The hydrocarbon (I) was prepared with considerable difficulty and in very poor yield by the pyrolysis of 4,5-dimethylbiphenylene iodonium iodide with cuprous oxide. The over-all yield for the whole series of reactions starting with 100 g. of 2-amino-3-nitrotoluene was only 100 mg. of a pale yellow hydrocarbon crystallizing in plates from methanol. It melted at 79–80° and formed a picrate crystallizing in long crimson needles from ethanol and melting at 126°. It was lower melting and less highly colored than its isomer, 2,7-dimethylbiphenylene,[2] but otherwise similar.

For the preparation of II, a series of reactions previously reported[3] was followed but with variations in procedure materially improving the yields of all steps. Acetylation of *p*-anisidine (97%) followed by nitration with dilute nitric acid at room temperature (78%), and hydrolysis with alcoholic hydrochloric acid (95%) gave 3-nitro-*p*-anisidine[4] III. This when coupled by the procedure of Atkinson, *et al.*,[5] gave 2,2′-dinitro-*p*,*p*′-bianisole IV contaminated by a con-

(1) Lothrop, THIS JOURNAL, **63**, 1187 (1941).

(2) Recrystallization and careful drying of the picrate of this compound gave needles (m. p. 110–111°) which were evidently free of the alcohol of crystallization previously reported.[1] *Anal.* Calcd. for $C_{14}H_{12}\cdot C_6H_3O_7N_3$: N, 10.27. Found: N, 9.90, 10.43.

siderable amount of orange material which was evidently 4,4′-azobis-3-nitroanisole V,[6] since on reduction and benzoylation it gave only 3,4-dibenzamidoanisole.

It is interesting to note that Atkinson's coupling procedure applied to 2-amino-3-nitrotoluene yields only 24% of 6,6′-dinitro-*o,o′*-bitolyl and 16% of 2,2′-azobis-3-nitrotoluene, possibly due to steric hindrance; the identity of the latter was proved by its conversion to 2,3-dibenzamidotoluene and comparison with an authentic sample.

Conversion of IV to the diamine and then to the iodonium iodide, followed by the usual pyrolysis, gave dimethoxybiphenylene in 2% yield, as glistening lemon yellow plates melting at 108° and forming a picrate crystallizing from alcohol in black needles melting at 125°. All attempts to convert II into dihydroxybiphenylene failed, since it was inert to alkaline reagents, as expected, and was rapidly cleaved by acids to give solutions of a deep purple color resembling permanganate, and from which only tar could be obtained. Experiments conducted in an atmosphere of nitrogen were identical with those performed in air.

This result may not be entirely unexpected since 2,7-dihydroxybiphenylene is seen to be an isomer of 4,4′-biphenylquinone which was found by Willstätter and Kolb[7] to be an unstable substance reacting even with warm water to give decomposition products.

Experimental Part

6,6′-Dinitro-*o,o′*-bitolyl was prepared in the manner of Wittig and Stichnoth[8] by the reaction of 2-iodo-3-nitrotoluene with copper. An attempt to obtain it directly from 2-amino-3-nitrotoluene (11 g.) by following exactly the procedure of Atkinson, *et al.*,[5] (called by them Method 2) gave a mixed product which was separated by extraction with 40 cc. of boiling alcohol. The alcoholic solution gave 2.4 g. of pale buff needles which after recrystallization melted at 107–108° and represented a 24% yield of dinitrobitolyl.

The alcohol-insoluble material was recrystallized from glacial acetic acid in bright orange needles weighing 1.8 g.; 16% yield; m. p. 199°. Reduction of this **2,2′-azobis-3-nitrotoluene** with zinc dust and boiling acetic acid and benzoylation of the water-soluble diamine by the Schotten–Baumann procedure gave **2,3-dibenzamidotoluene**, m. p. 228–229°, which crystallized from acetic acid in white needles. It was identical with the product obtained by reduction and benzoylation of 2-amino-3-nitrotoluene.

Anal. Calcd. for $C_{21}H_{18}O_2N_2$: C, 76.34; H, 5.49; N, 8.48. Found: C, 76.22; H, 5.58; N, 8.22.

6,6′-Diamino-*o,o′*-bitolyl was prepared as previously described[9] by reduction of the dinitro compound with stannous chloride and hydrochloric acid in acetic acid solution. The best yield obtainable was 55% of white plates, m. p. 132° after two crystallizations from alcohol.

When the above diamine was diazotized and treated with potassium iodide by the same procedure used for biphenylene iodonium iodide, a yield of 67% of crude **6,6′-diiodo-*o,o′*-bitolyl**[10] resulted. Since the product was completely soluble in dilute alcohol, it was apparent that no iodonium iodide had been formed in this case, doubtless due to the steric effects of the adjacent methyl groups.

1,8-Dimethylbiphenylene (I) resulted in very poor yield by pyrolysis of the above crude diiodide with cuprous oxide. It was isolated through its **picrate** which separated from alcohol in long, crimson needles; m. p. 126°.

Anal. Calcd. for $C_{14}H_{12}\cdot C_6H_3O_7N_3$: N, 10.27. Found: N, 10.27.

No trace of 4,5-dimethylphenazone could be found. This is in contrast to all other reaction series where the corresponding phenazone is present as an impurity.

Decomposition of the picrate with ether and ammonia gave a pale yellow hydrocarbon which crystallized from methanol in large, pearly plates, m. p. 79–80°, and had a slight odor reminiscent of biphenylene.

Anal. Calcd. for $C_{14}H_{12}$: C, 93.28; H, 6.72; mol. wt., 180. Found: C, 93.30; H, 7.04; mol. wt. (Rast micro), 182.

***p*-Acetamidoanisole** resulted in 97% yield by treatment of a solution of *p*-anisidine hydrochloride with sodium acetate in the presence of acetic anhydride.[11]

3-Nitro-*p*-acetamidoanisole[4] was prepared as follows: a sludge of 184 g. of acetaniside in 340 cc. of glacial acetic acid was mixed with a solution of 112 cc. of concentrated nitric acid in 615 cc. of water and allowed to stand at room temperature for one day. During this time the reaction warmed up to 60° spontaneously and all material went into solution while the product crystallized out on cooling in

bright yellow needles; m. p. 115° (literature m. p. 117°); yield 183 g. or 78%.

3-Nitro-*p*-anisidine (III) was obtained when 243.5 g. of the acetyl derivative, after refluxing for six hours with 500 cc. of alcohol and 245 cc. of concentrated hydrochloric acid, was neutralized with 300 cc. of concentrated ammonia and cooled. The product separated in deep orange-red needles, m. p. 122° (literature 122°), weighing 183 g. (94%).

2,2′-Dinitro-*p,p′*-bianisole (IV) was prepared from the diazonium solution of the above nitroanisidine by the action of a solution of cuprous hydroxide. When 340 g. of the amine was treated by the procedure described under Method 2[5] a crude product not entirely soluble in acetic acid resulted. The soluble material crystallized from the solution and weighed 141.5 g. (64%), m. p. 131° and was identical with material prepared by heating 4-iodo-3-nitroanisole with copper powder.[3]

The insoluble material was crystallized from nitrobenzene in bright orange prisms, m. p. 259°, and was evidently **4,4′-azobis-3-nitroanisole (V)** since on reduction with zinc dust and boiling acetic acid followed by benzoylation of the water soluble diamine it gave 3,4-dibenzamidoanisole.[12]

This crystallized from acetic acid in white needles and gave no depression of the m. p. (250°) of an authentic sample.

Anal. Calcd. for $C_{14}H_{12}O_6N_4$ (V): N, 16.86. Found: N, 17.05.

2,2′-Diamino-*p,p′*-bianisole.[3]—When 89 g. of dinitrobianisole was reduced by the action of 297 g. of tin, 960 cc. of concentrated hydrochloric acid and 165 cc. of acetic acid, the diamine (m. p. 110°) crystallized from alcohol in pearly plates weighing 53 g. (74% yield).

2,7-Dimethoxybiphenylene iodonium iodide was obtained in a crude condition in 77% yield by treatment of the above diamine in the usual manner,[1] so that from 62.5 g. of the diamine, 92 g. of light brown powder resulted. This was not purified further but was subjected to pyrolysis with cuprous oxide.

2,7-Dimethoxybiphenylene (II).—When the crude product of the above pyrolysis was subjected to prolonged steam distillation, 6 g. of yellow crystals was isolated from the distillate (20 liters) by ether extraction. This was fractionally crystallized from alcohol yielding first of all 1.12 g. of pure white plates, m. p. 174°, which were identified as *p,p′*-bianisyl[13] by comparison with an authentic sample. From the mother liquor the desired product crystallized in lemon yellow plates. These were purified by conversion to the **picrate** which separated from its deep red alcoholic solution in thick needles of a red color so deep as to be almost black; m. p. 125°.

(12) Meldola and Eyre, *J. Chem. Soc.*, **81**, 991 (1902).

(13) Gillmeister, *Ber.*, **30**, 2849 (1897).

Anal. Calcd. for $C_{14}H_{12}O_2 \cdot C_6H_3O_7N_3$: N, 9.52. Found: N, 9.78.

Decomposition of the pure picrate with ammonia and ether gave 1 g. of pure dimethoxybiphenylene crystallizing in large, bright yellow, striated plates from ethanol; m. p. 107–108°.

Anal. Calcd. for $C_{14}H_{12}O_2$: C, 79.24; H, 5.70; mol. wt., 212. Found: C, 79.07, 79.51; H, 5.80, 5.95; mol. wt., 214 (Rast micro).

2,2′-Diiodo-*p,p′*-bianisyl.—The residue left from the above steam distillation was dissolved in hot glacial acetic acid, treated with norite and after filtration and cooling gave a deposit of pale buff prisms of unreacted diiodide (0.15 g.). Repeated crystallization failed to remove all color but the melting point stayed constant at 131°.

Anal. Calcd. for $C_{14}H_{12}O_2I_2$: I, 54.45. Found: I, 54.95.

2,7-Dimethoxyphenazone was recovered from the mother liquors as a gummy yellow precipitate which in acetone solution gave an orange **picrate**; m. p. 231–233°.

Anal. Calcd. for $C_{14}H_{12}O_2N_2 \cdot C_6H_3O_7N_3$: N, 14.92. Found: N, 15.14.

From this the pure dimethoxyphenazone was obtained in fine yellow needles from dilute acetic acid; m. p. 202–203° (literature 197°).[3]

2,7-Dihydroxybiphenylene.—Attempts to cleave dimethoxybiphenylene were uniformly unsuccessful, alcoholic alkali being without effect, while various acid reagents failed to give workable products. When the diether was treated in acetic acid solution with 48% hydrobromic acid or with concentrated hydrochloric acid, in air or under an atmosphere of nitrogen, a pink color appeared even at room temperature and rapidly turned to a deep purple, requiring about one minute on the steam-bath. From this solution a deep indigoid precipitate was obtained (m. p. above 360°) which was insoluble in alkali and all ordinary solvents and resisted attempts at acetylation. Parallel experiments with biphenylene showed that these effects were due to the methoxyl groups, since the hydrocarbon was untouched by such treatment.

An attempted cleavage in acetic anhydride solution gave a deep green solution and a gummy green precipitate which could not be crystallized.

Summary

Using methods previously employed for the preparation of biphenylene, 1,8-dimethylbiphenylene and 2,7-dimethoxybiphenylene have been prepared. Attempts to cleave the latter to form 2,7-dihydroxybiphenylene were unsuccessful.

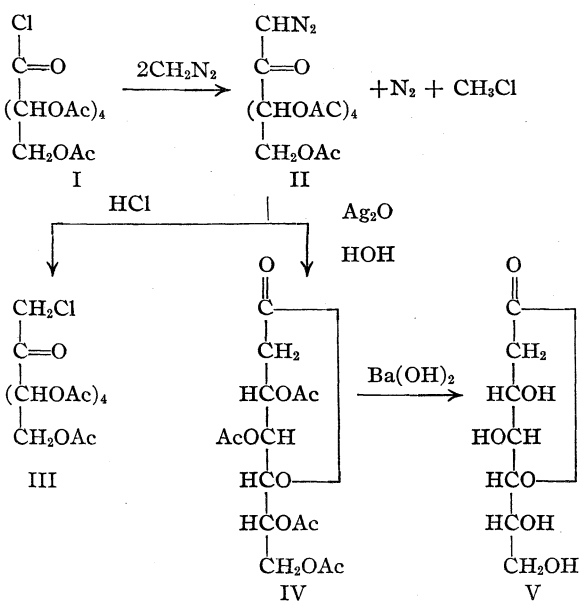
The Action of Diazomethane upon Acyclic Sugar Derivatives.[1] II[2]

BY M. L. WOLFROM, S. W. WAISBROT AND ROBERT L. BROWN

In continuation of our work on the products obtained by the action of diazomethane upon the acid chlorides of fully acetylated sugar acids, we record the synthesis of 1-diazo-1-desoxy-*keto*-*d*-fructose tetraacetate from *d*-arabonyl chloride tetraacetate and diazomethane.

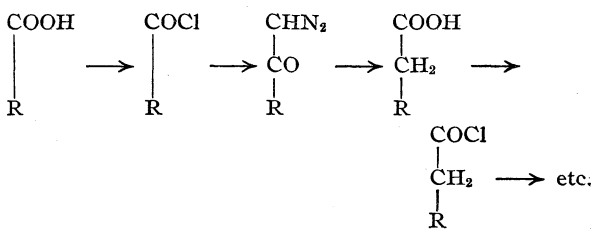


Treatment of the previously reported[2] 1-diazo-1-desoxy-*keto*-*d*-glucoheptulose pentaacetate (II) with ethereal solutions of dry hydrogen chloride and dry hydrogen bromide produced 1-chloro (III) and 1-bromo-*keto*-*d*-glucoheptulose pentaacetate, respectively. Similar treatment of 1-diazo-1-desoxy-*keto*-*d*-fructose tetraacetate produced 1-chloro and 1-bromo-*keto*-*d*-fructose tetraacetate. The chloro derivative III was the uncharacterized compound isolated in crude form from the mother liquors of our original preparations[2] of the diazomethyl ketone II. When the reaction was carried out under nearly anhydrous conditions, only traces of the chloro derivative were obtained. The 1-chloro-*keto*-*d*-fructose tetraacetate (m. p. 78°, spec. rot. +68°, $CHCl_3$) is isomeric with the chloro-*d*-fructose tetraacetate of Brauns[3] (m. p. 108°, spec. rot. +45°, $CHCl_3$,) to which the structural assignment of 6-chloro-*keto*-*d*-fructose has been made.[4]

In 1912 Wolff[5] described a characteristic rearrangement of diazoketones in their reaction with water or alcoholic ammonia in the presence of catalytic amounts of silver oxide.

$$R{-}CO{-}CHN_2 \xrightarrow{Ag_2O} N_2 + [R{-}CO{-}CH] \longrightarrow [R{-}CH{=}C{=}O] \xrightarrow{HOH} R{-}CH_2{-}CO_2H$$

It has not been until relatively recent years that the Wolff rearrangement has received any degree of attention. Arndt and co-workers[6] have developed the reaction as a general synthetic method for lengthening the carbon chain.



We have applied the Wolff rearrangement to the acetylated aldonic acids. Treatment of a suspension of II in hot water with catalytic amounts of silver oxide, followed by silver ion removal with hydrogen sulfide and concentration, yielded 2-desoxy-*d*-glucoheptono-δ-lactone tetraacetate (IV) of specific rotation +39.5° ($CHCl_3$). According to Lane and Wallis,[7] this rearrangement may take place with racemization provided that the terminal carbon of the migrating group R contains a hydrogen atom. This structural prerequisite is present in our compound and accordingly a mixture (not necessarily equimolecular) of 2-desoxy-*d*-glucoheptonic acid (or lactone) and 2-desoxy-*d*-mannoheptonic acid (or lactone) would be predictable. Only one product was isolated (*ca.* 70% yield). In the absence of any evidence for a second product, the 2-desoxy-*d*-glucoheptonolactone structure will be assigned provisionally to the substance isolated.

(1) An incomplete preliminary report of this work was published in THIS JOURNAL, **63**, 632 (1941). The work herein recorded was presented before the Division of Sugar Chemistry and Technology at the 101st Meeting of the American Chemical Society, St. Louis, Missouri, April 10, 1941.

Saponification of IV with barium hydrate, followed by removal of barium ion with sulfuric acid and concentration, yielded crystalline 2-desoxy-*d*-glucoheptonolactone (V) of specific rotation +20° (H_2O). The analytical data definitely indicate a lactone structure for IV and V. If, in accordance with the principles of Hudson's lactone rule, the rotations of these compounds are due almost in their entirety to the position of the lactone ring, then ring closure in IV and V must be on the right (as represented in the Fischer projection formula). The acceptance of such an hypothesis favors assignment to IV and V of a *delta* lactone structure, since carbon four in these structures is on the left. The *delta* lactones of the normal sugar acids are relatively unstable and exhibit moderately rapid hydrolysis. Further evidence for the 1,5 ring in IV, then, lies in the fact that it was found to be rapidly titratable to a stable end-point within a period of one and one-half minutes from the time of solution in acetone-water. It was found that V was too slowly soluble to allow rapid titration but was titratable to a stable end-point within four and one-half to five minutes. Contrary to expectation, IV exhibited no mutarotation in either methanol or aqueous acetone. V was too slowly soluble in water for early polarimetric readings in that medium; however, no mutarotation was observed after an initial rotation of +20° at twenty minutes. Attempts were made to follow lactonization of the free acid by the general method of Levene and Simms.[8] An initial reading at three minutes gave a specific rotation of +20°. Thereafter there was no observable mutarotation over a period of eighty hours.

Explanation of the apparently anomalous optical behavior of IV and V may lie in an effective increase in the rate of hydrolysis due to the influence of the 2-desoxy carbon. Again, the explanation may lie in an extraordinary similarity in rotation between the lactone and its acid, in the event of which Hudson's lactone rule would not be applicable. The expectation would be that in V *gamma* lactone formation would be sufficiently slow to be readily observable and an appreciable quantity of the *gamma* lactone in the equilibrium mixture should yield a more negative value. As more information is obtained concerning the little known group of 2-desoxy sugar acids, it may well be that their behavior will be found to differ markedly from that of the normal sugar acids. Thus, an abnormally high rate of hydrolysis has been found[9] for the glycopyranosides of the 2-desoxy sugars in comparison with the rate exhibited by the normal sugar pyranosides.

Further extension of these reactions is in progress in this Laboratory.

Experimental

1-Diazo-1-desoxy-*keto*-*d*-fructose Tetraacetate.—*d*-Arabonic acid tetraacetate[10] (7.1 g.), prepared according to the excellent method of Robbins and Upson,[11] was dissolved in 20 cc. of benzene and 3 cc. (2 moles) of thionyl chloride added. The solution was warmed until the evolution of hydrogen chloride ceased, as shown by ammonia test. The excess thionyl chloride was removed by solvent concentration under reduced pressure followed by repeated additions of benzene and subsequent removal in the same manner. The sirupy residue was dissolved in 50 cc. of anhydrous ether and the solution cooled to 0°. Two moles of diazomethane gas was then added and the solution allowed to stand overnight. At the end of this period, some separated polymethylenes were removed by filtration and the filtrate was concentrated with a stream of dry air until crystallization occurred. The cream-colored crystals were removed by filtration and washed with cold ether; yield 5.7 g.; m. p. 88.5–89°. Pure material was obtained on recrystallization from methanol–ether; yield 5 g.; m. p. 93–94°; spec. rot. −11° (23°, *c* 4, abs. $CHCl_3$).[12]

The purified substance possessed a slight cream color. It was soluble in alcohol, acetone and warm ether but was insoluble in petroleum ether and water. It reduced boiling Fehling solution.

Anal. Calcd. for $C_{14}H_{19}O_9N_2$: C, 46.93; H, 5.06; N, 7.82. Found: C, 46.93; H, 5.21; N, 7.67.

1-Chloro-*keto*-*d*-fructose Tetraacetate.—Two grams of 1-diazo-1-desoxy-*keto*-*d*-fructose tetraacetate was suspended in anhydrous ether and dry hydrogen chloride passed into the solution until the evolution of nitrogen ceased. The solution was cooled and an equal amount of petroleum ether was then added. The crystals which formed were removed by filtration and washed with ether–petroleum ether; yield 1.5 g.; m. p. 75–77°. Pure material was obtained on two further crystallizations from ether–petroleum ether; yield 1 g.; m. p. 77.5–78°; spec. rot. +68° (22°, *c* 4, abs. $CHCl_3$).

The substance reduced boiling Fehling solution but no precipitate formed on boiling with alcoholic silver nitrate.

Anal. Calcd. for $C_{14}H_{19}O_9Cl$: C, 45.85; H, 5.22; Cl, 9.66. Found: C, 45.81; H, 5.40; Cl, 9.50.

1-Bromo-*keto*-*d*-fructose Tetraacetate.—1-Diazo-1-desoxy-*keto*-*d*-fructose tetraacetate (3.5 g.) was treated in the same manner as in the above-described synthesis of the corresponding 1-chloro derivative, using hydrogen bro-

mide instead of hydrogen chloride. The product which crystallized was removed by filtration and washed with ether–petroleum ether; yield 3.4 g.; m. p. 67.5–68°. Pure material was obtained on crystallization from ether; yield 3 g.; m. p. 68°; spec. rot. +62.5° (26°, *c* 4, abs. $CHCl_3$).

The substance reduced boiling Fehling solution but no precipitate formed on boiling with alcoholic silver nitrate.

Anal. Calcd. for $C_{14}H_{19}O_9Br$: Br, 19.43. Found: Br, 19.12.

1-Chloro-*keto*-*d*-glucoheptulose Pentaacetate (III).—1-Diazo-1-desoxy-*d*-glucoheptulose pentaacetate[2] (1.0 g.) was suspended in anhydrous ether (15 cc.) and dry hydrogen chloride gas was passed into the solution until the compound was dissolved. The solution was then allowed to stand for two hours, after which the excess hydrogen chloride was removed by washing with aqueous sodium bicarbonate solution. An equal volume of petroleum ether was added to the dried (sodium sulfate) ethereal solution and the crystalline product which formed was removed by filtration and washed with petroleum ether; yield 0.6 g.; m. p. 100–101°; spec. rot. −5.5° (22°, *c* 5, abs. $CHCl_3$). These constants were unchanged on two further crystallizations from ether–petroleum ether.

The substance was soluble in the common solvents except petroleum ether and water. It reduced boiling Fehling solution. No precipitate was formed on boiling with alcoholic silver nitrate.

Anal. Calcd. for $C_{17}H_{23}O_{11}Cl$: C, 46.52; H, 5.28; Cl, 8.08. Found: C, 46.52; H, 5.28; Cl, 8.05.

This substance was the uncharacterized compound isolated in crude form from the mother liquors of our original preparations[2] of 1-diazo-1-desoxy-*d*-glucoheptulose pentaacetate (II). When the preparation of II was carried out under nearly anhydrous conditions only traces of the chloro compound were obtained.

1-Bromo-*keto*-*d*-glucoheptulose Pentaacetate.—1-Diazo-1-desoxy-*d*-glucoheptulose pentaacetate (3.5 g.) was treated in the same manner as in the synthesis of the corresponding 1-chloro derivative, using hydrogen bromide in place of hydrogen chloride. The product which crystallized was removed by filtration and washed with ether–petroleum ether; yield 3.3 g.; m. p. 80–82°. Pure material was obtained on three recrystallizations from ether–petroleum ether; m. p. 86–87°; spec. rot. −4° (24°, *c* 5, abs. $CHCl_3$).

This compound was slightly less soluble than the corresponding chloro derivative. It reduced boiling Fehling solution and yielded no precipitate on boiling with alcoholic silver nitrate.

Anal. Calcd. for $C_{17}H_{23}O_{11}Br$: Br, 16.54. Found: Br, 16.72.

2-Desoxy-*d*-glucoheptonolactone Tetraacetate (IV).—1-Diazo-1-desoxy-*d*-glucoheptulose pentaacetate (1 g.) was suspended in 40 cc. of water with 0.2 g. of silver oxide. The mixture was warmed to about 70° and 0.2 g. of silver oxide was added portionwise over a period of fifteen minutes. The mixture was then refluxed for fifteen minutes, after which the silver oxide was removed by filtration. The silver ion was removed with hydrogen sulfide, followed by filtration. The clear filtrate was then concentrated to about 15 cc. The fibrous crystals that formed were removed by filtration and washed with water; yield 0.5 g.; m. p. 129–130°, unchanged on further recrystallization from hot water; spec. rot. +40° (20°, *c* 4, abs. chloroform, no detectable mutarotation). The mother liquors on further concentration yielded 0.1 g. of additional material.

The substance did not reduce boiling Fehling solution.

Anal. Calcd. for $C_7H_8O_6(CH_3CO)_4$ (lactone tetraacetate): C, 50.00; H, 5.60; saponification value (five equivalents), 13.88 cc. 0.1 *N* sodium hydroxide per 100 mg. Calcd. for $C_7H_9O_7(CH_3CO)_5$ (acid pentaacetate): C, 48.57; H, 5.75; saponification value (six equivalents), 14.27 cc. Found: C, 49.76; H, 5.58; saponification value, 13.8 cc.

The analytical data indicate that in the course of the rearrangement one mole of acetic acid was lost, presumably by lactonization. In a study of the position of ring closure the following experiments were performed.

(*a*) 2-Desoxy-*d*-glucoheptonolactone tetraacetate (0.2766 g.) was dissolved in acetone (50 cc.). Boiled distilled water (100 cc.) was quickly added and the solution immediately titrated to a phenolphthalein end-point. Time elapsed from introduction of the acetone to complete neutralization was one minute and thirty seconds. A volume of 7.75 cc. of 0.1005 *N* sodium hydroxide which, less a blank of 0.15 cc., gives a volume of 7.60 cc. required for neutralization. The neutralization equivalent calculated therefrom is 362.1; theory for the lactone tetraacetate, 360.3. That the compound was instantaneously titratable is evidence in support of a *delta*-lactone structure.

(*b*) In absolute methanol solution there was no observable mutarotation (initial reading, four minutes) over a period of forty-five hours; spec. rot. +34° (22°, *c* 2.5).

(*c*) A sample of the lactone was dissolved in dry acetone (8 cc.) and made up to 15.00 cc. with water. There was no observable mutarotation (initial reading, six minutes) over a period of twenty hours; spec. rot. +35° (23°, *c* 4).

2-Desoxy-*d*-glucoheptonolactone (V).—2-Desoxy-*d*-glucoheptonolactone tetraacetate (5 g.) was treated with an equivalent amount of a saturated barium hydrate solution (10.95 g. of barium hydrate octahydrate) and allowed to stand at room temperature overnight. The barium ion was then removed with an equivalent amount of sulfuric acid (69.4 cc. *N*) and the barium sulfate removed by filtration. The clear filtrate was concentrated to about 10 cc. and on cooling crystallization ensued; yield 1 g.; m. p. 170°, unchanged on further recrystallizations effected by solution in water and subsequent concentration; spec. rot. +20° (26°, *c* 5, H_2O, no mutarotation).

The compound was soluble in warm water and insoluble in the common organic solvents except glacial acetic acid.

Anal. Calcd. for $C_7H_{12}O_6$ (lactone): C, 43.75; H, 6.29; sapon. equiv., 192. Calcd. for $C_7H_{14}O_7$ (acid): C, 40.00; H, 6.71; sapon. equiv., 210. Found: C, 43.44; H, 6.27; sapon. equiv., 196.

The lactone was too slowly soluble in water to allow early initial polarimetric readings in that medium. No mutarotation was observed after a reading of +20° at twenty minutes. Attempts were made to follow lactonization of the free acid, according to the general procedure of Levene and Simms.[8] The lactone (0.4717 g.) was suspended in water and 4.70 cc. of 0.5008 *N* sodium hydroxide was added. The compound went into solution slowly and

after about four minutes the alkaline color of phenolphthalein faded. Two additional drops (0.1 cc.) of base were required for complete neutralization (total 4.8 cc.). A further 0.2 cc. of alkali was added followed by the addition of an equivalent volume (5.00 cc.) of 0.5007 *N* hydrochloric acid. The solution was quickly made up to 15.00 cc. and the polarimetric reading taken (initial reading, three minutes); spec. rot. +20.1° (23°, *c* 3.1). Thereafter there was no observable mutarotation over a period of eighty hours.

We acknowledge the general assistance of Messrs. Percy McWain (N.Y.A. Project O.S.U. 170) and Clarence M. Clevenger.

Summary

1. 1-Diazo-1-desoxy-*keto*-*d*-fructose tetraacetate has been synthesized by the action of diazomethane upon *d*-arabonyl chloride tetraacetate.

2. The 1-chloro and the 1-bromo derivatives of the *keto*-forms of *d*-fructose and of *d*-glucoheptulose acetates have been synthesized by the action of the hydrogen halides upon the corresponding diazomethyl ketone acetates (II).

3. 1-Diazo-1-desoxy-*keto*-*d*-glucoheptulose pentaacetate (II) underwent the Wolff rearrangement to produce a lactone form of 2-desoxyglucoheptonic acid tetraacetate, from which 2-desoxyglucoheptonolactone was obtained by saponification.

4. The above 2-desoxyaldonolactone and its acetate exhibited anomalous properties.

5. The above reactions represent transformations from the aldose series to (*a*) the ketose series and to (*b*) the 2-desoxyaldonic acid series.

Anthochlor Pigments. III. The Pigments of *Cosmos Sulphureus*

BY T. A. GEISSMAN

Previous studies on the sap-soluble flower pigments of certain species of *Compositae* have shown that the petals of these species contain substances which form intensely red salts with alkalies. For convenience these pigments have been described by the term "anthochlor." The tetrahydroxychalcone butein (I) has been identified as one member of this class of pigments and has been isolated from *Dahlia variabilis*[1] and from two species of *Coreopsis*.[2]

It was noted in the paper describing the studies on *Coreopsis gigantea*[2b] that in this flower a second substance accompanies butein, and it was suggested on the basis of the analytical figures for its crystalline acetate that this substance was a pentahydroxychalcone hexoside. This compound has now been isolated from the ray florets of *Cosmos sulphureus* ("Orange Flare"). *C. sulphureus* is a garden annual whose bright orange rays and yellow disk florets give the anthochlor reaction with alkali. Ether extraction of the dried, powdered rays yielded the glycoside as a yellow amorphous powder which separated from the ether during the extraction. Further treatment of the ether-extracted rays by a somewhat more lengthy procedure yielded an additional amount of the pigment. It formed a white crystalline acetate identical with that of the pigment previously isolated from *Coreopsis gigantea*. It is proposed to call this pigment "coreopsin."

The previously reported analytical figures on the basis of which coreopsin was assumed to be a pentahydroxychalcone hexoside were somewhat in error since it has been found that the aglycone of the pigment is butein. Hydrolysis of coreopsin acetate (the acetate was chosen since it is readily crystallized while the pigment itself has been obtained only in an amorphous, although apparently homogeneous, condition), followed by acetylation of the ether-extractable products, yielded the triacetate of butin (II), the flavanone isomeric with butein. The formation of butin in the hydrolysis is undoubtedly due to the isomerization of the butein first produced from the glycoside. The isomerization of *o*-hydroxychalcones to the corresponding flavanones under these conditions is a well-known reaction[3] and the sample of butin triacetate used for purposes of comparison was synthesized by treating a sample of synthetic butein under conditions identical with those used for the hydrolysis of the glycoside. That coreopsin is a glycoside of butein and not of butin

(3) (a) Perkin and Hummel, *J. Chem. Soc.*, **85**, 1462 (1904); (b) Göschke and Tambor, *Ber.*, **45**, 186 (1912). These describe the preparation of butin.

is indicated by a number of considerations. The pigment is a bright yellow in color, while the corresponding flavanone and glycosides of similar flavanones are colorless substances; it dissolves instantly in cold, dilute aqueous alkali with the formation of a red color; it gives no color when reduced with magnesium and hydrochloric acid.

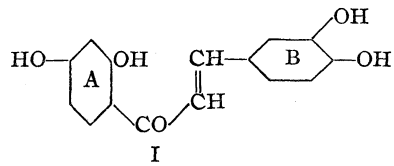
The aqueous solution from the hydrolysis of coreopsin acetate, after removal of the coloring matter, was found to reduce Fehling solution, but positive identification of the sugar has not yet been accomplished. On the basis of the analytical figures for coreopsin acetate it is probably a hexose. The position of attachment of the sugar has not yet been established, but it is very probable that it is attached to either the 2′ or 4′ position. The red color of alkaline solutions of coreopsin is similar to that shown by other chalcones hydroxylated in the 3,4-positions and is deeper than the colors of alkaline solutions of 4-hydroxy- or 4-hydroxy-3-methoxychalcones. Further, no naturally-occurring member of the large class of substances having the C_6–C_3–C_6 structure found in butein carries a sugar residue in the phenyl ring corresponding to the catechol nucleus of butein.

The study of the flowers of *Cosmos sulphureus* has been extended to include the remainder of the flower-head, consisting of the yellow disk-florets and the scarious involucral bracts. From this material there have been isolated a glycoside of quercetin, probably isoquercitrin, and (as the acetate)[4] luteolin (IV). Quercetin (III) was obtained in calculated amount from the hydrolysis of a weighed amount of the glycoside and identified by conversion to its acetate and comparison of this with an authentic sample. Although the disk-florets as well as the rays show the anthochlor reaction when touched with alkali, no pigment of this class was isolated from them except as a probable component of a crystalline acetate mixture which developed an intensely red solution when hydrolyzed with alcoholic alkali but which melted over a broad range.

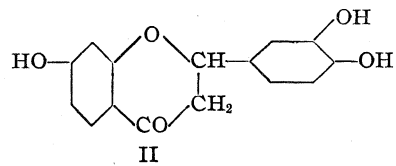
It appears likely that luteolin occurs as the free flavone since it was extracted from the flowers with ether and isolated without the use of any hydrolytic step.

(4) Since several thousand flower-heads yield an amount of dried material of the order of only a hundred grams, relatively small amounts of isolated substances have been available. For this reason it has proved convenient and often necessary to work up crude pigment fractions by acetylation, followed by purification of the readily crystallizable acetates. The pigments themselves are difficult to purify from the crude condition without considerable loss.

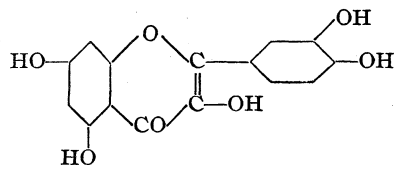
A comparison of the structures of the substances present in the flowers of *C. sulphureus* (I, III, and IV) adds an interesting example of a biogenetically and chemically related group of compounds to a number already recorded from studies on other plants.



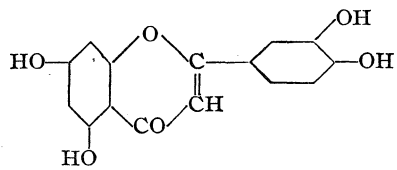
I



II



III



IV

All of these compounds have the $C_{6(A)}$–C_3–$C_{6(B)}$ carbon skeleton (*cf.* (I)) which is widespread in the plant kingdom and all of them contain the catechol nucleus as the $C_{6(B)}$ part of the molecule. They differ in the degree of oxidation in the $C_{6(A)}$–C_3 part of the molecule and in this respect bear to each other the same kind of relationship that exists between such related pairs of substances as pelargonidin and apigenin or pelargonidin and kampferol.

In view of the fact that all of the flowers so far known to belong to the anthochlor group, with the single recorded exception of the legume, *Butea frondosa*, are closely related taxonomically[5] a detailed study of their flower pigments should furnish a basis for evaluating in terms of the results obtained certain of the proposals that have been made concerning the biogenesis of plant materials, particularly those of the "flavone" (C_6–C_3–C_6) type.

(5) This close relationship is indicated by the fact that they have sometimes been classified as a sub-tribe *Coreopsidinae* of the tribe *Heliantheae*.

Experimental

All melting points are uncorrected.

Cosmos sulphureus was grown from commercially available seed. The flowers were collected at intervals, the rays separated immediately, and the rays and disk florets (with the involucral bracts) air-dried, ground to a powder and stored in stoppered containers.

Ray Flowers: Coreopsin.—Sixty grams of the dried, ground rays was extracted (Soxhlet) with petroleum ether (30–60°) until fresh portions of the solvent were no longer colored. The solution contained carotenoid pigments but no pigments of the anthochlor type. The powder was freed of petroleum ether and extracted with ether. The ether extract was greenish-yellow in color and contained a small amount of suspended solid. This was removed and dried. It weighed 0.130 g. It was a bright yellow substance, insoluble in ether, soluble in hot methanol, slightly soluble in hot water and gave an intense crimson solution in cold, dilute sodium hydroxide. Upon acidification of its alkaline solution, it separated as spherical globules of a glassy nature. The behavior of the crude material on melting indicated that it was not crystalline: it sintered at about 150° and decomposed at 190–195°.

Anal. Calcd. for $C_{21}H_{22}O_{10}\cdot 1.5H_2O$: C, 54.40; H, 5.39. Found: C, 54.50; H, 5.25.

From the ether solution was isolated by extraction with sodium carbonate solution, acidification and extraction with ether 40 mg. of a yellow-brown amorphous substance which could not be crystallized or converted into a crystalline acetate.

The ether-extracted petal-meal was dried and extracted with methanol. The filtered extract was evaporated, the sirupy residue dissolved in water and the solution washed with ether and clarified by filtration through Hyflo Supercel. To the deep red filtrate saturated lead acetate solution was added until no further precipitate was formed. The brick-red precipitate was removed and suspended in methanol and hydrogen sulfide passed into the suspension. The precipitated lead sulfide was removed and the deep orange-red solution evaporated under reduced pressure. The red-brown tar thus obtained was acetylated with acetic anhydride–sodium acetate and the tarry acetylation product separated into ether-soluble and ether-insoluble fractions by dissolving it in alcohol, adding ether and washing the resulting solution with water. The process was repeated with the tar which separated during the water washing. The nearly colorless ether solution finally resulting was evaporated and the gummy residue allowed to stand overnight with 20 ml. of 10% sodium hydroxide solution. The deep red alkaline solution resulting was decanted from some unchanged tarry material, washed with ether, acidified and the acidified solution saturated with ammonium sulfate. A yellow powdery solid separated on standing. It weighed 0.280 g. and was shown to be coreopsin by conversion into its crystalline acetate.

Coreopsin Acetate.—A portion of the pigment was acetylated with sodium acetate–acetic anhydride. The acetate formed soft, white needles; m. p. 171–172° after one recrystallization from alcohol. Mixed with a sample of the acetate, m. p. 171–2.5°, from *Coreopsis gigantea* no depression in melting point was observed. The two acetates gave identical colors when heated with alcoholic sodium hydroxide.

Anal. Calcd. for $C_{35}H_{36}O_{17}$: C, 57.67; H, 4.98. Found: C, 57.27, 57.22; H, 4.88, 4.79.

Hydrolysis of Coreopsin Acetate.—A suspension of 0.265 g. of coreopsin acetate (m. p. 171–172°) in a mixture of 50 ml. of 2% hydrochloric acid and 10 ml. of methanol was refluxed for four hours. The solid dissolved after about one hour and a pale yellow solution resulted. The solution was cooled and extracted with ether and the ether extract was dried and evaporated, leaving a red-yellow gum. This was acetylated by boiling it for about a minute with 2 ml. of acetic anhydride and 0.2 g. of sodium acetate. A nearly colorless solution resulted. After several hours ice and water and a few ml. of ether were added and upon standing colorless crystals (70 mg.) formed in the ether layer. After two recrystallizations from alcohol this material formed shining white leaflets, m. p. 120.5–121°. It was found to be butin triacetate by comparison with a sample prepared from synthetic butein by a procedure identical with that described above for the hydrolysis of coreopsin acetate. The melting points of both products and of a mixture of the two were identical, as were the colors produced by the magnesium and hydrochloric acid reduction test.

The behavior of butin triacetate when reduced with magnesium and hydrochloric acid in alcohol is noteworthy. The color produced is an intense red-violet to blue-violet (depending upon the concentration), and is markedly bluer than the colors shown by flavanones hydroxylated in the 5,7-positions, such as naringenin, eriodictyol and homoeriodictyol. This color test is the subject of another investigation now being carried on in this Laboratory. Butin triacetate has been previously reported to have a melting point of 123–125°[3a] and 123°.[3b] The sample from the hydrolysis of coreopsin acetate was analyzed.

Anal. Calcd. for $C_{21}H_{18}O_8$: C, 63.28; H, 4.57. Found: C, 63.01; H, 4.92.

The aqueous solution from which the butin had been removed was treated with lead carbonate and the lead removed with hydrogen sulfide. The solution reduced Fehling solution but no crystalline derivative of the sugar could be isolated in amount sufficient for identification.

Disk-florets and Involucral Bracts.—After a preliminary treatment with petroleum ether the powdered material was extracted with ether. The ether solution was washed with sodium carbonate solution and the deep red extract acidified and extracted with ether. The ether extract was dried and evaporated, leaving a brown, tarry residue which was induced to crystallize partially by adding small amounts of ether and allowing evaporation to proceed slowly between fresh additions. There was finally obtained 50 mg. of a yellow, powdery solid. An attempt to recrystallize this resulted in a product which did not melt below 250° but darkened from about 230°, and was obviously still impure. It was finally acetylated and yielded a white, crystalline acetate which after two recrystallizations from alcohol melted at 217–219°. It was similar in melting point and behavior to luteolin tetraacetate which has been reported by various investigators to melt at 213–

215°,[6] 223–226°,[7] 222–224°.[8] A sample of luteolin tetraacetate was synthesized according to the method of Kostanecki, Rozycki and Tambor,[8] starting with methyl veratrate and trimethoxyacetophenone. The synthetic material melted at 221–222° and a mixture of this and that from the natural source melted at 219–221°. In a repetition of the isolation from the florets and bracts there was obtained a product melting at 220–222°. The natural and synthetic samples gave identical red-orange colors when to their solutions in alcohol were added a fragment of magnesium and a drop of concentrated hydrochloric acid, and both samples dissolved in hot alcoholic sodium hydroxide to form yellow solutions. Unfortunately too little of the material from the natural source was obtained for satisfactory analytical figures. Each of the two samples described was analyzed.

Anal. Calcd. for $C_{23}H_{18}O_{10}$: C, 60.78; H, 4.00. Found: C, 61.74, 60.15, 60.29; H, 4.27, 4.04, 3.80.

It is felt, however, that the information from the melting point and color-test observations, coupled with the approximate agreement in the analyses is sufficient to establish the identity of the compound isolated.

From the oily mother liquor from which the crude luteolin separated was obtained a crystalline mixture of acetates; m. p. 130–190°. It formed a deep red solution in hot alcoholic alkali. Too little of it was obtained to permit of its separation into its components.

Isoquercitrin.—The alcohol extract of the ether-extracted meal (disk-florets and bracts) was diluted with water and concentrated to remove most of the alcohol. Saturated lead acetate was added in small portions and the brown precipitates which first appeared were discarded. The bright orange-yellow precipitate which then formed was removed, suspended in hot water and decomposed with hydrogen sulfide. The filtered solution was saturated with salt and extracted with ethyl acetate. Removal of the ethyl acetate left a yellow gum which on standing in alcohol–water solution deposited 60 mg. of a yellow powder. This crystallized from dilute alcohol as lemon-yellow needles; m. p. 217–219° after shrinking at about 115° (loss of water of hydration). It dissolved in alkali to a deep yellow solution, gave a deep olive-green color with aqueous-alcoholic ferric chloride and a rose-red solution when reduced in alcoholic solution with magnesium-hydrochloric acid. These observations are in agreement with those recorded for isoquercitrin (quercetin-3-glucoside); m. p. reported as 217–219°,[9] 218–220°,[10] 219°.[11]

Hydrolysis of 24.0 mg. of the glycoside with 6 ml. of 1 *N* sulfuric acid yielded 14.1 mg. of quercetin; calcd. for isoquercitrin, 14.4 mg. The product of the hydrolysis was converted into its acetate, m. p. 192–193°; no depression on mixing with an authentic sample, m. p. 193–194°, of quercetin pentaacetate.

Anal. Calcd. for quercetin pentaacetate, $C_{25}H_{20}O_{12}$: C, 58.58; H, 3.94. Found: C, 58.66; H, 3.99.

Summary

1. The flowers of *Cosmos sulphureus* ("Orange Flare") contain coreopsin (rays), luteolin and a quercetin glycoside which is probably isoquercitrin (disk-florets and involucral bracts).

2. Coreopsin has been found to be a butein glycoside. The nature and position of the sugar residue are as yet undetermined.

The Catalysis of the Thermal Decomposition of Acetaldehyde by Hydrogen Sulfide

BY WALTER L. ROTH AND G. K. ROLLEFSON

In some previous work it has been shown that the acceleration of the rate of the thermal decomposition of acetaldehyde when iodine is added is due to a series of reactions in which the iodine reacts with the aldehyde and then is regenerated by reactions between the products of the first reaction.[1] In this paper we are presenting the results of some investigations of the nature of the action of hydrogen sulfide which has also been reported to accelerate the decomposition of acetaldehyde.[2]

Fromherz reported that the rate of the decomposition in the presence of hydrogen sulfide is dependent only on the pressure of the catalyst. In accordance with this statement the rate was constant throughout a considerable portion of any given run and the ratio of the time required for three-fourths completion to that required for half completion was approximately 1.5 as it should be if the rate were independent of the aldehyde pressure. On the other hand, if we utilize this linear character of the pressure–time curves to calculate the initial rates, we find continuous variation of the rate constants calculated on the assumption of independence of the aldehyde according to the

law $-d(CH_3CHO)/dt = k'(H_2S)$. The results for a series of aldehyde pressures are shown in Table I along with the times given by Fromherz for a pressure change one-half and three-fourths of the final value.

TABLE I

Temperature 510°, H_2S 20 mm.

383	2.77	4.61	1.66	34.60

If the reaction were truly of the zero order with respect to the acetaldehyde the value in the fourth column should be 1.5 and the value in the fifth column should be constant. It is apparent that while the values of the ratios $t_{3/4}/t_{1/2}$ are approximately constant the value is too large and k' shows a marked trend with the initial pressure of the aldehyde. The experiments reported in this paper were designed to determine the true rate law for this reaction and to test several hypotheses concerning the mechanism of the catalysis.

Apparatus, Methods, and Materials.—The apparatus was of the type usually employed in the study of gaseous reactions in which the progress of the reaction can be followed by pressure measurements. The volume of the system was kept constant and the pressure measured by means of a click gage with the aid of a sulfuric acid manometer for the low pressures and a mercury manometer for the higher pressures. The reaction vessel was placed in a cylindrical electrical furnace, wired concentrically, and equipped with end heaters to eliminate temperature gradients. The furnace temperature was kept constant to 1° by manually controlled rheostats. Temperatures were measured with a chromel–alumel thermocouple which had been calibrated at the melting points of lead, tin and zinc. The thermocouple was placed in a well which extended to the center of the reaction vessel.

On account of the extreme sensitivity of the reaction to traces of air, all operations were carried out in a system which could be evacuated to a pressure of 10^{-6} mm. before starting an experiment. The sulfuric acid manometer was always separated from the reaction vessel by the click gage.

Experiments were performed with two Pyrex and one quartz reaction vessel. One of the Pyrex vessels was packed with glass tubing to increase the surface/volume ratio in some of the experiments. The surface/volume ratios were approximately unity in the unpacked vessels and 12 in the packed one. The volumes of the unpacked vessels ranged from 219 cc. to 379 cc. with a surface/volume ratio of *ca.* unity and the packed vessel had a free volume of 180 cc. with a surface/volume ratio of 12.

Acetaldehyde was purified by three different procedures. The only sample which was free from the effects which were found to be due to the presence of small amounts of air was one for which the entire preparation was carried out in a system which had been thoroughly evacuated. Merck paraldehyde which had been washed with sodium bicarbonate, dried over calcium chloride, and fractionated was depolymerized with a trace of concentrated sulfuric acid. The middle fraction was refluxed under vacuum, put in contact with recrystallized hydroquinone and calcium sulfate for twenty-four hours and fractionated, the middle fraction being saved for use. This sample was stored at 0° behind a mercury cutoff and small amounts distilled as needed into a second reservoir where it was given an additional degassing at −78° before using.

Some of the experiments were performed with hydrogen sulfide which had been obtained from the Ohio Chemical Company and had been degassed by repeated evacuations at −180°. The final results were obtained with a sample made from electrolytic hydrogen and sulfur.

Electrolytic hydrogen, free from oxygen, was supplied by Professor Giauque of this Laboratory.

The sulfur used was a sample prepared by Eastman and McGavock for heat capacity investigations.[3]

Carbonyl sulfide was prepared from ammonium thiocyanate and sulfuric acid.[4]

Nitric oxide which had been prepared by the method of Johnston and Giauque[5] was supplied by Dr. K. Atwood.

Eastman Kodak Company methyl mercaptan and Kahlbaum dimethyl sulfide were distilled and degassed in the vacuum system.

Distilled water was degassed thoroughly by boiling and distilling off the first half in the vacuum line.

The procedure followed in making a typical run and analysis was: The reaction vessel was first flushed with acetaldehyde, evacuated, and then hydrogen sulfide introduced and the pressure measured. Next the acetaldehyde was admitted and an electric clock started simultaneously. Pressure readings were taken at regular intervals, usually of one-half minute, during the initial stages of the reaction. The initial total pressure was determined by extrapolating the pressure–time curve to zero time.

When the pressure change indicated that the reaction had proceeded as far as was desired for that experiment the gases were drawn from the reaction vessel by means of a Toepler pump. Two spiral traps immersed in liquid air inserted between the vessel and the pump served to freeze out all of the condensable gases. The non-condensable gases were transferred to a gas buret and samples were analyzed by the micromethods which have been described by Blacet, Leighton, MacDonald and others.[6] The condensable gases were analyzed for hydrogen sulfide by treating them with a solution of lead nitrate and titrating the liberated acid with a solution of 0.01 *N* sodium hydroxide. Blank experiments showed that acetaldehyde and lead sulfide did not interfere with this analysis.

Results and Discussion.—Preliminary experiments showed that consistent results could not be obtained unless the reactants were carefully purified especially so as to eliminate oxygen. This observation is in agreement with that of Letort[7] who found that the thermal decomposition of acetaldehyde is accelerated by small amounts of oxygen. Furthermore with reactants which had not been carefully purified the reaction was found to be partially heterogeneous but it was immaterial whether the surface was quartz or Pyrex glass. With carefully purified reactants the reaction was found to be homogeneous as is shown by the data in Table II. The packed vessel had a surface/volume ratio twelve times that of the unpacked one. The remainder of this paper is concerned with this homogeneous reaction.

TABLE II

COMPARISON OF RATES IN QUARTZ AND PACKED PYREX REACTION VESSELS AT 713°K.

Initial pressure, cm. of mercury H_2S	CH_3CHO	Initial rate/(H_2S) cm./min.	Reaction vessel
3.68	18.79	0.324	Packed Pyrex
4.04	19.77	.296	Quartz
4.04	18.62	.268	Packed Pyrex
4.03	19.19	.265	Quartz
2.12	17.36	.821	Packed Pyrex
1.98	20.72	.824	Quartz

Analysis of the reaction mixture at various degrees of completion showed that the only products present in appreciable amounts were methane and carbon monoxide. Within the limits of accuracy of the methods used, the hydrogen sulfide was present in its original form throughout the course of the reaction. Some of the analytical results are shown in Table III. It follows from these observations that the pressure change at any time is a measure of the extent of the reaction.

Some typical pressure time curves are shown in Fig. 1. It is apparent that the curves are practically linear for the first half of the reaction or even more at high pressures but at low initial pressures and toward the end of the reaction the deviations from linearity are appreciable. These observations are in accord with those of Fromherz to the effect that over a wide range in any given run the rate is independent of the acetaldehyde pressure. However, the markedly different slopes of the three curves shown in Fig. 1 show that the initial rates are dependent on the aldehyde pressure. From a large number of initial rate measurements,

(7) Letort, *J. Phys. Chem.*, **34**, 355 (1937).

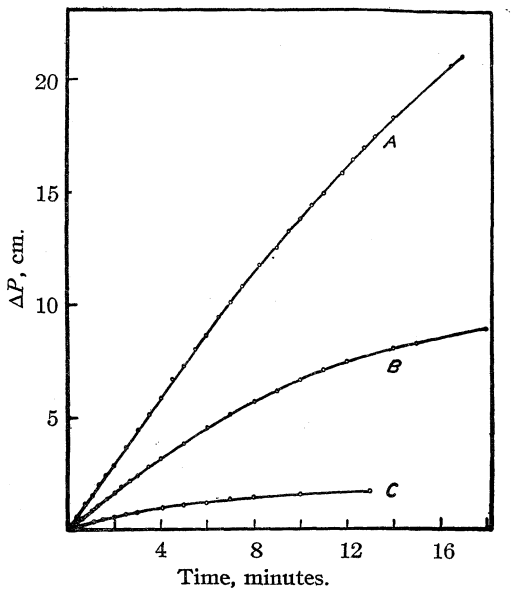

Fig. 1.—Pressure–time curves of the sensitized decomposition of acetaldehyde: 713°K.; H_2S, 4.00 cm.; CH_3CHO: A—31.70 cm., B—10.94 cm., C—2.01 cm.

the details of which are listed in Table V, it was found that the initial rates could be expressed by

$$-d(CH_3CHO)/dt = k_1(H_2S)(CH_3CHO) + k_2(H_2S)(CH_3CHO)/(1 + k_3(CH_3CHO))$$

in which the formulas in parentheses represent the initial pressures of aldehyde and hydrogen sulfide and the constants have the following values at 713°K.

$k_1 = 0.0081$ cm.$^{-1}$min.$^{-1}$ $= 1.82 \times 10^{-6}$mole^{-1}liter min.$^{-1}$
$k_2 = 0.0833$ cm.$^{-1}$min.$^{-1}$ $= 1.88 \times 10^{-5}$mole^{-1}liter min.$^{-1}$
$k_3 = 0.667$ cm.$^{-1}$ $= 1.50 \times 10^{-4}$mole^{-1}liter

It was found that the decomposition products, methane and carbon monoxide do not affect the rate. Furthermore, the addition of a fresh charge of aldehyde at the end of a run gave the same rate as if the aldehyde and hydrogen sulfide had been mixed directly, thus showing that the catalytic activity of the sulfide was not reduced by use. In Table III the last column gives the rate as calculated by the above equation. The rate during any given run could be fitted by a similar

TABLE III

ANALYTICAL RESULTS

Initial pressure, cm. of Hg. H_2S	CH_3CHO	% completion	Non-condensable gases, % CH_4	CO	H_2S found, %

776	2.03	21.15	4.57
786.5	2.00	21.10	5.98

Since the analyses failed to give any indication of the nature of the intermediary steps in the catalysis a number of experiments were performed with various substances which might be present in the reaction mixture in very minute amounts or which on the basis of structural similarity might be expected to have an effect similar to that of hydrogen sulfide. The results obtained, all at 713° K., were as follows:

Sulfur causes the aldehyde to decompose approximately five times as fast as in the presence of the corresponding amount of hydrogen sulfide. Within a few minutes the sulfur is converted into hydrogen sulfide, and the rate of decomposition becomes that determined by the latter substance.

If it is assumed that the hydrogen sulfide catalysis involves the hydrogen sulfide–sulfur equilibrium the addition of hydrogen to the reaction mixture should decrease the rate of the reaction. Actually it was found that the addition of 30.91 cm. of hydrogen decreased the rate only 14%. At intermediate pressures the effect was proportional to this value. The dependence of the rate on the aldehyde and hydrogen sulfide pressures was not altered by the addition of hydrogen. This result in itself tends to exclude the hypothesis of the sulfide–sulfur equilibrium. Additional ground for excluding that idea is supplied by the fact that the observed rate was 28 times that calculated from the data in the literature on the equilibrium and our observations on the effect of sulfur.

The effect of carbonyl sulfide on the rate was found to depend on the length of time the carbonyl sulfide was heated before the aldehyde was admitted to the reaction vessel. Extrapolation to zero preheating time indicated that the carbonyl sulfide had no appreciable effect on the rate. The observed behavior is attributed to the slow decomposition of the added substance into sulfur and carbon monoxide.

The addition of nitric oxide to the reaction mixture gave results of the type indicated in Table VI. It is apparent that the catalytic effect of a

mixture of nitric oxide and hydrogen sulfide is greater than the sum of the effects of these gases taken separately.

TABLE VI

EFFECT OF NITRIC OXIDE AT 713°K.

Initial pressure, cm. of Hg			Initial rate
H_2S	NO	CH_3CHO	cm./min.
4.00	0	20.00	1.11
3.88	0.14	20.70	3.27
4.03	0.33	21.12	4.00
4.29	5.89	17.30	4.32
0	3.98	20.67	0.28

The effect of methyl mercaptan and dimethyl sulfide on the rate of decomposition of the aldehyde is of interest both because of the possibility that they are intermediates and because of their similarities in structure to hydrogen sulfide. The rates of decomposition of these substances were too great to study any specific effects due to them. It was noted, however, that the decomposition products catalyzed the aldehyde decomposition more than the corresponding amount of hydrogen sulfide. This may be an effect similar to that found with mixtures of nitric oxide and hydrogen sulfide or it may be due to the presence of some sulfur in the decomposition products of the mercaptan and sulfide added. An analysis of the gaseous products obtained from the complete decomposition of methyl mercaptan showed the composition in per cent. to be 29.2 methane, 7.1 ethane, 9.4 ethylene and 54.2 hydrogen sulfide. The non-gaseous products were not analyzed. The absence of ethane and ethylene in the products of the hydrogen sulfide catalyzed decomposition of the aldehyde indicates that the mercaptan is not an important intermediate.

Water had no appreciable effect on the rate of decomposition of acetaldehyde at 713°K.

The possibility that the reaction was caused by the dissociation of the hydrogen sulfide into hydrogen atoms and hydrosulfide radical followed by the reaction of these substances with the aldehyde to initiate a chain reaction was considered. The equilibrium concentration of the products of such a dissociation as calculated from data in the literature would be sufficient to account for the observed rates but the observed temperature coefficient seems to be too low to be compatible with such a mechanism. None of the mechanisms which we have considered will account for the results quantitatively so they will not be discussed in detail.

Summary

A study has been made of the catalysis of the thermal decomposition of acetaldehyde by hydrogen sulfide. The reaction results in the formation of equivalent amounts of methane and carbon monoxide with no net loss of hydrogen sulfide. The decomposition is homogeneous and the initial rates are given by $-d(CH_3CHO)/dt = k_1 \cdot (H_2S)(CH_3CHO) + (H_2S)(CH_3CHO)/(1 + k_3 \cdot (CH_3CHO))$. Values for the constants are given. The effect of temperature on the rate has been studied. The effects of adding hydrogen, sulfur, carbonyl sulfide, methyl mercaptan, dimethyl sulfide, and water to the reaction mixture have also been studied. The results indicate that none of these substances are of importance as intermediate in the hydrogen sulfide catalyzed reaction. Mixtures of nitric oxide and hydrogen sulfide were found to have a greater catalytic effect than the sum of the effects of these gases taken separately.

[COMMUNICATION NO. 852 FROM THE KODAK RESEARCH LABORATORIES]

Theory of Solutions of High Polymers[1]

BY MAURICE L. HUGGINS

Introduction

In recent years it has become increasingly evident that the large deviations from "ideal" behavior shown by solutions of long-chain molecules are due primarily to deviations from ideality of the *entropy* of mixing, rather than to any *heat* of mixing effect, such as is responsible for most deviations in solutions containing only small molecules.

The entropy of mixing of chain molecules with small molecules has been discussed qualitatively by Meyer.[2] Recently, Flory[3] and the writer[4] have, independently, treated the subject in a quantitative manner, with results which are essentially equivalent.

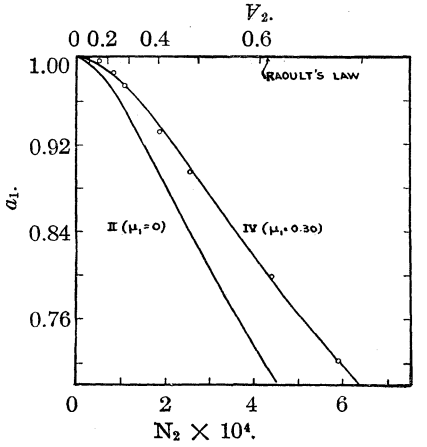

Fig. 1.—Activity as a function of mole fraction for the rubber–chloroform system at 25°. Vapor pressure data by Stamberger[5]; the curves correspond to Eq. 1; V_2/V_1 = 3644.

We consider a hypothetical solution consisting of N_1 spherical molecules (Type 1) and N_2 chain molecules (Type 2), each of the latter consisting of n submolecules of the same size as each Type 1 molecule. We assume that there is no volume change on mixing and that the intermolecular energy interactions are not such as to interfere with the randomness which would result if the heat of mixing were zero. We distribute the Type 1 molecules and Type 2 submolecules among $N_1 + nN_2$ sites, first adding the Type 2 molecules, one submolecule at a time, and then the Type 1 molecules. We count the number of different ways in which each can be added and then multiply these numbers together to obtain the total number of configurations. From the total number of *different* configurations possible, we proceed by well-known methods to the desired equations for the entropy of mixing and the activities of the components.

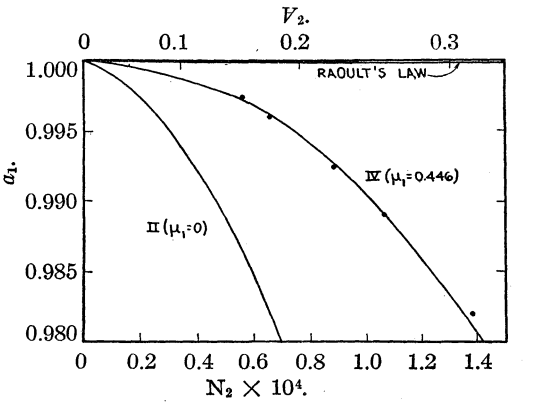

Fig. 2.—Activity *vs.* mole fraction for the rubber–benzene system at 15–20°. Swelling pressure data by Posnjak.[6] V_2/V_1 = 3307.

Equations for the Activities.—For the logarithms of the activities, we obtain the equations

$$\ln a_1 = \ln V_1 + \left(1 - \frac{\overline{V}_1}{\overline{V}_2}\right) V_2 + \mu_1 V_2^2 \qquad (1)$$

and

$$\ln a_2 = \ln V_2 + \left(1 - \frac{\overline{V}_2}{\overline{V}_1}\right) V_1 + \mu_2 V_1^2 \qquad (2)$$

with the empirical constants, μ_1 and μ_2, related by the equation

$$\mu_1 \overline{V}_2 = \mu_2 \overline{V}_1 \qquad (3)$$

V_1 and V_2 refer to the volume fractions[7] and $\overline{V}_1$ and $\overline{V}_2$ to the partial molal volumes of the two components. (With negligible error for our purpose we can assume the partial molal volumes to be equal to the actual molal volumes of the pure

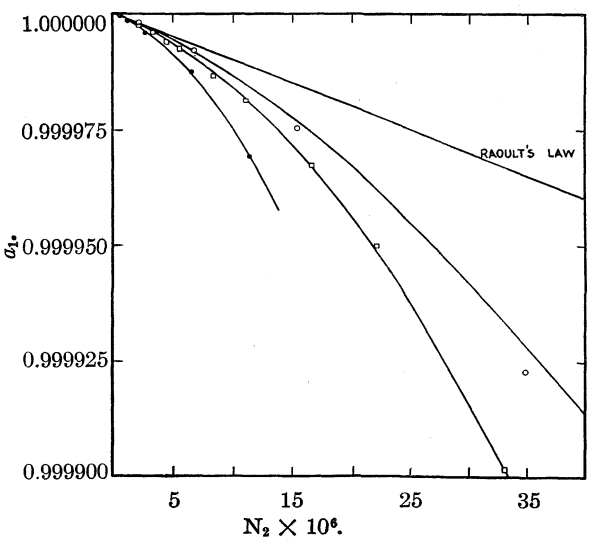

Fig. 4.—Activity *vs.* mole fraction for solutions of nitrocellulose in acetone: osmotic pressure data on three samples, differing with regard to the degree of nitration, the average chain length, and the temperature. Dots represent data by Dobry[9] ($\mu_1 = 0.265$; $V_2/V_1 = 793$; $t = 22°$). Squares represent data by Schulz[10] ($\mu_1 = 0.300$; $V_2/V_1 = 550$; $t = 27°$). Circles represent data by Duclaux and Wollman[8] ($\mu_1 = 0.19$; $V_2/V_1 = 330$; $t = 20°$).

For testing the equations just given, we may use activities calculated from vapor pressure, osmotic pressure, swelling pressure, boiling point elevation, or other measurements. A thorough survey of the pertinent data in the literature shows the agreement to be excellent, for both short- and long-chain molecules.[4] This agreement is exemplified by Figs. 1 to 8, in which the activity of the solvent is shown as a function of the mole fraction of the solute for solutions of various long-chain compounds in small-molecule solvents. In each of these figures the straight line represents Raoult's law; the other curves represent Eq. 1 with μ_1 equal to zero (curves II) or an empirical value (curves IV).

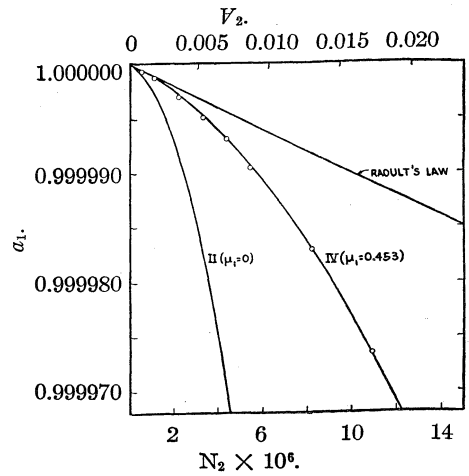

Fig. 5.—Activity *vs.* mole fraction for solutions of polyethylene oxide in water at 27°: osmotic pressure data by Schulz[10]; $V_2/V_1 = 1614$.

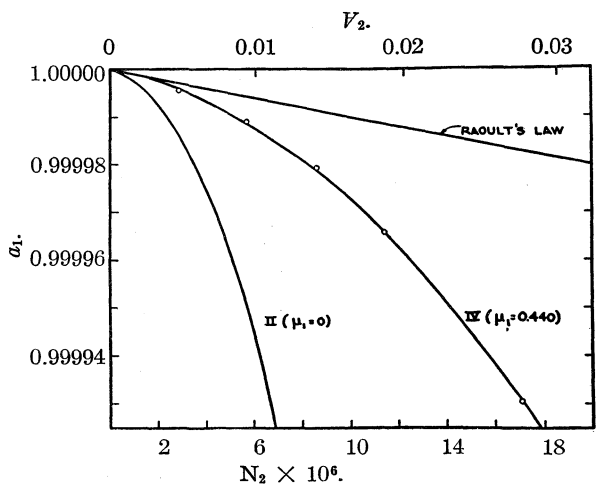

Fig. 6.—Activity *vs.* mole fraction for solutions of polystyrene in toluene at 27°: osmotic pressure data by Schulz[10]; $V_2/V_1 = 1667$.

Osmotic Pressure.—The osmotic pressure of a solution is related to the activity of the solvent by the equation

$$\Pi = -\frac{RT}{\overline{V}_1}\ln a_1 \qquad (4)$$

R is the gas law constant and T the absolute temperature. Combining this with equation (1), we obtain

$$\frac{\Pi}{V_2} + \frac{RT}{\overline{V}_1}\left(\frac{\ln V_1}{V_2} + 1\right) = \frac{RT}{\overline{V}_2} - \frac{RT\,\mu_1 V_2}{\overline{V}_1} \qquad (5)$$

Since

$$\ln V_1 = -V_2 - \frac{V_2^2}{2} - \frac{V_2^3}{3} - \cdots \qquad (6)$$

we can write, for dilute solutions (small V_2)

$$\frac{\Pi}{V_2} - \frac{RTV_2^2}{3\overline{V}_1} = \frac{RT}{\overline{V}_2} + \frac{RT}{\overline{V}_1}\left(\frac{1}{2} - \mu_1\right)V_2 \qquad (7)$$

For concentrations in weight fractions (W_2) or in grams of solute per cubic centimeter of solution (C_2), the corresponding equations are

$$\frac{\Pi}{W_2} - \frac{RT\,d_1^4W_2^2}{3M_1d_2^3} \approx \frac{RT\,d_1}{M_2} + \frac{RT\,d_1^3}{M_1\,d_2^2}\left(\frac{1}{2} - \mu_1\right)W_2 \qquad (8)$$

and

$$\frac{\Pi}{C_2} - \frac{RT\,d_1C_2^2}{3M_1\,d_2^3} = \frac{RT}{M_2} + \frac{RT\,d_1}{M_1\,d_2^2}\left(\frac{1}{2} - \mu_1\right)C_2 \qquad (9)$$

where d_1 and d_2 are the densities and M_1 and M_2 the molecular weights of the components.

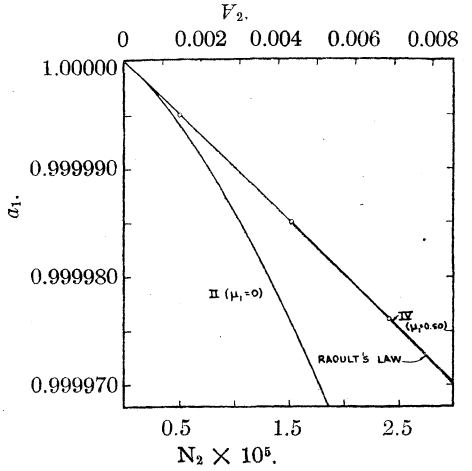

Fig. 7.—Activity *vs.* mole fraction for solutions of polyvinyl chloride in dioxane at 27°: osmotic pressure data by Staudinger and Schneiders[11]; $V_2/V_1 = 286$.

Given a set of accurate osmotic pressure values for different concentrations of a given solution, a plot of the quantity represented on the left side of one of these Eqs., 7, 8, or 9, against the concentration (V_2 or W_2 or C_2) should yield a straight line. From its intercept with the axis of ordinates (concentration = 0), one can obtain the molecular weight of the solute; from its slope one can compute μ_1.

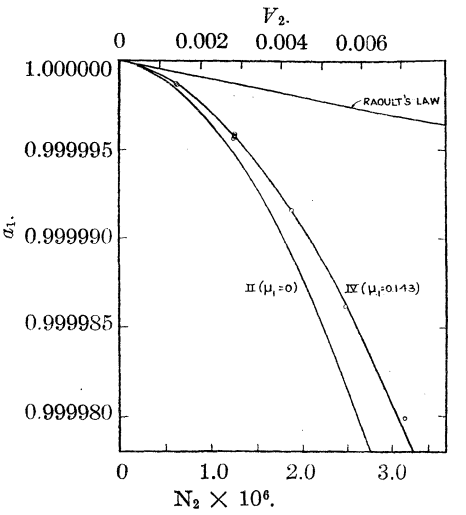

Fig. 8.—Activity *vs.* mole fraction for solutions of polyvinyl chloride in tetrahydrofuran at 27°: osmotic pressure data by Staudinger and Schneiders[11]; $V_2/V_1 = 2264$.

The second term on the left side of each of these equations is negligible at most concentrations at which osmotic pressure measurements of solutions of high molecular compounds are made. We thus have a theoretical basis for the well-known[12] rectilinear relationship between Π/C_2 and C_2 (or between Π/W_2 and W_2).

Since μ_1 should be independent of the chain length of the solute molecules—assumed to be alike in other respects—the slopes of the lines obtained for a series of fractions of a given type of polymer should all be equal. On the other hand, a change of either the solvent or the type of solute (*e. g.*, from a nitrocellulose of a certain degree of nitration to one with a different degree of nitration) should change the slope.

These conclusions are amply borne out by the experimental facts, as shown by Figs. 9 to 13.

Separation of Phases. Gels.—Assuming Eq. 1 to hold, the activity of the small-molecule component, in equilibrium with long-chain molecules having $\overline{V}_2/\overline{V}_1$ equal to 100 or ∞, varies with composition as shown in Figs. 14 and 15. If μ_1 is larger than a certain critical value, the calculated curve for activity *vs.* N_2 (or V_2 or W_2 or C_2) exhibits a minimum and a maximum, indicating a separation of the system into two phases. The critical value of μ_1 depends on the ratio of the partial molal volumes according to the equation

(11) H. Staudinger and J. Schneiders, *Ann.*, **541**, 151 (1939).

(12) *Cf.* H. Mark, "Physical Chemistry of High Polymeric Systems," Interscience Publishers, New York, N. Y., 1940, p. 240.

$$\mu_1 \text{ (crit.)} = \frac{1}{2}[1 + (\bar{V}_1/\bar{V}_2)^{1/2}]^2 \qquad (10)$$

This dependence is shown graphically in Fig. 16.

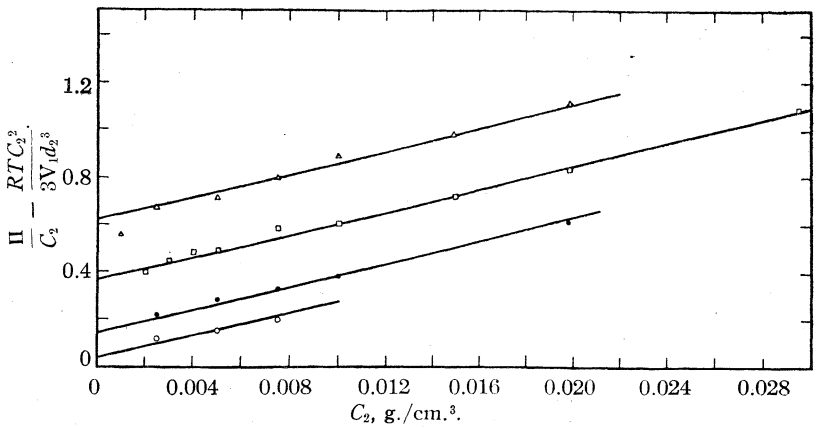

Fig. 9.—Osmotic pressure dependence on concentration for solutions of certain nitrocellulose fractions in acetone at 27°: data by Schulz.[10] The straight lines represent Eq. 9; $\mu_1 = 0.300$.

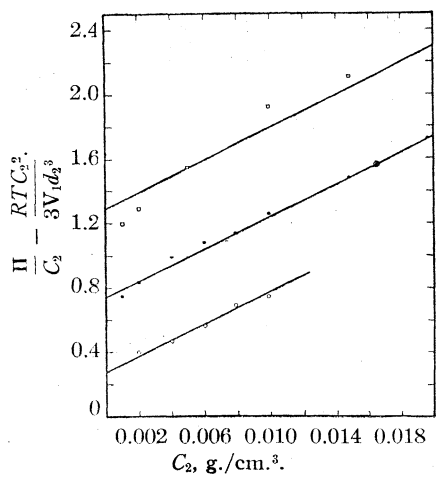

Fig. 10.—Osmotic pressure dependence on concentration for polyethylene oxide fractions in water at 27°: data by Schulz[10]; $\mu_1 = 0.453$.

For high molecular solutes, unless μ_1 is very near the critical value

$$a_1 \approx 1 \qquad (11)$$

for both phases. One phase is practically pure solvent, in agreement with the experimental findings of Brønsted and Volqvartz,[13] on the swelling of polystyrene in laurate esters. The composition of the other phase is related to μ_1 and the molal volume ratio according to the following equation, obtained by substituting Eq. 11 into Eq. 1.

$$\ln V_1 = \left(\frac{\bar{V}_1}{\bar{V}_2} - 1\right) V_2 - \mu_1 V_2^2 \qquad (12)$$

If the concentration and intermolecular attractions of the long-chain molecule component are such that the motion of each such molecule is greatly restricted by its neighbors, the solution will have a degree of rigidity—it will have the properties of a gel. The effective molecular weight and molecular volume will be very large, relative to the values for the small-molecule component. Hence

$$\ln V_1 = -V_2 - \mu_1 V_2^2 \qquad (13)$$

We should expect this equation to be applicable to gels in general, since the theoretical derivation of Eqs. 1 and 2 is such that they would be expected to hold as well for flexible *network* molecules as for *chain* molecules.

Figure 17 shows the solubility, as function of μ_1, of a small-molecule compound in a gel, for effective molal volume ratios $(\bar{V}_2/\bar{V}_1)$ of 100 (Eq. 12) and ∞ (Eq. 13). It can be seen that the composition is very sensitive to the value of μ_1, but not to the relative sizes of the molecules—unless μ_1 is close to the critical value.

The data of Brønsted and Volqvartz on the swelling of polystyrene in alkyl laurates at different temperatures make it possible to determine the variation of μ_1 with temperature for each of

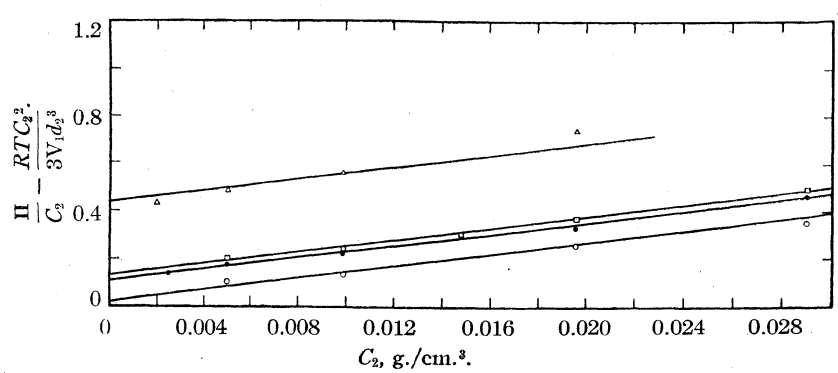

Fig. 11.—Osmotic pressure dependence on concentration for polystyrene fractions in toluene at 27°: data by Schulz[10]; $\mu_1 = 0.440$.

(13) J. N. Brønsted and K. Volqvartz, *Trans. Faraday Soc.*, **35**, 576 (1939).

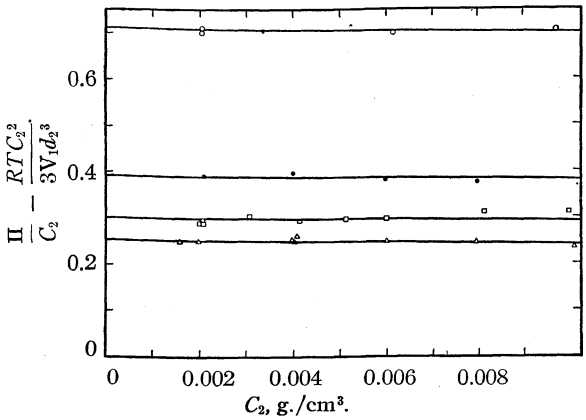

Fig. 12.—Osmotic pressure dependence on concentration for polyvinyl chloride fractions in dioxane at 27°: data by Staudinger and Schneiders[11]; $\mu_1 = 0.523$.

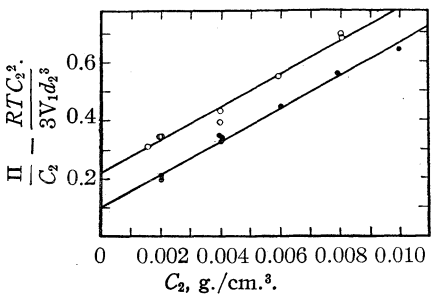

Fig. 13.—Osmotic pressure dependence on concentration for polyvinyl chloride fractions in tetrahydrofuran at 27°: data by Staudinger and Schneiders[11]; $\mu_1 = 0.143$.

the systems studied. As Fig. 18 shows, the relation

$$\mu_1 = \alpha_1 + \beta_1/T \qquad (14)$$

holds, within the probable experimental error. The straight lines in this figure are drawn for a constant value (−0.83) for α_1, with values of β_1

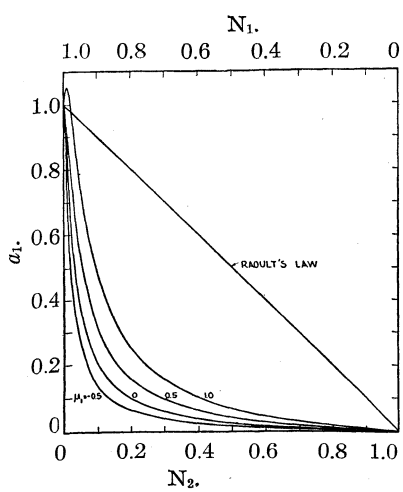

Fig. 14.—Activity *vs.* mole fraction, according to Eq. 1, for $V_2/V_1 = 100$, with certain values of μ_1.

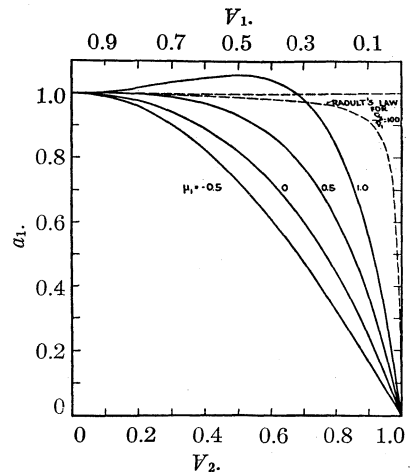

Fig. 15.—Activity *vs.* volume fraction, according to Eq. 1, for $V_2/V_1 = \infty$, with certain values of μ_1. The corresponding curves for finite values of the molal volume ratio are lower than those shown; for $V_2/V_1 \geqslant 100$ the difference is approximately the width of the lines, or less.

varying from 388 for ethyl laurate to 518 for isoamyl laurate. The experimental data, however, are insufficient to establish whether or not the α_1 values really are accurately the same for all of these systems.

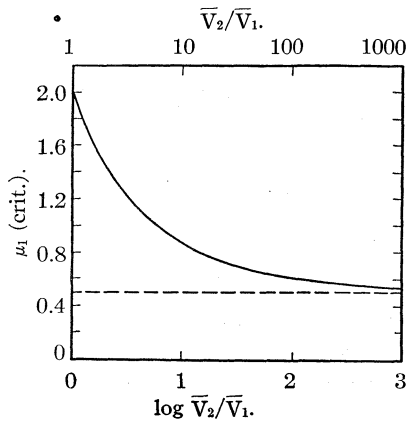

Fig. 16.—Dependence on the molal volume ratio of the critical value of μ_1 for separation of a solution into two phases, according to Eq. 10.

Probably the most important of the terms contributing to μ_1 is the heat of mixing term. From the work of van Laar,[14] Scatchard,[15] and Hildebrand,[16] this term would be expected to be approximately of the form $\overline{V}_1A_{12}/RT$, where A_{12} is a constant which measures the difference between the average cohesive energy density due to at-

(14) J. J. van Laar, *Z. physik. Chem.*, **A137**, 421 (1928).

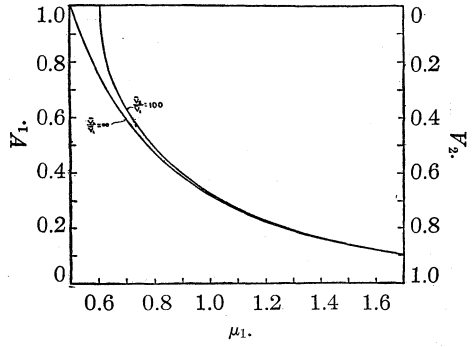

Fig. 17.—Dependence on μ_1 of the composition (volume fraction) of the polymer-rich phase in a two-phase system, for V_2/V_1 equal to ∞ and 100. Except for $\mu_1 \approx \mu_1$ (crit.), the curves agree with Eq. 12.

traction between *like* molecules and that due to attraction between *unlike* molecules. The greater the tendency of like molecules to cluster together, the larger is A_{12} and, in general, μ_1.

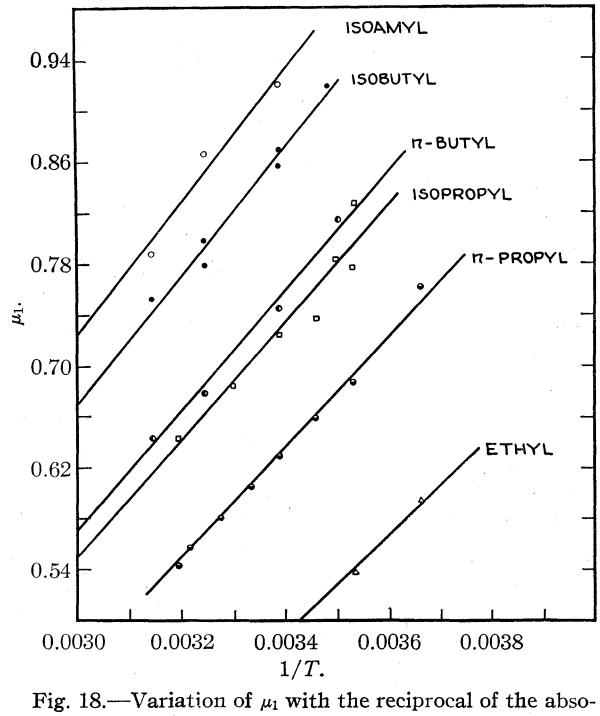

Fig. 18.—Variation of μ_1 with the reciprocal of the absolute temperature, for polystyrene swollen in alkyl laurates. The straight lines represent Eq. 14, with $\alpha_1 = -0.83$ in each case and β_1 equal to 388, 431, 460, 467, 500 and 518 for ethyl, *n*-propyl, . . . isoamyl laurates; data by Brønsted and Volqvartz.[13]

Figure 19 shows that for the alkyl laurates in polystyrene, β_1 is roughly proportional to V_1 (and so to $\overline{V}_1$). The inexactness of this proportionality is probably attributable in part to variation in A_{12} and in part to the existence of other terms contributing to μ_1.

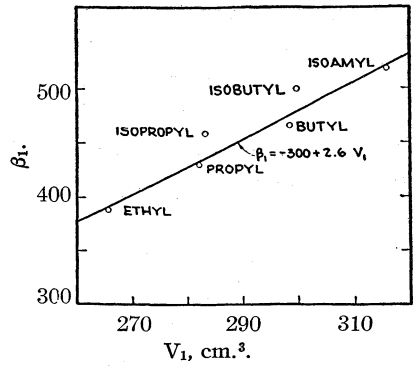

Fig. 19.—Relation between the constant β_1 of Eq. 14 and the molal volume of the small-molecule component, for polystyrene–alkyl laurate gels.[13]

Figure 20 shows the measure of agreement between the experimental polystyrene–laurate gel compositions and those computed from Eqs. (13) and (14).

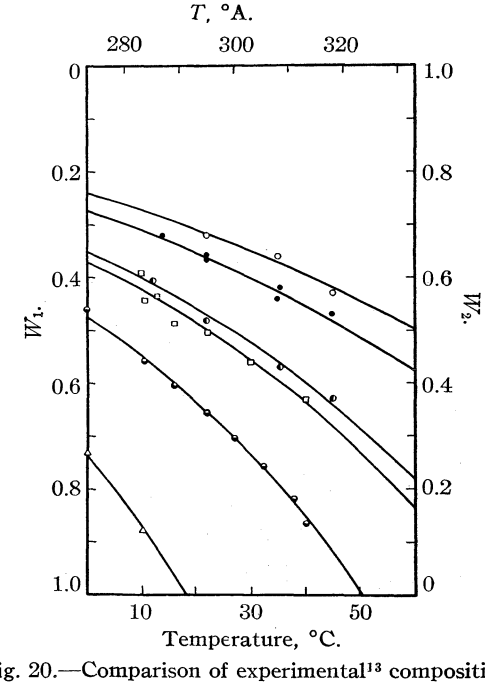

Fig. 20.—Comparison of experimental[13] compositions of polystyrene–alkyl laurate gels and the theoretical curves corresponding to Eqs. 12 and 14: ○, isoamyl; ●, isobutyl; ◐, *n*-butyl; □, isopropyl; ◒, *n*-propyl; △, ethyl.

Solubility of a Polymer in a Small-Molecule Liquid.—For equilibrium between a solid and its (saturated) solution in a liquid, the fugacity of the substance composing the solid must be the same in the two phases. Assuming the heat of fusion (ΔH_f) of the solid not to vary with the temperature between the temperature of the system and the melting point (T_f), the following

relation holds. (Compare Hildebrand's[17] treatment of ideal solutions.)

$$\ln a_2 = -\frac{\Delta H_f}{R}\left(\frac{T_f - T}{TT_f}\right) \qquad (15)$$

Combining this equation with Eq. 2 and making the approximation that

$$\mu_2 = \frac{\bar{V}_2}{\bar{V}_1}\mu_1 = \frac{\bar{V}_2 B_{12}}{RT} \qquad (16)$$

where B_{12} is a constant independent of temperature, we obtain

$$\ln V_2 = -\frac{\Delta H_f}{R}\left(\frac{T_f - T}{TT_f}\right) - \frac{\bar{V}_2 B_{12} V_1^2}{RT} + \left(\frac{\bar{V}_2}{\bar{V}_1} - 1\right)V_1 \qquad (17)$$

This equation accounts quantitatively (Fig. 21) for the temperature dependence of the solubility of the normal paraffins, $C_{34}H_{70}$ and $C_{60}H_{122}$, in decalin (decahydronaphthalene, $C_{10}H_{18}$). In computing the theoretical curves for this figure, we have made use of the thermodynamic relation

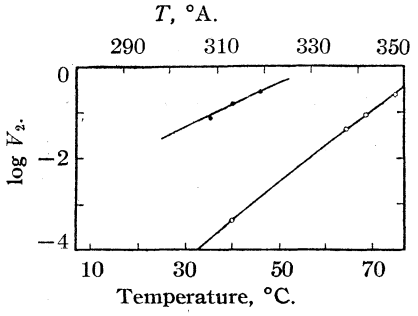

Fig. 21.—Solubility (volume fraction) of n-$C_{34}H_{70}$ and n-$C_{60}H_{122}$ in decalin, as a function of temperature. The curves correspond to Eq. 17, after substitution of Eqs. 18, 19, 20 and 21; experimental data by Meyer and van der Wyk[18]: ●, n-$C_{34}H_{70}$, B_{12} = 1.97; ○, n-$C_{60}H_{122}$, B_{12} = 2 66.

$$T_f = \Delta H_f / \Delta S_f \qquad (18)$$

and the following empirical expressions:[19,20,21]

$$\Delta H_f = -1750 + 608.5n \qquad (19)$$

$$\Delta S_f = 4.04 + 1.491n \qquad (20)$$

$$\bar{V}_2 = V_2 = 26.96 + 16.49n + (29/n) \qquad (21)$$

Here, n denotes the number of carbon atoms in the paraffin.

In these systems, the ratio V_2/V_1 is small (3.73 and 6.44), hence it is not surprising that the empirical values of B_{12} are slightly different (1.97 and 2.66) for the two systems. For very long chains which are similar in other respects, B_{12} would be expected to be independent of chain length.

For long chains in general we may make the approximations

$$\Delta H_f = nh_2 \qquad (22)$$

$$\Delta S_f = ns_2 \qquad (23)$$

and

$$V_2 = nv_2 \qquad (24)$$

where h_2, s_2 and v_2 are heats of fusion, entropies of fusion, and volumes per "monomeric unit" of the chain compound. Then

$$\ln V_2 = -V_1 + n\left[\frac{s_2}{R} + \frac{v_2 V_1}{\bar{V}_1} - \frac{h_2}{RT} - \frac{v_2 B_{12} V_1^2}{RT}\right] \qquad (25)$$

If the polymer is not very soluble, V_1 is approximately equal to unity. Then (provided the quantity in brackets in this equation is not close to zero)

$$\ln V_2 \approx n\left(\alpha - \frac{\beta}{T}\right) \qquad (26)$$

and

$$V_2 \approx \exp\left[n\left(\alpha - \frac{\beta}{T}\right)\right] \qquad (27)$$

where

$$\alpha = \frac{s_2}{R} + \frac{v_2}{\bar{V}_1} \qquad (28)$$

and

$$\beta = \frac{h_2}{R} + \frac{v_2 B_{12}}{R} \qquad (29)$$

These equations show the dependence of the solubility of a slightly soluble high polymer on the temperature and on other factors.

Further discussion and experimental tests of these solubility relations, together with a treatment of the solubility of polymers in mixed solvents, will be given at a later time.

The writer is glad to express here his indebtedness to Mrs. Dorothy Owen Davis for much help with the calculations and figures for this paper.

Summary

1. Theoretical equations derived for the activities of the components of a solution of chain molecules in a small-molecule solvent are in good agreement with experimental vapor pressure, osmotic pressure, swelling pressure and solubility measurements. A single constant, μ_1, partly but not entirely due to the heat of mixing effect, must be evaluated empirically.

2. Equations deduced for osmotic pressure as a function of composition account for the known straight-line relationship obtained when the ratio of osmotic pressure to concentration is plotted

against the concentration. For long chains the slope of this line depends on μ_1, but not on the chain length of the solute molecules.

3. The quantitative relationships derived for flexible chain molecules should also be applicable to flexible network molecules. For values of μ_1 greater than a critical value, the theoretical activity-composition curve indicates separation into two phases. One consists of the nearly pure small-molecule component. The other is usually a gel; its composition depends primarily on the value of μ_1. From experimental values of equilibrium compositions for polystyrene–alkyl laurate gels at different temperatures, μ_1 is a rectilinear function of V_1/T, the ratio of the molal volume of the small-molecule component to the absolute temperature.

4. An equation for the solubility of a solid chain compound in a small-molecule liquid is derived and found to be in agreement with measurements at various temperatures of the solubilities of n-$C_{34}H_{70}$ and n-$C_{60}H_{122}$ in decalin. Simplified solubility equations, applicable to long-chain polymers, are deduced.

Studies in Dehydrogenation.[1] II. Spirocyclopentane-1,1′-tetralin

BY MEYER LEVITZ[2] AND MARSTON TAYLOR BOGERT

The investigation of the rearrangement and dehydrogenation of spirocyclohexane-1,1′-indane[1] over a palladium on charcoal catalyst showed the importance of cautious postulation of structure based on the products obtained by dehydrogenation. Thus, a compound thought to be a hydrophenanthrene must be carefully examined if the only proof of its structure is dehydrogenation to phenanthrene, especially if its synthesis can theoretically yield isomeric spiranes.

When passed over Pd–C at 370–375°, spirocyclohexane-1,1′-indane was rearranged and dehydrogenated to phenanthrene while at 400–420° the main product was anthracene. This formation of both phenanthrene and anthracene from a tricyclic spirane has since been applied to the detection of spiranes.[3] It therefore appears important to study the action of other spiranes under similar dehydrogenation conditions. The closest isomer to the spirane previously studied is spirocyclopentane-1,1′-tetralin. This compound was therefore passed over the Pd–C catalyst in the vapor phase in a new apparatus especially designed to allow this repeated exposure of the hydrocarbon to the catalyst without the necessity of removing it from one end of the apparatus and reintroducing it at the other.

The heating element (A) was a brass tube 16 mm. in diameter and 75 cm. long, wound with nichrome wire. The closely fitting Pyrex dehydrogenation tube (B), inserted in the heating element, was closed at one end and had a stopcock sealed on the other end for the removal of samples during the dehydrogenation. The temperature inside this tube was checked beforehand with the temperature inside the thermometer well (C) enclosed by the heating coil. T-Tubes (D and D′) were sealed on the dehydrogenation tube 7 cm. from each end of the brass tube. Two 3-way stopcocks (E and E′) were connected to these T-tubes in such a way that either end of the dehydrogenation tube could be opened to the mercury trap (F) and a bubble counter (G), while the other end was opened to tube (H) leading to the supply of nitrogen or hydrogen. The palladium catalyst was prepared according to the method of Linstead and Thomas.[4] It was thoroughly mixed with twice its weight of asbestos and packed into the dehydrogenation tube with a space of 8 cm. left at each end as a preheating zone for the compound. The catalyst was changed for each run.

In operation the compound was pipetted into the dehydrogenation tube through (D) while the apparatus was tilted to prevent contact with the catalyst. Washed and dried nitrogen was passed into the apparatus through (H) to displace the air while the temperature was raised to the desired point. During this time stopcock (E) was open to (H) while stopcock (E′) led to the mercury trap.

(1) For the first paper in this series see Levitz, Perlman, and Bogert, *J. Org. Chem.*, **6**, 105 (1941).

(2) Visiting Scholar, Columbia University.

(3) Marvel and Walton, *J. Org. Chem.*, **7**, 88 (1942).

(4) Linstead and Thomas, *J. Chem. Soc.*, 1127 (1940).

The flow of nitrogen was then stopped and washed and dried hydrogen was admitted to displace the nitrogen. Stopcock (E) was then closed. The tube was tilted to allow the compound to flow slowly into the heated zone. After passing through, the compound condensed and collected in the cool portion. Stopcock (D′) was then closed and stopcock (D) was opened to the mercury trap. Any solid which had collected was melted by means of the radiant heat from an electric cigar lighter. The tube was tilted in the opposite direction and the compound was again passed over the catalyst. The process was repeated until dehydrogenation was complete.

The first run was made at 355–375° for six hours. The spirane was rearranged and dehydrogenated to phenanthrene. Another run was made at 420–430° to see whether anthracene would be produced as in the case of the spirocyclohexane-1,1′-indane. Phenanthrene was the only aromatic compound found in the product of this present dehydrogenation.

Experimental

Spirocyclopentane-1,1′-tetralin was prepared according to the method of Perlman, Davidson and Bogert.[5] Phenylpropyl bromide from phenylpropyl alcohol and phosphorus tribromide was put through a Grignard reaction with cyclopentanone. The resulting carbinol was cyclodehydrated by means of 85% sulfuric acid to the hydrocarbon; yield 32%, b. p. 135–137° (10 mm.), $n^{25}D$ 1.5539; previously reported[5]: yield 30%, b. p. 137–138° (10 mm.), $n^{25}D$ 1.5533.

Dehydrogenation at 355–375°.—The apparatus was charged with 8 g. of spirocyclopentane-1,1′-tetralin and the temperature was raised to 355°. Dehydrogenation started as soon as the hydrocarbon was passed over the catalyst, as evidenced by the rapid flow of hydrogen through the bubble counter. In twenty minutes all of the compound had passed completely over the catalyst and had condensed in the cool part of the tube. A considerable amount solidified as a low melting white solid. After one and one-half hours of continuous recirculation the rate of flow of hydrogen decreased materially. The temperature was raised to 365° and dehydrogenation was continued for three and one-half hours and finally at 375° for one hour, at the end of which time only solid collected. This was melted and removed from the apparatus. It weighed 6.5 g. and solidified at about 60°. It was crystallized by dissolving in petroleum ether (Skellysolve B) and chilling in a dry-ice–acetone bath. Recrystallization from ethyl alcohol produced phenanthrene melting at 98–99°, not depressed by an authentic sample. A picrate made with a saturated alcoholic solution of picric acid melted at 144–145°, not depressed by an authentic sample. No other aromatic compound could be isolated.

The catalyst was thoroughly washed with hot benzene. The highly fluorescent solution obtained yielded 0.6 g. of solid material when the benzene was evaporated. Purification produced only phenanthrene.

Dehydrogenation at 420–430°.—Six grams of spirocyclopentane-1,1′-tetralin was passed over the catalyst at 420–425° for ten hours. There was evidence that decomposition was taking place at this temperature. The product obtained showed a deep yellow-green fluorescence when liquid. Most of the product solidified at about 40° but 1 g. collected in the apparatus as a liquid. The liquid and solid were removed separately. Refluxing the liquid fraction with an alcoholic solution of picric acid yielded a picrate melting at 140–141° after recrystallization from hot ethyl alcohol. The melting point was not depressed by an authentic sample of phenanthrene picrate.

The solid, which weighed 3.7 g., was dissolved in petroleum ether and chilled in an ice–salt-bath. Filtration yielded 1.5 g. of solid melting at 90°. Recrystallization from ethyl alcohol gave phenanthrene, m. p. 98–99°, not depressed by an authentic sample of phenanthrene. The petroleum ether filtrate was chilled in a dry-ice–acetone bath and filtered. The 0.8 g. of solid melted at 94–95° and recrystallization from ethyl alcohol raised the melting point to 97–98°, not depressed by an authentic sample of phenanthrene.

The petroleum ether filtrate was still highly fluorescent. It was passed through an aluminum oxide adsorption column and developed with 4:1 petroleum ether–benzene. The non-fluorescent fraction which came through first was chilled in a dry-ice–acetone bath. White crystals of m. p. 93–94°, not depressed by an authentic sample of phenanthrene, were obtained. The fluorescent fraction turned out to be quite small when the solvent was evaporated. Refluxing with an alcoholic solution of picric acid gave no picrate on chilling. Picrates made from the phenanthrenes obtained above melted at 143–144°, not depressed by an authentic sample of phenanthrene picrate.

The catalyst was thoroughly digested with hot benzene. Evaporation of the benzene gave only dark carbonaceous material (0.4 g.), evidently the result of decomposition at the elevated temperature.

Summary

1. Spirocyclopentane-1,1′-tetralin was rearranged and dehydrogenated to phenanthrene when passed over palladium on charcoal at 355–375°.

2. Phenanthrene was the only aromatic compound produced when the reaction was carried out at 420–430°.

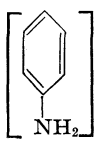
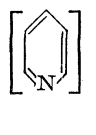
Esters of Pyridinecarboxylic Acids as Local Anesthetics

BY F. F. BLICKE AND E. L. JENNER[1,2]

The nuclear amino group in dialkylaminoalkyl aminobenzoates (I)[3] contributes in some manner which is not understood to the local anesthetic activity of these compounds. It is a matter of interest to know the extent to which this activity would be affected by a shift of the nitrogen atom into the ring. Some information relative to this point could be gained by pharmacological examination of dialkylaminoalkyl esters of pyridinemonocarboxylic acids (II)[4]



$COO(CH_2)_xNR_2$
I



$COO(CH_2)_xNR_2$
II

It has been reported by Ingersoll and Robbins[5] that β-diethylaminoethyl and γ-diethylaminopropyl nicotinate are inactive as local anesthetics. They stated that these esters were prepared by them by interaction of the required basic alcohol with nicotinyl chloride; the "nicotinyl chloride" which was employed melted at 264–265° and was preserved over calcium chloride and paraffin. It has been shown by Meyer and Graf[6] that the true nicotinyl chloride melts at 15–16° and that it is so sensitive to moisture that it cannot be kept unchanged in a desiccator over alkali.

It seems that the material which Ingersoll and Robbins used as "nicotinyl chloride" was somewhat impure nicotinic acid hydrochloride; the latter, when pure, melts at 273–274°.[7]

We prepared nicotinyl chloride according to the procedure of Meyer and Graf and also by the method of Douglass and Forman.[8] In one instance the acid chloride was allowed to react with β-diethylaminoethanol and, in another, nicotinic acid was heated with β-diethylaminoethyl chloride in isopropyl alcohol. β-Diethylaminoethyl nicotinate hydrochloride was obtained in both cases but the properties of our ester hydrochloride were markedly different from those mentioned by Ingersoll and Robbins. When the ester salt was converted into the ester base, the latter was found to boil at a temperature which corresponds to that reported for this product by Knunyantz and Katznel'son.[9]

An examination of β-diethylaminoethyl nicotinate by L. W. Rowe, who tested all of our products in the Parke, Davis and Company Laboratories, showed that the base, as well as the hydrochloride, was practically inactive when applied to the rabbit's cornea. Local anesthesia was produced by injection of a 1–2% solution of the hydrochloride but the activity by this route of administration is greatly inferior to that of procaine or cocaine.

The fact that β-diethylaminoethyl nicotinate is soluble in about three parts of cold water, whereas bases of active esters are fairly insoluble, may account to some extent for its lack of action.

Although ethyl nicotinate has been known for some time, no statement relative to its effectiveness as a local anesthetic could be found. We submitted this ester for examination and it was shown to be practically inactive by topical application. Ethyl *p*-aminobenzoate is the well-known and widely used local anesthetic anesthesin (benzocaine).

Several other esters of nicotinic acid which we prepared are listed in Table I. Their potency is very slight.

In view of the fact that 1-alkyl 2-dialkylaminoalkyl 3-aminophthalates,[10] 1-dialkylaminoalkyl 2-alkyl 3-aminophthalates[11] and 1-alkyl 2-dialkylaminoalkyl 4-aminophthalates[12] are active local anesthetics it seemed desirable to prepare corre-

(1) This paper represents part of a dissertation submitted to the Horace H. Rackham School of Graduate Studies by E. L. Jenner in partial fulfillment of the requirements for the degree of Doctor of Philosophy in the University of Michigan.

(2) Parke, Davis and Company Fellow.

(3) β-Diethylaminoethyl *p*-aminobenzoate is procaine. Corresponding esters of *o*- and *m*-aminobenzoic acids exhibit local anesthesia according to the German Patent 170,587 [*Frdl.*, **8**, 1002 (1906)].

(4) In the naphthalene series it has been found that β-diethylaminoethyl 4-amino-1-naphthoate is a strong local anesthetic [Blicke and Parke, THIS JOURNAL, **61**, 1200 (1939); Rowe, *J. Am. Pharm. Assoc.*, **29**, 241 (1940); Haury, Gruber and Drake, *J. Pharmacol. Exp. Therap.*, **70**, 315 (1940)]. We have been unable to find any reference with regard to the activity of dialkylaminoalkyl esters of quinoline-4-carboxylic acid, however, 2-alkyloxy derivatives of the latter are potent products [Wojahn, *Arch. Pharm.*, **269**, 422 (1931)].

sponding esters in the pyridine series. Accordingly, we synthesized a series of 2-alkyl 3-dialkylaminoalkyl quinolinates (Table III) in the following manner. 8-Hydroxyquinoline was oxidized to quinolinic acid (pyridine-2,3-dicarboxylic acid), the latter converted into quinoline anhydride and the anhydride heated with the required alkanol. The 2-alkyl acid quinolinates[13] obtained (Table II) were treated with a dialkylaminoalkyl chloride whereby the 2-alkyl 3-dialkylaminoalkyl esters were produced.

The local anesthetic activity of these esters, in comparison with those of the aminophthalic acid esters mentioned above, is relatively low. The most active product is 2-amyl 3-(γ-dibutylaminopropyl)-quinolinate.

Bis-(β-diethylaminoethyl) quinolinate dihydrobromide was found to be inactive, even in 4% solution, when applied to the rabbit's cornea.

Experimental Part

Dialkylaminoalkyl Nicotinate Hydrochlorides.—(A) To 0.05 mole of nicotinyl chloride, dissolved in 75 cc. of dry benzene, there was added 0.05 mole of the dialkylaminoalkanol dissolved in an equal amount of the same solvent. In some instances the product separated almost immediately as an oil or solid. After one to four days the precipitate was isolated and recrystallized.

(B)[14] A mixture of 0.05 mole of the dialkylaminoalkyl chloride and 0.05 mole of nicotinic acid in 50 cc. of dry isopropyl alcohol was refluxed on a steam-bath for twelve hours. After removal of the solvent under reduced pressure, the residue was triturated with anhydrous ether. In the event that the product remained oily, it was dissolved in water, the cold solution treated with Norit, filtered, the solution extracted with ether and the base liberated from the aqueous layer with concd. potassium carbonate solution. The oily base was extracted with ether and the solution dried over anhydrous magnesium sulfate. The solvent was removed and the base treated with the calculated amount of concentrated hydrobromic acid necessary for the formation of the hydrobromide. The material became crystalline when rubbed under dry ether.

Our β-diethylaminoethyl nicotinate hydrochloride melted at 128–129°, after recrystallization from acetone, was not hygroscopic, and could be recrystallized from ethyl or isopropyl alcohol. The "β-diethylaminoethyl nicotinate hydrochloride" described in the literature[5] melted at 140–160°, after recrystallization from acetone, was hygroscopic, and could not be recrystallized from the lower alcohols.

We found that the ester base is soluble in about three parts of cold water and precipitates upon the addition of solid potassium carbonate to the solution. It boiled at 120–125° (2 mm.); the boiling point 155–157° (10 mm.) has been reported.[9] The ester base produced a burning sensation when placed on the tip of the tongue but no anesthesia was experienced.

α-Phenyl-γ-diethylaminopropanol.—A solution of 24.2 g. of phenyl diethylaminoethyl ketone hydrochloride[15] in 50 cc. of water was treated with hydrogen under an initial pressure of three atmospheres in the presence of Raney nickel catalyst.[16] The calculated amount of hydrogen was absorbed in eight hours. The solution was filtered and the cold filtrate shaken with Norit, then with Filter-Cel, filtered again and the filtrate made strongly alkaline by addition of solid sodium hydroxide. After extraction of the product with ether the solution was dried over anhydrous magnesium sulfate. The product boiled at 122–124° (2 mm.).

When hydrogen chloride was passed into an ether solution of the basic alcohol, the hydrochloride precipitated as an oil. The latter was cooled and rubbed under dry ether whereupon it became crystalline; m. p. 84–86° after recrystallization from ethyl acetate.

Anal. Calcd. for $C_{13}H_{22}ONCl$: Cl, 14.54. Found: Cl, 14.57.

β-Dicyclohexylaminoethanol.—A mixture of 25.0 g. of ethylene bromohydrin and 72.4 g. of dicyclohexylamine[17] was heated for three days on a steam-bath, the precipitated dicyclohexylamine hydrobromide filtered and washed with toluene. From the filtrate there was obtained 28.0 g. (62%) of the desired ethanol; b. p. 131–134° (2 mm.).[18]

2-Alkyl Acidquinolinates.—The necessary quinolinic acid was obtained by oxidation of 8-hydroxyquinoline according to the procedure of Sucharda[19] but the purification of the acid was effected in the following manner. The residue of crude, moist quinolinic acid nitrate obtained from 250 g. of 8-hydroxyquinoline was pulverized, placed on a Jena funnel and washed thoroughly with five 20-cc. portions of 30% nitric acid. After recrystallization from 500 cc. of 40% acetic acid, 212 g. of dark orange product was obtained. The latter was dissolved in 2 liters of boiling water and treated successively with Norit and Filter-Cel. A large portion of the material separated from the cold solution and a further amount was obtained by concentration of the mother liquor; the total yield of nearly colorless acid was 178 g. (62%); m. p. 185–190° (decomp.).[20]

In order to convert quinolinic acid into quinolinic anhydride, a mixture of 100 g. of finely powdered acid and 200 cc. of acetic anhydride was maintained at 65° and fifteen 1-cc. portions of concd. hydrochloric acid[21] were added over a three hour period. The solution was poured into 2 liters of carbon tetrachloride and the precipitated, crystalline anhydride was recrystallized from 600 cc. of dry benzene; yield 64 g. (72%); m. p. 136–138°.[22]

(13) According to Kirpal [*Monatsh.*, **21**, 957 (1900)] the major product formed from quinolinic anhydride is the 2-alkyl ester and not the isomeric 3-alkyl compound.

(14) This general procedure was used originally by Horenstein and Pählicke [*Ber.*, **71**, 1644 (1938)] for the preparation of basic alkyl esters of hydroxy acids.

(15) Blicke and Burckhalter, THIS JOURNAL, **64**, 453 (1942).

(16) "Organic Syntheses," **21**, 15 (1941).

(17) The amine was dried for three days over stick sodium hydroxide prior to use; b. p. 129–134° (121 mm.).

(18) The boiling point reported is 135° (2 mm.) (German Patent 556,324). The method of preparation was not mentioned.

(19) Sucharda, *Ber.*, **58**, 1728 (1925).

(20) Skraup [*Monatsh.*, **2**, 148 (1881)] reported 190–195° (decomp.).

(21) German Patent, 442,221; *Frdl.*, **15**, 1632 (1927).

(22) Dox [THIS JOURNAL, **37**, 1948 (1915)] found 134°.

TABLE I

DIALKYLAMINOALKYL NICOTINATE HYDROCHLORIDES, C_5H_4N-COOR·HCl

	R	M. p., °C.[a]	Formula	Chlorine, % Calcd.	Chlorine, % Found
1	$CH_2CH_2N(C_2H_5)_2$	127–128[b]	$C_{12}H_{19}O_2N_2Cl$	13.71	13.77
2	$CH_2CH_2CH_2N(C_4H_9)_2$	104–105	$C_{17}H_{29}O_2N_2Cl$	10.78	10.79
3	$CH_2CH_2N(C_6H_{11})_2$[c]	163–165	$C_{20}H_{31}O_2N_2Cl$	9.66	9.75
4	$CH(C_6H_5)CH_2CH_2N(C_2H_5)_2$	145–146	$C_{19}H_{25}O_2N_2Cl$	10.16	10.20

[a] Compound 1 was recrystallized from isopropyl alcohol; 2 from ethyl acetate; 3 and 4 from a mixture of absolute alcohol and ethyl acetate. [b] The melting point 140–160° has been reported (ref. 5). [c] C_6H_{11} = cyclohexyl.

2-Methyl acidquinolinate was obtained when a solution of 38 g. of quinolinic anhydride in 200 cc. of absolute methyl alcohol was refluxed for eight hours, the excess alcohol removed and the oily residue dissolved in 100 cc. of hot water. When the solution was cooled with ice, 39.8 g. of crude, crystalline ester separated. The latter was recrystallized from 40 cc. of water and then from 100 cc. of ethyl acetate; yield 19.1 g. (41%).

2-Amyl acidquinolinate was prepared by the same general procedure.

TABLE II

2-ALKYL ACIDQUINOLINATES

	R	M. p., °C.[a]	Formula	Neutralization equivalent Calcd.	Neutralization equivalent Found
1	CH_3	125–126[b]	$C_8H_7O_4N$	181.1	180.4
2	$CH_2(CH_2)_3CH_3$	110–111	$C_{12}H_{15}O_4N$	237.2	237.5
3	$CH_2(CH_2)_6CH_3$	104–105	$C_{15}H_{21}O_4N$	279.3	279.7
4	$CH_2(CH_2)_{10}CH_3$	106–107	$C_{19}H_{29}O_4N$	335.4	335.2
5	$CH_2CH_2C_6H_5$	139–140	$C_{15}H_{13}O_4N$	271.3	271.1

[a] Compounds 1, 3 and 4 were recrystallized from ethyl acetate; compounds 2 and 5 from water. [b] Kirpal [*Monatsh.*, **20**, 766 (1899)] reported 123°.

In the case of the 2-octyl, 2-lauryl and 2-β-phenylethyl esters, the calculated amount of the required alcohol was refluxed with the anhydride in dry toluene (50 cc. for 0.1 mole of anhydride). The crude esters were washed thoroughly with hot water before recrystallization.

2-Alkyl 3-Dialkylaminoalkyl Quinolinates.—These diesters were prepared from the dialkylaminoalkyl chloride and the 2-alkyl acidquinolinates by general procedure B, described under dialkylaminoalkyl nicotinate hydrochlorides.

To obtain γ-dibutylaminopropyl chloride, the hydrochloride[23] of this compound obtained from 18.7 g. of γ-dibutylaminopropyl alcohol was dissolved in water, the solution made alkaline with solid potassium carbonate, the liberated base extracted with ether and the extract dried with anhydrous magnesium sulfate. Upon distillation there was obtained 16.4 g. (80%) of the basic alkyl halide; b. p. 73–75° (2 mm.).

Bis-(β-diethylaminoethyl) Quinolinate Dihydrobromide.—To 20.4 g. (0.10 mole) of quinolinyl chloride,[24] dissolved in dry benzene, there was added a benzene solution of 46.8 g. (0.40 mole) of β-diethylaminoethanol. The mixture refluxed vigorously during the addition of the ethanol and β-diethylaminoethanol hydrochloride precipitated. The mixture was warmed for eight hours on a steam-bath, the precipitate removed, the benzene solution shaken with water and then with a 10% sodium carbonate solution. The benzene solution was dried with anhydrous magnesium sulfate, the solvent removed and the base triturated with the amount of 48% hydrobromic acid required for the formation of the dihydrobromide. The product became crystalline when rubbed under anhydrous ether; m. p. 157–159° after recrystallization from alcohol.

Anal. Calcd. for $C_{19}H_{33}O_4N_3Br_2$: Br, 30.31. Found: Br, 30.28.

[a] Compounds 1 and 2 were recrystallized from isopropyl alcohol; 5 from ethyl alcohol; 4 from ethyl acetate; 3 from a mixture of acetone and petroleum ether (30–40°); 6 was washed repeatedly with dry ether. [b] Hygroscopic.

Summary

Dialkylaminoalkyl nicotinates, 2-alkyl acidquinolinates and 2-alkyl 3-dialkylaminoalkyl

(23) Blicke and Otsuki, THIS JOURNAL, **63**, 2435 (1941).

(24) Obtained in 84% yield by the method of Scheiber and Knothe [*Ber.*, **45**, 2256 (1912)].

quinolinates have been described. None of the esters possessed marked activity as a local anesthetic.

ANN ARBOR, MICHIGAN RECEIVED FEBRUARY 10, 1942

[COMMUNICATION NO. 853 FROM THE KODAK RESEARCH LABORATORIES]

The Reaction of β-Isodurylaldehyde Cyanohydrin with Phenylmagnesium Bromide[1]

BY A. WEISSBERGER AND DUDLEY B. GLASS

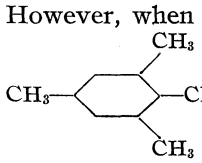
Benzoin and a number of substituted benzoins and other acyloins have been prepared by the reaction of aryl- or alkylmagnesium halides with the cyanohydrins of aryl aldehydes.[2,3] Omitting the reaction of the Grignard reagent with the active hydrogen of the cyanohydrin, and the acid used in decomposing the magnesium complex, the course of the reaction may be represented as

$$ArCHOHCN + RMgX \longrightarrow ArCHOHC(=NMgX)R \quad (1)$$

$$ArCHOHC(=NMgX)R + H_2O \longrightarrow ArCHOHC(=NH)R + Mg(OH)X \quad (2)$$

$$ArCHOHC(=NH)R + H_2O \longrightarrow ArCHOHCOR + NH_3 \quad (3)$$

The yields vary considerably, but no total failure of the reaction is reported in the literature. However, when β-isodurylaldehyde cyanohydrin,



magnesium bromide in an attempt to prepare 2,4,6-trimethylbenzoin for a study of its oxidation rate, the compound expected was not obtained. Instead, the product of the reaction was a nitrogen-containing substance with the properties of an α-aminoketone; the compound is a monohydric base, is oxidized by Fehling solution and by nitrosobenzene to 2,4,6-trimethylbenzil, and autoxidizes in alkaline solution.[4] The same substance was obtained by the following series of reactions

$$C_6H_3(CH_3)_3 + C_6H_5CH_2COCl \longrightarrow C_6H_2(CH_3)_3COCH_2C_6H_5 + HCl$$

$$C_6H_2(CH_3)_3COCH_2C_6H_5 + C_4H_9NO_2 \longrightarrow C_6H_2(CH_3)_3COC(=NOH)C_6H_5 + C_4H_9OH$$

$$C_6H_2(CH_3)_3COC(=NOH)C_6H_5 + 4H(SnCl_2) \longrightarrow C_6H_2(CH_3)_3COCHNH_2C_6H_5 + H_2O$$

I

This synthesis establishes the position of the oxygen and nitrogen atoms in respect to the mesitylene and benzene nuclei and identifies the compound as 2,4,6-trimethyldesylamine (I) or its tautomer (II).

If one considers the work of Kohler[5] and of Fuson,[6] who have shown that in compounds of the types $C_6H_2(CH_3)_3COCH=$ and $C_6H_2(CH_3)_3CHOHC\equiv$ the mesitylene residue promotes the formation and enhances the stability of the enolic form $C_6H_2(CH_3)_3C(OH)=C<$, the anomalous course of the reaction of β-isodurylaldehyde cyanohydrin with phenylmagnesium bromide can be understood. With the mesitylene derivative, the imino compound, which ordinarily undergoes acid hydrolysis, eq. 3, is transformed by enolization into the amino compound II, eq. 4, which resists hydrolysis. This or the tautomeric amine I separates from the acid solution as the hydrochloride.

$$C_6H_2(CH_3)_3CHOHC(=NH)C_6H_5 \longrightarrow C_6H_2(CH_3)_3C(OH)=C(NH_2)C_6H_5 \quad (4)$$

II

The phase in the sequence of reactions in which the enolization occurs is indicated by the reaction of β-isoduraldehyde cyanohydrin with methylmagnesium iodide.[7] β-Isoduraldehyde cyanohydrin consumes two moles of the Grignard reagent and evolves one mole of methane. This agrees with the structure of the resulting complex as that of the imino derivative $ArCH(OMgBr)C(=N-MgBr)R$. The tautomeric enamino compound $ArC(OMgBr)=C(NHMgBr)-R$ should evolve another mole of methane. Hence, the amino compound is not formed before the hydrolysis of the Grignard complex.

The explanation of the anomalous reaction of β-isoduraldehyde cyanohydrin with phenylmag-

nesium bromide as given above is corroborated by the results of the hydrolysis of desylamine and of 2,4,6-trimethyldesylamine by heating with dilute hydrochloric acid. Under conditions that yield 40% of benzoin from desylamine, the 2,4,6-trimethyldesylamine remains unchanged. Under more drastic conditions a quantitative yield of benzoin is obtained while only about 20% of the 2,4,6-trimethyldesylamine is affected. Such results would be expected if the reaction mixture of the desylamine contains appreciable quantities of the imino compound, while the reaction mixture of the 2,4,6-trimethyldesylamine is composed almost exclusively of the enamine and/or the aminoketone.

On acetylation, trimethyldesylamine gives a monoacetate, and under very vigorous conditions, a triacetate. Formulation of these compounds as $(CH_3)_3C_6H_2C(OH)=C(NHCOCH_3)C_6H_5$ and $(CH_3)_3C_6H_2C(OCOCH_3)=CN(COCH_3)_2C_6H_5$ is in agreement with the solubility of the monoacetate in dilute and in concentrated hydrochloric acid, and the results of the "Grignard Machine" analysis. The monoacetate dissolves in a 1:1 mixture of alcohol and concentrated hydrochloric acid. Upon addition of more concentrated hydrochloric acid no precipitation occurs, while upon addition of water the acetate precipitates. The monoacetate shows two active hydrogen atoms and does not add methylmagnesium iodide. As in acetanilide, the acetyl group in the monoacetate is too tightly bound to be eliminated under the conditions of this analysis. The triacetate has no active hydrogen and uses up four moles of methylmagnesium iodide in splitting off two of the acetyl groups; from the reaction mixture the monoacetate can be recovered. The monoacetate of desylamine on the other hand reacts as $C_6H_5COCH(NHCOCH_3)C_6H_5$, showing only one active hydrogen, and using up one mole of methylmagnesium iodide, presumably in an addition to the carbonyl group. These results again demonstrate the difference between the derivative of benzene and of mesitylene, and the enolizing effect of the mesityl group.

The oxidation of trimethyldesylamine with molecular oxygen at a *p*H of 12.8 is about ten times faster than that of desylamine[8] under the same conditions. Since the reactive species of the α-aminoketone in this reaction is the enolate ion,[4] this result again indicates the higher tendency for enolization of the mesitylene derivative.

The reasons for this higher degree of enolization may be tentatively discussed. The stability of the enolic double bond depends on the degree of resonance between this double bond and the aromatic system. Several conditions might favor this resonance. A steric factor comes first to mind in connection with a compound of the marked stereochemical characteristics of mesitylene. For maximum degeneracy the resonating system must lie in one plane. It might, therefore, be suggested that the stability of the enolic double bond in mesitylene derivatives is increased because the double bond is forced into the plane formed by the aromatic system. However, a repulsion between the two methyl groups in the ortho positions and a group on the α-carbon atom would not produce such an effect. An attraction between the methyl groups and a group on the α-carbon atom would serve the purpose, but is, in itself, not likely to occur. A more probable reason for the increased stability of the aromatic-olefinic conjugated system in mesitylene derivatives lies in the high electron density in the mesitylene nucleus. The latter is indicated by the direction of the dipole moments of toluene and of *m*-xylene, and by the great reactivity of mesitylene with anionotropic reagents. It appears that the electron distribution of mesitylene, as compared with that of benzene, increases the degeneracy of the enolic-aromatic conjugation, and stabilizes the enolic double bond.

Experimental

β-Isodurylaldehyde was prepared from mesitylene, zinc cyanide, and hydrogen chloride by the method of Hinkel, Ayling and Morgan.[9] The yield of aldehyde was 75%. The aldehyde was purified by conversion to the anil, distillation and crystallization of the anil and, after hydrolysis of the anil, redistillation of the aldehyde. The yield of pure aldehyde was 60%, b. p. 113–115° (11 mm.), $n^{20}D$ 1.5505.

β-Isodurylaldehyde Cyanohydrin.—A solution of 44.4 g. (0.3 mole) of β-isodurylaldehyde in 240 cc. of petroleum ether was shaken vigorously for fifteen minutes with a solution of 52 g. (0.8 mole) of potassium cyanide and 44.4 g. (0.83 mole) of ammonium chloride in 135 cc. of water. The flask was closed tightly during the agitation. The resulting crystals were removed by filtration, washed with water and then petroleum ether, and dried in a vacuum desiccator over calcium chloride. There resulted 48 g. (91%) of cyanohydrin which melted at 106–107° (sealed tube) after recrystallization from two volumes of benzene.

(8) We are indebted to Mr. D. S. Thomas of these laboratories for the determination of the autoxidation rates.

Anal. Calcd. for $C_{11}H_{13}ON$: C, 75.40; H, 7.48; N, 7.99. Found: C, 75.30; H, 7.50; N, 8.00.

2,4,6-Trimethyldesylamine Hydrochloride from β-Isodurylaldehyde Cyanohydrin and Phenylmagnesium Bromide.—To a Grignard solution prepared from one-half molar quantities of magnesium and bromobenzene in 375 cc. of ether, was added with stirring a solution of 17.5 g. (0.1 mole) of β-isodurylaldehyde cyanohydrin in 200 cc. of dry ether during a period of five minutes. The reaction mixture was heated under reflux on a steam-bath for fifteen minutes and then was poured onto a mixture of 1 kg. of ice and 200 cc. of concentrated hydrochloric acid. The mixture was stirred for a minute, the layers were separated, and the aqueous layer was extracted immediately with 200 cc. of ether and filtered. Then 200 cc. of concentrated hydrochloric was added. The flask was stoppered and allowed to stand for two days at 25±5°. The precipitate was removed by filtration, washed with water and ether, and dried in air. The yield was 16 g. (55%) of hydrochloride which melted at 287–289° (sealed tube). The substance was brought to analytical purity by dissolving in 150 cc. of 70% aqueous alcohol, filtering the solution and precipitating the hydrochloride with 300 cc. of concentrated hydrochloric acid. After cooling to around 15°, the hydrochloride was collected on a filter and recrystallized from 70% alcohol to which had been added 1% of hydrochloric acid; m. p. 290–291° (sealed tube).

Anal. Calcd. for $C_{17}H_{20}ONCl$: C, 70.45; H, 6.96; N, 4.83. Found: C, 70.10; H, 6.70; N, 4.88.

2,4,6-Trimethyldesoxybenzoin was prepared from mesitylene, phenylacetyl chloride and aluminum chloride in petroleum ether by the method of Klages.[10] There was obtained an 88% yield of ketone which boiled at 136–137° (0.5 mm.).

Isonitroso-2,4,6-trimethyldesoxybenzoin.—The 2,4,6-trimethyldesoxybenzoin was converted into the isonitroso derivative by a method similar to that used by Hartung and Munch[11] for the preparation of isonitrosopropiophenone. A solution of 88 g. (0.37 mole) of 2,4,6-trimethyldesoxybenzoin and 42 g. (0.41 mole) of redistilled butyl nitrite (b. p. 78–79°) in 275 cc. of ether was stirred, and dry hydrogen chloride was introduced at the rate of four to five bubbles per second for two and one-half hours. At the end of this time the flask was stoppered and allowed to stand overnight. Ether (300 cc.) was added and the oxime was extracted from the ethereal solution with one 450-cc. portion of 5% sodium hydroxide solution, and three 150-cc. portions of 3% sodium hydroxide solution. The alkaline extracts were combined, filtered and run into a mixture of ice and excess concentrated hydrochloric acid. The precipitate was removed by filtration and dried in air; yield 75 g. (76%); m. p. 152–153.5°. A sample recrystallized from alcohol melted at 156–156.5°.

2,4,6-Trimethyldesylamine Hydrochloride by the Reduction of Isonitroso-2,4,6-trimethyldesoxybenzoin.—A solution of 225 g. (1.0 mole) of stannous chloride in 500 cc. of concentrated hydrochloric acid was added rapidly to a solution of 53.4 g. (0.2 mole) of isonitroso-2,4,6-trimethyldesoxybenzoin in 500 cc. of alcohol. The reaction mixture was then heated under reflux on the steam-bath for one and one-half hours. After standing overnight at room temperature, the precipitate was removed by filtration and dried in air; yield 50 g. (86%). A sample was recrystallized from 60% alcohol to which had been added a little hydrochloric acid; m. p. 289–290° (sealed tube).

Anal. Calcd. for $C_{17}H_{20}ONCl$: N, 4.83. Found: N, 4.74.

Acetates of 2,4,6-Trimethyldesylamine: Monoacetate.—Ten grams of 2,4,6-trimethyldesylamine hydrochloride prepared by the Grignard method was added to a mixture of 100 cc. of acetic anhydride and 20 cc. of pyridine and the mixture was heated on the steam-bath for ten minutes. At the end of this time, the reaction mixture was poured onto ice and stirred until the anhydride had decomposed. The product was removed by filtration and crystallized from a benzene–ligroin mixture (1:2); m. p. 174.5–175°.

Anal. Calcd. for $C_{19}H_{21}O_2N$: C, 77.26; H, 7.17; N, 4.74; mol. wt., 295. Found: C, 77.50; H, 7.03; N, 4.76; mol. wt. (in benzene), 296, 300.

The 2,4,6-trimethyldesylamine hydrochloride prepared by the reduction method was carried through the same procedure. It acted in all ways identically with the amine hydrochloride prepared by the Grignard method. The acetates gave no depression in a mixed melting point test.

Triacetate.—Five grams of 2,4,6-trimethyldesylamine hydrochloride prepared by the Grignard method was added to a mixture of 50 cc. of acetic anhydride and 10 cc. of pyridine and the mixture was heated for seven hours on the steam-bath under a reflux condenser closed by a calcium chloride tube. After standing overnight, the reaction mixture was diluted with 250 cc. of warm (*ca.* 50°) water and stirred until the anhydride had decomposed. The precipitate was ground in a mortar with water and then recrystallized from 15 cc. of alcohol; m. p. 125–126°.

Anal. Calcd. for $C_{23}H_{25}O_2N$: C, 72.80; H, 6.64; N, 3.69; mol. wt., 379. Found: C, 73.01; H, 6.65; N, 3.71; mol. wt. (in benzene), 373, 368.

The 2,4,6-trimethyldesylamine hydrochloride prepared by reduction behaved identically with that prepared by the Grignard method. The triacetates gave no depression in a mixed melting point test.

Hydrolysis of Triacetate to Monoacetate.—One gram of triacetate was dissolved in 15 cc. of warm alcohol and 5 cc. of concentrated hydrochloric acid was added. The solution was boiled on the steam-bath for ten minutes, cooled and diluted with 50 cc. of water. The precipitate was removed by filtration and recrystallized from ligroin; m. p. 173–174°. On addition of known monoacetate, the melting point was unchanged.

Hydrolysis of Triacetate to Amine.—One gram of triacetate was added to a mixture of 10 cc. of alcohol and 10 cc. of concentrated hydrochloric acid and the solution boiled for five hours under reflux. The solution was cooled and allowed to stand in the ice box for two hours. The precipitate of 2,4,6-trimethyldesylamine hydrochloride was removed by filtration, washed with alcohol and dried in air; m. p. 283–285° (sealed tube). A small sample of the product was dissolved in 70% alcohol and allowed to stand in an unstoppered test-tube for one week. The precipitate was removed by filtration and dried in air; m. p. 134–135°. A mixed melting point with a known sample of 2,4,6-trimethylbenzil showed no depression.

(11) Hartung and Munch, THIS JOURNAL, **51**, 2262 (1929).

Acetates of Desylamine. Monoacetate.—The monoacetate of desylamine[12] was prepared by the method used for the preparation of the monoacetate of 2,4,6-trimethyldesylamine; m. p. 135–136°.

Anal. Calcd. for $C_{16}H_{15}O_2N$: C, 75.87; H, 5.97; N, 5.53. Found: C, 76.12; H, 5.89; N, 5.51.

Triacetate.—Five grams of desylamine hydrochloride was heated on a steam-bath for eight hours with 50 cc. of acetic anhydride and 10 cc. of dry pyridine. At the end of this time 200 cc. of water was added and the mixture was stirred until the anhydride had decomposed. The aqueous portion was decanted and the gummy residue was washed with water. The gum was dissolved in 125 cc. of ligroin, and the solution was treated with Norit and filtered. After standing for twenty hours, the precipitate was collected on a filter and recrystallized from four volumes of methanol; m. p. 130–131°.

Anal. Calcd. for $C_{20}H_{19}O_4N$: C, 71.20; H, 5.68; N, 4.15. Found: C, 71.20; H, 5.62; N, 4.05.

RESULTS OF THE "GRIGNARD MACHINE" ANALYSES[7]

Compound	Reaction time	Active hydrogen	Addition
2,4,6-Trimethyldesylamine hydrochloride	10 min.[a]	3	0
2,4,6-Trimethyldesylamine monoacetate	1 hr.	2	0
2,4,6-Trimethyldesylamine triacetate[b]	1 hr.	0	4
β-Isodurylaldehyde cyanohydrin	10 min.	1	1
Desylamine monoacetate	1 hr.	1	1

[a] Upon prolonged heating the value of the active hydrogen approached 4. [b] The reaction mixture yielded the monoacetate upon being worked up.

(12) Davidson, Weiss and Jelling, *J. Org. Chem.*, **2**, 319 (1937).

Hydrolysis of 2,4,6-Trimethyldesylamine and of Desylamine.—(a) A mixture of 1 g. of the amine hydrochloride, 5 cc. of water, 5 cc. of concentrated hydrochloric acid, and 10 cc. of ethanol was heated at 95° in a sealed tube under nitrogen for twenty hours. Benzoin in a 40% yield separated and was collected on the filter. Under the same conditions 2,4,6-trimethyldesylamine was unaffected.

(b) Same as (a) except heated at 130° for twenty-four hours. Desylamine gave a quantitative yield of benzoin. 2,4,6-Trimethyldesylamine yielded 20% of a mixture of 2,4,6-trimethylbenzoin and 2,4,6-trimethylbenzil.

Summary

1. 2,4,6-Trimethyldesylamine has been prepared by the reaction of phenylmagnesium bromide with β-isodurylaldehyde cyanohydrin and also by the reduction of isonitroso-2,4,6-trimethyldesoxybenzoin.

2. The reactions of 2,4,6-trimethyldesylamine and desylamine with dilute hydrochloric acid were compared.

3. The autoxidation rate of 2,4,6-trimethyldesylamine was compared with that of desylamine.

4. The mono- and triacetate of 2,4,6-trimethyldesylamine were prepared and their reactions with dilute hydrochloric acid and with methylmagnesium iodide were studied.

5. The results obtained were ascribed to the propensity toward enolization shown by acetomesitylene derivatives.

Tri-*o*-tolyltin and the Instability of Organo-metallic Free Radicals

BY HUMBERT MORRIS, WARD BYERLY AND P. W. SELWOOD

Previous magnetic measurements on triphenylgermanium,[1] triphenyllead,[2] trimethyltin[3] and tricyclohexyllead[3] have shown that all these compounds exist in the diamagnetic or dimeric state. Molecular weight measurements by others have, on the contrary, consistently indicated partial or complete dissociation to the free radical. These results raise two questions: first, why do these compounds not exist as free radicals and, second, why do the magnetic measurements contradict the molecular weight measurements?

A possible answer to the first question is to be found in the much larger radius of the metal atoms as compared with carbon, as in triphenylmethyl. It has been suggested[3] that the increased radius leads to a much greater number of effective collisions leading to formation of the dimer, and that a compound such as tri-*o*-tolyltin, in which steric effects are large, might exist as a free radical. This hypothesis is tested in the work reported here.

An effort to answer the second question by repeating ebulliometric measurements on trimethyltin and on triphenyllead is also reported.

Experimental Part

Magnetic Measurements.—The magnetic susceptibilities were measured on the Gouy balance previously de-

scribed.[2] Measurements were made at 25 and 80°, benzene being used as the solvent. A field strength of about 13,100 oersteds was used throughout.

Ebulliometric Measurements.—These were made by means of a Swietoslawski differential ebulliometer.[4] The temperature differences were measured with an 8-junction thermocouple.

Preparation of Tri-*o*-tolyltin.—*o*-Bromotoluene was prepared from *o*-toluidine by diazotization and the Sandmeyer reaction.[5] Tetra-*o*-tolyltin was made by treating the Grignard reagent with stannic chloride. The Grignard reagent from 150 g. (0.88 mole) of *o*-bromotoluene and 21.5 g. of magnesium was refluxed with 33 g. (0.14 mole) of stannic chloride for twelve hours in ether. Water and dilute hydrochloric acid were added, and the ether evaporated off. The sludge was filtered dry and then refluxed in benzene to dissolve the tetra-*o*-tolyltin. The benzene solution was filtered and concentrated. White, powdery crystals were formed as the red-brown solution cooled. Two crops of crystals were obtained and recrystallized; yield, 15 g. ($^1/_{30}$ mole); melting point 200–215°. According to Krause and von Grosse[6] the melting point of tetra-*o*-tolyltin is 214–215°.

Tri-*o*-tolyltin bromide was prepared according to the method of Chambers and Scherer.[7] The tetra-*o*-tolyltin was dissolved in chloroform and treated with 6.5 g. of iodine. It was then shaken with 30% sodium hydroxide to convert it to the hydroxide and to remove di-*o*-tolyltin oxide, which is water-soluble. The water layer was separated, and the bromide was formed by shaking with dilute hydrobromic acid. The $(o\text{-tolyl})_3SnBr$ crystallizes with difficulty from chloroform, but it separates readily from petroleum ether; yield 1.5 g.; melting point 94–96°. The melting point is 97.5° according to Krause and von Grosse.[6]

The $(o\text{-tolyl})_3SnBr$ does not react with molecular silver; 0.1 g. of the halide was shaken with 0.1 g. of molecular silver for two hours. It was filtered and recrystallized from petroleum ether. The melting point of the product was 89–93°.

The halide was reacted with sodium in absolute alcohol, according to the method of Krause and Becker.[8] The halide in 18 cc. benzene was treated with 18 cc. of alcohol and 2 g. of sodium. Then it was shaken with water. The benzene layer was separated, washed, dried, concentrated, and cooled in snow. A fine white powder was obtained which melted at 208–212°. After recrystallization from petroleum ether, the melting point was 208–210°; yield, 0.25 g. It was dried in vacuum at 50°.

A molecular weight determination in freezing benzene gave the following results

Molality (as R_6Sn_2)	0.0175	0.0278	
Apparent mol. wt.	664	825	±30

The molecular weight calculated for $(o\text{-tolyl})_6Sn_2$ is 784. For reasons to be discussed below not much consideration should be given the molecular weight determination.

Analyses by T. S. Ma of the University of Chicago.

	Calculated for $(o\text{-tolyl})_6Sn_2$, %	Found, %	
Sn	30.4	29.73	29.95
H	5.4	5.19	5.20
C	64.4	63.27	63.16

This compound does not appear to have been previously reported.

Results

In order to treat the data it is necessary to know the diamagnetic susceptibility of hexa-*o*-tolylditin. The amount of this substance available was too small for direct measurement. The susceptibility was, therefore, calculated from Pascal's constants and the known susceptibility of hexamethylditin.[3] The susceptibility of this compound is -0.51×10^{-6} and the molar diamagnetism is -167×10^{-6}. The molar diamagnetism of quadricovalent tin is, therefore, nearer 39 than the usually accepted value of 30.[9]

For six phenylene groups plus six methyl groups the constants are $(6 \times 49.3) + (6 \times 14.85) \times 10^{-6} = 384.9 \times 10^{-6}$. Two quadricovalent tin atoms raise this to 462.9×10^{-6}. This number divided by the molecular weight gives -0.59×10^{-6} as the susceptibility of hexa-*o*-tolylditin per gram. Even if this value is as much as ten per cent in error it will not seriously affect the validity of the conclusions to be drawn from the work described here.

In the following table the susceptibilities of the solution are calculated for zero dissociation and for complete dissociation. These data are compared with the observed susceptibilities. Methods of calculation are given elsewhere.[2]

TABLE I

SUSCEPTIBILITY OF A 0.25 *M* SOLUTION OF TRI-*o*-TOLYLTIN IN BENZENE

Temp., °C.	Calcd. for zero diss. $\chi \cdot 10^6$	Calcd. for complete diss. $\chi \cdot 10^6$	Observed $\chi \cdot 10^6$
25	−0.700	−0.638	−0.7003
80	−0.701	−0.659	−0.705

It is clear from this table that the compound exists as hexa-*o*-tolylditin. At 25° as little as 2%, and at 80° as little as 4% dissociation could have been detected.

This work constitutes proof that steric considerations are in themselves insufficient to produce dissociation, although they may greatly modify

the degree of dissociation, as has been shown for the hexaarylethanes.[10,11] The work also increases the probability previously suggested[3] that no stable organo-metallic free radical has yet been prepared. The metal ketyls are, of course, dissociated, but the dissociation does not involve a metal-metal bond.

The question as to why organo-metallic free radicals are of such low stability remains unanswered. It is not simply a matter of relative sizes of metal and carbon atoms. It is apparently not a matter of relative electronegativities because tetraarylhydrazines are known to dissociate.[12] Whatever the underlying cause may be, it evidently inhibits the resonance, or other phenomenon, which is a necessary adjunct to free radical formation. The recent observation of Bauer and Beach [THIS JOURNAL, **64,** 1142 (1942)] on the structure of hexamethylethane suggests a clue to the instability of organo-metallic free radicals. They report a probable stretching of the central C–C bond to 1.58 ± 0.03 Å. It is possible that in hexaarylethanes still more stretching occurs with consequent weakening of the ethane bond. But in the cases of the organometallic compounds such as hexaphenylditin, the tin atoms are so large that no stretching of the Sn–Sn bond is necessary. There is, therefore, no weakening of the bond and no tendency to form free radicals. The same interpretation may be applied to the corresponding compounds of silicon, germanium and lead.

It may be worth noting that the known free radical forming elements are limited to carbon, nitrogen, oxygen, possibly sulfur, and chlorine. Thus paramagnetic molecules are formed by these elements, but the diboranes,[13] hexaaryldisilanes[14] and tetraaryldiarsines (*e. g.*, phenyl cacodyl),[15] which might be expected to dissociate, do not. Schönberg and Rupp[16] suggest that diphenylene disulfide may dissociate, while nothing is known of the tetraaryldiphosphines.

The remaining question is: why do the magnetic measurements contradict the molecular weight determinations? In this connection it should be pointed out that the dielectric measurements of Lewis, Oesper and Smyth[17] on triphenyllead exclude the remote possibility of an electrolytic type of dissociation.

Ebulliometric measurements were made on benzene solutions of trimethyltin and triphenyllead with the results given in Tables II and III.

TABLE II

BOILING POINT ELEVATION PRODUCED BY 0.9418 G. OF $(CH_3)_3Sn$ DISSOLVED IN 104 CC. OF BENZENE

10	0.049
25	.027
55	.024
145	.008
Calcd. elevation for the dimer	.073

It is clear from these results that decomposition rapidly occurs, and that, even during the ten-minute interval necessary for the apparatus to come to equilibrium, considerable destruction of the compound must take place. In no case was the apparent molecular weight less than that of the dimer. During the test on triphenyllead a visible precipitate was formed during the first 30 minutes. It is, therefore, obvious that ebulliometric measurements are of as little value for the study of organo-metallic free radicals as they are for hexaarylethanes.[18] No attempt was made to determine the nature of the decomposition products from these compounds, but it is possible that they were similar to those reported by Calingaert, Soroos and Shapiro[19] as disproportionation products of R_6Pb_2 compounds.

Summary

Tri-*o*-tolyltin has been prepared and shown by magnetic measurements to be dimeric. Ebulliometric measurements on solutions of trimethyltin and of triphenyllead emphasize the unreliability of such methods for the study of free radicals.

NOTES

The Crystal Structure of Calcium Cyanamide

By M. A. Bredig*

When the reactivity of calcium carbide as a function of its crystal structure was studied by means of X-ray diffraction methods,[1] calcium cyanamide, product of its reaction with nitrogen, also was included. Very considerable discrepancies were observed between the positions of the X-ray lines obtained and those reported in a previous attempt to determine the structure by U. Dehlinger.[2] Recently, calcium cyanamide was listed among the first thousand substances of which X-ray data were assembled for use with the Hanawalt X-ray method of chemical analysis.[3] An examination of the figures given for calcium cyanamide indicated that the preparation used must have contained very little calcium cyanamide and that merely the X-ray interferences of calcium carbonate, of calcium hydroxide, and of graphite, major impurities and decomposition products of calcium cyanamide, were recorded. A reëxamination of the X-ray data of this industrially important compound appeared desirable.

A Debye–Scherrer–Hull powder diagram of a commercial grade, finely pulverized calcium cyanamide, containing approximately 70% calcium cyanamide, was obtained with copper K_α radiation in an X-ray camera of 57.5 mm. diameter. The sample was contained in a thin-walled Lindemann glass tube, and was not rotated during the exposure. The X-ray interferences of calcium hydroxide, principal impurity of this sample, were very easily distinguished from the dotted lines of calcium cyanamide, due to the much coarser grains of the latter. They were used as reference lines with which the data, for calcium hydroxide, of Hanawalt, Rinn and Frevel, and those of Landolt-Börnstein, Supplement Vol. IIb, were in perfect agreement, as the table shows. The interplanar distances of calcium cyanamide, as measured and as calculated with new rhombohedral lattice constants, $\alpha = 39°55'$ and $a_{rh} = 5.40$ Å., corresponding to a hexagonal lattice with the constants $c =$ 14.85 and $a = 3.67$ Å., are in very satisfactory agreement. The specific gravity becomes 2.29.

The rhombohedral lattice constants $\alpha = 43°50'$ and $a_{rh} = 5.11$ Å., and the hexagonal lattice constants $c = 14.1$ and $a = 3.91$, as given by Dehlinger, do not agree with his own experimental data, nor are they even compatible with each other. Dehlinger pointed to the agreement between the rhombohedral angle, calculated by him for the larger unit cell, containing four molecules of calcium cyanamide, with a figure (74°), determined on single crystals under the microscope by C. H. Warren.[4] However, two different angles were erroneously compared by Dehlinger, namely, the angle between the rhombohedral axes of the larger cell, calculated by him as 73°, and the cleavage angle of 74°, measured by Warren. Actually, 68°, as measured by Warren for the angle of the rhombohedral axes of the cleavage rhombohedron would have been the figure with which to compare Dehlinger's figure 73°, with no agreement to be observed. With Warren's figure 68°, however, the angle 68°15', as calculated from the data of the present investigation, agrees very well, and the

same is true for the cleavage angle of 74°15′ (this paper) and 74° (Warren).

The structure of calcium cyanamide is entirely analogous to that of sodium azide, NaN_3, determined by S. B. Hendricks and L. Pauling[5] and confirmed recently by M. Bassière.[6] The cations occupy the positions 000, the carbon atoms the positions $\frac{1}{2}\frac{1}{2}\frac{1}{2}$, and the nitrogen atoms the positions $\pm$ (uuu). The parameter u was assumed by Dehlinger as 0.37. With this figure, the distance C–N was calculated by Dehlinger as 1.59 Å., while actually the calculation from his own data, $14.1\cdot(0.50 - 0.37)$, should have yielded 1.84 Å., an impossibly large value, compared with 1.17 Å. for the distance N–N, in sodium azide. A comparison of the intensities, as observed in the present investigation, with those calculated by using ionic scattering factors, as compiled by James and Brindley,[7] yields the parameter $u = 0.422 \pm 0.005$. The distance C–N becomes 1.16 ± 0.08 Å., and the distance Ca–N 2.49 ± 0.04 Å., which compares with 2.48 Å. for Na–N in sodium azide.

No attempt was made to refine the discussion of the X-ray intensities as much as to find the possible asymmetry in the position of the two nitrogen atoms, and to thereby determine whether the cyanamide anion has the carbodiimide structure —N=C=N— or the true cyanamide form =N—C≡N. The agreement between the values of the distances in the azide anion, in sodium azide, as obtained by M. Bassière[6] through a discussion of the X-ray intensities, 1.10 and 1.26 Å., and those previously determined for the azide radical in cyanogen azide $(CN)N_3$ by E. Knaggs,[8] 1.11 and 1.26 Å., and in methyl azide by Brockway and Pauling,[9] has not been supported by the former with sufficiently convincing proof. The asymmetry in the N_3^- ion is, in fact, highly improbable.[10] It also seems quite doubtful whether the accuracy of the method employed was sufficient to determine, from the agreement of the X-ray intensities, as observed and as calculated, the asymmetry in the distances C–O (1.13 Å.) and C–N (1.21 Å.),[11] in sodium isocyanate, NaNCO, another compound, isomorphous with calcium cyanamide.

The thanks of the author are due to Professor L. Thomassen for the permission to use the X-ray equipment of the Department of Chemical and Metallurgical Engineering of the University of Michigan.

Photoactivation of Adsorption of Hydrogen on Thorium Oxide[1]

BY A. LUYCKX,[2] J. BODART AND G. RENS

It is known[3] that activated adsorption of hydrogen requires an energy of activation. The hydrogen so adsorbed is supposed to be dissociated into atoms, this dissociation occurring on the surface of the catalyst during the adsorption. Confirmation of this assumption has been sought in the following experiments.

The temperature at which activated adsorption is observable is often several hundred degrees higher than the temperature of van der Waals adsorption, notably on oxide surfaces. We have sought to employ light instead of heat as the activating agent. In earlier work it has been found[4] that adsorption of certain solutes in solution could be photoactivated. Also, at 230°, the reaction between nitrous oxide and hydrogen in presence of boron nitride phosphors indicated a slight rise in reaction rate when irradiated with ultraviolet light. Other reactions on several catalysts and at different temperatures gave negative results.

We have studied the photo-activation of hydrogen adsorption on various catalysts with positive results which we shall illustrate with thorium oxide, prepared by calcination of the nitrate. The oxide so obtained was heated and evacuated in a quartz vessel at 700° for several hours. Electro-

(1) The original version of this Note was received from the authors on August 13, 1941, and was accepted by the Editorial Board subject to some revisions which were embodied in a revised manuscript kindly prepared by Professor Hugh S. Taylor, which was sent to the authors on November 13, 1941, for their approval. Since it has proved impossible to get any word from occupied Belgium where the authors reside, it has seemed wisest, in order to avoid any further delay, to publish this present version now, in spite of the fact that the authors have had no opportunity to express their approval or disapproval of it.—THE EDITOR

lytic hydrogen was introduced to the cold adsorbent, to give a pressure of 2 mm. During the first seconds following the introduction of hydrogen a slight fall in pressure was observed owing to van der Waals adsorption.

Irradiation of the system, after the pressure becomes constant, with the light from a mercury lamp produces a regular and continuous decrease of pressure, which could be followed by means of a McLeod gage, during several hours. In favorable cases an irradiation of ten hours results in practically complete hydrogen adsorption. Further additions of hydrogen are adsorbed upon irradiation. Rates up to 1 cc. of hydrogen at 2.3 mm. pressure per minute, for 40 sq. cm. of irradiated surface and 18 g. of ThO_2, have been observed. In one case, more than 8 cc. of hydrogen at N. T. P. was taken up by 100 g. of thoria. Thermally activated adsorption on our thoria sample was observable at 420°.

Adsorption is only observable with the irradiation from a cold mercury lamp, which indicates that resonance radiation is involved and that it is atomic hydrogen which is taken up by the adsorbent. The formation of atomic hydrogen may occur in the gas phase by the Frank–Cario mechanism with excited mercury atoms. We can also imagine molecules adsorbed on the surface by van der Waals forces being dissociated by transference of energy from mercury atoms. We cannot yet decide between these alternatives. Comparison with the rate of reduction of tungstic oxide in the Frank–Cario experiment suggests a diffusion of atomic hydrogen to the surface.

At 20–30 mm. pressure no photoactivation is measurable. After subsequent lowering of the pressure to 2 mm., photoactivation is again observable, but at one-half to one-third the normal rate. We interpret this as due to an adsorbed molecular layer of hydrogen protecting the adsorption centers. Lowering the pressure does not uncover all such centers. Complete evacuation is necessary. When this is done the normal rate of photoactivated adsorption at 2 mm. pressure is found.

After many days of alternate irradiation and evacuation at 700° the rate of adsorption slowly decreases and falls to one-tenth of its initial value. If after evacuation at 700° air is introduced at atmospheric pressure and room temperature and then evacuated at room temperature, introduction of hydrogen at 2 mm. pressure followed by resonance irradiation restores the initial rate of hydrogen adsorption. The presence of oxygen on the surface of the catalyst is thus essential. This is confirmed by the observation that thoria samples heated in hydrogen to 700–800° and then evacuated at this temperature do not show hydrogen adsorption on irradiation unless oxygen is again introduced. Analysis of the gas desorbed after either thermal or photoactivated adsorption shows the presence of oxygen only.

We have found an increase in the rate of thermally activated adsorption of hydrogen by chromium oxide and by reduced nickel when a certain amount of oxygen was introduced to the adsorbent.

Hedvall uses the term photoactivation of adsorption when the light is absorbed by the crystals and their activity is changed by the irradiation. We must consider, however, the cases in which adsorbent and gas are both excited by irradiation or the gas alone. In practice it will not be easy to decide between the several processes. We use the general term photo-activation of adsorption when we can measure an adsorption of gas by a surface owing to light irradiation.

On the Structure of Fucosterol

BY H. B. MACPHILLAMY

Fucosterol was first isolated from the alga, *Fucus vesiculosus*, by Heilbron, Phipers and Wright.[1] These workers showed that the sterol had the empirical formula $C_{29}H_{48}O$ and that it was a bond isomer of stigmasterol. They further stated that both double bonds were situated in the nucleus, since treatment with ozone failed to give ethylisopropylacetaldehyde. Additional evidence indicated the absence of a conjugated system, while the ease with which stigmastanol was formed on hydrogenation showed the lack of any "inert" double bonds. Later it was proved that one of the ethylenic linkages occupied the 5-6 position.[2] In view of Sobotka's[3] suggestion that the second double bond might be located in the 11–12 position, which would render the sterol a suitable starting material for the synthesis of cortical

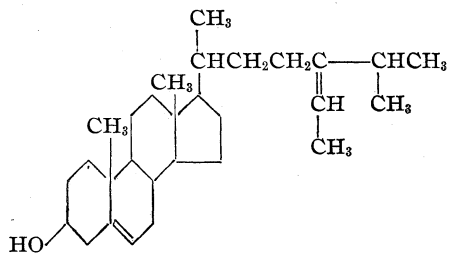
hormones, the complete elucidation of its structure seemed desirable.

It was decided, first of all, to reinvestigate the ozonization reaction. The failure of Heilbron, *et al.*,[1] to isolate ethylisopropylacetaldehyde cannot be considered conclusive evidence for the lack of unsaturation in the side chain, since the later work of this author on zymosterol[4] has shown that side chain double bonds in sterols may occupy positions other than 22–23. The result of our study showed that fucosterol indeed presents a similar case. In two separate experiments acetaldehyde could be isolated as the *p*-nitrophenylhydrazone from the products of the ozonolysis. The yield of aldehyde was over 30% in both cases, which precludes the possibility that it may have been derived from an impurity or formed in a secondary reaction. Since position 24–28 for the double bond in question is the only one which would account for the formation of acetaldehyde by ozonolysis, is it suggested that the structure of fucosterol is best represented by the accompanying formula.



Experimental

Isolation of Fucosterol.—The material used for this work was obtained from a quantity of *Fucus vesiculosus* gathered along the New Jersey coast. About 22.5 kg. of the dried sea weed was ground and percolated thoroughly with ether. After evaporation of the solvent 650 g. of extracted material remained. The residue was saponified overnight at room temperature and on purification yielded 40 g. (0.18%) of sterol. Several recrystallizations from methanol gave pure fucosterol, the physical properties of which agreed quite closely with those given by Heilbron,[1] as shown in the following table

	MacPhillamy M. p., °C.	$[\alpha]_D$	Heilbron M. p., °C.	$[\alpha]_D$
Sterol	124	−41	124	−38.4
Acetate	118	−45	118–119	−43.8
Benzoate	121	−16	120	..

Ozonization of Fucosterol.—A finely divided suspension of 1.15 g. of fucosterol in 12 cc. of glacial acetic acid was ozonized for one-half hour at an ozone concentration of about 2%, the exit gases being led through 50 cc. of water. Over-ozonization had to be avoided as it results in low if not negligible yields. The reaction mixture, combined with the wash water, was distilled through an efficient fractionating column. After approximately 20 cc. of distillate had been collected, the receiver was removed, and a solution of 500 mg. of recrystallized *p*-nitrophenylhydrazine in 20 cc. of 50% acetic acid was gradually added. The hydrazone crystallized out immediately. It was filtered, washed with cold water, and after drying weighed 175 mg. (33.6%); m. p. 124–125°. After three recrystallizations from dilute alcohol the substance had a constant m. p. of 128–129°. The melting point of a mixture with authentic acetaldehyde *p*-nitrophenylhydrazone showed no depression.

Olefin Rearrangements. The Equilibrium of Olefins from Pinacolyl Alcohol[1]

BY ROBERT KINSEL SMITH

The dehydration of saturated alcohols and the attendant rearrangement of olefins formed during the reaction have long been investigated experimentally. The mechanisms of these rearrangements have been studied intensively on the basis of experimental results. The absence of thermodynamical data has in general prevented the calculation of equilibrium constants for the ratios of different olefins obtained from a particular dehydration. Recently, thermal data have been published[2,3] concerning the heats of hydrogenation of 2,3-dimethyl-1-butene, 2,3-dimethyl-2-butene and 3,3-dimethyl-1-butene and the relative heat contents of 2,2-dimethylbutane and 2,3-dimethylbutane. These provide a basis for the calculation of the equilibrium mixture of these olefins produced in the dehydration of methyl-*t*-butylcarbinol. The equilibrium values for the ratios of the olefins obtained in this reaction are of importance because widely variant results are obtained through the use of different catalysts to effect the dehydration.

Meunier and Whitmore[4] dehydrated methyl-*t*-butylcarbinol with phosphoric acid on silica gel

(1) Original manuscript received August 7, 1941.

(2) (a) Dolliver, Gresham, Kistiakowsky and Vaughan, THIS JOURNAL, **59**, 831 (1937); (b) Kistiakowsky, Ruhoff, Smith and Vaughan, *ibid.*, **58**, 142 (1936).

at 350° and obtained 90% rearrangement. The products formed were 1.5% of *t*-butylethylene (I) which is the normal dehydration product, 34.5% of 2,3-dimethyl-1-butene (II) and 64% of 2,3-dimethyl-2-butene (III). Whitmore, Laughlin and Nash[5] passed (II) and (III) separately over the same catalyst and found 3% of (I), 31% of (II) and 61% of (III). This indicated that approximate equilibrium had been obtained.

Cramer and Glasebrook[6] dehydrated methyl-*t*-butylcarbinol over activated alumina at 350°. The results obtained by this procedure were greatly different from those obtained by Whitmore and co-workers with a more acidic catalyst.[4,5] Cramer and Glasebrook found alumina yielded 64.4% of (I), 27% of (II) and 8.6% of (III). When the more acidic aluminum sulfate was used as a catalyst, the proportions were 3.5% of (I), 34% of (II) and 62.5% of (III). These latter check closely with the results obtained with the phosphoric acid catalyst of Whitmore.[4,5]

Calculations.—The calculation of the equilibrium constant requires the experimental determination of the heat of reaction and the evaluation of the entropy change of the system.

The heats of hydrogenation and the heat of isomerization of the resulting saturated hydrocarbons as determined by the differences in their heat content provide a simple method for the evaluation of the heats of isomerization of the olefins. The values for the heats of hydrogenation of I, II and III have been found[2a,b] to be 30.341, 27.997 and 26.633 kcal./mole, respectively, at 355°K. The heat contents of 2,2-dimethylbutane and 2,3-dimethylbutane have been found[3] to be −2016 and −4095 cal., respectively, when compared to the heat content of normal hexane. In the subsequent calculations, the heat of isomerization has been assumed to remain essentially constant with change in temperature. This assumption is justified by the knowledge that the difference in the heat content of saturated isomeric hydrocarbons is little changed by temperature over the range involved here.

With these values, the complete calculation of the equilibrium constants is possible if the difference in entropy of the olefins is known. The entropies of (I) and (III) have been determined[7] through calorimetric measurements up to 298° K. The value for (II) was not found and thus estimations must be made to calculate the complete equilibria conditions.

The equation for the translational and rotational entropy of any molecule in the gas phase at a given temperature, T, and a pressure, P, may be expressed by

$$S = 8/2\,R\ln T - R\ln P + 3/2\,R\ln M + R/2\ln ABC - R\ln\sigma + 265.35 \quad (1)$$

The products of the moments of inertia were calculated by the method of Eidinoff and Aston.[8] The ordinary atomic distances of C–H as 1.09 Å., C–C as 1.54 Å., and C=C as 1.33 Å. were used in the calculations with the angle C–C–C taken as 109°28′ and the C=C–C angle as 124°20′.

The entropy due to hindered rotation and internal rotation must be separately determined by Pitzer's method.[9] The expression which has been developed for the internal rotational entropy is

$$S_{i.r.} = R(-0.767 + 1/2\ln T + 1/2\ln I_r \times 10^{-40} - \ln n) - (S_f - S) \quad (2)$$

where I_r is the reduced moment of the two rotating groups, n is the number of potential minima and $(S_f - S)$ is determined by the potential barrier restricting rotation, the temperature, the reduced moment and n.

The potential barrier restricting rotation of a methyl group was assumed to be 3200 cal. except in the instances wherein a double bond was adjacent to the methyl group where the hindering potential was taken to be 2000 cal. The rotation of two alkyl groups about each other was assumed to have a potential barrier of 8500 cal. unless one of the carbons in the bond about which rotation was being considered has a double bond in which the potential was assumed to be 7500 cal.

The vibrational entropy involved has not been determined spectroscopically. A self-consistent method of approximating wave lengths was used and the results adjusted so that the final entropy of the compound agreed reasonably well with heat capacity data for the entropy of the gas at the boiling point. The approximations made are listed in Table I with values obtained for different molecular properties.

The entropy change from I to III is then 3.31 e. u. and the heat of isomerization is

$$-30{,}341 + 4095 - 2.016 + 26.633 = -1.629\ \text{kcal.} \quad (3)$$

(5) Whitmore, Laughlin and Nash, THIS JOURNAL, **56**, 1395 (1934).

(6) Cramer and Glasebrook, *ibid.*, **61**, 230 (1939).

(8) Eidinoff and Aston, *J. Chem. Phys.*, **3**, 379 (1935).

(9) Pitzer, *ibid.*, **5**, 46 (1937).

The free energy change is

$$\Delta F = -1629 - 3.31T \quad (4)$$
$$K_{623} = 20.1 \quad (4a)$$

The corresponding changes for II to III are

$$-27.997 + 26.633 = -1.664 \text{ kcal. and } -1.10 \text{ e. u.}$$
$$\Delta F = -1664 + 1.10 \quad (5)$$
$$K_{623} = 1.81 \quad (5a)$$

$S_{int.\ rot.}$	4.65	5.18	4.4
$S_{trans.}$	68.58	68.22	65.92
Total S	104.87	109.28	108.18

[a] Observed entropies[7] extrapolated to boiling point by continuing C_v curves from 298°K. and adding 29.6 e. u.

[b] According to Kincaid and Eyring, *J. Chem. Phys.*, **6**, 620 (1938) the difference between C_v(liq.) and C_v(gas) is normally between 6 and 7 cal./mole deg. for complex materials. The differences observed here are 7.1 for I and 6.9 for III, which is quite reasonable. C_v(liq.) was found by using the value from entropy data[7] and subtracting an approximate factor obtained from the Landolt-Börnstein "Tabellen" in the following manner:

$$C_p - C_v = T\alpha^2 V/\beta = 3 \text{ cal./mole deg.}$$

The constant for the same reaction at 350° as calculated from the data of Whitmore and coworkers[5] was 20.3 for the ratio of III to I and 1.96 for the ratio of III to II. The results of Cramer and Glasebrook[6] were 18 and 1.81, respectively.

Discussion.—The results obtained by these methods cannot be regarded as final inasmuch as the calculations involving the vibrational entropy are not exact. However, assuming that the internal potential barriers for rotation are those assigned, little change in the relative entropy would be observed when the vibrational frequencies are consistently changed. The agreement of the calculated and observed entropy and the reasonable approximation of the specific heat of the perfect gas at the boiling point indicate that the assigned vibrations must be of the right order of magnitude.

Changes in the hindering potentials of the various groups by 500 cal. would change the difference in entropy by no more than 0.1 e. u. for I to III and even less for II to III.

The values for the vibrational frequencies were assigned by comparison of the molecules involved with similar olefins reported in Kohlrausch, "Der Smekal-Raman Effekt" and data in Hibben. The frequency assignments were made on the basis of similar work done on methylacetylene.[10]

Conclusion.—The rearrangement of these olefins using acidic materials as catalysts has been found to proceed in agreement with estimated thermodynamic values. The comparison of the dehydrations using acidic catalysts and those which do not furnish hydrogen ions indicates that the latter catalysts act merely in the removal of an equivalent of a water molecule with no effect upon the isomerization of the compounds formed. On the other hand, the catalytic action of hydrogen ion in the isomerization of olefins is definitely indicated.

The author wishes to thank Dr. F. C. Whitmore and Dr. J. G. Aston of the Pennsylvania State College and Dr. H. Eyring of this Laboratory for their assistance.

The Utilization of Aliphatic Nitro Compounds. IV. Nitrodiols (Nitroglycols) Prepared from Simple Aldehydes[1]

BY C. AUSTIN SPRANG[2] WITH ED. F. DEGERING

In a recent paper[3] the authors discussed the condensation of nitroparaffins with aldehydes to form nitroalcohols. In a continuation of this work nitromethane has been condensed with aldehydes to form nitrodiols. Any primary nitroparaffin condenses with formaldehyde to form a nitrodiol,[4] but only nitromethane condenses with

(1) Presented before the Division of Organic Chemistry at the Memphis meeting of the American Chemical Society, in April, 1942. Abstracted from a thesis presented to the Faculty of the Graduate School of Purdue University in partial fulfillment of the requirements for the degree of Doctor of Philosophy, in June, 1941.

(2) Present address: Emery Industries, Inc., Cincinnati, Ohio.

other aldehydes to form dihydric alcohols.[5,6] Sodium hydroxide is a suitable catalyst for condensations with formaldehyde but for other condensations the only catalysts which have been used successfully have been mild alkalies[7] such as calcium hydroxide or sodium or potassium carbonates. A large excess of the aldehyde is used to force the reaction as nearly to completion as possible and this is subsequently removed by low temperature distillation.

Procedure

4-Nitro-3,5-heptanediol.—The flask is charged with 61 g. (1 mole) of nitromethane, 50 ml. of 95% ethanol, and 3 g. of potassium carbonate. While stirring vigorously, 130 g. of propanal is added dropwise. External cooling is used to keep the temperature between 28–35°. A small amount of water is added to give a homogeneous solution which is left for four days at room temperature. The potassium carbonate is neutralized and the salt and aqueous layer removed. The solution is then stripped overnight with the water pump at room temperature to remove volatile substances. The salt, which precipitates, is removed by filtration and the stripping continued at room temperature at 1.5 mm. The residue is chilled to complete crystallization and then filtered (yield, about 50%) and finally recrystallized from a butanal–toluene mixture.

Unsymmetrical nitrodiols are prepared by first forming the nitroalcohol[2,6] from nitromethane and the more complex of the aldehydes and then treating this product with the second aldehyde in the presence of potassium carbonate as described above.

Nitrodiols are white, crystalline substances, soluble in water or alcohol, but insoluble in hydrocarbon solvents. Some data for three nitrodiols are listed in the table.

NITRODIOLS

Compound	Melting point, °C.	Empirical formula	Carbon or nitrogen, % Calcd.	Found
4-Nitro-3,5-heptanediol	97	$C_7H_{15}NO_4$	47.46	47.30[a]
3-Nitro-2,4-hexanediol	94	$C_6H_{13}NO_4$	8.58	8.47[b]
8-Nitro-7,9-pentadecanediol	66–67	$C_{15}H_{31}NO_4$	4.87	4.74[b]

[a] Percentage carbon by the "Wet Method," Pollard and Forsee, *Ind. Eng. Chem., Anal. Ed.*, **7**, 77 (1935).

[b] Percentage nitrogen by "Kjeldahl," Harte, *ibid.*, **7**, 432–3 (1935).

Because of the presence of three functional groups, these compounds are quite reactive and have unusual possibilities in organic synthesis.

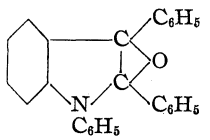
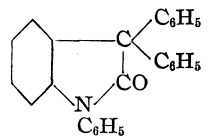
The Reaction of Phenylmagnesium Bromide with N-Phenylisatin

BY WARD C. SUMPTER

Stollé[1] obtained two products from the reaction of N-phenylisatin with excess phenylmagnesium bromide: a colorless compound melting at 161° and a yellow compound melting at 238°. Stollé described the colorless compound as 1,2,3-triphenylindole-oxide-2,3 (I). No formula was assigned to the yellow compound.

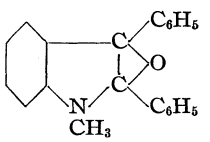


I

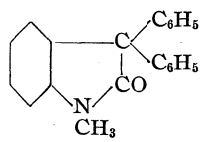


II

Myers and Lindwall[2] found that 2,3-diphenyl-1-methylindole-oxide-2,3 (III) is a yellow compound exhibiting greenish fluorescence and that a second colorless compound (IV) is obtained along with III when N-methylisatin reacts with excess phenylmagnesium bromide.



III



IV

In the light of these facts it seemed likely that Stollé's characterization was in error and that the colorless compound (m. p. 161°) was compound II and that the yellow compound (m. p. 238°) was in reality compound I.

To test this conclusion the experimental work of Stollé has been repeated. Analyses of both compounds are in agreement with the formula $C_{26}H_{19}ON$. That the colorless compound (m. p. 161°) is in reality 1,3,3-triphenyloxindole (II) was confirmed by its synthesis from 3,3-dichloro-1-phenyloxindole, benzene and aluminum chloride. The yellow compound exhibits green fluorescence in solution and is analogous in color and fluorescence to compound III of Myers and Lindwall. Accordingly it seems reasonable to assign structure I to the yellow compound (m. p. 238°).

Treatment of compound II with phosphorus pentachloride yields 2,2-dichloro-1,3,3-triphenyl-di-hydroindole (V).

V

Experimental Part

1,3,3-Triphenyloxindole (II) and 1,2,3-Triphenylindole-oxide-2,3 (I).—N-phenylisatin (0.025 mole) was added slowly, over a period of one hour, to a solution of phenylmagnesium bromide (0.125 mole) in 150 ml. of dry ether. After addition of the last portion the mixture was heated at the boiling temperature for one hour and then poured into a mixture of ice and concentrated sulfuric acid. The ether layer was separated, dried over anhydrous sodium sulfate and the ether removed under reduced pressure. The yellow mass which was obtained was crystallized from ethyl alcohol. Repeated crystallization yielded 5.75 g. of colorless plates; m. p. 161°, and a small yield of yellow crystalline powder, m. p. 238°. The yellow compound exhibited marked fluorescence in solution.

Anal. of compound m. p. 161° (II). Calcd. for $C_{26}H_{19}ON$: N, 3.87. Found: N, 3.84, 3.67. *Anal.* of compound m. p. 238° (I). Calcd. for $C_{26}H_{19}ON$: N, 3.87. Found: N, 3.87.

Compound II. By the Friedel–Crafts Reaction.—Powdered anhydrous aluminum chloride (0.05 mole) was added slowly to a solution of 3,3-dichloro-1-phenyloxindole (0.01 mole) in 40 ml. dry benzene and the reaction mixture heated for one hour at 60°. The benzene was removed under reduced pressure and the residue treated with ice and hydrochloric acid. The entire reaction mixture was then extracted with ether and the ether removed under reduced pressure after decolorizing with charcoal and drying over anhydrous sodium sulfate. The product was purified by crystallization from ethyl alcohol from which it separated as colorless plates, m. p. 161°. Mixed melting points with samples of the colorless compound from the Grignard reaction showed no depression.

2,2-Dichloro-1,3,3-triphenyl-di-hydroindole (V).—A mixture of 2 g. of 1,3,3-triphenyloxindole (II) with 10 g. of phosphorus pentachloride was heated for four hours at 150°, the mixture cooled and water added, the residue collected and crystallized from ethyl alcohol from which it separated as colorless prisms; m. p. 200°.

Anal. Calcd. for $C_{26}H_{19}NCl_2$: N, 3.36. Found: N, 3.36, 3.33.

The Preparation of *m*-Hydroxybenzoic Acid

BY H. E. UNGNADE AND A. S. HENICK

m-Hydroxybenzoic acid has been prepared by fusion of *m*-chlorobenzoic acid with alkali,[1] by diazotization of *m*-aminophenol, subsequent replacement with the cyano group and hydrolysis,[2] by alkaline fusion of the sodium *m*-sulfonate of benzoic acid,[3] and by action of nitrous acid on *m*-aminobenzoic acid, followed by hydrolysis of the diazonium salt.[4]

It has been found in this Laboratory that the acid can be prepared conveniently from methyl *m*-aminobenzoate. The ester is used rather than the acid since methyl *m*-nitrobenzoate is readily obtained in a pure state, is easily reduced, and is an intermediate in the preparation of *m*-nitrobenzoic acid.[5]

The reduction of methyl *m*-nitrobenzoate may be carried out catalytically with Raney nickel either under low pressure or more rapidly under high pressure and at a slightly elevated temperature. The yields in the reduction are 93–95%.

Diazotization and hydrolysis of methyl *m*-aminobenzoate give *m*-hydroxybenzoic acid directly in yields of 80–87%.

Experimental

Methyl *m*-Aminobenzoate.—Methyl *m*-nitrobenzoate (20 g.)[6] in ethyl acetate (100 cc.) was reduced with hydrogen at 50 lb. in the presence of Raney nickel (3 g.). The theoretical amount of hydrogen was absorbed in twelve hours. A 100-g. sample of the nitro compound in 100 cc. of methanol could be reduced at 50° in two and one-half hours at 2000–3000 lb. with Raney nickel (3 g.). After removal of catalyst and solvent the product was dried in ether solution. The ether was distilled off and the residual oil distilled under reduced pressure. The pure methyl *m*-aminobenzoate boiled at 152–153° (11 mm.); f. p. 37° (from the cooling curve); yield 93–95%.

Acetyl Derivative.—The acetyl derivative was obtained by refluxing the amine for twenty minutes with acetic anhydride. It melted at 136–137° after crystallization from water.

Anal. Calcd. for $C_{10}H_{11}O_3N$: C, 62.17; H, 5.70. Found: C, 62.16; H, 5.87.[7]

***m*-Hydroxybenzoic Acid.**—Methyl *m*-aminobenzoate (50 g.) was dissolved in a solution of 75 cc. of concentrated sulfuric acid and 150 g. of ice. The solution was then treated with 100 g. of ice, cooled to 0° and diazotized by the addition of 25 g. of sodium nitrite in 60 cc. of water. The resulting diazonium salt solution was added all at once to a hot solution of 100 g. of anhydrous sodium sulfate and 40 cc. of concentrated sulfuric acid in 400 cc. of water. The mixture was refluxed for three hours. Then the reaction mixture was boiled with norite, filtered, and allowed

Identification of Amides through the Mercury Derivatives

BY JONATHAN W. WILLIAMS, WILLIAM T. RAINEY, JR., AND ROBERT S. LEOPOLD

In characterizing amides the most general procedure is hydrolysis, followed by identification of the two products. With unsubstituted amides, solid derivatives may be prepared directly by reaction with phthalyl chloride.[1] Another procedure, the use of which obviates hydrolysis, is the preparation of the mercury derivative. This procedure is simple and gives satisfactory derivatives for a large number of unsubstituted amides.

The reaction represented by the equation

$$2R{-}\underset{\underset{O}{\|}}{C}{-}NH_2 + HgO \longrightarrow (R{-}\underset{\underset{O}{\|}}{C}{-}NH)_2Hg + H_2O$$

was first reported in 1852 by Dessaignes,[2] who prepared the mercury derivatives of benzamide and acetamide. Mercury derivatives of several other amides have since been described.[3]

Two general procedures were investigated for the preparation of these mercury compounds. Procedure 1, patterned after the work of Dessaignes,[2] consisted of bringing a mixture of yellow mercuric oxide and excess amide to the melting point of the amide, maintaining that temperature and adding more mercuric oxide in small portions until no further reaction occurred, and then purifying the product by recrystallization from ethanol or by leaching with hot ethanol. This process is the more generally applicable one, and the one that must be used with aliphatic amides. Procedure 2, based on the process described by Mann and Saunders,[4] consisted of refluxing about 0.04 mole of amide with excess (around 0.025 mole) yellow mercuric oxide in 50 ml. of 95% ethanol for one hour, filtering while hot, cooling, removing the crystalline mercury derivative, and purifying by recrystallization or leaching.

(2) Dessaignes, *Ann.*, **82**, 231 (1852).

(3) For summary and complete references, see Whitmore, "Organic Compounds of Mercury," Chemical Catalog Company (Reinhold Publishing Corporation), New York, N. Y., 1921, pp. 159–161.

(4) Mann and Saunders, "Practical Organic Chemistry," Longmans, Green and Company, London, 1938, p. 79.

In Table I are listed the melting points and mercury analyses[5–7] of the compounds successfully prepared. Due to low solubility in boiling ethanol, the purification of the mercury derivatives of *p*-anisamide and *m*-chlorobenzamide must be accomplished by leaching.

TABLE I

Amide	M. p., °C. (uncor.)	M. p. of mercury derivative, °C. (uncor.)	Mercury, % Calcd.	Found

p-Toluamide	166	260	42.6	42.5	..
o-Anisamide	128	241	40.1	39.8	40.3
p-Anisamide	167	222	40.1	39.9	40.3
Salicylamide	139	190	42.4	42.7	..

Unsuccessful attempts were made to prepare the mercury derivatives of isovaleramide, stearamide, *m*-anisamide and benzenesulfonamide. In the first two cases, decomposition occurred at the temperature used, making isolation of the mercury derivative impossible. With the latter two substances, reaction occurred readily, but the products obtained could not be rendered analytically pure.

Experimental

Procedure 1.—In a test-tube were placed 1.5 g. of the amide and 0.5 g. of yellow mercuric oxide. Using a small flame, the mixture was heated at the melting point of the amide until all mercuric oxide had reacted (disappearance of color) and the water vapor had been dispelled. More mercuric oxide was then added in small portions until no more would react. If an excess of mercuric oxide was obtained, enough of the amide to react with it was added and the yellow color removed completely. The melt was cooled somewhat, then taken up in the minimum amount of boiling ethanol and allowed to cool. The crystals were filtered and washed with cold ethanol or ether. Considerable variations were found in the solubilities of the mercury derivatives in alcohol. The derivatives of aliphatic amides were quite soluble, even in cold ethanol. On the other hand, the derivatives of *p*-anisamide, *m*-chlorobenzamide and benzenesulfonamide were quite insoluble in

boiling ethanol, and were best purified by leaching out the unreacted amide with boiling ethanol.

Procedure 2.—This process was found to be satisfactory for amides whose mercury derivatives were soluble in hot ethanol, insoluble in cold. It was used successfully with benzamide, *p*-chlorobenzamide, the bromobenzamides, the toluamides, *o*-anisamide and salicylamide. Five grams of yellow mercuric oxide and 4 g. of amide were added to 50 ml. of 95% ethanol, the mixture refluxed for one hour, filtered while hot through a fluted filter, chilled in an ice-bath, and the crystals removed by suction. Purification, where necessary, was accomplished as in Procedure 1.

VENABLE CHEMICAL LABORATORY
UNIVERSITY OF NORTH CAROLINA
CHAPEL HILL, N. C. RECEIVED APRIL 23, 1942

Crystalline Xylitol

BY M. L. WOLFROM AND E. J. KOHN

Fischer[1] and Bertrand[2] prepared xylitol as a sirup in 1891 by the sodium amalgam reduction of *d*-xylose. Xylitol has been prepared subsequently by other investigators but, to our knowledge, no record of its crystallization has appeared in the literature. We wish to report that the crystallization of xylitol now has been effected in this Laboratory. The xylitol was prepared by the high-pressure catalytic reduction of highly purified *d*-xylose and the crystalline reduction product was characterized by elementary analysis, behavior with periodate and by the preparation of two known crystalline derivatives. The crystals were anhydrous, low-melting (61°) and hygroscopic.

Experimental

A solution of 300 g. of highly purified *d*-xylose in 750 cc. of water containing 60 g. of a nickel catalyst supported on kieselguhr was reduced in a steel shaking autoclave (American Instrument Company) at an initial hydrogen pressure of 1700 lb. per sq. in. (113 atm.) at 30°. A maximum temperature of 150° at a pressure of 2400 lb. per sq. in. (160 atm.) was attained in one hour and maintained for an additional four hours. The catalyst was removed from the cooled solution by filtration followed by treatment with an excess of hydrogen sulfide and by heating at 55° with decolorizing charcoal. The clear sirup obtained on solvent removal below 50° under reduced pressure, crystallized on standing for some weeks under absolute ethanol and at icebox temperature; yield 255 g. Pure material was obtained on recrystallization from anhydrous methanol; m. p. 61–61.5° (cor.), optically inactive (H_2O, D line of sodium). The hygroscopic, crystalline product was very soluble in water and was fairly soluble in hot methanol. It did not reduce boiling Fehling solution.

Anal. Calcd. for $C_5H_{12}O_5$: C, 39.47; H, 7.95. Found: C, 39.43; H, 7.85. Sodium periodate analysis[3]: moles periodate consumed, 4.0 (calcd., 4); moles formic acid formed, 2.8 (calcd., 3); moles formaldehyde formed,[4] 1.8 (calcd., 2).

The crystalline substance was further characterized by the preparation of two previously known crystalline derivatives, the pentaacetate[5] (m. p. 62.5–63°, cor.) and the dibenzylidene derivative[6] (m. p. 187.5–188°, cor.). Hockett and Hudson[5] record 61.5–62.5° (cor.) as the melting point of xylitol pentaacetate. Lobry de Bruyn and Alberda van Ekenstein[6] record 175° as the melting point of dibenzylidene-xylitol but previous experience in this Laboratory with sirupy xylitol preparations has indicated the higher melting point of 187.5–188° (cor.).

Nitrovinylnaphthalene

BY DAVID E. WORRALL AND ABRAHAM TATILBAUM

Since α,β-unsaturated compounds containing a naphthalene group have not as yet been described, it appeared worth while to prepare 2-(α-nitrovinyl)-naphthalene and some of its derivatives.

2-(α-Nitrovinyl)-naphthalene.—A condensation of 0.1 g. mole each of β-naphthaldehyde and nitromethane in the presence of alcoholic sodium hydroxide yielded 16 g. of the crude product, which, when recrystallized from alcohol, gave yellow needles, m. p. 120.5–122°.

Anal. Calcd. for $C_{12}H_9NO_2$: C, 72.4; H, 4.5. Found: C, 72.3; H, 4.8.

Aliphatic amines instead of alkali proved unsuitable for promoting the reaction because of the formation of polymers. Thus, using amylamine, considerable amounts of an amorphous, tan-colored substance relatively insoluble in common solvents was obtained, which, after digestion with hot nitric acid, washing with alcohol and drying, melted indefinitely with decomposition at about 253°.

Anal. Calcd. for $(C_{12}H_9NO_2)_x$: C, 72.4; H, 4.5. Found: C, 72.2; H, 4.6.

2-(α-Bromo-α-nitrovinyl)-naphthalene.—The dibromide of the original compound was prepared by the action of bromine on a chloroform solution of the unsaturated substance. The bromination which did not go smoothly gave best results on long standing at room temperature in sunlight. Spontaneous evaporation left a crystalline residue which after washing with cold alcohol to remove oily impurities, crystallized from alcohol as white needles, m. p. 125–126°. Warm alcoholic potassium acetate converted

it into the vinyl derivative, yellow needles from alcohol, m. p. 107–108°.

Anal. Calcd. for $C_{12}H_8BrNO_2$: Br, 28.7. Found: Br, 28.8.

Attempts to prepare addition products with aniline, phenylhydrazine, etc., were fruitless. Using fuming nitric acid a yellow amorphous substance, apparently containing two added nitro groups, was isolated.

PEARSON MEMORIAL LABORATORY
TUFTS COLLEGE
MEDFORD, MASSACHUSETTS RECEIVED APRIL 28, 1942

Anhydrous Tantalum Tribromide

BY RALPH C. YOUNG AND THOMAS J. HASTINGS, JR.

If tantalum pentabromide vapor and hydrogen are passed through a tube at 700°, reduction of the compound occurs and lower bromides are produced prior to the formation of tantalum metal.[1] Complete reduction to the metal occurs, however, if the reaction at 700° is continued for a long enough time.

By the employment of the St. Claire-Déville principle it has been found possible to obtain the anhydrous tribromide of tantalum by a process analogous to that by which the tribromide[2] of titanium and the tribromide[3] of zirconium were formed. A Pyrex tube 27 mm. in diameter and 100 cm. long was used as the reaction tube and the middle section (33 cm. in length) was heated in an electric furnace at 700°. Into the forward end which held the tantalum pentabromide[4] was passed pure dry hydrogen at a rate of 24 liters per hour. During this interval 18 g. of tantalum pentabromide was volatilized and carried with the hydrogen into the heated zone. The reduction product and unchanged pentabromide collected on the surface of an inner tube through which water at 0° flowed. This inner tube extended to within 15 cm. of the forward end of the furnace.

At the conclusion of the experiment the apparatus was cooled to room temperature and dry carbon dioxide substituted for the hydrogen. The apparatus was so constructed that the products of the reaction could be directed into an arm sealed to the lower side of the reaction tube about 20 cm. from the end. After the arm had been sealed off from the apparatus, the outer end which was provided with a stopcock was sealed directly to a high vacuum system and the excess tantalum pentabromide was removed from the reduced product by sublimation at 1×10^{-5} mm. pressure at a temperature of 160°. The residue, which weighed 1 g., was a grayish-green powder which under a lens appeared uniform. *Anal.* Calcd. for $TaBr_3$: Ta, 43.0; Br, 57.0. Found: Ta, 43.4, 45.5; Br, 59.5, 58.3, 55.5.

The analyses indicate the formation of the tribromide, mixed with higher and lower bromides.

The tribromide reacts with water and alkali. Hydrogen is evolved and in the absence of air in an amount that corresponds to a change of the tantalum from an oxidation state of 3 to 4. In accord with this fact a brown tetravalent oxide was formed, the composition of which corresponded to $TaO_2 \cdot 2H_2O$ after it had been washed with water, alcohol, and ether and dried at a pressure of 0.05 mm. for ten minutes. The dioxide is slowly oxidized in the air at room temperature and rapidly at elevated temperatures to the white Ta_2O_5. The latter is quickly formed from the tribromide and dioxide by the action of strong oxidizing agents such as nitric, permanganic and dichromic acids.

(3) Young, *ibid.*, **53**, 2148 (1931).
(4) Tantalum pentabromide was prepared by the action of bromine on a mixture of sugar charcoal (2 moles) and tantalum oxide (0.1 mole). This mixture was first heated in a silica tube at 700° in a current of nitrogen to remove water. Subsequently the reaction tube was raised to 860°. The sublimate was resublimed at 0.05 mm. pressure and at a temperature of 400°; yield 80%.

d-Allulose and Some Methylated Derivatives

BY F. W. ZERBAN AND LOUIS SATTLER

In the industrial fermentation of cane molasses to produce ethyl alcohol, part of the sugar remains unfermented, and we have shown[1] that the unfermentable residue of a molasses distillery contains a ketohexose whose osazone is identical with the osazones of *d*-allose and *d*-altrose. Consequently the ketose must be *d*-psicose. Because of

HC=O	HC=O	H_2COH
|	|	|

H_2COH	H_2COH	H_2COH
d-Allose	*d*-Altrose	*d*-Allulose

(1) Presented at the Atlantic City meeting of the American Chemical Society, Sept., 1941.

the relationship of the ketose to the two aldoses, we prefer the name *allulose* proposed by Professor William Lloyd Evans.

From commercial distillery residues we have now obtained *d*-allulose by way of its diacetone derivative. This compound when heated with dilute acetic acid decomposes to form the free sugar. The sirup thus prepared was dissolved in water and read in a saccharimeter.

$$[\alpha]^{20}D = \frac{+0.05°S \times 100}{1.2044 \times 0.5} \times 0.3462 = +2.9°$$

Steiger and Reichstein[2] reported $[\alpha]^{20}D$ +3.1°.

Methylation of the crude allulose concentrate followed by a high-vacuum distillation of the product yielded 1,3,4,6-tetramethyl ($\alpha \rightleftarrows \beta$) methyl *d*-alluloside which distilled as a thick oil from a bath temperature of 105–140° at a pressure of 8×10^{-5} mm.

Anal. Calcd. for $C_{11}H_{22}O_6$: C, 52.77; H, 8.86; OCH_3, 62.00. Found: C, 53.00; H, 9.24; OCH_3, 59.70; $n^{21.5}D$ 1.4572.

When 0.3199 g. of the tetramethyl methyl alluloside was dissolved in 25 ml. of methyl alcohol containing four drops of concentrated hydrochloric acid and heated in a pressure bottle for two hours at 100°, the product (probably an equilibrium mixture of tetramethyl methyl allulosides) had a specific rotation in sodium light of +36° at 20°.

Further work with allulose derivatives is in progress.

NEW COMPOUNDS

N,N′-Piperazinium Bis-(2-methyl-5-isopropylbenzenesulfonate)

Smith and Pollard[1] have prepared a number of N,N′-piperazinium bis-(arylsulfonates) and found them moderately soluble in cold water, and quite soluble in hot water. McKee and Bahner[2] found that, while the benzenesulfonate and 2,4-dimethylbenzenesulfonate salts of ethylenediamine and also the 2-methyl-5-isopropylbenzenesulfonate salts of diethylenetriamine and triethylenetetramine are all relatively soluble in water at room temperature, the 2-methyl-5-isopropylbenzenesulfonate salt of ethylenediamine is only slightly soluble. This property was used to separate ethylenediamine from mixtures.

We have prepared N,N′-piperazinium bis-(2-methyl-5-isopropylbenzenesulfonate) and have found that, while it is readily soluble in hot water, it is only slightly more soluble at room temperature than the corresponding salt of ethylenediamine. It is soluble only to the extent of 1 part in 80 of water at 30° or 1 part in 200 at 0°.

The salt was prepared by mixing aqueous solutions of recrystallized sodium 2-methyl-5-isopropylbenzenesulfonate and N,N′-piperazinium dichloride, the former being in excess at all times.[3] The product, obtained in almost the theoretical yield, consisted of small, white leaflets which did not melt below 300°. After recrystallization from water and drying at 110° it was analyzed by the Kjeldahl method.

N-Substituted Piperonylamides

These compounds were prepared by treating a benzene solution of piperonoyl chloride with slightly more than two equivalents of the appropriate amine in the same solvent and heating the solution under reflux for thirty minutes. The mixture was treated with water to dissolve the hydrochloride of the amine and the benzene was removed by distillation under reduced pressure with a water pump. The remaining aqueous solution containing the amide in suspension was filtered and the amide washed with water. This procedure was found preferable to distilling separately the benzene solution of the amide as some amides tended to separate from this solvent as an oil. The yield of crude amide was 90% or more in all cases. Purification of the amide was effected by recrystallization from dilute alcohol. The nitrogen determinations were made by the Kjeldahl method.

Selenium Tetracysteine

To an aqueous solution of 0.01 mole of cysteine hydrochloride an aqueous solution of 0.0025 mole of sodium selenite was added. On cooling, a white granular material separated. It was removed by filtration, washed with water, and recrystallized from hot water. The yield was 80–85% of the theoretical amount. Under the microscope, the crystals had the form of clusters of small rods. The substance began to darken at 164–165° and decomposed at 195–196°. The analysis of the substance indicated that it was apparently identical with selenium tetracysteine.

Calcd. for $Se(SC_3O_2NH_6)_4$	25.73	4.29	10.01	14.16	

Selenium tetracysteine is moderately soluble in cold water, readily soluble in hot water. It is soluble in dilute mineral acids, but decomposes on heating the acid solution to yield what appears to be elementary selenium (brick-red in color, characteristic odor, gives intense codeine test). It readily decomposes in cold dilute alkali yielding elementary selenium. An aqueous solution of selenium tetracysteine gives a negative test for free SH— with nitroprusside and ammonia. On treatment with sodium cyanide, the nitroprusside test becomes positive.

The ready reactivity of the selenite toward cysteine is analogous to that of arsenious acid toward cysteine to give arsenious tricysteine. The latter compound was prepared by Johnson and Voegtlin[1] using arsenious trichloride. We found in unpublished studies that arsenious acid also reacts with cysteine to give the tricysteine in 90% yields.

The cysteine derivatives of selenium and arsenic are of interest in connection with the selenium poisoning in animals, and the well-known inactivation of certain enzymes by arsenious acid and the selenite.

COMMUNICATION TO THE EDITOR

SOME X-RAY DIFFRACTION MEASUREMENTS ON BIOTIN

Sir:

About one milligram of free biotin, $C_{10}H_{16}O_3N_2S$, was made available to the writer through the courtesy of Dr. Vincent du Vigneaud, of the Cornell Medical School. Repeated micro-recrystallizations produced a few crystals large enough for single crystal X-ray studies.

Biotin crystallizes in long thin needles. Under the polarizing microscope, the extinction is straight, the fast vibration direction, α, being along the length. The needle cross-section is approximately a rhombus, the acute angle of which is about 55°. This value could not as usual be determined accurately by the use of optical reflections, as the prism faces were not perfect enough. The intermediate vibration direction, β, is the obtuse angle bisector, and γ the acute. Optically the crystal is negative. These data suggested that the crystal was orthorhombic, a choice confirmed by the subsequent X-ray work. The a, b and c axes were taken to coincide with the corresponding principal optic directions α, β and γ.

Oscillation films about all three crystallographic axes were made as well as "a" axis Weissenberg films of the equator, first and second layers. The only systematic absences found were the extinctions of the odd orders of the (h00), (0k0), and (00l) reflections. The space group is therefore $P2_12_12_1$. This space group has four general positions.

The lengths of the a, b and c axes were found to be 5.25, 10.35 and 21.0 Å., respectively. If the molecules are asymmetric and identical, then there would be four molecules per unit cell. The density of the crystals as measured by immersion in a mixture of carbon tetrachloride and methylene dichloride was 1.41. The X-ray molecular weight, computed from these data, is 245 ± 6. The molecular weight computed from the chemical formula is 244.

Some idea as to the possible character of the molecule may be obtained from the X-ray data without making a detailed analysis. The short "a" axis and the fact that it is parallel to the fast vibration direction, α, suggests a flattish molecule lying approximately in the bc plane. The width would be approximately in the "b" direction and the length in the "c" direction. The molecules will almost certainly deviate somewhat from be-

ing parallel with the crystallographic directions but nevertheless a molecule about 5 × 5.5 × 10.5 Å. in size is indicated.

The equatorial "*a*" axis Weissenberg shows an interesting pseudo-halving of the (0*kl*) reflections; *i. e.*, the (0*kl*) reflections for *k* odd are generally weak. A possible explanation can be given in terms of a pseudo-symmetry of the biotin molecule. A molecule which in projection is approximately symmetrical to a plane normal to the "*c*" axis could result in such an intensity distribution.

Another interesting systematic pseudo-halving exists which was not noticed until a Patterson synthesis of the (0*kl*) reflections was made. The two largest peaks (excluding of course the identity peak at 0,0) were found at $^1/_2$, 0 and $^1/_4$,$^1/_2$. The first of these peaks is merely the expression of the first mentioned pseudo-halving. The peak at $^1/_4$,$^1/_2$ can be traced to the second pseudo-halving; (0*kl*) reflections, where *k* is even and $k/2 + l$ is odd, were generally weak. This suggests that the flattish molecules are packed approximately side by side, neighbors being related to one another by a two-fold screw axis. In the direction of their lengths the packing would be imbricated. The one sulfur atom per molecule of biotin should be fairly near the central bisecting pseudo-plane of symmetry.

It should be emphasized that much of the foregoing note is highly speculative; indeed only the great interest in biotin could warrant its publication in its present form. The actual X-ray cell determinations are probably accurate to within about 1%. The picture of the molecular size and shape, however, is merely a reasonably plausible explanation of some of the X-ray and optic data. A more complete study of the X-ray data is now under way.

Much of the experimental work was done while the writer was National Research Fellow in Protein Chemistry at the Massachusetts Institute of Technology.

NEW BOOKS

Anhydrous Aluminum Chloride in Organic Chemistry. By CHARLES ALLEN THOMAS, Central Research Director, Monsanto Chemical Company, in collaboration with MARY BALUK MOSHIER, HERBERT E. MORRIS and ROSS W. MOSHIER, Thomas and Hochwalt Laboratories, Monsanto Chemical Company. (A. C. S. Monograph Series.) Reinhold Publishing Corporation, 330 West 42nd St., New York, N. Y., 1941. xiii + 972 pp. 15.5 × 23.5 cm. Price, $15.00.

This is truly a monumental work, 878 pages of text, an author index of some 7000 names, a subject index of over 20,000 entries and a patent index with 594 U. S. patents and more from other countries.

The book opens with an historical sketch of Friedel and Crafts. This is followed by a chapter on the physical and chemical properties of aluminum chloride and its many combinations and one on the mechanisms of the reactions catalyzed by it. The manufacture, handling and storage of this material are also cared for. The main portion of the book, 656 pp., is a well-ordered, comprehensive and detailed presentation of the reactions of aromatics with alkyl halides, olefins, acyl halides, anhydrides and the like, with their numerous modifications. This is what every organic chemist knows, only a great deal more of it. Three chapters, 107 pages, are given to the new, tremendously important applications of aluminum chloride to aliphatic compounds. This section with its thousand references, largely patents, covers among other things the isomerization of hydrocarbons and the addition of olefins to paraffins to make high octane gasoline, the production of ethyl chloride from ethylene and hydrogen chloride, the polymerization of olefins to lubricants, high molecular weight, semi-solid products and resins and the cracking and refining of petroleum products.

The enormous amount of information is concisely yet clearly presented and should be of great service to organic chemists whether interested in pure chemistry or in its applications.

E. EMMET REID

A Treatise on Physical Chemistry. Third Edition—In Five Volumes. Volume One. **Atomistics and Thermodynamics.** Edited by HUGH S. TAYLOR, David B. Jones Professor of Chemistry, Princeton University, and SAMUEL GLASSTONE, Professor of Chemistry, The University of Oklahoma. D. Van Nostrand Company, Inc., 250 Fourth Avenue, New York, N. Y., 1942. vii + 679 pp. Illustrated. 15.5 × 23.5 cm. Net price, $7.50; $6.50 on order for set.

If Mr. Gallup were to poll the country's middle-aged physical chemists for the book that had the greatest in-

fluence on their professional training the returns would very likely show Nernst's "Theoretical Chemistry" to be it, although the younger generation seems to be hardly better acquainted with this book than they are with the Bible! But beginning with the early 'twenties the rapidly expanding science demanded, and got, a whole set of working-textbook-reference books individually addressed by very competent authors to special fields, which in some cases involved a developing body of knowledge treated by Nernst in only a few pages or a few chapters, and which in other cases involved facts and approaches not even hinted at or dreamed of before 1920 by Nernst or anybody else.

The persistent and very proper demand for a summarizing story of how we stand in certain special fields as explained to us by a few persons who are gifted with the power to swallow a field whole, digest it, and come up with a clear, logical and interesting account of it, has brought to American chemists a really excellent review-service and colloquium-service, as well as our special-field book service.

Professor Hugh Taylor and the nineteen authorities who collaborated with him in writing the various summarizing chapters of "A Treatise on Physical Chemistry" (first edition—October, 1924, second edition—December 1930) did a great service to American chemistry. All who have used these two volumes are much interested to know what the third edition, now expanded to five volumes, will be like. The first volume is off the press, March, 1942. Professor Taylor and Professor Samuel Glasstone have combined forces as editors of the enlarged Treatise.

Volume I, labelled Atomistics and Thermodynamics, contains four chapters, an appendix (Values of Physical Constants) and a subject index.

Its Chapter I, The Atomic Concept of Matter, by Hugh S. Taylor, runs 1–117 pages as compared with 1–34 pages in the second edition. It carries extensive revisions and many additions of new material including more comprehensive treatments of radioactivity and the mass spectrograph and very helpful sections on separation of isotopes, nuclear structure, nuclear fission, nuclear processes, and a most useful table of induced radioactivities. In this chapter one can get a brief but excellent and well-balanced picture of how we stand at present with respect to the nucleus.

Chapter II, Quantum Theory of Atomic Spectra and Atomic Structure, is written by Saul Dushman in his incomparably fine manner of exposition. The chapter runs from page 119 to 436, as compared with 276 pages in the second edition. Dr. Dushman's treatment runs the whole gamut of the quantum effects of interest to chemists, including sections on: Quantum Phenomena, Photoelectric Effect, Inverse Photoelectric Effect, Compton Effect, Raman Effect, Quantum Theory of Radiation, Matter Waves, Corpuscles and Waves, The Bohr–Sommerfeld Theory of Electronic Orbits, The Wave Mechanics Treatment of the Hydrogen Atom, Inner Quantum Number and Electron Spin, Effect of Magnetic and Electrostatic Fields on Spectral Terms, Electron Configuration in Atoms and Periodic System of the Elements, Quantum Numbers for Inner Electrons, Multiplet Levels in Optical Spectra, Intensities of Spectral Lines, Magnetic Properties of Atoms and Ions in Relation to Spectral Type, Hyperfine Structure of Spectral Lines, Quantum Theory of Valence.

Chapter III, First and Second Laws of Thermodynamics, by Hugh S. Taylor, follows along for about one-half its length very much the same pattern of the chapter "The Energetics of Chemical Change" in the second edition, with some changes and additions, and then treats Partial Molal Quantities, The Activity Function, Thermodynamics and Statistics. The last section gives a very nice discussion of partition functions.

Chapter IV, The Third Law of Thermodynamics and Statistical Mechanics, is a beautifully written treatment by John G. Aston, a professor of *organic* chemistry (let it be noted) and a new addition to the staff of contributing authors. Seventy-five listed topics are organized under section headings as follows: The Third Law of Thermodynamics; Statistical Mechanics; Nuclear Spin Effects; Gases; The Third Law and Statistical Mechanics; Heat Content, Free Energy and Equilibrium Constants; Solids; Magnetic Cooling; and several valuable appendices. Throughout the chapter *entropy* is naturally Professor Aston's most absorbing theme.

Many chemists will be looking forward with freshly aroused interest to the other four volumes. The authors of the forthcoming chapters will indeed have to exert themselves to rival the excellent performance of their colleagues in this first volume. The publishers, too, have done a piece of first-class book manufacture.

EDWARD MACK, JR.

Advances in Enzymology and Related Subjects. Edited by F. F. NORD, Fordham University, New York, N. Y., and C. H. WERKMAN, Iowa State College, Ames, Iowa. Volume II. Interscience Publishers, Inc., 215 Fourth Avenue, New York, N. Y., 1942. viii + 374 pp. 23 illustrations. 15.5 × 23.5 cm. Price, $5.50.

The second volume of "Advances in Enzymology" is characterized by a breadth of interest far transcending its chosen field of enzyme chemistry or "Enzymology" as the editors have so unhappily chosen to express it. In accordance with this, we find a comprehensive report "Vitamin K, its Chemistry and Physiology," by Henrik Dam, once of Copenhagen, now of Rochester. A few years ago the inclusion of such vitamin chemistry in a treatise on enzymes would seem incongruous indeed. With the striking developments in biological oxidations where riboflavin, thiamin and nicotinic acid, once identified as vitamins, have now been shown to be the prosthetic groups of many important enzyme systems, vitamin K appears to "belong." Perhaps this foreshadows the development of a role for vitamin K among the enzymes of the body. Typical also of the all-inclusive nature of this volume are the reviews "The Adrenal Cortical Hormones" by J. J. Pfiffner and "Bacterial Viruses (Bacteriophages)" by Max Delbrück.

Dealing with the purely hydrolytic enzymes, there are three papers of very great value. The first of these, "The Kinetics of Hydrolytic Enzymes and Their Bearing on Methods for Measuring Enzyme Activity," by Donald D. Van Slyke, should be carefully studied by any investigator in this field. In it the author analyzes the kinetic behavior of simple hydrolyses of this type, develops the mathematical treatment of such reactions and then shows how the

experimental conditions should be chosen and interpreted so that valid and significant results may be obtained. Undoubtedly many false and misleading reports which now find publication could be transformed into valuable contributions by strict observance of the rules as Dr. Van Slyke has elaborated them. There are, then, two reviews of proteolytic enzymes, "A Classification of Proteolytic Enzymes," by Max Bergmann, and "The Enzymatic Properties of Peptidases," by M. J. Johnson and J. Berger. These are in many ways complementary. The latter authors, restricting their attention to the "peptidases," summarize the occurrence of these enzymes in nature, with emphasis on the varied nature of the same type of enzyme from different sources. For instance, there are really many different kinds of enzymes which split leucyl peptides; there is no justification to consider them all a single enzyme, "leucyl peptidase," and far less to label them "amino peptidase" or "peptidase" as some authors have a tendency to do. Dr. Bergmann's attention is focussed on the recent work from his Laboratory at the Rockefeller Institute. He presents a new working classification of the proteolytic enzymes, in which peptidases and proteinases, as groups, are discarded in favor of endopeptidases and exopeptidases. Again, emphasis is placed on the like and unlike characteristics of enzymes from different sources in nature. Thus, there are enzymes in beef spleen, beef kidney, swine kidney, cattle pancreas (trypsin), and the papaya which split benzoyl-*l*-arginineamide and benzoyl-*l*-lysineamide at proportionate rates, but which differ strikingly in other properties such as their *p*H requirements and dependence upon activators. The accumulated evidence suggests that such proteolytic enzymes are composed of several determinant groupings of amino acid or other residues—one common to them all which controls the specificity of the family as a whole, and others peculiar to each member, which influence the *p*H and activation requirements. It is likely that when normal conditions return, striking advances will be made in this direction.

There is also a group of reports dealing more or less with carbohydrate metabolism, "Heterotrophic Assimilation of Carbon Dioxide" by C. H. Werkman and H. G. Wood, "Cellulose Decomposition by Microorganisms," by A. G. Norman and W. H. Fuller, and "A Unified Hypothesis of the Reciprocal Integration of Carbohydrate and Fat Catabolism" by E. J. Witzemann. "Diamin–Oxydase" by E. A. Zeller, "The Chemistry of Tea Fermentation," by E. A. Houghton Roberts and a paper on the respiration and metabolism of Aspergillus[1] by Hiroshi Tamiya complete the contents.

W. F. ROSS

The Spectrochemical Analysis of Metals and Alloys. By F. TWYMAN, F.R.S., Managing Director, Adam Hilger, Ltd. Chemical Publishing Company, Inc., 234 King Street, Brooklyn, New York, 1941. vii + 355 pp. 61 figs. 14.5 × 22 cm. Price, $8.50.

As managing director of Adam Hilger, Ltd., Mr. Twyman has had a great deal to do with the instrumental design of spectrographs and accessory apparatus, and also with the general furtherance of spectrochemical analysis. He is thus in a position to write an authoritative book on the subject. In the preface the author states that he had three classes of readers in mind when writing the book, namely, "(1) teachers and students of metallurgy who wish to acquaint themselves with the scope and nature of spectrochemical analysis as carried out in industrial laboratories; (2) metallurgists already engaged in industry to whom it may fall to introduce the method for routine control or research; (3) those already engaged in this field of analysis." To these he might well have added directors of research or heads of analytical laboratories who may be considering the application of spectrochemical analysis to their own particular problems.

Chapter I, The History of the Development of Spectrochemical Analysis, is based on a similar chapter in Kayser's "Handbuch der Spektroskopie." Chapter II, The Elements of Atomic Spectrum Theory, is a revised version of the section of the same title that A. C. Candler contributed to "Spectrochemical Analysis in 1938." Chapter III deals with Spectrographs and Accessory Apparatus. In this chapter the author discusses both grating and prism types of instruments, with a distinct preference for the latter. It is interesting to note that two commercial grating instruments of American manufacture have been joined by the "Technal" grating spectrograph for metallurgical analysis, which was put on the market by Adam Hilger, Ltd., in 1940. Chapter IV, The Microphotometer, is one of the most readable yet concise discussions the reviewer has seen. It is a pity that the visual comparator type of instrument was not discussed in this chapter.

Part II opens with Chapter V, Methods of Exciting Emission Spectra. This is a comprehensive survey of the various methods and the apparatus required for each. Chapter VI deals with the Taking of Spectrograms, Measuring Wavelengths, and Identifying Elements: Books and Tables. Chapter VII covers the Techniques of Spectrochemical Analysis, which the author defines as the proper selection of apparatus, mode of excitation of the spectrum, and the evaluation of the photographic plate applied to a particular analytical problem. In this chapter the logarithmic sector, the step sector and the step diaphragm, etc., are discussed. Chapter VIII, Types of Problem to which Spectrochemical Analysis is Applicable, should be read by every research director who may not know either the advantages or disadvantages of this mode of analysis. From the purely practical standpoint, the practising spectrochemical analyst will probably get the most out of Chapter IX, dealing as it does with the Practice of Spectrochemical Analysis of Metals and Alloys. The commercial analysis of Aluminum and its Alloys, Cadmium, Gold, Iron, Steel and Ferrous Alloys, Lead and its Alloys, Magnesium and its Alloys, the Platinum Metals, Silver, Tin, Zinc and Zinc-base Alloys, are all discussed. Chapter X, The Analysis of Substances not in Metallic Form including Gases, concludes the text. This is followed by two appendices, the first on Units and Definitions, and the second Additional Notes on methods.

The style of the book is very simple and readable. References are to paragraph numbers throughout the book, and literature references are made by the authors' names

followed by the year in which the paper appeared. These are all listed at the end of the book under the heading Bibliography and Author Index. Without a doubt this book is the best exposition of the principles and practice of emission spectrum analysis that has appeared in English. It is a "must own" book for the library of every analyst who has anything to do with spectrochemical analysis.

Since the American edition was undoubtedly printed from the British plates (or perhaps the printed forms were imported into the United States) it is a pity that a better quality of paper was not used. The paper quality in the American edition is worse than that in the British. The American publisher did not even see fit to print the spectrum plates, such as the frontispiece, on glazed paper. In view of these things, it is strange that the American edition should be priced at $8.50, which seems exorbitant in comparison to the British price of one guinea. After all, the cost of the plates would be absorbed in the British publisher's cost, and even allowing for an import duty, the American cost is exorbitant.

Heats of Organic Reactions. XIII. Heats of Hydrolysis of Some Acid Anhydrides

BY JOHN B. CONN, G. B. KISTIAKOWSKY, RICHARD M. ROBERTS AND ELGENE A. SMITH

For the purpose of quantitative estimation of the effect of substitution on the stability of cyclic structures, it would be of interest to compare the heats of hydrolysis of straight-chain acid anhydrides with those of cyclic acid anhydrides. It is necessary to obtain the heat of the reaction

$$\text{Anhydride (g)} + H_2O\text{ (g)} = \text{Acid (g)} + \Delta H \quad (1)$$

since only in the gas phase, where entropy changes would be very nearly the same for a series of reactions of the type contemplated here, would the ΔH values be a fair measure of stability. Unfortunately no cyclic anhydrides are of sufficient volatility, and no acid anhydrides, whether cyclic or straight-chain, are reactive enough with water to permit application of the technique of gas calorimetry. Nevertheless, as the first step toward obtaining heats of the above reaction 1, we have carried out calorimetric measurements in solution which allow calculation of heats of the following type of reaction

$$\text{Anhydride (s or l)} + H_2O\text{ (l)} = \text{Acid (s or l)} + \Delta H \quad (2)$$

Some of the heats of reaction 2 which we report here can be computed from existing heats of combustion; however, our data cover a wider range of compounds, and we believe that our direct measurements are of greater accuracy than the heats of hydrolysis obtainable from these older combustion data.

Experimental Procedure

The calorimeter used in these measurements has been described in a previous paper of this series.[1] It was used in this work as a single calorimeter. The chemical reaction was carried out in one calorimeter; the other calorimeter was filled with water and allowed to attain its equilibrium temperature due to stirring, thus serving as a reference bath for the main thermel.

An electrical calibration of the calorimeter preceded and followed each chemical run. The procedure was as follows.

The calorimeter was filled and was brought by electrical heating to a suitable temperature somewhat below that of the bath. After waiting fifteen minutes for the attainment of a steady state, observations on the main thermel were made every five minutes for half an hour. A current of approximately 0.4 ampere was then passed through the calorimeter heater for about five minutes. The time interval was measured with an error of less than 0.1% by a chronograph connected with the heater switch. Measurements of the potential across the calorimeter heater and across a 0.1 ohm standard resistance in series with the heater were made frequently during the heating period. Current from the batteries was allowed to pass through a ballast coil of the same resistance as the calorimeter heater for at least half an hour before making a run, and was thrown directly from the ballast coil to the heater. Following the heating period, readings on the main thermel were made frequently until a steady state was reached, then every five minutes for half an hour. From the readings of the half-hour periods before and after the heating period the equilibrium temperature and the cooling constant of the calorimeter and contents were determined. The effective microvolt rise due to electrical heating was then calculated by logarithmic extrapolation of the two cooling curves to the middle of the heating period. The effective microvolt rise, together with the potential readings across the heater and standard resistance gave the calibration constant of the calorimeter and contents in calories per microvolt. In this paper 1 cal. = 4.1833 int. joule. The electrical calibrations before and after the chemical run differed by less than 0.1%.

The method of making the chemical run will now be de-

(1) Conn, Kistiakowsky and Roberts, THIS JOURNAL, **62**, 1895 (1940).

scribed. After purification, the various compounds were packed in previously weighed thin-walled soft glass sample bulbs whose outside dimensions were about 5 × 80 mm. Solid compounds were introduced into the sample bulbs in a dry box and sealed off immediately after filling. Sample bulbs were filled with liquid compounds in the absence of air by distillation into special receivers (described below) holding the sample bulbs. The sample bulbs for liquids had capillary tips, and were quickly sealed off after filling and removing from the receiver. The sample bulb was held in place in the calorimeter by four stainless steel strips wired at the bottom, forming a cage for the bulb. At the top the strips were fastened to a stainless steel truncated cone ground to fit the truncated conical sample aperture in the top of the calorimeter.[2] The cone had a threaded hole in its center, into which was screwed a threaded stainless steel rod terminating in a sharp conical tip at its lower end. The upper end of the threaded rod was above the thermostat bath, and was attached to a small reversible motor making it possible to screw the rod up or down. When a sample tube was in place, upon screwing the rod downward the sharp tip on the lower end of the rod drove into the sample bulb and shattered it, allowing the sample to dissolve and react with the alkali. The heat of breaking the sample bulb was determined and was taken into account in calculating the results of the chemical run.

At the beginning of the chemical run the sample bulb was broken, and main thermel readings were made every thirty seconds while the heat evolution was rapid, later at longer intervals, until the cooling constant resumed its normal value. Correction for heat loss during the reaction period was made by numerical computation of the area under a plot of cooling constant × thermal head against time.

Direct measurement of the heat of hydrolysis of the acid anhydrides in pure water was first attempted, with fair success in the case of acetic anhydride, but the rate of hydrolysis of propionic anhydride proved too slow. The plan was therefore revised, and the hydrolysis was carried out in a slight excess of alkali, so that the sum of the heat of hydrolysis and the heat of neutralization of the acid was measured. Under these conditions the reaction was complete in most cases in about an hour. Heats of neutralization of the acids were subsequently measured. To increase the solubility of some of the compounds studied, the reaction was carried out in a dioxane-water mixture. Heats of dilution of these mixtures were determined.

Preparation of Compounds

Acetic Acid and Anhydride.—Merck Blue Label acetic acid was purified first by partial freezing and then carefully fractionated through Column B.[3] In this and subsequent distillations, the receiver which was to contain the calorimetric sample was specially designed so as to carry within it six previously weighed bulbs. At the conclusion of the distillation, the bulbs were filled by pumping out the receiver and then admitting dry air; as soon as they were full, they were removed and immediately sealed and reweighed. The calorimetric sample was taken in the middle of the distillation after the head thermometer had been registering a constant temperature for some time (usually an hour). The acetic acid fraction used for calorimetric measurement boiled at 118.03 ± 0.01° (770 mm.)[4] Merck Blue Label acetic anhydride was similarly distilled; the fraction used boiled at 138.70 ± 0.01° (770 mm.).

Propionic Acid and Anhydride.—Eastman Kodak Co. best grade materials were distilled through Column B. The acid boiled at 141.28 ± 0.01° (766 mm.). The anhydride boiled at 166.94 ± 0.04° (777 mm.).

Isobutyric Acid and Anhydride.—Commercial isobutyl alcohol was oxidized to the acid as described by Pierre and Puchot.[5] After preliminary purification, a precision distillation yielded a calorimetric sample boiling at 154.68 ± 0.02° (767 mm.). Isobutyryl chloride was made from the acid by distillation with benzoyl chloride;[6] yield 91%; b. p. 92.8–92.9° (765 mm.). Isobutyric anhydride, prepared from the above chloride and sodium isobutyrate (67% yield), gave a calorimetric sample boiling at 92.41 ± 0.04° (34.1 mm.). It froze at −56.37° with a drift of 0.065° to the point where jamming of the stirrer by solid made thermocouple readings unreliable.

Trimethylacetic Acid and Anhydride.—A quantity of trimethylacetic acid was kindly furnished us by Professor P. D. Bartlett of these Laboratories; a further amount was obtained from Eastman Kodak Co. The portion reserved for the calorimeter boiled at 164.18 ± 0.01° (763 mm.). Conversion to the chloride as previously described gave a 96% yield of material boiling at 104.8–105.0° (762 mm.). The anhydride was prepared from the chloride and the dry sodium salt[7]; yield, 78%. The calorimetric sample boiled at 95.00 ± 0.01° (28 mm.) and froze at −4.24° with a drift of 0.03° to jamming of the stirrer.

Succinic Acid and Anhydride.—Mallinckrodt Analytical Reagent succinic acid was used for the neutralization measurements. The anhydride was prepared from this acid by phosphorus oxychloride dehydration[8]; yield, 92%. The product was recrystallized from acetyl chloride (m. p. 119–120°), and then sublimed *in vacuo* at 91°. The sublimator is of all-metal construction; vaporization takes place on a circular plate through the center of which the condenser tube runs. Condensation occurs below the plate; the solid is removed by a rotary scraper, and falls into a series of glass cups carried on a movable tray. The sublimator bell and plate are heated electrically; glass windows in the bell and receiver carriage permit observation of the process. The sublimate, which was in the form of an almost impalpable powder, was preserved in a desiccator over phosphorus pentoxide until transferred to the bulbs.

Maleic Acid and Anhydride.—Eastman Kodak Co. best grade maleic anhydride was recrystallized from acetyl chloride. The best material was sublimed *in vacuo;* f. p. 52.27° with 0.08° drift to jamming of the stirrer. Some of the best anhydride was hydrolyzed to the acid.

(2) See ref. 1 for a diagram of the calorimeter.

(3) Column B is described by Kistiakowsky, Ruhoff, Smith and Vaughan, THIS JOURNAL, **57**, 877 (1935).

(4) This value may be in error in absolute magnitude, inasmuch as the only correction applied to it was for barometric fluctuation. The deviation includes the uncertainty in reading the thermometer used plus the magnitude of the random fluctuations.

(8) "Organic Syntheses," Vol. XII, 1932, p. 66.

After two recrystallizations from water, the m. p. was 130–131°, with some decomposition.

Methylenesuccinic (Itaconic) Acid and Anhydride.—Mallinckrodt Analytical Reagent citric acid was converted to methylenesuccinic anhydride as described in "Organic Syntheses."[9] The yield of crude acid anhydride mixture from 4400 g. of citric acid was 45%. The solid acid which separated on standing was systematically recrystallized from water until no further alteration in melting behavior occurred, then twice more; m. p. 162–166°, dec. Some of the best acid was converted to the anhydride by means of acetyl chloride[10]; yield 79%; m. p. 67–68°. It was then sublimed *in vacuo* at 90°.[11]

Methylmaleic (Citraconic) Acid and Anhydride.—Methylmaleic anhydride was prepared by distillation of crude itaconic anhydride[12]; yield 80%; b. p. 119–120° (37 mm.). Precise fractionation through Column B yielded a calorimetric sample with b. p. 110.35±0.01° (28.8 mm.) and f. p. +6.03°, drift, 0.04° to jamming of the stirrer. A sample of the best anhydride was hydrated with a slight excess of water.[12] After prolonged drying in a vacuum desiccator over phosphorus pentoxide, the acid melted at 91–92°.

Methylsuccinic Acid and Anhydride.—Methyl cyanosuccinic ester was prepared from purified ethyl α-bromopropionate (b. p. 80.0–80.1° at 46 mm.) and ethyl cyanoacetate (b. p. 103.0–103.1° at 17.5 mm.).[13] Condensation was carried out in 3.75 mole lots; yield of product boiling flatly at 162.7° (22 mm.), 67%. Hydrolysis of the cyanosuccinic ester (2.5 liters of concentrated hydrochloric acid suffices for 1 kg. of ester) gave 84% yield of methylsuccinic acid; m. p. 112–112.5° after recrystallization from water and absolute ether. The acid was converted to the anhydride by means of phosphorus oxychloride; yield 67%. The calorimetric sample boiled at 135.78±0.02° (24 mm.). The anhydride crystallizes very sluggishly and will remain in the supercooled state almost indefinitely unless it is seeded or strongly cooled in dry-ice.

***dl*- and *meso*-α,β-Dimethylsuccinic Acid; *trans*- and *cis*-α,β-Dimethylsuccinic Anhydride.**—Much confusion exists in the literature as to the configuration of these two acids, and the impression seems to be prevalent that neither of them has ever been resolved,[14] although the resolution of the low melting isomer was carried out by Werner and Basyrin in 1913,[15] and confirmed by Ott in 1928.[16] Thus the "*anti*" acid of Bischoff and Voit[17] and the "*cis*" acid of Bone and W. H. Perkin, Jr.,[18] and of Bone and Sprankling[13] is the *dl*- form and will be so described here; while the "*para*" or "*trans*" acid is *meso*-. The correctness of the configurations assigned is further indicated by the fact that the lower-melting acid gives the higher-melting anhydride, which would be expected in view of its greater symmetry.

Diethyl α-methyl α′-cyanosuccinate was methylated with purified methyl iodide[13] in 2.5 mole lots. An excess of both sodium and methyl iodide was employed so as to insure completeness of the process; this is necessary since the two esters boil within a few degrees of each other. The yield of product boiling flatly at 161.1° (21 mm.) was 85%. Hydrolysis was effected with concentrated hydrochloric acid (3 liters of acid for 968 g. of ester). The *meso*-acid, which crystallized on cooling, was repeatedly recrystallized from water with intervening treatments with cold acetyl chloride as recommended by Bone and Sprankling.[13] The melting point attained the value 209° given by these workers only on very rapid heating, inasmuch as decomposition to the anhydride is noticeable around 180°, and becomes rapid at 190°. The mother liquor from the *meso*-acid was evaporated to dryness and extracted with boiling acetone, giving the racemic acid contaminated with some of the *meso*- acid (total recovery, 83%). The dry extract was converted to the *trans*-anhydride by refluxing with acetyl chloride and distilling (b. p. 232–233°)[19]; yield, 84%. The *trans*-anhydride was recrystallized from benzene–absolute ether mixture and then sublimed *in vacuo;* m. p. 87–88°. The corresponding *cis*-anhydride was prepared from some of the best *meso*-acid by means of acetyl chloride and subsequent recrystallization from this solvent; m. p. 42°. Owing to its lability when heated, sublimation was not attempted.

Hydration of the best *trans*-anhydride yielded a calorimetric sample of *dl*-acid, m. p. 126°, with some decomposition. The behavior of both the *meso*-α,β-dimethylsuccinic acid and the corresponding *cis*-anhydride in the calorimeter was abnormal; a secondary reaction was indicated by a failure of the calorimeter to return to its normal cooling rate. The only side reaction which would seem to be possible is that of epimerization. The following test was carried out: 1 g. of the best *meso*-acid was dissolved in an excess of C. P. base at room temperature and allowed to stand for nineteen hours. At the end of this time the solution was acidified with C. P. hydrochloric acid, taken to dryness at room temperature *in vacuo* and the residue extracted with C. P. anhydrous ether in a Soxhlet apparatus. The dry extract melted over a wide range of temperature, becoming completely fluid at 184°. Epimerization would thus seem to be established.

α,α-Dimethylsuccinic Acid and Anhydride.—The procedure of Vogel[20] was adopted; the yield of ethyl α-cyanodimethacrylate boiling at 122.9–123.0° (20 mm.) was 52%. Treatment of this ester with sodium cyanide and subsequent hydrolysis with concentrated hydrochloric acid gave a 62% yield of α,α-dimethylsuccinic acid. After three recrystallizations from water the m. p. was 141–142° (dec.). Conversion to the anhydride with acetyl chloride gave an 82% yield; b. p. 222–223°. A precision distillation was unsuccessful because the anhydride solidified in the condenser; likewise sublimation failed because the material condensed as liquid, then froze and jammed the scraper.

(9) "Organic Syntheses," Vol. XI, 1931, p. 70.

(10) Anschütz and Petri, *Ber.*, **13**, 1539 (1880).

(11) The alkaline hydrolysis of methylenesuccinic anhydride pursued an abnormal course, as was shown by the failure of the calorimeter to return to its normal cooling rate after the main reaction was over. The calorimeter liquid was also brownish in color. The abnormality was not observed during neutralization of the acid, nor during hydrolysis of the isomeric methylmaleic anhydride.

It was finally recrystallized from a mixture of anhydrous ether and ligroin.

Tetramethylsuccinic Acid and Anhydride.—As starting material, commercial phorone was used. Neither repeated fractionation through our tall columns nor partial freezing sufficed to obtain a flat boiling fraction.[21] The best sample (1065 g. from 1 gallon) boiled at 103.0–104.2° (35 mm.), began to freeze at 23.4°, and had $n^{20}D$ 1.4912. Following the synthesis of Francis and Willson,[22] the steps were: (1) phorone to phorone tetrabromide, yield, 50%; (2) phorone tetrabromide to dibromophorone, yield, 67%; (3) dibromophorone to 2,2,3,3-tetramethyl-4-bromo-5-hydroxy-Δ^4-cyclopentenone-1, yield of crude product, nearly quantitative; (4) oxidation to α-ketotetramethylglutaric acid, yield, 86%; (5) keto-acid to tetramethylsuccinic acid, quantitative. The crude acid was dissolved in excess acetyl chloride and distilled. The anhydride, b. p. 218–220°, formed a white powder which quickly became sticky and reverted to a waxy mass. That this is not due to hydration has been shown by Auwers and Meyer.[23]

Successive calorimetric runs on this material showed a steadily diminishing heat of hydrolysis. Since this seemed to be due to alteration in crystal form, a portion of the anhydride was left for two weeks in contact with a saturated ether solution of the material, the ether being allowed to evaporate slowly. Large waxy crystals were deposited which underwent no change on standing. This presumably stable form of the solid was used in the calorimeter.

A portion of the best anhydride was dissolved in sodium hydroxide solution, and the acid recovered by acidification. It melted at 200–201° with decomposition (bath preheated to 190°).

Results and Discussion

The experimental results to be presented here are heats of three types of reaction. For the straight-chain anhydrides the three reactions are

$$1\text{ Anhydride (l)} + H_2O\text{ (dioxane-water)} + 2NaOH\text{ (d - w)} = 2NaA\text{ (d - w)} + 2H_2O\text{ (d - w)} + \Delta H_1 \quad (3)$$

$$1HA\text{ (s or l)} + 1NaOH\text{ (d - w)} = 1NaA\text{ (d - w)} + 1H_2O\text{ (d - w)} + \Delta H_2 \quad (4)$$

$$1H_2O\text{ (l)} = 1H_2O\text{ (d - w)} + \Delta H_3 \quad (5)$$

In Eqs. 3 and 4 A represents the acid radical. Taking (3) − (2 × (4)) + (5), one obtains

$$1\text{ Anhydride (l)} + 1H_2O\text{ (l)} = 2HA\text{ (s or l)} + \Delta H_1 - 2\Delta H_2 + \Delta H_3 \quad (6)$$

Equation (6) is identical with Eq. 2, in which the heat of hydrolysis is

$$\Delta H = \Delta H_1 - 2\Delta H_2 + \Delta H_3 \quad (7)$$

For the cyclic anhydrides the equation corresponding to (6) is

$$1\text{ Anhydride (s or l)} + 1H_2O\text{ (l)} = H_2A\text{ (s or l)} + \Delta H_1 - \Delta H_2 + \Delta H_3 \quad (8)$$

where ΔH_2 is now the heat of neutralization of one mole of the dicarboxylic acid by two moles of sodium hydroxide.

Table I consists of the heats of hydrolysis and neutralization of the anhydrides. The letters A, B and C in the column headed "Solution" refer to the compositions of the solutions in which the reactions were carried out; these compositions are given in Table III along with the heats of dilution. Table II contains heats of neutralization of the acids. Heats of neutralization are given for some acids for which the heats of hydrolysis and neutralization of the corresponding anhydrides could not be obtained, due to side reactions. These cases were discussed in the section on preparation of materials. In Tables I and II the mean temperatures listed refer to the temperature of the thermostat bath during the reaction. This temperature was measured with a five-junction thermel, one end of which was immersed in ice. This thermel was previously calibrated against a platinum resistance thermometer. The temperature of the calorimeter during reaction in no case differed by more than one degree from that of the bath.

data of Table IV to the gaseous state by determining heats of vaporization and sublimation. A static all-glass vapor pressure apparatus was constructed which permitted accurate vapor pressure measurements in the range 0.01 to 100 mm. With this equipment measurements on many of the compounds listed in the above tables were made over a range of temperatures, with good results for liquids but with indifferent success in the case of solids. The solid compounds showed extraordinary delays in the establishment of constant vapor pressure. Furthermore, the solid dicarboxylic acids were recrystallized from solvents, and in order to free them from traces of these impurities, sublimation *in vacuo* into the vapor pressure apparatus was attempted. It was found, however, that at temperatures at which sublimation could be effected with reasonable speed, some decomposition, attended by formation of water, occurred. This work was therefore abandoned and the incomplete data will not be reported here, since no use can be made of them in the following discussion.[24]

Our failure to reduce the data to a common and readily interpretable standard state destroys much of the force of the conclusions to be drawn from Table IV. Nevertheless, some interesting qualitative points can be brought out. In this discussion more weight will be given to values obtained in this investigation than to those determined from heats of combustion, also given in Table IV. The justifications for this choice are: (a) carefully purified materials used by us, and (b) formation of our data of Table IV as rather large differences of relatively small directly determined heat values. We are unable, however, to explain in detail the causes of the discrepancies of the two sets of data of Table IV. It will be noted first of all that methyl substitution in acetic acid has substantially no effect on the heats of hydrolysis of the corresponding anhydrides. The trimethylacetic anhydride is no exception since the heat of fusion of the acid is probably of the order of 1 to 2 kcal.,[25] thus making the heat of the liquid to liquid reaction about 13 to 14 kcal. This is in marked contrast to the well-known effect of methyl groups on the acid strength, demonstrated also by the series of the heats of neutralization given in Table II.

In the series of cyclic anhydrides of Table IV, however, methyl substitution has a very marked and systematic effect. If one allows again 1 to 2 kcal. for the heats of fusion and computes all reactions to the same state of aggregation, one sees that *unsymmetrical* methyl substitution invariably increases the heat of hydrolysis while symmetrical substitution decreases it still more markedly. Even the comparison of the *trans*-α,β-dimethylsuccinic and the tetramethylsuccinic anhydrides bears out this conclusion. Although we are unable to account for these effects even semiquanti-

(24) The work of F. H. MacDougall on acetic and propionic acids [THIS JOURNAL, **58**, 2585 (1936); **63**, 3420 (1941)] indicates that the very considerable association of the vapors of these acids even at low pressures seriously impairs the calculation of heats of vaporization from vapor pressures of the carboxylic acids.

(25) The heat of fusion of trimethylacetic acid is not recorded in the literature. The heats of fusion of propionic and isobutyric acids are 1.8 and 1.2 kcal., respectively.

tatively, it is more than probable that interactions are here involved similar to those which show themselves in the heats of hydrogenation of some five-membered carbon ring compounds[26] and which have been interpreted as "steric hindrance" between hydrogen atoms on adjacent carbons. In line with this conclusion is also the difference in the heats of hydrolysis of maleic and of succinic anhydrides, while the conventional view would take maleic anhydride for the more strained of the two five-membered rings, the data actually indicate the reverse, in line with the above-mentioned data on the cyclopentene–cyclopentane relationship.[27]

Finally, the absence of methyl substitution effects in straight-chain anhydrides, where complete freedom of orientation exists, points again to "steric hindrance" as the main if not the sole cause of the observed variations of the heats of hydrolysis. It may be noted in passing that these effects seem to bear no relation to the heats of ionization of the corresponding acids, for which Table II gives a series of relative values.

Without knowledge of the entropy changes concerned, it is rather futile to discuss in detail the relation of the thermal data obtained to the thermodynamic stability of the anhydrides and acids. It may be noted, however, that the increased stability of cyclic, as against the straight-chain, acid anhydrides, can be accounted for by their generally lower heats of hydrolysis and a probably less positive entropy change caused by a loss of mole numbers in their reaction with water. On the other hand, it is not at all probable that the increasing stability in the series succinic to tetramethylsuccinic anhydrides[28] can be so explained. Possibly some purely rate factors are here of more importance.

The authors wish to thank the Rockefeller Foundation for the grant under which this investigation was carried out.

Summary

Heats of the hydrolytic reaction: Anhydride (s or l) + H_2O (l) = Acid (s or l) computed from heats of reaction in solution are reported here for a number of straight-chain and cyclic (five-membered ring) acid anhydrides.

Acetic, propionic, isobutyric and trimethylacetic anhydrides were found to have the same heat of hydrolysis, showing no effect due to methyl substitution.

Methyl substitution in the ring compounds markedly alters the heat of hydrolysis. Unsymmetrical substitution of methyl groups in succinic anhydride increases the heat of hydrolysis, while symmetrical substitution decreases it. The presence of a double bond in the ring also decreases the heat of hydrolysis.

These effects are qualitatively discussed, and similarities to the trend of heats of hydrogenation of five-membered carbon ring compounds are pointed out.

The Electron Diffraction Investigation of Propargyl Chloride, Bromide, and Iodide

BY LINUS PAULING, WALTER GORDY,[1] AND JOHN H. SAYLOR

The surprising discovery that the carbon–carbon single-bond distance in methylacetylene[2] and some related substances[2c] is less than the normal value suggested that the study of the propargyl halides would be of interest. We have carried out this study, and have found that the carbon–carbon triple-bond and single-bond distances are the same in these molecules as in methylacetylene, and that the carbon–halogen bond distances are somewhat larger than normal.

Experimental Methods

The propargyl halides were prepared in these Laboratories by Mr. Allan Grossberg from α-chloroallyl alcohol ($H_2C{=}CClCH_2OH$) kindly furnished by the Shell Development Company. This substance was converted into propargyl alcohol by the method described by Henry.[3] Propargyl chloride and propargyl bromide were then prepared by treating the alcohol with phosphorus trichloride and phosphorus tribromide, respectively.[4] Propargyl iodide was prepared from propargyl bromide and sodium iodide.[5]

The electron diffraction photographs were made in the usual way, with film distance 10.85 cm. and electron wave length 0.0613 Å. For each substance the ring diameters were measured separately by two observers on about ten photographs and the resultant values of $q_{obs} = 40 (\sin \theta/2)/\lambda$ were averaged. Estimates were made of the intensities of the apparent maxima and minima, and in addition curves were sketched reproducing the appearance of the photographs.

Radial distribution curves were calculated by the equation

$$lD(l) = \sum_k C_k \sin \frac{\pi}{10} q_k l$$

with use of coefficients C_k obtained from the estimated intensities by multiplication by the damping factor e^{-aq^2}.

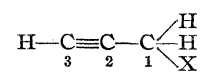
(4) L. Henry, *ibid.*, **7**, 761 (1874); **8**, 398 (1875); A. Kirsmann, *Bull. soc. chim.* [iv], **39**, 698 (1926).

(5) L. Henry, *Ber.*, **17**, 1132 (1884).

The simplified theoretical intensity curves were calculated by the equation

$$I(q) = \sum_i \sum_j (\psi_i \psi_j / l_{ij}) \sin \frac{\pi}{10} q l_{ij}$$

The scattering powers ψ were taken proportional to the atomic numbers of the atoms. The values C_3—H = 1.06 Å. and C_1—H = 1.09 Å. were assumed, and as the bond angle C_2–C_1–X was varied the other five angles of C_1 were kept equal in value. The atoms $HC_3C_2C_1$ were assumed to be collinear, as indicated by the bonds in the model



All calculations were made with use of punched cards and International Business Machines.

Interpretation of the Data

Propargyl Chloride.—The photographs of propargyl chloride, showing about thirteen maxima and thirteen minima, have the appearance indicated by curve Chloride Obs. in Fig. 2. The radial distribution curve calculated from the data of Table I is given in Fig. 1. The peaks of this curve are at 1.18, 1.48, 1.81, 2.72, and 3.72 Å. The same values, to within 0.01 Å., were found for the three principal peaks for other curves calculated with somewhat changed values of the coefficients C. These distances correspond, respectively, to C_3—C_2, C_2—C_1, C_1—Cl, C_2—Cl (plus C_3—C_1), and C_3—Cl.

We make the following assumptions: 1. The distance C_3—C_2 has the triple-bond value 1.20 Å. 2. The carbon chain is linear. 3. The three carbon–chlorine distances have approximately (to within about 0.02 Å.) the values 1.81, 2.72, and 3.72 Å. given by the three principal peaks of the radial distribution curve.

These assumptions determine the structure completely, except for the uncertainty resulting from the possible small deviations from the radial distribution values. The bond angle α = C_2–C_1–Cl is indicated to be near 112°. If the distance C_2–C_1 were equal to 1.47 or 1.48 Å., as indicated by the radial distribution curve and by the values for methylacetylene and related molecules, and the three carbon–chlorine distances were to

					Average deviation	0.008

[a] A small apparent maximum could be seen between maxima 3 and 4.

show the minimum deviations from the above values, the bond angle would be 111°.

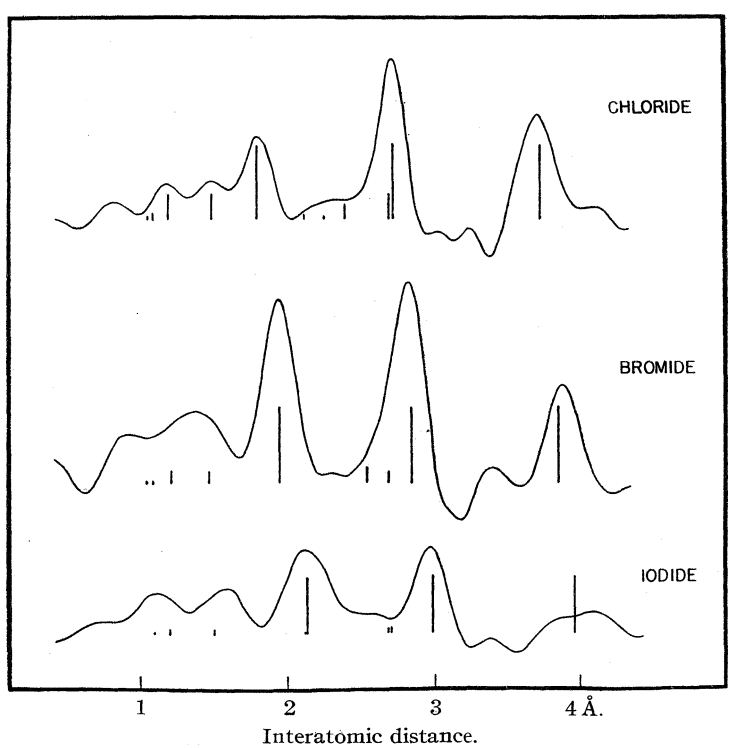

Fig. 1.—Radial distribution curves for the propargyl halides. The vertical lines correspond to the finally accepted structures.

In Fig. 2 calculated intensity curves are given for models with $\alpha = 109° 30'$, 111°, and 112° 30′ and with the above assumptions satisfied (Table IV). These curves, A, B, and C, agree well with the appearance of the photographs; the agreement is best for the curve with $\alpha = 111°$, in particular with respect to the relative intensities of maxima 7 and 8, and we accept the value of this angle as $\alpha = 111° \pm 2°$.

Curves for various other models for which interatomic distances differ from those for this model by as much as 0.03 Å., such as those for models D and E (Fig. 2, Table IV), were found to be less satisfactory, and those for models with larger deviations were unsatisfactory.

The quantitative comparison of values of q_{ob} and q_{calcd} for model B given in Table I leads to the average ratio $q_B/q_{obs} = 1.006$. Giving equal weight to this and the radial distribution values, we accept as the final values for propargyl chloride the following: C_3—C_2 = 1.20 Å. (not varied), C_2—C_1 = 1.48 ± 0.02 Å, C_1—Cl = 1.82 ± 0.02 Å., angle C_2—C_1—Cl = 111 ± 2°, C_2—Cl = 2.72 ± 0.03 Å., C_3—Cl = 3.73 ± 0.03 Å.

Propargyl Bromide.—The data for propargyl bromide given in Table II lead to a radial distribution curve (Fig. 1) with the two carbon–carbon peaks unresolved and with well-defined carbon–bromine peaks at 1.95, 2.84, and 3.85 Å. The three intensity curves F, G, and H of Fig. 2 are calculated for the assumed values C_3—C_2 = 1.20 and C_1—Br = 1.95 Å., the angle α and C_2—C_1 distance being varied in such a way as to give the longer carbon-bromine distances approximately the radial distribution values. It is seen that all three curves are in good agreement with the appearance of the photographs as represented by the curve shown in Fig. 2; the C_1—C_2 distance and bond angle accordingly cannot be determined directly. We assume that the C_1—C_2 distance has the value 1.47 Å., the average of those found in methylacetylene (1.46 Å.) and the chloride (1.48 ± 0.02 Å.); the corresponding curve, G, is a little better than the other two, of which F makes the 8th maximum too weak and H makes the 5th too weak.

TABLE II

ELECTRON DIFFRACTION DATA FOR PROPARGYL BROMIDE

8		+ 4	+ 4	57.1	57.7	1.011
9		+ 7	+ 4	63.6	64.1	1.008
10		+ 7	+ 2	70.6	73.4	(1.039)
					Average	1.003
					Average deviation	0.003

Various other models were found to be unsatisfactory; for example, models I and J (Fig. 2), with C_1—Br given the value 1.91 equal to the sum of the single bond radii and the C—C—Cl angle chosen so as to make the long C—Br distances close to the radial distribution values, fail to give the observed relative intensities of maxima 6, 7, and 8.

The quantitative comparison of q_{obs} and q_{calcd} for model G leads to the average ratio q_G/q_{obs} = 1.003 (omitting values which seem less reliable than the others). We accept the following parameter values: C_3—C_2 = 1.20 Å., C_2—C_1 = 1.47 ± 0.02 Å., C_1—Br = 1.95 ± 0.02 Å., angle C_2—C_1—Br = 112° ± 2°, C_2—Br = 2.85 ± 0.03 Å., C_3—Br = 3.85 ± 0.03 Å.

[a] A shelf at q = 44.7 could be seen on the outer edge of this ring.

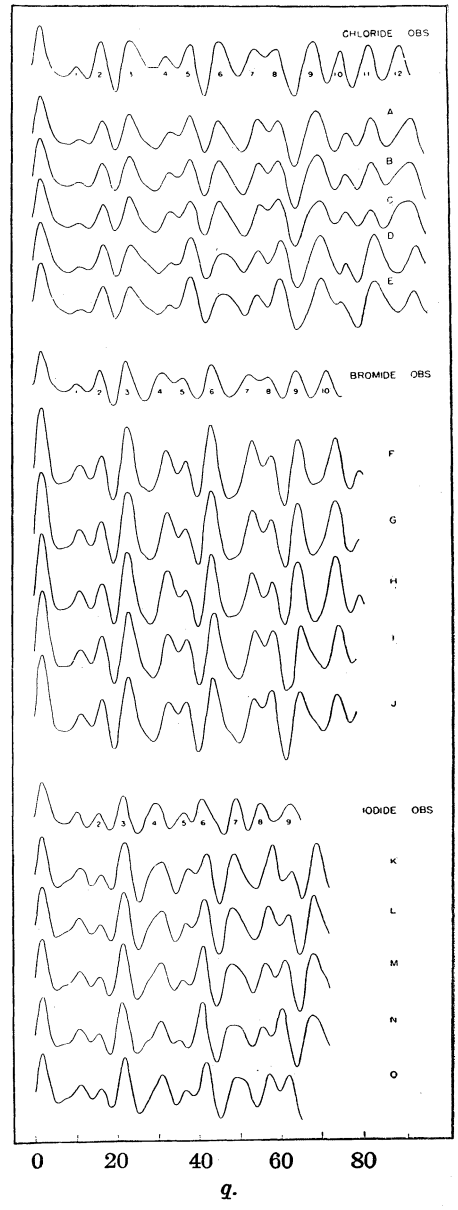

Fig. 2.—Curves (marked Chloride Obs., Bromide Obs., Iodide Obs.) drawn to represent the appearance of electron diffraction photographs, and calculated intensity curves for the propargyl halides.

Propargyl Iodide.—The photographs of propargyl iodide were not so good as those of the bromide, which were themselves inferior to those of the chloride. The radial distribution curve of Fig. 1, corresponding to the data in Table III, has well-defined maxima at 2.13 and 2.96 Å., and poorer ones at 1.2, 1.5, and 4.1 Å.

TABLE IV

DISTANCES AND BOND ANGLES FOR PROPARGYL HALIDE MODELS

Model X = Cl	C_1-X	C_3-C_2	C_2-C_1	Angle α	C_2-Cl	C_3-Cl
A	1.81	1.20	1.50	109°30′	2.71	3.72
B	1.81	1.20	1.47	111°	2.71	3.72
C	1.81	1.20	1.44	112°30′	2.72	3.72
D	1.81	1.20	1.50	111°	2.69	3.72
E	1.76	1.20	1.47	113°40′	2.71	3.72
X = Br						
F	1.95	1.20	1.52	110°	2.85	3.85
G	1.95	1.20	1.47	112°	2.85	3.85
H	1.95	1.20	1.42	114°	2.84	3.85
I	1.91	1.20	1.47	112°	2.81	3.82
J	1.91	1.20	1.47	115°	2.86	3.88
X = I						
K	2.13	1.20	1.47	108°	2.95	3.90
L	2.13	1.20	1.47	110°	2.98	3.95
M	2.13	1.20	1.47	112°	3.01	4.00
N	2.13	1.20	1.47	114°	3.05	4.05
O	2.10	1.20	1.47	110°30′	2.95	3.94

There is no possibility of evaluating the carbon-carbon distances from the data. We assume the values C_1–C_2 = 1.47 Å. and C_2–C_3 = 1.20 Å. With these, the two C–I distances 2.13 and 2.96 Å. lead to the value 109° for the C—C—I bond angle. Curves K, L, M, and N of Fig. 2 are calculated for models with C—I = 2.13 Å. and with bond angle 108, 110, 112, and 114°, respectively (Table IV); of these K and N are unsatisfactory, especially with respect to the intensities of maxima 8 and 9. The best agreement is obtained for the curve interpolated between L and M; because of the poor quality of the photographs, however, this cannot be given much significance. Various other models also give unsatisfactory curves, such as that for model O (with C_1–I = 2.10 Å., angle 110°30′) shown in Fig. 2.

The quantitative comparison in Table III is for the model with angle 111°, intermediate between L and M. It leads to the ratio $q_{calcd}/q_{obs} = 0.997$. We accept for this molecule the values C_3–C_2 = 1.20 Å., C_2–C_1 = 1.47 Å., C_1–I = 2.13 ± 0.03 Å., angle C_2–C_1–I = 111° ± 3°, C_2–I = 3.00 ± 0.05 A., C_3–I = 3.98 ± 0.07 Å.

Discussion of the Structures

There is only one surprising feature of the structures found for these molecules; this is that the carbon–halogen bond distances are larger than those usually observed. Each of the values found, C–Cl = 1.83 Å., C–Br = 1.95 Å., and C–I = 2.13 Å., exceeds the normal single-bond value (1.76, 1.91, and 2.10 Å., respectively) by a significant amount, the difference being largest (0.07 Å.) for the chloride and smallest for the iodide.

A plausible *ad hoc* explanation for this is that there occurs resonance between the normal structure H—C≡C—CH_2(:X:) and an ionic structure H—C^+=C=CH_2 (:$\ddot{X}$:$^-$) (in addition to the usual ionic structure H—C≡C—$\overset{+}{C}H_2$ (:$\ddot{\underset{\cdot\cdot}{X}}$:$^-$) which confers ionic character on the C–Cl bond). This explanation accounts for the decrease in magnitude of the deviation in the sequence chloride, bromide, iodide, for which the electronegativity of the halogen decreases.[6]

A much greater deviation, about 0.30 Å., of nitrogen–halogen interatomic distances from the single-bond values was observed for nitrosyl chloride and nitrosyl bromide by Ketelaar and Palmer,[7] who offered a similar explanation, based on resonance with the ionic structure :O^+≡N: (:$\ddot{X}$:$^-$).

We are indebted to Dr. V. Schomaker for valuable help in this work.

Summary

The electron diffraction investigation of the propargyl halides has been carried out, leading to the interatomic distances C≡C = 1.20 Å. (assumed), C–C = 1.47 ± 0.02 Å., C–Cl = 1.82 ± 0.02 Å., C–Br = 1.95 ± 0.02 Å., and C–I = 2.13 ± 0.03 Å. and the angles C–C–Cl = 111 ± 2°, C–C–Br = 112 ± 2°, and C–C–I = 111 ± 3°.

PASADENA, CALIFORNIA RECEIVED MAY 1, 1942

(6) It was suggested by Dr. S. Winstein [Dissertation, California Institute of Technology (1939)] that the large values of the mole refraction of the allyl halides could be explained as resulting from large polarizabilities of the molecules due to resonance of the type discussed in the text above. This would lead to large values of the mole refraction for the propargyl halides also.

Cyanates and Thiocyanates of Phosphorus, Arsenic and Antimony

BY HERBERT H. ANDERSON

Forbes and Anderson[1] recently isolated cyanates or isocyanates, or both, of silicon, phosphorus and boron by the action of silver (iso)cyanate upon the corresponding chlorides. In the present report similar halogenoid derivatives have been prepared from $POCl_3$, $AsCl_3$ and $SbCl_3$, and some interesting transformations have been noted in the compounds thus obtained. Thiocyanates, $PO(SCN)_3$ and $As(SCN)_3$, have been prepared also.

Phosphoryl Isocyanate and Cyanate

Preparation.—The preparation was made in two sections, each of which gave about the same yield of product. A total of 300 g. of powdered silver (iso)cyanate and 200 g. of phosphoryl chloride in 225 ml. of pure benzene was used in a forty-four hour reflux, with occasional shaking. Filtration removed silver chloride and phosphoryl cyanate, $PO(OCN)_3$, a hydrolyzable yellowish compound (from the thermal transformation of soluble liquid into insoluble solid). After removal of benzene, there remained 12.5 g. of a colorless liquid; an 11% yield of isocyanate. Formation of the insoluble cyanate was the chief reason for the low yield. Lead cyanate reacted extremely slowly with phosphoryl chloride under similar conditions. Vacuum distillation of $PO(NCO)_3$ was necessary. *Analysis* of the purified material: a weighed sample was hydrolyzed in a large excess of 3 *N* sodium hydroxide, and then heated in 6 *N* nitric acid for an hour; ammonium phosphomolybdate was precipitated from a volume of 100 ml., 2 *N* in nitric acid. $PO(NCO)_3$: phosphorus found 17.4, 17.7%, average 17.6%; calculated 17.90%. The molecular weights were determined by the Dumas method, with determination and subtraction of the weight of phosphoryl-cyanate, non-volatile, from thermal transformation of the isocyanate during the experiment. Found: 171.4, 169.9, average 170.7; calculated 173.04.

Properties.—The m. p. was 5.0 ± 0.5°. Density measurements were obtained by the delivery from a pipet; the index of refraction was obtained at 20° using an Abbé refractometer, with thermostated prism. Boiling points at various pressures were obtained via the dynamic method in an all glass apparatus, with a calibrated thermometer. A slight uncertainty exists, because of a non-volatile form, $PO(OCN)_3$ possibly having a slight solubility; this cyanate is produced very slowly by heating the isocyanate above 100°.

A summary of the data obtained: colorless compound; b. p. (760 mm.) 193.1 ± 2°; m. p. 5.0 ± 0.5°; vapor pressure, $\log_{10} p$ (mm.) = $9.1682 - 2931/T$; λ_v = 13,410 cal.; λ_v/T = 28.8 cal./deg.; density, 1.570 ± 0.003 g./cc.; refractive index 1.4804; vapor pressure at 25°, calculated 0.2 mm. As a lachrymator it is much weaker than phosphoryl chloride.

(1) Forbes and Anderson, THIS JOURNAL, **62**, 761 (1940).

Non-volatile Form; Phosphoryl Cyanate.—This form was prepared from pure phosphoryl isocyanate by heating at 156° for five hours, and then removing unchanged $PO(NCO)_3$ in a high vacuum. Analysis for phosphorus, 17.6%; calculated 17.90%. This cyanate was a light yellow powder without evident crystalline structure. A gas was evolved when the substance was treated with acid. About 2% of the isocyanate was converted into an insoluble form in twenty hours at 100°. This cyanate darkened when warmed in a high vacuum, and was non-volatile. It has been previously[1] shown that phosphorus triisocyanate and its insoluble product are in equilibrium; one form can be converted into another—high temperatures favor the liquid form.

Phosphoryl Thiocyanate[2]

Preparation.—The preparation was made with benzene as solvent, to preclude loss of any low-boiling isothiocyanate. One hundred and ten grams of powdered silver thiocyanate, 80 g. of phosphoryl chloride, and 130 ml. of pure benzene were heated forty hours on a steam-bath, with shaking. Twenty grams of product was obtained by fractional distillation at diminished pressure. The middle fraction was redistilled and the new middle fraction taken for measurements.

Analysis.—A weighed sample was hydrolyzed in 6 *N* nitric acid—since the hydrolysis in water alone would have been very slow. $PO(SCN)_3 + 3H_2O = H_3PO_4 + 3HSCN$. Nitric acid, especially hot concentrated acid, converts thiocyanic acid into ammonium acid sulfate and hydrocyanic acid. The solution was kept at 100° for a half hour, to ensure presence of phosphorus at its highest oxidation level. Ammonium phosphomolybdate was precipitated in a volume of 100 ml., 2 *N* in nitric acid. Phosphorus found 13.9, 13.5, 14.2%, average 13.9%; calculated 14.00%. Molecular weights were obtained from the freezing point lowering of benzene; found 222, 232, average 227; calculated 221.2.

Properties.—The purest liquid when freshly prepared was colorless, although old samples tended to become orange colored. This liquid supercooled below 0° before freezing; m. p. 13.8 ± 1.0°; boiling point 300.1 ± 2°; slight decomposition and darkening set in during vapor pressure determinations, especially at temperatures over 250°. Vapor pressure equation: $\log_{10} P = 8.5330 - 3240/T$; λ_v = 14.820 cal.; λ_v/T = 25.8 cal./deg.; density 1.484 g./cc.; isomeric changes, none. Thiocyanate test on 0.01 ml. of pure fresh liquid, with acidified ferric nitrate was very strong. Vapor pressure at 25°: calculated 0.005 mm.; no lachrymatory properties.

Arsenic Tricyanate

Preparation.—The analog of phosphorus tricyanate[1] was prepared by reaction of 45 g. of silver (iso)cyanate and 17 g. of arsenic trichloride in 100 ml. of benzene (all operations

(2) Previously prepared in solution, only; Dixon, *J. Chem. Soc.*, **79**, 541 (1901).

were carried out under a hood, with special precautions to avoid inhalation or physical contact with poisonous arsenic compounds). The reaction was complete after thirty minutes of reflux on a steam-bath, with much shaking. Filtration yielded a very pale yellow solution; evaporation of the solution under diminished pressure resulted in a white solid of only moderate solubility in benzene at 30°. Upon warming the solid melted. Attempts to distil the liquid were made at various pressures: at 1 atmosphere, little distillation, product isomerizing from $As(NCO)_3$ into non-volatile $As(OCN)_3$ as shown later; at 150 mm., in an all-glass system, 10–11 g. or 60% distillation; at 73 mm. and 150.7°, about 80% distillation. Two products were obtained, volatile $As(NCO)_3$, and non-volatile $As(OCN)_3$; both liberated carbon dioxide with water or acid.

Analysis was accomplished by hydrolysis of weighed pellets in hydrochloric acid. $As(NCO)_3 + 3HCl = AsCl_3 + 3HNCO$. Then $3HNCO + 3H_2O + 3HCl = 3NH_4Cl + 3CO_2$. The solution was made alkaline, then acid, and finally a large excess of sodium bicarbonate was added. Arsenic was determined by titration with standard iodine solution, with addition of starch indicator near the end-point. Found, arsenic 37.28, 37.20%, average 37.24; calcd. 37.28%. This end-point is quite sharp at room temperature.

Properties.—Because of the poisonous nature of the arsenic compound and because of its instability, only limited observations were made. A boiling point at 760 mm., 224.0 ± 2°, was obtained by rapid comparison with that of naphthalene under similar conditions, and with the same thermometer; m. p. 97.1 ± 1°. Color was pure white; crystalline form, long needles. Vapor pressure equation, from 73 and 760 mm. points: $\log_{10} P = 8.7638 - 2924/T$. At room temperature the vapor pressure of the solid is estimated at 0.05 mm. Needles were obtained by cooling a saturated benzene solution. Approximately: $\lambda_v = 14{,}800$ cal.; $\lambda_v/T = 26.9$ cal./deg.

Non-volatile Form; Arsenic Cyanate.—This was prepared by refluxing $As(NCO)_3$ at about 230°, with fairly rapid production of the solid form; excess $As(NCO)_3$ was removed in a high vacuum. Heating of the solid form, presumably $As(OCN)_3$, at 0.001 mm. pressure resulted only in darkening, without volatilization.

Arsenic Thiocyanate

Miquel[3] thought he had volatilized a few centigrams of this compound when he heated arsenic trichloride with lead thiocyanate. He may have obtained a mixture of arsenic trioxide with some diluent. A reaction of arsenic trichloride with silver thiocyanate, in benzene as solvent, did produce a substance containing arsenic and thiocyanate. This supposed arsenious thiocyanate was soluble in benzene, but did not crystallize from benzene. Upon heating in a molecular still (tested with mercury) the substance did not distil or sublime; there was no melting point, and the solid merely darkened. Color, yellow to orange-yellow, perhaps due to free thiocyanic acid.

Antimony Cyanates

Preparation.—Twenty-seven grams of distilled antimony trichloride was dissolved in 150 ml. of pure benzene, and 60 g. (an excess) of powdered silver cyanate was added, with shaking. After ten minutes on a steam-bath the reaction started, with extremely vigorous boiling of the solvent. After thirty minutes, with shaking and addition of more benzene, the solution was filtered hot. Some $Sb(NCO)_3$ deposited as needles from the solution upon cooling. Three hundred ml. of hot benzene was used in washing the solid mixture, but the major fraction of the antimony isocyanate remained undissolved; the solubility of this isocyanate is much less than (2 g./100 ml.) of benzene at 30°. Upon careful evaporation of all the benzene, the solid was transferred to a molecular still, and partially sublimed—P = 0.001 mm. approximately; temperatures, upper bath −78°, lower bath 175°; distance between surfaces about 25 mm.

Analysis for antimony (*cf.* arsenic isocyanate): found 48.9, 49.2%; calculated 49.13% Sb.

Properties.—The color was pure white; small crystals in sublimation; larger crystals from a benzene solution. The vapor pressure was roughly 0.002 mm. at 125°. At 160° this $Sb(NCO)_3$ isomerizes, with considerable swelling, to $Sb(OCN)_3$, even with gradual elevation of temperature. The calculated m. p., 196°, is above the isomerization point.

Non-volatile Form; Antimony Cyanate.—The outstanding features of the supposed $Sb(OCN)_3$ are: its non-volatility at 0.001 mm.; the swelling at 160°, during its production from $Sb(NCO)_3$; lastly, evolution of gas when the cyanate is hydrolyzed in water.

Discussion of Results

Outside of the fifth group of the periodic table, the only available boiling points were $Si(SCN)_4$, b. p. 314.2°,[4] $Si(NCO)_4$, b. p. 185.6°,[1] and $Si(OCN)_4$, b. p. 247.2°.[1] The cyanate and isocyanate isomers were obtained in a definite ratio in several experiments; no evidence has been obtained indicating transformation of one isomer into the other.

In the fifth group definite trends have been observed. Isomeric changes are: $P(NCO)_3 \underset{100°}{\overset{\text{slowly}}{\rightleftharpoons}} P(OCN)_3$.[1] As shown above, $PO(NCO)_3 \xrightarrow{\text{heat}} PO(OCN)_3$. $As(NCO)_3 \xrightarrow{\text{heat}} As(OCN)_3$. $Sb(NCO)_3 \xrightarrow{\text{heat}} Sb(OCN)_3$. The evidence with the thiocyanates is not so clear-cut. Miquel[3] said his $P(SCN)_3$ boiled between 260 and 270° (average 265); Dixon[2] described $P(SCN)_3$ as follows, "A reddish-yellow, clear, dense oil . . . at 170° . . . suddenly changed to a sticky black solid which presently became hard and brittle." $PO(SCN)_3$ shows no marked isomeric changes. The behavior of $As(SCN)_3$ seems intermediate, between $P(SCN)_3$ and $PO(SCN)_3$: upon expulsion of the last trace of solvent at reduced pressure, the liquid turned into a yellowish solid which was not volatile—not even in a molecular still.

(3) Miquel, *Ann. chim. phys.*, [V] **II**, 343 (1877).

(4) Reynolds, *J. Chem. Soc.*, **89**, 397 (1906).

Regularity of Boiling Points.—A comparison of the boiling points of isocyanates with those of the corresponding chlorides shows interesting regularities. The difference between the boiling points of PCl_3 and $P(NCO)_3$ divided by the number of halogenoid groups is $31.9° - (169.3 - 73.5)/3$. When $PO(NCO)_3$, $As(NCO)_3$, and $Si(NCO)_4$ are included, the average increment is 31.0°. The only volatile *cyanate*, $Si(OCN)_4$, yields a higher increment, 47.4°.

Upon comparing the *thiocyanate* series with the corresponding chlorides, the increment is also found identical; $P(SCN)_3$, $PO(SCN)_3$, and $Si(SCN)_4$ yield an average increment of 64.1°. All of these three thiocyanates have been shown to be thiocyanates, not isothiocyanates.

Further work in this field is planned. The author is much indebted to Professor George S. Forbes, of this Laboratory, for valuable suggestions during the experimental work.

Summary

1. Phosphoryl isocyanate, $PO(NCO)_3$, arsenic isocyanate, $As(NCO)_3$, and antimony isocyanate, $Sb(NCO)_3$, have been prepared by the action of silver (iso)cyanate with the appropriate chloride.

2. Thermal transformations of these volatile isocyanates into the corresponding non-volatile cyanates have been observed.

3. Phosphoryl thiocyanate has been isolated; arsenic thiocyanate, provisionally reported by Miquel, has been found non-volatile.

4. Various physical properties have been investigated quantitatively and an apparent regularity of boiling points has been observed.

The Preparation and Properties of Potassium Oxalatostannate[1]

BY HOBART H. WILLARD AND TAFT Y. TORIBARA[2]

Previous workers[3] prepared and studied the complex oxalatostannates. Pechard[3b] claimed to have isolated a complex oxalatostannic acid, but he made no investigation of it. Hausmann and Löwenthal[3a] and Rosenheim and Platsch[3c] found that such an acid of constant composition could not be obtained.

Pechard prepared a potassium salt by dissolving stannic acid in potassium bioxalate solution and reported a formula $K_2SnO(C_2O_4)_2 \cdot 7H_2O$. Rosenheim and Platsch repeated Pechard's work but got entirely different results and reported a formula $K_6Sn_2(C_2O_4)_7 \cdot 5H_2O$. They state that the usual qualitative reactions for stannic tin and for oxalic acid are completely concealed and attribute this to the formation of a complex.

In connection with some proposed studies on oxalatothiostannates, further studies were made on the oxalatostannates.

Experimental

Preparation of Oxalatostannates.—The previous use of stannic acid in preparing solutions of oxalatostannates was tedious as well as undesirable because of the introduction of adsorbed impurities. For this reason a scheme was devised for preparing a solution of stannic tin in excess of oxalic acid only. Attempts to isolate an oxalatostannic acid proved unsuccessful as previous workers had found. The potassium salt was prepared and studied.

A mixture of 25 g. of metallic tin (30-mesh) and 125 g. of oxalic acid in 800 ml. of distilled water was cooled in an ice–salt-bath to about 5°. With continuous mechanical stirring, 150 ml. of 30% hydrogen peroxide (superoxol) was gradually added, and the reaction mixture was kept cool until all the tin had dissolved. Such a procedure required six hours or more. The excess of hydrogen peroxide was decomposed by adding 40 mg. of finely divided platinum black, and the solution was kept cool in an ice–salt bath during this procedure to prevent hydrolysis of the tin. The platinum was removed by filtration and the filtrate was the desired solution of oxalatostannic acid in excess of oxalic acid.

To prepare the potassium salt, the solution was analyzed for total oxalate and for tin. Allowing two moles of oxalate per mole of tin, the excess oxalic acid was neutralized by adding the calculated quantity of solid potassium bicarbonate. The solution was cooled to 0°, and the solid was filtered off. To recrystallize the salt obtained, it was dissolved in the smallest amount of water at 60°, allowed to cool to room temperature and then cooled to 0°. This salt was found to be very stable, and the air-dried solid gave a very definite composition, $K_6Sn_2(C_2O_4)_7 \cdot 4H_2O$. The potassium was determined gravimetrically as the perchlorate after first removing the tin by dropping hydrobromic acid into a boiling perchloric acid solution. The tin was determined gravimetrically as stannic oxide, using

ammonium hydroxide to precipitate the tin after the oxalate had been removed with concentrated sulfuric acid. The quantity of stannic oxide after ignition was determined by difference, using solid ammonium iodide in the second ignition. The amount of oxalate present was determined gravimetrically by oxidizing it to carbon dioxide with permanganate and absorbing the gas on ascarite.

Anal. Calcd.: K, 20.22; Sn, 20.46; C_2O_4, 53.11; H_2O, 6.21. Found: K, 20.23, 20.18; Sn, 20.41, 20.46, 20.51; C_2O_4, 53.13, 53.16, 53.20; H_2O, 6.21, 6.21.

It will be noticed that the formula obtained is identical with that of Rosenheim and Platsch[3c] with the exception of the water of hydration. In this work the water of hydration was determined directly by driving it off by heat and absorbing it on dehydrite. Previous workers determined the amount of water by difference. In order to make certain that the tetrahydrate was the solid phase in equilibrium with a saturated solution at 25°, a solution of the salt was evaporated at that temperature until the solid precipitated out. This solid was then centrifuged and analyzed immediately for water. Analyses gave 6.27% and 6.24% of water as compared to 6.21% theoretical for a tetrahydrate.

Titration of $K_6Sn_2(C_2O_4)_7$ by Alkali.—It was noticed in preparing the salt that the *p*H was low even after the calculated quantity of potassium bicarbonate had been added. A water solution of the pure compound gave the same acidic solution. Standard potassium hydroxide was added, and the *p*H change was followed with a glass electrode. The titration curve is shown in Fig. 1.

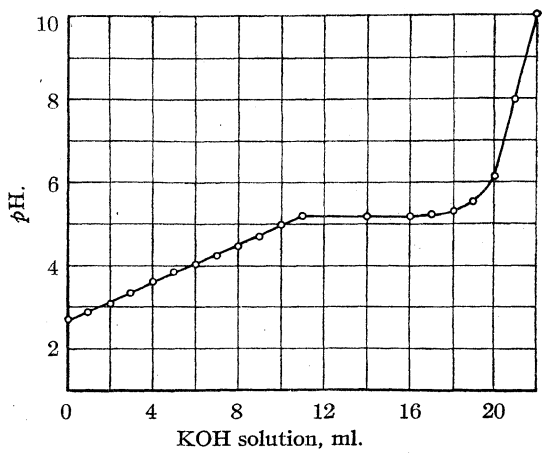

Fig. 1.—Titration of $K_6Sn_2(C_2O_4)_7$ solution with alkali.

The *p*H increased uniformly with the addition of the base until a value of 5.2 was attained. At the point where the solution became turbid from the precipitation of stannic hydroxide, the ratio $KOH/K_6Sn_2(C_2O_4)_7$ was 4.0. The *p*H remained constant until nearly all the tin had been precipitated and then increased rapidly. At the point where the steep rise in the curve occurs, the ratio $KOH/K_6Sn_2(C_2O_4)_7$ is 8.0, or just enough potassium hydroxide to precipitate all the tin in the compound as stannic hydroxide. The low value of the *p*H of a water solution of the compound may be explained on the basis of the hydrolysis of the tin.

The System $K_2C_2O_4$–$Sn(C_2O_4)_2$–H_2O.—The compound $K_6Sn_2(C_2O_4)_7 \cdot 4H_2O$ may be considered as composed of $3K_2C_2O_4$, $2Sn(C_2O_4)_2$ and $4H_2O$. Rosenheim and Platsch[3c] reported the composition of the barium salt as $Ba_2Sn(C_2O_4)_4 \cdot 8H_2O$. For these reasons it appeared as if a complex might result from other combinations of $K_2C_2O_4$, $Sn(C_2O_4)_2$ and H_2O.

The system was studied at 25°. In order to obtain true equilibrium between the solid phase and the saturated liquid phase, the solid was caused to precipitate out of the liquid phase at the temperature desired by slow evaporation. This was accomplished by the use of an isothermal evaporator constructed by attaching a number of side-arms just below the neck of a one-liter round-bottom flask. Rubber stoppers were placed on the side-arms so that 8-inch test-tubes containing the solutions could be attached. Sulfuric acid was placed in the flask as the desiccant, and the system was evacuated to hasten evaporation.

The solutions were made by adding appropriate quantities of potassium oxalate to a properly neutralized oxalatostannate solution with an oxalate to tin ratio of 2.9 and to a nearly saturated solution of potassium oxalatostannate. When a sufficient amount of solid phase had been deposited, the tubes were removed from the evaporator and allowed to stand a few days in the thermostat to ensure equilibrium between the solid and liquid phases. Samples of the solution were measured in weight pipets and the wet solid in weighing bottles. Both solution and solid were analyzed for total oxalate and tin; the water was determined by difference. The composition of the solid in equilibrium with the liquid was determined by the well-known residue method of F. A. H. Schreinemakers.[4]

The data in Table I are shown plotted on triangular coördinates in Fig. 2.

(4) Schreinemakers, *Z. physik. Chem.*, **11**, 75–109 (1893).

TABLE I

THE SYSTEM $K_2C_2O_4$–$Sn(C_2O_4)_2$–H_2O AT 25°

Wt. in liquid phase		Wt. in wet residue	
$K_2C_2O_4$	$Sn(C_2O_4)_2$	$K_2C_2O_4$	$Sn(C_2O_4)_2$
1.90	5.54	24.06	37.84
1.80	2.14	24.91	29.32
4.11	0.79	28.31	33.04
7.44	0.72	30.99	34.79
13.64	1.41	36.53	40.19
22.37	0.79	38.57	38.81
27.25	2.81	69.94	2.82
27.80	1.25	71.20	0.29
27.21	0.54	68.16	0.47
27.12	0.00	$K_2C_2O_4 \cdot H_2O$	

The tie lines indicate that only two solid phases, $K_6Sn_2(C_2O_4)_7 \cdot 4H_2O$ and $K_2C_2O_4 \cdot H_2O$, were found in the region of oxalate to tin ratio greater than 3.5, showing that tin does not form any complex with potassium oxalate in which the oxalate to tin ratio is greater than this. Since the purified product obtained from a neutralized oxalatostannate solution with an oxalate to tin ratio less than 3 was $K_6Sn_2(C_2O_4)_7 \cdot 4H_2O$, there is reason to believe that it is the only compound formed from a combination of the three components.

That point on the isotherm representing the solubility of pure potassium oxalatostannate in water, was determined from both under- and super-saturation; equilibrium was reached very slowly from the latter direction, but the results obtained were in close agreement, giving an average of 3.94% of the anhydrous salt as the solubility. The aqueous solubility of potassium oxalate at 25° here reported, 27.12% (averaged from 6 determinations ranging between 27.09 and 27.15), differs somewhat from previous values: 27.40,[5] 27.36,[6] 27.2,[7] 27.40.[8] Equilibrium in this work was approached from both sides. The disagreement may result from the difference in analytical methods: whereas previous workers used the permanganate titration, oxalate was here determined gravimetrically as already described. Because of the absence of interferences and because larger samples may be used, the precision of the gravimetric method is greater than that of the volumetric method, which must be carried out under carefully controlled conditions. The density 25°/4° of the potassium oxalate solution, 1.2135, agrees with Rivett and O'Conner's value, 1.215.

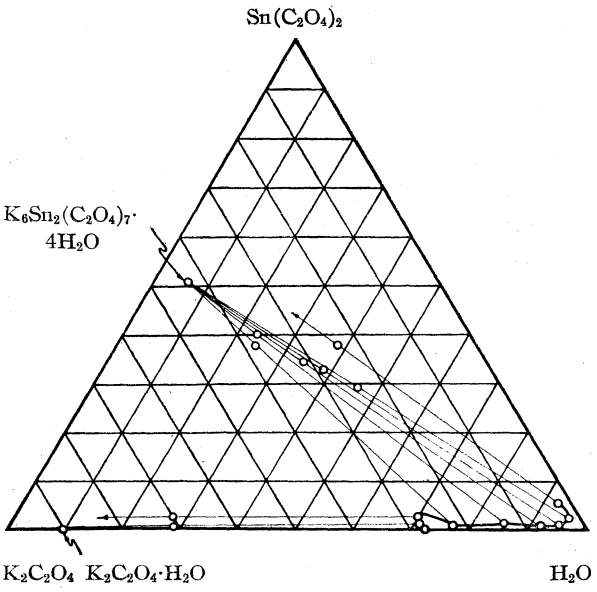

Fig. 2.—The system $K_2C_2O_4$–$Sn(C_2O_4)$–H_2O at 25°.

Summary

1. Tin was dissolved directly in oxalic acid, using hydrogen peroxide as an oxidizing agent.

2. Crystallized potassium oxalatostannate was shown to have the formula $K_6Sn_2(C_2O_4)_7 \cdot 4H_2O$.

3. The titration of a solution of potassium oxalatostannate was followed by *p*H measurements.

4. The solubility relations in the system, $K_2C_2O_4$–$Sn(C_2O_4)_2$–H_2O at 25° were determined, and the only solid phases present in the region of oxalate to tin ratio greater than 3.5 were $K_6Sn_2(C_2O_4)_7 \cdot 4H_2O$ and $K_2C_2O_4 \cdot H_2O$.

A Study of Complex Dioxalatothiometastannates[1a]

BY HOBART H. WILLARD AND TAFT Y. TORIBARA[1b]

F. W. Clarke[1c] first noticed the unusual phenomenon that hydrogen sulfide will not precipitate stannic tin from an oxalic acid solution. This fact was used as the basis of a separation of tin from arsenic, antimony, molybdenum, lead, bismuth, copper and cadmium by a number of later investigators. Among them Thompson[2] was the first to recognize that hydrogen sulfide was actually absorbed by the solution of the oxalate of tin, and he suggested that a sulfostannate might be formed. Wheeler[3] found that under proper conditions one mole of sulfur was absorbed for every mole of tin present. He was interested in its application as a volumetric method for tin and made no attempt to study the complex. It was the purpose of this work to isolate this complex and to study its properties.

Experimental

Preparation of Dioxalatothiometastannates.—Tin was dissolved in oxalic acid using hydrogen peroxide[4] as the oxidizing agent. To the solution of oxalatostannic acid, an additional quantity of oxalic acid was added to increase the oxalate to tin ratio to a value greater than 10, following Wheeler's directions, to prevent precipitation of stannic sulfide in the next step. Hydrogen sulfide to saturation was passed into the solution near the boiling temperature. At room temperature, continued passage of hydrogen sulfide caused precipitation of stannic sulfide even from these high oxalate ratios, before the complex apparently could be formed. The excess of the gas was swept out of the cooled solution by passing carbon dioxide or nitrogen through it. By cooling this solution to 0°, a large part of the free oxalic acid but none of the dioxalatothiometastannic acid was precipitated. Attempts to isolate this acid proved unsuccessful because of its instability. Cautious evaporations to deposit a solid phase removed all the hydrogen sulfide along with the water. A number of other schemes were tried in an attempt to precipitate out either the desired acid or oxalic acid, but the properties of the two were found to be quite parallel.

The subsequent studies were made on the potassium salt, which was chosen because it was much less soluble than the impurity of potassium oxalate, and this made separation by crystallization a simple matter. The dipotassium dioxalatothiometastannate was prepared by neutralizing the excess of oxalic acid in much the same manner as in preparing potassium oxalatostannate. Allowing the one atom of sulfur and one mole of oxalate for each atom of tin, the excess of oxalic acid was neutralized with potassium bicarbonate.

At this stage it is very important that hydrogen sulfide be passed in long enough to give a 1:1 ratio between sulfide and tin. If the ratio is less than unity, part of the tin will be in the form of the more insoluble potassium oxalatostannate. It is also important that the *p*H after neutralization be high enough to convert all the excess oxalic acid to the neutral oxalate but still low enough to ensure that all the carbonate be present as undissociated carbonic acid. A consideration of the ionization constants of oxalic acid and carbonic acid shows that a *p*H of 6 will give a ratio $C_2O_4^{=}/HC_2O_4^{-}$ of 61, whereas the same *p*H will give a ratio H_2CO_3/HCO_3^{-} of 30. The most favorable *p*H is, therefore, somewhat under 6. In one experiment in which a quantity of potassium bicarbonate calculated from the analysis of the solution was gradually added, the *p*H during the process was followed with a glass electrode. The final *p*H obtained was 5.64, which agrees with that calculated to be the most favorable.

In order to obtain a good separation by fractional crystallization, it is important that the impurities be more soluble substances. Both potassium oxalatostannate and potassium bioxalate are much less soluble than the desired salt, but potassium oxalate is much more soluble.

An oxalatostannic acid solution was prepared as previously described,[4] and an additional 100 g. of oxalic acid was added to the solution. After heating the solution to about 80°, hydrogen sulfide was passed into the hot solution for 1.5 hours. The excess of hydrogen sulfide was swept out at room temperature by passing nitrogen or carbon dioxide through the solution for forty minutes. A sample of the solution was taken at this point and titrated with iodine to determine the sulfide content in order to ensure the equality of the tin and sulfur present. When this had been established, the solution was cooled to 0° to freeze out most of the excess of oxalic acid. After removing this oxalic acid, the solution was allowed to warm up to room temperature. Solid potassium bicarbonate was added cautiously until a *p*H of 5.6 was attained. Upon cooling this solution to 0°, it was found that most of the salt crystallized out in pure form. It was recrystallized from water by dissolving the solid at 50–60° and cooling to 0°. Prolonged standing at the higher temperature was avoided because of the relative instability of the salt. The solid was filtered off and vacuum-dried over sulfuric acid, then kept in a desiccator in an atmosphere of nitrogen. Of a theoretical quantity of 93 g., a total of 81 g. of the recrystallized salt was obtained, a yield of 87%.

It was found much more convenient to use concentrated solutions of oxalatostannic acid for the preparation because the relative losses due to solubility at 0° were small. Although concentration of a dilute solution is not possible,

(1a) From a dissertation submitted by Taft Y. Toribara in partial fulfillment of the requirements for the degree of Doctor of Philosophy in the University of Michigan, 1939. The material in this paper was presented before the Division of Physical and Inorganic Chemistry at the Memphis meeting of the American Chemical Society, April, 1942.

it is still possible to obtain almost complete recovery by adding 3 volumes of ethyl alcohol to precipitate the solids in solution. Alcohol also precipitates all the potassium oxalate, but this can be removed by fractional crystallization. The use of more dilute solutions necessitates an extra recrystallization to obtain a very pure salt.

Since the compound was dried immediately after preparation to prevent decomposition, the amount of water of hydration varied with the time of drying. For this reason the samples for the analyses of the several constituents were all weighed at one time and after a short period of drying to remove surface moisture. The analyses gave the ratio of the components in the compound.

Anal. Found (moles $\times 10^3$ per gram): K, 4.532, 4.528; Sn, 2.265, 2.270; S, 2.265, 2.267; C_2O_4, 4.537, 4.531; H_2O (by difference), 4.50. Indicated formula: $K_2SnS(C_2O_4)_2 \cdot 2H_2O$.

Hydration and Stability of Dipotassium Dioxalatothiometastannate.—Water was determined directly on a salt which had been crystallized by cooling a solution saturated slightly above room temperature and which had been centrifuged at 1600 r. p. m. for thirty minutes. Analysis showed 9.11% of water, including surface moisture, or 2.25 moles of water per mole of salt. Some of this salt was dried at 95° for four hours without any decomposition. An analysis showed 8.30% of water, or 2.03 moles of water of crystallization. Continued drying at 60° for two weeks left only 0.6 molecule of water. Continued desiccation over sulfuric acid in a vacuum was also found to remove most of the water. A drastic process of desiccation, using the best vacuum obtainable from a Cenco Megavac pump and phosphorus pentoxide as the desiccant at a temperature of 60° for ten days, was found to remove all the water of hydration. No odor of hydrogen sulfide was evident when the flask was opened; such was not the case when the compound was decomposed by strong heating. The results indicate that the dihydrate is the phase which crystallized out of the solution and that it is quite stable. The stability of the compound to drastic drying was quite unexpected, especially in view of its behavior when wet.

The wet compound and the compound in solution were found to be unstable for two reasons: because of hydrolysis and because of atmospheric oxidation of the sulfide. A saturated solution of the compound remained clear for several weeks; a 0.1 *M* solution became tinged with yellow stannic sulfide within a few days; and more dilute solutions became tinged in even shorter periods of time. Boiling a solution of the compound caused separation of stannic sulfide, and prolonged heating at somewhat lower temperatures had the same effect. For this reason the process of recrystallization was accomplished in the shortest time possible. If the wet solid were allowed to remain in contact with air for any appreciable length of time, the sulfide was partially oxidized to free sulfur. When the compound had been dried, contact with air had no deleterious effects.

Reduction of the pressure above a solution of the salt at room temperature caused the liberation of hydrogen sulfide sufficient to precipitate stannic sulfide, making it impossible to use a low pressure evaporation to recover the salt. Complete removal of the water by such a process did not remove all the sulfur as in the case of the dioxalatothiometastannic acid.

Solubility of Dipotassium Dioxalatothiometastannate in Water.—The solubility of the salt at 25° was determined by saturating a solution at a slightly higher temperature in contact with the solid and then allowing it to come to equilibrium in the thermostat at the desired temperature. The average values obtained (based on oxalate, tin and sulfur analyses; the first two as already described[4] and sulfur by a titration with iodine) were: at 0°, 2.87% (±0.015); at 25°, 10.31% (±0.01); at 50°, about 30%, no exact determination being possible because of the instability of the solution.

***p*H of Water Solutions.**—A solution 0.1 *M* in dipotassium dioxalatothiometastannate, kept free from oxygen, was prepared, and the first *p*H was determined with a glass electrode as soon after solution as possible. It was found that the *p*H of this solution did not change definitely in a period of one week, the readings varying in the range of 3.38 to 3.31. After two days the solution started to take on a tinge of yellow from small amounts of stannic sulfide. The quantity of stannic sulfide formed was sufficient to impart a yellowish tint to the solution but was not an appreciable quantity. This seems to indicate that all the time-change of *p*H must have occurred in the first few minutes while the solid was being dissolved.

The 0.1 *M* solution was then diluted to make solutions approximately 0.025 *M* and 0.01 *M*. The initial *p*H for the 0.025 *M* solution was 3.48, dropping to 2.38 in twenty-five minutes and returning to 3.48 as a steady value. For the 0.01 *M* solution, the initial *p*H was 3.40, dropping to 2.33 in fifteen minutes and increasing to 3.52 on long standing. Noticeable formation of colloidal stannic sulfide took place during these changes. It appears from these results that an equilibrium *p*H between 3.3 and 3.5 exists for solutions of dipotassium dioxalatothiometastannate. The fact that the neutral salt gives an acid solution indicates hydrolysis of the tin. The decrease in *p*H with dilution suggests a dissociation of the complex with further hydrolysis of the tin, and the subsequent rise in *p*H with the precipitation of stannic sulfide a reversal of the hydrolysis.

Reactions in Solution.—Different cations were added to an approximately 0.1 *M* solution of dipotassium dioxalatothiometastannate. The metals giving sulfide precipitates in acid solution with hydrogen sulfide gave an interesting set of reactions. The metals forming the more insoluble sulfides as silver, bivalent copper, bismuth, pentavalent antimony and bivalent mercury precipitated immediately as sulfides when added to the solution of dipotassium dioxalatothiometastannate. Bivalent lead and cadmium produced white precipitates which gave a test for sulfur, indicating that oxalatothiometastannate precipitates of those metals were formed. Zinc gave no precipitate. From these data a rather qualitative estimation may be made of the concentration of the sulfide ion. Lead and cadmium did not give sulfide precipitates, but it may be reasoned that this might be caused by the lesser solubilities of their oxalatothiometastannates. In the case of zinc, the fact that no precipitate was formed may serve as a limit for the concentration of sulfide ion, for zinc can be completely precipitated by hydrogen sulfide from a solution in which the *p*H is between 2 and 3. Although zinc forms a complex in an oxalate solution, the introduction of hydro-

gen sulfide in such a solution (pH about 3) causes precipitation of zinc sulfide.

The alkaline earths gave precipitates of a complex oxalatothiometastannate in all cases when the concentration of dipotassium dioxalatothiometastannate was made sufficiently large. The qualitative order of decreasing solubility was found to be magnesium, strontium, calcium and barium. In the case of magnesium, it was necessary to use a saturated solution of the potassium salt and allow it to stand for some time after solid magnesium chloride had been dissolved in it. The strontium and calcium precipitates formed rather slowly. Solid lithium chloride and solid sodium sulfate were added to saturated solutions of the potassium salt. The lithium salt dissolved and then gave a dense precipitate of an oxalatothiometastannate salt, but the sodium salt caused no precipitation.

E. m. f. Measurements with Silver–Silver Sulfide Electrodes.—An attempt was made to determine the sulfide ion concentration by means of e. m. f. measurements, using a $Ag-Ag_2S$ electrode. The silver–silver sulfide electrodes were prepared according to Noyes and Freed,[5] but the value of E did not agree with their value. Several other sets of electrodes were prepared in an attempt to check their value, but no two identical sets of electrodes could be prepared. It was found that consistent results could be obtained by using the same electrodes in different solutions of the same strength. For this reason one set of electrodes was used for all the measurements.

The standard potential, E_0, of this electrode was determined on the cell

Ag, Ag_2S, H_2S (0.0685) HCl (0.1) || satd. calomel electrode,

using the apparatus shown in Fig. 1. This cell gave 0.0780 v. for E at 25°, based on the value 0.2448 v. for the calomel electrode. Calculating the sulfide ion activity through the usual ionization constants for hydrogen sulfide (7.4×10^{-8} for K_1 and 1.2×10^{-15} for K_2), E_0 was then derived through the Nernst equation

$$E = E_0 - \frac{RT}{2F} \ln \frac{1}{a_{S^-}}$$

giving $E_0 = 0.7051$ v.

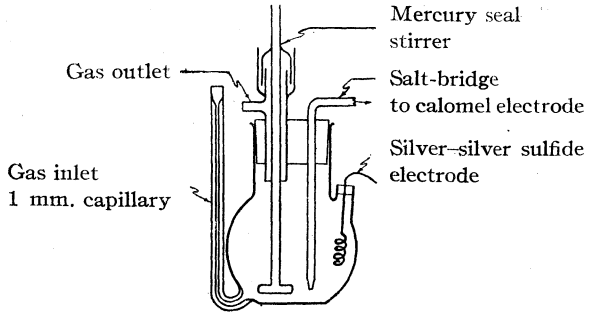

Fig. 1.—Electrode vessel.

Having found the value for E_0, e. m. f. measurements on solutions of different concentrations of dipotassium dioxalatothiometastannate were made. The solutions were made with water which had been freed of dissolved air by bubbling through it nitrogen for a sufficient length of time. After removing air from the apparatus, both the gas inlet and outlet were closed off. The results obtained are shown in Table I.

.0466[a]	.1110	8.0×10^{-21}

In the results marked a the maximum value of the e. m. f. was used. The e. m. f. was found to rise to a maximum and then to decrease. The solutions were examined and found to be colored with a yellow tinge from colloidal stannic sulfide. The other e. m. f. values were all steady, indicating equilibrium conditions, and the solutions were not colored by colloidal stannic sulfide. Equilibrium as evidenced by steady readings for eight hours or more was reached in about twelve hours.

The behavior of the solutions which showed the maximum e. m. f. values may be explained by stating that the hydrolysis of the salt proceeded to the point where the sulfide ion concentration built up sufficiently to produce a stannic sulfide precipitate. Since the electrode followed the concentration of the sulfide ion, the e. m. f. would rise to this point and then start to diminish as precipitation removed the sulfide ions. This point is probably the same point as that indicated by the minimum pH value noticed in the study of the pH of solutions of different concentrations.

The sulfide ion concentrations of the solutions of dipotassium dioxalatothiometastannate are in accord with the more qualitative observations on the addition of different metallic ions. In a solution of pH 2, the sulfide ion concentration in a saturated hydrogen sulfide solution would be approximately 6×10^{-20}. This is about the lower limit of pH at which zinc can be precipitated. Comparing this value with that of an approximately 0.1 M solution of dipotassium dioxalatothiometastannate as shown in Table I, it can be seen readily why zinc does not precipitate as a sulfide when added to a solution of the salt. Both lead and cadmium can be precipitated as

(5) Noyes and Freed, THIS JOURNAL, **42**, 476 (1920).

sulfides in a solution with such a sulfide ion concentration, but the complexes are precipitated instead probably because of their greater insolubility.

Summary

1. Dipotassium dioxalatothiometastannate was isolated for the first time and proved to have the formula $K_2SnS(C_2O_4)_2 \cdot 2H_2O$.

2. The compound was stable enough to permit removal of all of the water of hydration.

3. The solubilities of dipotassium dioxalatothiometastannate in water at 25 and 0° were determined.

4. The *p*H of water solutions of varying concentrations of dipotassium dioxalatothiometastannate was studied.

5. The reactions of a water solution of dipotassium dioxalatothiometastannate with various cations were studied.

6. E. m. f. measurements in solutions of dipotassium dioxalatothiometastannate with a silver–silver sulfide electrode were made in an attempt to determine the concentration of the sulfide ion.

The Reduction of Unsaturated Hydrocarbons at the Dropping Mercury Electrode. I. Phenyl Substituted Olefins and Acetylenes

BY H. A. LAITINEN AND S. WAWZONEK

Isolated ethylenic and acetylenic linkages are not reducible at the dropping mercury electrode. However, double bonds which are either conjugated with carbonyl groups or present in heterocyclic nuclei like pyridine and quinoline can be reduced.[1] We have found that other types of unsaturated linkage are electroreducible. In the present paper the results of a polarographic study of phenyl substituted olefins and acetylenes are reported. The reduction of other types of unsaturated hydrocarbons will be described in forthcoming publications.

Experimental

Dioxane–water mixtures containing 75% dioxane were used as a solvent, with 0.175 *M* tetrabutylammonium iodide as a supporting electrolyte. Since the half-wave potentials were unaffected by the *p*H of the solution (v. i.) unbuffered solutions were suitable for the measurements. Dioxane was found to be superior to acetone, isopropanol or methanol as a solvent in permitting the attainment of very negative potentials. In 50 to 85% dioxane solutions, using tetrabutylammonium iodide as the supporting electrolyte, the decomposition potential of the solvent was essentially constant at about −2.9 volts (*vs.* saturated calomel electrode), showing that the negative potential limit is determined by the discharge of the cation. Tetrabutylammonium salts were found to be superior to tetramethylammonium salts in having a more negative discharge potential.

The dropping mercury electrode had the following characteristics. At a pressure of 46.5 cm. of mercury, the drop time in the solvent used was 3.34 seconds (open circuit). The value of m was 2.05 mg. sec.$^{-1}$, with a calculated value of $m^{2/3}t^{1/6}$ of 1.973 mg.$^{2/3}$ sec.$^{-1/2}$ (open circuit). Values of $m^{2/3}t^{1/6}$ at various potentials are given in Table II.

The electrolysis cell had a simple cylindrical shape with a mercury pool anode, and was provided with side arms for anode connection and for admission of nitrogen for the removal of dissolved oxygen. The anode potential was measured against a saturated calomel electrode (S. C. E.) by using a sintered glass salt bridge of the type described by Laitinen.[2] Its value was found to be reproducible at −0.452 volt in solutions of constant electrolyte concentration.

The current–voltage curves were determined with a Model XI Heyrovsky Polarograph having a current scale calibrated in microamperes. Data for the logarithmic analyses of the curves were obtained with a Fisher Elecdropode having specially calibrated current and voltage scales. The average resistance of the electrolytic cell was determined by the conventional Wheatstone bridge method, and found to be 2000 ohms. The half-wave potentials given in Table I are corrected for *iR* drop. All experiments were carried out at 25° in a water thermostat regulated to ±0.1°.

Materials.—The tetrabutylammonium iodide was prepared by a slight modification of the method used by Cox, Kraus and Fuoss.[3] Tri-*n*-butylamine (200 ml.) and *n*-butyl iodide (100 ml.) were heated together on a steam-bath for sixty-five hours. The resulting solid was filtered, washed with a small amount of ethyl acetate and then dissolved in the least amount of cold ethanol. The resulting solution was mixed with an equal volume of 10% potassium hydroxide in ethanol and poured into water. Removal of part of the alcohol under reduced pressure gave a crystalline precipitate of tetrabutylammonium iodide

which, after three recrystallizations from anhydrous ethyl acetate, melted at 141–142°; yield 150 g.

The dioxane was purified by refluxing with sodium for ten hours and distilling.

Stilbene, triphenylethylene, diphenylbutadiene, heptyne-1, *o*-allylanisole, and phenylacetylene were obtained from stock and were purified before using. The styrene was first treated with K_2HgI_4 and then freshly distilled.

1,1-Diphenylethylene,[4] β-methylstyrene[5] and tetraphenylethylene[6] were prepared by appropriate methods given in the literature.

Diphenylacetylene was prepared by a modification of the method used by Limpricht and Schwanert.[7] Stilbene dibromide was refluxed with 200 ml. of 30% potassium hydroxide in methanol for twelve hours. The potassium bromide formed was filtered off while hot and washed with ether. Water was next added to the filtrate, the methanol removed by distillation and the resulting solution extracted with ether. Removal of the ether followed by distillation under reduced pressure gave 14.6 g. of diphenylacetylene; b. p. 111–112° (1 mm.).

Results

All of the hydrocarbons investigated showed a single well-defined reduction wave. Tracings of typical polarograms are shown in Fig. 1 for styrene and in Fig. 2 for triphenylethylene. Only a slight tendency toward the appearance of maxima was observed. With low concentrations of hydrocarbons no maxima were found, whereas slight maxima were obtained in most cases with increasing hydrocarbon concentration. The most prominent maxima are shown in Fig. 2, and never were found to interfere with diffusion current measurements. The maxima were not suppressed by methyl red. Hence half-wave potential measurements were made only on curves having no maxima.

Table I shows a summary of the observed half-wave potentials and diffusion current constants.

The half-wave potential was found quite generally to be independent of the concentration of hydrocarbon even in unbuffered solution. Since the solution at the electrode surface becomes more alkaline at the half-wave point with increasing hydrocarbon concentration it may be inferred that the half-wave potential is independent of the *p*H of the solution. Actually it was shown (Table I) that stilbene has the same half-wave potential in alkaline solution as in neutral solution when proper correction for anode potential is made.

The diffusion current showed a proportionality with concentration in every case studied. It is evident that the polarographic method offers a possible quantitative procedure for the determination of these hydrocarbons in the absence of more readily reducible substances.

A comparison of the half-wave potentials of the series of phenyl ethylenes (I, III, IV, VI, VII in Table I) shows the increasing ease of electroreduction with increasing substitution. The comparison between stilbene and 1,1-diphenylethylene (compounds III and IV) clearly demonstrates the increased activation of the double bond in stilbene. Styrene (I) was found to be distinctly more readily reduced than β-methylstyrene (II).

1,4-Diphenylbutadiene-1,3 (V) was shown to undergo a 1,4-reduction, because a comparison of its diffusion current constant with those of ethylenic hydrocarbons of similar molecular weight (III and IV) showed that only two electrons per molecule are involved in the reduction. No indication of a second reduction step was found.

Phenylacetylene (VIII) and diphenylacetylene (IX) were found to have slightly more negative half-wave potentials than the corresponding ethylenic compounds (I and IV). A complete reduction involving four electrons per molecule, giving rise to a single polarographic wave, was found in each case by a comparison of the observed diffusion current constants.

Heptyne-1 and *o*-allylanisole did not give polarographic waves under these conditions, showing that isolated double or triple bonds are not electroreducible.

Mechanism of the Reduction.—Logarithmic analyses of the reduction waves of stilbene and diphenylacetylene were made by plotting the quantity $\log i/(i_d - i)$ against the potential. The results are shown in Fig. 3. In each case a straight line was obtained. The slopes of the lines were 0.062 and 0.069 volt for stilbene and diphenylacetylene, respectively. These results are in essential agreement with the theoretical slope of 0.059 volt (25°) for a reversible, potential-determining reaction involving one electron.

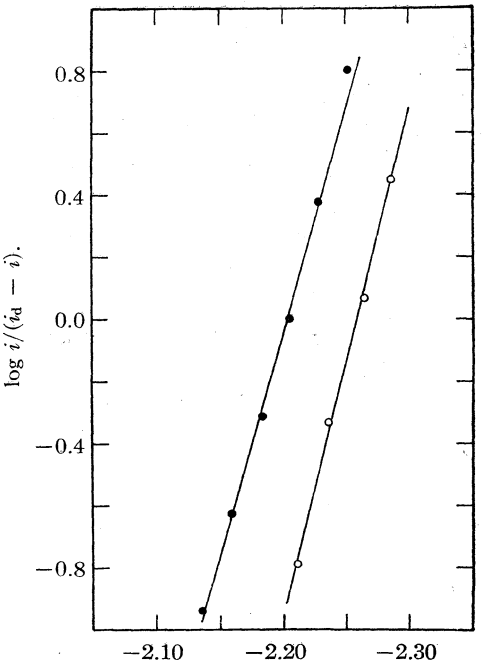

Fig. 3.—Analysis of current–voltage curves: O, C_6H_5-CH=CHC$_6H_5$; ●, $C_6H_5C{\equiv}CC_6H_5$; in 75% dioxane, 0.175 *M* tetrabutylammonium iodide.

Considering the fact that the half-wave potential is independent of the *p*H, the following mechanism is suggested for the electroreduction of olefins in neutral or alkaline solution.

$$R + e^- \rightleftarrows R^- \text{ (reversible, potential determining)} \quad (1)$$

$$R^- + e^- \longrightarrow R^= \text{ (irreversible)} \quad (2)$$

$$R^= + 2H_2O \longrightarrow RH_2 + 2OH^- \text{ (irreversible, rapid)} \quad (3)$$

The first reversible reaction would yield a univalent negative ion, the surface concentration of which would be proportional to the current, *i*. The concentration of the original hydrocarbon is porportional to the quantity $i_d - i$, where i_d is the diffusion current. The potential π would be determined by the ratio $C^0_R/C^0_{R^-}$ of the surface concentrations of R and R^-. Then

$$\pi = \text{const} + \frac{RT}{F} \ln \frac{C^0_R}{C^0_{R^-}} = \pi_{1/2} + \frac{RT}{F} \ln \frac{i_d - i}{i} \quad (4)$$

Equation 4 is the observed current–voltage relationship, with the theoretical slope of the logarithmic plot equal to 0.059 volt at 25°.

The second step of the reduction cannot involve the addition of a proton to form a free radical RH unless the rate of the reaction $R^- + H_2O \rightarrow RH + OH^-$ would be independent of the pH, because the surface concentration $C^0_{R^-}$, and hence the half-wave potential, would be a function of the pH. Hence the simplest assumption is made, namely, that the second step involves the irreversible addition of a second electron to form a divalent negative ion of the type postulated as a product of sodium addition to unsaturated hydrocarbons in liquid ammonia.[8] The subsequent addition of two protons to the divalent ion could not affect the concentration of the potential-determining system; hence the reduction potential would not depend on the pH.

For acetylenic hydrocarbons, a similar two-step electron addition is postulated as the first stage. Since the half-wave potential of an acetylenic hydrocarbon is in general more negative than that of the corresponding ethylenic compound, it is readily understood that a single reduction wave must be obtained. The reduction potential, according to the proposed mechanism, is determined by the ease of addition of the first electron. The corresponding ethylenic compound at this potential would be rapidly reduced completely to the substituted ethane.

Diffusion Coefficients.—A knowledge of the relative diffusion coefficients of organic compounds as a function of the molecular weight is helpful in determining the number of electrons involved per molecule in the electrode reaction. For an accurate calculation it is necessary to correct the observed values of the diffusion current constants for the change of drop time with potential, particularly at extremely negative values of the potential.[9] At potentials more negative than −2 volts (*vs.* S. C. E.) the drop time becomes so small that a direct measurement no longer is convenient. Hence the relative value of $m^{2/3}t^{1/6}$ as a function of potential was measured by determining the diffusion current of nitrobenzene over a wide range of potentials (−1.4 to −2.8 volts). From the relative values, the absolute values of $m^{2/3}t^{1/6}$ were easily calulated.

Table II gives the values of $m^{2/3}t^{1/6}$ at the potentials, π_d, at which the diffusion currents were measured, together with the relative values of the diffusion coefficient taking that of styrene as unity. The absolute values in the last column were calculated from the Ilkovic equation,[1,10] using average values of the diffusion current constants from Table I. The decrease in the diffusion coefficients with increasing molecular weight is evident. Although there may be some question as to the accuracy of the Ilkovic equation at very negative potentials because of the rapid drop rate, the results given are certainly sufficiently exact to be useful in interpreting diffusion current data in 75% dioxane in unknown cases.

TABLE II

COMPARISON OF DIFFUSION COEFFICIENTS OF HYDROCARBONS IN 75% DIOXANE

Compound	π_d	$m^{2/3}t^{1/6}$, mg.$^{2/3}$sec.$^{-1/2}$	D, rel.	D_1 cm.^{2} sec.$^{-1}$ × 10^5

VII	2.21	1.852	.440	.248
VIII	2.55	1.782	.793	.440
IX	2.35	1.820	.521	.293

Summary

The polarographic reduction of a series of phenyl substituted olefins and acetylenes has been studied. The most suitable solvent medium was found to be a dioxane–water mixture containing 75% dioxane, with tetrabutylammonium iodide as a supporting electrolyte.

Each compound was found to give a single reduction wave in neutral or alkaline medium with a half-wave potential which is independent of the pH. The diffusion current was found to be proportional to the hydrocarbon concentration. The polarographic method has been shown to be useful in the detection and determination of olefins and acetylenes with activated double or triple bonds.

The half-wave potential is suggested as a measure of the relative activation of ethylenic and acetylenic linkages by substituent groups.

The equations of the rising portions of the waves have been determined for an olefin and an acetylenic hydrocarbon, and a reduction mechanism is suggested.

The diffusion coefficients of the hydrocarbons have been calculated from diffusion current data.

High-temperature Heat Content of Mn_3O_4, $MnSiO_3$ and Mn_3C[1]

BY J. C. SOUTHARD[2] AND G. E. MOORE[3]

This paper is a report of part of a program of study of the thermodynamic properties of manganese compounds that is being conducted at the Pacific Experiment Station of the Bureau of Mines, U. S. Department of the Interior. Entropies of Mn_3O_4,[4] $MnSiO_3$[5] and Mn_3C[6] have been determined previously. Heats of formation of these substances are given in standard reference tables, so that high-temperature heat contents are the only additional quantities required for the calculation of their free energies at high temperatures. These calculations will not be presented here, however, because present values of the heats of formation are not considered satisfactorily accurate and a redetermination of them is in progress.

Apparatus and Materials

The high-temperature heat contents were determined in an apparatus previously described.[7] The apparatus was calibrated electrically, using the relation 1 calorie = 4.1833 Int. Joules. During the measurements Mn_3O_4 was contained in an unsealed platinum-alloy capsule, $MnSiO_3$ in a sealed platinum-alloy capsule, and Mn_3C in an evacuated and sealed silica-glass capsule.

Mn_3O_4 was prepared by roasting a high-purity sample of $MnSO_4$ in air at about 1000°. Analysis for active oxygen by titration with ferrous sulfate and potassium permangate gave 7.01 and 7.03% before the measurements and 6.96% afterward (calcd. 6.99%). Manganese was determined to be 71.89 and 71.92% (calcd. 72.02%). The sample was sintered at 1200° before use. Description of the preparation and analysis of the $MnSiO_3$ sample has been given by Kelley.[5] Mn_3C was prepared by F. S. Boericke from ground electrolytic manganese and high-purity, degassed carbon black by heating three days at 850°. Analysis showed that the sample contained about 98.8% Mn_3C and 1.2% free manganese. No correction will be made for this impurity, since it would be of the order of 0.1%.

Results

The experimentally determined heat contents above 298.1° K. of Mn_3O_4, $MnSiO_3$ and Mn_3C are given in Tables I, II, and III in the order in which they were taken. Graphs of the data show transitions in Mn_3O_4 at 1445 ± 40° K. amounting to 4500 cal./g. f. w., and in Mn_3C at 1310 ± 2° K. amounting to 3140 cal./g. f. w. The heat-content curve of $MnSiO_3$ shows no discontinuities. No previous high-temperature heat-content data for these substances appear in the literature.

This table, in combination with similar tables for oxygen, carbon, and silicon, permits ready calculation of free energies at these temperatures from whatever values of the heat of formation an investigator may select.

Summary

The heat contents of Mn_3O_4, $MnSiO_3$ and Mn_3C from room temperature to temperatures between 1140 and 1500° have been determined. These determinations have disclosed transitions of Mn_3O_4 at 1172° and Mn_3C at 1037°.

A table summarizing the increments in the heat contents and entropies of these substances above room temperature at 100° intervals has been prepared from these data and others in the literature.

Heat of Formation and High-temperature Heat Content of Manganous Oxide and Manganous Sulfate. High-temperature Heat Content of Manganese[1]

BY J. C. SOUTHARD[2] AND C. HOWARD SHOMATE[3]

The free energy of formation of manganous oxide at high temperatures has been uncertain because of the lack of satisfactory high-temperature heat content data. Further, the heat of formation of manganous oxide has been based almost entirely on heats of combustion. The combustion of manganese metal with oxygen in the bomb calorimeter does not proceed according to any definite reaction but yields a mixture of oxides assumed to be manganous oxide and manganomanganic oxide.[4,5] The mixture consists of 10 to 50 per cent. manganous oxide. The heat of formation of manganous oxide therefore has depended on the combustion of manganous oxide to manganomanganic oxide. This requires the use of paraffin oil and also yields a product of varying composition. Under these conditions the heat of reaction is only 5 per cent. of the total heat measured.[5] The heat of reaction also seemed to depend on whether the fraction converted to manganomanganic oxide was determined by increase in weight or by actual analysis.[4] Determination of the heat of formation of manganous oxide by a completely independent, more direct, method appears advantageous.

The thermodynamic properties of manganese sulfate have been studied and entropies of the substances involved already have been determined, as well as the high-temperature heat-content data, with the exception of manganous sulfate. The heat of formation of manganous sulfate has not been determined since the days of Thomsen and Berthelot, at which time pure manganese was not available.

Methods and Materials

The high-temperature heat contents were determined in an apparatus previously described.[6] The apparatus was calibrated electrically, using the relation 1 calorie = 4.1833 Int. joules. During the measurements manganous oxide and manganous sulfate were contained in a sealed platinum-alloy capsule and manganese metal in an evacuated and sealed silica-glass capsule. The heats of formation of manganous oxide and manganous sulfate

were determined by the solution of manganese, manganous oxide and manganous sulfate in 1.006 *N* sulfuric acid solution in a calorimeter also described previously.[7] The time of solution was about twelve minutes for manganese and manganous sulfate and about twenty to thirty minutes for manganous oxide.

The manganese metal was an electrolytic product at least 99.9 per cent. pure. It was degassed by heating to 850° in a vacuum corresponding to 10^{-5} mm. and allowed to cool slowly (sample A). A portion of this sample was quenched from 800° in the high-temperature calorimeter (sample B) for use in certain heat-of-solution measurements. The metal was sized by passing through a 20- onto a 28-mesh screen. The manganous oxide was prepared by Millar[8] by reduction of higher oxides with hydrogen at 1100°. It was further purified for this work by removing visible particles of silica by flotation with tetrabromomethane, followed by drying in a high vacuum up to 250°. Analysis showed that it contained less than 0.04% silica and 77.42, 77.45% Mn (calcd. 77.44%). Manganese sulfate was prepared from a hydrated "C. P." preparation. It was found to contain 36.33% Mn by analysis (calcd. 36.38%). It was dried to constant weight in the capsule and bulbs at 400° before being weighed and sealed.

Results

Heat of Formation.—The heats of solution of manganese, manganous oxide, and manganous sulfate are summarized in Table I. Determinations were made at the dilution of 1 gram-atom of manganese to 100.27 kg. of acid solution. Correction for the vaporization of water by evolved hydrogen was made on the assumption that none of the hydrogen remained in solution by the time equilibrium was attained, and that it was saturated with water vapor when it left the solution. The partial pressure of water vapor over the acid solution was taken to be 23.34 mm. at 25° with a temperature coefficient of 0.14 mm. per degree. The heat of vaporization of water from 1 *N* sulfuric acid was taken to be 10,501 cal./g. f. w. at 25°. The final temperature lay between 25.0 and 25.2° in every case.

The heat of formation of manganous oxide, according to Eq. 5, is calculated from the heats of the following reactions, all at 298.1° K.

$$Mn_\alpha + 49.05\ H_2SO_4 \cdot 5299\ H_2O(soln.) \longrightarrow MnSO_4 \cdot 48.05\ H_2SO_4 \cdot 5299\ H_2O(soln.) + H_2(g) \quad (1)$$

$$MnO(s) + 49.05\ H_2SO_4 \cdot 5299\ H_2O(soln.) \longrightarrow MnSO_4 \cdot 48.05\ H_2SO_4 \cdot 5300\ H_2O(soln.) \quad (2)$$

$$MnSO_4 \cdot 48.05\ H_2SO_4 \cdot 5299\ H_2O(soln.) + H_2O(l) \longrightarrow MnSO_4 \cdot 48.05\ H_2SO_4 \cdot 5300\ H_2O(soln.) \quad (3)$$

$$H_2(g) + {}^1/_2O_2(g) \longrightarrow H_2O(l) \quad (4)$$

$$Mn_\alpha + {}^1/_2O_2(g) \longrightarrow MnO(s) \quad (5)$$

$$\Delta H_5 = \Delta H_1 + \Delta H_4 - \Delta H_2 + \Delta H_3$$

The heats of reactions (1), (2) and (3) are given in Table I. The heat of reaction (4) was determined by Rossini[9] as −68,318 ± 9 cal./g. f. w. The heat of formation of manganous oxide from the elements at 298.1° K. is thus computed to be −92,040 ± 110 cal./g. f. w. The limits of error are estimated as the sum of the average deviations from the mean of the heats of solution of manganese and manganous oxide, plus 0.05% of the total energy measured, plus 10% of the correction for vaporization of water plus 9 calories uncertainty in the heat of formation of water. The value computed here allows the maximum correction for vaporization of water by the evolved hydrogen. Any other assumption would decrease the magnitude of the heat of formation. A comparison of the present value of the heat of formation of manganous oxide with those previously determined is given in Table II. Virtually all previous data were obtained by combustion methods from Le Chatelier's day on.

The value determined here by solution methods is believed to be more trustworthy than that obtained by combustion methods, for two reasons. (1) The combustion process does not proceed ac-

TABLE II
HEAT OF FORMATION OF MANGANOUS OXIDE

	Year	Method	$\Delta H_{298.1}$ cal./g. f. w.
Le Chatelier[10]	1896	Combustion with oxygen and charcoal	−90,900
Guntz[11]	1896	Not stated	−98,200
Roth[4]	1929	Combustion with oxygen and oil	−96,200
Siemonsen[5]	1939	Combustion with oxygen and oil	−93,100
This work	1942	Solution in 1 *N* sulfuric acid	−92,040 ± 110

cording to any definite reaction, while the initial and final states in the solution method are well-defined. (2) The total amount of heat per g. f. w. of manganous oxide measured in the combustion method is 5 to 7 times that measured by the solution method. The agreement between the present work and that of Siemonsen is evidence of extremely careful calorimetry on his part. The result of Roth and Müller is higher because they used a sample contaminated by silicon and aluminum and probably because it contained hydrogen.

The heat of formation of manganous sulfate from the elements (Eq. 8) is calculated from Eq. (1) above, in combination with the following reactions, all at 298.1° K.

$$H_2 + S(rh) + 2O_2 + MnSO_4\cdot 48.05\ H_2SO_4\cdot 5299\ H_2O(soln.) \longrightarrow MnSO_4\cdot 49.05\ H_2SO_4\cdot 5299\ H_2O(soln.) \quad (6)$$

$$MnSO_4(s) + 49.05\ H_2SO_4\cdot 5299\ H_2O(soln.) \longrightarrow MnSO_4\cdot 49.05\ H_2SO_4\cdot 5299\ H_2O(soln.) \quad (7)$$

$$Mn_\alpha + S(rh) + 2O_2(g) \longrightarrow MnSO_4(s) \quad (8)$$

$$\Delta H_8 = \Delta H_1 + \Delta H_6 - \Delta H_7$$

The heat of reaction (7) is given in Table I. ΔH_6 is calculated from the heats of the reactions

$$H_2(g) + S(rh) + 2O_2(g) \longrightarrow H_2SO_4(l) \quad (9)$$

$$H_2SO_4(l) + 49.05\ H_2SO_4\cdot 5299\ H_2O(soln.) \longrightarrow 50.05\ H_2SO_4\cdot 5299\ H_2O(soln.) \quad (10)$$

$$H_2(g) + S(rh) + 2O_2(g) + 49.05\ H_2SO_4\cdot 5299\ H_2O(soln.) \longrightarrow 50.05\ H_2SO_4\cdot 5299\ H_2O(soln.) \quad (11)$$

$$\Delta H_{11} = \Delta H_9 + \Delta H_{10}$$

The heat of reaction 9 was calculated to be −194,100 ± 100 cal./g. f. w. from the heat of formation of sulfur dioxide of Eckmann and Rossini[12] and the heat of oxidation of sulfur dioxide and heats of solution of sulfur dioxide, sulfur trioxide and sulfuric acid obtained by Roth, Grau and Meichsner.[13] It was necessary to correct some of the data to 25°. The limits of error are those set by Roth. The heat of reaction (10) has been calculated from the data of Grau and Roth[14] at about 290° K. as −17,350 calories. No correction was made to 298.1° K., and the error is estimated at ±50 cal. The heat of reaction (11) must necessarily be assumed the same as that of reaction (6) but little error can arise from this source because the ionic strengths of the solutions are the same. The heat of formation of manganous sulfate from the elements is thus calculated to be −254,180 ± 250 cal./g. f. w. at 298.1° K. The limits of error are estimated as the sum of the average deviations from the mean of the heats of solution of manganese and manganous sulfate, plus 0.05% of the total energy measured, plus 10% of the correction for vaporization of water by the hydrogen in Eq. 1, plus 100 calories in the heat of formation of sulfuric acid plus 50 calories for the heat of reaction (10).

Previous determinations of the heat of formation of manganous sulfate at room temperature by Thomsen (ΔH = −249,730) and Berthelot (ΔH = −249,400) are discussed by Kelley.[15] Maier[16] has calculated a value of $\Delta H_{298.1}$ = −250,700 from the dissociation pressure measurements of Marchal.[17] This value is not changed much by using the present high-temperature heat-content data, but may be changed by the proposed investigation of the heat of formation of manganomanganic oxide. However, Marchal's data lead to an abnormally high entropy of manganous sulfate so that not much weight can be given to values of the heat of formation calculated from them.

The difference in the heats of solution of annealed and "quenched" manganese is computed from Table I to be 65 calories per g. f. w. This heat is required for the calculation of heat contents of manganese above the transition at 1012° K.

High-temperature Heat Contents.—The measurements of the heat content at T° K., minus the heat content at 298.1° K. for manganese, manganous oxide, and manganese sulfate, are given in Tables III, IV and V. Manganous oxide and manganous sulfate show no transitions. Manganese metal shows a transition at 1012° K. Known transitions at higher temperatures could not be investigated in this work because of devitrification of the silica-glass capsule and reaction of the manganese with it. The correction of 65 cal./g. f. w. must be applied to the data of Table III above 1012° K. because the manganese did

not come to the same final state in the calorimeter when dropped from temperatures above this as when dropped from temperatures below it. It is not supposed that this quantity represents the difference in heat content between α and β manganese at 298.1° K. but merely that it is a correction that must be applied to the calorimetric heat obtained when the capsule was dropped from the temperature range in which β manganese is stable.

1082.3	26,060

The heat of transition $\alpha \rightarrow \beta$ manganese is calculated from the heat-content data to be 615 calories per g. f. w. at 1012° K. This includes the above-mentioned 65 calories. Gaylor[18] reported the transition as occurring at 1013 ± 2° K., with distilled manganese. Umino[19] observed that this transition occurred at 1108° K., accompanied by a heat effect of but 68 calories per g. f. w. Other investigators of the high-temperature heat content observed none at all. There was no evidence in the present work of a transition reported by Gaylor at 943° K.

Previous measurements on the high-temperature heat content of manganese have been surveyed by Kelley.[20] The present work lies between that of Umino and that of Wüst, Meuthen and Durrer[21] and not far from that of Laemmel.[22] The present work is believed to be more reliable because it was done with a higher-purity sample of manganese, completely protected from oxidation, and with a higher-precision calorimeter than was previous work.

No previous determinations have been reported on the heat content of manganous oxide and manganous sulfate at high temperatures.

Table VI is a summary at 100° intervals of the heat content and entropy above 298.1° K. of manganese, manganous oxide and manganous sulfate. The 65-cal. correction to the heat content of manganese in the β range has been applied. Table VI also includes values of the free energy of formation of manganous oxide from gaseous oxygen and the form of manganese stable at the stated temperature. The present value of −92,040 cal./g. f. w. for the heat of formation of manganous oxide is used in conjunction with the values 7.61, 24.52 and 14.4 for the entropies of manganese, $^1/_2$ oxygen and manganous oxide, respectively,[23] to calculate a free energy of formation of manganous oxide of −86,760 cal./g. f. w. at 298.1° K. Values at higher temperatures were calculated with the aid of the present high-temperature heat-content data on manganese and manganous oxide and the tables of free energy of oxygen given by Johnston and Walker.[24] Comparison may be made with the experimental data of Aoyama and Oka[25] for the reaction $Mn + H_2O(g) \rightleftarrows MnO + H_2(g)$. They made five determinations in the temperature range 1,048 to 1,460° K. Their data were recalculated to the reaction $Mn + {}^1/_2O_2 \rightarrow MnO$ by adding the free energy of formation of water vapor, which was calculated from the tables of A. R. Gordon[26] and W. F. Giauque,[27] and the free energy of formation of water vapor at 298.1° K.

given by Rossini.[9] The three lowest of Aoyama and Oka's points lie within a few hundred calories of values interpolated from Table VI, which may be said to be in good agreement. In general, however, their data give a larger ΔH and ΔS for the reaction than may be calculated from the third law.

Summary

The heat of formation of manganous oxide has been determined to be −92,040 ± 110 calories per g. f. w. and of manganous sulfate to be −254,180 ± 250 calories per g. f. w. at 25°.

The heat contents of manganese, manganous oxide, and manganous sulfate from room temperature to temperatures between 811 and 1500° have been determined. These observations have disclosed a transition in manganese at 739°.

A table summarizing increments of heat contents, entropies and free energies at 100° intervals has been prepared from these data and others in the literature.

Isomers of Crystal Violet Ion. Their Absorption and Re-emission of Light

BY GILBERT N. LEWIS, THEODORE T. MAGEL AND DAVID LIPKIN

The possibility of a new type of isomerism in such substances as triphenylmethyl and its ions was pointed out recently.[1] An extensive investigation of the light absorption of the free radicals has not given us positive evidence of such isomerism.[2] On the other hand, in the derivatives of triphenylmethyl ion we have sought, and believe to have found, these isomers.

It is often observed that the absorption curve of what is apparently a single substance, such as the ion of crystal violet (tris-(dimethyl-*p*-aminophenyl)-methyl ion, Fig. 6) as it exists in neutral or alkaline solution, has a shoulder as seen in Fig. 1. This shoulder suggests the superposition of two neighboring bands, which might result from (1) a partial resolution of the vibrational structure belonging to a single electronic level, which, according to the work of Dr. Goldschmid,[2] seems to be the explanation of a similar shoulder in the adsorption curve of methylene blue, or (2) two neigh-

(1) Lewis and Calvin, *Chem. Rev.*, **25**, 273 (1939).

(2) The two absorption bands of triphenylmethyl in the visible which were obtained by Meyer and Wieland [*Ber.*, **44**, 2557 (1911)] and which were resolved into three bands by Anderson [THIS JOURNAL, **57**, 1673 (1935)] were shown by Dr. O. Goldschmid [Ph.D. Thesis, University of California (1939)] to be vibrational bands belonging to a single electronic band. This was shown by comparison of the absorption and fluorescence spectra of triphenylmethyl. We have further confirmed his results, but with a very high resolution we have found a much more intricate structure. This will be discussed in another place.

boring electronic levels, or finally (3) two isomers in rapid equilibrium with one another. We shall find that it is the last of these theories which accounts for the crystal violet spectrum. In the experimental work that has led to this conclusion several perplexing phenomena have appeared which will be dealt with in their turn, and about 200 absorption curves have been obtained, of which only a few can be shown.

When we study the light absorption of crystal violet in a variety of solvents the curves fall roughly into three classes, exemplified by the solid curves in Figs. 1, 2 and 3. In each curve the ordinates (α) are proportional to the molar extinction coefficient, ϵ, the proportionality factor being so chosen that in each case $\alpha_{max.}$ is unity.[3]

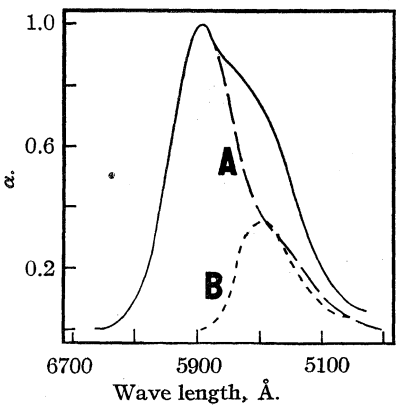

Fig. 1.—Relative extinction coefficient of 10^{-6} M crystal violet (chloride) in absolute ethanol at 293°K. (solid curve). Curve A (dashed line) is the curve of malachite green in ethanol, displaced horizontally to coincide with solid curve at maximum. This is also assumed to be the A band of crystal violet. Curve B (dotted) obtained from the two other curves by subtraction.

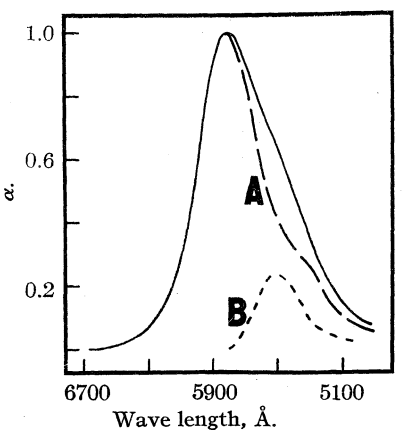

Fig. 2.—Relative extinction coefficient of 5×10^{-7} M crystal violet (chloride) in chloroform at 293°K. Curve A, malachite green curve in chloroform, displaced. Curve B obtained as in Fig. 1.

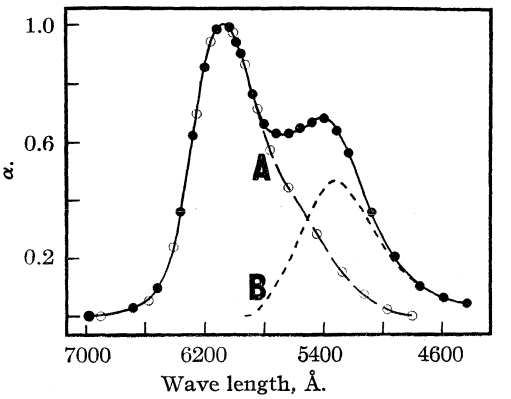

Fig. 3.—Relative extinction coefficient of 10^{-6} M crystal violet (chloride) in toluene containing 0.1% β-naphthol at 293°K. Curve A is malachite green curve in same solvent, displaced. Curve B obtained as in Fig. 1. In this case the actual experimental points are shown.

In order to show that in all three cases the absorption curve is a summation of two bands which differ in position and relative height, we may use a crude but apparently effective mode of analysis. We have noticed that the absorption curve of malachite green, which shows no pronounced shoulder, if displaced horizontally to bring the maximum into coincidence with that of the crystal violet curve, coincides with the latter in the whole left-hand portion. This is shown in Fig. 3 where the open circles represent experimental points for malachite green and the black circles those for crystal violet. If we assume now that this coincidence would continue all the way for the first (A) band of crystal violet, then we may construct the other (B) band by subtracting the dashed from the solid curve. When this is done we obtain the dotted curve which is marked B. Similarly, using the malachite green curve for the corresponding solvent we have obtained the A and B bands in Figs. 1 and 2.

It seems that in spite of the different appearance of the three solid curves of Figs. 1–3, they differ chiefly in the positions and the relative intensities of the A and B bands.

All of the solvents which we have studied can be classified roughly according to the resemblance of the absorption curves of crystal violet in the several solvents to the curves of Figs. 1, 2 and 3.

(3) We have chosen this method of representation best to display the shapes of the several curves. Furthermore, our determinations of relative extinction are far more accurate than our absolute values. The values of $\epsilon_{max.}$ that we actually obtained for these three curves were 8.1×10^4 in absolute ethanol, 8.5×10^4 in chloroform and about 7×10^4 in toluene.

Class I comprises all the solvents that we have examined of high, or moderately high, dielectric constant: namely, ethanol, methanol, *t*-butanol, water, glycol, glycerol, glucose (supercooled), ethylene chlorohydrin, methyl cyanide, acetone, acetaldehyde, glacial acetic acid, pyridine, and aniline. In all of these $\lambda_{max.}$ (A) lies between 5830 and 5940 Å., except that aniline gave 5990 Å.

Class II comprises chloroform,[4] *trans*-dichloroethylene, methyl iodide, chlorobenzene and a saturated solution of chloral hydrate in water. For all of these $\lambda_{max.}$ (A) lies between 5780 and 5800 Å., except for chlorobenzene, 5940 Å. It will be noted that all of these solvents of Group II contain halogen and therefore have, if not for the molecule as a whole, at least for some part of it, a considerable dipole moment.

On the other hand, the tetrahedrally symmetrical carbon tetrachloride and the linearly symmetrical carbon bisulfide, both with high bond moments, fall into our third class, which also contains toluene, hexane, dioxane, isopentane, ether, methylal, carbon tetrachloride and carbon bisulfide. Here $\lambda_{max.}$ (A) varies widely from 5930 Å. for methylal to 6140 Å. for carbon bisulfide. In all of these solvents small amounts of phenol, β-naphthol or ethanol were added to make the crystal violet chloride soluble. It seems to make no difference in the absorption curve which is used or at what concentration, provided that it does not exceed 1 or 2%.

The observation by Lewis and Seaborg[5] that crystal violet can be made to dissolve freely in toluene by the addition of a small amount of a substance with labile hydrogen seemed to show "that crystal violet in toluene forms complexes with alcohols and acids, and the stability of these compounds reaches a maximum in the case of phenol." At first it seemed likely that such complexes, formed by hydrogen bonds at the nitrogen atoms, might account for the peculiarities in the absorption curve of Fig. 3. However, it was later found that other salts of crystal violet (perchlorate, iodide, acetate) are of themselves soluble in toluene, and in one experiment pure, dry crystal violet acetate was dissolved in very dry toluene. The absorption curve was identical with that of Fig. 3.

(4) Mr. J. Biegeleisen, to whom we are indebted for several of our absorption curves, has measured the absorption of crystal violet in mixtures of chloroform and ethanol. The curves change continuously from one pure solvent to the other, the main difference being in the height of the B band which, relative to that of the A band, is 0.22, 0.35, 0.38, 0.40 and 0.40 with 0, 25, 50, 75, and 100% ethanol.

(5) Lewis and Seaborg, THIS JOURNAL, **61**, 1894 (1939).

Absorption Spectra in Alcohol and Other Solvents of Class I.—Solutions in solvents of Class I are the only ones, as we shall see, in which we have the isolated ion of crystal violet. In these solvents the absorption curve proves extremely insensitive to any isothermal change.[6] In alcohol identical curves were obtained at 10^{-4} and 10^{-6} *M*, and in less exact measurements over a still wider range. Moreover, the curve was in no way affected by the nature of the anion (chloride, bromide, acetate or perchlorate). Even when large amounts of sodium chloride or bromide were added (10^{-2} *M*) the absorption curve was not altered.

Even the change from one to another solvent of Class I has, as we have seen, very little effect upon the absorption spectrum. The formation of complexes through hydrogen bonds,[7] which we have just shown to have no effect upon the spectrum in toluene, appears also to have very little effect in solvents of Class I. From cases where these complexes should be prominent, such as glacial acetic acid and ethanol containing considerable amounts of phenol, to cases such as acetone and pyridine, where such complexes must be absent, there is an increase in $\lambda_{max.}$ of only about 50 Å.

When the temperature of the alcoholic solution is lowered, beginning at room temperature, there is a gradual but readily noticeable change in the character of the absorption curve. The shoulder (B band) becomes less marked and nearly disappears as we approach the temperature of liquid air. This phenomenon occurs in methanol and ethanol. We have studied most carefully ethanol containing 5% water,[8] the curves being shown in Fig. 4. Here again we have made $\alpha_{max.} = 1$ for each curve. As we go to lower temperatures there is the usual slight steepening of the curve at the left. The value of $\epsilon_{max.}$, allowance having

(6) It is true that in water at very high concentration (2×10^{-3} *M*) a new absorption band at about 5400 A. was found by Holmes [*Ind. Eng. Chem.*, **16**, 35 (1924)] which probably is due to a dimeric ion such as has recently been studied experimentally and theoretically in the case of the thionine dyes by Rabinowitch and Epstein [THIS JOURNAL, **63**, 69 (1941)].

(7) It was noted by Lewis and Seaborg[5] that the trinitrotriphenylmethide ion seems to form complexes with substances like alcohol, phenol or acetic acid by attachment through hydrogen to the nitro groups, without causing any marked change in color. However, when hydrogen ion was similarly attached to a nitro group the color changed from blue to orange. In our present case the production of various solvates may be considered to produce slight shifts in the absorption band while the addition of hydrogen ion or other strong acid, such as stannic chloride [Lewis, *J. Franklin Institute*, **226**, 293 (1938)], produces an altogether new absorption band. Evidently what has become known as the hydrogen bond differs not only in degree but in kind from a true chemical bond.

(8) It has been shown by Prietzschk [*Z. Physik*, **117**, 482 (1941)] that a small amount of water greatly inhibits the crystallization of alcohol at low temperatures.

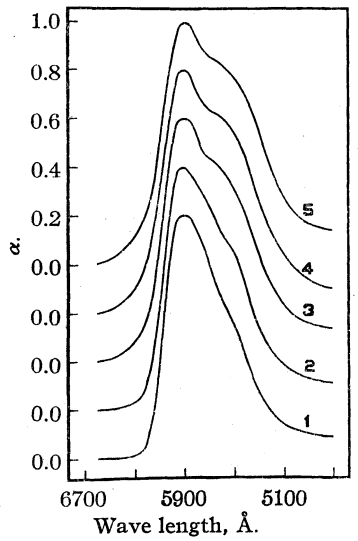

Fig. 4.—Relative extinction coefficient of 10^{-6} *M* crystal violet (chloride) in 95% ethanol at (1) 114°, (2) 162°, (3) 193°, (4) 240° and (5) 294°K.

been made for thermal contraction, increases 16 per cent. in going from 294° to 114°K. Some such increase is to be expected if we assume that much of the B isomer existing at room temperature has gone over to the A isomer at low temperature.

That the two bands are actually to be ascribed to two isomers is made nearly certain by a simple analysis of the absorption curves.[9] If we subtract from the other curves of Fig. 4 the one obtained at 114°K. we obtain a set of curves given in Fig. 5 (the scale is twice that of Fig. 4). Although in this subtraction of curves the errors are exaggerated,

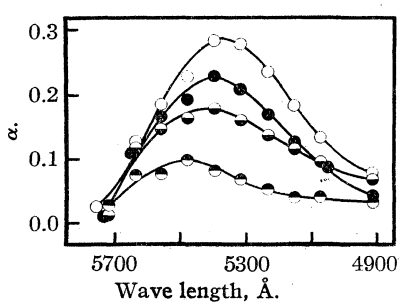

Fig. 5.—Curves obtained by subtracting successively Curve 1 from each of the other curves of Fig. 4. Since in this subtraction the experimental errors are greatly magnified the actual experimental data are shown.

(9) A previous detection of isomers by spectrophotometric methods occurred in the study of the infrared vibrational spectrum of *o*-chlorophenol. Two neighboring vibrational bands were found by Wulf and Liddel [THIS JOURNAL, **57**, 1464 (1935)] and attributed by Pauling [*ibid.*, **58**, 94 (1936)] to *cis* and *trans* forms. This interpretation has been confirmed by Davies [*Trans. Faraday Soc.*, **34**, 1427 (1938)] and more quantitatively by Zumwalt and Badger [THIS JOURNAL, **62**, 305 (1940)].

it is evident that the experimental points fall on curves which are essentially the same except for height. Even at 114°K. there must be some of the B isomer. Assuming the correctness of our calculation of the height of the B band at room temperature in Fig. 1, namely, $\alpha_{max.}$ (B) = 0.36, we obtain the following values for $\alpha_{max.}$ (B) at the several temperatures by adding 0.08 to the maximum values at the several temperatures shown in Fig. 5.

T, °K.	114	162	193	240	294
$\alpha_{max.}$ (B)	0.08	0.17	0.26	0.30	0.36

These values should be proportional to the ratio of the amount of B isomer to the amount of A isomer at each temperature. If we plot the logarithms of these values against $1/T$, all but the point at 193°K. lie on a straight line, from which we may conclude that we are dealing with an equilibrium between two substances. From the slope of the line we find that the B isomer has the greater energy by about 580 cal., while a similar but less exact set of measurements in pure ethanol gave 500 cal. On the other hand, the two isomers in their electronically excited states differ much more in energy. From $\lambda_{max.}$ (A) and $\lambda_{max.}$ (B) we find that the difference in energy is increased by 3300 cal.

The Nature of the A and B Isomers

We shall attempt to visualize the two isomers A and B with the aid of Fig. 6, which shows approximately the atomic distances in the crystal violet ion. Of the hydrogen atoms only the six in the ortho positions of the rings are shown. If the rings and the six ortho hydrogens were all to be in a plane, two adjacent hydrogens such as 2 and 6″ would be only about 0.5 Å. apart. Although the amount of repulsion of two such atoms is unknown, it must be considerable. The re-

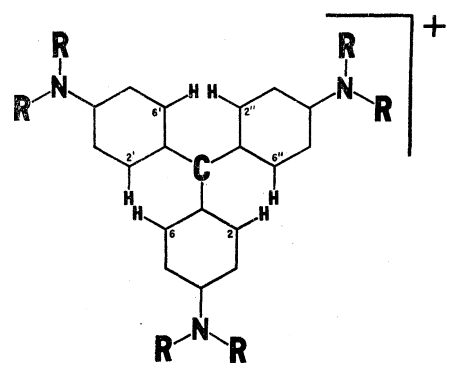

Fig. 6.—Representation of the crystal violet ion, the atomic distances being approximately to scale.

sulting strain can best be relieved by a small rotation of the benzene rings around their axes (the lines connecting the central carbon atom with an atom para to it). Such a rotation at the beginning meets no restoring forces, but these forces of restoration become large as the amount of rotation increases. The nature of these forces of restoration will best be understood if we ascribe to each bond from the central carbon atom one-third double bond character.

As a result of these rotations, we visualize the actual structure of the crystal violet ion as a non-planar one in which two adjacent ortho hydrogens have moved far enough from each other so that the force of repulsion is balanced by the force that opposes free rotation. If in the figure the atoms 2, 2′ and 2″ lie above the plane of the diagram and 6, 6′ and 6″ lie below, we have a model analogous to a windmill or propeller of three blades. It has complete screw or helical symmetry.[10] If in this model one pair of adjacent hydrogens such as 2 and 6″ are forced by each other, or if one of the rings rotates through nearly 180°, we obtain a form like a propeller of three blades in which one blade is turned in the opposite sense from the other two. This distorted helical structure would presumably have more energy than the symmetrical one. Also, since the kind of resonance that favors light absorption would presumably be more inhibited, we should expect for it a lower value of $\lambda_{max.}$. On both these grounds we believe that our isomer A is of the symmetrical helical type and isomer B is of the distorted helical type. The transition from one isomer to the other is apparently rapid in alcohol even at 114°K., so that presumably the heat of activation for isomerization is not more than 2 or 3 kcal. We cannot judge whether the actual process takes place chiefly through the rotation of one ring or the slipping by each other of two adjacent hydrogen atoms. The latter may occur only when the rings are momentarily separated by the vibrations of the molecule.

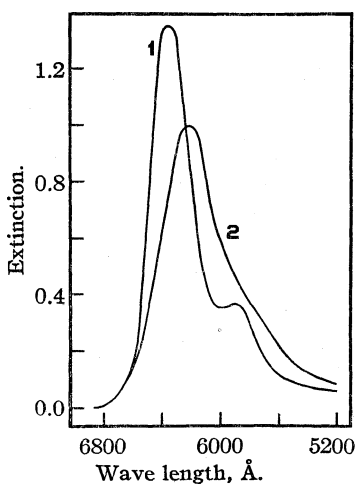

Fig. 7.—Extinction of the same sample of malachite green in 95% ethanol, corrected for temperature expansion. (1) 114°K. and (2) 294°K.

We have observed that the shoulder on the absorption band, indicating two isomers, is nearly always found in dyes of the triaminotriphenylmethyl group. On the other hand, we know of no case in which it has been reported in the diaminotriphenylmethyl dyes such as malachite green (phenyl-bis-(dimethyl-*p*-aminophenyl)-methyl chloride). In these dyes the unsubstituted phenyl group does not participate in the main resonance of the molecule. It should, therefore, be nearly free to occupy various positions of rotation about its axis. We should expect, however, two positions to be of somewhat lower energy than the rest, corresponding to the A and B forms of crystal violet. In fact, we have found that at low temperatures the absorption curve of malachite green is resolved into two narrower bands A and B as shown in Fig. 7. The great increase in $\alpha_{max.}$ of 35% (correction having been made for temperature contraction of the solvent) and the appearance of the two narrow bands indicate pretty clearly that the molecules with varying positions of rotation that exist at room temperature, and each of which has a different $\lambda_{max.}$, have at the low temperature been largely converted into the A and B forms. Our experiments at several low temperatures show that the difference in energy between these two forms is too small to measure.

Absorption Spectra in Solvents of Classes II and III.—In solvents of low dielectric constant it has been shown by the work of Kraus and his associates[11] that the number of free ions is extremely small. While we have reason to believe that the number of free ions is greater in our case than in theirs, most of the dissolved salt must be present as ion pairs and larger ion clusters. It is the absorption spectra of such aggregates that we obtain in Figs. 2 and 3 and it is surprising, therefore, that these curves show as little difference as

(10) The term symmetry is not used in the same sense as in discussing optical isomerism. Indeed, each of the two isomers here discussed must represent a pair of optical isomers, which may ultimately be resolved.

(11) For example, Fuoss and Kraus, THIS JOURNAL, **55**, 3614 (1933), and Batson and Kraus, *ibid.*, **56**, 2017 (1934).

they do from the absorption curve of the free ion. Even this difference can be made to disappear in part.

The absorption curve in chloroform at 5×10^{-7} M is given again as Curve 1 of Fig. 8. As the concentration of the crystal violet is increased, at first there is little change in the curve except a slight broadening, but by the time we reach 1×10^{-4} M (Fig. 8, Curve 3) a shoulder appears at the position of the B band. This phenomenon, which looks at first like an ordinary case of polymerization, proves to be a real enhancement of the B band through a salt effect. Identical results may be obtained by adding foreign salts to the very dilute solution. Thus, Fig. 8, Curve 2 shows the absorption of 5×10^{-7} crystal violet in the presence of 10^{-2} M tetra-*n*-butylammonium iodide, and in this solution the absorption curve is independent of the crystal violet concentration. While the addition of the tetra-*n*-butylammonium iodide produces the same result as an increase in the concentration of the crystal violet chloride, its effectiveness is far less. When the solution contains only 10^{-4} M tetra-*n*-butylammonium iodide the absorption curve hardly differs from Curve 1.[12]

The salt effect is much less noticeable in solvents of Class III than in those of Class II, but a careful examination of many absorption curves

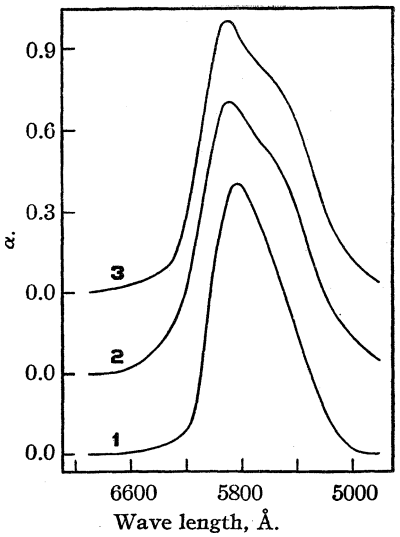

Fig. 8.—Relative extinction coefficient of crystal violet (chloride) in chloroform at 293°K.: (1) dye at 5×10^{-7} M; (2) dye at 5×10^{-7} M, but 10^{-2} M in tetra-*n*-butylammonium iodide; (3) dye at 1×10^{-4} M.

shows that the effect exists and, in this case also, increasing salt concentration brings the curve nearer to the curve in alcohol. In the solutions in toluene (plus β-naphthol) in going from 5×10^{-6} to $2 \times 10^{-4}M$, $\lambda_{max.}$ (A) remains unchanged but $\lambda_{max.}$ (B) becomes about 50 Å. greater and the B band appears to be a little broader. These changes in the B band may be reproduced and enhanced in the very dilute solutions in benzene or toluene by the addition of tetra-*n*-butylammonium iodide or silver perchlorate.[12]

For the difference between the absorption curves of Classes II and III we have no definite explanation. It appears not to be due to differences in dielectric constant and we may surmise that it depends upon the extent and the manner in which the solvent itself goes into the polyionic clusters, as it sometimes enters into crystals as "solvent of crystallization."

The Phosphorescent States of Crystal Violet.—In studying the absorption curve of crystal violet in glycerol, we encountered a phenomenon so strange that it was not understood until we had turned aside to make a thorough study of the phosphorescent state.[13] The phenomenon is illustrated in Fig. 9 where Curves 1 and 2 show the measured extinction of a given sample of crystal violet in glycerol at 228° and 178°K., respectively. As we cool the solution from room temperature, there is a gradual increase in the ab-

(12) We are thus led, merely by a careful inspection of absorption curves, to suspect the existence of a salt effect, in electrolytes such as crystal violet chloride, at concentrations far below those in which similar effects have been obtained with other electrolytes. Preliminary experiments fully justify this suspicion. While Vernon, Luder and Giella [THIS JOURNAL, **63**, 862 (1941)] found that the solubility of tetrabutylammonium iodide in benzene is about doubled in the presence of tetrabutylammonium picrate or nitrate at 10^{-3} M, we find similar and indeed greater effects with salts of crystal violet at concentrations as low as 10^{-6} M.

Vernon, Luder and Giella postponed a theoretical consideration but state that "it seems likely that association is the primary factor," and this is certainly correct. When a very dilute solution of a salt consists chiefly of the species X^+Y^-, $X_2^+Y_2^-$, $X_3^+Y_3^-$, ..., and we add a second salt which consists chiefly of the species X^+Z^-, $X_2^+Z_2^-$, $X_3^+Z_3^-$, ..., the species of one set will not sensibly affect the activities of the other species as such. However, new species are now possible, since we have what may formally be written as the two new species $X_2^+Y^-Z^-$ and $X_2^+Z^-Y^-$ for the quadruplet and $X_3^+Y_2^-Z^-$, $X_3^+Z^-Y_2^-$, $X_3^+Y^-Z_2^-$ and $X_3^+Z_2^-Y^-$ for the sextuplet. In the special case that Y^- and Z^- are sufficiently similar so that their interchange in the clusters produces little change in energy or entropy, but not similar enough so that the solid salts form solid solutions, the mutual solubility effect, when the equilibrium between species of each set is known, could be calculated from probability considerations alone.

In the crystal violet ion the positive charge may be considered to be shared equally by the three amino groups, and when a negative ion comes as close as possible to one of these groups, even allowing for induction, the resulting dipole moment must be at least 50% greater than in any of the ion pairs studied by Kraus. The ion pair should therefore be far less stable in our case, but on the other hand the higher multiplets, especially the sextuplet, should be extremely stable even at dilutions where other types of salts would show no appreciable association.

(13) Lewis, Lipkin and Magel, THIS JOURNAL, **63**, 3005 (1941).

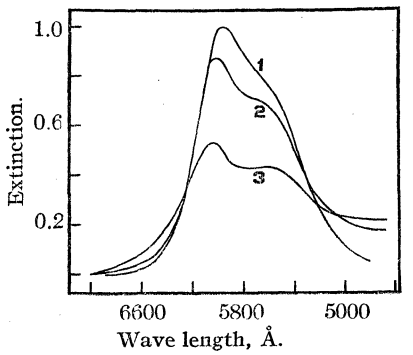

Fig. 9.—Extinction of a single sample of crystal violet (chloride) in glycerol: (1) at 233°K., with or without illumination by mercury arc; (2) at 178°K., no illumination except that used in measurements; and (3) at 178°K., illuminated also by mercury arc.

sorption corresponding to the contraction of the medium. However, at about 200°K. the apparent absorption begins to diminish rapidly and the absorption curve becomes broader. The whole phenomenon occurs in the same range of temperature where Gibson and Giauque[14] found the specific heat of glycerol to diminish about one-half. It is in this range that glycerol changes from a very viscous liquid to a rigid glass, and it is in this same region that the solution of crystal violet in glycerol begins to phosphoresce. A similar diminution in the apparent absorption coefficient of crystal violet in alcohol appears when the temperature is so low that the alcohol is rigid.

We have shown that when fluorescein in a rigid solvent is exposed to intense illumination, the greater part of the molecules go over into the isomer that is characteristic of the phosphorescent state. In that case the phosphorescent molecules had an absorption in a different part of the spectrum from that in which the normal molecules absorbed. Unfortunately in the case of crystal violet the molecules in the phosphorescent state have an absorption of smaller intensity and lying in the same region as the normal absorption. It has not been possible, therefore, to obtain the pure spectrum of the isomeric phosphorescent state, but it probably is not far different from that shown in Curve 3 of Fig. 9, which is obtained when the sample is exposed to illumination of high intensity from a high-pressure mercury arc. The difference between Curves 1 and 2 was found to be due to illumination by the light used in the measurements. At 228°K., where there is no phosphorescence, Curve 1 was obtained regardless of the intensity of the light to which the sample was exposed. At 178°K. the extinction at 5960 Å. fell off with increasing intensity of illumination in a way entirely parallel to that shown for fluorescein in Curve 2, Fig. 8, of our preceding paper.[13] The resemblance between Curves 2 and 3, the former being obtained with light containing almost no ultraviolet, indicates that the phenomenon is not connected with the green phosphorescence to be described later.

The Fluorescence and Phosphorescence Spectra.—We have already[13] mentioned and discussed the fact that crystal violet shows appreciable fluorescence only when the solvent is nearly in a rigid state; as in alcohol a little above the temperature of liquid air, in glycerol at about 215°K., and in supercooled glucose at room temperature. At these or slightly lower temperatures phosphorescence also appears.

When a solution of crystal violet, for example in glycerol, is illuminated at various temperatures with a mercury arc, and the phosphorescence observed, an apparently anomalous result is obtained. At 160°K. a bright red phosphorescence is seen, but at 90°K. the phosphorescence is green. It was found, however, that the green phosphorescence is due to an entirely distinct phosphorescent state which is excited only at wave lengths less than 4000 Å. When excited by visible light there is a strong red phosphorescence at the higher temperature (sufficiently intense to mask the green in the preceding experiment) which nearly disappears at the lower temperature. The visible red phosphorescence is nearly all due to an alpha band, the intensity of which diminishes as the temperature is lowered, but there is also a beta band that lies chiefly below the visible.

We have studied photographically the phosphorescence and fluorescence of crystal violet in glycerol at 178°K. From the spectrograms, together with suitable calibrations described later, we have obtained the Curves 1 and 2 of Fig. 10. The ordinates of each curve are proportional to the absolute emission at each wave length, but the ordinates of one curve are not comparable with those of the other. Curve 2 shows the spectrum of fluorescence accompanied by a small amount of phosphorescence. Curve 1 shows the pure phosphorescence spectrum as excited by visible light. For reference we give also Curve 3, the absorption spectrum, (Curve 1 of Fig. 9), as well as Curve 4, which is a rough determination of

(14) Gibson and Giauque, THIS JOURNAL, **45**, 93 (1923).

the spectrum of the green phosphorescence. In both curves the ordinates involve an arbitrary factor. It will be seen that as in other cases the alpha band is identical with the band of fluorescence. This band diminishes as the temperature is lowered and nearly disappears at the temperature of liquid air.

The lifetime of the phosphorescent state is much less than that of fluorescein, being of the order of 10^{-1} second for the green phosphorescence and 10^{-2} second for the red and infrared phosphorescence. We have not, therefore, measured the heat of activation corresponding to the alpha process, but we may obtain it by the principle of Jablonski.[15] From the positions of the emission maxima of Fig. 9 we find that the fluorescent state is 43.8 kcal. and the phosphorescent state 38.0 kcal. above the ground state. The difference, which represents the heat of activation from the phosphorescent to the fluorescent state, is 5.8 kcal. When we compare this with the 9 kcal. similarly obtained for fluorescein in boric acid we understand why the alpha band of fluorescein disappears at only a little below room temperature, while the alpha band of crystal violet is still prominent at 178°K.

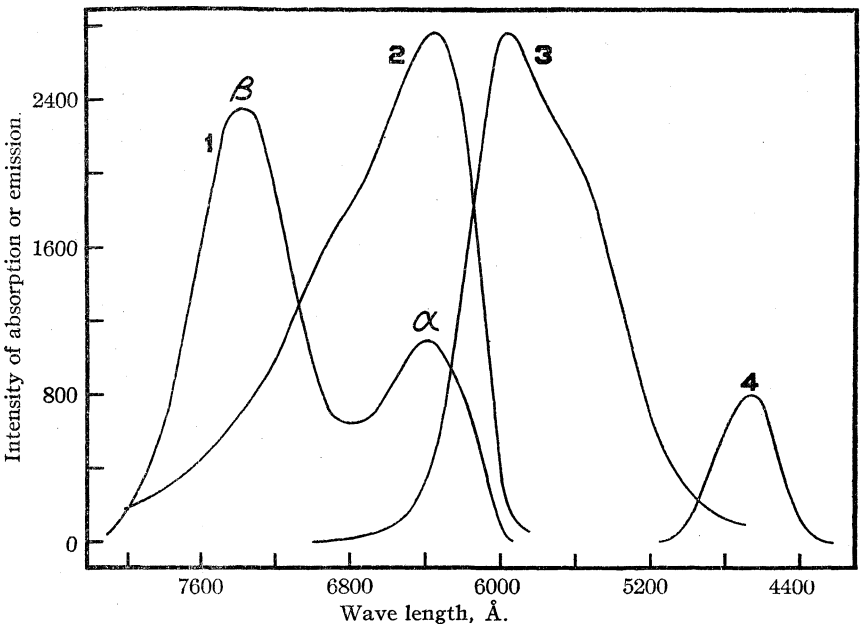

Fig. 10.—Curve 1: absolute intensity (except for an arbitrary constant) of the phosphorescent emission of crystal violet in glycerol at 178°K., showing the alpha and beta bands. Curve 2: similar absolute intensity of fluorescent emission (plus 5–10% phosphorescence), at 178°K. Curve 3: for reference, the absorption spectrum. Curve 4: intensity of green phosphorescence band (not corrected for plate characteristics).

We believe that all of the observed fluorescence and phosphorescence of crystal violet are due to the A isomer alone. If we correct Curve 2 for the small contribution of phosphorescence (say 10% of Curve 1 as drawn) the fluorescence spectrum looks very like a mirror image of one of our A bands of absorption. If there were any contribution of isomer B to the fluorescence we should have an emission band to the right of Curve 2, and such a band is certainly missing. The situation seems to be analogous to that of *cis*- and *trans*-stilbene where we have shown[16] that *trans*-stilbene fluoresces strongly while *cis*-stilbene, the isomer of greater steric strain, gives no observable fluorescence.

The green phosphorescence of crystal violet[17] which is stimulated by ultraviolet shows that the molecule is capable of existence in a second phosphorescent state. That this green phosphorescence is due to a beta process is certain, since we have observed it down to 20°K. From the frequency of the emission maximum we find that the energy of the corresponding phosphorescent state is 60 kcal. above the ground state, while the phosphorescent state corresponding to the infrared beta emission we have seen to be 38 kcal. above the normal state. It would be interesting to find whether any dye has a still greater number of phosphorescent states. Such observations might clarify our ideas as to the exact nature of the phosphorescent state itself.

Evidence for Another Isomeric State.—In addition to the two stereoisomers A and B, and the two fleeting isomers or electromers produced from the former when it goes into its phosphorescent states, we have found some evidence of still another isomeric condition of the crystal violet ion in rigid media. When a colorless compound of

(15) Jablonski, *Z. Physik*, **94**, 38 (1935).

(16) Lewis, Magel and Lipkin, THIS JOURNAL, **62**, 2973 (1940).

(17) Nearly half a century ago in a similar dye, methyl violet, a green phosphorescence was observed by Schmidt [*Ann. Physik*, **58**, 103 (1896)].

crystal violet ion with a strongly basic anion such as cyanide, borate or sulfide is ionized, the crystal violet ion would initially have a pyramidal structure and in a rigid solvent might have difficulty in going over to one of the nearly planar forms which are strongly colored. In fact, we sometimes find that, when one of these compounds, in a rigid solvent at liquid air temperature, is illuminated by ultraviolet light, the solution remains colorless or nearly so, but after the illumination has ceased and the solution is slowly warmed the characteristic absorption of crystal violet appears, although the color may disappear at a still higher temperature. This phenomenon is being further investigated.

Experimental

Many of our experiments were made with commercial crystal violet but for all crucial cases the dye was purified as follows. To a large volume of nearly saturated crystal violet chloride in water a small amount of sodium hydroxide was added. After the lapse of sufficient time for the formation of the carbinol, the latter was extracted by shaking several times with benzene and discarded. To the remaining aqueous solution a larger amount of sodium hydroxide was added to convert about one-half of the chloride into carbinol. This was shaken into benzene and kept. This last solution was shaken several times with water containing a little hydrochloric acid, and finally with water containing hydrochloric acid equivalent to one-half the remaining carbinol. From the aqueous solution thus obtained, after washing with benzene, the final product was obtained by crystallization. Other salts of crystal violet were obtained in a similar way.

The absorption and emission of light were measured by methods which we have already described.[13] In the present case the fluorescence and phosphorescence spectra shown in Fig. 10 were obtained as absolute values, except for a constant factor attending each curve, in the following way. On the same plates as the emission spectrograms, photographs were taken, through wire screens of varying transparency, of the light from a tungsten lamp operating at a color temperature of 2430°K. From the photometric tracings of all the plates, and from the known spectral distribution of the lamp, the absolute emission spectra were obtained by familiar methods.

Summary

The absorption of light by crystal violet has been studied under varying conditions and in numerous solvents. With respect to the appearance of the absorption curves solvents may be roughly placed in three classes, of which the first is typified by ethanol, the second by chloroform, and the third by toluene. All three types of curves show on analysis two absorption bands called A and B. The curve in ethanol is entirely independent of every isothermal change. With diminishing temperature the relative height of the B band in alcohol decreases and the two bands are thus shown to belong to two isomers of crystal violet ion, A and B, of which B has the higher energy by 580 cal. A theory as to the nature of these stereoisomers is given and is supported by experiments on the absorption curve of malachite green at low temperatures.

In solvents of Classes II and III (all of low dielectric constant) there is no appreciable number of free ions, but rather ion clusters of the sort described by Fuoss and Kraus. Small changes in the curves of Class III and a remarkable change in the chloroform curve, with increasing concentration of dye, are shown to be due to a salt effect and can be duplicated by adding other salts. That such salt effects exist, and in much higher degree than in any other known cases, is shown by other experiments.

The fluorescent and phosphorescent emission from crystal violet has been studied quantitatively. As in the previously described case of fluorescein, visible light of high intensity converts most of the dye into the phosphorescent state, so as to change greatly the absorption spectrum. The phosphorescent state gives rise to alpha and beta bands in the red and infrared, respectively. In this case the heat of activation from the phosphorescent to the fluorescent state is only 5.8 kcal. With ultraviolet light a new phosphorescent state is produced giving a green emission band. All the phosphorescence and fluorescence are attributed to isomer A.

There is evidence of still another isomeric condition of crystal violet ion, when produced from a leuco compound by illumination in a rigid solvent. This condition persists in the dark until the solvent is melted.

The Formation of Cyclopropanes from Monohalides. III.[1] Action of Sodium Alkyls on Aliphatic Chlorides. Relation to the Wurtz Reaction

BY FRANK C. WHITMORE AND HARRY D. ZOOK[2]

The formation of benzene and ethylene in addition to ethylbenzene from the reaction of sodium phenyl and ethyl bromide has been explained by Schlubach and Goes[3] on the basis of a disproportionation between two free radicals. Since the postulation of sodium alkyls as intermediates in the Wurtz reaction,[4] Morton has studied the reaction of sodium amyl, prepared from amyl chloride and sodium, with various alkyl halides.[5] Low yields of the coupling products were obtained. Little attention has been given, however, to the "disproportionation products" from such reactions.

It appeared to us that, since sodium alkyls are strong hydrocarbo bases, the so-called disproportionation products may not arise by a free radical mechanism, but may be formed by the action of the hydrocarbo base on the halide.[6] Such a mechanism would give the saturated hydrocarbon corresponding to the sodium alkyl and the olefin corresponding to the halide in each case, rather than two saturated and two unsaturated hydrocarbons.

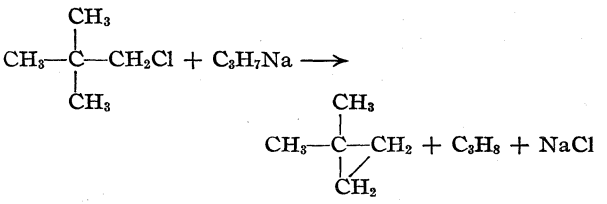
We have prepared sodium ethyl and sodium propyl from the corresponding mercury compounds and have treated these sodium alkyls with alkyl halides.

The reaction of sodium with excess mercury diethyl in *n*-pentane solution at 25° gave an 80% yield of sodium ethyl, the other product being a 5.8% sodium amalgam. This reaction mixture, when treated with *n*-hexyl chloride at −10° to 0°, gave a 40% yield of *n*-octane, a 46% yield of 1-hexene, and a 52% yield of ethane along with a small amount (2%) of ethylene.

$$C_2H_5Na + C_6H_{13}Cl \longrightarrow \begin{cases} C_4H_9CH{=}CH_2 + C_2H_6 + NaCl \\ n\text{-}C_8H_{18} + NaCl \end{cases}$$

To see what would happen when a halide having no alpha hydrogen atoms was treated with an alkylsodium compound, we have investigated the reaction of sodium *n*-propyl and neopentyl chloride. This sodium alkyl was prepared in 88% yield from sodium and excess mercury di-*n*-propyl in *n*-octane solution. No appreciable reaction took place between the sodium propyl and neopentyl chloride at temperatures below 50°, in contrast to the action of sodium ethyl and *n*-hexyl chloride. However, reaction proceeded smoothly at 50–60° to give a 75% yield of **1,1-dimethylcyclopropane** and a 4% yield of the coupled product, 2,2-dimethylhexane. The other products were **propane** (70%) and propene (5%), the latter compound probably coming from the decomposition of part of the propyl sodium at the temperature used. No neopentane was formed. It was found that neopentyl chloride would not react with a 6% sodium amalgam such as was present in this case from the preparation of the sodium propyl.

The hydrocarbo base has caused cyclization by the removal of a beta hydrogen atom as hydrogen halide.



Although 3-ring closure has been accomplished many times by the removal of hydrogen halide with an aquo or alcoholo base, the hydrogen removed has usually been activated by an adjacent carboxyl or other strongly negative group.[7] The first step in our reaction may be the removal of one of the nine beta hydrogens by the sodium propyl to give propane.[8] Some indication of the base strength of the sodium alkyl may be seen from the fact that neopentyl chloride is inert to alcoholic potassium hydroxide in a sealed tube for twenty hours at 100°.[9] The reaction of sodium alkyls as well as other bases on halides of this type is being investigated further.

Yields of sodium alkyls from the mercury compounds were obtained indirectly in three ways: from the mercury recovered from the hydrolysis

of the amalgam, from the sodium hydroxide thus obtained, and from the sodium chloride formed in the main reaction. The yields of sodium ethyl calculated by these three methods were 80 ±1%. Quantitative sodium and chlorine material balances were obtained in each case. Solvents were recovered in better than 90% yields, showing that metalation of the normal paraffin hydrocarbons is not appreciable under the conditions used.

Mechanism of the Wurtz Reaction

Sodium alkyls[4] and free radicals[10] have been postulated by many workers as intermediates in the Wurtz reaction.

It has been shown that the Wurtz reaction may be carried out in such a manner that sodium alkyls play a major part in the mechanism.[11] Morton and Richardson found that by increasing the sodium surface per mole of amyl chloride the yields of acids formed by carbonation of the intermediate sodium compounds may go as high as 95% as the decane formed approaches zero.[11]

Part of the evidence for the free radical theory is based on the formation of disproportionation products such as ethane and ethylene in equimolar amounts from the reaction of ethyl iodide and sodium.[10b] Our work indicates that in cases where sodium alkyls play a major part in the reaction, the by-product saturated and unsaturated hydrocarbons obtained do not arise from the disproportionation of free radicals but from the action of the sodium alkyl as a hydrocarbo base with the alkyl halide.

Thus *n*-hexyl chloride and sodium ethyl give 40% *n*-octane by coupling and about 50% each of 1-hexene and ethane. The coupling product may be formed by a Walden inversion type of reaction. This is similar to the action of *n*-hexyl chloride with alcoholic bases to give mainly *n*-hexyl ethyl ether and a little 1-hexene.[12] The failure of neopentyl chloride and sodium propyl to give more than a few per cent. of coupling product is probably connected with the sluggishness of this halide in metathetical reactions of the Walden type.[13] In this case the by-product hydrocarbons become the main product and the "unsaturated" one appears as 1,1-dimethylcyclopropane. It would thus seem that the earlier work from this Laboratory on the action of sodium with neopentyl chloride[10a] and neohexyl chloride[1] may go through sodium alkyls formed from free radicals. These would react with the halides as does sodium propyl in the present study.

Experimental

The Reaction of Sodium Ethyl and *n*-Hexyl Chloride.—The apparatus consisted of a three-necked flask equipped with a reflux condenser, thermometer, dropping funnel, and mercury sealed stirrer. Gases were led from the reflux condenser through two dry-ice–acetone traps and collected over saturated sodium chloride solution. The air from the entire apparatus was swept out by a stream of nitrogen.

Exactly 23.1 g. of freshly cut sodium was weighed out in a glass-stoppered bottle under pentane. The sodium was then cut into very thin slices under pentane, the pentane decanted, and the sodium dried with a stream of nitrogen. The dry sodium was transferred in an atmosphere of nitrogen to the reaction flask and covered with 122.5 g. of olefin-free *n*-pentane; b. p. 36° (737 mm.), $n^{20}D$ 1.3580. The addition of 200 g. of mercury diethyl, b. p. 67.5° (30 mm.), required thirty minutes during which time the flask was held at 25° by adding small pieces of dry-ice to an acetone-bath in which it was immersed. Reaction was rapid giving a fine suspension of sodium ethyl and sodium amalgam. No gas was formed. The mixture was allowed to stir for an hour, after which the flask was cooled to −10°.

The addition of 121.5 g. of *n*-hexyl chloride, b. p. 134° (738 mm.) and $n^{20}D$ 1.4200, took place over a period of two and one-half hours. Gas was evolved at the rate of a liter an hour for twelve hours at temperatures between −10° and 0°. The reaction mixture was charged directly to a 13-plate column and 118 g. (96%) of the pentane solvent was removed; b. p. 35.5–37° (734 mm.); $n^{20}D$ 1.3580–1.3592.

The clear liquid portion of the residue was decanted. The solid amalgam and sodium chloride were washed with small portions of pentane and filtered. The amalgam was decomposed with 500 cc. of water and 250 cc. of 0.927 *N* sulfuric acid. Back-titration with 23.7 cc. of standard sodium hydroxide (1 cc. base = 1.08 cc. of acid) indicated the presence of 4.76 g. of sodium in the amalgam. The mercury, after washing well with water, acetone, and dry ether, weighed 78.5 g. Analysis of the neutralized aqueous solution showed the presence of 47.1 g. of sodium chloride.

The yields of sodium ethyl in the first step of the reaction calculated from the mercury formed, from the sodium present in the amalgam, and from the sodium chloride formed by the reaction are 40.8, 41.4 and 41.8 g., respectively.

The liquid organic products from the reaction were fractionated at 733 mm. through a 13-plate column. Fractions: 3–9, 10.9 g., b. p. 44–62°, $n^{20}D$ 1.3605–1.3872; 10–18, 23.7 g., 62–65°, 1.3880–1.3881; 19–21, 6.3 g., 75–123°, 1.3898–1.4000; 22–27, 29.9 g., 123°, 1.4020–1.4032; 28–31, 19.1 g., 124° (733 mm.) to 60° (40 mm.). The yields of 1-hexene and *n*-octane, taken from boiling point and refractive index curves, were 30.7 g. and 36.1 g., respectively.

The gas from the reaction was analyzed in a modified Orsat apparatus using a solution saturated with bromine and sodium chloride to remove the ethylene.[14] The gas evolved consisted of 0.50 g. of ethylene and 12.6 g. of ethane.

Identification of 1-Hexene.—Fractions 9–18 (24 g.) from the products of the reaction of sodium ethyl and *n*-hexyl chloride were diluted with 200 cc. of olefin-free pentane, and a stream of oxygen containing 3% ozone passed through at an average rate of 25 l. per hour for seven hours. The ozonide was decomposed according to the method of Whitmore and Church.[15] Formaldehyde was found in the water layer from the decomposition, and was identified by its dimethylcyclohexanedione derivative; m. p. 190.5–191.5°. Fractionation of the oil layer gave 8.2 g. of valeraldehyde; b. p. 95–99° (715 mm.); identified by its 2,4-dinitrophenylhydrazone, m. p. 107–108° and mixed m. p. with an authentic sample 107.5–108.5°.

Reaction of Sodium *n*-Propyl and Neopentyl Chloride.—The same apparatus and technique were used as for the reaction of sodium ethyl and *n*-hexyl chloride. The two cold traps were held at −40° in order to retain 1,1-dimethylcyclopropane but not propane. *n*-Octane, 232 g., b. p. 124.5° (729 mm.) and $n^{20}D$ 1.3982, was used as the dispersing medium. The propyl sodium was prepared from 23.0 g. of sodium and 202.5 g. of mercury di-*n*-propyl; b. p. 86.5° (25 mm.). No gas was evolved while stirring for an hour at room temperature. The reaction mixture was cooled to 0° for the addition of 89.5 g. of neopentyl chloride; b. p. 82–84° (740 mm.) and $n^{20}D$ 1.4048. After about a third of the chloride was added the mixture was slowly warmed to 50° at which temperature a slow evolution of gas began. The remainder of the chloride was added over a period of three hours. Gas was evolved at the rate of 500 cc. per hour for a period of about eight hours. At this point the stirrer was replaced by a 10-plate column to which was attached a series of traps held at −15, −80 and −80°, respectively. Ice water was circulated through the head and jacket of the column as the flask was gradually heated to 107° over a period of fifteen hours in order to complete the reaction and drive off all low boiling products. The residue was decomposed with water and standard acid as previously described. There was obtained 87.7 g. of mercury representing an 88% yield of sodium propyl. The amount of sodium in the amalgam (4.56 g.) and the sodium chloride from the reaction (46.1 g.) correspond to a 79% yield of sodium propyl. (Some sodium propyl decomposed, however, to give propylene.)

Material collected in the traps held at −80° was distilled through a low temperature micro column to give 22.0 g. boiling below −38° and a residue which, together with material collected in the traps held at −40°, was fractionated at 730 mm. through a 40-plate low temperature column. Obtained were fractions: 1–4, 2.3 g., b. p. −15 to 17°; 5–6, 7.7 g., 18–19.8°; 7–11, 31.0 g., 20.2–20.8°, $n^{20}D$ 1.3660–1.3675. The material from fractions 7–11 would not react with bromine in carbon tetrachloride. The residue from this distillation was combined with the other liquid organic products from the reaction and fractionated through a 40-plate column. From a complete distillation curve of both fractionations there was calculated to be 41.3 g. (75%) of 1,1-dimethylcyclopropane; 3.0 g. of recovered neopentyl chloride; 4.0 g. (4%) of impure 2,2-dimethylhexane, b. p. 104–111° (722 mm.), $n^{20}D$ 1.3998–1.4001; 214 g. (92.5%) of recovered octane solvent, b. p. 120° (722 mm.) to 70° (40 mm.), $n^{20}D$ 1.3982–1.3986; and 74 g. of recovered mercury dipropyl, b. p. 95–97° (40 mm.).

The material collected below −38° was vaporized, and the gas collected over saturated sodium chloride solution. Analysis of all the gaseous products indicated that there was present 1.85 g. (5%) of propene and 27.5 g. (71%) of propane. Again, a solution saturated with sodium chloride and bromine was used to absorb the olefin.

Attempted Reaction of Neopentyl Chloride with Sodium Amalgam.—Into a 500-cc. flask was placed 59 g. of neopentyl chloride, b. p. 82–84° (740 mm.), $n^{20}D$ 1.4048 and 209 g. of freshly prepared 6% sodium amalgam. The flask was attached to a 20-plate column and the neopentyl chloride refluxed for six hours. Fractionation then gave 6 fractions, 56.3 g., b. p. 83° (745 mm.), $n^{20}D$ 1.4048 along with 1.8 g.; $n^{20}D$ 1.4060 driven from the column when the jacket was heated to 160°. No low boiling products were collected in a dry-ice trap connected to the column. The recovery of neopentyl chloride was 98%.

Summary

1. Sodium ethyl and sodium propyl were prepared from sodium and the corresponding mercury compounds in yields of 80 and 88%, respectively. No appreciable reaction took place between the alkylsodium compounds and *n*-paraffin hydrocarbon solvents.

2. Sodium ethyl reacts with *n*-hexyl chloride to give octane (40%), ethane (52%), 1-hexene (46%), and a trace of ethylene.

3. The products of the reaction of sodium propyl and neopentyl chloride were 1,1-dimethylcyclopropane (75%), propane (70%), propene (5%), and the coupled product, 2,2-dimethylhexane (4%).

4. The major reaction is one of a hydrocarbo base splitting out hydrogen chloride from an alkyl chloride.

5. The possible relationship of these results to the mechanism of the Wurtz reaction is discussed.

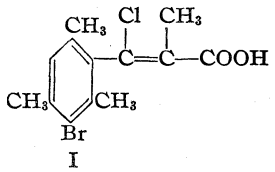
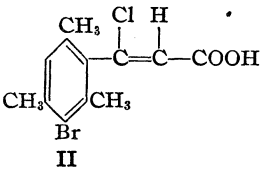
Restricted Rotation in Aryl Olefins. IV. Preparation and Resolution of β-Chloro-β-(2-methoxy-4,6-dimethyl-5-chlorophenyl)-α-methylacrylic and the Corresponding Acrylic Acid

BY ROGER ADAMS AND W. J. GROSS[1]

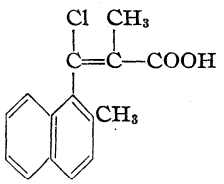
The molecules shown by formulas I, II, III and IV and a few of their derivatives have been resolved and the active forms shown to be very resistant to racemization. The half-life periods in boiling *n*-butanol are for I, no racemization; for II, two hundred minutes; for III, seventy hours; for IV, seventy minutes. These values show semi-



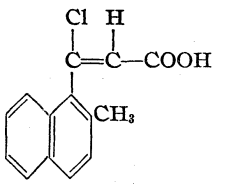
I



II



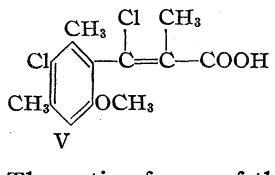
III



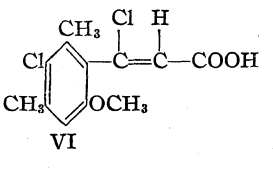
IV

quantitatively the relative interference effects of the hydrogen and methyl on the α-carbon to the carboxyl (compare I and II; also III and IV) and of the *ortho* methyl and —CH= group in the aromatic nucleus (compare I and III; also II and IV).

Analogous derivatives to compounds I and II have now been synthesized and resolved in which an *ortho* methyl group in the benzene ring has been substituted by the smaller methoxyl group (V and VI).



V



VI

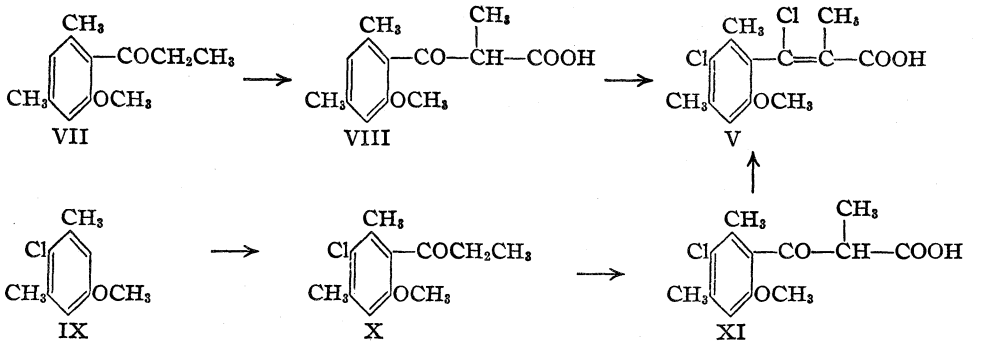
The active forms of these molecules racemized so rapidly in boiling *n*-butanol that quantitative racemization measurements were impossible under these conditions. The active form of compound V was consequently racemized in *n*-butanol at 44° and the half-life determined as one hundred and seventy-three minutes; the active form of compound VI had a half-life period of about nine minutes in *n*-butanol at 20°. Although the racemization values of compounds I, II, III and IV taken in boiling *n*-butanol cannot be compared quantitatively with those of compounds V and VI taken at other temperatures, the relative ease of racemization of the latter two is striking. It demonstrates forcibly the enormous difference in the interference effects of the methoxyl and methyl groups in the ring and again of the methyl and hydrogen on the α-carbon to the carboxyl. The alkaloidal salts of acids V and VI were obtained in only one form though mutarotation was not observed at room temperature.

No attempt has been made to determine whether compounds V and VI have the carboxyl *cis* or *trans* to the side-chain chlorine. From considerations presented in the previous papers,[1a,1b] the assumption is that the carboxyl is *trans*. A study of a model of compound VI indicates that only if the carboxyl is *trans* to the side-chain chlorine is interference possible.

The synthesis of compound V was effected in two ways. 1-Methoxy-3,5-dimethylbenzene was converted to 1-methoxy-3,5-dimethyl-2-propiophenone (VII) by means of propionic anhydride and aluminum chloride. Ethylmagnesium bromide followed by carbon dioxide gave α-methyl-(2-methoxy-4,6-dimethylbenzoyl)-acetic acid (VIII). The yield was only 40% and an unidentified by-product was obtained which probably originated from the action of the Grignard reagent on the keto form of the propiophenone. Since completely hindered ketones usually react entirely in the enol form with the Grignard reagent, the large by-product may be indicative of the decreased interference present as compared with that in the mesitylene analogs.

The usual procedure for obtaining the desired β-chloro-acrylic acid from the keto acid is by the use of phosphorus pentachloride in phosphorus oxychloride. In this instance, however, chlorination of the ring took place at the same time giving a mixture from which two compounds were isolated, one postulated as having structure V and

(1) For previous papers see (a) Adams and Miller, THIS JOURNAL, **62**, 53 (1940); (b) Adams, Anderson and Miller, *ibid.*, **63**, 1589 (1941); (c) Adams and Binder, *ibid.*, **63**, 2773 (1941).



the other with no chlorine in the ring. The position of the chlorine in the ring in V was determined by preparing 1-methoxy-3,5-dimethyl-4-chlorobenzene (IX) and converting it to the 1-methoxy-3,5-dimethyl-4-chloro-2-propiophenone (X). By following the same series of reactions through the keto acid (XI) as previously described, compound V was obtained. This latter method of preparation of V was distinctly superior to the former since the use of 1-methoxy-3,5-dimethyl-4-chlorobenzene as a raw material in place of 1-methoxy-3,5-dimethylbenzene served not only to prove the position of the chlorine in the ring but also permitted the formation of only one product in the final chlorination reaction.

The corresponding β-chloroacrylic acid (VI) was synthesized from 1-methoxy-3,5-dimethyl-4-chlorobenzene in a similar manner.

By starting with 1-ethoxy-3,5-dimethyl-4-chlorobenzene the 2-ethoxy derivatives corresponding to compounds V and VI were formed but no salts were found with suitable characteristics to make resolution studies possible.

Experimental

1-Methoxy-3,5-dimethyl-2-propiophenone.—To a mechanically stirred mixture of 300 g. of carbon disulfide, 136 g. of 1-methoxy-3,5-dimethylbenzene[2] and 130 g. of propionic anhydride, was added 267 g. of anhydrous aluminum chloride at such a rate that the solvent refluxed gently. Upon completion of the addition a plastic mass formed making further stirring impossible. After the reaction mixture had stood for twelve hours the solvent was decanted and the residue decomposed using iced hydrochloric acid. The oil which separated was extracted with ether, washed with aqueous sodium hydroxide and finally with dilute hydrochloric acid. Distillation gave a water-white liquid; b. p. 120–122° (2 mm.), $n^{24}D$ 1.5160; yield 144 g. (75%).

Anal. Calcd. for $C_{12}H_{16}O_2$: C, 75.00; H, 8.40. Found: C, 75.46; H, 8.44.

Demethylation, observed in every experiment, increased as the excess of aluminum chloride was increased. The yield reported is that obtained when minimum demethylation occurred.

1-Hydroxy-3,5-dimethyl-2-propiophenone.—Acidification of the sodium hydroxide washings obtained in the preparation of 1-methoxy-3,5-dimethyl-2-propiophenone gave 1-hydroxy-3,5-dimethyl-2-propiophenone. The crude product was recrystallized from a small amount of methanol, white crystals, m. p. 78° (cor.).

Anal. Calcd. for $C_{11}H_{14}O_2$: C, 74.11; H, 7.92. Found: C, 73.93; H, 7.98.

This substance was remethylated readily by dissolving it in the appropriate amount of aqueous sodium hydroxide and adding dropwise, with stirring, an excess of dimethyl sulfate. After heating the reaction mixture at 100° for one hour, it was cooled and extracted with ether. The ether extract was dried over anhydrous magnesium sulfate and then distilled to give 1-methoxy-3,5-dimethyl-2-propiophenone.

α-Methyl-(2-methoxy-4,6-dimethylbenzoyl)-acetic Acid.—A solution of 20 g. of 1-methoxy-3,5-dimethyl-2-propiophenone in 25 cc. of dry ether was added to 100 cc. of an ether solution containing slightly more than one mole equivalent of ethylmagnesium bromide. The mixture was refluxed for thirty minutes, then transferred to a catalytic hydrogenation apparatus, cooled in an ice-bath, and carbon dioxide[3] passed in at a pressure of 2–3 atm. After forty-five minutes the temperature was allowed to rise to that of the room and the addition of carbon dioxide continued for six hours.

The reaction mixture was then chilled in an ice-bath, and poured slowly into iced hydrochloric acid. The ether layer was extracted with aqueous sodium hydroxide and the aqueous extract immediately acidified with iced hydrochloric acid. The product was purified by dissolving it in an excess of petroleum ether (b. p. 60–110°) and concentrating by means of an air stream; white crystalline powder, m. p. 88–89° (cor.); yield 8 g. (30%). When pure the material is stable for several weeks.

Anal. Calcd. for $C_{13}H_{16}O_4$: C, 66.07; H, 6.82. Found: C, 66.57; H, 7.18.

Evaporation of the ether solution after extraction with aqueous sodium carbonate did not give the expected unreacted ketone but rather a substance of lower boiling point. This liquid, postulated as being a mixture of the tertiary alcohol and the corresponding dehydration product arising

from the normal Grignard addition reaction, was treated with acetic anhydride to effect complete dehydration. The purified product did not give the proper analysis, however, and no further investigation was attempted.

β-Chloro-β-(2-methoxy-4,6-dimethylphenyl)-α-methylacrylic Acid.—To a solution of 10 g. of α-methyl-(2-methoxy-4,6-dimethylbenzoyl)-acetic acid in 50 cc. of ice cold phosphorus oxychloride, was added 25 g. of phosphorus pentachloride. After heating at 70° for one hour, the solution was poured onto 300 g. of ice. The product separated as an oil which solidified on standing. The crude material, after many careful fractional crystallizations from benzene, was shown to be a mixture of β-chloro-β-(2-methoxy-4,6-dimethylphenyl)-α-methylacrylic acid and β - chloro - β - (2 - methoxy - 4,6 - dimethyl - 5 - chlorophenyl)-α-methylacrylic acid. Each was separated in a pure state but only in small amounts. β-Chloro-β-(2-methoxy-4,6-dimethylphenyl)-α-methylacrylic acid was obtained from benzene as white crystals, m. p. 163–164° (cor.).

Anal. Calcd. for $C_{13}H_{15}O_3Cl$: C, 61.29; H, 5.89. Found: C, 61.15; H, 6.03.

β-Chloro-β-(2-methoxy-4,6-dimethyl-5-chlorophenyl)-α-methylacrylic acid was obtained from benzene as white crystals, m. p. 178–179° (cor.).

Anal. Calcd. for $C_{13}H_{14}O_3Cl_2$: C, 54.00; H, 4.88; neut. equiv., 289. Found: C, 54.43; H, 5.05; neut. equiv., 287.

1-Methoxy-3,5-dimethyl-4-chlorobenzene (IX).—A solution of 313 g. of 1-hydroxy-3,5-dimethyl-4-chlorobenzene[4] in 85 g. of sodium hydroxide dissolved in a small amount of water was stirred and to it was added dropwise an excess of dimethyl sulfate. After refluxing for two hours, the resulting oil was removed and the water layer extracted with ether. The oil and ether extracts were combined and dried by means of anhydrous magnesium sulfate, the ether was then removed and the residue distilled; b. p. 94–96° (6 mm.), $n^{20}D$ 1.5365; yield 273 g. (80%).

Anal. Calcd. for $C_9H_{11}OCl$: C, 63.31; H, 5.91. Found: C, 64.09; H, 6.75.

1-Methoxy-3,5-dimethyl-4-chloro-2-propiophenone (X).—This product was prepared in a similar manner to 1-methoxy-3,5-dimethyl-2-propiophenone using 1-methoxy-3,5-dimethyl-4-chlorobenzene in place of 1-methoxy-3,5-dimethylbenzene. It was a white, crystalline solid, readily purified from petroleum ether (b. p. 60–110°), m. p. 66.5–67.5° (cor.); yield 125 g. (55%).

Anal. Calcd. for $C_{12}H_{15}O_2Cl$: C, 63.54; H, 6.66. Found: C, 64.01; H, 6.70.

Acidification of the sodium hydroxide washings gave 1-hydroxy-3,5-dimethyl-4-chloro-2-propiophenone, a white crystalline solid. This substance was not purified but was remethylated as described for the corresponding unchlorinated compound, 1-hydroxy-3,5-dimethyl-4-propiophenone.

Demethylation, observed in every experiment, increased as the excess of aluminum chloride was increased. The yield reported was that obtained when minimum demethylation occurred.

(4) Lesser and Gad, *Ber.*, **56B**, 974 (1923).

α-Methyl-(2-methoxy-4,6-dimethyl-5-chlorobenzoyl)-acetic Acid (XI).—A solution of 20 g. of 1-methoxy-3,5-dimethyl-4-chloro-2-propiophenone in 25 cc. of dry ether was added to 100 cc. of an ether solution containing slightly more than one mole equivalent of ethylmagnesium bromide. The mixture was refluxed for thirty minutes and carbonated as described for the corresponding unchlorinated propiophenone. The product was purified by crystallization from petroleum ether (b. p. 60–110°) and finally from benzene by dissolving it in an excess of the solvent and then concentrating; white crystalline powder, m. p. 118° (cor.); yield 12 g. (50%). When pure, the material was stable for several weeks. The crude product was satisfactory for conversion to β-chloro-β-(2-methoxy-4,6-dimethyl-5-chlorophenyl)-α-methylacrylic acid.

Anal. Calcd. for $C_{13}H_{15}O_4Cl$: C, 57.76; H, 5.58. Found: C, 57.65; H, 5.61.

Evaporation of the ether solution after extraction with sodium carbonate yielded a liquid which was probably a mixture of the tertiary alcohol and the corresponding dehydration product, arising from the normal Grignard addition reaction to the keto form of the propiophenone.

β-Chloro-β-(2-methoxy-4,6-dimethyl-5-chlorophenyl)-α-methylacrylic Acid (V).—A sample of 10 g. of α-methyl-(2-methoxy-4,6-dimethyl-5-chlorobenzoyl)-acetic acid was converted to the chloroacrylic acid derivatives by the procedure described for the corresponding unchlorinated phenyl derivative. It was purified by recrystallization first from petroleum ether (b. p. 60–110°) and then several times from benzene; white crystals, m. p. 178–179° (cor.); yield 5.5 g. (50%).

Anal. Calcd. for $C_{13}H_{14}O_3Cl_2$: C, 54.00; H, 4.88; neut. equiv., 289. Found: C, 54.00; H, 5.02; neut. equiv., 287.

Resolution of β-Chloro-β-(2-methoxy-4,6-dimethyl-5-chlorophenyl)-α-methylacrylic Acid (V).—A solution of 2.7 g. of β-chloro-β-(2-methoxy-4,6-dimethyl-5-chlorophenyl)-α-methylacrylic acid in 40 cc. of warm acetone was added to a solution of 2.9 g. of quinine in 40 cc. of warm acetone. After filtration the solution was allowed to stand for five days after which fraction A (2.5 g.) was removed. This was unchanged in rotation after recrystallization from acetone. The filtrate was then evaporated to 60 cc. and after standing two days fraction B (0.55 g.) was collected. Evaporation of the filtrate to 25 cc. yielded fraction C (1.2 g.) after standing four days. Evaporation to dryness gave fraction D. The rotations of fractions B and C were essentially identical with those of fraction A from which it was deduced that only one salt was obtained. No mutarotation was observed over a short period of time at room temperature.

Anal. Calcd. for $C_{33}H_{38}O_5Cl_2N_2$: C, 64.57; H, 6.24. Found: C, 64.68; H, 6.46. *Rotation.* (*l*Bd*A*) 0.050 g. made up to 25 cc. with benzene at 20° gave αD −0.12°; *l*, 2; $[\alpha]^{20}D$ −30.0°.

***d*-β-Chloro-β-(2-methoxy-4,6-dimethyl-5-chlorophenyl)-α-methylacrylic Acid.**—To a suspension of 2 g. of salt (fraction A) in 30 cc. of water was added 5 cc. of concentrated hydrochloric acid. After stirring at 5° for thirty minutes the product was filtered, washed with 5% hydrochloric acid and finally with water. The above was re-

peated until the product was quinine free; m. p. 177° (cor.).

Rotation. (*d*-acid) 0.100 g. made up to 25 cc. with *n*-butanol at 20° gave α_D +0.18; *l*, 2; $[\alpha]^{20}D$ +22.5°.

Racemization of *d*-β-Chloro-β-(2-methoxy-4,6-dimethyl-5-chlorophenyl)-α-methylacrylic Acid (V).—A solution of 0.1 g. of the above *d*-acid in 25 cc. of *n*-butanol was placed in a polarimeter tube equipped with a water jacket through which was passed water at 44° from a constant temperature bath. The following α_D values were obtained: at the start +0.18; after thirty minutes +0.16; after one hour +0.15; after one and a half hours +0.13; after two hours +0.11; after two and a half hours +0.09; after three and a half hours +0.07; after four and a half hours +0.06; after seven and a half hours +0.02. Calculated for a reversible unimolecular reaction, the half-life period is 173 minutes.

1-Methoxy-3,5-dimethyl-4-chloro-2-acetophenone.—To 300 g. of carbon disulfide, 171.5 g. of 1-methoxy-3,5-dimethyl-4-chlorobenzene and 102 g. of acetic anhydride, was added 267 g. of anhydrous aluminum chloride using exactly the same procedure employed to produce 1-methoxy-3,5-dimethyl-4-chloro-2-propiophenone. Distillation gave a white crystalline solid; b. p. 134–136° (3 mm.). It was purified by crystallization from dry ether, m. p. 76–77° (cor.); yield 127 g. (50%).

Anal. Calcd. for $C_{11}H_{13}O_2Cl$: C, 62.09; H, 6.16. Found: C, 61.92; H, 6.23.

As in the preparation of 1-methoxy-3,5-dimethyl-4-chloro-2-propiophenone, demethylation occurred. The product could be remethylated and purified readily, however, in exactly the same manner as the 1-hydroxy-3,5-dimethyl-4-chloro-2-propiophenone previously described.

2-Methoxy-4,6-dimethyl-5-chlorobenzoyl Acetic Acid.—A solution of 20 g. of 1-methoxy-3,5-dimethyl-4-chloro-2-acetophenone in 25 cc. of dry ether was added to 100 cc. of an ether solution containing slightly more than one mole equivalent of ethylmagnesium bromide. The bromomagnesium enolate precipitated and was carbonated in the same manner as 1-methoxy-3,5-dimethyl-4-chloro-2-propiophenone. Recrystallization of the crude product gave a white crystalline powder, m. p. 113° (cor.); yield 11 g. (45%).

Anal. Calcd. for $C_{12}H_{13}O_4Cl$: C, 56.11; H, 5.11. Found: C, 55.73; H, 5.24.

As in the case of α-methyl-(2-methoxy-4,6-dimethyl-5-chlorobenzoyl)-acetic acid (XI), normal addition of the Grignard reagent apparently took place, for the main constituent of the residue was a liquid which was presumably the dehydrated tertiary alcohol.

β-Chloro-β-(2-methoxy-4,6-dimethyl-5-chlorophenyl)-acrylic Acid (VI).—To a solution of 10 g. of 2-methoxy-4,6-dimethyl-5-chlorobenzoyl acetic acid in 50 cc. of ice-cold phosphorus oxychloride was added 25 g. of phosphorus pentachloride. The mixture was heated in a water-bath at 70° for one hour, then poured onto 300 g. of ice. A solid separated and was purified by crystallization from petroleum ether (b. p. 60–110°) and finally from benzene; white crystals, m. p. 181–182° (cor.); yield 5.2 g. (48%).

Anal. Calcd. for $C_{12}H_{12}O_3Cl_2$: C, 52.34; H, 4.34. Found: C, 52.18; H, 4.49.

Resolution of β-Chloro-β-(2-methoxy-4,6-dimethyl-5-chlorophenyl)-acrylic Acid (VI).—A solution of 6.3 g. of β - chloro - β - (2 - methoxy - 4,6 - dimethyl - 5 - chlorophenyl)-acrylic acid in 50 cc. of ethyl acetate was added to a solution of 7.5 g. of quinine in 70 cc. of ethyl acetate. After filtration the solution was evaporated to 40 cc. and at two-day intervals the crystals were filtered and 5 cc. of solvent was removed. The rotations of the various fractions thus obtained were essentially the same and the same *d*-acid was obtained from all fractions, indicating the formation of only one salt. The various fractions were unchanged in rotation after recrystallization from ethyl acetate. No mutarotation was observed over a short period of time at room temperature.

Anal. Calcd. for $C_{32}H_{36}O_5N_2Cl_2$: C, 64.05; H, 6.05. Found: C, 64.15; H, 6.22. *Rotation.* (*l*BdA) 0.050 g. made up to 25 cc. with benzene at 20° gave α_D −0.10°; *l*, 2; $[\alpha]^{20}D$ −25.00°.

***d*-β-Chloro-β-(2-methoxy-4,6-dimethyl-5-chlorophenyl)-acrylic Acid.**—To a suspension of 2 g. of salt in 30 cc. of water was added 5 cc. of concentrated hydrochloric acid. After stirring at 5° for thirty minutes the product was filtered and washed with 5% hydrochloric acid and finally with water. The above was repeated until the product was quinine free; m. p. 180° (cor.).

Rotation. (*d*-acid) 0.100 g. made up to 25 cc. with *n*-butanol at 20° gave α_D 0.10°; *l*, 2; $[\alpha]^{20}D$ +12.5°.

Racemization of *d*-β-Chloro-β-(2-methoxy-4,6-dimethyl-5-chlorophenyl)-acrylic Acid (VI).—A solution of 0.100 g. of the *d*-acid made up to 25 cc. with *n*-butanol at 20° gave the following values: at the start +0.10; after five minutes +0.08; after eight minutes +0.06; after fifteen minutes +0.04; after twenty minutes +0.02; after twenty-five minutes 0.00. Calculated for a reversible unimolecular reaction, the half-life period is approximately nine minutes.

1-Ethoxy-3,5-dimethyl-4-chlorobenzene.—This compound was prepared from 1-hydroxy-3,5-dimethyl-4-chlorobenzene in exactly the same manner as 1-methoxy-3,5-dimethyl-4-chlorobenzene was obtained from 1-hydroxy-3,5-dimethyl-4-chlorobenzene except that diethyl sulfate was used in place of dimethyl sulfate. The yield was 85%.

Anal. Calcd. for $C_{10}H_{13}OCl$: C, 65.00; H, 7.09. Found: C, 65.31; H, 7.15.

1-Ethoxy-3,5-dimethyl-4-chloro-2-propiophenone.—To 300 g. of carbon disulfide, 185 g. of 1-ethoxy-3,5-dimethyl-4-chlorobenzene and 130 g. of propionic anhydride was added 267 g. of anhydrous aluminum chloride using exactly the same procedure employed to produce 1-methoxy-3,5-dimethyl-4-chloro-2-propiophenone. It had a b. p. of 155–156° (7 mm.) and solidified to a crystalline mass which was purified from petroleum ether (b. p. 60–110°); white crystals, m. p. 53–54° (cor.); yield 123 g. (62%).

Anal. Calcd. for $C_{13}H_{17}O_2Cl$: C, 64.83; H, 7.10. Found: C, 64.77; H, 7.21.

As in the preparation of 1-methoxy-3,5-dimethyl-4-chloro-2-propiophenone deëthylation occurred. However, the product could be reëthylated and purified readily. The yield reported was that obtained when minimum deethylation occurred.

α-Methyl-(2-ethoxy-4,6-dimethyl-5-chlorobenzoyl)-acetic Acid.—A solution of 20 g. of 1-ethoxy-3,5-dimethyl-4-chloro-2-propiophenone was added to 100 cc. of an ether solution containing slightly more than one mole equivalent of ethylmagnesium bromide. The bromomagnesium enolate was insoluble and was carbonated in the same manner as the previously described bromomagnesium enolate of 1-methoxy-3,5-dimethyl-4-chloro-2-propiophenone. The crude product was recrystallized from dry ether; white crystalline powder turning yellow upon standing for twenty-four hours, m. p. 115.5–116.5° (cor.); yield 10 g. (41%).

Anal. Calcd. for $C_{14}H_{17}O_4Cl$: C, 59.02; H, 6.01. Found: C, 58.75; H, 5.95.

As in the preparation of α-methyl-(2-methoxy-4,6-dimethyl-5-chlorobenzoyl)-acetic acid (XI), normal addition of the Grignard reagent to the keto form was observed. The main component of the residue was a liquid which boiled lower than the original ketone and was postulated as the corresponding dehydrated tertiary alcohol.

β-Chloro-β-(2-ethoxy-4,6-dimethyl-5-chlorophenyl)-α-methylacrylic Acid.—This compound was prepared in exactly the same manner as β-chloro-β-(2-methoxy-4,6-dimethyl-5-chlorophenyl)-α-methylacrylic acid using α-methyl-(2-ethoxy-4,6-dimethyl-5-chlorobenzoyl)-acetic acid as starting material. It formed faintly pink crystals from benzene, m. p. 141–142° (cor.); yield 6 g. (56%).

Anal. Calcd. for $C_{14}H_{16}O_3Cl_2$: C, 55.42; H, 5.31. Found: C, 55.41; H, 5.22.

1-Ethoxy-3,5-dimethyl-4-chloro-2-acetophenone.—To 300 g. of carbon disulfide, 185 g. of 1-ethoxy-3,5-dimethyl-4-chlorobenzene and 102 g. of acetic anhydride was added 267 g. of anhydrous aluminum chloride using the same procedure employed to produce 1-methoxy-3,5-dimethyl-4-chloro-2-propiophenone. It had a boiling point of 145–147° (7 mm.) and solidified on cooling to a crystalline mass which was purified by crystallization from petroleum ether (b. p. 60–110°); white crystals, m. p. 74° (cor.); yield 136 g. (60%).

Anal. Calcd. for $C_{12}H_{15}O_2Cl$: C, 63.54; H, 6.66. Found: C, 63.36; H, 6.73.

Deëthylation occurred to a certain extent. However, the product from the aqueous sodium hydroxide extract could be reëthylated.

The yield reported was that obtained when minimum deëthylation occurred.

2-Ethoxy-4,6-dimethyl-5-chlorobenzoylacetic Acid.—A solution of 20 g. of 1-ethoxy-3,5-dimethyl-4-chloro-2-acetophenone in 25 cc. of dry ether was added to 100 cc. of an ether solution containing slightly more than one mole equivalent of ethylmagnesium bromide. The bromomagnesium enolate precipitated and was carbonated in the same manner as 1-methoxy-3,5-dimethyl-4-chloro-2-propiophenone. Recrystallization of the crude product from dry ether gave a white crystalline powder, m. p. 103–104° (cor.); yield 13 g. (55%).

Anal. Calcd. for $C_{13}H_{15}O_4Cl$: C, 57.65; H, 5.88. Found: C, 57.65; H, 5.56.

The usual liquid by-product was observed, similar to that obtained in the carbonation experiments previously described.

β-Chloro-β-(2-ethoxy-4,6-dimethyl-5-chlorophenyl)-acrylic Acid.—This compound was prepared in exactly the same manner as β-chloro-β-(2-methoxy-4,6-dimethyl-5-chlorophenyl)-α-methylacrylic acid using 2-ethoxy-4,6-dimethyl-5-chlorobenzoylacetic acid as starting material. It formed faintly pink crystals from benzene, m. p. 176–177° (cor.); yield 5.5 g. (51%).

Anal. Calcd. for $C_{13}H_{14}O_3Cl_2$: C, 53.96; H, 5.40. Found: C, 54.05; H, 5.01.

Summary

1. β-Chloro-β-(2-methoxy-4,6-dimethyl-5-chlorophenyl)-acrylic acid, β-chloro-β-(2-methoxy-4,6-dimethyl-5-chlorophenyl)-α-methylacrylic acid, β-chloro-β-(2-ethoxy-4,6-dimethyl-5-chlorophenyl)-acrylic acid, and β-chloro-β-(2-ethoxy-4,6-dimethyl-5-chlorophenyl)-α-methylacrylic acid have been synthesized. The first two were resolved. The last two did not form salts suitable for resolution.

2. The active forms of the first two compounds had half-life periods, respectively, of nine minutes in *n*-butanol at 20° and one hundred and seventy-three minutes in *n*-butanol at 44°. This demonstrates the large increase in interference effected by substitution of the α-hydrogen by an α-methyl group. By comparison of these half-life periods with those of the previously described analogous mesitylene derivatives, the increased interference effect produced by an *ortho* methyl over an *ortho* methoxyl is exemplified once again.

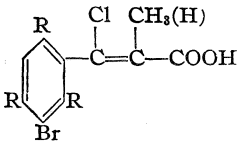
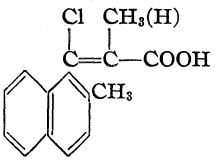
Restricted Rotation in Aryl Olefins. V. β-Bromo-β-(2-alkoxynaphthyl)-α-alkylacrylic Acids[1]

BY ROGER ADAMS, L. O. BINDER[2] AND F. C. MCGREW

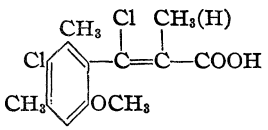
The half-life periods of the active forms of the molecules of the substituted β-arylacrylic acid type shown in I, II and III have been described in previous papers.[3]



I



II

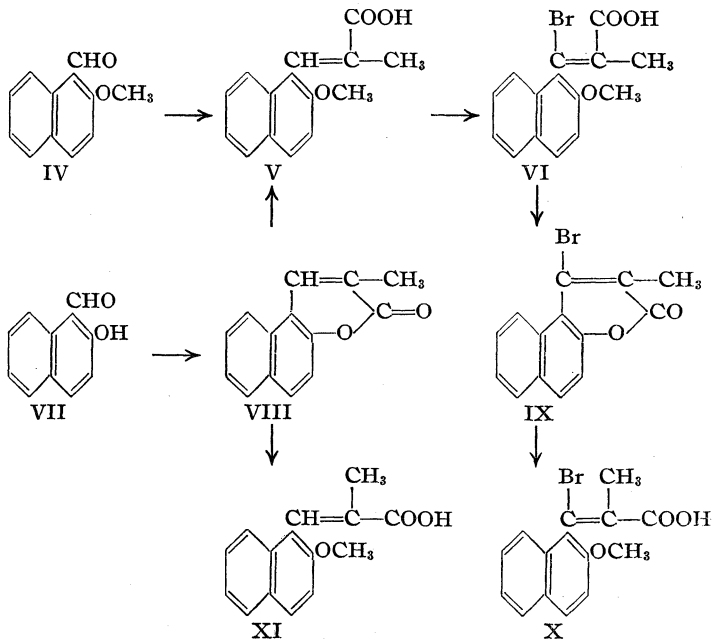


III

The remarkable stability of types I and II as contrasted to that of type III demonstrated the relatively greater steric effect of the methyl than the methoxyl when *ortho* to the acrylic acid side chain. The effect of the —CH= group of the aromatic nucleus in II is much smaller than that of an *ortho* methyl group in type I. An investigation of certain analogous derivatives from β-methoxynaphthalene was carried on simultaneously with the study of the xylenol derivatives (III). The synthesis of β-bromo-β-(2-methoxy-1-naphthyl)-α-methylacrylic acid was accomplished and both geometric forms were obtained (VI and X). The series of reactions employed is shown in formulas IV–X.

By a Perkin synthesis with propionic anhydride and sodium propionate, β-methoxynaphthaldehyde (IV) was converted to the β-(2-methoxy-1-naphthyl)-α-methylacrylic acid (V, α-form). A single geometric isomer was always obtained. Upon bromination of compound V two atoms of bromine added to the double bond and hydrogen bromide was eliminated to give β-bromo-β-(2-methoxy-1-naphthyl)-α-methylacrylic acid (VI, α-form). The position of the bromine in the side chain was established by oxidation of VI to β-methoxynaphthoic acid. By means of hydrobromic acid compound VI was demethylated after which rearrangement and ring closure took place with formation of 2-methyl-3-bromo-4,3-β-naphthopyrone (IX). This pyrone, on hydrolysis and methylation, gave the β-bromo-β-(2-methoxy-1-naphthyl)-α-methylacrylic acid (X, β-form) isomeric with compound VI. From the procedure used for synthesis it is reasonable to conclude that compound X has the carboxyl *cis* to the methoxyl while in its isomer VI the carboxyl group is *trans* to the methoxyl.

β-Hydroxynaphthaldehyde (VII) by a similar



Perkin synthesis led to the 2-methyl-4,3-β-naphthopyrone (VIII). Upon hydrolysis and methylation this pyrone was converted either to the acrylic acid (V) or to its geometric isomer (XI, β-form). The exact conditions for controlling the direction of this synthesis were not found. In two experiments the expected isomer (XI) resulted but in

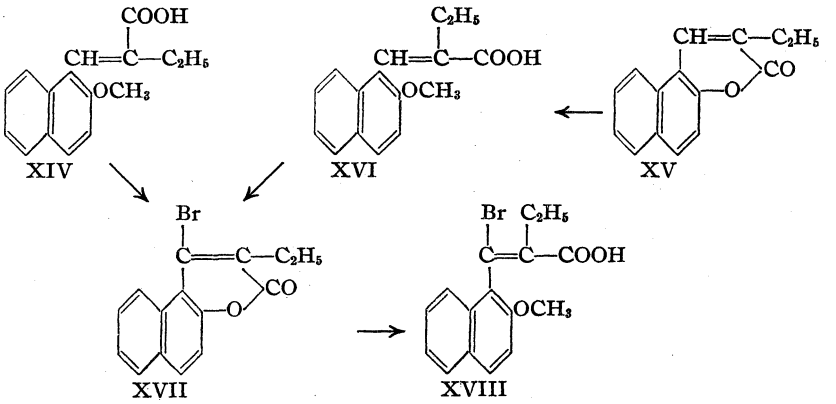
(1) For previous paper, see Adams and Gross, THIS JOURNAL, **64**, 1786 (1942).

(2) An abstract of a thesis submitted in partial fulfillment of the requirements for the degree of Doctor of Philosophy in Chemistry.

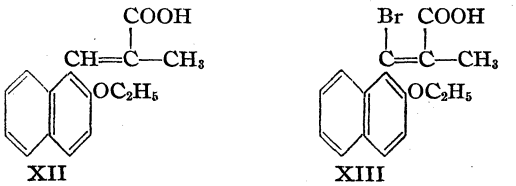
(3) Adams and Miller, *ibid.*, **62**, 53 (1940); Adams, Anderson and Miller, *ibid.*, **63**, 1589 (1941); Adams and Binder, *ibid.*, **63**, 2773 (1941).

most trials rearrangement occurred and only compound V was isolated.

The assignment of the structure with the carboxyl *trans* to the methoxyl to isomer V, obtained directly from β-methoxynaphthaldehyde is based on the results (1) of similar reactions in the benzene series in which the methyl ether of salicylaldehyde gives *trans-o*-methoxycinnamic acid whereas the *cis* form is produced by hydrolysis of coumarin followed by methylation and (2) of the condensation of β-methoxynaphthaldehyde and β-hydroxynaphthaldehyde with *n*-butyric anhydride which is to be discussed later. If the formulas proposed for the brominated acids (VI and X) are correct, it must be concluded that no rearrangement occurs during bromination of compound V to form the bromo derivative (VI). The isomeric acid (XI) with the carboxyl *cis* to the methoxyl did not undergo smooth bromination. From the reaction was isolated a small amount of compound VI along with non-acidic material which was not identified. The pyrone (VIII) brominated only with difficulty and no pure substance was isolated from the product.



β-Ethoxynaphthaldehyde, in a similar Perkin synthesis, gave a single product, β-(2-ethoxy-1-naphthyl)-α-methylacrylic acid, assigned the configuration XII. It brominated to β-bromo-β-(2-ethoxy-1-naphthyl)-α-methylacrylic acid (XIII).



β-Methoxynaphthaldehyde in a Perkin synthesis with *n*-butyric anhydride and sodium *n*-butyrate gave a single product, β-(2-methoxy-1-naphthyl)-α-ethylacrylic acid postulated as the *trans* isomer (XIV); β-hydroxynaphthaldehyde in a similar reaction yielded 2-ethyl-4,3-β-naphthopyrone (XV) which was hydrolyzed and methylated to XVI, the geometric isomer of XIV. Unlike the experience in the hydrolysis of the 2-methyl-4,3-β-naphthopyrone which yielded sometimes one and sometimes the other geometric isomer, always one product resulted which was isomeric with that from the direct condensation of the β-methoxynaphthaldehyde. Both acids (XIV and XVI) upon bromination yielded the same compound, 2-ethyl-3-bromo-4,3-β-naphthopyrone (XVII), even when the precaution was taken to have present an alkaline reagent to react with the hydrogen bromide liberated. The bromopyrone (XVII) was hydrolyzed and methylated to the β - bromo - β - (2 - methoxy - 1 - naphthyl) - α - ethylacrylic acid (XVIII).

From these experiments, it may be concluded, (1) that, in general, when no pyrone formation is possible the geometric isomer formed from the aldehyde has the carboxyl group *trans* to the alkoxyl, and (2) that the hydrolysis and methylation of a pyrone leads to an isomeric acid with the carboxyl *cis* to the alkoxyl.

Attempts to resolve acids VI, X, XIII and XVIII failed. The acids formed well-crystallized salts but only single salts which did not mutarotate were obtained and decomposition of each salt resulted in an inactive acid.

Although deductions from negative experiments on resolution are hazardous, the physical properties of these salts were so favorable that it is believed these acids cannot be resolved. If these conclusions are correct the relatively minor change in the molecule III (half-life, 173 minutes in *n*-butanol at 44°), consisting of replacement of the *ortho* methyl by a —CH= of a fused ring, serves to eliminate restricted rotation. Even the replacement of the β-methoxyl by β-ethoxyl or the α-methyl by an α-ethyl was not sufficient to render resolution possible. The bromine and chlorine atoms have been shown in the biphenyl series to have essentially the same effect, so that this modification should not alter the results.

Experimental

2-Methoxy-1-naphthaldehyde.—This was prepared either by the method of Adams and Montgomery[4] or according to the directions in "Organic Syntheses" for 2-ethoxy-1-naphthaldehyde,[5] using 2-methoxynaphthalene in place of 2-ethoxynaphthalene. Material prepared by the latter method was more easily purified.

β-(2-Methoxy-1-naphthyl)-α-methylacrylic Acid (V, α-Form).—A mixture of 9 g. of 2-methoxy-1-naphthaldehyde, 9 g. of fused sodium propionate, and 36 g. of propionic anhydride was refluxed for twenty-four hours at 170°. The mixture was poured into iced dilute aqueous sodium hydroxide, and the alkaline solution extracted with ether to remove colored impurities. Upon acidification of the aqueous solution, the product separated as a gummy mass which crystallized on rubbing. It was recrystallized from water–acetic acid mixture and then from ethanol; colorless needles, m. p. 155–156° (cor.); yield, 7.9 g. (62%).

Anal. Calcd. for $C_{15}H_{14}O_3$: C, 74.35; H, 5.83. Found: C, 74.21; H, 5.87.

β-Bromo-β-(2-methoxy-1-naphthyl)-α-methylacrylic Acid. (VI, α-Form).—To 4.6 g. of β-(2-methoxy-1-naphthyl)-α-methylacrylic acid in 30 cc. of chloroform was added 3.1 g. of bromine in 15 cc. of chloroform. The solution was set aside in the dark for sixty hours. After evaporating the chloroform by means of an air stream, the solid residue was taken up in dilute aqueous potassium hydroxide, and the alkaline solution was extracted with ether to remove colored impurities. The solution was then treated with decolorizing charcoal at 90° and filtered. Upon acidification of the filtrate, the product appeared as an oil which solidified on rubbing. The material was recrystallized from water–acetic acid mixture and from ethanol giving nearly white needles, m. p. 208° (cor.); yield, 2.3 g. (38%).

Anal. Calcd. for $C_{15}H_{13}O_3Br$: C, 56.07; H, 4.08. Found: C, 55.62; H, 4.03.

The bromine was shown to be in the side chain by oxidation to 2-methoxy-1-naphthoic acid. A mixture of 0.1 g. of β-bromo-β-(2-methoxy-1-naphthyl)-α-methylacrylic acid and 0.5 g. of potassium permanganate in 25 cc. of water was refluxed for six hours. The manganese dioxide was removed by filtration and the filtrate acidified. The fine needles which formed were filtered and recrystallized from ethanol; colorless needles, m. p. 176°. The value found in the literature for 2-methoxy-1-naphthoic acid is 176°.[5a]

2-Methyl-4,3-β-naphthopyrone (VIII).—A mixture of 5 g. of 2-hydroxy-1-naphthaldehyde,[6] 5 g. of sodium propionate, and 20 g. of propionic anhydride was refluxed at 170° for twenty-four hours. The mixture was decomposed with aqueous sodium bicarbonate solution, and the material remaining undissolved was washed thoroughly on a filter and then recrystallized from ethanol; fine white needles, m. p. 156° (cor.); yield, 4.1 g. (60%).

Anal. Calcd. for $C_{14}H_{10}O_2$: C, 79.97; H, 4.80. Found: C, 80.22; H, 4.63.

β-(2-Methoxy-1-naphthyl)-α-methylacrylic Acid. (XI, β-Form).—By heating to 90° for one hour, 4 g. of 2-methyl-4,3-β-naphthopyrone was dissolved in a solution of 2.48 g. of potassium hydroxide in 120 cc. of water. After cooling, 5.6 g. of dimethyl sulfate was added slowly with vigorous stirring. The precipitate which formed was dissolved by making the solution strongly alkaline and warming. Acidification of the resulting clear solution caused the product to separate as an oil which solidified on cooling. Several crystallizations from a water–acetic acid mixture and then four or five times from benzene resulted in the formation of thick yellow rhombs, m. p. 167° (cor.); yield, 1 g. (23%).

Anal. Calcd. for $C_{15}H_{14}O_3$: C, 74.35; H, 5.83. Found: C, 74.69; H, 5.95.

Various attempts to repeat this experiment resulted sometimes in obtaining the same product and sometimes in formation of the α-form. The critical conditions for each were not found.

β-(2-Ethoxy-1-naphthyl)-α-methylacrylic Acid (XII).—From 2-ethoxy-1-naphthaldehyde,[2] by the same method used for the preparation of β-(2-methoxy-1-naphthyl)-α-methylacrylic acid, β-(2-ethoxy-1-naphthyl)-α-methylacrylic acid was obtained; white needles from water–acetic acid mixture, then from ethanol, m. p. 130° (cor.); yield 8 g. (43%).

Anal. Calcd. for $C_{16}H_{16}O_3$: C, 74.97; H, 6.30. Found: C, 74.51; H, 6.32.

β-Bromo-β-(2-ethoxy-1-naphthyl)-α-methylacrylic Acid (XIII).—By bromination of 8 g. of β-(2-ethoxy-1-naphthyl)-α-methylacrylic acid in the manner described for the formation of β-bromo-(2-methoxy-1-naphthyl)-α-methylacrylic acid the bromo ethoxy derivative was obtained; white needles, m. p. 172° (cor.); yield, 3 g. (29%).

Anal. Calcd. for $C_{16}H_{15}O_3Br$: C, 57.31; H, 4.51. Found: C, 57.03; H, 4.51.

2-Methyl-3-bromo-4,3-β-naphthopyrone (IX).—A mixture of 5 g. of β-bromo-β-(2-methoxy-1-naphthyl)-α-methylacrylic acid (VI), 15 cc. of 48% hydrobromic acid and 45 cc. of glacial acetic acid was refluxed for four hours and then poured into 400 cc. of water. The crude product which separated was filtered, taken up in chloroform and treated with decolorizing charcoal. The solvent was removed by evaporation and the residue recrystallized from ethanol; long, nearly white needles, m. p. 186° (cor.); yield, 2.5 g. (56%).

Anal. Calcd. for $C_{14}H_9O_2Br$: C, 58.13; H, 3.14. Found: C, 58.46; H, 3.42.

β-Bromo-β-(2-methoxy-1-naphthyl)-α-methylacrylic Acid (X, β-Form).—A solution of 2.5 g. of 2-methyl-3-bromo-4,3-β-naphthopyrone in 50 cc. of absolute ethanol containing 1 g. of potassium hydroxide was refluxed for ten minutes. The solvent was removed under diminished pressure on a steam cone and the residue taken up in 75 cc. of water. An additional 1 g. of potassium hydroxide was added to the solution, and then 2 g. of dimethyl sulfate, over a period of thirty minutes, with stirring. The mixture was stirred for three hours and then acidified with hydrochloric acid and extracted with ether. The ether solution was extracted with two 30-cc. portions of 5% aqueous sodium hydroxide. On acidification of the

alkaline extract the product separated as a solid which was recrystallized from ethanol: slightly yellow rhombs, m. p. 187° (cor.).

Anal. Calcd. for $C_{15}H_{13}O_3Br$: C, 56.07; H, 4.08. Found: C, 56.27; H, 4.23.

Evaporation of the ether solution resulted in the recovery of 1.5 g. of unchanged pyrone.

Bromination of β-(2-Methoxy-1-naphthyl)-α-methylacrylic Acid (XI, β-Form).—To 1 g. of β-(2-methoxy-1-naphthyl)-α-methylacrylic acid (XI) dissolved in 15 cc. of chloroform was added 0.75 g. of bromine, and the solution was set aside in the dark for twenty-four hours. The solvent was then removed by evaporation without removing the precipitate which had formed, and the residue was taken up in 150 cc. of chloroform. The chloroform solution was extracted with two 30-cc. portions of 5% aqueous sodium hydroxide. Acidification of the alkaline extract precipitated the product, which was recrystallized from glacial acetic acid. The material melted at 208° (cor.), and gave no depression of the melting point when mixed with β-bromo-β-(2-methoxy-1-naphthyl)-α-methylacrylic acid (VI, α-form).

Evaporation of the chloroform solution yielded an alkali-insoluble material which crystallized from glacial acetic acid in fine needles; m. p. 93° (cor.); this was not investigated.

β-(2-Methoxy-1-naphthyl)-α-ethylacrylic Acid (XIV, α-Form).—The product was obtained from 20 g. of 2-methoxy-1-naphthaldehyde, 20 g. of fused potassium butyrate and 80 g. of butyric anhydride; crystallized from water–acetic acid mixture, it formed nearly colorless needles, m. p. 110° (cor.); yield, 11 g. (40%).

Anal. Calcd. for $C_{16}H_{16}O_3$: C, 74.97; H, 6.30. Found: C, 75.15; H, 6.73.

Bromination of β-(2-Methoxy-1-naphthyl)-α-ethylacrylic Acid (XIV. α-Form).—Treatment of 10 g. of β-(2-methoxy-1-naphthyl)-α-ethylacrylic acid (XIV) with bromine in the usual fashion yielded no alkali-soluble material. The dark solid was extracted thoroughly with petroleum ether (b. p. 60–110°). The extract was evaporated to dryness and the solid residue crystallized repeatedly from carbon tetrachloride and finally from water–acetic acid mixture. It proved to be 2-ethyl-3-bromo-4,3-β-naphthopyrone (XVII); light brown needles, m. p. 137° (cor.); yield, 3 g. (25%).

Anal. Calcd. for $C_{15}H_{11}O_2Br$: C, 59.41; H, 3.66. Found: C, 59.98; H, 3.81.

2-Ethyl-4,3-β-naphthopyrone (XV).—From 20 g. of 2-hydroxy-1-naphthaldehyde, 20 g. of fused potassium butyrate, and 80 g. of butyric anhydride by the method used for the preparation of 2-methyl-4,3-β-naphthopyrone, 2-ethyl-4,3-β-naphthopyrone was obtained; white needles, m. p. 111° (cor.); yield, 13 g. (51%).

Anal. Calcd. for $C_{15}H_{12}O_2$: C, 80.32; H, 5.40. Found: C, 80.49; H, 5.36.

β-(2-Methoxy-1-naphthyl)-α-ethylacrylic Acid (XVI, β-Form).—A solution of 10 g. of 2-ethyl-4,3-β-naphthopyrone (XV) and 6 g. of solid potassium hydroxide in 100 cc. of absolute ethanol was refluxed for ten minutes. On cooling the potassium salt separated. This was filtered and dissolved in 150 cc. of water containing 6 g. of potassium hydroxide. To this solution was added 6 g. of dimethyl sulfate over a period of thirty minutes with stirring. and the mixture was then stirred for three hours. The solution was acidified and extracted with ether and the ether solution extracted with 5% aqueous sodium hydroxide. Acidification of the alkaline extract precipitated the product. It was recrystallized from ethanol to which was added water at the boiling point of the solution until incipient turbidity; white crystals, m. p. 120° (cor.); yield, 3.5 g. (30%).

Anal. Calcd. for $C_{16}H_{16}O_3$: C, 74.97; H, 6.30. Found: C, 75.13; H, 6.36.

About 3.5 g. of unchanged pyrone was recovered.

β-Bromo-β-(2-methoxy-1-naphthyl)-α-ethylacrylic Acid (XVIII).—A solution of 2 g. of 2-ethyl-3-bromo-4,3-β-naphthopyrone (XVII) in 50 cc. of absolute ethanol containing 1 g. of potassium hydroxide was refluxed for ten minutes. The solvent was then removed under reduced pressure, and the residue dissolved in 75 cc. of water to which was added 1.5 g. of solid potassium hydroxide. With stirring, 2.5 g. of dimethyl sulfate was added over a period of thirty minutes and stirring continued for three hours. The solution was then acidified, extracted with chloroform, and the chloroform solution extracted with 5% aqueous sodium hydroxide. Upon acidification of the alkaline extract the product appeared as an oil which solidified on standing. The material was recrystallized from an ethanol–water mixture; fine white needles, m. p. 138° (cor.).

Anal. Calcd. for $C_{16}H_{15}O_3Br$: C, 57.31; H, 4.51. Found: C, 57.27; H, 4.52.

From the chloroform solution 1.5 g. of unchanged pyrone was recovered.

Bromination of β-(2-Methoxy-1-naphthyl)-α-ethylacrylic acid (XVI, β-Form).—To 2 g. of β-(2-methoxy-1-naphthyl)-α-ethylacrylic acid in 16 cc. of chloroform was added 1.5 g. of bromine, and the solution was set aside in the dark for twenty-four hours. The solvent was then removed, the residue taken up in chloroform and the chloroform solution extracted with 5% aqueous sodium hydroxide. Acidification of the alkaline extract gave no product. The chloroform was evaporated and the residue recrystallized from ethanol–water mixture; light yellow needles, m. p. 137° (cor.); yield 1.5 g. (57%). This material gave no depression when melted with 2-ethyl-3-bromo-4,3-β-naphthopyrone obtained by bromination of the α-form of the acid.

Summary

1. The synthesis of the two geometric forms of β-bromo-β-(2-methoxy-1-naphthyl)-α-methylacrylic acids, one geometric form of β-bromo-β-(2-ethoxy-1-naphthyl)-α-methylacrylic acid and one geometric form of β-bromo-β-(2-methoxy-1-naphthyl)-α-ethylacrylic acid has been effected.

2. None of these molecules could be resolved. This is probably due primarily to the decreased steric effect of the —CH= group of the benzene nucleus as compared to a methyl group.

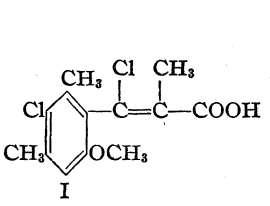
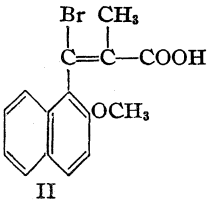
Restricted Rotation in Aryl Olefins. VI. Substituted β-(2,7-Dimethoxy-1-naphthyl)-α-methylacrylic Acids[1]

BY ROGER ADAMS, M. W. MILLER, F. C. MCGREW AND A. W. ANDERSON

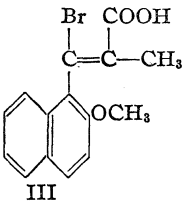
Failure to resolve the aryl olefins II, III, IV and V was reported in the preceding paper.[1] Compound I, on the other hand, was resolved[2] and an active form had a half-life period of 173 minutes in *n*-butanol at 44°. The difference between I and



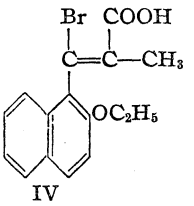
I



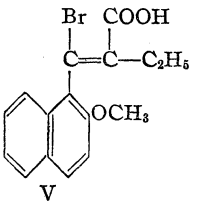
II



III

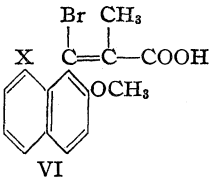


IV

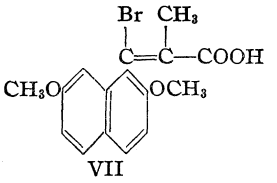


V

the other molecules lies primarily in the replacement of the methyl group in the 2-position of the benzene nucleus by the —CH= of an aromatic residue, thus allowing free rotation and resulting in non-resolvability of the molecules. The present investigation was undertaken to obtain molecules of the type shown in VI which resemble II, III, IV and V in all respects except for the additional group in the 8-position. Such a group should increase the interference and might result in a steric effect sufficient to allow resolution.

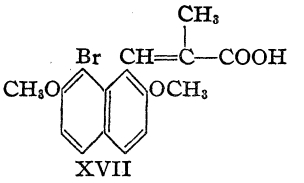


VI

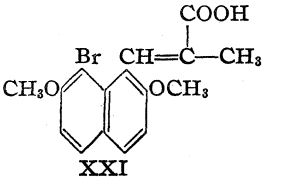


VII

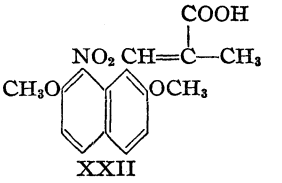
The synthetic problem of preparing such molecules was not simple. The approach selected was that involving the preparation of a compound (VII) by the general procedure used in the previous paper.[1] It contains a methoxyl group in the 7-position which should activate substitution in the 8-position and thus allow the formation of a molecule of the desired type (VI) after the substituent groups in the 1- and 2-positions have been introduced. Unfortunately, complications prevented the attainment of the proposed objective. The compounds actually obtained and studied are shown in formulas XVII, XXI and XXII. The syntheses of these compounds and the factors which interfered with the preparation of the substances particularly desired are described below.



XVII



XXI



XXII

2,7-Dihydroxynaphthaldehyde (VIII) was methylated to 7-methoxy-2-hydroxynaphthaldehyde (IX) which by means of the Perkin synthesis, using propionic anhydride and potassium propionate, was converted to 2-methyl-9-methoxy-4,3-β-naphthopyrone (X). This last product was formed also by another route; treatment of the 2,7-dihydroxynaphthaldehyde with propionic anhydride and potassium propionate led to the 2-methyl-9-propionoxy-4,3-β-naphthopyrone (XI) which was saponified readily to 2-methyl-9-hydroxy-4,3-β-naphthopyrone (XII), and then methylated to give compound X.

Upon nitration, the 2-methyl-9-methoxy-4,3-β-naphthopyrone (X) gave a mononitro product, 2-methyl-10-nitro-9-methoxy-4,3-β-naphthopyrone (XIII), and upon bromination, 2-methyl-10-bromo-9-methoxy-4,3-β-naphthopyrone (XIV). The position of the bromine atom was established as in the ring by direct bromination of 7-methoxy-2-hydroxynaphthaldehyde to 7-methoxy-8-bromo-2-hydroxynaphthaldehyde (XV) and conversion of this product by a Perkin synthesis to compound XIV.

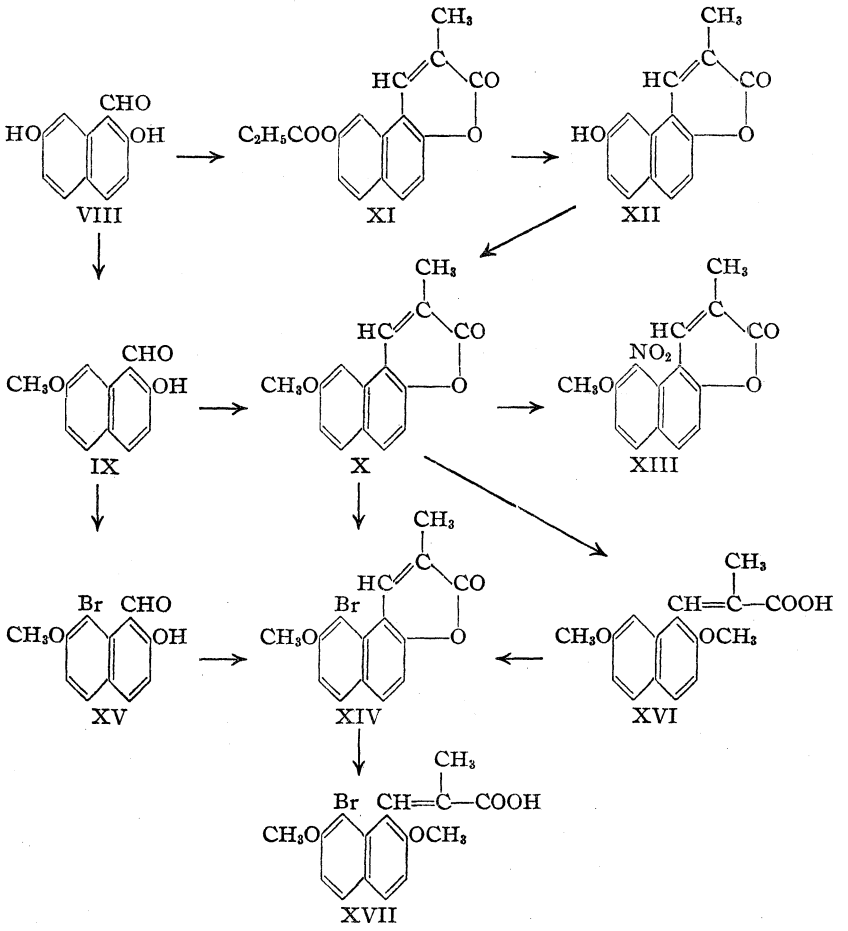
The 2-methyl-9-methoxy-4,3-β-naphthopyrone

(1) For previous paper, see Adams, Binder and McGrew, THIS JOURNAL, **64**, 1791 (1942).

(2) Adams and Binder, *ibid.*, **63**, 2773 (1941).

(X) was hydrolyzed and methylated to β-(2,7-dimethoxynaphthyl)-α-methylacrylic acid (XVI). Upon attempted bromination of compound XVI, however, compound XIV was produced, demethylation and pyrone formation taking place simultaneously. On the other hand, the bromination product, β-(2,7-dimethoxy-8-bromonaphthyl)-α-methylacrylic acid (XVII) resulted upon hydrolysis and methylation of the corresponding pyrone (XIV).

CHART I



2,7-Dihydroxynaphthalene was methylated to 2,7-dimethoxynaphthalene (XVIII) into which an aldehyde group was introduced to give 2,7-dimethoxynaphthaldehyde (XIX). A Perkin synthesis with potassium propionate and propionic anhydride converted this aldehyde to β-(2,7-dimethoxynaphthyl)-α-methylacrylic acid (XX). In contrast to compound XVI, this isomer (XX) brominates without demethylation and is converted to β-(2,7-dimethoxy-β-bromonaphthyl)-α-methylacrylic acid (XXI). Similarly, nitration gives the analogous nitro compound, β-(2,7-dimethoxy-8-nitronaphthyl)-α-methylacrylic acid (XXII).

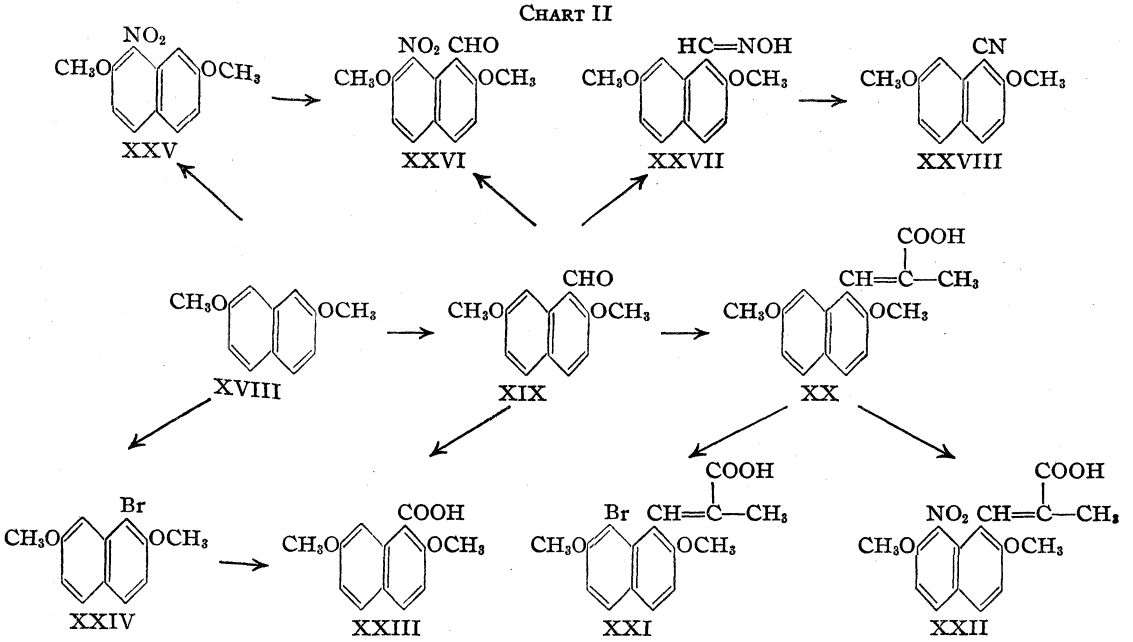
The position of the aldehyde group in 2,7-dimethoxynaphthaldehyde (XIX) was established by oxidation of the molecule to 2,7-dimethoxynaphthoic acid (XXIII). This same acid was obtained by bromination of 2,7-dimethoxynaphthalene (XVIII) to 2,7-dimethoxybromonaphthalene (XXIV) and replacement of the halogen by a carboxyl group through the corresponding lithium derivative and carbonation. Nitration of 2,7-dimethoxynaphthalene gave 2,7-dimethoxy-8-nitronaphthalene (XXV), into which an aldehyde group was introduced to form 2,7-dimethoxy-8-nitronaphthaldehyde (XXVI). This latter product was prepared also by direct nitration of 2,7-dimethoxynaphthaldehyde.

The 2,7-dimethoxynaphthaldehyde (XIX) formed an oxime (XXVII) which dehydrated to the nitrile (XXVIII). This nitrile proved very resistant to hydrolysis.

The configuration of compound XVI is assigned on the basis of its formation from the pyrone; the brominated product (XVII) probably has a similar structure. The carboxyl is *cis* to the 2-methoxyl group. The compounds XX and XXI are stereoisomeric with XVI and XVII prepared from 2,7-dimethoxynaphthaldehyde and consequently are written with the carboxyl group *trans* to the 2-methoxyl group. This conforms to the results previously reported on analogous compounds derived from β-methoxynaphthaldehyde.[1] Compounds XX and XXI are more soluble in organic solvents than their geometric isomers (XVI and XVII). By ultraviolet irradiation compound XVI is converted to its isomer (XX).

The position taken by the bromine atom in the bromination of compound X was shown to be in

CHART II



the naphthalene nucleus. Similarly, the bromine probably entered the 8-position in bromination of compound XX, although this was not proved. Compound XXI could not be brominated further which confirms the probability that the 8-position is substituted and indicates the steric influence of an 8-substituent upon the reactivity of the aliphatic double bond. Compound XVII, in which the position of the bromine atom is established, also could not be brominated. In an attempt to prove the nitro group to be in the 8-position in compound XXII, an effort was made to synthesize structure XXII by conversion of the nitroaldehyde (XXVI) to the acrylic acid; the Perkin condensation did not take place under the conditions usually used for effecting such a synthesis.

The acids XVII, XXI, and XXII were converted into alkaloidal salts and resolution attempted. Only a single salt was obtained in each instance and decomposition resulted in inactive acids. A study of Stuart models of these acids leads to the prediction that restricted rotation should exist in these molecules in spite of the presence of a hydrogen atom on the carbon atom attached to the ring, a condition which previously has been shown always to result in molecules with no restricted rotation.[3] The unreliability of accurate deductions from Stuart models is illustrated again.

Experimental

2,7-Dihydroxynaphthaldehyde (VIII).—A mixture of 20 g. of 2,7-dihydroxynaphthalene, 22 g. of anhydrous zinc cyanide and 200 cc. of dry ether was cooled with ice. Agitation was started and a brisk stream of dry hydrogen chloride was bubbled through until the yellow aldimine hydrochloride was precipitated completely. This usually took about an hour. The yellow precipitate was dissolved in 500 cc. of 30% ethanol and heated on a steam cone. During the hydrolysis, the excess ether distilled and the remaining solution was treated with Norite and filtered. On cooling the filtrate, it became semi-solid with greenish yellow crystals of the aldehyde; yield, 18 g. This product was pure enough for subsequent use. It can be recrystallized from 30% ethanol; yellow crystals; m. p. 159–160° (cor.). Morgan and Vining[4] report m. p. 159.5–160.5° when crystallized from benzene.

7-Methoxy-2-hydroxynaphthaldehyde (IX).—A solution of 10 g. of 2,7-dihydroxynaphthaldehyde in 100 cc. of water containing 6 g. of potassium hydroxide was stirred and 10 g. of dimethyl sulfate added over a period of two hours. The reaction mixture was filtered and the filtrate acidified with dilute sulfuric acid. The precipitate thus obtained was purified by crystallization from ethanol; white crystals, m. p. 128–129° (cor.); yield 6.2 g. (60%).

Anal. Calcd. for $C_{12}H_{10}O_3$: C, 71.29; H, 4.95. Found: C, 71.30; H, 5.30.

2-Methyl-9-methoxy-4,3-β-naphthopyrone (X).—A mixture of 2 g. of 7-methoxy-2-hydroxynaphthaldehyde, 2 g. of fused potassium propionate and 10 cc. of propionic anhydride was refluxed for six hours at 175–180°. After cooling, the excess anhydride was decomposed with 10% aqueous potassium hydroxide, the solid filtered by suction and recrystallized from ethanol; long silky needles, m. p.

(4) Morgan and Vining, *J. Chem. Soc.*, **119**, 177 (1921).

186.5–187.5°. The substance showed a blue fluorescence in ethanol solution.

Anal. Calcd. for $C_{15}H_{12}O_3$: C, 75.00; H, 5.04. Found: C, 74.94; H, 4.93.

2-Methyl-9-propionoxy-4,3-β-naphthopyrone (XI).—A mixture of 10 g. of 2,7-dihydroxynaphthaldehyde, 10 g. of freshly fused potassium propionate and 20 g. of propionic anhydride was refluxed for twenty-four hours. After cooling, the excess of propionic anhydride was decomposed with 10% aqueous sodium hydroxide and the pink precipitate filtered, washed well with water and dried. It was purified by crystallization from ethanol; slightly pinkish crystals, m. p. 161–162° (cor.); yield, 8.5–9 g. (60%).

Anal. Calcd. for $C_{17}H_{14}O_4$: C, 72.35; H, 5.02. Found: C, 72.32; H, 5.12.

2-Methyl-9-hydroxy-4,3-β-naphthopyrone (XII).—A mixture of 25 g. of 2-methyl-9-propionoxy-4,3-β-naphthopyrone and 200 cc. of 25% aqueous potassium hydroxide was refluxed for three hours. The solution was filtered while still hot and the filtrate upon cooling deposited a yellow precipitate of the potassium salt. The salt was not isolated but the mixture was acidified with 50% sulfuric acid and a purplish, gelatinous precipitate formed. It was purified by a crystallization from ethanol followed by solution in aqueous potassium hydroxide, refluxing the solution with Norite, precipitation with acid and finally crystallization again from ethanol; white needles, m. p. 263–266° (bloc Maquenne); yield, 18 g. (80%).

Anal. Calcd. for $C_{14}H_{10}O_3$: C, 74.34; H, 4.47. Found: C, 74.22; H, 4.62.

2-Methyl-9-methoxy-4,3-β-naphthopyrone (X).—To a mixture of 20 g. of 2-methyl-9-hydroxy-4,3-β-naphthopyrone and 100 cc. of dioxane, which was mechanically stirred until complete solution had taken place, was added 24 g. of pure dimethyl sulfate. Over a period of five to six hours, 150 cc. of 1% aqueous potassium hydroxide was allowed to run in. Colorless platelets of the product separated as the reaction proceeded. The compound was purified by recrystallization from ethanol; long silky needles, identical with the product prepared directly from 7-methoxy-2-hydroxynaphthaldehyde.

A third procedure was by direct conversion of the propionoxy compound to the methyl ether by the general method of Nierenstein.[5]

A solution of 0.5 g. of 2-methyl-9-propionoxy-4,3-β-naphthopyrone and 1 cc. of piperidine in 20 cc. of dioxane was treated with an ether solution of diazomethane and the mixture allowed to stand at room temperature for about three weeks. Upon evaporation nearly to dryness and addition of water a solid precipitated. This was purified by crystallization from ethanol. Unchanged material was first recovered. The more soluble portion proved to be the 9-methoxy derivative; yield, 0.1 g. The balance of the pyrone was recovered.

2-Methyl-10-nitro-9-methoxy-4,3-β-naphthopyrone (XIII).—To a suspension of 0.5 g. of 2-methyl-9-methoxy-4,3-β-naphthopyrone in 8 cc. of glacial acetic acid was added 1 cc. of nitric acid (sp. gr. 1.42). After shaking thoroughly, the reaction mixture was allowed to stand for one hour. The colorless crystals of the pyrone dissolved and yellow crystals separated. They were purified from ethanol, m. p. 276–278° (cor.); yield, 0.3 g. (50%).

Anal. Calcd. for $C_{15}H_{11}O_5N$: N, 4.90. Found: N, 4.74.

2-Methyl-10-bromo-9-methoxy-4,3-β-naphthopyrone (XIV).—To a solution of 10 g. of 2-methyl-9-methoxy-4,3-β-naphthopyrone in 150 cc. of chloroform was added 6.66 g. of bromine in 50 cc. of chloroform. The mixture was then placed in an icebox overnight. The hydrogen bromide was removed by a stream of air bubbled through the solution, then the chloroform was distilled. The red solid residue was washed with ethanol, then with dilute aqueous potassium hydroxide, and finally with water. It was purified by recrystallization from ethanol; white needles m. p. 218–219° (cor.); yield, 12 g. (91%).

Anal. Calcd. for $C_{15}H_{11}O_3Br$: C, 56.50; H, 3.45. Found: C, 56.11; H, 3.49.

The same product was made from 8-bromo-7-methoxy-2-hydroxynaphthaldehyde (XV) described below. A mixture of 0.25 g. of the bromoaldehyde, 0.25 g. of potassium propionate and 2 g. of propionic anhydride was allowed to react according to the procedure used for similar compounds previously described. It proved to be identical with the compound prepared by bromination of the bromine-free pyrone.

A third method for synthesis of this compound was also found. To a solution of 0.25 g. of the less-soluble β-(2,7-dimethoxynaphthyl)-α-methylacrylic acid (XVI), described below, in 25 cc. of carbon tetrachloride was added 0.117 g. of bromine dissolved in 5 cc. of carbon tetrachloride. The residue after evaporation of the solvent was alkali-insoluble and crystallized as colorless needles from ethanol, m. p. 218–219° (cor.).

7-Methoxy-8-bromo-2-hydroxynaphthaldehyde (XV).—To a solution of 5 g. of 7-methoxy-2-hydroxynaphthaldehyde in 200 cc. of carbon tetrachloride was dropped in slowly with stirring 4.25 g. of bromine in 25 cc. of carbon tetrachloride. After stirring for one hour the solution was washed with aqueous sodium bisulfite. The carbon tetrachloride was distilled until the solution was clear and then evaporated completely with a stream of air. The product was recrystallized from methanol; flaky yellow crystals, m. p. 97–99° (cor.); yield 4 g. (57%).

Anal. Calcd. for $C_{12}H_9O_3Br$: C, 51.27; H, 3.23 Found: C, 50.63; H, 3.18.

Less-soluble β-(2,7-Dimethoxynaphthyl)-α-methylacrylic Acid (XVI).—A mixture of 5 g. of 2-methyl-9-methoxy-4,3-β-naphthopyrone (X) and 5 g. of potassium hydroxide dissolved in 75 cc. of absolute ethanol was heated for about twenty minutes until complete solution had taken place. On cooling, long yellow needles of the potassium salt crystallized and were filtered. The potassium salt thus obtained was dissolved in 200 cc. of 5% aqueous potassium hydroxide. Over a period of four days with constant stirring at room temperature, 25 g. of dimethyl sulfate was added. If the dimethyl sulfate was added too rapidly, the unmethylated lactone precipitated. After complete addition, the red solution containing a small amount of precipitate was made acid to congo red with dilute sulfuric acid, then basic with 20% aqueous potassium hydroxide.

(5) Nierenstein, THIS JOURNAL, **52**, 4012 (1930).

The precipitate (about 2.3 g.) of unchanged lactone and methyl ether methyl ester separated and was filtered. The filtrate was acidified with dilute sulfuric acid whereupon there formed a gummy precipitate of the compound with only the phenolic group methylated. The mixture of lactone and methyl ether methyl ester was refluxed for one hour with 50 cc. of 20% aqueous potassium hydroxide, acidified and finally again made alkaline. This procedure served to give a precipitate of pyrone, the filtrate containing the potassium salt of the ether acid. Upon acidification of the filtrate, the ether acid was obtained and combined with the same material obtained in the earlier part of the procedure. It was purified by crystallization from ethanol; white needles, m. p. 158–159° (cor.); yield, 2.5 g. (44%).

Anal. Calcd. for $C_{16}H_{16}O_4$: C, 70.59; H, 5.88; neut. equiv., 272. Found: C, 70.64; H, 6.08; neut. equiv., 272.

Less-soluble β-(2,7-Dimethoxy-8-bromonaphthyl)-α-methylacrylic Acid (XVII).—The same procedure as used in other hydrolyses and methylations was employed with 2-methyl - 10 - bromo - 9 - methoxy - 4,3 - β - naphthopyrone (XIV). From 14.5 g. of bromopyrone was obtained 12 g. of crude product which after several recrystallizations from ethanol followed by crystallization from a mixture of chloroform and petroleum ether (b. p. 60–110°) was pure; white crystals, m. p. 166° (cor.) with decomposition; yield, 7.5 g. (47.5%).

Anal. Calcd. for $C_{16}H_{15}O_4Br$: C, 54.69; H, 4.27. Found: C, 54.67; H, 4.49.

Attempted Resolution of Compound XVII.—From 7 g. of β - (2,7 - dimethoxy - 8 - bromonaphthyl) - α - methylacrylic acid and 6.5 g. of quinine in 200 cc. of ethyl acetate was deposited 7.3 g. of salt on cooling. This and subsequent fractions and also the recrystallized salts all had the same rotation. No mutarotation was observed in the salt solutions and decomposition of the salts resulted in an inactive acid; m. p. of salt, 98–99° (cor.).

Anal. Calcd. for $C_{16}H_{15}O_4Br \cdot C_{20}H_{24}O_2N_2$: C, 64.00; H, 5.81. Found: C, 63.78; H, 5.99. *Rotation.* 0.0501 g. made up to 25 cc. with ethyl acetate at 28° gave α_D −0.26°; *l*, 2; $[\alpha]^{28}D$ −64.8°.

2,7-Dimethoxynaphthaldehyde (XIX).—To a solution of 10 g. of 2,7-dihydroxynaphthaldehyde (VIII) in 100 cc. of 10% aqueous potassium hydroxide was added slowly, with stirring, 10 cc. of dimethyl sulfate. The greenish gummy precipitate that formed was redissolved by addition to the reaction mixture of 25 cc. of 30% aqueous potassium hydroxide. This was followed by a slow addition of dimethyl sulfate until the solution was acid. The solid was filtered and washed with dilute aqueous sodium hydroxide, then purified by crystallization from methanol; colorless needles, m. p. 99–100° (cor.); yield, 8 g. (69%). Acidification of the alkaline wash waters gave 1 g. of crude 7-methoxy-2-hydroxynaphthaldehyde.

Anal. Calcd. for $C_{13}H_{12}O_3$: C, 72.19; H, 5.60. Found: C, 71.84; H, 5.45.

The product was made also by dissolving the 2,7-dihydroxynaphthaldehyde in toluene, adding solid potassium carbonate and then dimethyl sulfate, or by the zinc cyanide–hydrogen chloride method for 2,7-dimethoxynaphthalene (XVIII).

The semicarbazone, prepared in ethanol, formed colorless needles from cellosolve; m. p. 247° (bloc Maquenne).

Anal. Calcd. for $C_{14}H_{15}O_3N_3$: C, 61.51; H, 5.54; N, 15.38. Found: C, 61.13; H, 5.39; N, 15.18.

More-soluble β-(2,7-Dimethoxynaphthyl)-α-methylacrylic Acid (XX).—A mixture of 20 g. of dry crude 2,7-dimethoxynaphthaldehyde, 20 g. of fused potassium propionate and 80 cc. of propionic anhydride was refluxed at 170° for ten hours. Then a solution of 62 g. of potassium hydroxide in 200 cc. of water was added and the mixture heated until all but a small amount of tar dissolved. It was treated with Norite then acidified to congo red. The product was purified by crystallization from ethanol; colorless needles, m. p. 153° (cor.); yield, 12 g. (48%).

Anal. Calcd. for $C_{16}H_{16}O_4$: C, 70.59; H, 5.88. Found: C, 70.65; H, 6.00.

A mixed melting point of this isomer with the less-soluble gave a depression. This more-soluble geometric isomer was also formed by irradiation of the less-soluble acid (IX) with ultraviolet light.

In a 50-cc. quartz flask was placed a solution of 0.4 g. of the acrylic acid (XVI) in 40 cc. of ethanol. This solution was irradiated with ultraviolet light for sixty hours, then evaporated to dryness. The solid obtained was dissolved in dilute alkali, filtered and recovered by acidification. The compound was purified by several crystallizations from dilute ethanol; white, feathery needles; m. p. 152–153° (cor.). A mixed melting point with the parent compound was depressed to 127–129° while a mixed melting point with the more-soluble acid prepared from 2,7-dimethoxynaphthaldehyde gave no depression.

More-soluble β-(2,7-Dimethoxy-8-bromonaphthyl)-α-methylacrylic Acid (XXI).—A mixture of 8.6 g. of β-(2,7-dimethoxynaphthyl)-α-methylacrylic acid (XX) in 150 cc. of chloroform and 20.6 cc. of solution of 25 g. of bromine in 100 cc. of chloroform was allowed to stand in the dark for sixty-five hours. The chloroform was evaporated with a stream of air and the residue purified from ethanol using Norite, then from acetic acid; colorless needles, m. p. 190° (cor.); yield, 5 g. (45%).

Anal. Calcd. for $C_{16}H_{15}O_4Br$: C, 54.69; H, 4.27; Br, 22.82. Found: C, 54.80; H, 4.34; Br, 23.28.

Attempted Resolution of Compound XXI.—From 5.4 g. of β-(2,7-dimethoxy-8-bromonaphthyl)-α-methylacrylic acid and 5.1 g. of quinine, dissolved in 200 cc. of ethanol, was obtained upon cooling 4.35 g. of salt. More salt was obtained by concentrating the solution, but the rotations on each fraction and also on the salts obtained by recrystallization of these fractions were essentially the same. No mutarotation was observed in the salt and decomposition of the salt resulted in an inactive acid; m. p. of salt 183–184° (cor.).

Anal. Calcd. for $C_{16}H_{15}O_4Br \cdot C_{20}H_{24}O_2N_2$: C, 64.00; H, 5.81. Found: C, 63.51; H, 5.96. *Rotation.* 0.0501 g. made up to 25 cc. with ethanol at 28° gave α_D −0.31°; *l*, 2; $[\alpha]^{28}D$ −77.4°.

From 62 g. of acid and 8.3 g. of brucine in 100 cc. of ethyl acetate was deposited 7.0 g. of salt on cooling. Subsequent fractions and all the salts obtained by recrystallization had identical rotations. No mutarotation was observed in the salt and decomposition of it resulted in an

inactive acid; m. p. of salt, 208–210° (cor.) with decomposition.

Anal. Calcd. for $C_{16}H_{15}O_4Br \cdot C_{23}H_{26}O_4N_2$: C, 62.81; H, 5.54. Found: C, 62.49; H, 5.42. *Rotation.* 0.0500 g. made up to 25 cc. with ethyl acetate at 28° gave α_D −0.21°; *l*, 2; $[\alpha]^{28}D$ −52.5°.

β-(2,7-Dimethoxy-8-nitronaphthyl)-α-methylacrylic Acid (XXII).—A suspension of 2 g. of more-soluble β-(2,7-dimethoxynaphthyl)-α-methylacrylic acid (XX) in 20 cc. of glacial acetic acid was stirred rapidly and 2 cc. of concentrated nitric acid (sp. gr. 1.42) was dropped in slowly. After twenty minutes the starting material had been replaced by orange crystals. The mixture was cooled to 15° and filtered. The product was washed with water, extracted with boiling ethanol to remove color and then crystallized from acetic acid; yellow microcrystals; m. p. 197–198°; yield, 1.2 g. (50%).

Anal. Calcd. for $C_{16}H_{15}O_6N$: N, 4.42. Found: N, 4.86.

Attempted Resolution of Compound XXII.—This compound was converted to its quinine salt by mixing equivalent amounts of acid and base in an equal mixture of dioxane and ethanol. Five fractions were isolated by evaporation of the solvent and filtration at intervals. All five fractions gave essentially the same melting point and rotation and upon decomposition at 0° with 2 *N* hydrochloric acid only an optically inactive product was isolated; white crystals; m. p. 156°.

Anal. Calcd. for $C_{36}H_{39}O_8N_3$: N, 6.55. Found: N, 6.26. *Rotation.* 0.1482 g. made up to 10 cc. with pyridine at 0° gave α_D −0.508°; *l*, 1; $[\alpha]^0D$ −34.3°.

2,7-Dimethoxynaphthoic Acid (XXIII).—A mixture of 5 g. of 2,7-dimethoxynaphthaldehyde and a solution of 2.5 g. of potassium permanganate and 0.5 g. of sodium carbonate in 100 cc. of water was stirred for one hour at room temperature until the permanganate decolorized. The manganese dioxide was filtered and the alkaline filtrate on acidification gave the product. It was purified by crystallization from dilute ethanol; colorless needles, m. p. 112–113° (cor.); yield, poor.

Anal. Calcd. for $C_{13}H_{12}O_9$: C, 67.30; H, 5.18; neut. equiv., 232. Found: C, 67.50; H, 5.39; neut. equiv., 230.

The same compound was prepared from 2,7-dimethoxybromonaphthalene described below. To 0.200 g. of lithium in 50 cc. of dry ether was added 2.8 g. of butyl chloride and the reaction was stirred for one hour. A solution of 5 g. of 2,7-dimethoxybromonaphthalene in 40 cc. of dry ether was then added and the stirring continued for thirty minutes. The ether solution was cooled to 0° and carbonated with dry-ice chips. After warming to room temperature the addition compound was decomposed with iced hydrochloric acid and extracted several times with ether. The ether layer was extracted with dilute sodium hydroxide, the alkaline layer then acidified and the product filtered. It was purified by recrystallization from dilute ethanol; white needles, m. p. 112–113° (cor.); yield, 2.9 g. (68%). A mixed melting point of this compound with that obtained by the oxidation gave no depression.

2,7-Dimethoxybromonaphthalene (XXIV).—A solution of 10 g. of 2,7-dimethoxynaphthalene in 50 cc. of chloroform was brominated by slowly dropping in a solution of 8.5 g. of bromine in 20 cc. of chloroform. The reaction mixture was washed with water and evaporated to dryness. The pinkish residue was recrystallized from methanol; colorless crystals, m. p. 88–89° (cor.); yield, 13 g. (91%).

Anal. Calcd. for $C_{12}H_{11}O_2Br$: C, 53.92; H, 4.12; Br, 29.97. Found: C, 53.82; H, 4.07; Br, 30.29.

2,7-Dimethoxy-8-nitronaphthaldehyde (XXVI).—Into a suspension of 1 g. of 2,7-dimethoxynaphthaldehyde in 10 cc. of glacial acetic acid was dropped slowly with vigorous stirring 0.5 cc. of nitric acid (sp. gr. 1.42). After two hours the solution was poured into water. The precipitate was purified from acetic acid; yellowish crystals, m. p. 190° (cor.); yield, 0.8 g. (65%).

Anal. Calcd. for $C_{13}H_{11}O_5N$: C, 59.75; H, 4.25; N, 5.36. Found: C, 59.55; H, 4.17; N, 5.49.

A second method[6] involved the introduction of an aldehyde group into the 2,7-dimethoxy-8-nitronaphthalene (XXV). Into a mixture of 16.8 g. of 2,7-dimethoxy-8-nitronaphthalene (XXV), 29.5 g. of zinc cyanide and 84 g. of benzene, dry hydrogen chloride was passed for one hour. Then 25 g. of powdered anhydrous aluminum chloride was added and hydrogen chloride passed in for six hours. The mixture was decomposed by refluxing with dilute hydrochloric acid, cooled and filtered. The product was dried and extracted with boiling toluene to remove the product from tar. From the toluene crystals formed. They were further purified from ethanol; tan needles, m. p. 190° (cor.); yield, 4.7 g. (25%).

This product could not be made to condense in the Perkin reaction with potassium propionate and propionic anhydride.

2,7-Dimethoxynaphthaldoxime (XXVII).—A mixture of 0.5 g. of hydroxylamine hydrochloride in 3 cc. of water, 1.5 g. of 2,7-dimethoxynaphthaldehyde in 15 cc. of dioxane and 5 cc. of water, and 0.6 g. of sodium acetate was heated for twenty minutes on a steam-bath. After cooling, a precipitate formed. It was purified from ethanol; colorless prisms, m. p. 181–182° (cor.); yield, 1.5 g. (93%). The product was insoluble in aqueous alkali.

Anal. Calcd. for $C_{13}H_{13}O_3N$: N, 6.06. Found: N, 6.21.

2,7-Dimethoxynaphthonitrile (XXVIII).—A mixture of 1 g. of 2,7-dimethoxynaphthaldoxime and 5 cc. of acetic anhydride was refluxed for one hour. After addition of about 30 cc. of water, crystals appeared. These were purified from ethanol; colorless needles, m. p. 129° (cor.); yield, 0.9 g. (98%).

Anal. Calcd. for $C_{13}H_{11}O_2N$: N, 6.57. Found: N, 6.51.

No method was found for hydrolysis of the nitrile to the corresponding acid.

Summary

1. The following α-naphthylacrylic acids have been prepared: β-(2,7-dimethoxy-8-bromonaphthyl)-α-methylacrylic acids (both geometric isomers), and β-(2,7-dimethoxy-8-nitronaphthyl)-α-methylacrylic acid. None of these three compounds could be resolved.

(6) Weber, *Ber.*, **14**, 2206 (1881).

2. 7-Methoxy-2-hydroxynaphthaldehyde is converted by a Perkin synthesis to 2-methyl-9-methoxy-4,3-β-naphthopyrone. This compound brominates or nitrates in the 10-position. The resulting bromopyrone is hydrolyzed and methylated to β-(2,7-dimethoxy-8-bromonaphthyl)-α-methylacrylic acid. The unbrominated pyrone is also hydrolyzed and methylated and yields β-(2,7-dimethoxynaphthyl)-α-methylacrylic acid. Upon bromination of this acid, the halogen enters the 10-position, simultaneous hydrolysis of the methoxyl group occurs and pyrone formation results. The mode of preparation of the acrylic acid and the bromoacrylic acid leads to the conclusion that the carboxyl is *cis* to the 2-methoxyl group of the naphthalene nucleus.

3. These acids are both less soluble than the corresponding geometric isomers made directly by the appropriate Perkin reaction on 2,7-dimethoxynaphthaldehyde and bromination. No tendency to pyrone formation appears in this last reaction. The less-soluble acrylic acid is converted to the more soluble by irradiation with ultraviolet light.

Higher Hydrocarbons.[1] II. Five 11-Substituted Heneicosanes

BY F. C. WHITMORE, J. N. COSBY, W. S. SLOATMAN AND D. G. CLARKE

In the first paper[2] of this series the methods of preparation and the properties for seven alkyl substituted docosanes were given. A brief survey was made of the literature relating to the preparation of hydrocarbons containing more than twenty carbon atoms.

Whereas the first paper covered only isoparaffins, this paper reports on a variety of mixed type compounds. In this group of compounds the paraffin chain remains constant, but different type substituents are located in the 11-position. Changes of this type have considerably greater influence on the properties than moving a side chain or varying the molecular weight.[2]

Lubricating oil fractions in a given molecular weight range show large variations in properties. From the extensive studies[3] of Research Project No. 6 of the American Petroleum Institute these differences in the properties of the various lubricant fractions can only be due to differences in the hydrocarbon type. Therefore, this and future papers will describe series of hydrocarbons in which there are variations in hydrocarbon type. Generalizations on the properties and comparison with those in the literature will be published later.

Special emphasis has been placed on obtaining pure compounds. The requirements of purity and the methods of obtaining and determining the purity have been discussed in the earlier paper.[2]

The synthesis of these compounds involved the addition of an excess of *n*-decylmagnesium bromide to the following esters: ethyl caproate, methyl 2-ethylbutyrate, ethyl cyclopentanecarboxylate, and methyl benzoate. The resulting tertiary carbinols were dehydrated over copper sulfate in an atmosphere of nitrogen. The purified olefins were hydrogenated in a high pressure bomb over various nickel catalysts.

Only one intermediate, ethyl cyclopentanecarboxylate, presented any serious problem. Methods for its preparation in the literature did not seem promising. The method used in this work was the little used reaction[4] involving the addition of cyclopentylmagnesium bromide to an excess of ethyl carbonate.

With 11-phenyl-11-heneicosanol only one olefin can be obtained on dehydration. Therefore this was isolated and purified as usual. However it is probably an inseparable mixture of the *cis*- and *trans*-isomers.

The selective hydrogenation of the olefinic double bond in the presence of the phenyl group as in the case of 11-phenylheneicosane required special study. It was found possible to carry out this hydrogenation if the olefin was first very carefully purified by distillation and passage through silica gel. The hydrogenation was then carried out at room temperature over very active Raney nickel at a pressure of 1500 to 1800 lb. per sq. in.

Table I is a summary of the important properties of these hydrocarbons. The methods used

[a] In the first four cases based on the ester, in the last two on olefin used. [b] Based on pure hydrocarbon obtained. [c] The purity of the compounds was calculated from time–temperature melting curves. With compounds 2 and 4 glasses were formed on cooling which made the use of melting curves impossible. [d] Analyses of three of the compounds were carried out by the Esso Laboratories through the courtesy of Dr. L. A. Mikeska.

in the measurements and the designations are the same as those given for the earlier series of hydrocarbons.[2] None of these compounds has been reported before.

Experimental

Intermediates.—The greatest of care has been taken to obtain pure intermediates. Fractional distillation columns[5] with efficiencies of 25 to 35 theoretical plates have been used on all preparations. The thermometer readings on the boiling points of the intermediates are uncorrected. The constants given are those of the constant boiling point, constant index refraction fractions. Only this material was used as intermediates.

(a) **Decyl Bromide.**—Technical *n*-decanol was refluxed with the hydrobromic and sulfuric acids mixture resulting from the reduction of bromine with sulfur dioxide. This was described in detail in an earlier paper,[2,6] b. p. 124° (20 mm.); $n^{20}D$ 1.4558; yield 73%.

(b) **Cyclopentyl Bromide.**—This was prepared by passing hydrogen bromide into pure cyclopentanol at 100°. This was washed with one-half its volume of cold 95% sulfuric acid and then twice with an equal volume of water. After drying for twenty hours over anhydrous potassium carbonate, the product was distilled through an all-glass 25-plate column. The yield of pure bromide was 70%; b. p. 137° (737 mm.); $n^{20}D$ 1.4890.

(c) **Ethyl Caproate.**—Eastman Kodak Co. technical ethyl caproate was carefully fractionated: b. p. 165° (730 mm.); $n^{20}D$ 1.4078.

(d) **Methyl 2-Ethylbutyrate.**—Technical 2-ethylbutyric acid obtained from Carbide and Carbon Chemicals Corp. was dried over calcium chloride for several days. Of this, 812 g. (7.0 moles) was added to 2.0 l. of anhydrous methanol and 100 cc. of concentrated sulfuric acid. A heavy precipitate of calcium sulfate formed. This was filtered off, and the clear solution refluxed for four days. Part of the excess methanol was distilled off, and the reaction mixture then diluted with twice its volume of water. The ester layer was separated, and the water layer extracted with ether. This after drying over anhydrous sodium sulfate was fractionally distilled. The yield of pure ester was 75%, b. p. 134° (728 mm.); $n^{20}D$ 1.4018.

(e) **Ethyl Cyclopentanecarboxylate.**—Cyclopentylmagnesium bromide was prepared from 62 g. (2.5 moles) of magnesium, 363 g. (2.4 moles) of cyclopentyl bromide, and 500 cc. of anhydrous ether. After standing overnight the Grignard solution was removed from the reaction flask under an atmosphere of nitrogen, and filtered. The Grignard solution was added to 590 g. of distilled diethyl carbonate in 500 cc. of anhydrous ether over a period of five hours, with stirring, while the mixture was cooled in an ice-bath. After standing overnight the mixture was decomposed by pouring over crushed ice containing 35 cc. of concentrated sulfuric acid. Two such runs were made, and the combined products distilled through a 25-plate column; yield 275 g., 48.5%; b. p. 171.9° (737 mm.), 89.3° (45 mm.) (both Cottrell); d^{20}_4 0.9523; $n^{20}D$ 1.4360. Faworski and Boshowski[7] report a boiling point of 172–174° (752 mm.).

(f) **Methyl Benzoate.**—Methyl benzoate prepared by students in a preparation course was carefully fractionated; b. p. 95° (25 mm.); $n^{20}D$ 1.5170.

11-*n*-Amylheneicosane.—A Grignard solution was prepared from 660 g. (3.0 moles) of *n*-decyl bromide and 73 g. (3.0 moles) of magnesium in the usual manner. Titration of a sample of the Grignard solution indicated a yield of 95%. To this was added 154 g. (1.07 moles) of ethyl caproate. After stirring for several hours and allowing to stand overnight, the reaction products were poured on 1700 g. of ice and 150 cc. of concentrated sulfuric acid. After standing overnight the ether layer was separated and the water layer was extracted with ether. These ether solutions were combined and the ether removed by distillation through an indented column. In this preparation the tertiary alcohol was isolated. Distillation of the crude products indicated 80 g. of decane, 40 g. of 7-hexadecanone, and 345 g. of di-*n*-decylamylcarbinol; b. p. 225–229° (1 mm.); $n^{20}D$ 1.4580).

The tertiary alcohol was then dehydrated over anhy-

(5) Described in a separate publication to be submitted to the *Analytical Edition of Industrial and Engineering Chemistry.*

(6) Recently we have found that these higher alkyl bromides may be prepared in much better yields with less trouble by passing hydrogen bromide from the direct combustion of bromine and hydrogen into the alcohol at 110°.

(7) Faworski and Boshowski, *J. Russ. Phys.-Chem. Soc.*, **50**, 587 (1920).

drous copper sulfate in an atmosphere of nitrogen at 160–180°. The olefins were passed through a 50 × 1.5 cm. tube of silica gel. This step gave a water-white product, 310 g., which was then hydrogenated over 20 g. of U. O. P. nickel catalyst[8] at 120° and 1100 lb. per sq. in. pressure. At least 95% of the required hydrogen was absorbed in ten minutes. Hydrogenation conditions were continued for three hours to ensure completion. The nickel was removed by filtration and the product distilled slowly through the high vacuum column.[5] The fractions having constant refractive indices were combined and passed through a column of silica gel. The product, 11-*n*-amylheneicosane, was water-white and odorless. Table I gives the percentage yields and the analyses.

11-(3-Pentyl)-heneicosane and 11-Cyclopentylheneicosane.—These were prepared from the appropriate esters in the same manner as the 11-*n*-amylheneicosane. In each case approximately 2 moles of the ester was used. The tertiary alcohol was not isolated.

11-Phenyl-10-heneicosene.—In the usual manner a 7-mole Grignard solution was prepared from pure *n*-decyl bromide. To this was added 408 g. (3.0 moles) of methyl benzoate dissolved in an equal volume of ether. After stirring for a total of ten hours and allowing to stand overnight, the product was poured on ice and 200 cc. of concentrated sulfuric acid. The ether-product layer was separated and the water layer extracted once with 800 cc. of ether. These were combined, the ether removed, and most of the low boiling by-products (*n*-decane), etc., removed by distillation from a modified Claisen flask at 20 mm. pressure. The crude tertiary alcohol was then dehydrated over anhydrous copper sulfate at 160° in an atmosphere of nitrogen. This was then filtered through a column of silica gel to give an almost water-white product. Following this step the crude olefin was distilled through the vacuum column at a pressure of 0.95 mm. Ninety per cent. of the distillate had a constant index of refraction. These constant fractions were combined and passed through silica gel again to give a water-white, odorless finished product.

11-Phenylheneicosane.—The obtaining of this compound by the selective hydrogenation of the related olefin, 11-phenyl-10-heneicosene, required special study. The first two attempts failed. In the first, complete hydrogenation of the olefinic double bond was not obtained and in the second, hydrogenation of the phenyl group took place to the extent of about 5%. This was shown by the melting point curves, systematic solvent extraction[9] using acetone as a solvent, and chemical test.

It was found that if the olefin was purified (see the preparation of 11-phenyl-10-heneicosene) to the greatest possible extent, hydrogenation of 560 g., 1.5 moles, of the olefin proceeded smoothly and completely in a period of six hours over 30 g. of very active Raney nickel at room temperature and 1800 lb./sq. in. pressure of hydrogen. The product was then filtered through silica gel to remove the nickel and any remaining olefin. Distillation of the product through the vacuum column gave no evidence of other substances being present. All fractions had exactly the same index of refraction. This was not found in the other two attempts to prepare the compound. Some indication of separation was found if the compound was under or over hydrogenated.

11-Cyclohexylheneicosane.—The combined fractions, 445 g., 1.2 moles, from the distillations of the attempted preparations of 11-phenylheneicosane were combined and completely hydrogenated over 25 g. of U. O. P.[8] nickel at 150° and 1500 to 1800 lb./sq. in. pressure of hydrogen in a time of ten hours. The product was filtered through a tube of silica gel to remove the nickel and any remaining aromatic compounds. This product was then distilled through the vacuum column at 0.5 mm. Ninety-five per cent. of the distillate had a constant index of refraction. These constant fractions were combined and passed through a tube of silica gel a second time. This gave a water-white, odorless product.

Summary

The methods of preparation and six important properties of six new high molecular weight hydrocarbons are given.

The Concentration and Purification of Tobacco Mosaic Virus by Means of the Sharples Super-centrifuge

BY W. M. STANLEY

When the infectious juice pressed from frozen macerated mosaic-diseased Turkish tobacco plants is clarified and centrifuged at a sufficiently high speed, there may be recovered from the solid jelly-like sediment about 3 mg. of tobacco mosaic virus per cc. of juice.[1] Three or four successive sedimentations at high centrifugal force, each followed by clarification at low centrifugal force are required to yield a virus preparation sufficiently pure for most chemical work. The method is especially suitable for plant viruses, since in most cases practically all material of high molecular weight except the viruses is rendered insoluble by the freezing process.[2] The method should also be suitable for any virus that can be produced in a medium free of material possessing a sedimentation constant comparable to that of the virus. During the past five years, air-driven vacuum centrifuges of the type described by Bauer and Pickels[3] and by Biscoe, Pickels and Wyckoff[4] have been used to provide the high centrifugal force necessary to sediment medium and small sized viruses. In this laboratory duraluminum or magnesium–aluminum alloy heads from 6 to 8 inches in diameter and carrying from 6 to 14 Lusteroid tubes 0.75 × 3 inches in size have been spun at speeds from 24,000 to 36,000 r. p. m. to yield a centrifugal force of about 50,000 times gravity at the centers of the Lusteroid tubes. Since acceleration and deceleration each requires eight to ten minutes and the tobacco mosaic virus must be spun about an hour in order to secure complete sedimentation, about two working days with 2 centrifuges having a combined capacity of 350 cc. are required to prepare about 4 g. of purified tobacco mosaic virus. The equipment is admirably suited for the centrifugation of solutions up to a liter or so in volume and for work with unstable viruses, since the virus solution may be centrifuged near its freezing point.[5] However, for certain types of work amounts of tobacco mosaic virus of 100 g. or more are needed, and it is obvious that the centrifugation of the necessary 30 liters or so of infectious juice not only requires much time and effort, but also places a severe strain on the physical equipment. Consequently, during the past year other means for the centrifugation of large volumes of virus solutions have been sought.

In 1927 McKinney[6] attempted to use the commercially available Sharples Laboratory Super-centrifuge for the concentration of tobacco mosaic virus, but, because of the large volumes of liquid required, soon discarded it in favor of a small, specially constructed centrifuge with a closed bowl holding about 10 cc. of solution. However, by means of this centrifuge, which yielded a centrifugal force of about 50,000 times gravity, McKinney was able to demonstrate that tobacco mosaic virus could be concentrated by centrifugation. In 1933 Schlesinger[7] showed that a coli-bacteriophage could be concentrated and purified by means of a similar, specially constructed centrifuge having a closed hollow cylinder. The first real test with viruses of the Sharples Super-centrifuge equipped with a bowl for continuous flow, and hence useful for large volumes of fluid, appears to have been made by McIntosh and Selbie[8] in 1940. Using a considerably modified centrifuge, these workers demonstrated that the infectivity of large volumes of fluids containing bacteria, vaccine virus or either of two bacteriophages could be reduced at least 100 times by passage through the centrifuge. The infective particles that were removed from the effluent liquid were recovered in the sediment. In view of these results, it appeared desirable to make a thorough study of the usefulness of the Sharples Laboratory Super-centrifuge for the concentration and purification of tobacco mosaic virus.

Experimental

A regular model Sharples Laboratory Super-centrifuge with a compressed-air turbine drive and a monel metal

clarifier bowl was used. This model develops 62,000 times the force of gravity at the speed of 50,000 r. p. m. which was used in this work. A sheet of celluloid or of cellulose acetate, 14.5 × 19.8 cm. and about 0.4 mm. thick, was used as a liner for the bowl, and inside this was placed a second liner of filter paper. A cooling coil mounted between the rotating bowl and the outer shell of the centrifuge and composed of about 14 feet of 0.25-inch copper tubing, through which ice water was passed by means of a small electric centrifugal pump, was used to absorb heat generated by the rotating bowl. In preliminary experiments the smallest delivery jet supplied with the centrifuge was used with the infectious juice from mosaic-diseased Turkish tobacco plants or with purified preparations of tobacco mosaic virus in 0.1 *M* phosphate buffer to determine the effect of factors such as rate of flow, temperature, and *p*H of ingoing liquid on the yield of virus. Centrifugation at *p*H 5, 6, or 7 appeared to have no significant effect on the yield of virus. The temperature of the ingoing liquid also appeared to be of little importance for, regardless of this temperature, that of the bowl contents was usually 20–25° and that of the effluent liquid was usually about 17°. The temperature of the effluent liquid appeared to be governed by the evaporation caused by the rapid flow of air through the centrifuge. The evaporation was usually sufficient to reduce the volume of the effluent liquid by about 20%. The concentration of the effluent liquid caused by evaporation was neglected in the calculations of the yields of virus. The factor having the greatest influence on the yield of virus was found to be the rate of flow of the preparation. Flow rates of 30 cc. per minute or greater resulted in yields of 50% or less, whereas flow rates between 20 and 25 cc. per minute gave yields of 60 to 75%. In order to secure a uniform slow rate of flow, a short length of tubing from a No. 22 hypodermic needle was soldered into the original delivery jet. This gave a rate of flow of about 15 cc. per minute, which, as may be seen from the data presented in Table I, resulted in yields of 3 to 4 mg. of virus per cc. in the case of infectious juices and of 75 to 93% in the case of purified virus preparations.

TABLE I

REPRESENTATIVE DATA FOR SUPER-CENTRIFUGE RUNS IN WHICH A SATISFACTORY RECOVERY OF TOBACCO MOSAIC VIRUS WAS ACHIEVED

Starting material			Effluent	Yield of
Volume, cc.	Protein, mg./cc.	Rate of flow, cc./min.	protein, mg./cc.	virus, mg./cc. of juice

1200	10.4	14	1.69	84
3000	9.3	15	0.69	93

In one experiment the virus in 200 cc. of infectious juice containing 9.0 mg. of protein per cc. was purified by 3 successive sedimentations in the vacuum centrifuge and the virus in 5 liters of the same juice was purified by means of the Sharples Super-centrifuge. The supernatant fluid from the first centrifugation in the vacuum centrifuge contained 2.4 mg. of protein per cc., and the yield of virus following 3 sedimentations was 733 mg., equivalent to 3.66 mg. per cc. of juice. The effluent from the Sharples Super-centrifuge, on the other hand, contained 5.37 mg. of protein per cc. In order to remove the last portions of the juice from the bowl, there was introduced, immediately following the juice and without stopping the centrifuge, 500 cc. of 0.4 *M* phosphate buffer at *p*H 7. This buffer had the same density as that of the juice. On stopping the centrifuge, the material on the liner was dissolved in the bowl contents consisting of about 250 cc. of the buffer. The celluloid and filter paper liners were well washed with sufficient water, which, when added to the bowl contents, gave a final solution containing 0.1 *M* phosphate buffer. This solution, which was found to contain 16.9 g. of protein, was diluted with 0.1 *M* phosphate buffer at *p*H 7, so that the final protein concentration was 3 mg. per cc. This solution was passed through the Sharples Super-centrifuge under the same conditions described above, and the effluent was found to contain 0.75 mg. of protein per cc. The liner and bowl contents which contained 12.4 g. of protein were diluted to a protein concentration of 3 mg. per cc. and again passed through the centrifuge. The effluent was found to contain 0.69 mg. of protein per cc. and the liner and bowl contained 9.6 g. of virus. Under the conditions of the experiment, the yield of virus was 52.5% of that obtainable by means of the vacuum centrifuge.

However, the two final sedimentations with the vacuum centrifuge were carried out at a protein concentration of about 10 mg. per cc., as is customary in our laboratory, whereas in the case of the Sharples Super-centrifuge the 2 final sedimentations were made at a protein concentration of only 3 mg. per cc. It seemed possible that this might account in part for the difference in yields; hence, a test run was made by passing a liter of a solution containing 10.4 mg. of virus per cc. in 0.1 *M* phosphate buffer at *p*H 7 through the Sharples Super-centrifuge. Although the same delivery jet was used, the rate of flow of this solution was reduced to 12.3 cc. per minute, presumably due to the increased viscosity. The effluent was found to contain but 0.69 mg. of protein per cc.; hence, 93% of the virus was removed. As may be seen from the data presented in the second part of Table I, yields of the same order of magnitude were obtained in several experiments in which purified virus at a concentration of about 10 mg. per cc. was used. The fact that the protein concentration of the ingoing liquid could be increased from 3 to 10 mg. per cc. without appreciably affecting the concentration of protein in the effluent demonstrates that a more efficient recovery of virus may be accomplished at the higher virus concentration. When protein concentrations of about 10 mg. per cc. were used for all runs after the original juice was sedimented, the over-all yield of virus was increased to about 65%.

Discussion

The need for easily available and relatively inexpensive equipment by means of which purified tobacco mosaic virus may be prepared readily in quantity is met by the Sharples Super-centrifuge equipped with a cooling coil. It is necessary only to solder a short piece of tubing from a No. 22 hypodermic needle into the original delivery jet and to use a double liner of celluloid and filter paper in the rotating clarifier bowl. It is possible during the course of ten hours to prepare 10 to 15 g. of tobacco mosaic virus, purified by 4 sedimentations by using a flow rate of about 15 cc. per minute for the infectious juice used as starting material, and a flow rate of 12–15 cc. per minute for the final 3 sedimentations of the virus at a concentration of about 10 mg. per cc. The fact that the over-all recovery of virus from the starting material is somewhat less than that obtainable with the vacuum type centrifuge is more than offset by the fact that during a given period of time the amount of purified virus obtainable with the Sharples Super-centrifuge is over ten times that obtainable with a vacuum type centrifuge.

The amount of virus directly isolable from the infectious juice may be increased somewhat if the effluent juice is immediately passed through the centrifuge a second time. Although this expedient is hardly worth while in the case of tobacco mosaic virus, due to the relatively high virus concentration and the ease with which large amounts of infectious juice may be obtained, Dr. Knight of this laboratory has found the second passage of effluent juice to be quite advantageous in the case of cucumber virus 4. The concentration of this virus in the infectious juice from cucumber plants is only a few tenths of a mg. per cc.,[9] and it is somewhat more difficult to obtain large quantities of the infectious juice. After an initial concentration of this virus to about 10 mg. per cc., the recovery on sedimentation should be equivalent to that obtainable with a similar concentration of tobacco mosaic virus, since the two viruses have approximately the same sedimentation constant. It seems likely that, in general, a second passage of infectious juice will be advantageous in those cases where the concentration of the virus is less than about 1 mg. per cc. and in those cases where the sedimentation constant of the virus is appreciably less than that of tobacco mosaic virus.

The experiments described were conducted with the assistance of Mr. Marshall Barbour.

Summary

The concentration and purification of tobacco mosaic virus have been accomplished efficiently by means of a Sharples Laboratory Super-centrifuge, equipped with a regular clarifier bowl operated at a speed of 50,000 r. p. m. by means of compressed air. It was found advantageous to use a cooling coil, a celluloid and a filter paper liner in the bowl, and a modified delivery jet constructed from a small hypodermic needle. Using the clarified juice from mosaic-diseased Turkish tobacco plants as starting material, it was possible to prepare 10 to 15 g. of tobacco mosaic virus, sufficiently pure for most purposes, during the course of ten hours by means of such equipment

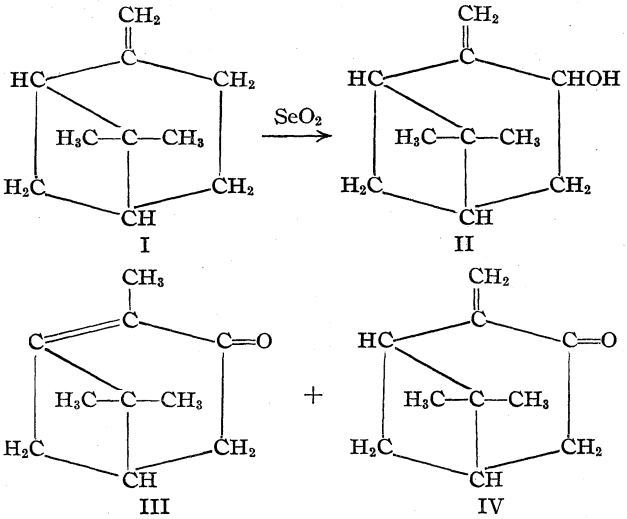
Reactions of β-Pinene. II. With Selenium Dioxide in Acetic Acid[1]

BY W. DAVID STALLCUP* AND J. ERSKINE HAWKINS

In the first paper of this series[2] it was pointed out that pinocarvone (IV) and carvopinone (III) are the steam-volatile products of the reaction of one mole of β-pinene (I) with one mole of selenium dioxide. Joshel and Palkin[3] have shown that pinocarveol (II) is the predominant steam volatile product if slightly less than one-half mole of selenium dioxide is used per mole of β-pinene.



In order to more completely study the formation of these compounds, the reaction has been carried out in acetic acid and acetic anhydride using both molar and half molar amounts of selenium dioxide per mole of β-pinene.

Experimental

β-Pinene was prepared by fractionating commercial material[4] through an efficient spiral screen column[5,6] and had a b. p. 59.2° (20 mm.), $n^{25}D$ 1.4768; $[\alpha]^{30}D$ −21.4°.

Selenium dioxide was prepared by nitric acid oxidation of selenium, washing, crystallizing and drying the product.

Oxidation of β-Pinene by Selenium Dioxide.—Selenium dioxide was added with stirring to β-pinene and 200 cc. of solvent in the amounts shown in Table I, the rate of addition being such that the temperature of the reaction mixture did not rise above 70°. When addition was complete the mixture was refluxed for four hours. It was then filtered to remove selenium and the filtrate was steam distilled. The distillate was treated with sodium bicarbonate and the ether extract distilled at 2–3 mm. pressure.

Separation of the Steam Volatile Oil

For Pinocarveol.—The oil was added to an equal volume of ethyl borate and heated for one hour at 125°. The non-alcoholic materials[7] were then removed by lowering the pressure and raising the temperature to 150°. The tarry residue was impure pinocarvyl borate. This was then hydrolyzed and simultaneously steam distilled from a sodium carbonate solution. The ether extract of the distillate was quite pure pinocarveol.

For Pinocarvyl Acetate.—The non-alcoholic oil from the borate treatment was extracted with twice its volume of sodium bisulfite as previously described.[2] When the ketonic materials were absorbed, the bisulfite was twice extracted with ether. Distillation of the ether extract at 2–3 mm. gave nearly pure pinocarvyl acetate.

For Carvopinone and Pinocarvone.—The bisulfite solution above was then selectively decomposed by the method previously developed.[2]

Essentially the same results as above were obtained when the oxidation mixture was first extracted with bisulfite and then treated with ethyl borate.

TABLE I

All oxidations listed were between 1 mole of β-pinene and 0.5 mole of selenium dioxide except the first reaction, which was between 1 mole of β-pinene and 1 mole of selenium dioxide and the second reaction which was between 0.5 mole of β-pinene and 0.5 mole of selenium dioxide.

Solvent	Se recov., g.	Steam volatile oil, g.	% Steam volatile oil recovered as Pinocarveol	Pinocarvyl acetate	Carvopinone	Pinocarvone

AcOH	None	41	3.7	22	20	2
AcOH–Ac_2O	6	27	13	44	2	8.5

Pinocarveol obtained by the above procedure was identical with that prepared from β-pinene and selenious acid in absolute ethanol by the method described by Joshel and Palkin.[3] It had the constants: b. p. 78–80° (3–4 mm.); $n^{25}D$ 1.4980; $[\alpha]^{25}D$ +65.5; d^{25}_4 0.976; M_D calcd. 45.52,[8] found 45.72. This pinocarveol solidified at about 5°. Schmidt[9] reports a thaw point of 7° for pinocarveol purified through the phenylurethan. The phenylure-

(7) Separate experiments proved pinocarvyl acetate to be stable in the presence of ethyl borate under the conditions used.

(8) Based on values of Auwers and Eisenlohr, and 0.48 for cyclobutane ring. No value assigned for methylene group attached to ring.

(9) Schmidt, *Ber.*, **63**, 1129 (1930).

than was prepared as described by Schmidt.[9] If the pinocarveol is not carefully purified, the urethan will crystallize only with great difficulty, if at all. The m. p. was 82–84°. Joshel and Palkin[3] report 84–86°. Schmidt[9] reports 84–85° and 88–90° for recrystallized products.

Pinocarvyl Acetate.—When prepared from β-pinene as described above it had the constants: b. p. 88–90° (2–3 mm.), 225° (cor.) (760 mm.); $n^{25}D$ 1.4750; d^{25}_4 0.991, $[\alpha]^{25}D$ −38°; saponification number calcd. 194.26, found 195 (or 100.3%). Schmidt[9] reports b. p. 227–8°; d^{20} 0.997; αD +15.8° for the *d*-isomer.

When prepared by the esterification of pinocarveol with acetic anhydride in the presence of sodium acetate[9] the constants are: b. p. 88–90° (2–3 mm.); $n^{25}D$ 1.4760; d^{25}_4 0.993; $[\alpha]^{25}D$ −20°. Saponification number calcd. 194.26, found 194 (or 100%). No explanation is offered for the variations in the values of the rotations of the esters when prepared by different methods.

Pinocarveol, like most secondary and tertiary terpene alcohols, will not readily esterify with acetic anhydride unless sodium acetate is present. It will not react to any observable extent with acetic acid even when refluxed in the presence of sodium acetate for two hours.

Pinocarvone.—When prepared as described above it had almost the same constants as previously given[2]; b. p. 83–84° (3–4 mm.); $n^{20}D$ 1.5039; semicarbazone, m. p. 210–212° recrystallized.

Carvopinone.—The constants of this compound, obtained as described above, were also similar to those previously reported[2]; b. p. 84–85° (3–4 mm.); $n^{25}D$ 1.4924. Its semicarbazone did not melt below 300°.

The Action of Selenium Dioxide on Pinocarveol

Twenty-five grams of pinocarveol was dissolved in 75 cc. of ethanol in a flask equipped with a reflux condenser and mechanical stirrer. Ten grams of selenium dioxide was slowly added. Upon heating, the solution first turned yellow, then red and finally brown. After refluxing for five hours, three and one-half grams of selenium was obtained and the liquid portion was steam distilled. This gave 15 g. of an oil; b. p. 84–85° (3–4 mm.); $n^{25}D$ 1.4931; d^{25}_4 0.982; αD +60.5° (10-cm. tube). This was largely impure carvopinone which was purified through the bisulfite compound to give 6.1 g. of carvopinone; b. p. 84–85° (3–4 mm.); $n^{25}D$ 1.4935; d^{25}_4 0.981; $[\alpha]^{25}D$ +62.7°. About 0.3 g. of pinocarvone was isolated, this had $n^{25}D$ 1.5010. Approximately one-half gram of oil was not extracted by the bisulfite. Judging by its refractive index and its action to heat, it was impure carvopinone.

Reduction Experiments

***d-cis*-Pinocampheol** is formed in nearly theoretical yield by the catalytic hydrogenation of pinocarveol in cyclohexane using a 10% palladium on charcoal catalyst and heating the mixture to 100° under a hydrogen pressure of 1200 lb. for two hours in a bomb. The catalyst was removed by filtration and the pinocampheol purified by distillation at reduced pressure. The constants were: m. p. 55.5–56.0°; $n^{25}D$ 1.4830 (super-cooled); $[\alpha]^{25}D$ +39° (10.5% in ether). When recrystallized from pet. ether (boiling range 35–65°) the α-naphthylurethan had a m. p 87.5–88.0° (cor.) which is the same as that reported by Kuwata[10] and Schmidt and Schultz[11] for *d-cis*-pinocampheol.

***d-cis*-Pinocamphyl acetate** may be obtained quite pure by the catalytic reduction of pinocarvyl acetate under the conditions described above. The reduction product is purified from the solvent by distillation at reduced pressure. It had the constants: b. p. 80–82° (2–3 mm.), 227–8° (cor.) (760 mm.); $n^{21}D$ 1.4641; d^{25}_4 0.979; $[\alpha]^{25}D$ +23°. Saponification number, calcd. 196.28, found 197 (or 100.3%). Upon saponification this ester produced *d-cis*-pinocampheol whose constants were in close agreement with those above. Kuwata[10] reports for *l-cis*-pinocamphyl acetate: b. p. 82–84° (3 mm.); d^{20}_4 0.9781; $n^{20}D$ 1.4638.

***l-trans*-Pinocamphone** is obtained by the catalytic hydrogenation of carvopinone by the procedure described above. The product was purified by washing with neutral bisulfite and distilling the unextracted oil at 2–3 mm. (b. p. about 70°); b. p. 212° (cor.) (760 mm.); $n^{25}D$ 1.4735; d^{25}_4 0.964; $[\alpha]^{25}D$ −13.5°. Its semicarbazone recrystallized as very fine white needles from dilute methanol, m. p. 227.5–228.0° (cor). Schmidt and Schultz[11] report for the semicarbazone of *l-trans*-pinocamphone m. p. 227° and for the semicarbazone of *l-cis*-pinocamphone, 219°.

Another pinocamphone was obtained upon the reduction of pinocarvone under the same conditions. It had the constants: b. p. 75° (2–3 mm.); $n^{29}D$ 1.4772; αD −29° (10-cm. tube). It forms a semicarbazone melting at 185°. This is apparently the β-form of the semicarbazone described by Gildemeister and Kohler.[12] The α-form described by these authors has a m. p. of 218–219° which corresponds to the semicarbazone of *cis* pinocamphone of Schmidt and Schultz.[11]

Discussion

The effect of the selenium dioxide β-pinene ratio in these solvents was not nearly as pronounced as it was for ethanol.[2,3]

It may be seen from Table I that the major portion of the steam volatile oil is pinocarvyl acetate. This finding is in accord with the mechanism proposed by Guillemonat[13] for the oxidation of ethylenic hydrocarbons in which a selenium complex is formed with the hydrocarbons. This, in turn, is decomposed by the solvent. In this case it results in the formation of pinocarvyl acetate.

Water is a product of the reaction in which the selenium complex is formed. A reaction between the complex and the water thus formed would account for the formation of pinocarveol. As already pointed out, pinocarveol is not esterified by acetic acid and the alcohol therefore becomes subject to oxidation by selenium dioxide. This would account for the formation of the ketones.

(10) Kuwata, THIS JOURNAL, **59**, 2509 (1937).
(11) Schmidt and Schultz, *Ber. Schimmel*, 91 (1934).
(12) Gildemeister and Kohler, *Chem. Centr.*, **80**, II, 2158 (1909).
(13) Guillemonat, *Ann. chim.*, **11**, 143 (1939).

It is believed that this latter oxidation also takes place through the medium of a selenium complex. This is supported by the fact that the reaction mixture becomes yellow, then red and finally deposits selenium, and upon steam distillation leaves a non-volatile selenium compound.

Since carvopinone yields *trans*-pinocamphone upon reduction it may be seen, by setting up a model, that the carbonyl group of carvopinone is close to the *gem*-dimethyl group. This proximity would tend to hinder the rate of reaction of the carbonyl group with large molecules. The slowness of the reactivity of the carbonyl group was pointed out in the previous paper[2] in respect to the formation of the semicarbazone. This steric relation may also be the cause of the relative ease of the rupture of the cyclobutane ring to form carvone.

The pinocarveol formed by the action of selenium dioxide on β-pinene is probably the *trans* form with respect to the hydroxyl group and the *gem*-dimethyl group. It is believed that the method of formation and purification would tend to give rise to the more stable form, which is *trans*.

Summary

1. The oxidation of β-pinene with selenium dioxide in acetic acid and acetic anhydride gave pinocarvyl acetate, pinocarveol, pinocarvone and carvopinone as steam volatile products. The main product was the acetate.

2. The oxidation product of pinocarveol by selenium dioxide is largely carvopinone.

3. The catalytic reduction of carvopinone yields l-*trans*-pinocamphone.

4. The method of formation and the structure of some of these compounds have been proposed.

The Oxidizing Power of Illinois Coal. II. The Effects of Extended Time[1]

BY G. R. YOHE[2] AND MYRON H. WILT[2]

Previous work[3] has shown that Illinois coals take on the ability to act as oxidizing agents toward titanous chloride upon exposure to air or oxygen, even for very short periods of time. In the present work, a similar study has been applied to another group of coals with emphasis upon the changes in oxidizing power over longer times of exposure to air.

Preparation of Samples.—The coal samples were obtained in the form of large fresh blocks at the mines, brought to the laboratory as soon as possible, and ground to pass a 100-mesh sieve. No precautions were taken to prevent atmospheric oxidation during the preparation of the samples. After grinding, portions were taken for analyses, and the remaining stocks were placed in 2-quart mason jars and deliberately exposed to air by leaving the covers loose and by occasionally mixing the contents of each jar. The time of exposure to air was measured in days from the date of grinding.

Determination of Oxidizing Power.—The determinations of oxidizing power were made by the titanous chloride–ferric chloride method previously described.[3] Parallel determinations of soluble ferric iron extractable from the coals under similar conditions were made, and the oxidizing power data reported here are corrected for soluble ferric iron. As a rule, the soluble ferric iron values were low compared to total oxidizing power. The results obtained with five whole coal samples are shown in Fig. 1 expressed in milliequivalents per gram of coal dried in contact with laboratory air, but not calculated to a moisture- and ash-free basis. Analytical data for the coals are given in Table I.

Measurement of Specific Surface.—In order to determine whether the variations in magnitude of oxidizing power were due entirely to differences in surface exposed, specific surface measurements were made. The procedure used is an adaptation of the air-permeability method of Lea and Nurse[4] with apparatus constructed according to specifications obtained from Battelle Memorial Institute.[5] Table II gives the results obtained and a comparison of the maximum oxidizing power values per unit surface.

Discussion

The mechanism of the reaction of oxygen with coal is obscure and will doubtless remain so until the chemical nature of coal is more clearly revealed. A number of workers in this field have considered that the initial step is the formation of a "coal-oxygen complex" or an unstable surface

combination.[6-9] Although some assume this to be adsorbed oxygen,[7] others believe it to be chemically combined, since evacuation does not lead to oxygen recovery in the way such treatment of an adsorption complex should do.[10] This "complex" has been referred to as "peroxide,"[8,11,12] yet little is known of its nature or properties.[13] Nevertheless, this loosely bound oxygen is commonly mentioned as an intermediate stage in the atmospheric oxidation of coal.[6,7,8]

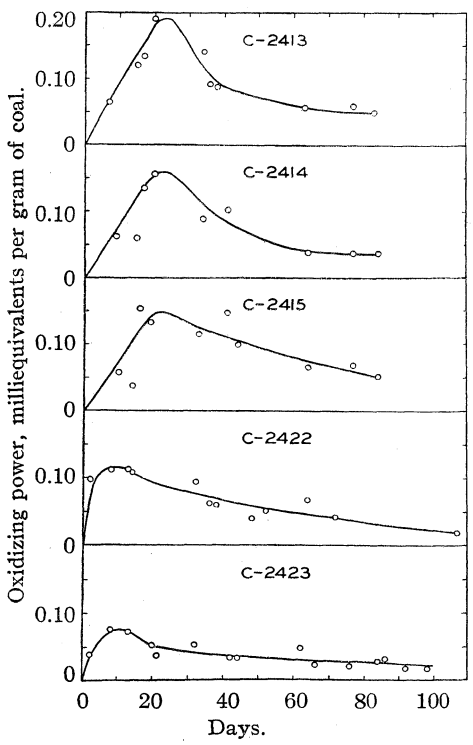

Fig. 1.—Change in oxidizing power with time of exposure to air.

In general form, the curves of Fig. 1 are suggestive of the existence of an intermediate such as B in consecutive reactions of the type

$$A \longrightarrow B \longrightarrow C^{14}$$

Although the atmospheric oxidation of coal is undoubtedly a complex process, the data presented herein may be considered as evidence supporting the hypothesis that loosely held oxygen (perhaps of a peroxide type) constitutes an intermediate stage in a part, at least, of the total change occurring in the oxidative degradation of these coals. It is of interest to note that data for the change in peroxide number of glyceryl trilinolen-

(13) Attempts to demonstrate the presence of peroxides in coal in this Laboratory have given inconclusive results. The common potassium iodide test is rendered valueless because of the avidity with which coal combines with iodine. The chemiluminescent oxidation of magnesium phthalocyanine [Cook, *J. Chem. Soc.*, 1845 (1938); Helberger and Hever, *Ber.*, **72B**, 11–15 (1939)] was tried with magnesium phthalocyanine kindly provided by Dr. R. P. Linstead of Harvard University. This reaction is apparently inhibited by coal; a chlorobenzene solution of tetralin which produced red luminescence ceased to do so when a small amount of powdered coal was added. The use of powdered coals as catalysts in the peroxide-catalyzed side chain chlorination of toluene and the addition of chlorine to the ethylenic double bond [Kharasch and Brown, THIS JOURNAL, **61**, 2142–60, 3432 (1939)] gave results which could be explained without assuming the presence of peroxides. A modification of the Yule–Wilson ferrous sulfate test [Yule and Wilson, *Ind. Eng. Chem.*, **23**, 1254–9 (1931)] gave positive results essentially like those obtained with the titanous chloride method. Although proof of the presence of peroxide structures is lacking, such groups must still be considered as possible causes of the oxidizing power observed.

ate[15] and of a soybean oil[16] give curves similar to those shown in Fig. 1.

There is no apparent correlation between the magnitude of the oxidizing power and properties within the group of coals having high-volatile C bituminous rank. It will be seen, however, that the one coal of higher rank (C-2423) exhibits a definitely lower oxidizing power per unit surface. It seems obvious from Table II that the magnitude of oxidizing power attained is not simply a function of the extent of the surface, but that the nature of the surface (which undoubtedly varies with the rank and source of the coal) is of utmost importance in this respect. It is hoped that this investigation may be extended to cover a series of coals of widely differing ranks.

It is possible that the different petrographic or "banded" ingredients of the coal may differ in their ability to take on oxidizing power. Such differences, as well as errors in sampling, might contribute to the irregularities in the curves. The present study is being continued with samples of separated banded ingredients of an Illinois coal.

Acknowledgment.—The authors wish to extend their thanks to Drs. F. H. Reed and O. W. Rees for valuable suggestions; to Mr. C. C. Boley for assistance in collecting samples and to Mr. K. F. Bursack and Mr. W. F. Wagner who made the coal analyses and specific surface measurements under the direction of Dr. Rees.

Summary

The oxidizing power exhibited by five Illinois coals has been shown to reach a maximum value and then decrease, suggesting that this "reactive oxygen" may play the role of an intermediate in the oxidative degradation of these coals.

The Oxidation of *n*-Butylboron Oxide[1]

BY OLIVER GRUMMITT

The reported[2] auto-oxidation of *n*-butaneboronic acid (n-BuB(OH)$_2$) to the mono-*n*-butyl ester of boric acid (n-BuO-B(OH)$_2$) suggested a parallel study of the auto-oxidation of *n*-butylboron oxide, (n-BuBO)$_3$, which is the trimeric anhydride of the boronic acid. This oxidation, because of the six-electron configuration of the boron atom, offered the possibility of proceeding through the intermediate formation of an oxygen coördination compound (or peroxide) comparable to those postulated for many oxidation processes.[3]

Preliminary measurements[4] on several alkylboron oxides showed that oxidation occurred readily but at widely different rates depending upon the nature of the alkyl group (Table I).

TABLE I

R of R–BO	Time required for the consumption of 2.0 cc. oxygen, 25°, min.
Et	33
n-Pr	36
n-Bu	71
s-Bu	3
t-Bu	2
n-Hex	105

Apparently the ease of oxidation decreases with an increasing chain length of the alkyl group and increases sharply in the order primary, secondary, and tertiary. The relative stability of the corresponding boronic acids in air is also of this order.[2,5]

Experimental Procedure

Apparatus.—The reaction flask is shown in Fig. 1. The total volume of this two-bulb flask is approximately 125 cc. and since none of the dimensions is of critical importance, they are not shown. Connected to the side arm of the flask are two mercury-filled gas burets in series. The first of these burets was made of a 10-cc. delivery pipet calibrated in divisions of 0.05 cc. and a three-way stopcock and was used to measure the consumption of oxygen during the earlier stages of the reaction. The second buret was the orthodox 100-cc. type with 0.2-cc. divisions. Each gas buret was fitted with a leveling bulb and a jacket through which thermostated water could be circulated. The use of two burets permitted accurate readings at the start of the auto-oxidation when an induction

(5) Johnson, Van Campen and Grummitt, THIS JOURNAL, **60**, 111 (1938); and unpublished work of Johnson and Grummitt.

period might be present and also allowed total volumes of oxygen up to about 100 cc. to react and be measured with fair accuracy.

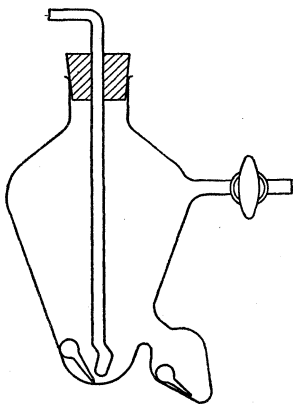

Fig. 1.—Reaction flask.

A small sample of the alkylboron oxide contained in a sealed ampoule made in the shape of a bulb with a fine capillary stem was placed stem-down in the bottom bulb of the reaction flask. A similar ampoule, tared and empty, was placed stem-down in the side bulb. The reaction flask and burets were very carefully dried and filled with dry oxygen so that the small buret contained about 7–8 cc. of gas, the large buret about 70 cc. of gas. The gas buret stopcocks were open to the flask and the leveling bulbs were adjusted so that atmospheric pressure existed in the whole system. The temperature of the system was maintained at 25° by circulating water from a thermostat through the buret jackets and through a container surrounding the flask. When the buret readings no longer changed over a ten-minute period showing that the enclosed gas had reached constant temperature, the stopcock on the large buret was shut off from the reaction flask. The bent rod in the reaction flask was twisted so as to smash the ampoule against the wall of the flask and the time was noted. Frequent adjustments of the leveling bulb on the small buret were made in order to maintain atmospheric pressure and readings were taken at the same time. When 2–5 cc. of oxygen had been consumed, the small buret was shut off and the large buret, by means of its stopcock, was opened to the reaction flask and occasional time–volume readings were made.

When the sample was completely oxidized as shown by a constant volume reading after a period of one-half hour, the stopcock at the connection between the flask and the first buret was closed and the rubber connection removed from the buret. The flask was connected to a vacuum pump through an arrangement of stopcocks which permitted the flask to be evacuated and then filled with dry, oxygen-free nitrogen without opening the flask to the atmosphere. The flask was thoroughly evacuated and rinsed with nitrogen four times while clamped in a vertical position. It was then tilted so that the product drained into the side-bulb, re-evacuated, and again filled with nitrogen. As the pressure approached atmospheric the liquid product filled the empty, tared ampoule. This was then removed, sealed by touching the tip in a flame, and, after weighing, was ready for analysis, molecular weight determination, etc.

The flask shown in Fig. 1 may be useful for other reactions where the reactants are gases and liquids which cannot be exposed to the atmosphere and where the product is also a liquid which cannot be exposed. A somewhat similar device described by Stock and Zeidler[6] does not permit the product to be removed in an ampoule.

(6) Stock and Zeidler, *Ber.*, **54**, 533 (1921).

Relative Oxidation Rates.—Samples of the various alkyl boron oxides listed in Table I were prepared by dehydration of the corresponding boronic acids with thionyl chloride.[2] A 0.2–0.3 g. (about 3.0 millimoles) sample was oxidized in the apparatus described above and the time noted for the consumption of 2.0 cc. of oxygen at 25°. Duplicate determinations were made. In each case there was practically no induction period so the data show in an approximate way the relative reactivity of the various compounds with respect to oxygen.

Oxidation of *n*-Butylboron Oxide.—A 0.2060-g. (2.46 millimoles) sample of *n*-butylboron oxide was quantitatively oxidized in the apparatus previously described. Volume readings were taken at two-minute intervals for the first eighteen minutes, at three-minute intervals for the next thirty-five minutes, and then at longer intervals until no more oxygen was consumed. These data are plotted in Fig. 2. As the curve shows there is no induction period. At the end of 800 minutes 31.5 cc. of oxygen had been consumed as compared to a theoretical consumption of 31.6 cc. (at 25° and 735 mm. pressure) based on the oxidation of *n*-butyl boron oxide to *n*-butyl metaborate (Eq. 1).

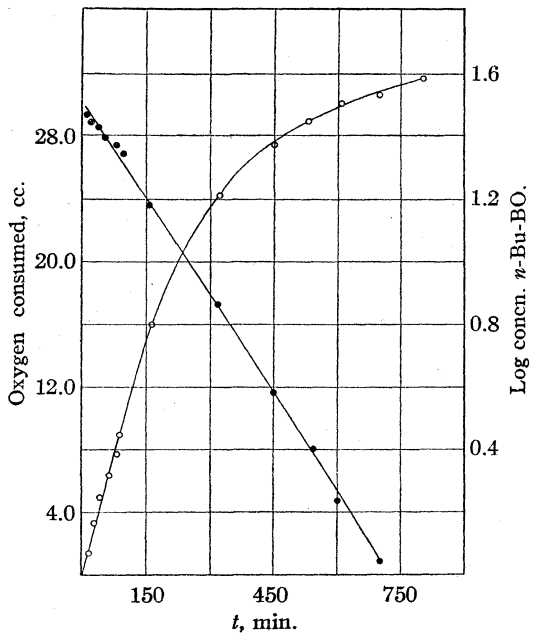

Fig. 2.—Oxidation of *n*-butylboron oxide.

The product from the oxidation of 0.6 g. of *n*-butylboron oxide was distributed into tared ampoules. The saponification equivalent of one of these samples was found to be 98.6; calculated for *n*-C_4H_9OBO, 99.9. A molecular weight determination by freezing point depression in benzene gave 97.6. This determination was very difficult because of the great ease of hydrolysis of the sample; not only must the apparatus and benzene be absolutely dry, but it must be so maintained by slowly passing dry nitrogen into one sidearm of the freezing point tube so as to prevent any air from entering while stirring.

One sample of the ester was hydrolyzed by the dropwise addition of water; some heat was generated and the odor

of *n*-butyl alcohol was apparent. A neutralization equivalent of the boric acid formed was determined by adding mannitol and titrating with standard sodium hydroxide in the presence of phenolphthalein; found 61.5, calculated 61.8. Another sample was hydrolyzed with a slight excess of water, distilled, and the *n*-butyl alcohol identified as the 3,5-dinitrobenzoate derivative, m. p. 63–64°, no depression in a mixed m. p. with an authentic sample.

Anal.[2] Calcd. for $C_4H_9BO_2$: B, 10.83. Found: B, 11.05.

Peroxide Tests.—Partially oxidized samples of *n*-butylboron oxide instantly liberated iodine from a slightly acidified solution of 5% potassium iodide in absolute ethanol. Further evidence that peroxides or peroxide-like compounds may be present was obtained by heating three 10-cc. portions of vinyl acetate on the water-bath at 70°; the first sample contained no catalyst, the second contained about 0.1 g. of partially oxidized *n*-butylboron oxide, and the third contained 0.1 g. of benzoyl peroxide. At the end of one-half hour the increase in viscosity, interpreted roughly as a measure of polymerization, was small for the blank, appreciable for the second, and very considerable for the third. It is possible of course that the partially oxidized butylboron oxide furnished other catalytic agents besides peroxides.

Catalytic Oxidation of *n*-Butylboron Oxide.—Samples containing approximately 0.1% of the catalyst were made by distilling *n*-butylboron oxide at reduced pressure into receivers containing inverted tared ampoules and a weighed portion of the catalyst. Before letting nitrogen into the system the receivers were gently warmed to dissolve the catalyst. Both hydroquinone and phenyl-β-naphthylamine dissolved readily, but cobalt linoleate and ammonium vanadate were only partially soluble. Nitrogen was admitted and the ampoules sealed and weighed in the usual way. These samples were then oxidized according to the procedure described before. The samples containing hydroquinone, cobalt linoleate, and ammonium vanadate gave time–oxygen consumed curves which substantially duplicated that shown in Fig. 2, but phenyl-β-naphthylamine inhibited the oxidation; for example, in 200 minutes only 1.2 cc. of oxygen had been consumed compared to 15.0 cc. in the absence of the catalyst and at the end of 13.5 hours where the oxidation normally would be completed only 10% of the theoretical amount of oxygen had been consumed.

Results and Discussion

Oxidation of *n*-butylboron oxide was found to proceed quantitatively according to the equation

$$(n\text{-BuBO})_3 + 1^1/_2O_2 \longrightarrow 3\text{BuO-BO} \qquad (1)$$

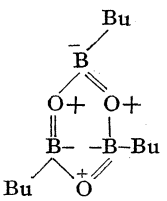
the product being the *n*-butyl ester of metaboric acid. This substance is an oily liquid with a faint ester odor. Like esters of boric acid it hydrolyzes immediately on contact with the atmosphere forming *n*-butyl alcohol and a mixture of metaboric and boric acids.[7]

(7) Schiff, *Ann.*, *Supp.*, **5**, 185 (1867), reported similar properties for methyl and ethyl metaborates which were prepared by the action of boric acid on the alkyl borate or alcohol.

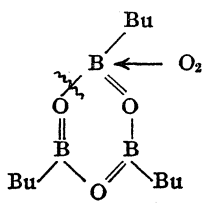
Since *n*-butyl metaborate is monomeric,[8] the oxidation process has been accompanied by a depolymerization reaction. The failure of *n*-butyl metaborate to retain the trimeric structure of *n*-butylboron oxide is probably due in part to the contribution of resonating forms such as I[9] in which the boron atom can no longer function as an acceptor center.

I

This function is necessary in order that the boron atom coördinate with oxygen to form the trimeric butylboron oxide[2,10,11]



The course of the oxidation of *n*-butylboron oxide is shown in Fig. 2, in which the volume of oxygen consumed is plotted against time. The shape of this curve differs from typical S-shaped auto-oxidation curves for benzaldehyde, linseed oil, etc.,[3] in that the induction period[12] is absent. This probably means that the concentration of peroxidic intermediate necessary for an appreciable rate of oxidation is established very rapidly. This intermediate could arise through the attack of a boron atom by oxygen with subsequent cleavage of the ring (2); the peroxide could then



$\longrightarrow$ Bu-BO(O₂) + 2Bu-BO[13] (2)

(8) Metaboric acid itself has been reported to be monomeric; Mellor, "Comprehensive Treatise of Inorganic Chemistry," Longmans, Green, and Co., New York, N. Y., 1924, Vol. 5, p. 48.

(9) Other resonating forms include *n*-Bu:Ö:B::Ö, *n*-Bu:Ö::B:Ö:⁻, and *n*-Bu:Ö:B:::Ö⁺. In the absence of bond length data the principal form cannot be selected, although ordinary valence considerations favor the first of these.

(10) Kinney and Pontz, THIS JOURNAL, **58**, 197 (1936), found that certain arylboric oxides are trimeric.

(11) Burg, *ibid.*, **62**, 2228 (1940), found that methylboric oxide is trimeric.

(12) The initial period of time in which the rate of oxygen absorption is zero or very low.

(13) An alternative initial step could involve peroxide formation from the action of oxygen directly on monomeric butylboron oxide if one assumes an equilibrium: (Bu-BO)₃ ⇄ 3Bu-BO. There is no evidence, however, for this dissociation.

oxidize monomeric butylboron oxide to form the metaborate in a reaction analogous to the interaction of benzoyl hydrogen peroxide with benzaldehyde to give two molecules of benzoic acid (3).

$$\text{Bu-BO}(O_2) + \text{Bu-BO} \longrightarrow 2\text{BuO-BO} \quad (3)$$

Some evidence in support of the intermediate peroxide is gained from experiments with partially oxidized butylboron oxide which show that it liberates iodine from alcoholic potassium iodide and catalyzes the polymerization of vinyl acetate as do other peroxides.

Efforts to establish a reaction mechanism on the basis of kinetic measurements were unsuccessful. When a sample of *n*-butylboron oxide was exposed to oxygen without agitation, the rate of oxygen absorption followed the unimolecular law as shown by the straight line in Fig. 2 obtained by plotting the logarithm of the concentration of *n*-butylboron oxide against time. The concentration of *n*-butylboron oxide was determined on the basis of the oxygen consumed in accordance with equation (1). This agreement with the unimolecular law is superficial, however, because mechanical agitation of the reaction mixture in other experiments not only increased the rate of oxidation but gave data which could not be interpreted kinetically. Apparently the rate of diffusion of unoxidized material to the surface of the reaction mixture is the rate-determining step in the absence of agitation.

The effect of catalysts on the rate of oxidation was observed in experiments with cobalt linoleate and ammonium vanadate as positive catalysts, and hydroquinone and phenyl-β-naphthylamine as typical anti-oxidants. The only one of these catalysts which had an appreciable effect on the rate of oxidation was phenyl-β-naphthylamine, which inhibited the reaction almost completely. It is interesting to note that aromatic amines are more effective anti-oxidants than phenols for aliphatic aldehydes.[14] This is a further point of resemblance between the alkylboron oxides (or boronic acids) and aliphatic aldehydes, Johnson, *et al.*,[2] having already pointed out that both types of compounds combine with oxygen, reduce ammoniacal silver oxide, and form cyclic trimers.

Summary

n-Butylboron oxide undergoes quantitative oxidation and depolymerization in the presence of dry oxygen to form monomeric *n*-butyl metaborate. There is evidence for the intermediate formation of a peroxidic substance. A possible reaction mechanism has been suggested, but could not be confirmed by rate measurements because the kinetics were complex. Phenyl-β-naphthylamine retards the oxidation but hydroquinone does not.

The Electrochemical Properties of Mineral Membranes. V. Beidellite Membranes and the Determination of Sodium[1]

BY C. E. MARSHALL[2] AND C. A. KRINBILL[2]

Introduction

Previous papers in this series[3] have dealt with the use of preheated montmorillonite membranes in the potentiometric determination of potassium and ammonium and with the application of this method to the electrochemical study of colloidal systems as typified by the clays. The hydrogen montmorillonite membranes used were preheated to 490°. This treatment conferred remarkable properties of stability and selectivity. The membranes were of high resistance (1–10 megohms), yet showed excellent reproducibility toward potassium and ammonium ions. Acids attacked them chemically and highly reproducible values could only be obtained at *p*H values above 4. Sodium salts alone gave poor reproducibility and asymmetry potentials were troublesome. However, mixtures of sodium and potassium salts measured against potassium chloride as standard gave values which suggested that the

(2) Associate Professor and Research Assistant in Soils, respectively.

(3) Marshall and Bergman, THIS JOURNAL, **63**, 1911 (1941); *J. Phys. Chem.*, **46**, 52 (1942); **46**, 325 (1942).

membrane was definitely sensitive to sodium ions and that both the mobility and the activity of the sodium were concerned in the establishment of the potential difference. These membranes possessed also the remarkable property of being insensitive to divalent and trivalent cations.

In an attempt to improve the conditions for the potentiometric estimation of sodium, W. E. Bergman in this Laboratory prepared hydrogen montmorillonite membranes (Wyoming bentonite, electrodialyzed fraction $< 0.2\ \mu$) preheated to 350°. These were found to lose their asymmetry potentials readily on soaking in N sodium chloride solution and then in 0.1 N solution. They gave potentials, for concentrations below 0.1 N, which agreed well with those calculated from the Nernst equation.

It was later found that these 350° membranes have quite different properties of ionic selectivity than those heated to 490°. They have a much lower resistance when wet, 5–20,000 ohms as against 1–10 megohms for the latter. They are sensitive to divalent cations as well as to monovalent. Hence their ionic behavior is qualitatively similar to that of chabazite and apophyllite membranes.[4] They have the advantages over the latter of easier preparation, of greater reproducibility and of lower resistance. However, a distinctly selective character is still present. Unlike the beidellite membranes described below, they are not sensitive to trivalent cations such as cerium.

In an attempt to secure even greater reproducibility toward sodium, membranes were prepared from another clay mineral, colloidal beidellite.[5] These membranes, whose preparation and properties are herein described, act as general cationic membranes. By their use we can look forward to the estimation of monovalent, divalent and possibly trivalent cations in pure solution. The present contribution is concerned chiefly with sodium. The application to calcium and other polyvalent cations will be considered in a later communication.

Experimental

Preparation of Membranes.—The beidellite membranes were prepared using essentially the same procedure as has been described for those of montmorillonite. The starting point was the heavy subsoil or B horizon of the Putnam silt loam soil taken from an experimental field at Moberly, Missouri. This is a calcium–hydrogen soil containing little organic matter. After treatment with hydrogen peroxide to remove the organic matter, the soil suspension in water was dispersed by adding sodium hydroxide to a *p*H of 7. The clay fraction was decanted after standing for twenty-four hours or more, and was then passed through a Sharples supercentrifuge running at 30,000 r. p. m., at such a rate of flow that all particles larger than 0.2 μ in equivalent spherical diameter were retained. The suspension of $< 0.2\ \mu$ clay which passed on was then concentrated by electrodialysis, the process being continued until all sodium and calcium were removed. The electrodialyzed clay was then diluted to 1–2% concentration. It was dispersed by being mechanically stirred for fifteen minutes at high speed and was then boiled to remove dissolved air. The hot suspension was poured into a shallow copper tray which had previously been rubbed over with a cloth saturated with neutral mineral oil. Evaporation was effected at about 80° by heating from above with an electric radiator. In this way a layer of suspension 1–2 cm. in depth evaporates to dryness and leaves a clay film 0.2–0.3 mm. in thickness which readily can be removed. This film consists of the mineral beidellite,[6] a clay of the montmorillonite group, but having a somewhat lower base exchange capacity than montmorillonite itself.

The beidellite film is less flexible than that of montmorillonite and, instead of using a cork borer, the membrane disks are prepared by breaking off corners from irregular fragments. They show some tendency to split or cleave parallel to the surface. They were mounted on the ground ends of 8-mm. Pyrex tubing with hard de Khotinsky cement or pliocene. Once mounted they showed remarkable stability and on soaking for only a few hours in salt solutions the asymmetry potentials disappeared. Over 90% of the membranes thus prepared gave reproducible potentials close to the anticipated values. Deviations of 1 millivolt were rarely found. Differences between individual membranes were most marked in the more concentrated and in the very dilute solutions.

The potentials were determined using saturated calomel electrodes with agar bridges on each side of the membrane. A known solution was placed inside the tube as standard. In some cases a silver chloride electrode was used with a standard chloride solution inside the membrane tube and a saturated calomel cell in the outer solution.

Special care was taken to make the liquid junction potentials as small and reproducible as possible. It was found, for instance, that a liquid junction potential of several millivolts could arise when a saturated calomel electrode with upturned agar tip was transferred from one solution of a sodium salt to another of different concentration. The reason for this was that in the first solution some potassium chloride was lost by diffusion and replaced by a more dilute mixture of potassium and sodium salts. This gave a junction potential against a second sodium salt solution; it diminished with time as more potassium chloride diffused toward the tip.

In making the final measurements, therefore, a calomel

(4) Marshall, *J. Phys. Chem.*, **43**, 1155 (1939).

(5) The preparation and properties of clay films were first described by Hauser and le Beau [*ibid.*, **42**, 961 (1938)], who used bentonite clay.

(6) Marshall, *Zeitschr. Kryst.*, **A90**, 8 (1935); **A91**, 433 (1935); Marshall, *J. Phys. Chem.*, **41**, 935 (1937).

cell was always used whose tip had been for some time in contact with saturated potassium chloride solution. A Leeds and Northrup thermionic amplifier was used in conjunction with a calibrated "student" type potentiometer and individual measurements were made to 0.1 millivolt. The amplifier could be dispensed with where the total resistance was less than 20,000 ohms. The resistances were determined approximately by applying a known voltage and measuring the current.

Comparison of Membranes.—The qualitative characteristics of membranes prepared in different ways are given in Table I.

It is evident that the effect of heat on the membrane characteristics is quite different for the two minerals. Further work will be needed to establish the exact causes of these differences in sensitivity to different cations.

In making quantitative comparisons of different membranes it is necessary to use a single salt such as potassium chloride. For details of the graphical method employed see ref. 3.

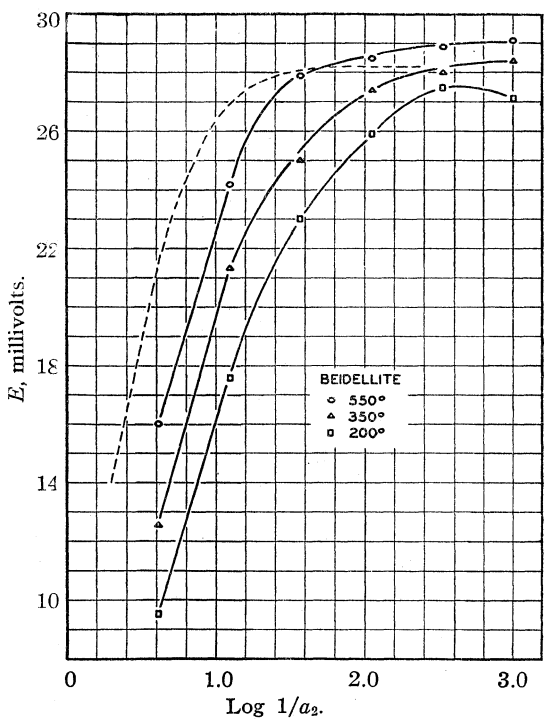

Fig. 1.—Experimental curves obtained with electrodialyzed beidellite membranes dried to various temperatures using potassium chloride solutions with an activity ratio $a_1/a_2 = 3$. The broken line is the theoretical curve for $Uc/U_A = 1$ and $A = 1$, A being the effective charge per unit volume of the membrane.

It will be seen from Fig. 1 that the beidellite membranes give curves lying farther to the right than those previously obtained with 490° montmorillonite.[3] This indicates a smaller ionic charge per unit volume, approximately 0.5 for the 550° beidellite whereas the 490° montmorillonite was 1.0. This is probably to be accounted for by the lower exchange capacity of the beidellite. In consequence, agreement within 1 millivolt with the Nernst equation can only be expected for solutions less concentrated than $N/30$. Even with this limitation the beidellite membranes are to be preferred over the 350 or 490° montmorillonite membranes where both can be used for the same ion. The beidellite membranes come to equilibrium with fresh solutions much more rapidly (within a few minutes, instead of after several hours), the initial asymmetry potentials disappear more rapidly on soaking, and the individual differences between membranes are smaller. This last point can perhaps best be seen by a comparison of typical numerical results for montmorillonite and beidellite membranes (Table II).

TABLE I

CHARACTERISTICS OF CLAY MEMBRANES PREPARED IN VARIOUS WAYS

Exchangeable cation	Temp. of pretreatment, °C.	Approximate resistance (megohms) Wet	Dry[a]	Cations to which sensitive
		Montmorillonite		
H	350	0.005–011	200	Mono-, divalent
H	490	1–10	400	Monovalent
H	550	Very low	...	None
		Beidellite		
H	110	0.005	3	Mono-, di-, trivalent
H	600	0.012	15–45	
H	750	0.015		
H	900	>1000	>1000	

[a] Dry indicates an atmosphere of 50% relative humidity.

TABLE II

COMPARISON OF INDIVIDUAL POTENTIALS FOR 350° MONTMORILLONITE AND 550° BEIDELLITE MEMBRANES IN SODIUM CHLORIDE SOLUTIONS AT 25°. THEORETICAL NERNST POTENTIAL IS 28.2 MILLIVOLTS

Activity ratio a_1/a_2	350° Montmorillonite 1	2	3	4	5
0.7101/0.2367	16.2	15.3	18.1	17.1	16.4
.2367/ .0789	23.0	20.5	24.2	22.9	22.0
.0789/ .0263	27.1	26.5	27.0	27.7	27.0
.0263/ .0088	29.0	28.1	28.4	29.2	28.9
.0088/ .0029	26.5	26.5	27.3	27.1	26.7
.0029/ .0010	27.6	27.2	27.1	27.6	27.3
	550° Beidellite				
0.7107/0.2367	16.3	16.0	15.8	16.7	16.6
.2367/ .0789	23.4	23.9	24.8	25.5	25.6
.0789/ .0263	27.5	27.2	27.6	27.6	27.5
.0263/ .0088	28.3	28.2	28.8	28.6	28.5
.0088/ .0029	28.4	28.3	28.4	28.3	28.3
.0029/ .0010	27.9	27.7	28.5	28.0	28.4

In Fig. 2 the results for sodium chloride solutions are presented, using the same 1:3 ratio of cationic activities as for potassium chloride in Fig. 1. It can be seen that the 550° beidellite membranes are superior both to the 750° beidellite and the 350° montmorillonite membranes.

Comparison of Different Sodium Salts.—Table III gives the mean potentials obtained for beidellite membranes with sodium salts. At least six membranes were used in each case. The standard solution used throughout was 0.1 *N* sodium chloride which gives an activity a_1 of 0.0789.

TABLE III

MEAN POTENTIALS OBTAINED WITH BEIDELLITE MEMBRANES IN SODIUM SALT SOLUTIONS (a_1 = 0.0789 Na^+)

Temp. of pretreatment, °C.	Salt	Activity of Na^+ in a_2	Observed potential, mv.	Calcd. potential, mv.
550	NaCl	0.0266	27.5	27.9
	NaCl	.00864	56.8	56.8
	NaCl	.00292	83.7	84.7
	NaCl	.00091	111.4	113.0
630	NaCl	.0263	27.5	28.2
	NaCl	.00877	56.1	56.4
	NaCl	.00292	83.7	84.7
	NaCl	.00097	111.2	112.9
550	Na_2SO_4	.0386	18.8	18.4
	Na_2SO_4	.00915	55.5	55.4
	Na_2SO_4	.00458	72.9	73.2
630	Na_2SO_4	.0386	18.5	18.4
	Na_2SO_4	.00915	55.2	55.4
	Na_2SO_4	.00458	72.9	73.2
550	Na citrate	.0395	21.2	17.8
	Na citrate	.00875	58.3	56.5
	Na citrate	.00452	75.4	73.5
630	Na citrate	.0395	21.0	17.8
	Na citrate	.00875	57.6	56.5
	Na citrate	.00452	74.6	73.5
610	$Na_4Fe(CN)_6$	.0410	16.8	16.8
	$Na_4Fe(CN)_6$	.00916	55.1	55.9
	$Na_4Fe(CN)_6$	.00475	71.2	72.1

Excellent agreement is found except in the case of the more concentrated solutions of sodium citrate where the experimental values are consistently high. It does not appear that this can be due to the high valence of the anion, since ferrocyanide gives almost perfect values. However, it has been shown[7] that sodium citrate solutions give low osmotic pressures at concentrations above 25 millimoles per liter. It seems logical, therefore, to assume that the activity of part of the sodium is reduced by some kind of complex formation.

(7) Adie, *J. Chem. Soc.*, **59**, 344 (1891).

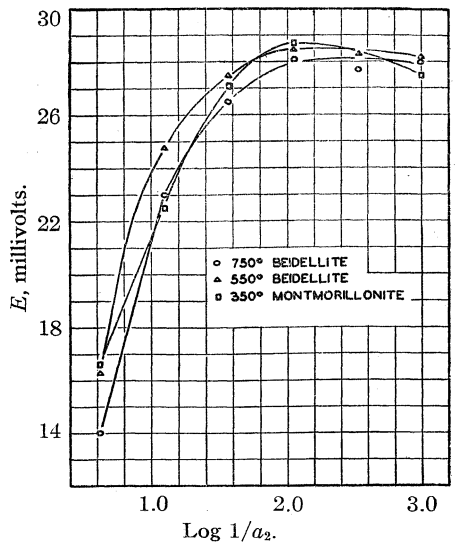

Fig. 2.—Experimental curves obtained with different membranes using sodium chloride solutions with an activity ratio $a_1/a_2 = 3$.

The Behavior of Cationic Mixtures.—In Part I[3] it was pointed out that the potentials established when a potassium salt is present on one side of the membrane and a sodium salt on the other may depend on the relative mobilities of the cations as well as on their activities. The exact relationship may be derived in two ways.

(1) In the range over which the membrane gives Nernst potentials for single salts, we can start out from the general Henderson equation for a liquid junction potential and incorporate the simplifying assumption that the mobility of the anions is negligible compared with that of the cations. For instance, with potassium chloride on one side of the membrane and a mixture of potassium and sodium chlorides on the other, the potential is given by the equation

$$E = \frac{RT}{F} \ln \frac{U_K a'_K}{U_K a''_K + U_{Na} a''_{Na}} \qquad (1)$$

If sodium chloride alone is present on one side of the membrane this reduces to the form

$$E = \frac{RT}{F} \ln \frac{U_K a'_K}{U_{Na} a''_{Na}} \qquad (2)$$

Here the mobilities, represented by U_K and U_{Na} are those of the respective cations within the membrane. These values are not necessarily those of the cations in pure water.

Using the Henderson equation as the starting point, more general cases can be dealt with. If the cation x accompanying potassium on the one side of the membrane has a valence n, then the equation becomes

$$E = \frac{RT}{F} \frac{U_K a''_K + U_x a''_x - U_K a'_K}{U_K a''_K + n U_x a''_x - U_K a'_K} \ln \frac{U_K a'_K}{U_K a''_K + n U_x a''_x} \quad (3)$$

and when there is only the polyvalent cation x on one side and potassium on the other, this reduces to

$$E = \frac{RT}{F} \frac{U_x a''_x - U_K a'_K}{n U_x a''_x - U_K a'_K} \ln \frac{U_K a'_K}{n U_x a''_x} \quad (4)$$

(2) An expression covering also the higher concentrations for which Nernst potential is not attained has been derived for binary salts by Meyer and Sievers.[8] In this equation the effective charge A of the membrane and the solubilities of the two salts in the membrane are additional variables. For those cases in which A is large compared with the cationic activities and in absence of solubility changes this equation reduces to the same form as (2) above.

These equations lend themselves readily to experimental verification and by their use the ratios of the mobilities of the cations within the membrane may be determined. For monovalent ions the most accurate procedure is to determine the mobility ratio under the conditions of Eq. 2 with one electrolyte on each side of the membrane. The validity of Eq. 1 may then be tested with mixtures using the determined value of the mobility ratio. It will be seen from Eq. 4 that for polyvalent cations the conditions are less favorable. However, if the activity of the monovalent ion is small compared with that of the polyvalent ion a satisfactory value of the mobility ratio should be obtained.

In Table IV, several determinations with monovalent cations are assembled. From the potentials the mobility ratios were calculated and these display reasonable constancy. Some variation of the mobility ratio with concentration might be expected. However, in Table IV the range covered runs only from about $N/30$ downward and the figures show no definite trend. In pure aqueous solutions also the variation in transport number is small for concentrations below $N/20$.

Values of the mobility ratios obtained are used in Table V in order to compare the experimental with the theoretical potentials.

The use of the mean mobility ratios U_{Na}/U_K and U_{Na}/U_H lead to excellent agreement between the observed and calculated potentials when measurements are made with a pure salt solution on one side of the membrane and a mixture on the other.

TABLE IV

DETERMINATION OF CATIONIC MOBILITY RATIOS WITHIN THE MEMBRANES

Membrane temp., °C.	Cations and activities Inside a_1		Outside a_2		Potential, mv.	Mobility ratio U_2/U_1
			Beidellite

550	K^+	.0270	Na^+	.0263	26.1	.371
630	K^+	.0270	Na^+	.0263	24.5	.396
600	K^+	.0270	Na^+	.00877	53.7	.372
600	K^+	.0270	Na^+	.00292	78.2	.430
600	K^+	.0090	Na^+	.00877	25.4	.395
600	K^+	.0090	Na^+	.00292	51.5	.409
			Mean value U_{Na}/U_K =			.392
610	Na^+	.00877	H^+	.000068	72.4	.130
610	Na^+	.00877	H^+	.000135	55.4	.134
610	Na^+	.00877	H^+	.000851	5.0	.119
			Mean value U_{Na}/U_H =			.128

(8) Meyer and Sievers, *Helv. Chim. Acta*, **19**, 649 (1936).

TABLE V

POTENTIALS OBTAINED WITH MIXTURES OF CHLORIDES OF MONOVALENT CATIONS, BEIDELLITE MEMBRANES

Membrane temp., °C.	Cations and activities Inside			Outside			Potential, mv. Observed	Calcd.
600	K^+	0.0270	K^+	0.00095	Na^+	0.00095	76.9	77.3
550	K^+	.0270	K^+	.00095	Na^+	.00095	77.0	77.3
630	K^+	.0270	K^+	.00095	Na^+	.00095	76.6	77.3
630	K^+	.0270	K^+	.00884	Na^+	.00443	23.4	24.0
630	K^+	.0270	K^+	.00442	Na^+	.00877	31.5	31.5
610	Na^+	.00877	Na^+	.00097	H^+	.000068	46.9	45.3
610	Na^+	.0877	Na^+	.00097	H^+	.000891	3.5	2.8

It is evident from the foregoing that the simple type of Nernst formula used in calculating the clay titration curves in Parts II and IV is inadequate. However, the difference in actual result between it and the correct expression involving the mobility ratio is negligible, except for those first additions of potassium or ammonium hydroxide which bring the clay to a *p*H below 4.5.

Acknowledgment.—The authors are indebted to the Research Council of the University of Missouri for a grant-in-aid which has made this work possible.

Summary

1. Clay membranes have been prepared which are sensitive only to monovalent cations (H-montmorillonite 490°); to monovalent and divalent cations (H-montmorillonite 350°); and to mono, di and trivalent cations (H-beidellite 600°).

2. For sodium estimations, beidellite membranes gave excellent reproducibility. The potentials obtained with solutions less concentrated than 0.03 N were within 1 millivolt of those calculated using the Nernst equation.

3. Sodium chloride, sulfate and ferrocyanide gave practically the theoretical potentials whereas low values were obtained with sodium citrate. This is ascribed to complex formation.

4. The behavior of mixtures of cations can be predicted and the mobility ratios of the cations within the clay membranes have been determined experimentally in certain cases. Using these values, the experimental and theoretical potentials for mixtures of cations are found to be in good agreement.

Crystal-Chemical Studies of the Alums. IV. Coefficients of Linear Thermal Expansion[1]

BY HAROLD P. KLUG AND LEROY ALEXANDER

In the systematic study of the crystal chemistry of the alums now in progress in this Laboratory, as many as possible of the physical and chemical properties of their crystals are being investigated. The only thermal expansion data on the commoner alums seem to be the somewhat uncertain results of Spring,[2-4] who determined the change in density with temperature for several alums, and calculated the volume changes therefrom. Spring concluded that his earlier values[2,3] were vitiated by partial dehydration of the alums and repeated the measurements.[4] He was unwilling, however, to claim that his final results solely expressed the volume change brought about by thermal expansion because of the possibility of some dissociation of the hydrates with increasing temperature.

In view of the uncertainty of these results, and of the ease with which such measurements can be made by means of X-ray diffraction, it seemed desirable to determine the coefficients of expansion of a few alums by the X-ray technique. Since the characteristic powder diffraction pattern of the alums is particularly sensitive to the effects of dehydration,[1] the X-ray method presents an important advantage over the pyknometric and dilatometric methods. This communication presents the results of such measurements, for the approximate temperature range 20 to 50°, on the following alums: $KAl(SO_4)_2 \cdot 12H_2O$, $NH_4Al(SO_4)_2 \cdot 12H_2O$, $TlAl(SO_4)_2 \cdot 12H_2O$ and $NH_4Cr(SO_4)_2 \cdot 12H_2O$.

Experimental

The potassium and ammonium alums used were from lots prepared for a previous study.[5] The thallium alum was a sample prepared by Dr. N. O. Smith,[6] and presented by Professor J. E. Ricci for an earlier study.[1] The ammonium chrome alum was the reagent grade salt used without further purification.

The experimental technique followed was that of Straumanis and co-workers,[7] which involves precision determination of the lattice constants at two different temperatures by thermostating the camera. Details of the thermostat and X-ray technique have been described previously.[5,7] FeK radiation was used throughout the study except in the case of the chrome alum where CrK radiation was used.

Results

The mean coefficient of linear thermal expansion α, the average increase per unit length per degree centigrade, can be obtained from the expression

$$\alpha = \frac{a_{t_2} - a_{t_1}}{a_{t_1}(t_2 - t_1)}$$

where a_t is the lattice constant at the corresponding temperature t.

The results of the study are tabulated in Table I. For each alum the temperatures and corresponding lattice constants of the separate determinations are listed together with the mean value of $\alpha \cdot 10^6$ obtained by using all possible combinations of lattice constants separated by at least a 25° interval. The error is expressed as the probable error of the mean.

Spring gives no data which can be compared directly with the values of α in Table I. When his best data[4] are recalculated, they lead to the follow-

52.2	12.1373	51.4	12.2179	51.1	12.2093		
$\alpha \cdot 10^6 = 11.0 \pm 0.3$		$\alpha \cdot 10^6 = 9.5 \pm 0.2$		$\alpha \cdot 10^6 = 13.1 \pm 0.3$		$\alpha \cdot 10^6 = 10.6 \pm 0.4$	

ing values of $\alpha \cdot 10^6$ for the first three alums listed above: 3.3, 6.8 and 18.3, respectively. These values are of the right order of magnitude but, otherwise, are in poor agreement with the X-ray values. No data are available for comparison with the result for ammonium chrome alum.

Potassium chrome alum was also studied at this same time but the inability, after numerous attempts, to get photographs in the vicinity of 50° without dehydration led to its abandonment.

The authors wish to express their thanks and appreciation to Dr. N. O. Smith and Professor J. E. Ricci for the sample of thallium alum. They also wish to acknowledge with gratitude a grant from the Graduate School of the University of Minnesota under which this study was carried out.

Summary

The linear thermal expansion coefficients α for several alums have been measured for the approximate range, 20–50°, by means of X-ray diffraction. The values of $\alpha \cdot 10^6$ observed are as follows: potassium alum, 11.0 ± 0.3; ammonium alum, 9.5 ± 0.2; thallium alum, 13.1 ± 0.3; and ammonium chrome alum, 10.6 ± 0.4.

The Vapor Phase Photo Decomposition of Methyl Formate

BY DAVID H. VOLMAN[1]

Recently, experiments on the photolysis of methyl formate have been reported by Royal and Rollefson.[2] Experiments on this same problem had been in progress in this Laboratory. The results for the photolysis products in this investigation are in substantial agreement with those given by Royal and Rollefson. In addition, data on the determination of methanol in the reaction products, and an approximate evaluation of the quantum yield for the reaction were obtained.

In a subsequent paper on the photolysis of methyl acetate, Roth and Rollefson[3] have given data on the determination of methanol as a photolysis product by oxidizing the alcohol to formaldehyde and treating with Schiff reagent. However, they were unable to analyze for the small amounts of methanol usually obtained in the decomposition runs, and were forced to obtain comparatively large amounts of decomposition products by carrying out the reaction in a three-liter bulb. The method given below using a Grignard reagent suffices for the small amounts usually obtained and enables analyses to be made for all of the decomposition experiments conducted.

Experimental Method

The apparatus employed was essentially the same as already reported.[4] The source of radiation was an Hanovia Alpine mercury lamp. Quantum yields were determined approximately by using monochloroacetic acid as an actinometer in a manner previously described[4,5] using the reliable value for the hydrolysis quantum yield given by Smith, Leighton and Leighton.[6]

Methyl formate was synthesized by allowing formic acid and methanol to react in the presence

(1) On leave of absence. Present address: The Technological Institute, Northwestern University, Evanston, Illinois.

(2) Royal and Rollefson, THIS JOURNAL, **63**, 1521 (1941).

of hydrochloric acid. The methyl formate was removed by distillation and washed with concentrated potassium hydroxide. After a second distillation, the ester was dried over phosphorus pentoxide and fractionated. The fraction used distilled at 31.8–32.0°.

After irradiation for definite periods, the gases non-condensable in a liquid-air trap were collected by means of a Toepler pump and analyzed by the use of a Blacet–Leighton apparatus for micro gas analysis.

The following method was used in analyzing for methanol. A methyl Grignard reagent in ethyl ether solution was placed in a trap connected to the photolysis apparatus by means of a stopcock. Prior to an experiment the Grignard reagent was thoroughly outgassed and frozen by use of liquid air. When it was desired to analyze for methanol, the condensable reaction products plus undecomposed ester were distilled into the trap containing the Grignard reagent. Then the mixture was allowed to warm to room temperature and successively frozen and warmed several times. Finally, the non-condensable gas, methane, was collected and determined, both by volumetric measurement and by combustion.

An attempt was made to produce hydrogen from methanol by passing the photo-decomposition products over a sodium mirror. However, the results were not reproducible and were consistently lower than expected or found by the Grignard reagent method.

Complete analytical results and values of decomposition quantum yield, Φ_d, are given in the accompanying table. The pressure of methyl formate was 75.0 mm. in each experiment. Irradiation was for twenty minutes at 25°, and approximately 600 cu. mm. of gas was collected each time. Φ_d is based on the sum of carbon dioxide and carbon monoxide.

TABLE I

METHYL FORMATE PHOTOLYSIS PRODUCTS AND QUANTUM YIELDS

CO, %	H_2, %	CH_4, %	CO_2, %	C_2H_6, %	CH_3OH, %	Φ_d
41.3	10.3	5.1	15.0	1.3	27.2	0.7
40.5	9.3	5.6	14.9	0.7	29.1	.7
39.1	9.0	6.0	14.9	1.6	29.5	.8
38.2	9.3	7.3	14.4	0.9	29.9	.8

Discussion

The demonstration that methanol is produced in the photolysis of methyl formate is evidence that

$$HCOOCH_3 \longrightarrow CO + CH_3OH$$

one of the net reactions postulated by Royal and Rollefson,[2] does occur.

The reaction products were found to be the same as previously reported.[2] The small variation in the mole percentages of the non-condensable products from the values given by Royal and Rollefson may be attributed to the difference in experimental details, especially pressure of methyl formate and time of illumination.

The variety of products indicates that the overall photolysis is complex. However, since Φ_d is less than unity, no appreciable chains are involved.

Summary

1. The presence of methanol in the photolysis products of methyl formate has been shown.

2. The decomposition quantum yield for the photolysis was found to be approximately 0.75 for an ester pressure of 75.0 mm. at 25°.

3. The reaction products were found to have the following average values: H_2, 9.5%; CO, 40.0%; CH_4, 6.0%; CO_2, 14.8%; C_2H_6, 1.1%; CH_3OH, 29.0%.

The Compressibility of Liquid *n*-Octane

BY W. A. FELSING AND GEORGE M. WATSON[1]

Introduction.—This investigation forms a part of the general program of this Laboratory of determining the pressure–volume–temperature relations for pure hydrocarbons and of their known mixtures, both in the liquid and gaseous state. Reports have been made on some of the isomeric hexanes.[2] In addition to the normal octane here reported, work is in progress on 2,2,4-trimethylpentane and on tetramethylbutane. The results on these octanes and on the remaining hexanes will be reported soon.

This investigation deals with the compressibility of pure *n*-octane at eight temperatures: at 25° intervals beginning with 100° and including 275°. No data over this range were found in the literature; vapor pressure and density data up to critical temperature (t_c = 296.2°) and pressure (p_c = 24.61 atm.) were recorded by Young.[3]

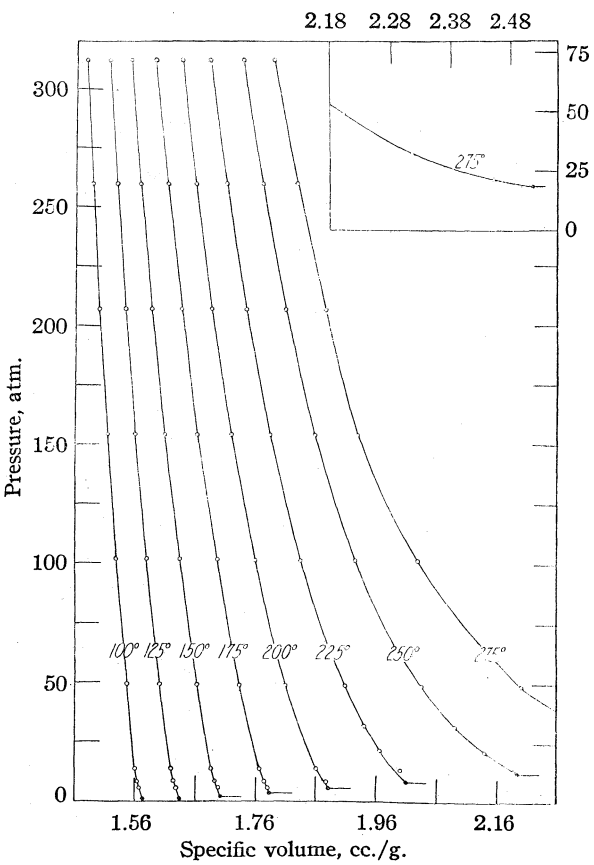

Fig. 1.—Specific volume of liquid *n*-octane as a function of the pressure (solid points from the data of Young[3]).

Method and Apparatus.—The dead-weight piston gage method and apparatus has been described elsewhere.[2,4] Minor improvements in accessory apparatus have been

made; the most important change was the development of a more convenient contact indicator.

Material Used.—The *n*-octane sample used in this work was prepared under the direction of Professor C. E. Boord of the Department of Chemistry of the Ohio State University as part of the American Petroleum Institute Hydrocarbon Research Project in the Industrial Research Foundation of the University. The material was stated to have the following constants: d (g./cc.) at 20° = 0.7019 (0.7019); f. p. = −56.90°; b. p. (normal) = 125.6°; and $n^{20}D$ 1.3976 (1.3975_8); the values in parentheses were obtained by the authors of this paper.

The Data.—The experimental results are presented graphically in the accompanying figure, specific volumes (cc./g.) as functions of the pressure at different temperatures. From such large-scale graphs, the specific volumes at each temperature were read off at rounded pressures; these values, together with the calculated molar densities, are presented in Table I. Specific volumes of the liquid in contact with the saturated vapor at the different temperatures and corresponding vapor pressures are presented in Table II.

TABLE II

SPECIFIC VOLUMES OF LIQUID *n*-OCTANE IN CONTACT WITH ITS SATURATED VAPOR

Temp., °C.	Vapor press., atm.	Cc./g.
100.00	1.00	1.574[a]
125.00	1.00	1.634[a]
150.00	1.88	1.702[b]
175.00	3.30	1.783[b]
200.00	5.40	1.882[b]
225.00	8.44	2.009[b]
250.00	12.63	2.196[b]
275.00	18.34	2.518[b]

[a] Calculated from the equation listed in "I. C. T.," Vol. III, p. 29. [b] "I. C. T.," Vol. III, p. 245, or ref. 3.

Discussion of Results.—The density data are believed to be accurate to 0.10% at the lower pressures and temperatures and to 0.1 to 0.2% at the higher pressures and temperatures. The uncertainty in the measurement of pressures is less than 0.03%, in the determination of mass less than 0.01%, and the measurement of volume from 0.05 to 0.1%. Temperature measurements are correct at least to 0.01°. At 250° and 275°, there was evidence of decomposition; after keeping the octane at these temperatures for twenty-four hours, the densities at the same pressures showed a slight decrease. The density–pressure values listed in the table for these temperatures were determined as rapidly as possible and with the precision indicated. Hence the density data for these temperatures are believed to be accurate to 0.2%. An inspection of the figure reveals that an extrapolation of the data at the different temperatures yields results in splendid agreement with the boiling-point densities recorded by Young.[3]

Acknowledgments.—The authors wish to express their appreciation to Dr. George Calingaert of the Ethyl Gasoline Corporation and to Professor Cecil E. Boord of The Ohio State University for the donation of the sample of the pure octane. They also wish to acknowledge with thanks the grants received from the University of Texas Research Institute for equipment and research assistance.

Summary

1. The compressibility of liquid *n*-octane has been determined at 25° intervals from 100 to 275° at pressures ranging from the vapor pressures to approximately 300 atmospheres.

2. The data are presented tabularly and graphically, the specific volume being related to the pressure at different temperatures.

The Dissociation of Hexaarylethanes. XII.[1] The Effect of Naphthyl and Biphenyl Groups

BY C. S. MARVEL, JOHN W. SHACKLETON, CHESTER M. HIMEL AND JOHN WHITSON

Work by Bachmann and Kloetzel[2] has indicated that the very high dissociations reported in the older literature for triarylmethyls containing *p*-biphenyl, α-naphthyl and β-naphthyl groups are in error. This communication confirms their results and extends them to a larger number of derivatives. The dissociations were measured by the magnetic susceptibility method previously described.[3]

To be comparable degrees of dissociation should be measured at the same concentration. This is not always possible because of solubility difficulties. It is possible, however, to calculate all the dissociations at 0.1 molar concentration by applying the mass law. That this calculation is justified for toluene solution has been shown recently by Preckel and Selwood.[4] We have extended this to benzene solutions and determined the degree of dissociation of di-α-naphthyltetraphenylethane at 25° at different concentrations. The results of these experiments are given in Table I.

TABLE I

DISSOCIATION OF DI-α-NAPHTHYLTETRAPHENYLETHANE AT 25° IN BENZENE SOLUTION

% Ethane	Molarity	$-\chi$ Sol. $\times 10^6$	α, %	α at 0.1 *M* calcd. from mass law, %
7.0	0.107	0.6315	25 ± 2	26 ± 2
6.63	.1	.6296	27 ± 2	27 ± 2
3.34	.05	.6550	36 ± 2	27 ± 2
1.67	.025	.6755	45 ± 4	26 ± 3
0.839	.0125	.6852	66 ± 7	29 ± 5

The aryl substituted ethanes which have been studied are reported in Table II.

TABLE II

Ethane	*M*	Concn. ethane, %	$-\chi$ Sol. $\times 10^6$	α Measured, %	α calcd. at 0.1 *M*, %
Tetra-*p*-biphenyldiphenyl-	0.1	8.9	0.6539	18 ± 2	18 ± 2
Hexa-*p*-biphenyl-	.0125	1.34	.6874	56 ± 10	26 ± 5
Di-β-naphthyltetraphenyl-	.1	6.16	.6887	6 ± 2	6 ± 2
Tetra-β-naphthyldiphenyl-	.1	7.85	.6668	13 ± 2	13 ± 2
Hexa-β-naphthyl-	.0062	0.56	.6928	80 ± 15	21 ± 10
	.0125	1.113	.6869	53 ± 10	24 ± 5
Di-α-naphthyldi-*p*-biphenyldiphenyl-	.1	8.3	.5512	54 ± 2	54 ± 2

Discussion of Results

All except one of the ethanes have been studied previously, and our methods of preparation and the properties of the intermediates in general checked those reported. The new ethane, diphenyltetra-β-naphthylethane, was prepared by standard procedures and characterized as the peroxide. Bachmann and Kloetzel measured the molecular weight in freezing benzene and calculated the dissociation of di-*p*-biphenyltetraphenylethane as 16% at 0.032 *M*, of hexa-*p*-biphenylethane as 76% at 0.0086 *M*, of di-α-naphthyltetraphenylethane as 28–31% at 0.04 *M*, and of di-β-naphthyltetraphenylethane as 6–9% at 0.04 *M*. If these values are calculated to 0.1 *M* by means of the mass law they become 9, 36, 20 and 5%, respectively. These values are in fair agreement with the values determined by the magnetic susceptibility method.

It should be noted that Müller, Müller-Rodloff and Bunge,[5] have shown that tri-*p*-biphenylmethyl is 100% free radical in the solid state. Apparently the free radical is less soluble than the ethane and in the solid state only the one phase exists, whereas in solution the radical and ethane are in equilibrium.

The dissociations of the series of β-naphthyl derivatives show that there is a steady increase in dissociation as the number of β-naphthyl groups increases, but the degree of dissociation of the hexa-substituted compound is less than that reported by Tschitschibabin and Korjagin.[6] The marked difference in the dissociation of the di-β-naphthyl derivatives (6 ± 2%) and of the di-α-naphthyl derivative (26 ± 2%) indicates again

the importance of the steric factor. This was also pointed out by Preckel and Selwood.[4]

Another point which should be emphasized is that there is a difference in the di- and tetra-substituted β-naphthyl derivatives (6 and 13%), whereas in the alkyl substituted compounds in this general series these differences between di- and tetra-substituted compounds were not found.[1] However, the hexa-substituted derivatives in the alkyl and aryl series all seem to fall in about the same range (25–35%). From the data of Gomberg and Schoepfle[7] it seems likely that our 0.1 *M* solutions of di-α-naphthyltetraphenylethane were supersaturated.

All of the aryl-substituted ethanes except tetra-*p*-biphenyldiphenylethane were relatively stable as indicated by the constant value for their magnetic susceptibilities over twenty-four hour periods. Tetra-*p*-biphenyldiphenylethane solutions deposited heavy white crystalline precipitates in twenty-four hours. Hexa-β-naphthylethane showed a decrease in color and a change in magnetic susceptibility on exposure to diffused daylight over a period of one week.

The following new compounds were characterized:

Phenyldi-β-naphthylmethylperoxide, m. p. 168–169°.

Anal. Calcd. for $C_{54}H_{38}O_2$: C, 90.25; H, 5.30. Found: C, 90.12; H, 5.84.

Phenyldi-*p*-biphenylmethylperoxide, m. p. 151–152°.

Anal. Calcd. for $C_{12}H_{46}O_2$: C, 90.51; H, 5.59. Found: C, 90.54; H, 5.94.

Phenyldi-β-naphthylmethylchloride, m. p. 159–160°.

Anal. Calcd. for $C_{27}H_{17}Cl$: Cl, 9.42. Found: Cl, 8.92.

Summary

The degrees of dissociation of several hexaphenylethanes combining α-naphthyl, β-naphthyl and *p*-biphenyl radicals have been examined by the magnetic susceptibility method. The dissociations observed are lower than reported in the older literature. The difference in the effect of an α- and a β-naphthyl group on the degree of dissociation is very marked.

The Preparation of Orthoesters

BY S. M. MCELVAIN AND J. WALTER NELSON

The work in this Laboratory to date indicates that the only general method that is available for the preparation of ketene acetals of the type $RCH{=}C(OEt)_2$ involves the elimination of the elements of ethyl hypohalite from an α-halogenated orthoester by the action of metallic sodium.[1] Consequently, the preparation and study of these higher ketene acetals are dependent upon the availability of the corresponding orthoesters as starting materials. The present paper is a summary of a large number of experiments which had as their objective practical and reliable procedures for the preparation of the esters of ortho acetic acid, certain of its derivatives and higher homologs.

Two methods of preparation of orthoesters that would seem to be of general applicability have been reported in the literature. One of these is the Tschitschibabin procedure[2] which involves the reaction of a Grignard reagent with ethyl orthocarbonate

$$RMgX + C(OEt)_4 \longrightarrow RC(OEt)_3 + EtOMgBr$$

This procedure is analogous to the widely used Tschitschibabin method for the preparation of acetals by the reaction of a Grignard reagent with ethyl orthoformate, $HC(OEt)_3$. While the latter reaction is a very useful preparational method, all of the experience in this Laboratory points to the conclusion that the reaction between a Grignard reagent and orthocarbonic ester is not a satisfactory method of preparation of orthoesters. Instead of the desired orthoester the reaction products are practically wholly a mixture of the ketal $R_2C(OEt)_2$ and the ether R_3COEt and all attempts to alter this result have been consistently unsuccessful.[3]

(1) Walters and McElvain, THIS JOURNAL, **62**, 1482 (1940).

(2) Tschitschibabin, *Ber.*, **38**, 563 (1905).

(3) McBane, M.S. Thesis, University of Wisconsin, 1941.

The other general method that appears in the literature was originated by Pinner[4] and involves the alcoholysis of an iminoester hydrochloride which is obtained from a nitrile. These reactions are

$$RCN + EtOH + HCl \longrightarrow RC(OEt){=}NH{\cdot}HCl \xrightarrow{EtOH} RC(OEt)_3 + NH_4Cl$$

Reiter and Hess[5] used Pinner's method and reported 40–64% yields of ethyl orthoacetate from the alcoholysis of the iminoester hydrochloride over a period of eight to fourteen days. Sah[6] used this procedure for the preparation of a number of alkyl esters of orthoacetic acid. He allowed the alcoholysis of the iminoester salt to proceed at room temperature for a period of two weeks. Brooker and White[7] have reported the preparation, by the same procedure, of the methyl esters of orthopropionic, -*n*-butyric, -*n*-valeric, -*n*-caproic and -isocaproic acids. With the exception of the propionate (69% yield) the yields of the orthoesters from the iminoester salts were quite low (9–40%) and the time required for the alcoholysis varied from five to thirty-five days.

In the work which is now reported it has been found possible to shorten considerably the time required for the alcoholysis of the iminoester hydrochlorides and to increase materially the yields of the esters of orthoacetic acid and certain of its higher homologs. This has been accomplished by carrying out the alcoholysis of these salts in a refluxing ether solution. Under these conditions the alcoholysis is complete in six to twenty-eight hours and the reaction temperature is kept below the point (60–80°) at which the competing decomposition of iminoester hydrochloride into the amide and ethyl chloride, $RC(OEt){=}NH{\cdot}HCl \rightarrow RCONH_2 + EtCl$, occurs. In marked contrast to these results is the strange fact that the iminoester hydrochloride derived from the negatively substituted acetonitrile, chloroacetonitrile, gives a better yield of the orthoester if the alcoholysis is carried out simply with the alcoholic solution of the hydrochloride stirred at a temperature of approximately 40°. In this case the use of ether is detrimental to the yield of the orthoester.[8]

Table I is a summary of (a) the reaction time required for the alcoholysis of the iminoester hydrochlorides when a ratio of 15 moles of alcohol to 1 mole of the salt is used (this ratio of alcohol to salt is necessary to completely dissolve the salt), (b) the optimum ratio *by volume* of alcohol to ether, (c) the reaction temperature (which is the refluxing temperature when ether is used) and (d) the yields of ammonium chloride and the orthoesters. Each entry in this table covers at least eight runs. When the amount of ether in the alcoholysis mixture was less than the optimum ratio shown in Table I, the yields of the first six unsubstituted orthoesters dropped markedly. When no ether was used the yields were generally 30–50% of those shown in Table I. The yields of ethyl orthochloroacetate varied from 40% with an alcohol–ether ratio of 1:2 through 50% for a 1:1 ratio and up to the yields indicated in Table I when no ether was used.

Table I

Alcoholysis of Iminoester Hydrochlorides, RC(OEt)=NH·HCl

R is	Reaction time, hr.	Alcohol ether ratio	Reaction temp., °C.	Yield, % NH_4Cl	Yield, % RC(OEt)
CH_3	6	1:1	46	100	75–78
C_2H_5	9	1:2	42	95	75–78
n-C_3H_7	18	1:3	41	96	60–63
i-C_3H_7	24	1:5	39	54	27–30
n-C_4H_9	12	1:3	42	88	59–61
i-C_4H_9[a]	28	1:5	39	56	21–23
$ClCH_2$	6	1:0	40	89	70–73

[a] This ester was prepared by Robert L. Clarke. In addition to the orthoester a 14% yield of isovaleramide and a 21% yield of ethyl isovalerate were isolated.

It is seen from the data in Table I that under these optimum reaction conditions the alcoholysis of those iminoester hydrochlorides in which R is a primary and normal alkyl group is quite complete. The yield of ammonium chloride is obviously the most accurate measure of this reaction since it is obtained by simply filtering off the salt from the alcoholysis reaction mixture. The nitrogen that is not in the form of ammonium chloride appears as the amide, $RCONH_2$, and in those cases (R is a branched chain) in which the yield of the ammonium salt is low, the amide is a troublesome factor in the purification of the orthoester. While the yield of the orthoester theoretically should be the same as that of the ammonium chloride, it is generally considerably lower due, quite probably, to some hydrolysis to the normal ester, RCOOEt, during the necessary washing of the ethereal reaction mixture to remove

any unchanged salt and amide as well as to the incomplete separation of the orthoester by fractionation.

Experimental

Iminoester Hydrochlorides.—The following general procedure was followed for the preparation of these salts. To an ice-cooled solution of 1 mole of the appropriate nitrile (distilled from phosphorus pentoxide) in 1.1 moles of absolute alcohol, dry hydrogen chloride was added until 1.1 moles had been absorbed. The resulting solution then was allowed to stand at 0° in the refrigerator for the time indicated in the second column of Table II, after which time absolute ether was added in the quantity shown in the third column of Table II. In the cases of acetonitrile and chloroacetonitrile the precipitation of the hydrochloride was so rapid that it was found advisable to mix the ether with the alcohol solution of the nitrile *prior* to the addition of the hydrogen chloride in order to prevent the solidification of the reaction mixture before the addition of the hydrogen chloride was completed; upon cooling to −30° the first crop of crystals of these hydrochlorides could be filtered off immediately. In the cases of the other iminoester hydrochlorides the resulting ethereal solution[9] was allowed to stand in the refrigerator overnight after which it was cooled to −30° in dry-ice and the precipitated salt rapidly filtered by suction. The salt was dried in a vacuum desiccator over dishes of solid potassium hydroxide and phosphorus pentoxide after which it was triturated under sufficient cold (−40°) anhydrous ether to cover it and again filtered and dried in the desiccator. On standing for a few more days in the refrigerator the mother liquor generally yielded additional crops of crystals. After the ether washing the salt does not give an acid reaction to moistened congo red paper and is in the proper condition for alcoholysis. If placed in tightly stoppered bottles or in a vacuum desiccator it may be kept for several weeks without deterioration.

TABLE II

IMINOESTER HYDROCHLORIDES, RC(OEt)=NH·HCl

R is	Reaction time at 0°	Alcohol–nitrile ether ratio[a]	Yield, %, hydrochloride
CH_3	2 hr.	1:0.5[b]	85–95
C_2H_5	6 hr.	1:4	85–95
n-C_3H_7	4 days	1:4	65–70
i-C_3H_7	4 days	1:4	70–90
n-C_4H_9	5 days	1:4	70–80
i-C_4H_9	6 days	1:6	35–40
$ClCH_2$	..	1:8[b]	80–90

[a] This is the ratio *by volume* of the alcohol–nitrile mixture to ether. [b] In these runs the ether was added to the alcohol solution of the nitrile before the addition of the hydrogen chloride.

The conditions for the preparation and the yields of the various iminoester hydrochlorides are shown in Table II.

Preparation of Orthoesters.—A mixture of 0.2 mole of the iminoester hydrochloride and 3 moles of absolute alcohol in a flask of suitable size fitted with a reflux condenser, an efficient stirrer and a thermometer dipping into the reaction mixture was carefully protected against moisture and stirred until the salt went into solution. Then the quantity of anhydrous ether indicated in Table I was added through the neck holding the thermometer. The ethereal solution was refluxed (in the cases when ether was not used the alcohol solution was kept at 40°) by an electrically heated oil-bath for the time indicated in Table I. After this time the reaction mixture was cooled to 0° and the precipitated ammonium chloride filtered off by suction. The filtrate (50 ml. of ether was added before filtration in those cases in which ether was not used in the alcoholysis) was washed with an equal volume of 10% sodium carbonate solution and then with 50 ml. of a saturated solution of sodium carbonate and after drying over anhydrous potassium carbonate it was fractionated under about 10–30 mm. pressure. In the case of ethyl orthoacetate it was found necessary to carry out the fractionation at atmospheric pressure and with an efficient Widmer column to obtain the yields that are reported in Table I. The boiling points of the various orthoesters together with other properties and analyses of those not previously described in the literature are listed in Table III.

TABLE III

[a] Found ethoxy values of these orthoesters generally are lower than the theoretical just as they are with the ketene acetals. [b] Ref. 6. [c] Ref. 1. [d] Prepared and analyzed by Robert L. Clarke. [e] Beyerstedt and McElvain, THIS JOURNAL, 59, 1273 (1937).

(9) The use of ether at this point is for the purpose of preventing the formation of a hard cake and to cause the salt to precipitate as small and more pure crystals.

Summary

The conversion of acetonitrile, certain of its higher homologs and chloroacetonitrile into iminoester hydrochlorides, and the alcoholysis of these salts to the corresponding orthoesters in good and reproducible yields are described.

MADISON, WISCONSIN RECEIVED MARCH 25, 1942

[Contribution from the Laboratory of Organic Chemistry of the University of Wisconsin]

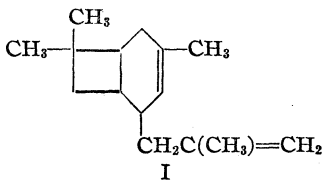
The Constituents of the Volatile Oil of Catnip. II. The Neutral Components. Nepetalic Anhydride

By S. M. McElvain, Philip M. Walters[1] and Robert D. Bright[2]

In the first paper[3] of this series the structures of the compounds, nepetalic acid (III) and nepetalactone (VI), that are extractable from the volatile oil of catnip by dilute alkali were discussed. These alkali-soluble components comprise 85–90% of the oil, depending upon the method of extraction; when the oil is shaken vigorously with a 10% solution of sodium hydroxide at 60° for fifteen minutes only about 10% of the oil remains undissolved. It is with this alkali-insoluble portion that the present paper deals.

Hixon[4] has reported an investigation of this alkali-insoluble portion of the oil. He subjected it to steam distillation and found that only about half of it was readily volatile and that a considerable portion of it did not distill with the steam. Fractionation of the steam-distilled material yielded a main fraction that boiled at 245–255° (11 mm.) and which from its odor and physical properties was thought to be a dicyclic sesquiterpene.

In the present work careful fractioning of this neutral portion of the oil divided it into a number of fractions that appeared to have constant boiling points and that attained maxima or minima in their refractive indices. The lowest boiling of these fractions was found to be a colorless azeotropic mixture that was composed of about 70% of a $C_{15}H_{24}$ hydrocarbon and 30% of nepetalactone (VI). The lactone was readily removed from the hydrocarbon when the mixture was refluxed with 10% aqueous sodium hydroxide. The properties of this hydrocarbon and of its dihydrochloride correspond to those of the sesquiterpene, β-caryophyllene (I), that has been isolated from oil of cloves by Ruzicka.[5]



I

The next fraction that distilled from the neutral portions of the oil was nepetalactone (VI) which was readily identified as the semicarbazone of nepetalic acid. After the nepetalactone two very small fractions (see Table I) were obtained. The first of these was colorless and from analyses and physical properties appeared to have the molecular formula, $C_{14}H_{24}O$. The oxygen of this compound seemed to be in the form of an ether since it shows no hydroxyl or carbonyl function. The other of these fractions is deep yellow in color and has a tea-like odor. Analyses show it to have an empirical formula of $C_9H_{14}O_2$; saponification in standard alkali indicates that it is an ester with a saponification equivalent of 176. On account of the scarcity of both of these materials, no further work was done on them.

The last fraction was relatively large and was obtained as a yellow, viscous oil that boiled at 200–210° (0.1 mm.). On standing this oil slowly crystallized. The crystalline material, after recrystallization from petroleum ether, melted at 139–140° and was optically active, $[\alpha]^{25}D$, 136° in chloroform. Analyses and molecular weight determinations showed it to have the molecular formula, $C_{20}H_{30}O_5$. It contained no readily oxidizable or titratable groups, but hydrolysis with dilute hydrochloric acid converted it into nepetalic acid. These facts lead to the conclusion that the compound is the anhydride (V) of nepetalic acid formed by the loss of a molecule of water between two molecules of the hydroxylactone form (II) of the acid. It is obvious that an anhydride formed from either of the other two tautomeric forms of nepetalic acid (III and IV) would contain highly reactive functional groups.

Nepetalic anhydride (V) is formed in considerable amounts together with the acetate of II when nepetalic acid is treated with acetyl chloride. In this connection it is interesting to note that acetic anhydride converts nepetalic acid quantitatively into the acetate.[3] The anhydride, V, slowly forms at ordinary temperatures in non-crystalline samples of nepetalic acid on standing; such samples, which originally were completely alkali soluble, after a year or more of standing may con-

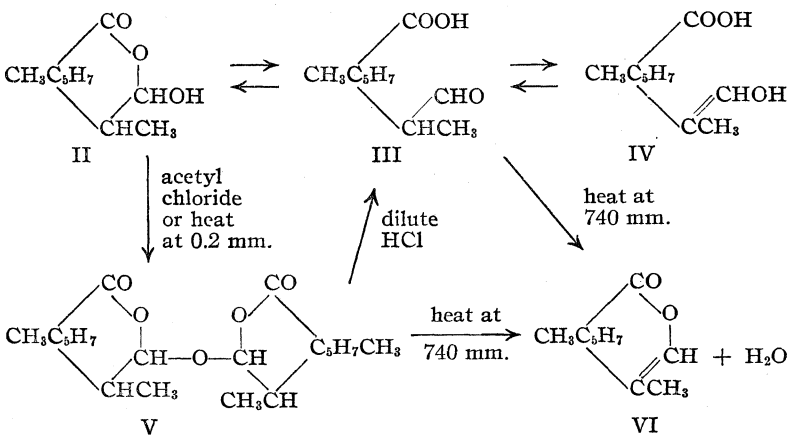
tain as much as 4% of this anhydride. Nepetalic anhydride may also be prepared by heating nepetalic acid under 0.2 mm. pressure; at this pressure as high as 30% intermolecular dehydration occurs with the formation of V.[6] At atmospheric pressure the dehydration of nepetalic acid is intramolecular with the formation of nepetalactone[3] (VI). Similarly, when nepetalic anhydride either as pure crystalline material or as the viscous oil, obtained from the mother liquor after the crystallization of V, is heated at atmospheric pressure it readily decomposes into 2 molecules of VI and one molecule of water. The following formulas illustrate these transformations, in which $CH_3C_5H_7$ is a methylcyclopentane nucleus



In Table I are listed the various components that have been isolated from the portion of the volatile oil of catnip that is insoluble in aqueous alkali at 60°, the percentage of this neutral portion which each component comprises and certain of the physical properties of the pure compound. The percentage values in the second column of this table include both the pure material, having the properties shown, and that estimated to be present in the intermediate fractions from the chemical and physical properties of these fractions.

(6) A compound with a structure analogous to V has been reported by Carrière [*Ann. chim.*, **17**, 84 (1922)]. It was formed to the extent of about 25% when the trimer of the half-aldehyde of succinic acid was subjected to distillation and depolymerized into the monomer

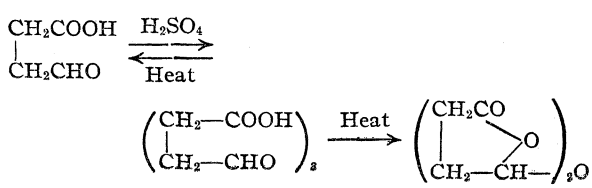


TABLE I

COMPONENTS OF THE NEUTRAL FRACTION OF THE VOLATILE OIL OF CATNIP

Component	% of neutral oil[a]	B. p., °C.	mm.	$n^{25}D$	d^{25}_4
β-Caryophyllene[b]	14	59–60	0.03	1.4962	0.9027
Nepetalactone	42	70–71	.03	1.4870	...
$C_{14}H_{24}O$	3	85–87	.03	1.4942	.9592
$C_9H_{14}O_2$[c]	2	115–117	.1	1.4790	...
Nepetalic anhydride[d]	36	200–210	.1	....	...

[a] This neutral oil comprises 10% of the original oil of catnip. [b] $[\alpha]^{25}D$, −11°; the dihydrochloride of this hydrocarbon melts at 68–69°. [c] Since this compound appears to be an ester it is likely that its molecular formula is double this empirical formula to account for the relatively high boiling point of the compound. [d] The melting point of the crystalline material from this fraction is 139–140°.

It is seen from the above table that β-caryophyllene, nepetalactone and nepetalic anhydride comprise over 90% of the alkali-insoluble portion of the oil of catnip. Since this portion represents only about 10% of the original oil it follows that over 99% of the volatile oil of catnip is accounted for as nepetalic acid (III) and its derivatives, nepetalactone (VI) and nepetalic anhydride (V), which comprise about 98% of the oil, and β-caryophyllene (I) which is present to the extent of about 1.4%. The ether, $C_{14}H_{24}O$, and ester, $C_9H_{14}O_2$, together represent only about 0.5% of the oil.

Since both nepetalic acid and its anhydride are odorless, it seemed probable that nepetalactone (VI) and possibly the caryophyllene are the constituents of the oil that are responsible for the odor of the catnip plant that is so attractive to many species of the cat family. Through the courtesy and coöperation of Mr. Fred Winkelmann, superintendent of the Vilas Zoo at Madison, it was possible to test this supposition. Small pledgets of cotton soaked in a dilute alcoholic solution of each of these constituents were placed, after the evaporation of the alcohol, in the different cages of the African lions at the Zoo. The nepetalactone that was used was prepared from the odorless nepetalic acid. There were ten of these animals available for the test. They represented both sexes and varied in age from cubs a few months old to a lioness so old (25–30 years) that she was partially blind. With the exception of the three cubs that were present, all of the

lions responded immediately to nepetalactone in the same manner that they do to the oil of catnip and to the fresh plant, the latter of which is given to them regularly during the summer. They showed no interest in the caryophyllene. The reaction of the lions to either nepetalactone or the catnip plant is quite similar to that of an ordinary house cat. They can be aroused immediately from a state of lethargy to one of intense excitement by the odor of the lactone, and will follow the odor to its source. When they acquire the material with the odor they become ludicrously playful and their main interest seems to be to get the odoriferous material transferred to their fur. They show no desire to eat the material, nor is there any evidence of sexual stimulation.

Experimental

Fractionation of the Neutral Portion of the Oil of Catnip.—A 100-g. sample of the neutral fraction of oil of catnip (which represented the undissolved material from 1 kg. of the oil of catnip that had been shaken with 10% aqueous sodium hydroxide at 60° for fifteen minutes) was distilled through an 8-cm. still-head at 0.1 mm. This crude fractionation separated the lower boiling fractions, 63 g., from the higher boiling material, principally nepetalic anhydride, 36 g., which remained as the residue. Careful fractionation of the distillate from the above distillation gave four fractions, (a) 23 g., b. p. 55–60° (0.03 mm.); $n^{25}D$ 1.4900–1.4921; (b) 31 g., b. p. 61–71° (0.03 mm.); $n^{25}D$ 1.4870–1.4900; (c) 5 g., b. p. 72–110° (0.03 mm.); $n^{25}D$ 1.4900–1.4920; (d) 3 g., b. p. 110–122° (0.03 mm.); $n^{25}D$ 1.4833–1.4880. Refractionation of each of the above fractions gave the quantities of material with a constant refractive index that are shown in Table II.

Table II

Fractions of the Lower Boiling Neutral Components of Oil of Catnip

Fraction	Weight, g.	B. p. °C.	Mm.	$n^{22}D$
a	20	59–61	0.03	1.4931
b	29	68–71	.03	1.4878
c	4	83–88	.03	1.4930
d	2	115–117	.1	1.4790

Isolation and Identification of β-Caryophyllene (Fraction a).—Carbon–hydrogen analyses and molecular weight determinations indicated fraction *a* to be a constant boiling mixture of about 70% of a C_{15} hydrocarbon and 30% of an oxygen-containing component. On the assumption that the oxygen compound was nepetalactone which had not been completely removed by the alkaline extraction of the oil, fraction *a* (20 g.) was refluxed with 10% sodium hydroxide for one hour, and then extracted thoroughly with ether. The ether extracts were combined and distilled. There was obtained 12 g. of a hydrocarbon that proved to be β-caryophyllene,[5] b. p. 112–113° (10 mm.); $n^{25}D$ 1.4962; d^{25}_4 0.9027; $[\alpha]^{25}D$ −11.42 (in chloroform); mol. wt. (Beckmann), 192 (calcd. 204); M_D, 66.13 (calcd. 66.16).

Anal. Calcd. for $C_{15}H_{24}$: C, 88.2; H, 11.8. Found: C, 88.0; H, 11.8.

β-Caryophyllene was further identified by conversion to its dihydrochloride; m. p. 68–69°. This was done by saturating a solution of 1 g. of the hydrocarbon in 10 ml. of anhydrous ether with dry hydrogen chloride. This solution was allowed to stand in the refrigerator for four days, after which time the ether was removed by evaporation under diminished pressure. The residual oil was dissolved in 2 ml. of absolute alcohol and crystallization induced by the introduction of a crystal of dry-ice into the alcoholic solution. The white crystalline dihydrochloride was filtered off and recrystallized from absolute alcohol. The yield of β-caryophyllene dihydrochloride so obtained amounted to 0.2 g. It melted at 68–69° and contained 25.9% chlorine (calcd. 25.6%).

Ruzicka[5] has reported the following properties for β-caryophyllene that was isolated from the oil of cloves, b. p. 119–121 (12 mm.); d^{16}_4 0.9074; $n^{16}D$ 1.5009 ($n^{25}D$ 1.4973); $[\alpha]D$ −8.9°; M_D 66.28 (calcd., 66.14); m. p. of dihydrochloride, 69°.

The alkaline extract of fraction *a* was acidified to congo red with 10% sulfuric acid, and thoroughly extracted with ether. The ether extracts were combined and on distillation yielded 5 g. of nepetalic acid, identified by its semicarbazone,[3] m. p. 158–159°, which showed no depression of melting point when mixed with an authentic sample of nepetalic acid semicarbazone.

Nepetalactone (Fraction *b*).—Analysis and physical constants of fraction *b* indicated it probably was composed of approximately 85% nepetalactone and 15% of β-caryophyllene. Accordingly a 12-g. sample of fraction *b* was shaken with 35 g. of 10% aqueous sodium hydroxide at 80° for thirty minutes, and then extracted thoroughly with ether. The ether extracts were combined and distilled to yield 1.8 g. of a material boiling from 112 to 135° (12 mm.) and which had the characteristic odor of β-caryophyllene. The alkaline extract was acidified with 10% sulfuric acid to congo red and thoroughly extracted with ether. The ether extracts were combined and on distillation yielded 9.6 g. of nepetalic acid.

Fractions *c* and *d*.—A 4-g. sample of fraction *c* on alkaline extraction with hot aqueous alkali solution yielded 2 g. of a neutral oil which showed no reaction with semicarbazide or with acetic anhydride in refluxing dioxane after two hours. This compound, which appears to be an ether, $C_{14}H_{24}O$, boils at 136–138° (9 mm.); $n^{25}D$ 1.4942; d^{25}_4 0.9592.

Anal. Calcd. for $C_{14}H_{24}O$: C, 80.7; H, 11.6. Found: C, 80.9; H, 11.2.

The alkaline extract of this fraction yielded 2 g. of nepetalic acid.

Fraction *d* was rich yellow in color and had a faint tea-like odor. It failed to give an oxime or semicarbazone when treated with hydroxylamine or semicarbazide. Its yellow color suggested a 1,2-diketone structure, but it failed to show any reduction of Fehling solution, a fact which would seem to eliminate that type of structure. Saponification with alcoholic alkali indicated that it is an ester with a saponification equivalent of 176. This compound boiled at 115–117° (0.1 mm.); $n^{25}D$ 1.4790. Analyses indicated it to have an empirical formula of $C_9H_{14}O_2$.

Anal. Calcd. for $C_9H_{14}O_2$: C, 70.1; H, 9.2. Found: C, 69.6; H, 9.3.

No further work was done with either the ether of fraction *c* or the yellow fraction *d*.

Nepetalic Anhydride.—A 15-g. sample of the residue remaining from the initial crude fractionation of the neutral portion of the oil was distilled from glass wool in a 25-ml. flask without a fractionating column and 13 g. of a yellow viscous oil, b. p. 200–210° (0.1 mm.), obtained. This viscous oil on standing slowly crystallized. Over a two-month period 2 g. of white crystalline nepetalic anhydride, m. p. 139–140°, was isolated from the semi-crystalline mass by recrystallization from petroleum ether (40–60°).

Nepetalic anhydride also was isolated from a sample of non-crystalline nepetalic acid that had been standing for several years. From a 40-g. sample of this acid 1.8 g. of the anhydride remained as alkali-insoluble material. Upon recrystallization from alcohol it melted at 139–140°; $[\alpha]^{25}D$ +136 (in chloroform); mol. wt. (Rast), 347 (calcd. 350).

Anal. Calcd. for $C_{20}H_{30}O_5$: C, 68.5; H, 8.7. Found: C, 68.7; H, 8.8.

Nepetalic anhydride was obtained from an acetylation of nepetalic acid with acetyl chloride. Fractionation of a solution of 3.9 g. of acetyl chloride and 5.0 g. of nepetalic acid in 5 ml. of carbon tetrachloride that had stood overnight at room temperature yielded 2.4 g. of nepetalic acid acetate,[3] b. p. 120–126° (0.1 mm.) and 2.7 g. of the anhydride, b. p. 203–206° (0.1 mm.). The latter fraction partially crystallized on cooling and after recrystallization from petroleum ether yielded the solid anhydride; m. p. 138–139°.

Hydrolysis of 0.65 g. of the anhydride in a refluxing solution of 2 ml. of concentrated hydrochloric acid in 10 ml. of water over a period of fourteen hours yielded 0.62 g. of nepetalic acid which was identified as the semicarbazone.

Nepetalactone from Nepetalic Anhydride.—In a distilling flask of about 2 ml. capacity 0.5 g. of nepetalic anhydride was carefully heated at its boiling point with a microburner for thirty minutes during which time a small amount of water distilled out. Then the residue was distilled under diminished pressure and 0.4 g. of nepetalactone, b. p. 67–70° (0.1 mm.); $n^{28}D$ 1.4843, was obtained as distillate.

A 10-g. sample of the viscous, non-crystalline material remaining from the petroleum ether crystallization of the anhydride distillate was heated in a metal bath at 280° for two hours. During this time 0.2 g. (38%) of water distilled out. The residue on distillation under diminished pressure yielded 3.9 g. (41%) of nepetalactone which was identified as the semicarbazone of nepetalic acid.

Summary

An investigation of the alkali-insoluble portion (10%) of the volatile oil of catnip shows that it consists of β-caryophyllene (14%), nepetalactone (42%) and nepetalic anhydride (36%). This latter compound is the anhydride of the hydroxylactone form of nepetalic acid.

In addition to these compounds two other substances which comprise not more than 0.5% of the oil have been isolated but not identified.

It is shown that nepetalactone is the component of the oil, the odor of which makes the catnip plant so attractive to certain species of the cat family.

α-Alkoxyvinyl- and α-Alkoxyethylbarbituric Acids

BY S. M. MCELVAIN AND HOWARD BURKETT[1]

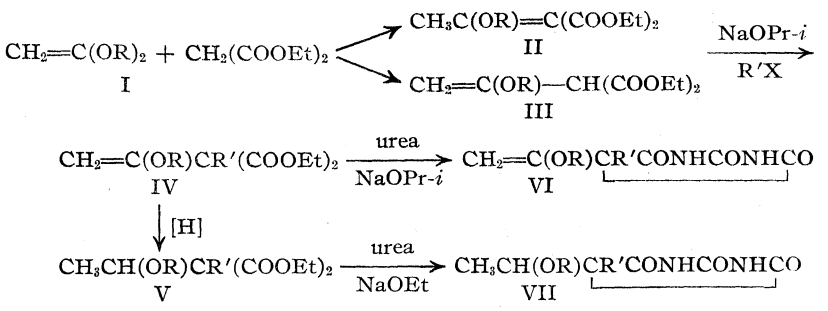
The formation of (α-ethoxyethylidene)-malonic ester (II, R is ethyl) from the reaction of ketene diethyl acetal and malonic ester[2] suggested a study of this reaction with other ketene dialkylacetals[3] (I) and the conversion of the resulting α-alkoxyethylidenemalonic esters into the corresponding 5-(α-alkoxyvinyl)-5-alkyl-barbituric acids (VI) by the sequence of reactions shown below. It seemed possible also that the vinyl group could be hydrogenated at the malonic ester stage (IV) and a series of 5-substituted (α-alkoxyethyl)-barbituric acids (VII) prepared from the saturated malonic esters (V).

(1) Eli Lilly and Company Fellow, 1940–1942.

(2) Barnes, Kundiger and McElvain, THIS JOURNAL, **62**, 1281 (1940).

(3) McElvain and Walters, *ibid.*, **64**, 1059 (1942).

In the original study of the reaction between ketene diethyl acetal and malonic ester the (α-ethoxyethylidene)-malonic ester (II), m. p. 26–27°, was obtained in 55% yield. It has been found possible in the present work to increase the yield of this product to 66% and to obtain in addition the isomeric (α-ethoxyvinyl)-malonic ester (III, R is ethyl) in 11% yield. The structure of the latter ester, which is a liquid, is shown by its ozonolysis into formaldehyde, and by the fact that the two isomers yield the same malonic ester and barbituric acid in the reactions shown below. By long heating (125° for twenty hours) with a trace of sodium ethoxide the liquid ester (III) may be converted into its solid isomer (II).



Only in the case of the compounds (II and III, R is ethyl) derived from ketene diethylacetal was an attempt made to separate the isomers. In each of the other cases the mixture of the isomers was directly alkylated. When this alkylation was carried out in ethyl alcohol the yields of the disubstituted malonic esters (IV) were quite low (20–25%) but with isopropyl or *t*-butyl alcohols as solvents the yields of these malonic esters generally were between 55–85% of the theoretical.

The hydrogenation of the vinyl substituted ester (IV) to the saturated ester (V) was carried out only with the compound in which R = R′ = ethyl. While the hydrogenation went quite satisfactorily, this method did not seem as practicable as the direct introduction of the alkoxyethyl group through the interaction of the appropriate chloroethyl ether prepared from acetaldehyde, the alcohol and hydrogen chloride[4] and the sodio derivative of the mono-substituted malonic ester as illustrated by the reactions

$$CH_3CHO + ROH + HCl \longrightarrow CH_3CHClOR \xrightarrow{NaCR'(COOEt)_2} V$$

It was found necessary to carry out this reaction in the sequence shown, since all attempts to further alkylate a malonic ester containing an α-alkoxyethyl substituent yielded only polymeric products.

As may be seen from Table V in the experimental part, the yields in the conversion of the vinyl substituted malonic esters (IV) into the corresponding barbituric acids were quite low due, in considerable part, no doubt, to the cleavage of the malonic ester into the corresponding acetic ester and derivatives thereof.[5] In fact, in two cases (IV, R is ethyl, R′ is *n*-propyl and R is *n*-butyl, R′ is ethyl) it was not possible to isolate any of the barbituric acid VI even when the condensation was carried out in isopropyl alcohol.

(4) Henze and Murchison, This Journal, **53**, 4077 (1931).
(5) *Cf.* Cope and McElvain, *ibid.*, **54**, 4319 (1932).

In contrast to this behavior, the saturated esters V condensed with urea in ethyl alcohol solution to give good yields of the barbituric acids (VII). In the case of the barbituric acid in which R is *n*-propyl and R′ is methyl-*n*-propylcarbinyl a pair of racemates that had sufficiently different physical properties to allow them to be separated were formed (see Table VI). The corresponding compound in which R is ethyl failed to yield a similar pair of racemates.

Pharmacological Data

The barbituric acids that have been prepared in this work are being studied pharmacologically by Mr. E. E. Swanson of The Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, Indiana, who has kindly furnished a preliminary report that is summarized in Table I. Corresponding data for amytal (Sodium Isoamyl Ethyl Barbiturate, Lilly) are included for comparison. The pharmacological values were determined intraperitoneally in white rats, and are expressed as minimum anesthetic dose (M.A.D.) and minimum lethal dose (M.L.D.) in mg. of barbiturate per kg. of animal weight. The "therapeutic index" is the ratio of these values. The pair of racemates in which R′ is the methyl-*n*-propylcarbinyl group are listed in Table I in the same order that they appear in Table VI.

Discussion of the Pharmacological Data

It may be seen from the M.A.D. column of Table I that the 5-(α-alkoxy-ethyl)-5-alkylbarbituric acids (no. 5–16) as a group are more effective anesthetics than the corresponding alkoxyvinyl compounds (no. 2–4). As a matter of fact quite a number of these alkoxyethyl substituted compounds appear to be more effective in producing anesthesia in white rats than is amytal (no. 1), although some of them cause very noticeable preanesthetic tremors or convulsions. Nos. 6 and 13 are particularly striking since each of them has a low anesthetic dose coupled with a sufficiently low toxicity (M.L.D.) to give them decidedly higher therapeutic indices than that shown by amytal. It should be noted also that the duration of the anesthesia produced in the white rat by both 6 and 13 are considerably less than that of amytal.

TABLE I

SUMMARY OF THE PHARMACOLOGICAL DATA

No.	R is	R′ is	M.A.D., mg./kg.	Duration of anesthesia, min.	M.L.D., mg./kg.	Therapeutic index, M.L.D./M.A.D
	5-(α-Alkoxyvinyl)-5-alkylbarbituric Acids $CH_2{=}C(OR)CR'CONHCONHCO$					
1	Amytal		90	200	200	2.22
2	Ethyl	Ethyl	200	600	400	2.00
3	Ethyl	Allyl	100	300	210	2.10
4	Isoamyl	Ethyl	120	63	240	2.00
	5-(α-Alkoxyethyl)-5-alkylbarbituric Acids $CH_3CH(OR)CR'CONHCONHCO$					
5	Ethyl	Ethyl	150[a]	460	400	2.67
6	Ethyl	*n*-Propyl	80	162	300	3.75
7	Ethyl	*n*-Butyl	150	120	300	2.00
8	Ethyl	Isoamyl	125	102	275	2.02
9	*n*-Propyl	Ethyl	80[b]	150	120	1.50
10	*n*-Butyl	Ethyl	60[b]	150	70	1.16

12	Ethyl	Allyl	100	300	160	1.60
13	Ethyl	Methyl-*n*-propylcarbinyl	60	108	160	2.67
14	*n*-Propyl	Allyl	50[a]	204	100	2.00
15	*n*-Propyl	Methyl-*n*-propylcarbinyl	300[a]	300	450	1.50
16	*n*-Propyl	Methyl-*n*-propylcarbinyl	120[a]	150	200	1.67

[a] Caused pre-anesthetic tremors. [b] Caused pre-anesthetic convulsions.

There is an interesting difference in the pharmacological behavior of the diastereoisomeric pair of racemates 15 and 16. Although they both have practically the same therapeutic indices, the lower melting (see Table VI) compound (no. 16) is over twice as effective as an anesthetic and twice as toxic as its higher melting isomer.

Experimental

Diethyl α-Ethoxyethylidenemalonate and Diethyl α-Ethoxyvinylmalonate.—One hundred and fifty grams (1.3 moles) of ketene acetal, 105 g. (0.65 mole) of diethyl malonate and 2.2 g. (0.03 mole) of sodium ethoxide were thoroughly mixed and heated by an oil-bath at 125–130° for twelve hours. The reaction mixture was then distilled rapidly. First, 95 g. (0.58 mole) of almost pure ethyl orthoacetate was collected. Following 5 g. of an intermediate fraction, 130 g. of material, b. p. 96–106° (0.4 mm.), $n^{25}D$ 1.4573, was collected. Upon cooling in an ice–salt mixture, this material became a thick slush, which then was poured onto a suction funnel surrounded by a freezing mixture. In this manner 83 g. of diethyl α-ethoxyethylidenemalonate, m. p. 25–27°, was obtained.

The filtrate (47 g.) from this cold filtration was carefully fractionated. After a small forerun, 16.4 g. (11%) of diethyl α-ethoxyvinylmalonate, b. p. 69–70° (0.03 mm.); $n^{25}D$ 1.4380; d^{25}_{25} 1.048; $M^{20}D$, calcd., 57.53; found, 57.62, was collected. This product contained 58.2% ethoxyl (calcd. 58.7%). Following an intermediate fraction, 16.7 g. of diethyl α-ethoxyethylidenemalonate, b. p. 84° (0.03 mm.); m. p. 26–27°; $n^{25}D$ 1.4634; d^{25}_{25} 1.068; $m^{20}D$ calcd., 57.53; found, 59.36, was collected. This exaltation of the molecular refraction would be expected in this structure. The total yield of diethyl α-ethoxyethylidenemalonate was 99.7 g., 66% of theoretical.

Anal. Calcd. for $C_{11}H_{18}O_5$: C, 57.4; H, 7.9; OC_2H_5, 58.7. Found: C, 57.6; H, 7.9; OC_2H_5, 58.6.

The diethyl α-ethoxyvinylmalonate was ethylated and the resulting diethyl ethyl-(α-ethoxyvinyl)-malonate condensed with urea according to the procedures given below. The resulting barbituric acid melted at 188–189° and was identical with the one produced in like manner from diethyl α-ethoxyethylidenemalonate.

The liquid ethoxyvinylmalonic ester could be converted into its solid isomer by the following procedure: 9 g. of diethyl α-ethoxyvinylmalonate was heated with 0.25 g. of sodium ethoxide at 125° for twenty hours. Fractionation of the reaction mixture gave none of the starting material in the pure state but did yield 5.34 g. (59%) of diethyl α-ethoxyethylidenemalonate, b. p. 79–83° (0.03 mm.); m. p. 25–26°; $n^{25}D$ 1.4621.

Ozonolysis of Diethyl α-Ethoxyvinylmalonate.—A solution of 4.7 g. of diethyl α-ethoxyvinylmalonate in 14 ml. of glacial acetic acid and 1 ml. of acetic anhydride was treated with ozonized oxygen until no more was taken up. The solution was then poured into a three-necked flask containing 15 ml. of water, 4 g. of zinc dust, and a few crystals each of hydroquinone and silver nitrate. The flask was equipped with a stirrer and a reflux condenser, the upper end of which was connected to a tube leading to the bottom of a test-tube containing 10 ml. of water. Nitrogen was passed into the flask while it was heated on the steam-bath so that any formaldehyde liberated would be carried over into the test-tube of water. After four hours, the water containing the formaldehyde was poured into a solution of dimethyl dihydroresorcinol in aqueous potassium carbonate and the resulting solution just acidified with acetic acid. The precipitate which was obtained weighed 8 mg., melted at 184–185° and gave no depression when mixed with an authentic specimen prepared from formaldehyde and dimethyldihydroresorcinol.

Similar treatment of the diethyl α-ethoxyethylidenemalonate gave no detectable amount of formaldehyde.

Diethyl α-Alkoxyvinyl-alkylmalonate and Diethyl α-Alkoxyvinyl-malonate Mixtures.—A series of diethyl α-alkoxyethylidenemalonates were prepared by mixing the appropriate dialkyl ketene acetal,[3] diethyl malonate, and sodium ethoxide in the same molecular ratio as given in the previous section and heating the mixture in an oil-bath at the temperature and for the length of time given in Table II. No attempt was made to separate the isomers in these cases, but the material collected over the boiling range indicated in Table II was ethylated without further purification.

TABLE II

MIXTURES OF THE ISOMERIC DIETHYL α-ALKOXYETHYLIDENEMALONATES, $CH_3C(OR)=C(COOC_2H_5)_2$ AND DIETHYL α-ALKOXYVINYL-MALONATES, $CH_2=C(OR)CH(COOC_2H_5)_2$[a]

n-Butyl	140	24	135–140	2.5	54
i-Amyl	130	24	120–130	0.05	81

[a] These esters were prepared by Mr. Bruce Stevenson, to whom the authors wish to acknowledge their indebtedness.

The α-alkoxyvinyl-alkylmalonic esters were prepared by the following general procedure. To a solution of 2.3 g. (0.1 atom) of sodium in about 15 times its weight of the solvent alcohol shown in Table III, 0.1 mole of the appropriate diethyl α-alkoxyethylidenemalonate was added. The alkyl bromide or iodide was then added to this alkaline solution and the mixture refluxed until it was neutral. After cooling, sufficient water was added to dissolve all of the salt, the oily layer separated and the aqueous layer extracted with ether. The combined ether extract and oily layer was washed with water, dried over anhydrous sodium carbonate and distilled. Since it was practically impossible to obtain analytically pure compounds when an alcohol other than ethyl was used as a solvent, fractions with the ranges of boiling points and refractive indices shown in Table III were used for the preparation of barbituric acids.

Diethyl α-Alkoxyethyl-alkylmalonates.—Diethyl α-ethoxyethyl-ethylmalonate was prepared by catalytic hydrogenation of the corresponding α-ethoxyvinylethylmalonic ester by the following procedure. A solution of 8 g. of the vinyl ester in 70 ml. of absolute ethyl alcohol together with 1 g. of Raney nickel was placed in a steel bomb and shaken with hydrogen at a pressure of 1850 pounds. The hydrogenation proceeded readily at 120°. Fractionation of the product gave 4.62 g. (53%) of diethyl α-ethoxyethyl-ethylmalonate, b. p. 73° (0.04 mm.); $n^{25}D$ 1.4279; d^{25}_{25} 1.000.

Anal. Calcd. for $C_{13}H_{24}O_5$: C_2H_5O, 51.9. Found: C_2H_5O, 51.9.

Diethyl α-ethoxyethyl-malonate was prepared from sodium malonic ester and α-chloro-ethyl ether in 28% yield as in the general procedure described below. It possessed the same properties as the product obtained from the catalytic hydrogenation of α-ethoxyethylidene-malonic ester.[2]

Attempts to ethylate diethyl α-ethoxyethyl-malonate produced only polymeric material. This may be due to a partial elimination of the ethoxyl group as ethyl alcohol and the polymerization of the resulting unsaturated ester. Support for this supposition comes from the fact that the highest ethoxyl analysis for diethyl α-ethoxyethylmalonate prepared by either of the above methods was 57.4% (calcd. 58.2%).

Diethyl α-ethoxyethyl-ethylmalonate was also prepared as follows. In a dry 1-liter 3-necked flask, equipped with an inlet tube, stirrer, and reflux condenser connected to a soda–lime drying tower, which in turn was connected to a gas trap, was placed 0.3 g. of hydrated ferric nitrate. The flask was cooled in a dry-ice–acetone bath and 300 ml. of liquid ammonia added. The stirrer was started, the cooling bath removed, and a small piece of sodium added. As soon as the initial blue color had disappeared, 12.7 g. (0.55 mole) of sodium in small pieces was added rapidly. As soon as all of the sodium had reacted as noted by the disappearance of the blue color, the cooling bath was replaced and 94 g. (0.5 mole) of diethyl ethylmalonate was added from a separatory funnel in a small stream. The reaction mixture was stirred for fifteen minutes with the cooling bath and for fifteen minutes without it. Then 50 ml. of dry ether and 300 ml. of dry benzene were added in a small stream. After the reaction mixture had reached

room temperature, it was refluxed on the steam-bath until all of the ammonia was removed. This was facilitated by passing a slow stream of dry nitrogen into the flask. When all of the ammonia had been removed, the flask was cooled with cold water and 76 g. (0.7 mole) of α-chloroethyl ether added dropwise. After the addition of the chloroether, stirring was continued for about one hour at room temperature and for about ten minutes at the refluxing temperature of the benzene. The reaction mixture was then cooled and 300 ml. of water added. The benzene layer was separated and washed with two 100-ml. portions of water. The combined aqueous portions was extracted with ether. The benzene layer combined with the ether extract was washed with 50 ml. of 10% sodium carbonate, dried over anhydrous sodium carbonate, and finally distilled.

Other members of the series described in Table IV were prepared by the same procedure using the appropriate malonic ester and α-chloroethyl alkyl ether. All of the α-chloro-ethers were prepared by the procedure of Henze and Murchison.[4]

5-α-Alkoxyvinyl-5-alkylbarbituric Acids.—5-α-Ethoxyvinyl-5-ethylbarbituric acid was prepared as follows. To an alcoholic solution of sodium ethoxide, prepared from 4.6 g. (0.20 mole) of sodium and 75 ml. of absolute ethyl alcohol, was added 7.5 g. (0.125 mole) of urea and 17 g. (0.065 mole) of diethyl α-ethoxyvinylethylmalonate. After the mixture had refluxed for twelve hours, the alcohol was removed by distillation, and the residue dissolved in 80 ml. of ice-water. The aqueous solution then was extracted with ether. Evaporation of the ether left 6 g. of oil, the distillation of which gave 2 g. of material that was lower-boiling than the starting material and was probably the corresponding acetic ester $CH_3C(OC_2H_5)=C(C_2H_5)COOC_2H_5$; also, 4 g. of material with the boiling range of the starting ester was obtained. From this latter fraction was isolated 0.2 g. of a solid, m. p. 55–59°, which analyses indicated to be the amide $CH_3C(OC_2H_5)=C(C_2H_5)CONH_2$, corresponding to the above acetic ester.

Anal. Calcd. for $C_8H_{15}O_2N$: N, 8.98. Found: N, 8.92.

Crystallization from 50% ethyl alcohol of the precipitate produced by acidification of the aqueous alkaline solution yielded 3.8 g. (25% of theory) of 5-α-ethoxyvinyl-5-ethyl-barbituric acid. Properties of this compound and the others of this series that were prepared are listed in Table V. Other members of the series were prepared in a similar manner with certain variations. It was not possible to obtain any of either of the barbituric acids in which R and R′ are, respectively, ethyl and *n*-propyl or *n*-butyl and ethyl. The time of reflux generally was between ten and twenty hours. Comparison of the yields, using ethyl, *i*-propyl, or *t*-butyl alcohol as the solvent, is shown in columns 3 and 4 of Table V. The ether extractable material from others of the series varied in amount but in no other case was an attempt made to fractionate this material or isolate a pure compound.

5-α-Alkoxyethyl-5-alkylbarbituric Acid.—5-α-Ethoxyethyl-5-ethylbarbituric acid was prepared as follows. To a solution of 3.5 g. (0.15 atom) of sodium in 50 ml. of absolute alcohol was added 6 g. (0.10 mole) of urea and 13 g.

[a] After 3 recrystallizations from 50% alcohol the melting point of this product was 169–169.5°.

(0.05 mole) of diethyl α-ethoxyethylethylmalonate. After the mixture had refluxed eighteen hours, the alcohol was removed by distillation. About 100 ml. of ice-water was added to the residue. The resulting solution was extracted with 75 ml. of ether in three portions. Evaporation of the ether left 0.3 g. of oil, which slowly crystallized upon standing. This material was not characterized. The crude barbituric acid was precipitated by acidification of the aqueous alkaline solution with an excess of concentrated hydrochloric acid. Recrystallization from 35% ethyl alcohol gave 3.7 g. (32.5%) of 5-α-ethoxyethyl-5-ethyl barbituric acid.

Others of the series were prepared by the same procedure. In no case was the amount of material from the ether extract more than 0.5 g. In all cases except the two containing the methyl-*n*-propyl-carbinyl substituent one crystallization of the barbituric acid from 30–50% ethyl alcohol was sufficient to give each of the 5-α-alkoxyethyl-5-alkyl barbituric acids shown in Table VI in a pure state. The mixture of the pair of racemates that contained the methyl-*n*-propyl-carbinyl substituent was obtained in 75% yield, but after their separation into the products that melted as shown in Table VI the yield of each of these products amounted only to about 15%.

Summary

A number of ketene dialkylacetals have been condensed with malonic ester and the resulting mixture of (α-alkoxyethylidene)- and (α-alkoxyvinyl)-malonic esters have been alkylated to the (α-alkoxyvinyl)-alkylmalonic esters. These esters have been condensed with urea to produce the corresponding barbituric acids.

A number of related (α-alkoxyethyl)-alkylmalonic esters also have been prepared by the condensation of the appropriate chloroethers with alkylmalonic esters. The (α-ethoxyethyl)-ethylmalonic ester was also prepared from the (α-ethoxyvinyl)-alkylmalonic ester by catalytic hydrogenation. These malonic esters have been converted into barbituric acids.

A brief summary and a discussion of the pharmacological properties of these barbituric acids are given.

The reaction product from the condensation of ketene diethylacetal with malonic ester has been separated into the isomeric (α-ethoxyethylidene)-malonic ester and (α-ethoxyvinyl)-malonic ester, the structures of which have been proved by ozonolysis.

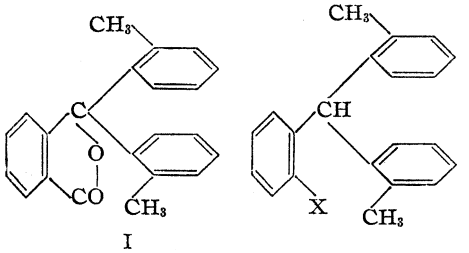
Tri-o-tolylmethane

BY PAUL D. BARTLETT AND J. ELMORE JONES[1]

The results of Marvel and his co-workers[2] suggest that the unknown hexa-o-tolylethane would, if prepared, be largely if not completely dissociated into free radicals. Because the ortho-substituted triarylmethyls are incapable of assuming the coplanar arrangement demanded by the usual resonance structures,[3] their further study seems to offer an approach to the puzzling question of the role of resonance in promoting free radical dissociation. In connection with another research we had some 2,2′-dimethyl-2″-carboxytriphenylmethane (II); from this we have prepared the hydrocarbon tri-o-tolylmethane and studied its exchange reaction with phenylisopropylpotassium. This was done in the hope that from the potassium derivative so formed the free radical might be made by means of tetramethylethylene dibromide.

Our starting material was produced from di-o-tolylphthalide (I)[4] by high-pressure hydrogenation over copper chromite.

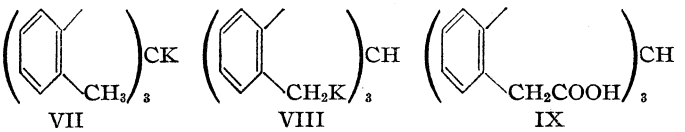


I

II X = COOH
III X = $CONHC_6H_5$
IV X = $CH{=}NC_6H_5$
V X = CHO
VI X = CH_3

This was reduced by way of the anilide (III) to the anil (IV) of the related aldehyde (V), which was characterized through its oxime. Wolff–Kishner reduction converted this aldehyde into tri-o-tolylmethane (VI), m. p. 130.5–131.5°. This hydrocarbon showed a behavior on melting like that of camphor, in that it sintered 4–5° below its melting point and showed large depressions of the melting point when impure.

When tri-o-tolylmethane was treated in ethereal solution with phenylisopropylpotassium a smooth exchange reaction took place with the precipitation of an orange–red potassium derivative. However, this was not the hoped-for potassium tri-o-tolylmethide (VII), but instead the tripotassium derivative VIII. Its structure was shown by carbonation yielding a tribasic acid which could be recovered unchanged after solution in concentrated sulfuric acid at 100°, and which was accordingly neither a triarylacetic acid nor a malonic acid. Since only the aliphatic hydrogen atoms would be expected to be acidic enough to yield potassium exchange, this constitutes evidence that the triacid has the structure IX. The triester could be formed by Fischer's method, showing that the carboxyl groups were not highly hindered.



VII VIII IX

In view of the fact[5] that triphenylmethane is much more strongly acidic than less arylated methanes, the metalation of tri-o-tolylmethane in the methyl groups, rather than on the central carbon atom, indicates an abnormally low activity of the hydrogen in the latter position. In seeking to explain this we investigated the potassium exchange by o-tolyldiphenylmethane, phenyldi-o-tolylmethane and tri-p-tolylmethane for comparison. All these hydrocarbons yielded monopotassium derivatives, which were carbonated to carboxylic acids that readily lost carbon monoxide on gentle warming in concentrated sulfuric acid. Even 3,3′,3″,5,5′,5″-hexamethyltriphenylmethane does likewise.[6] Tri-o-tolylmethane is, therefore, unique in its series in yielding only a side-chain rather than a central metalation product.

Phenyldi-o-tolylmethane represents a curious intermediate case. In 0.059 *N* solution of phenylisopropylpotassium it yields an exchange product which is carbonated to a mixture containing at

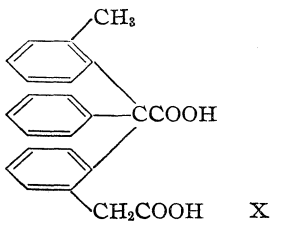
least 86% phenyldi-*o*-tolylacetic acid and at least 8.6% of a dibasic acid. The latter, in contrast to the tribasic acid IX, is sensitive to concentrated sulfuric acid, no crystalline material being recoverable from the solution, although carbon monoxide is not evolved. In the absence of a satisfactory proof of structure it seems most likely that this is the acid X, with one carboxyl group on the central carbon atom and one on a methyl group. Increasing the concentration of the reactants to saturation (0.083 *N*) for phenylisopropylpotassium and 0.107 *N* for the hydrocarbon increases the fraction of the dibasic acid to 39%.



X

There are at least two admissible explanations of the behavior of tri-*o*-tolylmethane on metalation. In the first place, the acidity of the central hydrogen atom must bear some relation to the resonance energy of the carbanion which remains when the proton is transferred to another base. The resonance of the tri-*o*-tolyl carbanion involves the same type of secondary structures (with double bond character between the central carbon and the benzene rings) as is required for the resonance of the free radical, and this resonance must be damped in a carbanion which cannot occupy the coplanar position which this double-bond character demands. This explanation leaves something to be desired since, according to it, the central hydrogen atom should still be as acidic as the hydrogens in the *o*-methyl groups themselves, which are easily replaced by potassium. The second possible explanation is that the transfer of the central proton to the base, phenyldimethylcarbanion, naturally requires these two molecules to come into direct juxtaposition in the act of effecting the transfer. The hindrance in tri-*o*-tolylmethane is probably sufficient to make an effective collision of this kind very improbable. If this is the correct explanation, it is a rare example of prohibitive steric hindrance to a reaction which is essentially an acid–base interchange.

Another explanation has been considered, based upon the fact that only the acid and not the potassium derivative has been isolated and analyzed. The precipitated potassium derivative might in fact be a tetra-potassium compound, but the *carbonation* of the central potassium might be prohibitively hindered, in which case this link would merely be hydrolyzed eventually with the formation of the tribasic acid. Against this is the high yield of triacid on the basis of phenylisopropylpotassium used: 0.024 mole of the latter metalated 0.0073 mole of tri-*o*-tolylmethane with the final isolation of 0.0071 mole of pure triacid. The hypothesis of hindered carbonation would demand the waste of one potassium atom in four, which did not occur.

The fact that the *o*-methyl groups are metalated in the tri-*o*-tolylmethane, less in the di-*o*-tolylphenylmethane and not at all in *o*-tolyldiphenylmethane is probably not a sign of any enhanced activity of the side-chain hydrogens in the first compound, but merely a case of a reaction proceeding in the direction of the first insoluble product. We have observed a similar example in the interaction of excess phenylisopropylpotassium with toluene in dry ether solution to yield benzylpotassium. The difference in acidity of the α-hydrogen in the two benzene derivatives is probably small, but the equilibrium is shifted toward benzylpotassium by reason of its insolubility.

In contrast to the observations of Conant and Wheland[5] in the case of the exchange between triphenylmethane and phenylisopropylpotassium, in which the reaction was judged to go to completion almost instantaneously, the corresponding exchanges involving the various tolylmethanes appeared to proceed slowly, over a period of hours, to an equilibrium between the hydrocarbons and potassium derivatives involved. This may be regarded as somewhat favoring the idea that there is hindrance to the actual metal-exchange reaction and not merely to the carbonation, in the case of the tri-*o*-tolylmethane.

Experimental

Preparation of the Hydrocarbons

Di-*o*-tolylphthalide (I).[4]—To 75 g. of magnesium in a three-necked flask equipped with a mercury-sealed stirrer was added 370 cc. of *o*-bromotoluene in 1 liter of absolute ether over the course of seven hours. It was often necessary to add a crystal of iodine in order to start the reaction. After all the bromo compound had been added and the ether solution had ceased boiling, a hot suspension of 215 g. of phthalic anhydride in 2250 cc. of anhydrous benzene was added at a rate such that the solution boiled gently (two hours), after which the solution was allowed to stand overnight at room temperature. Decomposition by dilute

hydrochloric acid and steam distillation of the solvents produced a yellow solid from which the last traces of solvent were removed with difficulty. The residue was boiled with five 2-liter portions of 8% aqueous sodium hydroxide, filtered, washed thoroughly with water and sucked dry. Crystallization from glacial acetic acid produced 280 g. (61.5%) of the phthalide in two crops, m. p. 173–176°, suitable for use in the next step.

Di-*o*-tolylphenylmethane-*o*-carboxylic Acid (II).—A mixture of 31.4 g. of the phthalide and 3.0 g. of copper chromite 37KAF was shaken under hydrogen at 2325 lb. initial pressure and at 235°. In ten minutes the temperature had risen to 250° and the theoretical amount of hydrogen had been absorbed. The product was dissolved in 500 cc. of hot 1% aqueous sodium hydroxide and filtered to remove the catalyst. Acidification of the filtrate produced a white solid which was separated and crystallized from glacial acetic acid. There was obtained 26.2 g. (83%) of colorless needles in two crops, m. p. 241–242°. The acid was suitable for use in the next steps without further purification. Larger runs on one mole of slightly less pure phthalide afforded yields of 70–75%.

In one preliminary run a mixture of 6.28 g. of the phthalide, 0.6 g. of copper chromite, and 10 cc. of dioxane was shaken with hydrogen at 2000 lb. and 250°. In eight hours the theoretical amount of hydrogen had been absorbed. The contents of the bomb were added to 25 cc. of a hot 10% sodium hydroxide solution and the catalyst filtered. A small amount of an oily substance insoluble in alkali was noted at this point. Acidification produced a white precipitate which was crystallized from ethanol after being decolorized by Norit. Five fractional crystallizations afforded 3.24 g. (51%) of the monoacid and 0.18 g. (2.8%) of neutral colorless rhombic plates, m. p. 145.5–146.0°.[7] Mixed melting points with phthalide and with the monoacid were lower.

Anal.[8] Calcd. for $C_{22}H_{20}O_2$: C, 83.50; H, 6.38. Found: C, 83.78, 84.37, 84.31; H, 6.00, 6.13, 5.95.

Because of the small amount of material obtained and the fact that in no other reductions was it isolated, it was not investigated further. The analysis did not correspond to that calculated for any logical reduction product.

Di-*o*-tolylphenylmethane-*o*-carboxylic Acid Anilide (III).—To a suspension of 95.0 g. of the monoacid in 200 cc. of anhydrous benzene was added 65 g. of phosphorus pentachloride. After the initial vigorous reaction at room temperature had subsided, the solution was refluxed with gentle heating for one hour. The solvent and phosphorus oxychloride were removed by vacuum distillation at 120° (10 mm.), and 100 cc. of aniline was added. The solution became very hot and slowly solidified on cooling. The solid was dissolved in benzene–ether, and the solution was extracted with dilute hydrochloric acid, washed with a solution of 10% sodium carbonate, and finally with water. After drying over sodium sulfate, the solution was boiled down to a volume of about 100 cc. and 300 cc. of ligroin (70–90°) was added. Cooling to 0° produced a dark crystalline solid which was filtered and sucked dry. Crystallization from ethanol at 0° after clarification by Norit afforded 83.4 g. (71%) of the anilide in three crops, m. p. 163–165°. The third crop (5.2 g.) was somewhat dark in color, but it could be used in the next step without further purification.

Repeated crystallization from ethanol did not produce a product having a sharp melting point and seemed to cause some decomposition. The anilide crystallized from benzene–hexane in clusters of colorless prisms, m. p. 164.0–164.7°.

Anal. Calcd. for $C_{28}H_{25}ON$: C, 85.90; H, 6.44; N, 3.58. Found: C, 85.62, 86.33; H, 6.61, 6.69; N, 3.63.

Di-*o*-tolylphenylmethane-*o*-aldehyde (V).—To a solution of 66.0 g. of the anilide in 80 cc. of dry toluene was added 50.0 g. of phosphorus pentachloride. After the initial reaction at room temperature had subsided, the solution was heated on the steam-bath for one and one-half hours. The viscous oily residue remaining after removal of the toluene and phosphorus oxychloride by vacuum distillation at 100° was poured into a solution of 125 g. of anhydrous stannous chloride in 500 cc. of absolute ether saturated with dry hydrogen chloride at 0°. The mixture slowly turned deep red, two phases formed, and an orange-red solid crystallized from the solution. After two days the complex was filtered and boiled for four hours with 300 cc. of 3 *N* hydrochloric acid. The yellow solid was filtered, washed with water and sucked dry. There was obtained 22.4 g. (44%) of the aldehyde melting at 124–132° with previous sintering at 120°. This product was suitable for the next step without purification.

The aldehyde was purified best by sublimation at 140–150° (3 mm.). It formed colorless prisms, m. p. 134.5–135.5°, with previous sintering at 131°. The later sublimates were yellow but had essentially the same melting point.

Anal. Calcd. for $C_{22}H_{20}O$: C, 87.96; H, 6.71. Found: C, 88.18; H, 6.83.

The **oxime** crystallized from ligroin (70–90)–(90–120) in pale yellow micro-crystalline prisms, m. p. 174.8–175.2°.

Anal. Calcd. for $C_{22}H_{21}ON$: C, 83.78; H, 6.71; N, 4.44. Found: C, 83.64; H, 6.70; N, 4.92, 4.62.

In an attempt to make the semicarbazone colorless blades were obtained which melted at 208.5–209.5°, after crystallization three times from ethanol–water. Recrystallization and drying at 150° *in vacuo* did not alter the analysis.

Anal. Calcd. for $C_{23}H_{22}ON_3$: C, 77.50; H, 6.22; N, 11.08. Calcd. for: $C_{23}H_{24}O_2N_3$: C, 73.78; H, 6.46; N, 11.22. Found: C, 75.29, 75.33, 75.51; H, 6.49, 6.40, 6.51; N, 10.46.

All attempts to make a pure hydrazone failed. It is very likely that the aldehyde group is too hindered to allow the formation of a stable hydrazone.

Tri-*o*-tolylmethane (VI).—A mixture of 29.0 g. of the aldehyde, 4.0 g. of sodium dissolved in 50 cc. of absolute ethanol, and 30 cc. of 85% aqueous hydrazine hydrate was heated in the autoclave at 200–210° for twenty-four hours. The contents of the bomb were neutralized with dilute acetic acid and the hydrocarbon was extracted with benzene–ether. The residue obtained after boiling the extract to dryness was dissolved in ethanol and 10 g. of semicarbazide hydrochloride and 20 g. of sodium acetate were added

(7) All melting points below 230° are corrected. Those above 230° were made on a copper block and are correct to ±2°.

(8) All microanalyses are by Miss E. Werble.

to the boiling solution. Water was added until the solution became milky, and the hydrocarbon crystallized on cooling. Recrystallization from ethanol after decolorizing with Norit produced 15.8 g. (83%) of colorless blades, m. p. 130.5–131.5°, in three crops. The melting point of the product was similar to that of camphor in that noticeable sintering was observed about 4–5° below the true melting point. Slight amounts of impurities caused large depressions in the melting point.

Anal. Calcd. for $C_{22}H_{22}$: C, 92.26; H, 7.74. Found: C, 91.07, 92.03; H, 7.90, 7.75.

Diphenyl-*o*-tolylmethane.[9]—To 7.0 g. of magnesium was added a small amount of a solution of 50 g. of *o*-bromotoluene in 100 cc. of absolute ether. After the reaction had been started by the addition of a few drops of an ethylmagnesium bromide solution, the rest of the *o*-bromotoluene solution was added with stirring over the course of three and one-half hours, and the reaction mixture was refluxed for one and one-half hours longer. A solution of 18.0 g. of benzophenone in 100 cc. of dry benzene was added and the resulting solution was refluxed overnight. On decomposing the reaction mixture with dilute sulfuric acid and distilling volatile by-products with steam, there was obtained a viscous reddish-orange oil, which was taken up in ether. After removal of the ether, the residual oil was refluxed with 100 cc. of 85% formic acid[10] until the evolution of carbon dioxide ceased. The mixture was poured into water and extracted with ether. The ether extract was washed with 10% sodium hydroxide solution and by water and was dried over potassium carbonate. Vacuum distillation produced a colorless oil, b. p. 180–210° (9 mm.), which solidified on standing. Crystallization from methanol after cooling in ice afforded 13.5 g. (53%) of colorless prisms, m. p. 81–83°, in two crops. Recrystallization for use in the exchange experiments did not alter the melting point of the hydrocarbon.

Phenyldi-*o*-tolylmethane.[12]—The phenyldi-*o*-tolylcarbinol was prepared by the above procedure using 9.7 g. of magnesium, 62.8 g. of *o*-bromotoluene and 23.0 g. of ethyl benzoate. Treatment of the crude carbinol with 85% formic acid and vacuum distillation of the ethereal extract produced a colorless oil, b. p. 190–220° (11 mm.), which solidified on scratching. Crystallization from methanol afforded 18.7 g. (45%) of colorless prisms of the hydrocarbon, m. p. 100–104°. Recrystallization for use in the exchange reaction raised the melting point to 102–104°.

Tri-*p*-tolylmethane.—Tri-*p*-tolylchloromethane (14.0 g.), m. p. 163–168°, prepared by the method of Tousley and Gomberg,[11] was boiled under reflux with 100 cc. of 85% formic acid. Isolation by the usual procedure produced 10 g. (80%) of a colorless oil, b. p. 232° (11 mm.). Since a crystalline product could not be obtained, the oil was used in the exchange reaction.

Exchange Reactions with Phenylisopropyl Potassium

Tri-*o*-tolylmethane.—To 5.0 g. of tri-*o*-tolylmethane under an atmosphere of nitrogen was added 400 cc. of a 0.059 *N* ethereal solution of phenylisopropylpotassium. The resulting solution was allowed to stand at room temperature in the dark for twenty-four hours, during which time the deep red color slowly faded and an orange-red solid crystallized. Dry carbon dioxide was passed through the mixture slowly until all of the solid had been decolorized. By extraction of the ether suspension of the potassium salt with water and acidification of the extract with hydrochloric acid, there was obtained a white flocculent precipitate. Filtration and crystallization of the residue from glacial acetic acid afforded 2.95 g. (98.3% on the basis of the hydrocarbon used in the reaction) of microcrystalline prisms of the triacid (IX) in two crops. When heated on the copper block, the compound decomposed over the range 265–295°, but when it was dusted on the block at 310° and above, the product melted with subsequent decomposition. The triacid dissolves in concentrated sulfuric acid and can be recovered unchanged by dilution of the solution with water. Heating the sulfuric acid solution to 100° does not change the acid.

Anal. Calcd. for $C_{25}H_{22}O_6$: C, 71.76; H, 5.30; neut. equiv., 139.5. Found: C, 71.94; H, 5.50; neut. equiv., 139, 141.

After removal of the ether from the ether layer in the above extraction, there was obtained an oil from which 2.4 g. (86%) of isopropylbenzene, b. p. 150–160°, was distilled. The residue consisted of slightly impure tri-*o*-tolylmethane (2.9 g.) from which there was obtained 2.6 g. of pure hydrocarbon on crystallization from ethanol after decolorizing with Norit.

The **triethyl ester** was prepared by saturating a suspension of the acid in absolute ethanol with dry hydrogen chloride and refluxing it for twenty-four hours. At the end of this time the mixture was cooled and filtered. Recrystallization of the residue from ethanol afforded colorless blades, m. p. 196.5–197.5°.

Anal. Calcd. for $C_{31}H_{34}O_6$: C, 74.08; H, 6.82. Found: C, 74.08; H, 6.91.

Diphenyl-*o*-tolylmethane.—The solution from the addition of 200 cc. of a 0.059 *N* ethereal solution of phenylisopropylpotassium to 3.0 g. of diphenyl-*o*-tolylmethane was allowed to stand in the dark at room temperature for twenty-four hours. During this time the color of the solution did not change appreciably, and a small amount of a reddish-orange solid precipitated. Dry carbon dioxide was bubbled through the solution until it had been decolorized completely, and the white suspension was extracted with water. Acidification of the aqueous extract and crystallization of the residue from glacial acetic acid afforded 1.73 g. (98.7% based on the hydrocarbon used) of **diphenyl-*o*-tolylacetic acid** as colorless prisms, m. p. 228–229°. On a copper block the acid melts with decomposition at 190–200°.

A solution of 0.8 g. of the acid in 20 cc. concentrated sulfuric acid started evolving carbon monoxide at an appreciable rate at 50° and slowly changed in color from yellow to bright reddish-orange. On pouring the solution into water there was obtained a white suspension which was extracted with ether. A red color and all fluorescence from the ether solution were removed by washing it with 10% sodium hydroxide solution. Drying over potassium carbonate and removal of the ether produced 0.6 g. (82.5%) of diphenyl-*o*-tolylcarbinol, m. p. 95–98°. Recrystallization

(9) Acree, *Ber.*, **37**, 993 (1904).

from ligroin (70–90°) raised the melting point to 98–99° (lit., 98°).[9]

Anal. Calcd. for $C_{21}H_{18}O_2$: C, 83.35; H, 6.00; CO, 9.26; neut. equiv., 302.4. Found: C, 82.66, 83.72; H, 5.92, 6.00; CO, 8.94; neut. equiv., 298.

From the ether solution after removal of the acid was isolated 1.0 g. of isopropylbenzene and 1.5 g. of impure diphenyl-*o*-tolylmethane.

In another run in which 4.0 g. of the hydrocarbon was used and the reaction time was extended to forty-eight hours, there was obtained 2.25 g. of the acid.

Phenyldi-*o*-tolylmethane.—Upon standing for forty-eight hours in the dark at room temperature, a solution of 8.8 g. of phenyldi-*o*-tolylmethane in 400 cc. of a 0.059 *N* ethereal solution of phenylisopropylpotassium deposited a red-black film on the sides and bottom of the flask. Carbon dioxide was bubbled through the deep red solution until it and the sediment had been decolorized. The pale orange suspension was extracted with water, and the cold extract was acidified. Extraction with ether and evaporation of the ethereal solution produced a yellow oil which was taken up in dilute sodium hydroxide, filtered, and reprecipitated with acid. There was obtained 3.5 g. of a colorless product (neut. equiv., 318), m. p. 100–140°, which was a mixture of **phenyldi-*o*-tolylacetic acid** and a dibasic acid.

The high neutral equivalent shows that some inert material, possibly hydrocarbon retained in the aqueous layer in the extraction process, must be present in the crude mixture. From the ether solution after removal of the salts were obtained 2.0 g. of isopropylbenzene and 5.6 g. of the methane.

The crude product was boiled with two 300-cc. portions of ligroin (70–90°), and the filtered solution was allowed to crystallize at 0°. Three further crystallizations afforded 3.0 g. (80.7% based on the hydrocarbon used) of clusters of colorless prisms, m. p. 184.0–185°.

As the powdered acid dissolved at room temperature in concentrated sulfuric acid it started evolving carbon monoxide immediately at a high rate, and the color of the solution changed rapidly from orange to deep red. After the initial reaction had subsided, the removal of the carbon monoxide was completed by heating the solution to 100°.

Anal. Calcd. for $C_{22}H_{20}O_2$: C, 83.51; H, 6.37; CO, 8.83; neut. equiv., 316.4. Found: C, 83.65; H, 6.80; CO, 8.94; neut. equiv., 315.

Working up the product from the above carbon monoxide fission by the procedure outlined previously produced only a viscous red oil. By repeating the reaction but allowing the solution to stand at room temperature without heating until the reaction was complete, a colorless substance, m. p. 68–73°, could be isolated from the reaction mixture. Crystallization from ligroin (70–90°) gave colorless prisms with the same melting point. The product dissolved in concentrated sulfuric acid with an orange **color.**

Anal. Calcd. for $C_{21}H_{20}O$: C, 87.46; H, 6.99. Found: C, 87.34; H, 6.62.

Since presence of ketonic cleavage products was suspected, the substance was dissolved in ethanol with hydroxylamine hydrochloride and a few cc. of 10% sodium hydroxide solution was added. On evaporation the solution became cloudy, and cooling caused the separation of a colorless oil. Crystallization of the oil from ligroin (70–90°) produced a small amount of colorless prisms, m. p. 82–95°, possibly impure phenyldi-*o*-tolylcarbinol (m. p. 107–108°).[12] There was too little material for further crystallization.

Anal. Calcd. for $C_{21}H_{20}O$: C, 87.46; H, 6.99. Found: C, 86.98; H, 6.93.

From the ethanol solution there crystallized after further evaporation a small amount of colorless prisms, m. p. 75–81°, possibly impure di-*o*-tolylketoxime (m. p. 105°).[13]

Anal. Calcd. for $C_{15}H_{15}ON$: C, 79.97; H, 6.71. Found: C, 80.43; H, 7.03.

The residue from the ligroin extraction of crude phenyldi-*o*-tolylacetic acid was crystallized from glacial acetic acid, and there was obtained 0.30 g. (7.1%) of a dibasic acid in microscopic prisms, m. p. 265–267°, dec. A mixed melting point with the acetic acid was forty degrees lower. Its bright orange solution in concentrated sulfuric acid did not evolve carbon monoxide even at 125°, but all attempts to isolate any cleavage products or the unchanged acid were unsuccessful.

Anal. Calcd. for $C_{23}H_{20}O_4$: C, 76.65; H, 5.59; neut. equiv., 180.2. Found: C, 76.85; H, 5.89; neut. equiv., 182.

The **dimethyl ester**, prepared by refluxing a methanol solution of the acid saturated with dry hydrogen chloride for two hours, crystallized from methanol in colorless needles, m. p. 105.0–106°.

Anal. Calcd. for $C_{25}H_{24}O_4$: C, 77.31; H, 6.23. Found: C, 77.56; H, 6.24.

In a reaction in which a solution of 11.7 g. of the hydrocarbon and 10 g. of the methyl ether of phenyldimethylcarbinol in 400 cc. of absolute ether was shaken with sodium–potassium alloy (80% potassium) for three days, there was obtained 3.2 g. of the dibasic acid from 7.6 g. of hydrocarbon used up in the reaction. This doubling of concentration shifted the product composition in favor of the more insoluble product, a dipotassium derivative of the hydrocarbon.

Tri-*p*-tolylmethane.—A solution of 6.0 g. of tri-*p*-tolylmethane in 450 cc. of a 0.059 *N* ethereal solution of phenylisopropylpotassium was carbonated after standing for twenty-six hours. Acidification of the aqueous extract and crystallization from glacial acetic acid afforded 3.3 g. (73.5% based on the hydrocarbon used) of tri-*p*-tolylacetic acid as colorless prisms, m. p. 224–226° (lit.,[14] 226–228°).

Anal. Calcd. for $C_{23}H_{22}O_2$: CO, 7.84; neut. equiv., 320.4. Found: CO, 8.68; neut. equiv., 332.

The solution of the acid in sulfuric acid started evolving carbon monoxide slowly at 50–60° and the reaction was completed at 100°. Working up the product in the usual way afforded the tri-*p*-tolylcarbinol, m. p. 85–88°. Crystallization twice from ligroin (70–90°) raised the melting point to 92–94° (lit.,[11,15] 94°, 96.4°).

(12) Bredereck, Lehmann, Schönfeld and Fritzsche, *Ber.*, **72**, 1414 (1939).

(13) Grignard, Bellet and Cortot, *Ann. chim.*, [9] **12**, 381 (1919).

(14) Schmidlin and Hodgson, *Ber.*, **41**, 438 (1908).

(15) Kovache, *Ann. chim.*, [9] **10**, 199 (1918); Motwurf, *Ber.*, **37**, 3153 (1904).

From the ether solution there were isolated 2.55 g. of isopropylbenzene and 2.0 g. of tri-*p*-tolylmethane, b. p. 230–240° (13 mm.). The recovered methane contained an impurity, probably an anthracene derivative, which exhibited an intense blue–violet fluorescence. Not all the unused hydrocarbon was recovered as some of it could not be distilled from the tar remaining in the distilling flask, and some was carried into the aqueous layer by the salt in the extraction process.

Summary

Tri-*o*-tolylmethane undergoes slow exchange with phenylisopropylpotassium to yield a tripotassium derivative which is converted by carbonation into the potassium salt of triphenylmethane-2,2′,2″-triacetic acid. The related compounds, phenyldi-*o*-tolylmethane, diphenyl-*o*-tolylmethane and tri-*p*-tolylmethane, under the same conditions, all form monopotassium derivatives which by carbonation yield triarylacetic acids. Explanations based upon damped resonance and steric hindrance are considered for the relative inertness of the central carbon atom of tri-*o*-tolylmethane.

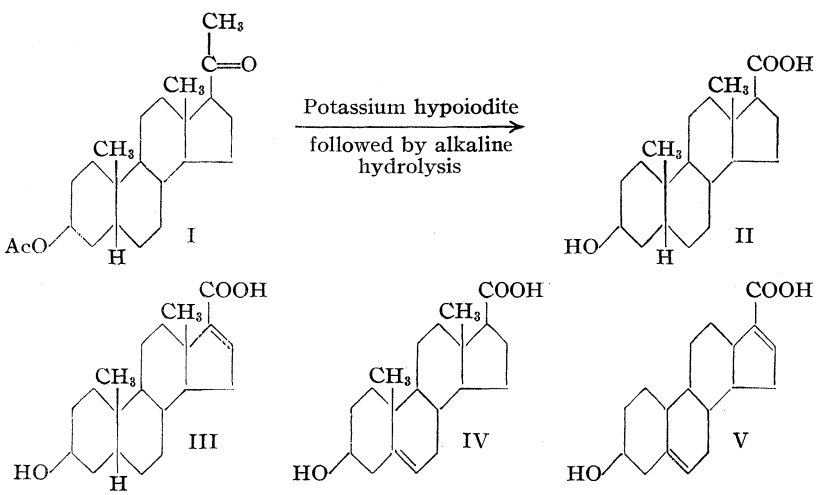
Sterols. CXLIX. The Hypoiodite Oxidation of Pregnanolones and Pregnenolones

BY RUSSELL E. MARKER AND R. B. WAGNER

St. Goldschmidt, Middelbeek and Boasson[1] have recently shown that the claims of various patents[2] to the oxidation of 5-pregnen-3(β)-ol-20-one acetate with hypoiodite to obtain 3(β)-hydroxy-etio-5-cholenic acid are erroneous. We have investigated this type of reaction, treating not only 5-pregnen-3(β)-acetoxy-20-one but also 16-pregnen-3(β)-acetoxy-20-one, pregnan-3(β)-acetoxy-20-one (I) and 5,16-pregnadien-3(β)-acetoxy-20-one with excess hypoiodite. The reactions used by us gave in every case the corresponding etio-cholanic (II) and etio-cholenic acids (III), (IV), (V).



We wish to thank Parke, Davis and Company for their assistance.

Experimental

3(β)-Hydroxy-etio-cholanic Acid.—To a solution of 2 g. of pregnan-3(β)-ol-20-one acetate in 300 cc. of dioxane was added simultaneously in 5-cc. portions, 80 cc. of an aqueous solution of 20 g. of potassium iodide and 10 g. of iodine, and 80 cc. of an aqueous 10% potassium hydroxide solution. The mixture was stirred at room temperature for one hour and then warmed to 80°. The reaction mixture was cooled and acidified. After the excess iodine was destroyed with sodium bisulfite, the mixture was concentrated *in vacuo* and extracted with ether. The etheral solution was washed with 10% potassium hydroxide and the combined alkaline washings were warmed for thirty minutes on a steam-bath. After acidification the solid was extracted with ether. The product crystallized from methanol as white needles; m. p. and mixed m. p. with 3(β)-hydroxy-etio-cholanic acid, 224–226°; yield 0.6 g.

Anal. Calcd. for $C_{20}H_{32}O_3$: C, 74.9; H, 10.1. Found: C, 74.6; H, 10.0.

The methyl ester was prepared by treating an ethereal solution of 50 mg. of the above acid with an ethereal solution of diazomethane. The solvent was evaporated and the residue crystallized from methanol to give white needles; m. p. 128°. This material gave no depression in the melting point of the methyl ester of an authentic sample of 3(β)-hydroxy-etio-cholanic acid methyl ester.

Anal. Calcd. for $C_{21}H_{34}O_3$: C, 75.4; H, 10.3. Found: C, 75.6; H, 10.2.

3(β)-Hydroxy-etio-16-cholenic Acid.—A solution of 2 g. of 16-pregnen-3(β)-ol-20-one acetate in 300 cc. of dioxane was treated as described above with hypoiodite. After hydrolysis the product crystallized from methanol; m. p.

254–256°; yield 0.3 g. This substance gave a 10° elevation when mixed with 3(β)-hydroxy-17,20-pregnenoic acid-21; m. p. 254–256°.

Anal. Calcd. for $C_{20}H_{30}O_3$: C, 75.4; H, 9.5. Found: C, 75.6; H, 9.5.

The methyl ester was prepared as described above. It crystallized from methanol as white plates; m. p. 150–152°. It depressed the melting point of the methyl ester of 3(β)-hydroxy-17,20-pregnenoic acid-21 (m. p. 153–155°) twenty-five degrees.

Anal. Calcd. for $C_{21}H_{32}O_3$: C, 75.9; H, 9.8. Found: C, 75.8; H, 9.8.

Catalytic Reduction of 3(β)-Hydroxy-etio-16-cholenic Acid.—A solution of 100 mg. of the above 3(β)-hydroxy-etio-16-cholenic acid in 100 cc. of acetic acid was shaken with hydrogen and Adams catalyst for two hours at 3 atm. pressure and room temperature. The reaction mixture was filtered and the filtrate was evaporated to dryness *in vacuo*. The residue was crystallized from methanol as white needles; m. p. and mixed m. p. with 3(β)-hydroxy-etio-cholanic acid, 224–227°. A mixed melting point with 3(β)-hydroxy-pregnanoic acid (m. p. 219–221°) was at 195°.

Anal. Calcd. for $C_{20}H_{32}O_3$: C, 74.9; H, 10.1. Found: C, 75.0; H, 10.0.

3(β)-Hydroxy-etio-5-cholenic Acid.—From the reaction of 2 g. of 5-pregnen-3(β)-ol-20-one acetate with potassium hypoiodite as described above was isolated a product which crystallized from dioxane; m. p. and mixed m. p. with an authentic sample of 3(β)-hydroxy-etio-5-cholenic acid, 273–274°; yield 0.2 g. pure product.

Anal. Calcd. for $C_{20}H_{30}O_3$: C, 75.4; H, 9.5. Found: C, 75.2; H, 9.3.

3(β)-Hydroxy-etio-5,16-choladienic Acid.—From the reaction of 2 g. of 5,16-pregnadien-3(β)-ol-20-one acetate as described above was isolated a product which crystallized from methanol as white plates; m. p. 255–257°; yield 250 mg.

Anal. Calcd. for $C_{20}H_{28}O_3$: C, 75.9; H, 8.9. Found: C, 76.0; H, 8.8.

Summary

Conditions are described for the hypoiodite oxidation of 20-keto-pregnane derivatives to the corresponding 20-carboxylic acids. 3(β)-Hydroxy-etio-cholanic (II), 3(β)-hydroxy-etio-16-cholenic (III), 3(β)-hydroxy-etio-5-cholenic (IV), and 3(β)-hydroxy-etio-5,16-choladienic (V) acids have been produced by this method.

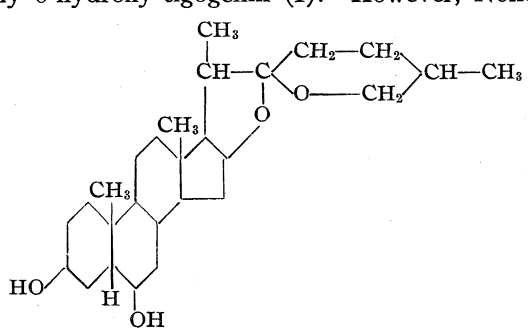
Sterols. CL. Sapogenins. LXIII. The Position of the Hydroxyl Groups in Digitogenin*

BY RUSSELL E. MARKER, D. L. TURNER AND PAUL R. ULSHAFER

The position of the hydroxyl groups in chlorogenin has been established with certainty by a large number of interconversions reported from this Laboratory[1,2,3] and chlorogenin is undoubtedly 6-hydroxy-tigogenin (I). However, Noller[4]



is unable to reconcile this structure of chlorogenin with the fact that the oxidation of chlorogenin gives a keto-dibasic acid which is neither identical to digitoic acid nor to digitogenic acid. A revision of Noller's interpretation of the non-identity of the two acids is now necessary since the structure of chlorogenin is certain.

We find that oxidation of 6-keto-tigogenone[2,3] (tigogen-3,6-dione) prepared from diosgenin gives a keto-dibasic acid identical to that from natural chlorogenin and this acid differs from digitoic and digitogenic acid. The keto-dibasic acid melts with decomposition and gas evolution. Cholestane-3,6-dione was oxidized by Windaus[5] to a ketodibasic acid which melts with decomposition and gas evolution. This acid can be converted by Wolff–Kishner reduction[6] to cholestane–2,3–diacid the structure of which is certain.[6,7] We have also effected this reduction by the Clemmensen method. It, therefore, seems reasonable to suppose that the oxidation of 6-keto-tigogenone

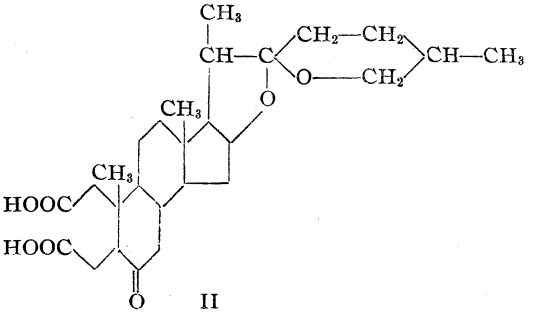
takes a similar course and gives an acid of structure II. Noller[8] found that the acid from chloro-

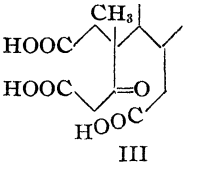


II

genin which he has named chlorogenonic acid can be reduced by the Wolff–Kishner method to gitogenic acid. Consequently, structure II is secure for chlorogenonic acid.

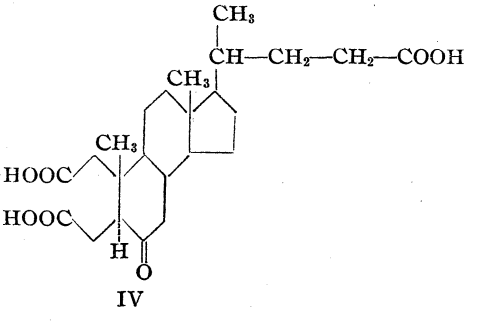
Neither digitogenic acid nor digitoic acid can have the same structure as chlorogenonic acid. Tschesche[9] has shown that digitogenic acid can be reduced to gitogenic acid and this indicates that two of the hydroxyl groups of digitogenin are at C–2 and C–3. If the third hydroxyl group of digitogenin is at C–6 as assumed by Tschesche, digitogenic acid and digitogenin would probably be of the coprostane configuration and digitoic acid of the cholestane configuration since the last acid is the stable form.[10,11,12] The side-chains of chlorogenin and digitogenic acid are the same because they have both been related to tigogenin. All three sapogenins are unaffected by treatment with hydrochloric acid in ethanol at the boiling point. This indicates that they all have the iso-configuration of the side-chain.[13]

The fact that chlorogenonic acid is not identical with digitoic acid therefore indicates that the assumption of Tschesche concerning the 6-position of the third hydroxyl group in digitogenin is incorrect.[14] Moreover the reactions of digitogenic acid and digitoic acid are completely different from those which would be expected from the known behavior of 6-keto-cholestane-2,3-diacid and similar substances of established structure. Thus 6-cholestanone was oxidized by Windaus[15] to cholestane-6,7-diacid using chromic acid or nitric acid.[16] The oxidation of digitogenic acid and digitoic acid, whether with permanganate or chromic acid, gives acids supposed by Tschesche to have structure III. These acids include oxydigitogenic acid, digitic acid[17] and acid "A" of Windaus and Willerding.[18] It would be peculiar that digitogenic and digitoic acids should not be oxidized to a 6,7-diacid if there was really a carbonyl group at C–6.



III

Much more significant is the result of catalytic reduction of digitoic and digitogenic acids. We have now found that hydrogenation in ethanol or acetic acid gives a hydroxydicarboxylic acid, the same acid being obtained from both digitoic acid and digitogenic acid. The fact that this product is not a lactone is incompatible with the supposed carbonyl group at C–6. Hyodesoxy-iso-bilianic acid (IV) was catalytically reduced by Windaus[11]



IV

and the resulting 6-hydroxy-"Staden acid" was not capable of existence as a hydroxy-acid, but immediately gave a lactone. The formation of lactones following the reduction of 6-keto-2,3-diacids of the type of IV is a general phenomenon.[19] Thus we have observed lactone formation in the reduction of 6-keto-cholestane-2,3-diacid. Only one carboxyl group of the product can be titrated in the cold.

It is interesting that the 6-keto-2,3-diacids melt with decomposition and gas evolution, *e. g.*, 6-keto-cholestane-2,3-diacid,[5] and chlorogenonic acid. This is not reported for digitogenic acid nor digitoic acid. The ester of digitoic acid can be distilled unchanged[18] *in vacuo*, and the ester of digitogenic acid is converted to that of digitoic acid. Distillation of the trimethyl ester of 6-

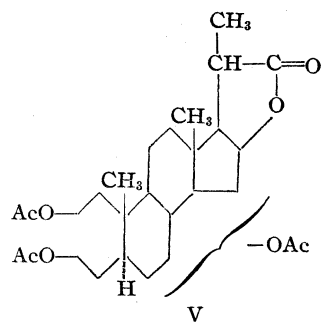
keto-Staden acid gives an unsaturated lactone with the loss of methyl alcohol.[20]

Another observation inconsistent with the C–6 position for the hydroxyl group in digitogenin is the fact that digitogenin was recovered unchanged after distillation with potassium bisulfate a method which readily dehydrates chlorogenin to 3,5-dehydrodesoxytigogenin.[21] In the case of hyodesoxycholic acid a similar dehydration occurs even more readily. Windaus[11,22] records that this acid gives hyocholadienic acid by simple distillation *in vacuo*.

Since it is impossible that digitogenin should have a hydroxyl group at C–6 it is necessary to revise all of the formulas proposed by Tschesche for the oxidation products of digitogenic acid. This is a difficult task at present because the assumption of Tschesche that oxydigitogenic acid, digitic acid, anhydrodigitic acid and their derivatives had an intact sapogenin side-chain is by no means a necessary one. Indeed, there are some indications that this may be true only of digitogenic and digitoic acids. Oxydigitogenic acid and digitic acids were prepared by treating digitogenic acid with alkaline permanganate. We have found that sarsasapogenin is oxidized to some extent by alkaline permanganate at room temperature, and this involves alteration of the side-chain.

Windaus and Weil[17] also treated oxydigitogenic acid with hydrochloric acid in acetic acid to decarboxylate it. Similar treatment of digitic acid gave anhydrodigitic acid. Heating a solution of sarsasapogenin or of gitogenin in acetic acid containing hydrochloric acid has been shown by Jacobs and Simpson[23] to remove the entire side-chain.[24] Windaus[17] records that similar treatment of oxydigitogenic acid merely caused the loss of 1 mole of carbon dioxide. The chemistry of the various acids obtained from digitogenic and digitoic acids is quite confused. It should be pointed out that the reasons given by Tschesche for considering oxydigitogenic acid a β-keto acid rather than an α-keto acid, as preferred by Windaus and Willerding,[18] depended on the 6-position of the hydroxyl group in digitogenin. The work of Bistrzycki and Siemiradzki[25] cited by Tschesche[10] is not relevant since oxydigitogenic acid loses carbon monoxide by simple heating without treatment with sulfuric acid.

In the case of acid "A" of Windaus and Willerding there is not only a difference of opinion between Windaus and Tschesche about the structure of the acid but even about the experimental facts. Indeed, it appears that only the following facts are known with any certainty about digitogenin. Two of the nuclear hydroxyl groups are at C–2 and C–3, the side-chain is identical to that of tigogenin and chlorogenin and the third hydroxyl group is adjacent to an asymmetric carbon atom and it is not at C–6. In addition the configuration at C–5 is *allo* since digitogenic acid has been converted to gitogenic acid and the side-chain is of the iso-configuration. The fact that digitogenin triacetate has been oxidized to the triacetate of a C_{22} lactone (V) by Marker and Rohrmann[26] indicates that the third hydroxyl



V

group is not in the side-chain. Consequently, only the positions 6, 7, 11 and 15 seem probable. We have eliminated the 6 position in this paper. Position 11 seems improbable because digitogenic and digitoic acids readily form semicarbazones[27] and digitogenin forms a triacetate without difficulty. The oxidation of a carbonyl group at C–7 leads to the formation of dicarboxylic acids. Thus cholestane-7-one was oxidized to cholestane-6,7-diacid[28] and 7-keto-cholanic acid to thilobilianic acid[29] (cholane-6,7,24-triacid). A hydroxyl group at C–7 is also improbable in digitogenin because it is not dehydrated by distillation over potassium bisulfate. Simple distillation of 3,7-dihydroxycholanic acid converts it to the diene acid.[30]

It would be premature to locate definitely the hydroxyl group at C–15, but there are indications that this may be the case. Digitoic acid and digi-

togenic acid would be isomeric at C–14 or at C–16. The Wolff–Kishner reduction to gitogenic acid does not exclude this. The Wolff–Kishner reduction of 6-keto-Staden acid gives both acids isomeric at C–5 although the original acid is of the stable *allo*-configuration.[7,11] Dimroth[31] has recently shown the possibility of inversion of configuration with a carbonyl group adjacent to C–14.

There are some indications that digitogenin differs from the other sapogenins in the reactions of its side-chain. This could be conditioned by a hydroxyl group at C–15. Thus we have found that dihydro-digitogenin and bromodigitogenin are formed only with difficulty. Tetrahydrodigitogenin could not be made since digitogenin was recovered unchanged when submitted to the Clemmensen reduction for twenty-four hours. This is in contrast to the behavior of the other sapogenins which give tetrahydrosapogenins readily.[21,32] Digitogenin was also largely recovered unchanged when heated with acetic anhydride in a bomb-tube under conditions which give pseudosapogenins readily.[33]

Another fact which might indicate that the hydroxyl group may be in the neighborhood of the side-chain is that Windaus[18] oxidized pure digitogenic acid to α-methylglutaric acid without detecting a trace of methylsuccinic acid. Using a similar vigorous oxidation method with digitogenin triacetate in which the hydroxyl groups are protected, we have obtained methylsuccinic acid as the major product of the oxidation. Methylsuccinic acid was obtained by Kiliani[34,18] by the vigorous oxidation of impure digitogenic acid, and, as Windaus has pointed out,[18] this probably arises from the gitogenic acid which was present as the impurity. If the hydroxyl group is at C–15 these facts can be explained readily.

Fieser,[35] in his defense of the Tschesche–Hagedorn formulation of the side-chain, has attempted to trace the formation of α-methylglutaric acid in the Windaus oxidation to an extensive degradation of the nucleus. This seems most improbable and his citation of the case of Wieland's 3,12-diketo-nor-cholane-3,24-diacid[36] does not apply because the splitting of this acid is probably due to the carbonyl group at C–12.

We thank Parke, Davis and Company for their help.

Experimental Part

6-Keto-cholestane-2,3-diacid.—To a solution of 50 g. of 3,6-dihydroxycholestane in 1500 cc. of acetic acid was added a solution of 50 g. of chromic anhydride in 500 cc. of 90% acetic acid during a period of ninety minutes. It was stirred for an additional hour at 70° on a steam-bath. Water was added and the product was extracted with ether. The ethereal solution was washed free of acetic acid and extracted with alkali. The alkaline extract was acidified with hydrochloric acid and the acid which precipitated was filtered and washed. It was crystallized from glacial acetic acid, m. p. 228–230° with bubbling.

Anal. Calcd. for $C_{27}H_{44}O_5$: C, 72.5; H, 9.9. Found: C, 72.3; H, 9.8.

Clemmensen Reduction of 6-Keto-cholestane-2,3-diacid.—To a refluxing solution of 2 g. of 6-keto-cholestane-2,3-diacid in 100 cc. of ethyl alcohol mixed with 50 g. of amalgamated zinc (20 mesh) was added 5 cc. of concentrated hydrochloric acid every fifteen minutes for four hours. Water was added and the product was extracted with ether. The ether was washed with water and the solvent was removed. The residue was hydrolyzed by refluxing with alcoholic potassium hydroxide, acidified with hydrochloric acid, and extracted with ether. The solvent was removed and the residue was recrystallized from glacial acetic acid, m. p. 194–195°, and gave no depression in mixed melting point with an authentic sample of cholestane-2,3-diacid.

Anal. Calcd. for $C_{27}H_{46}O_4$: C, 74.9; H, 10.7. Found: C, 74.8; H, 10.7.

Catalytic Reduction of 6-Keto-cholestane-2,3-diacid.—A mixture of 2 g. of 6-keto-cholestane-2,3-diacid, 500 mg. of platinum oxide catalyst and 100 cc. of acetic acid was shaken for two hours with hydrogen at 40 pounds pressure and room temperature. The catalyst was filtered and the solvent was removed *in vacuo*. The residue was crystallized from 70% acetic acid and then from methyl alcohol, in which it is quite insoluble, m. p. 188–190°.

Anal. Calcd. for $C_{27}H_{44}O_4$: C, 74.7; H, 10.2; neut. equiv. (for one carboxyl), 432.4. Found: C, 74.9; H, 10.4; neut. equiv. cold, 435.8.

Distillation of Chlorogenin over Potassium Bisulfate.—A mixture of 1 g. of naturally occurring chlorogenin and 5.5 g. of powdered potassium bisulfate was heated in a high vacuum at 200–210° until no more product sublimed. The sublimate was crystallized from acetone as white needles, m. p. 166–168°. When mixed with 3,5-dehydrodesoxytigogenin, prepared from diosgenin, there was no depression in melting point.

Anal. Calcd. for $C_{27}H_{40}O_2$: C, 81.7; H, 10.2. Found: C, 81.6; H, 10.4.

Catalytic Reduction of Digitogenic and Digitoic Acids.—The digitogenic acid was prepared by the oxidation of 8 g. of digitogenin at room temperature with chromic anhydride in acetic acid. The digitogenin used in these experiments

was purified by crystallization of the triacetate. The digitogenic acid can be best purified by crystallization from ether, giving a product melting at 170–172°. The digitoic acid was prepared by isomerization of digitogenic acid with alkali and was crystallized from dilute acetic acid. It is very soluble in comparison with digitogenic acid.

A mixture of 500 mg. of digitogenic acid, 500 mg. of platinum oxide catalyst and 100 cc. of methyl alcohol was shaken with hydrogen at 40 pounds pressure and room temperature for one hour. The solution was filtered and the solvent was distilled *in vacuo*. The residue was very soluble in methanol, acetic acid and ethyl acetate. It was quite insoluble in ether and pentane. It was crystallized by dissolving in a few drops of methanol and adding ether, m. p. 285–290° dec. Reduction in acetic acid gave the same product. Reduction of digitoic acid also gave the same product.

Anal. Calcd. for $C_{27}H_{42}O_7$: C, 67.8; H, 8.8; neut. equiv. (2 acid groups), 239. Found: C, 67.9; H, 8.9; neut. equiv. cold, 243.

Oxidation of 6-Keto-tigogenone.—The 6-keto-tigogenone was prepared by the oxidation of diosgenin with chromic acid, followed by boiling the oxidation product with zinc dust and water. It melted at 239–241° when crystallized from ether and gave no depression when mixed with chlorogenone obtained by the oxidation of naturally occurring chlorogenin.

To a solution of 9 g. of 6-keto-tigogenone in 400 cc. of acetic acid at room temperature was added a solution of 5.0 g. of chromic anhydride in 5 cc. of water and 25 cc. of acetic acid, keeping the temperature below 30°. It was allowed to stand at room temperature for twenty-two hours, diluted with water and extracted with ether. The ether was washed with water, followed with alkali. The alkaline extract was acidified and extracted with ether. The solvent was removed and the residue was crystallized from aqueous acetic acid, followed by crystallization from glacial acetic acid, m. p. 230° with bubbling. When mixed with chlorogenonic acid prepared by the oxidation of natural chlorogenin there was no depression in melting point.

The acid was prepared in better yield by the oxidation of 6-keto-tigogenone with Kiliani's chromic anhydride–sulfuric acid–acetic acid mixture. This product melted at 231–234° with bubbling and gave no depression in melting point when mixed with a sample of the acid prepared from naturally occurring chlorogenin.

When crystallized from ether it gave a product melting at 232–234°, whereas when digitogenic acid is crystallized from ether it melts at 170–172°. It is stable to alkali as would be expected from the cholestane configuration at C–5. When mixed with digitoic acid (crystallized from dilute acetic acid) it shrunk at 172° and ran at 210°. The acid crystallized with one mole of acetic acid of crystallization.

Anal. Calcd. for $C_{27}H_{46}O_7 \cdot C_2H_4O_2$: C, 64.9; H, 8.3. Found: C, 64.7; H, 8.5.

When treated with diazomethane it gave a dimethyl ester which melted at 156–159° when crystallized from ligroin and gave no depression in melting point when mixed with a sample of the ester prepared from natural chlorogenin.

Anal. Calcd. for $C_{29}H_{44}O_7$: C, 69.0; H, 8.8. Found: C, 69.3; H, 8.9.

Oxidation of Digitogenin Triacetate.—To a solution of 10 g. of digitogenin triacetate in 300 cc. of glacial acetic acid was added a solution of 15 g. of chromic anhydride in 100 cc. of 80% acetic acid. The product was heated on a steam-bath for ninety minutes, cooled and a small amount of water was added. The product was well extracted with ether and the total solvent was removed by vacuum distillation on a steam-bath. The residue was dissolved in ether and the acid fraction was removed by shaking with a small amount of 10% alkali. The neutral fraction upon evaporation of the ether crystallized. It was very insoluble in ether and was crystallized from acetone and from ether, m. p. 282–284° and gave no depression with an authentic sample of digitogenin lactone triacetate.

The alkaline layer was acidified and extracted ten times with a liberal amount of ether. The solvent was removed and the residue was sublimed in a high vacuum at 100°. The sublimate was crystallized from ether–pentane and from chloroform, m. p. 105–109°. Mixed with α-methylglutaric acid it melted at 55–62°.

Anal. Calcd. for $C_5H_8O_4$: C, 45.4; H, 6.1; neut. equiv., 66. Found: C, 45.9; H, 6.3; neut. equiv., 68.

Other Reactions of Digitogenin.—Digitogenin is recovered unchanged after four days of boiling with strong alcoholic hydrogen chloride mixture, indicating that it has the iso-configuration.

The greater portion of digitogenin is recovered unchanged when treated with amalgamated zinc and alcoholic hydrochloric acid even for twenty-four hours of continuous addition. The other sapogenins are converted in high yields into the tetrahydrosapogenins with three to six hours of similar treatment.

The greater part of digitogenin is unchanged upon treatment with acetic anhydride in a bomb tube at 200° for ten hours. The other sapogenins are converted almost quantitatively by this treatment into the pseudosapogenins.

Sublimation of digitogenin with potassium bisulfate at 210–220° gave only recovered digitogenin and no apparent dehydration.

Summary

Evidence has been presented indicating that there is no hydroxyl group at C–6 in digitogenin.

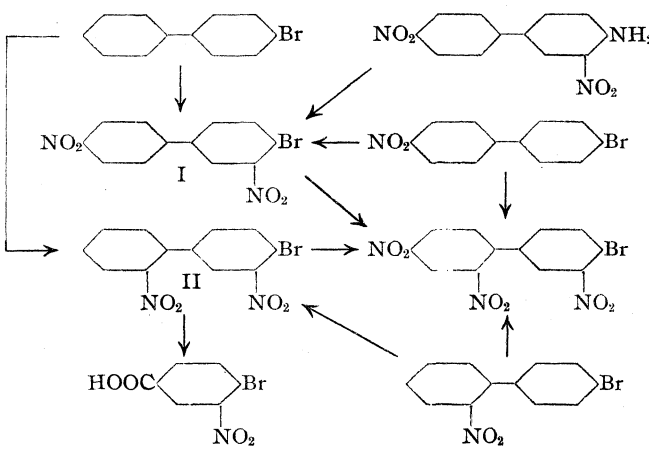
The Nitration of Certain Halobiphenyls. I. Nitro Derivatives of 4-Bromobiphenyl

BY FRANCIS H. CASE

In 1933 Mascarelli[1] obtained by the nitration of 4-bromobiphenyl two isomeric dinitrobromobiphenyls I (m. p. 205–206°) and II (m. p. 147–148°) whose structure was undetermined since they resisted oxidation. With a view to clearing up the structure of these compounds, we have repeated the nitration, again obtaining the two isomers with the revised melting points 210–211° and 154–155°, respectively. Isomer I, also obtained by the nitration of 4-nitro-4′-bromobiphenyl, has been shown by us to be identical with the product obtained from 3,4′-dinitro-4-aminobiphenyl by replacement of amino by bromine, and is therefore 3,4′-dinitro-4-bromobiphenyl. A substance[2] (m. p. 135°), obtained by the nitration of 4-nitro-4′-bromobiphenyl, was previously assigned this structure

FIG. 1.



without experimental proof. Isomer II has been shown by us to be identical with the dinitrobromobiphenyl obtained by Finzi and Bellavita[3] by the nitration of 4-bromo-2′-nitrobiphenyl. They assigned to it the structure 2′,3-dinitro-4-bromobiphenyl on the basis that it reacts with piperidine. We have confirmed this structure by oxidizing this substance to 3-nitro-4-bromobenzoic acid, thus avoiding the piperidine reaction,[3] which is sometimes misleading. LeFèvre and Turner[4] obtained by the nitration of either 4-bromo-2′-nitrobiphenyl or 4-bromo-4′-nitrobiphenyl the same trinitrobromobiphenyl. Since it reacts with piperidine they assigned to it the structure 2,3′,4-trinitro-4′-bromobiphenyl. This is confirmed without the use of piperidine by the fact that 3,4′-dinitro-4-bromobiphenyl also yields the same substance on nitration.

The nitration of 4-bromo-3′-nitrobiphenyl is of interest because in this compound the nitro group is in a position it would not normally assume on the nitration of 4-bromobiphenyl. It was found that if the nitration were carried out according to Mascarelli's general directions, *i. e.*, in a mixture of nitric and sulfuric acids initially kept below 40° but completed at 100° and the product extracted with ether, the ether-insoluble part yielded a constant-melting product III, the analysis of which indicates a trinitrobromobiphenyl mixed with a small amount of a dinitrobromobiphenyl. On oxidation the mixture yields 3-nitro-4-bromobenzoic acid. From the ether soluble portion could be isolated by fractional crystallization a dinitrobromobiphenyl IV (m. p. 143–144°), from alcohol–acetone.

If the nitration were effected under milder conditions, *e. g.*, nitric and sulfuric acids below 40°, nitric acid (sp. gr. 1.5) below 15°, or ethyl nitrate, the reaction product, now soluble in ether, when repeatedly crystallized from alcohol–acetone yielded a constant-melting mixture which analyzed correctly for a dinitrobromobiphenyl. On repeated crystallization from benzene, it yielded a pure isomeric dinitrobromobiphenyl V, m. p. 187–188°. On oxidation the mixture was partially converted into 3-nitro-4-bromobenzoic acid, leaving a residue of the pure isomer IV.

On more drastic nitration with nitric acid (sp. gr. 1.59), at 100°, 4-bromo-3′-nitrobiphenyl is converted into the isomeric trinitrobromobiphenyls VI (predominantly) and VIII.

The structure of isomer IV, suggested by the fact that it does not react with piperidine and on total reduction followed by oxidation yields no acid, was established by the following method: 4-amino-3′-nitrobiphenyl was nitrated to 2,3′-dinitro-4-aminobiphenyl (structure proven by de-

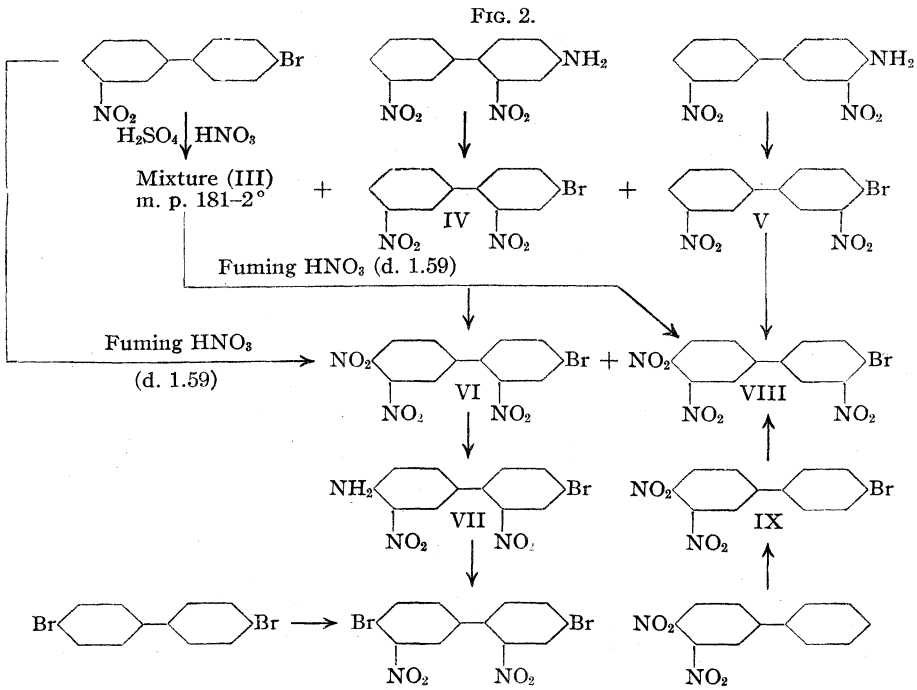
FIG. 2.



amination to 2,3′-dinitrobiphenyl), and the compound resulting from this by replacement of amino by bromine proved identical with IV.

Isomer V was synthesized by nitration of 4-acetamino-3′-nitrobiphenyl to 3,3′-dinitro-4-acetaminobiphenyl (structure proven by hydrolysis and deamination to 3,3′-dinitrobiphenyl) followed by hydrolysis and replacement of amino by bromine.

Isomers IV and V were now separately nitrated further (nitric acid (sp. gr. 1.59) at 100°). The trinitrobromo compound yielded by IV was now found to be identical with VI, obtained by the direct nitration of 4-bromo-3′-nitrobiphenyl under the same conditions. It was found that one nitro group of VI is replaced completely by amino in alcoholic ammonia at 150°. On deamination of the resulting compound (VII), however, IV is regenerated, indicating that the new nitro group is the one attacked by the ammonia. If, however, VII is subjected to the Sandmeyer reaction, the resulting dibromodinitro compound is shown to be identical with 2,3′-dinitro-4,4′-dibromobiphenyl, obtained by the nitration of 4,4′-dibromobiphenyl.[4,5]

Since the positions of both bromine atoms are known in one compound, and of both nitro groups in the other, the identity of these compounds constitutes a proof of the structure of VI and an independent proof of the structure of the dinitration product of 4,4′-dibromobiphenyl.

The replacement of a *p*- instead of a *m*-nitro group by amino in 2,3′,4′-trinitro-4-bromobiphenyl seemed somewhat surprising in view of the fact that such compounds as 3,4-dinitromethyl-, iodo-, chloro-, and bromo-benzene all yield *m*-amino derivatives under similar conditions. A study of the reaction of 3,4-dinitrobiphenyl with alcoholic ammonia showed that here, also, the nitro group para to the phenyl nucleus is substituted by amino.

The trinitrobromo compound VIII obtained by the further nitration of V was synthesized as follows: 3,4-dinitrobiphenyl, prepared by the action of copper on phenyl iodide and 3,4-dinitroiodobenzene at 270°, was brominated, and the resulting product (IX) on nitration yielded VIII. Since in IX the position of the two nitro groups is known and in VIII the positions of the bromine atom and of the other nitro group are known, the structures of both VIII and IX are simultaneously proved.

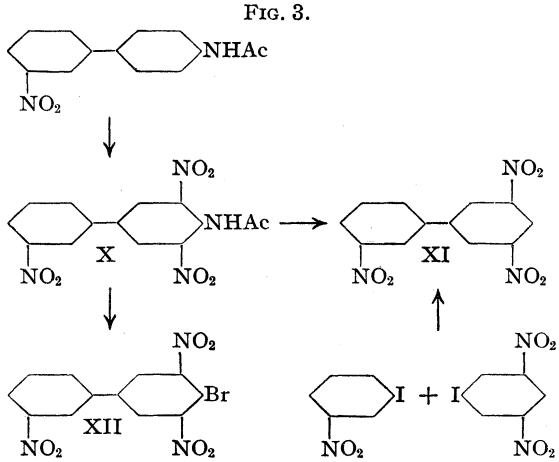
Since on nitration with nitric acid (sp. gr. 1.59) at 100° the previously described mixture (III) yields VIII and in view of the analytical data, it is concluded that it consists largely of VIII mixed with a small amount of a dinitrobromobiphenyl.

The synthesis of 3,3′,5-trinitro-4-bromobiphenyl (XII), another theoretically possible result

(5) Dennett and Turner, *J. Chem. Soc.*, 476 (1926).

of the further nitration of 3,3′-dinitro-4-bromobiphenyl, was accomplished by the dinitration of 4-acetamino-3′-nitrobiphenyl followed by hydrolysis and application of the Sandmeyer reaction. The structure of the intermediate trinitro base (X) was proven by deaminizing it to a trinitrobiphenyl (XI), which proved identical with that obtained by the Ullmann reaction on a mixture of 3,5-dinitroiodobenzene and *m*-nitroiodobenzene. From two moles of 3,5-dinitroiodobenzene, the hitherto undescribed 3,3′,5,5′-tetranitrobiphenyl was obtained. It was hoped to reduce one nitro group of this substance and convert it into the trinitro compound mentioned above, but the reduction proved to be unsuccessful.

FIG. 3.



Experimental

Nitration of 4-Bromobiphenyl.—The procedure was the same as that of Mascarelli.[1] Isomer I (ether-insoluble), crystallized from acetone, melted at 210–211°.

Anal. Calcd. for $C_{12}H_7N_2O_6Br$: Br, 24.74. Found: Br, 24.78.

Isomer II (ether-soluble), crystallized from alcohol, melted at 154–155°.

Anal. Calcd. for $C_{12}H_7N_2O_6Br$: Br, 24.74. Found: Br, 24.86.

Synthesis of 3,4′-Dinitro-4-bromobiphenyl (Method of Schoutissen[6]).—To a solution at 0° of 5.2 g. of 3.4′-dinitro-4-aminobiphenyl in 20 cc. of concd. sulfuric acid was added a solution of 2 g. of sodium nitrite in 20 cc. of concd. sulfuric acid. Phosphoric acid (70 cc.) was then added with stirring, keeping the temperature below 2°. After standing one-half hour the resulting solution was poured into a solution of 15 g. of bromine and 15 g. of sodium bromide in 100 cc. of ice-water. After one hour, copper powder was added and the mixture allowed to stand overnight. It was then heated for one hour and the precipitate filtered off and recrystallized from acetone; m. p. 207–208°. This was not depressed by admixture with isomer I, above.

(6) Schoutissen, THIS JOURNAL, **55**, 4538 (1933).

Nitration of 4-Nitro-4′-bromobiphenyl.—The procedure was again the same as that of Mascarelli.[1] From 17.7 g. of starting material, the ether-insoluble portion yielded 2.5 g. of pure isomer I.

Nitration of 4-Bromo-2′-nitrobiphenyl.—Six grams of 4-bromo-2′-nitrobiphenyl was added gradually to a mixture of 20 cc. of concd. sulfuric acid and 26 cc. of concd. nitric acid, keeping the temperature below 30°. After one hour of stirring at room temperature the mixture was poured into water and the precipitated solid crystallized from alcohol–acetone; yield 3 g., melting at 154–155°, and unchanged when mixed with isomer II. On oxidation with chromic acid, this substance yields 3-nitro-4-bromobenzoic acid.

Preparation of 2,3′,4-Trinitro-4′-bromobiphenyl.—This substance (m. p. 180–181°) was obtained by the action of fuming nitric acid (sp. gr. 1.59) at 100° on each of the following: 3,4′-dinitro-4-bromobiphenyl, 2,3′-dinitro-4-bromobiphenyl, 4-nitro-4′-bromobiphenyl, 2-nitro-4′-bromobiphenyl.

Nitration of 4-Bromo-3′-nitrobiphenyl

Method A.—4-Bromo-3′-nitrobiphenyl (17.7 g.) was added slowly to a mixture of 30 g. of concd. sulfuric acid and 20 g. of concd. nitric acid, keeping the temperature below 40°. The reaction was completed by heating on the steam-bath for one hour. The mixture was then poured into ice-water, filtered, washed and dried. After five extractions with ether, an insoluble residue was obtained which on crystallization from acetone–alcohol yielded 2 g. of a product melting constantly at 181–182°. The analysis indicated it to be an impure trinitrobromo derivative.

Anal. Calcd. for $C_{12}H_6N_3O_6Br$: Br, 21.72; N, 11.42 Found: Br, 22.42; N, 11.08.

On oxidation with chromic acid it yielded 3-nitro-4-bromobenzoic acid.

The ether soluble material was evaporated to dryness, and on repeated crystallization from alcohol–acetone yielded 2.5 g. of a product (IV) melting at 143–144°.

Method B.—Fifteen grams of 4-bromo-3′-nitrobiphenyl was added gradually to a stirred mixture of 30 g. of sulfuric acid and 20 g. of nitric acid, keeping the temperature below 40°. The reaction mixture, which proved to be soluble in ether, was poured into water, washed and dried. After eight crystallizations from benzene 0.4 g. of a product (V) melting at 189–190° was obtained. If the nitration mixture were crystallized from alcohol–acetone, 8.7 g. of a mixture melting at 129–130° was obtained.

Anal. Calcd. for $C_{12}H_7N_2O_6Br$: Br, 24.74. Found: Br, 24.91.

On oxidation with chromic acid the mixture yielded 3-nitro-4-bromobenzoic acid and pure isomer IV.

Method C.—Twenty grams of 4-bromo-3′-nitrobiphenyl was dissolved in 170 cc. of fuming nitric acid (sp. gr. 1.59) and the mixture heated for one hour on the steam-bath. It was then poured into water, and the resulting solid (VI) crystallized four times from alcohol–acetone; yield, 5 g.; m. p. 170–171°.

Anal. Calcd. for $C_{12}H_6N_3O_6Br$: Br, 21.72. Found: Br, 22.01.

From the filtrate of the first crystallization a solid separated on standing which after repeated crystallization from alcohol–acetone yielded 0.7 g. of a solid melting at 191–192° and unchanged when mixed with VIII.

Nitration of the Mixture (III).—Nitration according to the above procedure yielded a trinitrobromobiphenyl (VIII), m. p. 192–193°.

2,3′-Dinitro-4-aminobiphenyl.—Fifteen grams of 3-nitro-4′-aminobiphenyl was dissolved in a mixture of 13 cc. of 15% oleum and 50 cc. of concd. sulfuric acid. Potassium nitrate (7.5 g.) was added slowly, keeping the temperature below 6°. The reaction mixture was then allowed to warm to room temperature, poured into ice water and neutralized with potassium hydroxide. On crystallization from benzene, 11 g. of crude base, m. p. 154°, was obtained. The acetyl derivative was crystallized from alcohol, m. p. 215–216°.

Anal. Calcd. for $C_{14}H_{11}N_3O_5$: N, 13.96. Found: N, 13.84.

The pure base was obtained by hydrolysis of the acetyl derivative in dilute sulfuric acid. It was crystallized from benzene, m. p. 157–158°.

Anal. Calcd. for $C_{12}H_9N_3O_4$: N, 16.22. Found: N, 16.44.

On deamination the above base yielded a product melting unchanged when mixed with 2,3′-dinitrobiphenyl.

2,3′-Dinitro-4-bromobiphenyl.—This was prepared by Schoutissen's[6] method from 2,3′-dinitro-4-aminobiphenyl. After crystallization from alcohol–acetone it melted at 143–144°. The melting point was unchanged by admixture with isomer IV.

Anal. Calcd. for $C_{12}H_7N_2O_4Br$: Br, 24.74. Found: Br, 24.99.

3,3′-Dinitro-4-aminobiphenyl.—To a solution of 6 g. of 4-acetamino-3′-nitrobiphenyl in 30 cc. of glacial acetic acid and 10 cc. of acetic anhydride at 70° was added a solution of 1.5 cc. of nitric acid (sp. gr. 1.5) in 5 cc. of acetic acid. After one hour of stirring at this temperature, the mixture was poured into ice water, and the precipitated solid recrystallized from glacial acetic acid, yielding 4.5 g., m. p. 241–242°.

Anal. Calcd. for $C_{14}H_{11}N_3O_5$: N, 13.96. Found: N, 13.74.

The free base was liberated by hydrolysis with dilute sulfuric acid at 120°. On crystallization from benzene, it melted at 206–207°.

Anal. Calcd. for $C_{12}H_9N_3O_4$: N, 16.22. Found: N, 16.51.

On deamination the base was converted into 3,3′-dinitrobiphenyl.

3,3′-Dinitro-4-bromobiphenyl.—This was prepared from the above base in the same way as 2,3′-dinitro-4-bromobiphenyl. On crystallization from acetone–alcohol it melts at 187–188°.

Anal. Calcd. for $C_{12}H_7N_2O_4Br$: Br, 24.74. Found: Br, 24.95.

The melting point was unchanged by admixture with isomer V.

2,3′,4′-Trinitro-4-bromobiphenyl (VI).—This was prepared from 2,3′-dinitro-4-bromobiphenyl by the same method used to prepare it from 4-bromo-3′-nitrobiphenyl.

2,3′-Dinitro-4′-amino-4-bromobiphenyl.—2,3′,4-Trinitro-4-bromobiphenyl (4.5 g.), suspended in a solution of alcoholic ammonia, was heated in a sealed tube for ten hours at 150°. After evaporation of the alcohol, the residue was taken up in benzene and treated with dry hydrogen chloride. From the precipitated hydrochloride the free base was liberated with ammonium hydroxide and crystallized from alcohol–acetone; m. p. 223–224°.

Anal. Calcd. for $C_{12}H_8N_3O_4Br$: Br, 23.65. Found: Br, 23.85.

Deamination.—One gram of the above base suspended in 90 cc. of alcohol was treated with 20 cc. of 1–1 sulfuric acid and 3 g. of solid sodium nitrite. After one hour of heating on the steam-bath, the deaminized product was precipitated in ice-water and recrystallized from alcohol. It melted unchanged when mixed with 2,3′-dinitro-4-bromobiphenyl.

2,3′-Dinitro-4,4′-dibromobiphenyl.—This was obtained from the 2,3′-dinitro-4′-amino-4-bromobiphenyl by the method of Schoutissen as in the case of 2,3′-dinitro-4-bromobiphenyl. It melted at 152–153°, and was shown by mixed melting point to be identical with the product obtained by Dennett and Turner[5] from the nitration of 4,4′-dibromobiphenyl.

3,4-Dinitrobiphenyl.—The following method of synthesis was adopted after attempts to oxidize 3-nitro-4-aminobiphenyl with Caro's acid, and to apply Sandmeyer's reaction to it had failed. A mixture of 19 g. of 3,4-dinitroiodobenzene, 20 g. of iodobenzene and 22 g. of copper powder was heated for three hours in a sealed tube at 280°. The copper compounds were then removed by extraction with acetone, the acetone evaporated off, and the residue distilled in vacuum. The fraction boiling at 180–210° (3 mm.) was found to be unchanged 3,4-dinitroiodobenzene. The fraction boiling at 210–245° (3 mm.) was recrystallized from methanol, yielding 3.4 g. of 3,4-dinitrobiphenyl, m. p. 86–87°. The pure product melts at 87–88°.

Anal. Calcd. for $C_{12}H_8N_2O_4$: N, 11.48. Found: N, 11.70.

Ammonolysis of 3,4-Dinitrobiphenyl.—3,4-Dinitrobiphenyl (2.5 g.), dissolved in a large excess of alcoholic ammonia, was heated in a sealed tube at 150° for ten hours. After evaporation of the solvent the residue on crystallization from alcohol yielded 1 g. of product melting at 162–163°, or 0.6 g., m. p. 168°. This melted unchanged when mixed with 3-nitro-4-aminobiphenyl. From the filtrate no other pure compound could be isolated.

3,4-Dinitro-4′-bromobiphenyl (IX).—A solution containing 7.1 g. of 3,4-dinitrobiphenyl, 3.5 cc. of bromine, and 0.1 g. of ferric chloride in 30 cc. of glacial acetic acid was heated at 90° for forty hours until the bromine color had disappeared. The mixture was then poured into water, and the resulting solid crystallized eight times from alcohol, yielding 0.5 g. of a product melting at 167–168°. Since very incomplete bromination was indicated, the filtrates were all evaporated down and rebrominated, yielding an additional 1.2 g.

Anal. Calcd. for $C_{12}H_7N_2O_4Br$: Br, 24.74. Found: Br, 24.80.

3,3′,4-Trinitro-4′-bromobiphenyl (VIII).—This was obtained by the nitration of 3,3′-dinitro-4-bromobiphenyl

with nitric acid (sp. gr. 1.59) at 100°. When crystallized from benzene it melts at 192–193°.

Anal. Calcd. for $C_{12}H_6N_3O_6Br$: Br, 21.72. Found: Br, 22.08.

The same product was also obtained by the nitration of IX or of the mixture III.

3,3′,5-Trinitro-4-aminobiphenyl (X).—Ten grams of 3,3′-dinitro-4-acetaminobiphenyl was added gradually to 60 cc. of nitric acid (sp. gr. 1.5) keeping the temperature below 8°. On pouring the solution into water and recrystallizing from acetone–alcohol, the acetylated base was obtained yielding 4.5 g., m. p. 241–242°. The pure product melts at 242–243°.

Anal. Calcd. for $C_{14}H_{10}N_4O_7$: N, 16.19. Found: N, 15.83.

This product could also be obtained in a lower state of purity by direct nitration of 4-acetamino-3′-nitrobiphenyl.

The free base was obtained by hydrolysis of the acetamino compound with dilute sulfuric acid at 120°. On crystallization from glacial acetic acid it melted at 233°.

Anal. Calcd. for $C_{12}H_8N_3O_6$: N, 18.43. Found: N, 18.19.

Deamination of 3,3′,5-Trinitro-4-aminobiphenyl.—The deamination of 3,3′,5-trinitro-4-aminobiphenyl by the simple method used to prepare 2,3′-dinitro-4-bromobiphenyl proved ineffective in this case, as the base was recovered unchanged. The following procedure was therefore adopted: 3.5 g. of the trinitro base, dissolved in 30 cc. of concd. sulfuric acid, was treated at 0° with a solution of 1.5 g. of sodium nitrite in 20 cc. of concd. sulfuric acid. The mixture was treated at 2° with a solution of 70 cc. of phosphoric acid, and then with 40 cc. of 20% oleum, at 15–20°. The resulting solution was poured into 250 cc. of boiling ethanol, and refluxed for one hour. After pouring into ice-water, the resulting solid was filtered and crystallized from methanol–acetone, yielding 1 g. of a product melting at 167–168°. This was further purified by treatment with chromic acid which appeared to remove traces of unchanged base. The melting point of the pure product was 177–178°.

Anal. Calcd. for $C_{12}H_7N_3O_6$: N, 14.54. Found: N, 14.48.

3,3′,5-Trinitrobiphenyl (XI).—A mixture of 12 g. of 3,5-dinitroiodobenzene, 7.5 g. of *m*-nitroiodobenzene and 8 g. of copper powder was heated for an hour at 270°. From the ether extract it was possible to obtain by repeated crystallization from alcohol–acetone a small amount of a solid melting at 173–174° and unchanged when mixed with the deamination product of 3,3′,5-trinitro-4-aminobiphenyl.

3,3′,5-Trinitro-4-bromobiphenyl (XII).—This was prepared from the corresponding base by Schoutissen's method. From 3.5 g. of base was obtained 3 g. of pure product, melting at 222–223° (from alcohol–acetone).

Anal. Calcd. for $C_{12}H_6N_3O_6Br$: Br, 21.72. Found: Br, 22.04.

3,3′,5,5′-Tetranitrobiphenyl.—A mixture of 13 g. of 3,5-dinitroiodobenzene and 8.5 g. of copper powder was heated with stirring at 270° for one and one-half hours. The acetone extract, after evaporation, was crystallized from toluene, yielding 0.7 g. of a solid melting at 228–229°.

Anal. Calcd. for $C_{12}H_6N_4O_8$: N, 16.77. Found: N, 16.52.

The nitrogen analyses were carried out by Messrs. Richard Schock and Chester White.

Summary

1. The nitration of 4-bromobiphenyl according to Mascarelli is shown to yield 3,4′-dinitro-4-bromobiphenyl and 2′,3-dinitro-4-bromobiphenyl.

2. Depending on conditions, the following substances have been obtained from the nitration of 4-bromo-3′-nitrobiphenyl: 2,3′-dinitro-4-bromobiphenyl, 3,3′-dinitro-4-bromobiphenyl, 2,3′,4′-trinitro-4-bromobiphenyl and 3,3′,4′-trinitro-4-bromobiphenyl.

3. Proof of the structures of the above substances is given.

Syntheses of Epi-lactose and Lactose

BY W. T. HASKINS, RAYMOND M. HANN AND C. S. HUDSON

In continuation of our use of acetone-D-mannosan<1,5>β<1,6>[1] for the synthesis of disaccharides[2] having their linkage at carbon atom 4, we have now combined this substance with acetobromo-D-galactose and thereby produced, first, the epimer of lactose (4-[β-D-galactopyranosido]-D-mannose), which we shall designate epi-lactose for brevity, and, second, lactose (4-[β-D-galactopyranosido]-D-glucose) itself. Bergmann, Schotte and Rennert[3] discovered epi-lactose by the epimerization of lactose through the reactions *lactose → acetobromolactose → hexaaceiyl lactal → lactal → epi-lactose.* The reverse transformation of epi-lactose to lactose, which has now assumed importance, has been accomplished readily by the reactions *epi-lactose → acetobromo-epi-lactose → hexaacetyl lactal → lactose hexaacetate → lactose octa-*

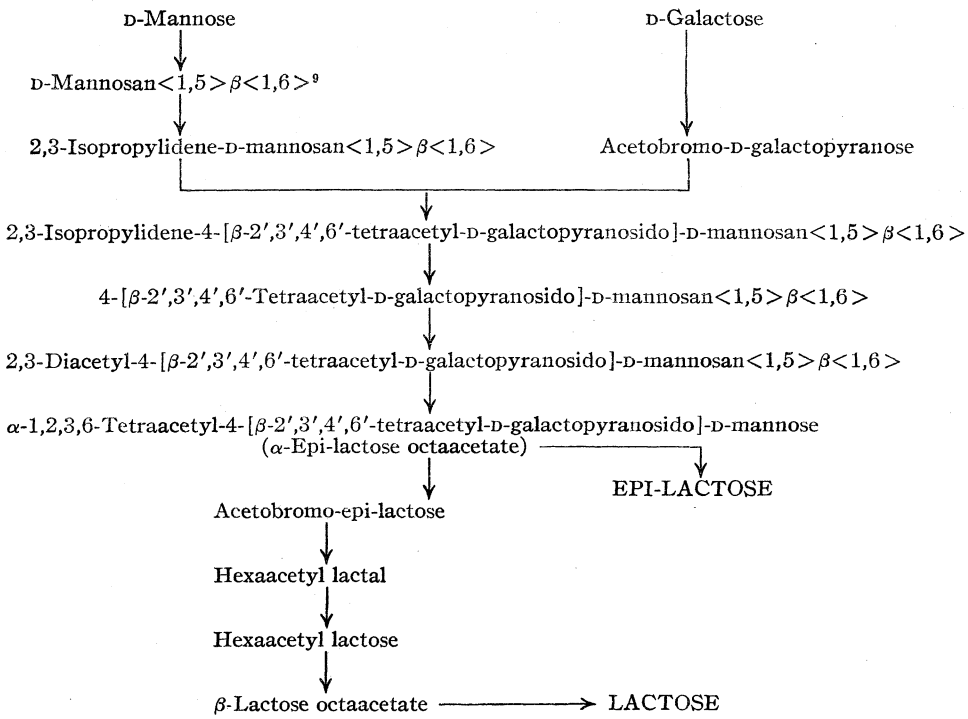
acetate → lactose, following the general method of Levene and Tipson[4] in the oxidation of the glycal hexaacetate, as used by us[2] recently in the transformation of epi-cellobiose to cellobiose. Several of the essential designations in the structure of lactose were established by Haworth and Long[5] when they identified the products of the acid hydrolysis of fully methylated lactobionic acid as 2,3,4,6-tetramethyl-D-galactopyranose and 2,3,5,6-tetramethyl-D-gluconic acid. The β-configuration of the galactose moiety has been inferred in the past from the fact that the enzyme lactase, which hydrolyzes lactose, likewise hydrolyzes β-methyl-D-galactopyranoside, but is without action on the α-modification; and also from a comparison of the rotatory powers of the methyl esters of the octamethyl derivatives of lactobionic, cellobionic and maltobionic acids, before and after acid hydrolysis.[6] The β-configuration of the galactose moiety is now conclusively established from the fact that acetobromo-D-galactose, which yields β-methyl-D-galactopyranoside when treated with methyl alcohol and silver carbonate by the Koenigs–Knorr reaction,[7] was employed in the present syntheses. The syntheses also represent total syntheses since such have been accomplished previously for D-mannose and D-galactose.[8] *Lactose, the unique disaccharide of mammalian life, is producible in the chemical laboratory, by structurally definitive reactions of organic chemistry, from the elements carbon, hydrogen and oxygen.* A flow diagram of the synthetic steps, beginning with D-mannose and D-galactose, is shown.



The synthesis of the enantiomorph of lactose, namely, 4-[β-L-galactopyranosido]-L-glucose, unquestionably could be made by parallel reactions provided sufficient supplies of the rare L-mannose and L-galactose should become available.

Historical Note.—A formation of lactose by the direct combination under catalytic conditions of supposedly pure glucose and galactose was reported in 1879 by Demole.[10] Pictet and Vogel[11] also reported such a formation. The reality of these reported formations of lactose remains in grave doubt; in any event, they have not contributed any new knowledge concerning the structure of lactose. In 1902 Emil Fischer and

E. F. Armstrong[12] reported a synthesis of a galactosido-glucose from acetochloro-D-galactose and sodium glucosate ("glucose-natrium"); a crystalline osazone, which was thought by them to be possibly melibiose osazone, was described; a later re-investigation of the subject by Schlubach and Rauchenberger[13] suggested that the osazone may be that of lactose. Biochemical syntheses of lactose from its constituent hexoses through the enzymotic activity of mammary gland tissue have been reported.[14]

Experimental

Acetobromo-D-galactose.—The general method of Levene and Raymond[15] was followed. A solution of 25 g. of β-D-galactopyranose pentaacetate (m. p. 140–142°; $[\alpha]^{20}D$ +24.0° in chloroform)[16] in 50 cc. of glacial acetic acid was cooled to 0° and saturated with gaseous hydrobromic acid; after standing two hours at 5°, the solution was diluted with 100 cc. of toluene and concentrated *in vacuo* at 45° to a thin sirup; three successive 100-cc. portions of toluene were added and removed in the same manner; the residual sirup was dissolved in 25 cc. of warm ether and as the solution cooled the acetobromogalactose crystallized. The yield was 23.6 g. (90%). The substance was recrystallized by solution in two parts of ether and the addition of one part of isopentane; it formed fine needles which melted at 84–85° (cor.). and showed a rotation of +217° (*c*, 1.2)[17] in chloroform and +242° (*c*, 1.2) in benzene. Fischer and Armstrong[18] report a melting point of 82–83° and a specific rotation $[\alpha]^{20}D$ of +236.4° in benzene for acetobromogalactose; Ohle, Marecek and Bourjau[19] record a melting point of 85° for the compound, but did not measure its rotation. Apparently the rotation in chloroform has not been recorded previously; its value is now found to be near that which was predicted some years ago.[20]

Anal. Calcd. for $C_{14}H_{19}O_9Br$: Br, 19.4. Found, Br, 19.7.

2,3-Diacetyl-4-[β-2′,3′,4′,6′-tetraacetyl-D-galactopyranosido]-D-mannosan<1,5>β<1,6>.—A solution of 10.1 g. (0.05 mole) of 2,3-isopropylidene-D-mannosan <1,5>β<1,6> in 100 cc. of dry alcohol-free chloroform, 50 g. of "Drierite," 25 g. of silver oxide and 35 g. of glass beads (4 mm. diameter) was placed in a 500-cc. brown glass stoppered bottle and agitated on a machine for one hour to ensure drying of the reagents; 2.5 g. of solid iodine and a solution of 20.6 g. (0.05 mole) of acetobromo-D-galactose in 50 cc. of pure chloroform were then added and shaking was resumed for seven days at room temperature (24°). The solid reaction products and excess of reagents were removed by filtration, and the filtrate (which gave no test for ionizable halogen) containing the 2,3-isopropylidene - 4 - [β - 2′,3′,4′,6′ - tetraacetyl - D - galactopyranosido]-D-mannosan<1,5>β<1,6>, was concentrated *in vacuo* to a sirup. A solution of the sirup in 200 cc. of 80% acetic acid was heated on the steam-bath until the rotation became constant (two hours), to remove the isopropylidene residue; the solvent was removed by concentration *in vacuo*, and the residual sirup, containing the partly acetylated 4-[β-D-galactopyranosido]-D-mannosan<1,5>β-<1,6>, was heated for one hour on the steam-bath with 2.5 g. of fused sodium acetate and 25 cc. of acetic anhydride. The reaction mixture was poured over crushed ice and the gum which precipitated was washed with water and dissolved in 10 cc. of warm alcohol; the new crystalline material (2,3-diacetyl-4-[β-2′,3′,4′,6′-tetraacetyl-D-galactopyranosido]-D-mannosan < 1,5 > β < 1,6 >) which deposited as the solution cooled was recrystallized from 15 parts of absolute alcohol and obtained in the form of elongated prisms which melted at 193–194° (cor.) and showed a rotation of −62.7° (*c*, 0.8) in chloroform. The yield was 8.8 g. (30%).

Anal. Calcd. for $C_{24}H_{32}O_{16}$: C, 50.00; H, 5.60; CH_3CO, 44.8. Found: C, 50.11; H, 5.62; CH_3CO, 44.7.

α-1,2,3,6 Tetraacetyl-4-[β-2′,3′,4′,6′-tetraacetyl-D-galactopyranosido]-D-mannose (α-Epi-lactose Octaacetate).—A solution of 12.5 g. of 2,3-diacetyl-4-[β-2′,3′,4′,6′-tetraacetyl-D-galactopyranosido]-D-mannosan<1,5>β<1,6> in 100 cc. of an acid acetylating solution (prepared by adding 2 cc. of concentrated sulfuric acid dropwise to an ice-cold mixture of 70 cc. of acetic anhydride and 30 cc. of glacial acetic acid) changed in rotation from +50.8°, after fifteen minutes, to a constant value of +55.1° in two hours at 20°. The reaction mixture was poured over crushed ice and the crystalline precipitate which formed was recrystallized from 3 parts of absolute alcohol. The yield was 14.5 g. (99%). The new substance (α-epi-lactose octaacetate) crystallized as elongated prisms which melted at 96–97° (cor.) and rotated +41.2° (*c*, 0.8) in chloroform.

Anal. Calcd. for $C_{28}H_{38}O_{19}$: C, 49.56; H, 5.64; CH_3CO, 50.8. Found: C, 49.44; H, 5.66; CH_3CO, 50.5.

4-[β-D-Galactopyranosido]-D-mannose (Epi-lactose).—To an ice-cold solution of 5.0 g. of epi-lactose octaacetate in 50 cc. of absolute methyl alcohol, 5 cc. of 0.5 *N* barium methylate solution was added and the mixture was allowed to stand at 5° for sixteen hours; the barium was precipitated by the addition of an equivalent amount of 0.1 *N* sulfuric acid and, following the removal of the barium sulfate, the solution was concentrated to a sirup, which was dissolved in 10 cc. of warm methyl alcohol. The β-form of the disaccharide deposited from the solution as it cooled; it was recrystallized by solution in 1 part of warm water and the addition of 5 parts of methyl alcohol and was obtained

(20) Hudson, THIS JOURNAL, **46**, 462 (1924). The difference between the molecular rotations in the pyranose pair, acetobromo-D-glucose and β-D-glucose pentaacetate, is +81,400 − 1,500 = 79,900, and in the similar pair, acetobromo-D-galactose and β-D-galactose pentaacetate, it is now found to be 89,200 − 9,000 = 80,200. According to the isorotation rules an equality of these differences, which are (A_{Br} + A_{ac}) in each case, is to be expected.

in the form of fine needles which melted at 195–196° (cor.); an aqueous solution (*c*, 1.2) of the substance exhibited a rotation of +18.0° three minutes after preparation and its equilibrium rotation was +27.2°. The unimolecular coefficient of the mutarotation at 20° was 0.0151, using minutes and decimal logarithms; the initial rotation of this β-form of the sugar is thus approximately +17°, in good agreement with the value (+16°) which Haworth, Hirst, Plant and Reynolds[21] obtained indirectly, through solubility measurements of the α-form. Bergmann, Schotte and Rennert[3] report a melting point of 196–197° and an equilibrium rotation of +30.0° for β-epi-lactose, and Haworth and co-workers[21] record an equilibrium value of +27° for anhydrous epi-lactose (calculated from that of α-epi-lactose monohydrate). It may be summarized for reference purposes that the initial rotations of the α- and β-forms of epi-lactose are +38°[21] and +17°, respectively, by direct measurements, and that the equilibrium rotation is +27°.

Anal. Calcd. for $C_{12}H_{22}O_{11}$: C, 42.10; H, 6.48. Found: C, 42.00; H, 6.53.

Lactal Hexaacetate from Epi-lactose Octaacetate.—To a solution of 10.0 g. of synthetic epi-lactose octaacetate in a mixture of 10 cc. of glacial acetic acid and 5 cc. of acetic anhydride, 40 g. of a 30% solution of hydrobromic acid in glacial acetic acid was added. The reaction mixture was allowed to stand at 5° overnight and after dilution with 50 cc. of chloroform, it was poured into 250 cc. of ice-cold water. The aqueous solution was extracted with chloroform in the usual manner, and the washed and dried chloroform extract was concentrated *in vacuo* to a sirup. A solution of the sirup, coutaining the acetobromo-epi-lactose, in 100 cc. of 50% acetic acid was cooled to 0° and 20 g. of zinc dust and 2 drops of a 0.5% solution of chloroplatinic acid in 50% acetic acid were added and the reaction mixture was stirred vigorously for two hours; the zinc was removed by filtration and the filtrate was poured into 200 cc. of ice-cold water; the crystalline lactal hexaacetate (4.1 g.; 50%) which precipitated was separated by filtration and recrystallized by solution in 3 parts of warm alcohol and the addition of 7 parts of water, being deposited in the form of needles which melted at 114° (cor.) and rotated −18.0° (*c*, 0.8) in chloroform. A mixed melting point with authentic lactal hexaacetate (from acetobromolactose) showed no depression. Haworth, Hirst, Plant and Reynolds[21] record a melting point of 114° and a specific rotation of −18° for lactal hexaacetate.

Anal. Calcd. for $C_{24}H_{32}O_{15}$: C, 51.43; H, 5.75; CH_3CO, 46.1. Found: C, 51.62; H, 5.69; CH_3CO, 46.2.

Lactose Octaacetate from Lactal Hexaacetate.—A solution of 5.0 g. of lactal hexaacetate in a mixture of 30 cc. of ethyl acetate, 5 cc. of water and 30 cc. of a 0.3335 *M* ether solution of perbenzoic acid (1.12 molecular equivalents) was agitated for twenty hours at 25°; at the expiration of this period titration of a one cubic centimeter aliquot indicated that 0.9 of a molecular equivalent of perbenzoic acid had been consumed in the oxidation. The reaction mixture was agitated with 10 cc. of water and 4.0 g. of sodium bicarbonate until the ether–ethyl acetate layer was neutral, and the aqueous layer was separated and extracted with chloroform; the combined ether and chloroform extracts were dried and concentrated *in vacuo* to a thick sirup. The sirup, which presumably contained lactose hexaacetate, was acetylated with acetic anhydride and fused sodium acetate and yielded 3.8 g. (58%) of β-lactose octaacetate. The product was recrystallized from 1.5 parts of alcohol and obtained as prisms which melted at 88–90° (cor.) and showed a rotation of −4.5° (*c*, 0.8) in chloroform solution, in good agreement with the reported values[22] of 90° and −4.7°, respectively, for β-lactose octaacetate. A mixed melting point with authentic β-lactose octaacetate showed no depression.

Anal. Calcd. for $C_{28}H_{38}O_{19}$: C, 49.56; H, 5.64; CH_3CO, 50.8. Found: C, 49.60; H, 5.58; CH_3CO, 50.9.

Lactose Monohydrate from β-Lactose Octaacetate.—A solution of 4.0 g. of β-lactose octaacetate in 100 cc. of methyl alcohol was deacetylated by barium methylate in the usual manner. The disaccharide monohydrate (2.0 g., 94%) was obtained in the form of prisms which melted with decomposition at 202° (cor.); a mixed melting point determination with authentic lactose monohydrate showed no depression; an aqueous solution of the substance exhibited initial and final rotations of +81° and +52.7° (*c*, 2.0), respectively, with a mutarotation rate of 0.0042 at 20°. Isbell and Pigman[23] report an initial rotation of +85.0° (*c*, 7.6), a final rotation of +52.6° and a mutarotation rate of 0.0047 for α-lactose monohydrate. The over-all yield of lactose monohydrate from epi-lactose octaacetate was 27% and from acetobromo-D-galactose it was 8%.

Anal. Calcd. for $C_{12}H_{22}O_{11}\cdot H_2O$: C, 40.00; H, 6.71; H_2O, 5.00. Found: C, 39.99; H, 6.80; H_2O, 5.04.

Summary

The condensation of 2,3-isopropylidene-D-mannosan<1,5>β<1,6>with acetobromo-D-galactopyranose yields a product from which, after removal of its acetone residue followed by acetylation of the two hydroxyl groups thus liberated, there was obtained crystalline 2,3-diacetyl-4-[β-2′,3′,4′,6′-tetraacetyl-D-galactopyranosido]-D-mannosan<1,5>β<1,6> in 30% yield. The action of an acid acetylating mixture upon this substance opened its 1,6-anhydro ring and produced the α-octaacetate of epi-lactose, from which epi-lactose was obtained by deacetylation. Epi-lactose octaacetate was converted by customary procedures to the known lactal hexaacetate, which, upon oxidation at the double bond with perbenzoic acid, generated the new hydroxyl group mainly in a position *trans* to the acetylated hydroxyl group on carbon three, since it was found that the product, upon complete acetylation, gave a 58% yield of the crystalline β-octaacetate of lactose, from which lactose was obtained by de-

acetylation. The over-all yield of lactose, based upon the acetobromo-D-galactose used in its synthesis, was 8%. The results constitute the structurally definitive syntheses of epi-lactose and lactose from D-mannose and D-galactose. They are total syntheses, since such syntheses of these hexoses were accomplished by Emil Fischer. The new crystalline substances that are described are 2,3-diacetyl-4-[β-2′,3′,4′,6′-tetraacetyl-D-galactopyranosido]-D-mannosan<1,5>β<1,6> and α-octaacetyl-epi-lactose; some other new substances, intermediates in the syntheses, were not isolated in crystalline form.

Isomerization of β-Carotene. Isolation of a Stereoisomer with Increased Adsorption Affinity

BY A. POLGÁR AND L. ZECHMEISTER

In spite of the fact that the phenomenon of carotenoid isomerization was first detected for β-carotene,[1] our knowledge in this special case is still very incomplete. These authors crystallized an isomer which they termed pseudo-α-carotene. and which appears immediately below β-carotene on the Tswett column. Gillam first assumed that the chromatographic process itself was responsible for the partial conversion, but it was shown later that the phenomenon occurs spontaneously and independently of a chromatographic experiment.[2] This conclusion was confirmed by Carter and Gillam.[3]

Early experiments in our laboratory showed that the reversible isomerization, for the explanation of which *trans–cis* shifts were suggested, can either increase or decrease the adsorptive power as compared with that of the respective all-*trans* carotenoid.[4] It was stated[5] as a rule that carotenoids with at least two free hydroxyl groups yield isomers which are adsorbed at higher sections of the column than the starting pigment. This result is in accordance with observations on the hydroxy-ketones capsanthine and capsorubine[6] as well as with investigations of Strain[7] concerning leaf xanthophylls. In the case of the monohydroxy-compound cryptoxanthin and especially of the hydrocarbons $C_{40}H_{56}$ the opposite behavior was observed; to this rule, however, the present paper provides an exception.

In systematic experiments now being carried out in our laboratory with a series of carotenoids mainly four methods of isomerization are applied, *viz.*, refluxing the pigment solution, iodine catalysis, hydrochloric acid catalysis (both at room temperature), and melting the crystals.[8] The first two procedures have already been described.[2,4,5] As a convenient method for the acid catalysis, a mechanical shaking of the petroleum ether solution with concentrated hydrochloric acid is used. The catalysis is here mainly effective at the continuously shifting intersurface of the two liquids.

It was assumed and confirmed by experiment that stereoisomers of a carotenoid which are formed and are present in the melt can be separated by rapid cooling and chromatography. Such a treatment, which is much milder than the so-called "thermal decomposition" of carotenoids,[9] is best carried out in a sealed tube, in the absence of oxygen. Under suitable conditions no carbonization occurs. The melting of β-carotene gave us four main types of products, *viz.*, unchanged starting material, reversibly formed stereoisomers of β-carotene, pigments with a much shorter chromophore than that of carotene, and finally colorless, strongly fluorescent substances with very low adsorption affinity. The ratio of these types depends on the conditions, especially on the temperature. A solution of a crude melt was found to show about one-half the initial color intensity, whereas "thermal decomposition" as practiced earlier leads to complete bleaching.

In the end-product of the heat, iodine, and melt isomerization the stereoisomers may be accompanied by minor pigments formed in an irreversible way. It is therefore important to test each zone of the chromatogram from this point of view. Only such pigments are qualified as stereoisomers of the starting material of which the solutions on addition of some iodine in the spectroscopic cell show a typical shift of the bands. The spectrum of an equilibrium mixture appears almost instantaneously in which the maxima are only a few millimicrons lower in wave length than those of the all-*trans* compound which was formed and predominates in the mixture. The result of the test may be confirmed by subsequent chromatography and the main zone of the chromatogram can be identified by means of a mixed chromatogram with a sample of the original carotenoid. The spectra of the chromatographic zones containing β-carotene stereoisomers are listed in Table I. All four isomerization methods yielded the pigments 1, 3, 5 and 8, while appreciable amounts of 2, 4 and 6 have been observed so far, mainly after melting or hydrochloric acid catalysis of β-carotene; 7 was obtained in a melt chromatogram of neo-β-carotene U.

TABLE I

SPECTRA OF REVERSIBLY FORMED STEREOISOMERS OF β-CAROTENE IN THE SEQUENCE OF DECREASING ADSORPTION AFFINITIES

No.	Extinction maxima (mμ)		
1	481	450	(neo-β-carotene U)
2	472.5	441.5	(neo-β-carotene V)
3	486	454	(β-carotene)
4	469	437.5	(neo-β-carotene A)
5	475.5	444.5	(neo-β-carotene B)
6	465.5	433	(neo-β-carotene C)
7	474.5	441.5	(neo-β-carotene D)
8	477.5	445	(neo-β-carotene E)
9	468.5	437	(No names given)
10	473.5	443	
11	476.5	445.5	
12	471	440	
13	473	444	

Pigment no. 5 is spectroscopically nearly identical with "pseudo-α-carotene."

Some uncertainty exists concerning the pigments 9–13 due to their great lability. In different experiments only one to two isomers appeared and could be differentiated below pigment 8. Because of this lability it was impossible to identify or differentiate two such zones originating from different kinds of experiments by mixed chromatography. In this case the spectral data depend on the time which elapses between elution and optical measurement, and even on the rapidity of the reading, considering the photochemical effect of the light source. Above and including pigment 8 the individuality of the pigments listed is well established in spite of great differences in stability, because in all experiments, using the melt and the hydrochloric acid methods, a series of five to seven zones appeared in this section. Some members of this section must also be investigated rapidly; pigment 6 showed *e. g.*, 6 mμ longer wave length maxima than listed when in another experiment the time factor was not taken into consideration.

For one of the main stereoisomers of β-carotene which is adsorbed above β-carotene in the column, we suggest the name neo-β-carotene U (U for ultra).[10] Depending on the conditions, 10–25% of β-carotene can be converted into this compound and 17% has been actually isolated in crystals.[11] The compound was also observed in extracts of pumpkin, squash, carrots, etc., where it was formed by spontaneous isomerization. A natural occurrence remains to be shown. The tendency for the formation of the U isomer is considerable and the fact that it was isolated only recently requires some explanation. While Gillam's pseudo-α-carotene (neo-β-carotene B) appears below the usually sharp bottom line of unchanged β-carotene in the column and can easily be observed under various conditions, the U isomer (which is spectroscopically not very different from β-carotene) is included in the upper, more blurred part of the β-carotene zone and separates under adequate conditions only. With the brand of calcium hydroxide now in use in this laboratory, developing with petroleum ether which contains some acetone promotes the differentiation and finally produces a colorless interzone between the two stereoisomers.

The following remarks may summarize briefly our present views with regard to the stereochemistry of β-carotene.

(10) A final nomenclature cannot yet be given as the respective configurations must first be established (*cf.* footnote 12).

(11) Our results are in accordance with a short remark of H. H. Strain [THIS JOURNAL, **63**, 3448 (1941)] that under the influence of acid "eschscholtzxanthine, cryptoxanthine and β-carotene were converted slowly into substances that were adsorbed both above and below the native pigments." (In the iodine catalysis no pigment located above β-carotene in the column seems to have been observed.) In unpublished experiments we observed stereoisomers of α-carotene which were adsorbed above the original pigment in the column. It is intended to report later on this subject.

According to Pauling[12] the steric interaction of hydrogen and methyl prevents the assumption of the *cis* configuration for double bonds with C-CH_3 adjacent. Therefore out of the eleven double bonds in β-carotene only five are stereochemically effective, *viz.*, numbers 3, 5, 6, 7 and 9 (see the formula).

The quantum mechanical treatment of the carotenoid spectra[13] leads to the conclusion that the greatest intensity of light absorption would be shown by the isomer with the all-*trans* configuration and that the shorter *cis* isomers would show decreased intensity. This is in agreement with our experiments, and with the *cis–trans* interpretation of the phenomena studied. Also, according to a private communication from Professor Linus Pauling who is working on the theoretical aspects of the problem discussed, the *cis* configuration for a double bond would be expected to produce a spectral shift in wave length toward the violet, with magnitude dependent on the position of the double bond in the long conjugated system.[7]

The following figures show that the spectral differences between the first maxima of all-*trans* polyene-hydrocarbons and their spectroscopically closest stereoisomers are about 4–6 mμ.

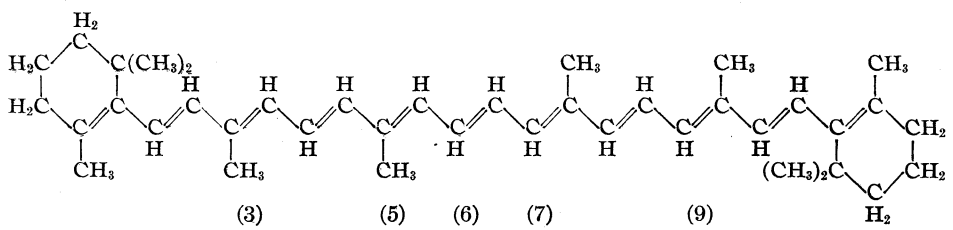
	mμ		mμ
β-Carotene	486	γ-Carotene	496
Neo-β-carotene U	481	Neo-γ-carotene A[14]	489.5
Lycopene		504.5 mμ	
Neolycopene A		500.5 mμ	

The stereoisomer so far observed which shows the greatest displacement from the β-carotene maxima has bands at 465.5 and 433 mμ. The position of the first band (Δ = about 20 mμ) indicates the presence of four or five *cis* bonds, that is, all but one or all of the available double bonds have the *cis* form. This stereochemical situation is closely similar to that suggested for prolycopene and pro-γ-carotene.[15] In the present case, however, its lability has prevented the crystallization of the substance.

Gillam's pseudo-α-carotene (Δ = 9 mμ) seems to contain two *cis* bonds while tentatively one such bond could be assigned to neo-β-carotene U (Δ = 5 mμ).

Possibly neo-β-carotene U contains in *cis* form that particular double bond (the central one) which on both sides is farthest from C-CH_3 groups and is attacked by the enzyme carotinase in the liver. It remains to be seen whether the biological formation of vitamin A is or is not preceded by a stereochemical shift. Neo-β-carotene U has no vitamin A activity when tested with rats.

Acknowledgment.—We wish to thank the Rockefeller Foundation for a grant which enabled the members of this Laboratory to carry out the experiments described below and in some previous papers. To Dr. G. Oppenheimer and Mr. G. Swinehart, the authors are indebted for microanalytical assistance, to Merck & Co., Inc. for a vitamin A assay.



β-Carotene (all-*trans*); the double bonds available for a *trans–cis* shift are numbered.

We tentatively assume with rough approximation that each *cis* double bond produces a spectral shift of the order of magnitude mentioned.

Experimental

Methods.—The pigment solutions were chromatographed on calcium hydroxide (Shell Brand lime, chemical hydrate; 98% through 325 mesh). For development petroleum ether (b. p. 60–70°) was used or, depending on the quality of the lime, the same solvent with 1–5% acetone. The figures on the left side of the described chromatograms denote width of the zones, in mm. Petroleum ether–alcohol mixtures are suitable eluents or else ether may be

(12) (a) L. Pauling, *Fortschritte Chem. Organ. Naturstoffe*, **3**, 203 (1939); connected paper, (b) L. Zechmeister, A. L. LeRosen, F. W. Went and L. Pauling, *Proc. Nat. Acad. Sci.*, **27**, 468 (1941).

(13) L. Pauling, see footnote 12b, and *ibid.*, **25**, 577 (1939); R. S. Mulliken, *J. Chem. Phys.*, **7**, 364 (1939).

(14) The denomination "neo-γ-carotene A" is now applied to that stereoisomer which appears immediately below unchanged γ-carotene on the Tswett column. Zones of the same pigment have been mentioned under the name "neo-γ-carotene" by R. F. Hunter and A. D. Scott [*Biochem. J.*, **35**, 31 (1941)] and by the authors [*J. Biol. Chem.*, **139**, 193 (1941)]. Preliminary experiments, using refluxing and iodine catalysis, have revealed the presence of at least one more reversibly formed stereoisomer which is adsorbed below the A compound and is termed neo-γ-carotene B.

(15) Footnote 12(b); A. L. LeRosen and L. Zechmeister, THIS JOURNAL, **64**, 1075 (1942); L. Zechmeister and W. A. Schroeder, *ibid.*, **64**, 1173 (1942).

used if an immediate crystallization is intended. The spectra (in petroleum ether unless otherwise indicated) were determined with an Evaluating Grating Spectroscope (Zeiss, light filter BG-7, 2 mm. thick). For the estimation of the concentrations a Pulfrich Gradation Photometer was used (light filter S 45 or S 47). The necessary data for neo-β-carotene U are given below. Values for β-carotene itself were published by Cholnoky.[16] Relative photometric values of components of a chromatogram are expressed in % of the extinction of the sum of the components.

(a) **Heat Isomerization of β-Carotene Solutions.**—A solution of 25 mg. of chromatographically homogeneous β-carotene crystals (from carrots) in 150 ml. of petroleum ether was refluxed in an all glass apparatus, in a slow carbon dioxide stream for 60 min. The following chromatogram was obtained (28 × 7 cm.):

2 brownish yellow: irreversible layer (heterogeneous, about 485, 453 mμ.)
15 colorless
35 reddish orange: neo-β-carotene U (481, 450)
2 almost colorless
0.5 yellow: irreversible layer[17] (479, 448)
2 almost colorless
85 dark orange: β-carotene (486, 454)
40 dark yellow: neo-β-carotene B (475.5, 443.5)
2 almost colorless
20 pale reddish: neo-β-carotene E (479.5, 447)
2 almost colorless
12 yellow: a labile isomer (473, 443)

Unchanged β-carotene and each stereoisomer (without irreversible zones) was cut out, transferred into petroleum ether and refluxed again. The relative photometric values of the zones thus formed are listed in Table II.

TABLE II

RELATIVE PHOTOMETRIC VALUES OF THE PIGMENTS REVERSIBLY FORMED BY SIXTY MINUTES OF REFLUXING OF β-CAROTENE AND SOME OF ITS STEREOISOMERS

Starting material	Relative photometric values (%) neo U	β-carotene	neo B	neo E	labile isomer
Neo-β-carotene U	31	40	19	10	
β-Carotene	4	86	8	1	1
Neo-β-carotene B	4	50	40	3	3
Neo-β-carotene E	14	49	19	18	
Labile isomer	10	22	24	30	14

(b) **Isomerization of β-Carotene by Iodine Catalysis, at Room Temperature.**—25 mg. of homogeneous β-carotene in 200 ml. of petroleum ether was kept in the presence of 0.5 mg. of iodine for sixty minutes and chromatographed (calcium hydroxide, 28 × 7 cm.). The same pigments as were listed in (a) appeared, except the 0.5-mm. yellow zone. Each zone was again submitted to this catalytic treatment with subsequent adsorption analysis. The relative photometric values of the isomers formed are summarized in Table III.

TABLE III

RELATIVE PHOTOMETRIC VALUES OF β-CAROTENE AND OF SOME OF ITS STEREOISOMERS AS FORMED BY IODINE CATALYSIS AT ROOM TEMPERATURE

Amount of iodine, 2% of the starting material; duration, 60 min.

Starting material	Relative photometric values (%) neo U	β-carotene	neo B	neo E	labile isomer
Neo-β-carotene U	24	47	24	3	2
β-Carotene	22	48	25	3	2
Neo-β-carotene B	21	51	23	3	2
Neo-β-carotene E	20	48	24	4	4
Labile isomer	18	45	16	13	8

(c) **Isomerization of β-Carotene with Hydrochloric Acid.**—25 mg. of homogeneous β-carotene in 200 ml. of petroleum ether was mechanically shaken with 100 ml. of concentrated hydrochloric acid for thirty minutes, then washed free of acid and developed with petroleum ether, containing 1% acetone, on a calcium hydroxide column (24 × 5.5 cm.)

7 orange: irreversible layer (heterogeneous)
4 almost colorless
2 orange-yellow: irreversible (459, 430.5 mμ)
90 reddish orange: neo-β-carotene U (480, 450)
5 almost colorless
40 dark orange: β-carotene (486, 454)
35 dark yellow: neo-β-carotene B (476.5, 444)
12 pale reddish: neo-β-carotene E (479.5, 447)
8 yellow: labile isomer (476.5, 445.5)
5 almost colorless
15 pale yellow: irreversible (479, 448.5)[18]

The relative photometric values of the zones were: β-carotene: neo U: neo B: neo E: labile isomer = 50:23:23:3:1. The chromatogram was subject to minor variations in different experiments. A reversible minor zone appeared on long development in most experiments below the U-isomer: neo-β-carotene V (474, 443 mμ), while in some other cases two isomers (471, 440 and 473, 444 mμ) were observed below neo-β-carotene E, both of which showed a very great tendency for spontaneous reisomerization into β-carotene. If the indicated volume of acid was diminished or the duration of the catalysis shortened, the irreversible bottom layer was missing. In longer exposure to the acid, the amounts of the bottom layer increased; furthermore, two minor stereoisomers of β-carotene appeared, both located above the U-compound.

The irreversible bottom layer has been crystallized. A fresh solution of the crystals did not separate from carrot α-carotene in the mixed chromatogram and will be investigated later.

(d) **Isomerization of β-Carotene by Melting.**—25 mg. of homogeneous β-carotene (m. p. 179.5°, cor.) crystals was melted in a sealed glass tube in carbon dioxide and kept in a bath at 190° for fifteen minutes. The melt was rapidly solidified in ice water, dissolved in petroleum ether and chromatographed. (The loss in the total photometric

(17) This minor layer has not been observed when stereoisomers of β-carotene were refluxed. If this pigment is refluxed separately, an irreversible pigment possessing 459, 430.5 mμ appears above it on the column. The same can be obtained from β-carotene by means of hydrochloric acid.

(18) 0.5–1% of the starting material.

value of the starting material amounted to about 60%.) The column (27 × 6.8 cm.) was developed with petroleum ether containing 2% acetone:

15 colorless
1 yellow: irreversible (457.5, 427 mμ)
63 reddish orange: neo-β-carotene U (481, 450)
2 pink: unidentified (very little)
7 yellow: neo-β-carotene V (474, 443)
7 almost colorless
30 dark orange: β-carotene (486, 453.5)
2 almost colorless
15 dark yellow: neo-β-carotene A (469, 437.5)
25 pale orange: neo-β-carotene B (475.5, 444.5)
1 yellow: neo-β-carotene C (471.5, 440.5)
3 colorless
15 pale reddish: neo-β-carotene E (477.5, 445)
5 colorless
10 yellow: labile isomer (468.5, 437)

Filtrate: yellow (432 mμ). This irreversible pigment (2% of the total photometric value of the melt) can be adsorbed on alumina (Alorco). The chromatographic filtrate of the latter contained a colorless substance showing greenish fluorescence in ultraviolet light.

The relative photometric intensities of the reversible zones (the width of which is printed in italics) were from top to bottom: 19:4:33:8:24:8:4.

(e) **Isolation and Properties of Neo-β-carotene U.**—To a solution of 50 mg. chromatographically homogeneous β-carotene (from carrots) in 250 ml. of petroleum ether 1 mg. of iodine (in 1 ml. of the solvent) was added and the liquid kept at room temperature for an hour. The solution was then developed with petroleum ether containing 3–5% acetone on a calcium hydroxide column (28 × 7 cm.) until the following sequence appeared: near the middle of the column the typical deep orange zone of β-carotene was located (about half of the total pigment), and this was followed by a strong zone of neo-β-carotene B and other minor neo-forms. Immediately above the β-carotene zone but well separated from it by a colorless intermediate section the light orange layer of neo-β-carotene U was observed. The latter was cut out, eluted with alcohol and eventually combined with an analogous eluate obtained by a second treatment with iodine of the unchanged β-carotene portion. On addition of water the pigment was transferred into petroleum ether, washed free of alcohol, dried and re-chromatographed on a smaller column. Only minor zones appeared below the main product which was eluted with peroxide free ether. After evaporating the dried solution, the residue was dissolved in the minimum amount of benzene, transferred into a centrifuge tube and crystallized out by cautious addition of several volumes of absolute methanol. The crystallization was almost complete within a few minutes at room temperature and the yield was 12.7 mg., *i. e.*, about 25% of the starting material. If the second treatment of β-carotene is omitted, the yield is reduced by about one third (obtained 41 mg., from 250 mg. of β-carotene).

Neo-β-carotene U was obtained as an orange crystalline powder which did not glitter. The basic microscopic form was a long narrow plate with one tapered end; the individuals were partly grouped in sheaves; m. p. 122–123° (cor., electrically heated Berl block; sealed tube filled with carbon dioxide); a fraction isomerized during the determination.

Anal. Calcd. for $C_{40}H_{56}$: C, 89.48; H, 10.52; mol. wt., 537. Found: C, 89.34; H, 10.58; mol. wt., 486 (in exaltone; a considerable fraction was isomerized).

Neo-β-carotene U is somewhat more soluble than β-carotene, especially in petroleum ether. It shows an epiphasic behavior in the partition test. The spectra, compared with those of β-carotene, are included in Table IV. On addition of iodine the following spectra appear: In carbon disulfide: 516, 481.5 mμ.; in pyridine: 498, 464.5 mμ; in benzene: 495.5, 462 mμ.; in chloroform: 494, 461 mμ.; in carbon tetrachloride: 493.5, 461 mμ.; in dioxane: 490.5, 458 mμ.; in cyclohexane: 486.5, 455 mμ.; in acetone: 485, 453.5 mμ.; in ligroin (b. p. 86–100°): 484, 453 mμ.; in ethanol: 482, 450.5 mμ.; in petroleum ether (b. p. 60–70°): 485, 453 mμ.; in ether: 484, 452 mμ.; in hexane: 483.5, 452.5 mμ., and in methanol: (479), (448) mμ.

A 0.1% benzene solution did not show optical activity in a 2-dm. tube. The concentration of petroleum ether solutions can be determined by means of the Pulfrich Gradation Photometer (k = extinction coefficient, c = mg. of pigment in 100 ml. of solution).

	k	0.2	0.4	0.6	0.8	1.0
Light filter S45	c	0.085	0.18	0.27	0.36	0.45
Light filter S47	c	0.095	0.19	0.29	0.39	0.49

TABLE IV

SPECTRA OF β-CAROTENE AND NEO-β-CAROTENE U IN DIFFERENT SOLVENTS (mμ)[a]

Solvent	β-Carotene		Neo-β-carotene U	
Carbon disulfide	520.5	484	512.5	478.5
Pyridine	503.5	469	498	464.5
Benzene	497.5	463.5	494	461
Chloroform	497.5	464	493.5	461
Carbon tetrachloride	497.5	463	492.5	460
Dioxane	494	462	490	458
Cyclohexane	490	457	485.5	454
Acetone	488.5	456	485	453.5
Ligroin (b. p. 86–100°)	487	455.5	483	452
Ethanol	486.5	453.5	482	450.5
Pet. ether (b. p. 60–70°)	486	453.5	481	450
Ether	485.5	453	481	449.5
Hexane	485	453.5	480	449.5
Methanol	484.5	452.5	480.5	449.5

[a] Gillam and El Ridi gave maxima for their pseudo-α-carotene in carbon disulfide: 507, 477 mμ.; in benzene, 491, 458 mμ.; in chloroform, 486, 456 mμ.; in ethanol, 478, 447 mμ.; and in petroleum ether (b. p. 70–80°), 477, 446 mμ.

Neo-β-carotene U is less easily adsorbed on lime from petroleum ether than pro-γ-carotene, much less than γ-carotene and considerably more strongly than β-carotene. The latter and neo-β-carotene U can be separated by developing with petroleum ether but more easily when 2–5% acetone is added to the solvent, depending on the quality of the adsorbent. On some brands of calcium hydroxide no separation takes place from pure petroleum ether but it occurs in many cases in the presence of 15% benzene.

Isomerization experiments with different methods, which started from crystallized neo-β-carotene U gave, with some variations, the stereoisomers mentioned above. The compound U is comparatively resistant to moderate heating, *e. g.*, a solution of 3 mg. in 25 ml. of petroleum ether, when kept at 60° for one hour, contained about three-fourths of the final pigment in the form of unchanged compound U. In melt experiments the same stereoisomers were obtained as in the corresponding experiments with β-carotene and a further reversible zone was observed (neo-β-carotene D, 474.5, 441.5 mμ). The melt was kept at 135° for fifteen minutes and because of the lower temperature (as compared with the β-carotene melt) and the partial formation of the more intensely colored β-carotene, the total loss in extinction was only one-fourth to one-fifth of the initial value in this case. Of the total photometric value of the melt 40% was caused by unchanged U-isomer, 22% by β-carotene formed and 38% by seven minor stereoisomers. No slightly colored or colorless and fluorescent breakdown products were observed.

Summary

As a contribution to the stereochemistry of polyenes, the isomerization of β-carotene was studied, under the influence of refluxing, iodine catalysis, hydrochloric acid catalysis, and by melting the crystals. The chromatograms showed a number of pigments, nine or ten of which were stereoisomers of β-carotene. Some of them are very labile. On addition of iodine they all yield a preponderant quantity of β-carotene and minor stereoisomers. One of the new isomers, "neo-β-carotene U," has been crystallized in a yield of 17% of the starting material. It is adsorbed above β-carotene and thus does not follow an earlier suggested rule concerning the location of polyene-hydrocarbon isomers on the Tswett column. It is tentatively assumed that the U isomer contains one *cis* double bond, and Gillam's pseudo-α-carotene two such bonds, out of the five stereochemically available double bonds. An observed labile stereoisomer which shows spectral maxima at 20 mμ. shorter wave lengths than β-carotene may possess four or five *cis* bonds in its molecule.

An Extension of the Acidity Scale

BY L. MICHAELIS AND S. GRANICK

After it had been recognized that the concentration of the hydrogen ion was only to a first approximation a useful concept for an acidity scale, *p*H was then defined as the logarithm of the reciprocal of the activity, instead of concentration, of the hydrogen ion. Because of the essential uncertainty involved in the definition of the activity of a single ionic species such as the hydrogen ion, one may avoid committing oneself to a definition in terms of strictly thermodynamical concepts and adopt the following working definition

$$p\mathrm{H} = \frac{E - E_0}{2.3RT}$$

where E is the e. m. f. of a cell composed of a hydrogen electrode, the solution to be measured, a saturated potassium chloride bridge and a calomel cell. The constant E_0 is chosen either so that in a very dilute solution of hydrochloric acid (say 10^{-4} M) *p*H equals the logarithm of the reciprocal of the concentration of the acid, or so that the *p*H in an equimolecular mixture of acetic acid and sodium acetate of infinitely low ionic strength equals the *p*K of acetic acid, whether this *p*K be determined by a thermodynamical or by a non-thermodynamical method, such as the conductivity method.[1] These two ways of fixing the value of E_0 are, for all practical purposes, compatible with each other.

This working definition is valid only on the assumption that the liquid junction potential of the above galvanic cell is irrelevant, either because it is negligibly small, or because it is constant for such cases of *p*H determinations as practically may occur. This assumption breaks down for solutions of large ionic strength and especially for solutions of very high acidity or alkalinity. Here, the liquid junction potentials can by no means be said to be irrelevant. If one tries to establish a *p*H scale for extremely acid solutions, another working definition of the acidity scale has to be chosen, and, possibly, such that in the region of lower acidities it coincides with the ordinary *p*H scale. One approach to this problem has been made by Hammett,[2] who, by means of colori-

(1) One of the more recent presentations of this much discussed problem is given by MacInnes in "The Principles of Electrochemistry," Reinhold Publishing Corporation, New York, N. Y., 1939.

(2) L. P. Hammett, *Chem. Rev.*, **16**, 67 (1935); "Physical Organic Chemistry," McGraw-Hill Book Company, New York, N. Y., 1940.

metric studies of a suitably chosen set of acidity indicators in the form of dyestuffs, has established an acidity scale in terms of an "acidity function," which in the range of pH, say 12 to 1, coincides with the pH scale.

The writers encountered during their studies on bivalent reversible oxidation–reduction systems an opportunity of establishing an acidity scale on a different basis. The principle of the method is this.[3]

In a bivalent, reversible system one may distinguish three levels of oxidation–reduction: the reduced (R), the semi-oxidized (S), and the totally oxidized (T) form. The normal potential of the R,S system, or the normal potential of the lower step of oxidation, will be designated as E_1; that of the S,T system, or that of the higher step of oxidation, as E_2; and the normal potential of the R,T system, or the mean normal potential, as E_m. These three normal potentials are related to each other as follows

$$E_m = (E_1 + E_2)/2$$

All of these normal potentials depend on pH. Hence, also the difference $E_2 - E_1$ depends on pH. This difference will be referred to as the "spread" of the normal potentials. On plotting E_1 and E_2 against pH, the curves consist to the first approximation of rectilinear sections with slopes of $n \times$ 0.06 volts per pH unit (at 30°), where n is an integer, including 0, and scarcely ever >3 (see, for instance, Fig. 1). From this approximation one arrives at the more correct form of the curves by rounding out the discontinuities. For example, the potential of the true, rounded-out curve at the pH of the intersection of two straight lines (pK) differs from that of the point of intersection by 18 millivolts.[4] This rule is of practical use for rounding out the preliminary discontinuities of the plots. Similarly, the E_m curve, as preliminarily plotted, consists of rectilinear sections with slopes of $n \times 0.03$ volts per pH unit, and here the correction for rounding out the edges is 9 millivolts at the pH of the intersection.

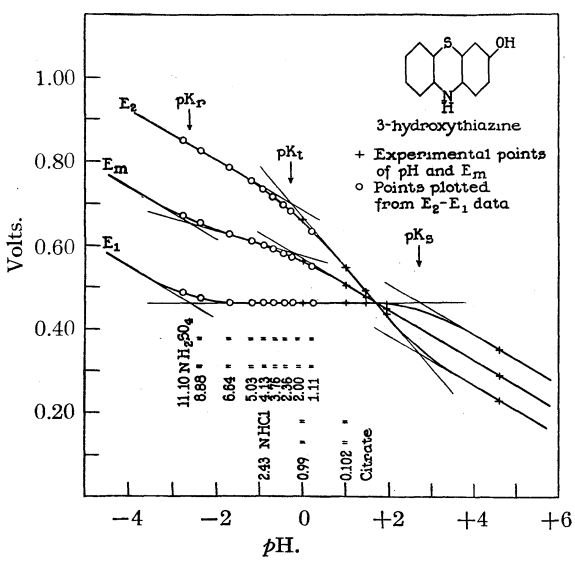

Fig. 1.

A further consequence of these rules is that also the spread, $E_2 - E_1$, depends on pH in a definite manner: in some pH intervals the spread may be independent of pH; in other pH intervals the spread may depend linearly on pH, the slope being either 0.06 or an integer multiple thereof. The transition from a region where the spread is independent of pH to a region where it is 0.06 is, of course, not a discontinuous one, but has to be rounded out according to the same principle as mentioned before. A change of this slope is brought about by a change of acidic ionization of the dye in one of its levels of oxidation–reduction.

Within the range of well definable pH values, plots of the three normal potentials against pH have been previously established for numerous dyestuffs. On working in very acid solutions there are two factors interfering with an unambiguous extension of the plot. First of all, there is no way of measuring pH by the hydrogen electrode. In the second place, there is no way of obtaining absolute values of the oxidation–reduction potential. It is true, that by a method described in a previous paper,[5] the liquid junction potential can be kept constant for all practical purposes during the time of the titration experiment, but the absolute value of the potential[6] cannot be determined. What one can measure is only the change of the potential during the titration. So, neither E_1 nor E_2 nor E_m can be measured, yet the spread, $E_2 - E_1$, can be measured.

(3) The writers are fully aware of the fact that what follows is not quite easy to follow for anybody not thoroughly familiar with the theory of the equilibrium in a reversible two-step oxidation–reduction system. Detailed presentations of this subject are L. Michaelis, *Chem. Rev.*, **16**, 243 (1935); L. Michaelis and M. P. Schubert, *ibid.*, **22**, 437 (1938); L. Michaelis, *Ann. N. Y. Acad. of Sciences*, XL, 39 (1940).

(4) Furthermore, at that pH which equals $pK \pm 1$ the analogous correction is 2.4 mv., and at any pH still further apart from pK this correction is practically negligible.

(5) L. Michaelis, M. P. Schubert and S. Granick, THIS JOURNAL, **62**, 204 (1940).

(6) "Absolute," of course, only in so far as the potential of the normal hydrogen electrode is arbitrarily taken as zero.

Now the spread depends on the acidity, and this functional relationship can be used for an acidity scale which, in the ordinary acidity range, coincides with *p*H. The procedure is best explained by an example. A suitable dyestuff is chosen. 3-Hydroxythiazine[7] is, by far, the best for reasons which will presently be understood. For this dyestuff it is easy to establish a plot of the normal potentials in the *p*H range from alkaline solution to acidities still measurable by the hydrogen electrode, say to *p*H 1 (the right-hand part of Fig. 1). Now the curves, which from *p*H 2 into the more acid region are all linear, can be extended into the region of higher acidity to the left, leaving all slopes unchanged, as long as one can be sure that no acidic ionization constant of the dye in any of its three forms, R, S or T interferes. Hereby one can establish a bridge from what may be called the known region of *p*H into the unknown region.

A series of potentiometric titrations in solutions of sulfuric acid furnishes the data for the spreads of the potentials at various concentrations of the acid (Table I). Thus, one can graphically correlate the spread with the concentration of the acid (Fig. 1). For instance, a titration experiment in 1.11 *N* sulfuric acid gave for the spread, $E_2 - E_1$, the value 174 millivolts. Now we mark that ordinate in the plot where the spread is 174 millivolts, and read on the abscissa that the *p*H here is +0.24. Hence, it is legitimate to ascribe to a 1.11 *N* sulfuric acid, the *p*H value +0.24. In a similar way, the *p*H values of sulfuric acid at other concentrations can be ascertained.

This procedure is legitimate for the extension of the *p*H scale to about 0. From here on, the oxidized form (t-hydroxythiazine) begins to change its state of acidic ionization by attaching a proton. Since the absorption spectra of the two forms of the oxidized dye are different, it is easy to find by a spectrophotometric method, such a concentration of sulfuric acid in which the ratio of the two forms is 1:1. The *p*H of this acid solution may be identified with the *pK* of the dye. The uncertainty involved in this simplified assumption will be discussed later on. To the left-hand side from *p*H 0, the E_2 curve must change its slope from 0.06 to 0.03. Now, one has to find the point of intersection in order to draw the straight line with slope 0.03 at the correct height above the abscissa. This is accomplished as follows. By a potentiometric oxidation-reduction experiment in such a sulfuric acid solution in which the ratio of the two acidic levels of the dye is 1:1, one finds a certain value of the spread for the normal potentials. In order to construct the two intersecting tangents and the correct value of the rounded-out curve at this point of intersection, one utilizes the rules stated above, saying that the normal potential of the T,S system at the point of intersection of the two tangents must be 18 millivolts lower than the point of intersection itself. In this way, the point of intersection is found to lie at *p*H −0.25. This, then, is also the exponent of acidic ionization, *pK*. Now, from the potentiometric oxidative titration experiments at higher acidities and the spreads derived from them, one can correlate the higher concentrations of sulfuric acid each with a definite *p*H value. This procedure can be extended to a *p*H about −2. Here, an acidic dissociation constant of the reduced form of the dye begins to interfere. By studying the ultraviolet absorption spectra of the reduced form, it was possible to obtain a semi-quantitative confirmation of the existence of this constant in the neighborhood of the acidity expected. It is safer to restrict the exploitation of this dye only to that region in which the *pK* of the reduced form of the dye does not yet interfere.

Now we select another dyestuff, 3-aminothiazine, utilizing the *p*H data obtained from oxythiazine. This is shown in Fig. 2. The points obtained within the ordinary *p*H range with aminothiazine are marked +. At higher acidities, up to −2, we can correlate the "spreads" with the *p*H of the acid solutions, as obtained from the first dye (Fig. 1). By optically determining the acidic ionization constant of the new dye in the same fashion as with the first, the plot can be extended up to *p*H −4. Here, again, a dissociation constant of the reduced form begins to interfere. For this reason, we proceed to another dye, 3,9-diaminothiazine (thionine) (Fig. 3) which permits us to extend the *p*H scale to about −6 in an analogous manner. This is as far as it was possible to go as yet.

On extending the *p*H scale by this method to the range of high acidity, there can be no objection to the procedure described, as long as the dye-

(7) As regards the nomenclature of the dyes, we follow our previous suggestion [S. Granick, L. Michaelis and M. P. Schubert, THIS JOURNAL, **62**, 1802 (1940)] of using the name of the leukodye which is always more convenient than that of the quinonoid form. When one of the three levels of oxidation–reduction is to be referred to in a special case, these three levels, then, are distinguished by the prefixes, r-, s- and t-.

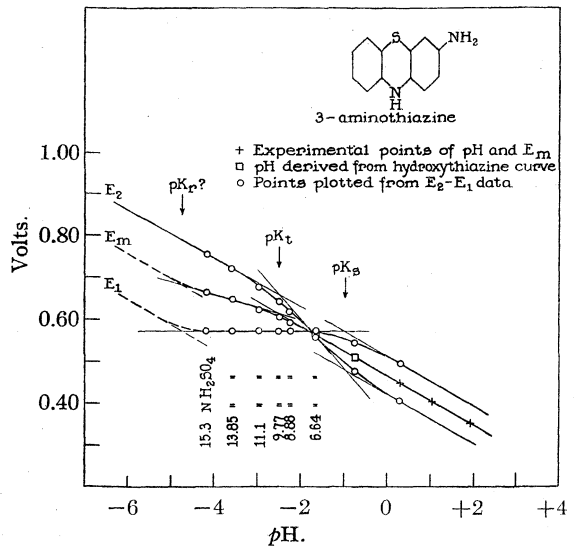

Fig. 2.

stuff in any of its three levels of oxidation–reduction (the R, S and T forms) does not change its state of acidic ionization. As soon as an acidic ionization constant of the dyestuff in one of its three levels of oxidation–reduction becomes noticeable, the following uncertainty begins to interfere. The optical method to be described presently yields that concentration of sulfuric acid where the ratio of the concentrations of the two forms of the dye, in their two levels of acidic ionization, is 1:1. What we want to know, however, is that concentration of the acid in which the ratio of the *activity* of the two forms is 1:1. Since the two forms of acidic ionization of necessity differ

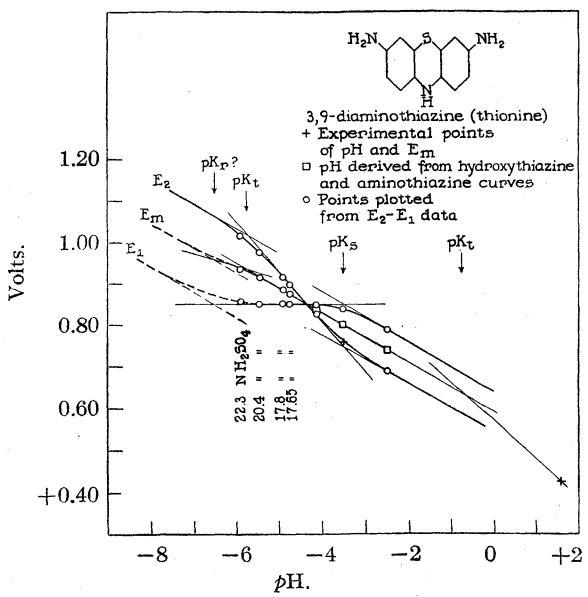

Fig. 3.

with respect to the number of free electric charges, the activity coefficients for the two forms will not be alike. On identifying the apparent ionization constant, as determined optically, with the thermodynamical ionization constant, one commits an error. This is the limitation of the method. Although the direction of the error may be recognizable from theoretical reasoning, there is no way of finding out a reasonable quantitative correction. For this reason, no correction will be applied at all in this paper, leaving any possible refinement for later work. Very likely, in sulfuric acid solutions the error in this procedure is small, and one should not over-emphasize it. The error may be estimated to rise up to a few tenths of a *p*H unit in the worst cases.

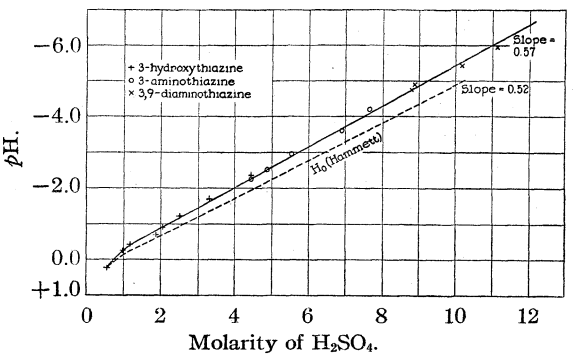

Fig. 4.

The results of the method may be understood, without further comment, from Figs. 1–4. The last of these figures permits of a comparison of this extended *p*H scale with Hammett's acidity function, H_0. It is striking that in both scales there is a linear relationship between *p*H (or acidity function) and the concentration of sulfuric acid above 1 *M* sulfuric acid.[8] Why this should be so is not yet explained. The slopes in the two methods are not quite the same: 0.52 for Hammett's function, 0.57 for ours. The writers are more impressed by the similarity than by the discrepancy between the two scales considering the different approaches used.

Optical Determination of the Ionization Constants.—Only two constants, those of the T forms of hydroxythiazine and aminothiazine, are essential for the plotting of the curves. The others that have been determined are not necessary but serve as a nice confirmation of the theory. For example, the *pK* value for the R form of oxythiazine in acid solution can be approximately es-

pK of TH^+ − TH_2^+ at 3.5 N H_2SO_4 (this pK value is only needed to get correct E_m, but is not necessary for the pH determination). pK of TH_2^{++} − TH_3^{+++} at 21.2 N H_2SO_4.

timated from the fact that the $E_2 - E_1$ values increase only slightly above 9 N sulfuric acid.

The pK values of the oxidized forms were determined by means of a Pulfrich photometer. The absorption spectra of the T and TH^+ forms of hydroxythiazine overlap. By selecting several suitable filters where the ratios of the absorption of the two components are different, the determination of the ionization constant is made possible. The pK values of aminothiazine TH^+ − TH_2^{++} and of thionine TH_2^{++} − TH_3^{+++} are more readily determined, since there is scarcely any overlapping of the absorption spectra. The acid concentration is increased until the extinction is found to be just half the extinction of the dye with one less proton (the dyestuff concentration, of course, remaining constant).

The determination of the ionization constant of the reduced form of oxythiazine is made possible, because the R form has a sharp absorption band at 3100 Å. in contrast to the RH^+ form which does not absorb at all in this region. By increasing the acidity in a series of steps, it was found that an absorption curve corresponding to one containing 50% of the concentration of the reduced form was obtained in a region between 8.5–12.0 N sulfuric acid, most probably in the neighborhood of 9.5 N sulfuric acid.

We wish to thank Dr. G. I. Lavin for taking the ultraviolet absorption plates of aminothiazine and Dr. E. G. Pickels for photometering these plates.

Summary

An extension of the pH scale for aqueous solutions of sulfuric acid up to 11 molar is accomplished by utilizing what is defined in the text as the spread of the normal potentials of certain dyestuffs which form large amounts of semiquinone radicals at suitable acidities. The results obtained from the use of three suitable dyes: hydroxythiazine, aminothiazine and thionine, can be compared with the Hammett acidity scale. In spite of the different approaches of Hammett's method and ours, we find a striking similarity between Hammett's results and our own.

The Autoxidation of Manganous Hydroxide

BY AMBROSE R. NICHOLS, JR.,* AND JAMES H. WALTON

The composition of the products obtained in the autoxidation of manganous hydroxide has received the attention of numerous investigators. The contributions of Meyer and Nerlich[1] and of Herman and Lievin[2] are of especial interest in this connection.

Meyer and Nerlich made a very complete study of the reaction in connection with the theories of the nature of trivalent manganese. They found that when manganous chloride, ammonium chloride and ammonium hydroxide were mixed and shaken in air, the product was manganic oxide, as evidenced by both the analysis of the product and the volume of oxygen absorbed. When potassium hydroxide, calcium hydroxide, or barium hydroxide was used, the product was stated to be manganese dioxide, although the volume of oxygen absorbed varied between 81 and 94% of the amount corresponding to the formation of manganese dioxide. According to Meyer and Nerlich, the autoxidation in the ammoniacal solution takes place through a mangano-ammonia complex which is oxidized to a mangani-complex. The latter is subsequently hydrolyzed with the formation of manganic hydroxide or manganic oxide. For the autoxidation of manganous hydroxide precipitated by fixed alkali, these authors accept the mechanism proposed earlier by Meyer.[3] Meyer postulated that the first step is the formation of a moloxide, H_2MnO_4, or $H_2MnO_2(O_2)$, which is not identical with manganic acid. The moloxide easily gives up oxygen to an acceptor such as manganous hydroxide. These authors find that other acceptors such as sodium sulfite and sodium arsenite have no effect. They did not attempt to investigate the rate of the reaction.

Herman and Lievin carried out experiments in which a bulb of manganous sulfate solution was broken within a flask containing potassium hydroxide solution, the flask being connected with a gas buret filled with oxygen. The volume of oxygen absorbed was plotted against time. With an excess of potassium hydroxide the curves obtained appeared to consist of two rectilinear portions connected by a curved portion. The ratio between the velocities indicated by the two sections varied with the amount of excess potassium hydroxide. These authors were unable to observe an absorption of more than 82% of the theoretical volume of oxygen necessary for the formation of manganese dioxide. With an excess of manganous sulfate, they found that there was a rapid absorption lasting about one minute, followed by a slow reaction at constant velocity, ending at a limit corresponding to the formation of manganic oxide. The greater the excess of manganous sulfate, the slower was the reaction, but in each case all of the manganese precipitated was in the form of manganic oxide.

The work described in this paper was undertaken to extend the knowledge of the factors affecting the rate of autoxidation of manganous hydroxide.

Apparatus and Procedure.—The apparatus was essentially that described by Filson and Walton.[4] An indented reaction flask containing a bulb of ammonium hydroxide or sodium hydroxide and the desired amount of manganous chloride solution was placed in a thermostated shaking device and connected with a gas buret. The system was evacuated and filled with oxygen. The reaction flask was rotated rapidly back and forth about a vertical axis which resulted in breaking the bulb and keeping the resulting reaction mixture saturated with oxygen. The volume of solution used was 60 cc. in each case. The reaction was followed by recording the buret readings at the end of definite time intervals. The temperature of the gas buret and the reaction flask was always 25° except as otherwise stated.

Autoxidation in Solutions Containing Manganous Chloride, Ammonium Chloride, and Ammonium Hydroxide.—Since ammonium chloride prevents the precipitation of manganous hydroxide by ammonium hydroxide, the effect of varying the ammonium chloride concentration was first studied. Because the reaction does not follow any ordinary rate law the results have been recorded (Table I) as volumes of oxygen absorbed in definite time intervals. A comparison of these volumes shows the effect of the concentration of ammonium chloride upon the reaction. The total volumes absorbed indicate definite limits. Each trial was continued until the buret level had remained constant for a period of from one-half to one hour.

The final volume of oxygen absorbed varied between 67 and 83% of the volume theoretically required for the formation of manganese dioxide (54.0 cc.). Curves represent-

ing duplicate runs varied by not more than 2%. The *p*H values listed were obtained by preparing reaction mixtures identical with those autoxidized and measuring the *p*H immediately by means of the glass electrode. A precipitate of manganous hydroxide was formed immediately in samples of *p*H above 9.3. Samples of *p*H 9.0 precipitated after standing a moment or two, while those of *p*H below 8.8 precipitated only very slowly. In each case the precipitate was white when first formed.

The rate of oxygen uptake decreased at first after the reaction had proceeded for a period, and then increased appreciably before finally decreasing as the reaction approached completion. The possibility of an autocatalytic effect, suggested by this observation, was investigated by adding to the reaction mixture a small amount of the solid oxidation product from previous trials. This resulted in a much more rapid reaction, and the rate was found to decrease continuously. Since the oxidation product was presumably largely manganese dioxide, a pure sample of this substance was tried. It also catalyzed the reaction. The effect of the manganese dioxide was found to depend upon its state of subdivision. Four reaction mixtures of the following composition were prepared: manganous chloride, 0.0692 mole per liter, ammonium hydroxide, 0.477 mole per liter, ammonium chloride, 2.25 moles per liter. The results, expressed in terms of the time required for the absorption of 20 cc. of oxygen when 0.5 g. of manganese dioxide of the indicated fineness was added to the reaction mixture, were: 60–80 mesh, 28 minutes: 120–140 mesh, 15 minutes; 200 mesh, 9 minutes. A similar sample to which no solid material had been added required 82 minutes.

Commercial manganese dioxide, ferric oxide, diatomaceous earth, and ground glass gave effects similar to that of the prepared manganese dioxide. Thus the effect appears to depend upon the surface of the particles rather than upon their chemical composition.

In connection with the study of these solid accelerators, powdered lead dioxide was tried. In this case the autoxidation was found to be completely inhibited. The manganese precipitated from this slightly alkaline solution is in a form which is not affected by oxygen. The reaction may take place through the steps:

$$PbO_2 + Mn^{++} + H_2O \rightleftarrows MnPbO_3 + 2H^+$$
$$MnPbO_3 + Mn^{++} + H_2O \rightleftarrows Mn_2PbO_4 + 2H^+$$

From these equations, the addition of neutral lead dioxide to manganous chloride solutions should result in a noticeable decrease in *p*H. That such a decrease actually occurs is shown by the following test: 1 g. of lead dioxide was added to 60 cc. of distilled water of *p*H 6.30. The *p*H of the supernatant liquid was 6.18. In a similar experiment with 60 cc. of 0.568 molar manganous chloride solution of *p*H 5.85, the *p*H was reduced to 3.20 by the addition of 1 g. of lead dioxide. The X-ray diffraction pattern of the product gave no lines other than those characteristic of lead dioxide, indicating that if a new product is formed, it is either amorphous or present in comparatively small amount. Powdered stannic oxide and red lead oxide had no effect upon the volume of oxygen absorbed; they showed, however, the accelerating effect of the other inert solids.

Since autoxidation reactions are frequently accelerated or retarded by phenols, nitrogen compounds, iodine compounds, etc., the effects of certain examples of these classes of compounds upon the autoxidation of manganous hydroxide were determined. The results may be summarized as follows:

Potassium iodide, urea, thiourea, aniline, β-naphthol, acetamide, ethylene glycol, ammonium thiocyanate, nickel chloride, calcium chloride, sodium chloride, and potassium chloride had no appreciable effect. Ammonium picrate and *m*-nitroaniline accelerated the reaction slightly. Dextrin, glycerol, and iodine retarded the reaction very markedly, but had no effect upon the total volume of oxygen absorbed. These substances perhaps act by being adsorbed at the surface of the oxidation product, thus reducing its catalytic effect. In some cases complex formation may also be a possibility.

Copper chloride, cobalt chloride, and ferric chloride accelerate the reaction, as shown by trials in which reaction mixtures of the following composition were used; manganous chloride, 0.0722 mole per liter, ammonium hydroxide, 0.477 mole per liter, ammonium chloride, 1.35 moles per liter. In each case the concentration of the catalyst used was 0.0018 mole per liter. The times required for the absorption of 20 cc. of oxygen were: cupric chloride, thirty-one minutes; cobaltous chloride, eleven minutes; ferric chloride, eight minutes. A similar sample to which nothing was added required 35.5 minutes. The effect of the ferric chloride is probably due to the large surface of the ferric hydroxide and is similar to that produced by other insoluble substances. The effects of copper and cobalt are probably due to their well-known property of acting as oxygen carriers. In the data recorded above, the concentration of the added salt was one-fortieth of the manganous chloride concentration. In other trials, the salt concentration was reduced to one-two-hundredth, but the accelerating effect was still noticeable.

In connection with the possibility of the formation of an intermediate peroxide in these solutions, it was of interest to determine whether or not the autoxidation of manganous hydroxide was capable of inducing the oxidation of certain acceptors. Dhar[5] and his co-workers have reported that the

(5) N. R. Dhar, *J. Proc. Asiatic Soc. Bengal Proc. 8th India Sci. Cong.*, **17**, CXXX (1921); through *Chem. Abs.*, **17**, 2220 (1923).

oxidation of sodium formate, sodium oxalate, sodium arsenite, sodium nitrite, and ferrous ammonium sulfate are induced by this reaction. In the present work these results were not confirmed. Sodium formate, sodium oxalate, sodium arsenite, sodium nitrite, and allyl alcohol were used as acceptors but in no case was any excess of oxygen absorbed over that required for the manganese alone. In view of these results the formation of a peroxide seems improbable.

When air was used in place of pure oxygen, the absorption was much slower and the total volume of oxygen taken up was much less. The volume absorbed with pure oxygen was about 32 cc., while with air it was about 18 cc. When air was used and the ammonium chloride concentration was varied, the volume of oxygen absorbed remained the same, while the effect of ammonium chloride upon the rate was the same as that observed when oxygen was used. In these trials all of the manganese was precipitated, although the volume of oxygen absorbed was only about 40% of that theoretically required for the formation of manganese dioxide. This surprising result may be explained if it is assumed that a secondary reaction takes place by which manganese is removed from solution without being oxidized. If this secondary reaction does not involve oxygen, it would be expected to continue at an undiminished rate when air is substituted for oxygen. Since the autoxidation reaction is slower in air, a larger proportion of the manganese would be removed by the secondary reaction, and the total volume of oxygen absorbed would be correspondingly reduced. The nature of the secondary reaction will be further discussed in connection with the effect of change in temperature.

Autoxidation of Manganous Hydroxide Precipitated by Sodium Hydroxide.—In the work described, ammonium hydroxide was used in the presence of such amounts of ammonium chloride as would give a conveniently measurable reaction velocity at 25°. It was of interest to determine the effect of temperature, but since the use of ammonium hydroxide did not lend itself satisfactorily to such measurements, a number of experiments were carried out in which sodium hydroxide was used. In all of these experiments the absorption of oxygen was very rapid, but the theoretical volume of oxygen required for the formation of manganese dioxide was never absorbed. However, temperature and the proportions of manganous chloride and sodium hydroxide were found to have a very great effect upon the extent of the reaction as shown by Tables II and III.

.200	1.76	38.4	39.1	39.5	.957

[a] Analysis of solutions remaining after oxygen absorption had ceased indicated that in these trials not all of the manganese had been precipitated.

At the end of each run the samples were removed and filtered. The clear filtrate was tested for manganous ion by treatment with an excess of sodium hydroxide. A solution at 0° which had contained 1.13 times the amount of sodium hydroxide theoretically required to precipitate all of the manganese was found to contain an appreciable amount of manganese in solution; while in the corresponding trial at 45°, all of the manganese had been precipitated. Analysis of the solid oxidation products gave results in agreement with the volumes of oxygen absorbed.

Certain peculiarities in the results of these experiments are worthy of further consideration.

(1) In those trials at 45° in which all of the manganese was not precipitated, the composition of the precipitate was approximately Mn_2O_3, while in similar trials at 0°, the product had a composition intermediate between Mn_2O_3 and MnO_2.

(2) With excess of sodium hydroxide, the degree of oxidation at 45° was never as high as that in corresponding trials at 0°.

(3) Under no circumstances, regardless of tem-

perature or excess of alkali, was the product 100% MnO_2.

(4) At 45° the less sodium hydroxide present, the more abruptly the reaction stopped, while at 0° the reverse was true.

(5) The equivalent amount of sodium hydroxide does not cause complete precipitation of the manganese as manganous hydroxide.

The fact that the composition of the product varies between that corresponding to MnO_2 and a product of lower degree of oxidation than Mn_2O_3 can be explained by either of two mechanisms, represented by the following series of reactions

I

$$6Mn(OH)_2 + O_2 \longrightarrow 2Mn_3O_4 + 6H_2O \quad (1)$$

$$4Mn_3O_4 + O_2 \rightleftarrows 6Mn_2O_3 \quad (2)$$

$$2Mn_2O_3 + O_2 \rightleftarrows 4MnO_2 \quad (3)$$

II

$$2Mn(OH)_2 + O_2 \longrightarrow 2MnO_2 + 2H_2O \quad (4)$$

$$MnO_2 + Mn^{++} + H_2O \rightleftarrows Mn_2O_3 + 2H^+ \quad (5)$$

$$Mn_2O_3 + Mn^{++} + H_2O \rightleftarrows Mn_3O_4 + 2H^+ \quad (6)$$

Series I would account for the results if steps (2) and (3) are equilibria which shift to the left at higher temperatures and to the right at higher sodium hydroxide concentrations. However, experiments showed that steps (2) and (3) do not take place in either direction under conditions comparable with those under which autoxidation was carried out.

Series II would explain the results provided steps (5) and (6) are rapid at high temperatures but almost negligibly slow at 0°. This mechanism also includes the secondary reactions needed to account for the results observed when air is used in place of oxygen. The fact that steps (5) and (6) do actually take place is indicated by the results of other investigators. Tillmans,[6] Hirsch, and Höffner in a very complete study of the reaction between manganese dioxide and manganous ions found that the reaction is favored by high temperature and by increasing *p*H in the range in which manganous hydroxide is not precipitated. They also found free acid is formed as indicated by step (5). The effect of excess alkali in repressing steps (5) and (6) would be expected since it would reduce the manganous ion concentration.

It will be noted that steps (5) and (6) correspond closely to the reactions previously proposed to account for the effect of lead dioxide.

As a further check on the nature of the oxidation product the X-ray diffraction patterns of samples prepared under different conditions were determined and compared with the published patterns of the known manganese oxides. A sample prepared at 90–100° in the presence of excess manganous chloride gave a pattern identical with that of hausmannite, Mn_3O_4. No patterns corresponding to Mn_2O_3 or MnO_2 were obtained from any of the samples prepared. Apparently if such products are formed they are amorphous. The product which approached the composition of MnO_2 most closely showed faint suggestions of a pattern but not enough to permit its definite identification.

Autoxidation in Solutions Containing Triethanolamine.—In order to permit the study of the effect of *p*H without the complicating effect of ammonium ions, triethanolamine was used as the precipitating agent. The oxidation was much slower than under any previously studied conditions, but no induction period was observed, although the *p*H was in the same range as that of the ammonium hydroxide–ammonium chloride solutions previously described. However, when ammonium chloride was added to the triethanolamine solution, the resulting curve did show an induction period. The extreme slowness of the reaction is shown by the following data which give volumes of oxygen absorbed for various time intervals at 25°. The reaction mixture had the following composition: $MnCl_2$, 0.0568; triethanolamine, 0.317 mole per liter.

Minutes	5	15	60	220	366
Gas abs., cc.	12.0	15.2	18.6	24.2	26.7
Minutes	477	605	1320	1440	
Gas abs., cc.	28.0	28.95	47.2	48.2	

The Nature of the Autoxidation Process in Ammoniacal Solution.—In considering the autoxidation of manganous hydroxide in the solutions containing ammonium chloride and ammonium hydroxide, the question arises as to the substances present in the solution and which of these is actually undergoing autoxidation. In addition to the presence of manganous ions, undissociated dissolved manganous hydroxide, and in some cases a precipitate of manganous hydroxide in these solutions, there is a definite possibility that a complex ion of the type $Mn(NH_3)_x^{++}$ is also present. The work of Brezena,[7] who made polarographic and cryoscopic studies of these solutions, has shown that manganous ions and

(6) J. Tillmans, P. Hirsch and J. Höffner, *Gas- u. Wasserfach.*, **70**, 26 (1927).

(7) J. Brezena, *Rec. trav. chim.*, **44**, 520 (1925).

ammonia molecules are both removed from solution with the formation of a complex when ammonium hydroxide is added to a manganous chloride solution containing ammonium chloride. The evidence of the present work seems to favor the existence of a mangano-complex in these solutions. The specific effect of ammonium chloride in producing a different shaped velocity curve from that obtained in triethanolamine solutions of the same *p*H, and the fact that changes in ammonium chloride concentration have no effect upon the composition of the final product may both be explained by the assumption of the existence of such a complex. However, since Brezena's work indicates that the amount of complex increases with increasing ammonium chloride concentration, while the present work has shown that the rate of autoxidation decreases with increasing ammonium chloride concentration, it is unlikely that the complex itself is the substance autoxidized. Undoubtedly precipitated manganous hydroxide is autoxidized, and it is probable that the dissolved undissociated manganous hydroxide behaves similarly. Since neutral solutions show no autoxidation, it is evident that manganous ions are not affected.

Summary

1. The rate of autoxidation of manganous hydroxide in ammoniacal solution has been found to decrease with increasing ammonium chloride concentration. An induction period exists when the ammonium chloride concentration is high.

2. Powdered manganese dioxide, stannic oxide, ferric oxide, red lead oxide, ground glass, and diatomaceous earth accelerate the reaction and eliminate the induction period.

3. In the presence of lead dioxide no autoxidation of divalent manganese occurs.

4. Cobalt chloride and copper chloride accelerate the reaction, while glycerol, dextrin, and iodine retard it. A large number of other substances were found to have no effect.

5. The autoxidation of manganous hydroxide does not induce the oxidation of sodium oxalate, sodium formate, sodium arsenite, sodium nitrite, or allyl alcohol.

6. The autoxidation by air is much slower and less complete than that by pure oxygen.

7. The autoxidation of manganous hydroxide precipitated by fixed alkali is very rapid. The product depends upon the temperature and the proportions of manganous ion and alkali. The X-ray diffraction patterns of the products were studied.

8. The autoxidation of manganous hydroxide precipitated by triethanolamine was found to be very slow. It did not display the induction period observed in ammoniacal solution.

9. A mechanism to account for the above results has been proposed.

The Dielectric Investigation of Polypeptides. II. The Dispersion of Simple Amino Acid Polypeptides

BY W. P. CONNER[1] AND C. P. SMYTH

Although important conclusions concerning the nature of polypeptide molecules have been drawn from consideration of their dielectric increments per mole of solute, it is recognized that a more complete picture may be obtained from measurement of the anomalous dispersion of the dielectric constants of their water solutions. The linear increase of increment values of the polypeptides with the number of glycine residues, as suggested by Wyman,[2] lends support to the view that there is almost complete freedom of rotation about the valence bonds which make up the backbone of the peptide chains. Statistical calculations by Kuhn[3] of the polarization of a straight-chain molecule in which there is free rotation about the valence bonds and electrostatic attraction between the oppositely charged ends of the chain show that the polarization as measured by the static dielectric constant would be the same whether the chains underwent orientation polarization or dilation–contraction polarization. Because of the apparent lack of restriction in position of the electrically

charged end groups of the peptide chains, Wyman suggested[2] that dispersion might not be found for these polypeptide chains inasmuch as they might undergo polarization by stretching rather than orientation. If this were the case, then, size and shape studies from dispersion measurements would be rendered impossible.

Before 1940, no unequivocal data existed in the literature which indicated dispersion in the simpler amino acids and their polypeptides. However, in that year, Bateman and Potapenko[4] reported dispersion measurements at 25.5 cm., for glycine and alanine and their dipeptides. Making use of the energy absorption accompanying dispersion, other investigators[5,6,7] have obtained relaxation times for some amino acid peptides. These data differ widely in the reported relaxation times for the simple peptides.

In this paper, dispersion measurements are reported for the glycine polypeptides and for the simpler di- and tripeptides of alanine, leucine, and glycine in the wave length region of 40 to 80 cm.

Experimental

Method.—For measurement of the static dielectric constant of the aqueous peptide solutions, the Twin-T impedance measuring circuit reported in the first paper of this series[8] was employed. The shortest wave length used was ten meters, which was only just within the region of slight anomalous dispersion for the larger molecules, as indicated by the high frequency measurements. For measurement of the dielectric constants in the dispersion region, approximately 60 cm., the first Drude method was followed. An ultra-high frequency oscillator, similar to that reported by Barrow,[9] was constructed making use of a WE 316-A vacuum tube. Copper was used throughout and catalin rings served for insulation and for mechanical support. To reduce the high frequency loss in the insulation as many holes were drilled in the insulating rings as were possible without lessening the mechanical rigidity. Since the frequency of oscillation is stabilized by the resonant concentric tubes, an attempt was made to increase the Q values of the circuit according to the relations reported by Reukema,[10] in which the influence of the radiative resistance of such transmission lines is fully considered. The tube conductor diameters were: plate, 1.834 and 0.437 inches; filament, 2.00 and 0.187 inches; all three tubes were 20 inches long. The selections were made with the intent to give a maximum Q value to the plate circuit and a maximum impedance to the filament tuned circuit at 50 cm. wave length by the use of copper tubing of standard dimensions. The equations followed were: for maximum Q of a shorted quarter wave length concentric line, $b/a = 4.22$ and $b = 0.0634\ \lambda^{0.9}$, and for maximum impedance, $b/a = 14.3$ and $b = 0.077\ \lambda^{0.9}$, in which a and b are the radii of the inner and outer conductors. A closer approach to the theoretical Q values was attained by the installation of the "standpipe" oscillator on its side, thereby enabling the use of a plunger mechanism for the determination of resonance lengths and thus avoiding slotting the out copper tubes. The theoretical Q value of 3400 at 600 Mc., is considerably less than that reported by Barrow since the equations by which he computed Q values do not consider radiative resistance losses. Since only loose coupling between this oscillator and the detector was desired, a short length of copper wire extending from the coaxial line power output connection into the chamber which contained the vacuum tube was found to be completely adequate. A maximum in the grid current and a minimum in the plate supply indicated oscillation of the instrument. The frequency range of the oscillator was approximately 300–750 Mc.

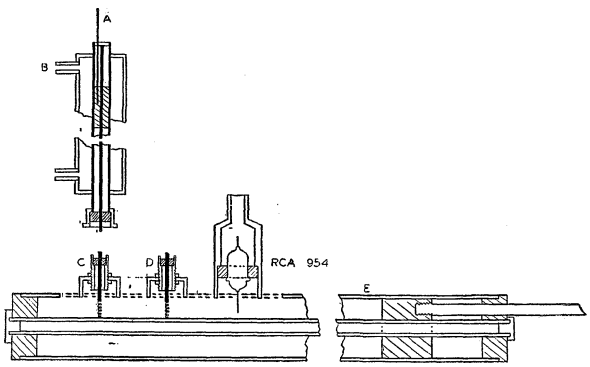

Fig. 1.—Apparatus for the determination of dielectric constants at ultra-high frequencies: A, water resonance chamber; B, water jacket; C, coupling lead to water resonance chamber; D, input lead from oscillator; E, air resonance chamber.

Dielectric measurements required the determination of the wave length of the high frequency oscillation in air and in the water solutions of the polypeptides. For the air measurements (see Fig. 1), standing electric waves were formed in a system of concentric tubes of the same dimensions as those used for the plate tank circuit of the oscillator, the length of which could be varied by means of a shorting plunger. The detector was a simple probe-type voltmeter[11] using an RCA-954 acorn tube capacitatively coupled to the inner tube of the resonance chamber by very short leads. The outer tube of the chamber was slotted so that the voltmeter might be inserted approximately at a voltage antinode. With this arrangement positions of resonance were quite sharp and could be set to ±0.01 cm. A micrometer was attached to the plunger so that the resonance length might be varied by small steps. With close coupling to the oscillator, a rather large decrease in the oscillator grid current was noted as the resonance chamber passed through a point of resonance. The

coupling was reduced to such an extent that the change in the grid current was less than one-half milliampere, since further loosening of the coupling had been shown to have no effect upon the measured wave length. The wave length was then considered equal to twice the distance between any two positions of the plunger for which the voltmeter indicated a maximum voltage.

The wave length in the water solutions was determined in much the same manner, except that, for this case, the resonance tubes were much smaller, $^3/_8$ and $^1/_8$ inches; and were water-jacketed at 25.00 ± 0.02° for most of the experiments. The smaller size was chosen to reduce the volume of material required for measurement and to gain a higher Q value, since the wave length in these media is one-ninth that in air. The water resonance chamber was coupled to the air chamber rather than directly to the oscillator in order to minimize any change in frequency of the oscillator resulting from interaction between the two circuits. The relative positions of the connective terminals on the air chamber were varied. However, those indicated in Fig. 1 were the most satisfactory. The connections between the instruments were all of $^3/_8$ inch coaxial cable with polystyrene bead insulation. Thus, the apparatus was completely shielded so that the position of the observer did not affect the measurements. This was a great improvement over the customary Lecher wire devices.

In making a measurement, the oscillator was first adjusted to one of its positions of most stable oscillation and the wave length determined with the air chamber. Customarily, the wave length was checked when the plunger in the water chamber was first set at a node and then at an antinode. The positions of resonance in the air chamber were different for these two positions in the water chamber but the actual wave length was not modified. With the plunger in the air chamber at a voltage node and with the consequent maximum in voltage indicated by the voltmeter, the plunger in the water chamber was withdrawn slowly. A minimum in the voltmeter now indicated the presence of standing waves in the water resonance chamber, since maximum power had been transferred from the air chamber to the water chamber. The wave length in the solution was considered equal to twice the distance between any two minima. Because of attenuation, the minima became too broad for accurate settings after about four nodes had been detected. Settings were made readily to ±0.015 cm., and greater accuracy could be attained when the voltage was recorded for each millimeter shift in the plunger and the minima read from the plot of these values. Considerable asymmetry was introduced into these plots of voltage against distance in the water chamber depending on the position of the plunger in the air chamber. If the air chamber was set at resonance when the water chamber was completely out of resonance, the curves were symmetrical except for the exponential absorption due to conductance.

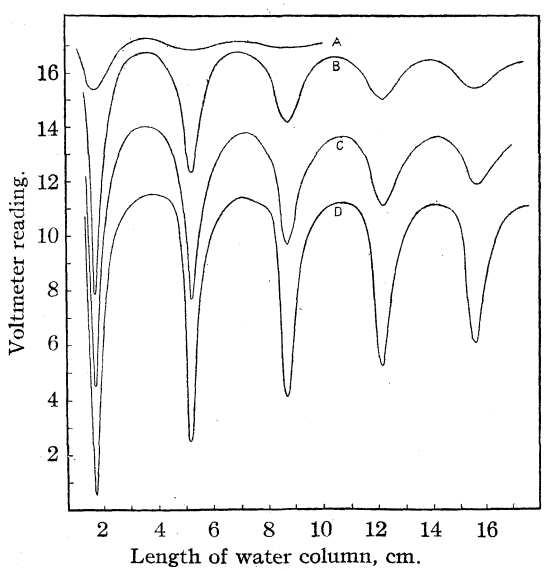

Fig. 2.—Resonance minima in aqueous potassium chloride solutions: specific conductance, A, 0.853 × 10^{-2}; B, 1.67 × 10^{-3}; C, 0.953 × 10^{-3}; D, 1.007 × 10^{-4} mhos. For each curve, the zero point of the voltmeter reading has been shifted arbitrarily to prevent overlapping.

In Fig. 2 is recorded such a plot for water solutions of potassium chloride of varied conductivity. The conductance of these solutions at 25° was measured with a one thousand cycle conductance bridge. Since the Debye–Hückel theory of electrolytes predicts an increase in the dielectric constant of aqueous salt solutions above that of pure water, it was of interest to calculate[12] this increase, $\Delta\epsilon_{DH}$, expected for these solutions (see Table I).

TABLE I

Spec. cond. × 10^3 ohm^{-1} cm.$^{-1}$	$\Delta\epsilon_{DH}$	$\Delta\epsilon_R$	$\epsilon_{obs.}$
0.1077	0.000325	0.0000	78.46 ± 0.13
0.953	.0202	.000	78.57 ± 0.13
1.666	.0529	.006	78.57 ± 0.13
8.53	.548	.157	79.5 ± 0.4

In addition to the increase in the dielectric constant resulting from the polarization of the ionic atmosphere around a central ion, $\Delta\epsilon_{DH}$, there arises an apparent increase, $\Delta\epsilon_R$, in the real dielectric constant resulting from the conduction in the dielectric medium in which the standing electric waves are produced. This effect is comparable with the apparent increase in capacity of a conducting condenser found in low frequency impedance measurements. The dielectric constant increase, $\Delta\epsilon_R$, was calculated according to an approximate treatment of the problem.[13] The dielectric constant values, $\epsilon_{obs.}$, observed for these potassium chloride solutions show small increases with increasing concentration, agreeing within the experimental error with the calculated increases.

(13) Drake, Pierce and Dow, *Phys. Rev.*, **35**, 613 (1930).

Since the specific conductivities of all peptide solutions were no greater than 1×10^{-4} ohm^{-1} cm.$^{-1}$, an error due to conduction was considered negligible. A slight initial decrease in the dielectric constant of salt solutions as the salt concentration is increased has been reported,[14] although a complete quantitative treatment has not been given. However, it is likely that this effect lies well within the experimental error of these measurements.

Most of the high frequency measurements were performed at 61.42 cm., the minimum being determined by a plot of the voltage against the length of the resonance chamber. For some measurements, a larger range of wave length, 40 to 80 cm., was used. However, because of the tedium involved in the selection of suitable positions of the three plungers of the oscillator from the many positions at which oscillation gave unstable or distorted frequencies, this procedure was discontinued.

Results

In Table II are recorded the dielectric data for the amino acids investigated, from which the dispersion calculation is made. Some of the high frequency measurements were made at room temperature before the thermostat was installed and have been included as taken without a correction to 25°. To correlate the dispersion data taken over a frequency range with solutions of different concentrations, the critical wave lengths, λ_c, have been calculated according to the dispersion equation[15]

$$\frac{\epsilon - \epsilon_\infty}{\epsilon_0 - \epsilon_\infty} = \frac{1}{1 + (\lambda_c/\lambda)^2} \qquad (1)$$

where ϵ is the dielectric constant of the aqueous solution at wave length λ; ϵ_∞ is taken equal to the dielectric constant of water, 78.54, at 25°; and ϵ_0 is the static dielectric constant of the solution considered equal to that measured with the Twin-T apparatus at approximately 10 meters. The critical wave length is related to the relaxation time by the expression

$$\lambda_c = 2\pi c\tau$$

in which c is the velocity of light in cm./sec., and τ is the relaxation time in seconds.

Viscosity corrections for different concentrations of solute and temperature of solution were applied by multiplying the critical wave length determined by Eq. (1) by the factor $\eta_{H_2O}/\eta_{solution}$. An Ostwald viscometer, with an efflux time for water of 24 sec., was used for the viscosity determinations listed in Table II and the viscosity of water at 25° was taken as 8.94 millipoises. The substances are represented in Tables II and III by abbreviations: A for alanine, L for leucine, G_1 for glycine, G_2 for diglycine, etc. All preparations were racemic mixtures.

Since both measuring cells were constructed of copper, there was a slight formation of the copper complex of the amino acids in solution. Except for those of high glycine content, the solutions were only faintly tinted after the measurements were completed. In view of the excellent agreement with reported data for the measurements at low frequencies, it was considered that, for this case, the formation of the copper complex was negligible. However, inasmuch as the solutions were left in contact with a larger surface of copper for a longer time during the high frequency measurements, the low frequency increments were always determined after the high frequency experiments on the same solutions. Thus the decrease in the dielectric constant of the solution resulting from the formation of the complex was not counted as dispersion of the dielectric constant.

The spread of the calculated results is large for glycine since λ_c in Eq. (1) is very sensitive to slight changes in ϵ when the difference $\epsilon - \epsilon_\infty$ is small, as it is when the measuring wave length is remote from the critical wave length. Thus the apparent trend with increasing concentration of glycine is not held to be significant. Equation (1) is a very much simplified description of the dielectric constants of these aqueous solutions, since it implies the presence of a kinetic unit having only one relaxation time. However, no well-defined trend in the critical frequencies calculated in this manner was noticeable as the viscosity and frequency were varied for any single compound. Since all measurements were made on the low frequency side of the complete dispersion curve, it is unlikely that the effect of a second smaller relaxation time would be greater than the error of the dielectric measurements.

Also the choice of ϵ_∞, the dielectric constant of the solution at a frequency sufficiently great so that dispersion due to the solute molecule has been completed and yet sufficiently small so that dispersion of the solvent has not begun, is some-

stant of the solution, the solution should behave as if non-polar molecules of the same total volume were dissolved in it. In this case of water acting as the solute, the presence of non-polar molecules would reduce the number of dipolar water molecules per cubic centimeter and thus reduce the dielectric constant of the solution. An estimation of this volume correction for the increment values is recorded in the preceding paper.[8]

In Table III are recorded the average values of the critical wave lengths taken from Table II and the critical wave lengths after the volume correction has been applied. Inasmuch as dispersion has been found for these polypeptides, it is of interest to compare the measured critical wave lengths with those calculated on the assumption that the rotating units are spheres of volumes equal to those of the dissolved molecules and moving according to the laws of hydrodynamics. For this case, the Debye equation

$$\lambda_0 = 2\pi c\tau = 2\pi c\frac{3\eta}{RT}v$$

applies in which η is the viscosity of the solvent and v is the partial molar volume of the solute. In Table III are listed the critical wave lengths, λ_0, thus calculated. The volume v was taken equal to the apparent molar volume plus the electrostriction. For those compounds for which v has not been measured, use was made of the additivity of atomic volumes[16] for their calculation. In addition, there is listed the shape factor a/b, the ratio of major to minor axis of the assumed molecular ellipsoid of revolution, as determined by the quotient of the observed and calculated critical wave lengths in the manner described by Perrin.[17] This calculation assumes, of course, a rigid particle undergoing orientation polarization. Inasmuch as the mechanism of polarization is not definitely known, these calculations must be regarded as tentative. Also, it must be emphasized that, in view of the error involved in the determinations of λ_c, small differences in a/b are not significant. Correction of the dielectric constant values for the effect of the volume occupied by the solute molecules according to the method previously employed[8] gave slightly smaller values λ_c' for the critical wave lengths and larger values $(a/b)'$ for the axis ratios.

Discussion of Results

The agreement of the ratio of the critical wave lengths listed here and those reported elsewhere is satisfactory in the cases of glycine and alanine. Bateman and Potapenko[4] reported ratios of 0.39 and 0.77, whereas Fricke and Parts[5] reported 0.55 and 0.63 as calculated from absorption measurements. For the higher peptides, Bateman and Potapenko listed ratios of 1.38, 1.60 and 1.67 for diglycine, glycylalanine, and alanylglycine, indicating shape factors of 1.8 to 2.2. However, Fricke and Parts reported ratios less than unity for such large molecules as α-aminobutyric acid, γ-aminobutyric acid, and ϵ-aminocaproic acid;

(16) Cohn, McMeekin, Edsall and Blanchard, THIS JOURNAL, **56**, 784 (1934).

(17) Perrin, *J. Physique*, **5**, 497 (1934).

and later Parts[6] reported ratios from 0.7 to 1 for the large molecules of *d,l*-phenylalanine, diglycine, and ϵ-aminocaproic acid. On the other hand, Linhart[7] found that the critical wave lengths for glycine, diglycine, and leucylglycylglycine lay between 80 and 100 cm., depending upon the concentration of the solute. It would appear that the results of Bateman and Potapenko are the most trustworthy since they were determined at 25.5 cm., where dispersion is most pronounced. In addition, a relaxation time of 1.29×10^{-10} sec., $\lambda_c = 24.4$ cm., for triglycine has just been reported by Wyman[18] from absorption measurements at 2.61 meters. For the two smallest molecules, glycine and alanine, the observed values for λ_c are less than the values calculated for a spherical model. This discrepancy is customary for investigations of this sort for small molecules of size comparable with those of the solvent, and has led to the suggestion that the inner viscosity is of smaller magnitude than the macroscopic viscosity.

Another approach to the whole process of dielectric relaxation may be obtained by considering it as a rate process involving the rotation of the molecule between two equilibrium positions separated by a potential barrier.[19,20,21] Following Eyring's treatment of relaxation times in general, one may calculate the free energy of activation for rotation, $\Delta F^{\ddagger}$, for these polypeptides from the equation

$$\tau = \frac{h}{kT} e^{\Delta F^{\ddagger}/kT}$$

Values of $\Delta F^{\ddagger}$ so determined are listed in Table IV, together with those of the apparent molar volume φ of the solute corrected by adding the electrostriction E. The ratio $\Delta F^{\ddagger}/(\varphi + E)$ is given to show that the increase of free energy of activation with increase of molecular volume becomes less as the molecules increase in size.

These $\Delta F^{\ddagger}$ values may be compared with the free energies of activation for viscous flow by the application of the equation

$$\eta = \frac{Nh}{V} e^{\Delta F^{\ddagger}/RT}$$

where V is the molar volume of the liquid in question. The heat content change $\Delta H^{\ddagger}$ for the same process may be determined from the slope of a log η against $1/T$ plot since

$$\Delta H^{\ddagger} = R \frac{\mathrm{d} \ln \eta}{\mathrm{d}(1/T)}$$

Unfortunately, this curve is not linear, and hence $\Delta H^{\ddagger}$ varies with the temperature. This temperature variation probably indicates a structural change in the flow process.[22] The results of such a calculation for water are listed below.

	$\Delta F^{\ddagger}$	$\Delta H^{\ddagger}$	$\Delta S^{\ddagger}$
Viscous Flow			
H_2O	2.21	4.058	6.0
Dipole Rotation			
H_2O	2.38		
40% H_2O (in dioxane)	2.57		

Since the temperature dependence of the relaxation time for water has not been determined, $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ cannot be calculated explicitly. In all likelihood, the temperature dependence is the same as that for viscosity, as is the case for many small dipole molecules. If this be so, then the entropy change is the same for both processes and requires the breaking of a somewhat organized structure in the formation of a more random system. Undoubtedly, the directed hydrogen bonds are fractured. Thus, the mechanisms of dipole rotation and viscous flow for water are equivalent.

The $\Delta F^{\ddagger}$ for the dipole rotation of the zwitterions increases but very slowly with increasing molecular volume except in the cases of smaller

molecules. Thus, in contrast to the linear viscous flow of pure liquids, a cavity proportional to the volume of the moving molecule need not be formed for this rotational motion. The temperature coefficient is probably that of water, as it is in the case of the larger protein molecules. Thus, the entropy change in this case is almost zero, perhaps slightly negative. Since the mechanism is basically the same as that of viscous flow in the pure solvent, *i. e.*, movement of one molecule of solvent over the same potential barrier to a second rest position, the entropy change is the sum of an increase due to the breaking of directed valence bonds of the solvent and a decrease which measures the number of molecules which must be organized in the flow process to permit rotary diffusion of the dipole molecule. This decrease in entropy is dependent upon the size and shape of the molecule in solution, and causes the rather large relaxation times found for large protein molecules.

The smallness of the variation of the $\Delta F^{\ddagger}$ values with change in the size of the molecules results from the fact that the range of relaxation times is extremely short. However, it is noted for both glycine and alanine that the free energy of activation is approaching that for water. From this fact it would appear that the number of solvent molecules which must coöperate in the rotary diffusion of these dipole ions is becoming smaller with the decrease in size of these ions and is approaching unity as it is for the rotary diffusion of water in water.

That the Debye equation for relaxation time fails for these small particles is evident in the fact that λ_c/λ_0 is less than unity. However, the reaction rate hypothesis affords a complete picture of this region of small molecules in which it has been customary to assume a difference between the macroscopic and microscopic viscosities. For large particles the reaction rate calculation and the Debye equation must agree, but the details of the transition have not been worked out.

The mere presence of dispersion in the half meter range of wave length does not completely prove the rigidity of these dipolar molecules. Since the heats of activation have not been determined, the actual mechanism of polarization is still in doubt. The free energies of activation are of such a magnitude that the slow process may be the movement of a water molecule over the potential barrier for viscous flow to create a space to be occupied by a part of the rotating dipolar molecule, or it may be the crossing of the potential barrier for rotation around the valence bonds within the dipolar molecule in polarization by stretching. Since $\Delta H^{\ddagger}$ for viscous flow changes with temperature and $\Delta H^{\ddagger}$ for rotation about a single bond does not, one might differentiate between the two processes from the temperature coefficient of the relaxation times. However, since in the stretching of a valence chain possessing free rotation, the rate of change of stress on its ends with the change in its elongation is inversely proportional to the number of chain links,[23] it becomes increasingly easier to stretch the chain as its length increases. Thus, one would expect that the relaxation time for this process would decrease with increasing chain length since the entropy change decreases. This view may be applied to a chain-stretching mechanism in which a potential barrier must be crossed if the barrier height does not change with chain length. It would appear, then, in view of the experimentally found increase in relaxation times with the chain length of the polypeptides, that stretching of the tangled backbone chain alone is not the slow process. If the slow process is that of the viscous flow of water, then the mechanism is still in doubt for a hole of some sort must be created about the dipolar molecule whether it occupies the new space by expansion and contraction or by orientation in the direction of the field.

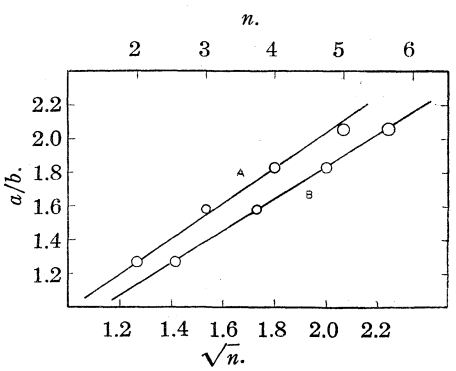

Fig. 3.—Variation of a/b with the number of glycine residues, n: A, variation with n; B, variation with $\sqrt{n}$.

However, it is evident that the orientation hypothesis gives reasonable values for the molecular shapes of the peptides. The shape factors of the glycine peptides appear to increase linearly with the square root of the number of glycine

(23) Mark, "Physical Chemistry of High Polymeric Systems," Vol. II, Interscience Publishers, Inc., New York, N. Y., 1940, p. 75.

residues (see Fig. 3). Although the accuracy of the determinations is not sufficient to exclude the possibility of a linear increase with the first power, the apparent linear dependence upon the square root of the number of glycine residues is what one would expect from a statistical consideration of rigid molecules randomly distributed in all possible configurations resulting from potential minima symmetrically distributed about the valence bonds of the backbone chain. The triglycines appear to have approximately the same shapes, except for alanylleucylglycine which appears somewhat more spherical as would be expected since the large isobutyl group has been attached to the middle of the chain. Leucylglycine is more spherical than would be predicted. Perhaps in this case the Perrin equation fails since the assumed ellipsoid of revolution is a poor approximation for this molecule. The dipolar part of the molecule may undergo motion with very little change in the position of the hydrocarbon chain at one end of the molecule. Undoubtedly a more satisfactory picture would be obtained for these small irregular molecules if it were possible to discard the hydrodynamic view-point and the prolate spheroid model in favor of more accurate knowledge of the nature of the process of rotation.

Other complicating factors which have not been considered are the change in the volume of the rotating unit due to hydration resulting from hydrogen bonding of the dipolar molecule with water, and, second, hydrogen bonding within the peptide chain, which must occur to stabilize the structures of protein molecules. The second factor is probably of little importance since these peptide chains act as denatured proteins.

The writers wish to express their gratitude to Professor Eugene Pacsu for his helpful discussions relating to the polypeptides used in this investigation.

Summary

An apparatus has been constructed for the measurement of the dielectric constants of liquids at wave lengths from 40 to 80 cm. by the first Drude method. The dielectric constants of aqueous solutions of ten amino acid peptides in this region of anomalous dispersion have been measured, as have the viscosities of the solutions. The mechanism of dispersion has been discussed and the results have been combined with previous dielectric constant measurements at 10 meters in this Laboratory to calculate the relaxation times and shape factors for the solute molecules. Although the results are not inexplicable in terms of internal rotation around valence bonds in the molecules, the values and their trend are consistent with the simple picture of rotation of the molecule as a whole.

The Apparent Molal Volumes of Aqueous Solutions of Sulfuric Acid at 25°

BY IRVING M. KLOTZ AND CHARLES F. ECKERT

It has been known for some time that the apparent molal volume of a strong electrolyte may be expressed as a linear function of the square root of its volume concentration. For aqueous solutions of sulfuric acid, however, the apparent molal volumes show an unusual dependence on the concentration. In contrast to most electrolytes, the volumes rise very rapidly in the dilute range but approach a linear function of the square root of the concentration at high molarities. This behavior has been explained qualitatively as being due to the ionization of bisulfate ion.[1] With data on the dissociation constants of bisulfate ion a quantitative explanation of the observed volume changes in terms of the apparent molal volumes of the component ions is also possible. We have determined the densities of solutions of sulfuric acid from 0 to 3 molar, and have calculated, by a method of successive approximations, the apparent molal volumes of $H^+ + HSO_4^-$ ions.

Experimental.—The solutions were placed in Pyrex containers immersed in a thermostat at 25° (±0.001°). The density of each solution was measured by means of the sinker method described by Wirth.[2] The method was sensitive to differences of less than one part per million in the density.

[a] d_3 is the density of the sulfuric acid solution and d_0 is that of pure water.

Concentrations were determined by titration against sodium hydroxide which had been standardized with potassium acid phthalate.

The Apparent Molal Volumes of $(H^+)(HSO_4^-)$.—To interpret our data we have assumed that a solution of sulfuric acid may be considered as a mixture of two components, $(H^+)_2(SO_4^=)$ and $(H^+)(HSO_4^-)$. For a concentration of c_3 moles per liter of sulfuric acid we should have c_1 moles per liter of $(H^+)_2(SO_4^=)$ and $c_3 - c_1$ moles per liter of $(H^+)(HSO_4^-)$ where c_1 is determined by c_3 and by K_c, the classical ionization constant of bisulfate ion. If the volume change due to the addition of N_3 moles of sulfuric acid to the quantity of water necessary to give the concentration c_3 is ΔV, then

$$\phi_3 = \Delta V/N_3 = (c_1/c_3)\phi_2 + [(c_3 - c_1)/c_3]\phi_1 \quad (1)$$

where ϕ_1 is the apparent molal volume of $(H^+)(HSO_4^-)$, ϕ_2 that of $(H^+)_2(SO_4^=)$ and ϕ_3 the observed value. Consequently

$$\phi_1 = [\phi_3 - (c_1/c_3)\phi_2]/(1 - c_1/c_3) \quad (2)$$

The classical ionization constant of bisulfate ion, K_c, is a function of the ionic strength, μ, and has been determined up to $\mu \sim 0.14$.[3] Since c_1 is a function of K_c and K_c is a function of μ, and consequently of c_1, it has been necessary to use a series of successive approximations to establish the value of c_1. For the dilute range the value of K_c for $\mu = 0$ was used to obtain the first provisional value of c_1. Then μ was estimated from this value of c_1, K_c interpolated from an appropriate graph, and a second value of c_1 determined. This process was continued until two successive evaluations of K_c agreed within the experimental error in the determination of this constant. At high concentrations no reliable data on K_c are available. In this range, however, the correction due to the ionization of bisulfate ion is small and not very sensitive to the value chosen for K_c. We have computed this correction for three different values of K_c, 0.01, 0.03 and 0.09, and have found only small differences in the results obtained for ϕ_1. The constant of 0.03, however, gave the best agreement with the molal volumes in the dilute region.

An alternative procedure for calculating ϕ_1 in concentrated solutions of sulfuric acid is to compute values of K_c from the data given by Harned and Hamer[4] combined with the ionization constant of bisulfate ion at infinite dilution determined by Hamer[5] or by Klotz.[3] This method, however, involves extensive computations, and since a precise value of K_c is unnecessary in the concentrated region, this alternative procedure was not adopted.

The apparent molal volumes of $(H^+)_2(SO_4^=)$ were calculated from the appropriate data for potassium chloride, hydrochloric acid and potassium sulfate[2,6] with the added assumption that the respective volumes are linear functions of the square root of the total ionic strength. Such a behavior is not fulfilled by hydrochloric acid or potassium sulfate[2,6] but the errors so introduced occur mainly in concentrated solutions where the correction of ϕ_3 for the ionization of bisulfate ion is small.

Knowing c_1 and ϕ_2 we can calculate the apparent molal volumes of $(H^+)(HSO_4^-)$ by entering the appropriate quantities in equation (2). The significant steps in the calculation are outlined in Table I.

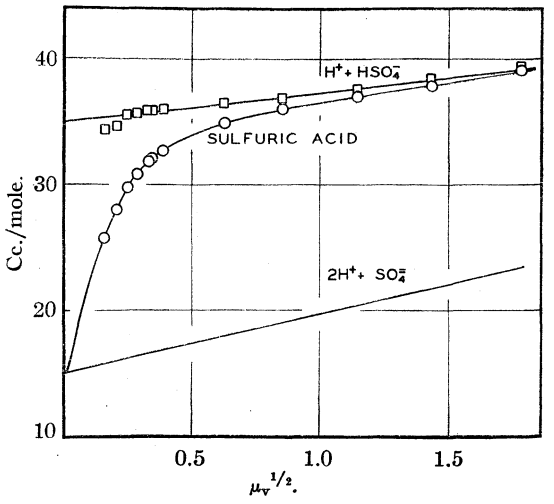

Fig. 1.—Apparent molal volumes of sulfuric acid and its constituents: O, observed volumes; □, calculated volumes.

Figure 1 shows the results for the calculated volumes of the constituents of sulfuric acid solutions as well as the experimental data. The curve for sulfuric acid in the very dilute range (up to $\mu^{1/2} = 0.15$) was calculated from the volumes of the ionic components and shows a definite cusp just beyond $\mu^{1/2} = 0$. The observed apparent molal volume rises very rapidly as the concentration is further increased because more and more bisulfate ion is formed. As we reach concentrated solutions ($\mu^{1/2} > 0.5$) the proportion of sulfate ions becomes progressively smaller and the observed volumes become, very nearly, those calculated for $(H^+)(HSO_4^-)$. Thus the observed volumes of sulfuric acid from 0 to 3 molar can be interpreted quantitatively in terms of the respective contributions of the constituent ions.

The Volume Change on Ionization of Bisulfate Ion.—Extrapolation to infinite dilution yields a value of 35.1 cc./mole for $\overline{V}^0$ of $(H^+)(HSO_4^-)$. Combining this figure with that for $(H^+)_2(SO_4^=)$ we find the volume change upon ionization of bisulfate ion at infinite dilution to be −20.2 cc./mole:

$$HSO_4^- = H^+ + SO_4^= \qquad \Delta\overline{V}_2^0 = -20.2 \text{ cc./mole}$$

Acknowledgment.—We are indebted to Professor Frank T. Gucker, Jr., and to Professor T. F. Young of the University of Chicago for a number of suggestions concerning the presentation of this material.

Summary

The densities of solutions of sulfuric acid have been determined over the concentration range of 0 to 3 molar and the apparent molal volumes interpreted in terms of the volumes of the hydrogen, sulfate and bisulfate ions.

The apparent molal volumes of hydrogen and bisulfate ions have been calculated by a series of successive approximations.

The Kinetics of the Thermal Reaction between Hydrogen and Cyanogen

BY N. C. ROBERTSON AND R. N. PEASE

Since the reactions of hydrogen with the various halogens have had such an important role in the development of chemical kinetics, it was thought that an investigation of the reaction with cyanogen might be profitable. The only reference to such a reaction is a report by Berthelot[1] that heating hydrogen and cyanogen in glass vessels in the neighborhood of 550° results in the formation of hydrogen cyanide together with a considerable amount of a polymer assumed to be paracyanogen.

The object of the present research was to establish the mechanism of this reaction in its relation to the other familiar reactions of hydrogen.

(1) M. Berthelot, *Compt. rend.*, **89**, 63 (1878).

Experimental Procedure

The reaction was studied in a static system employing a silica vessel for most of the runs. This bulb, which was spherical and of some 550-cc. capacity, was placed at the center of a large electrically heated furnace which was provided with an auxiliary winding for the reaction chamber by means of which the temperature of the chamber was controlled to ±0.1° by a photoelectric potentiometer device connected to control thermocouples. The temperature was measured by means of two thermocouples immediately adjacent to the reaction vessel, heat losses and temperature gradient being minimized by packing the space for 10 inches above and below the reaction chamber with asbestos fiber. Apiezon was found to be satisfactory for stopcock lubrication.

Tank hydrogen was purified by passage over platinized

asbestos at 350° and dried by condensing the water vapor in a trap surrounded by liquid air. Cyanogen was prepared by slowly dropping a concentrated solution of C. P. sodium cyanide onto powdered copper sulfate in a 500-cc. flask which was provided with a ground glass joint for the dropping funnel. The cyanogen was dried by passage through calcium chloride and was repeatedly fractionated from dry-ice and ether in an all glass system. Finally after admission to the storage vessel attached to the main vacuum system it was condensed several times in liquid air and the non-condensable gases evacuated with a mercury vapor pump. Cyanogen prepared by this method was found to contain only traces of hydrogen cyanide as shown by analysis, and the vapor pressure over dry-ice was that observed by Perry and Bardwell;[2] moreover, the consistency of the results obtained with a number of different preparations was considered good evidence for a reasonable degree of purity.

The hydrogen cyanide used in the experiments on inhibition was kindly furnished by Dr. J. Holmes of this Laboratory and was prepared by the action of sulfuric acid on sodium cyanide with subsequent drying and fractionation.

In making a run hydrogen as the lighter gas was first admitted to the thoroughly evacuated reaction chamber up to the desired pressure as indicated by a mercury manometer; then cyanogen was rapidly admitted from the storage bulb to give the desired total pressure. At the end of the run a sample amounting to approximately 60% of the reaction mixture was admitted to a previously evacuated analysis bulb of known volume, which was attached to the apparatus by a ground glass joint, the exact amount of the sample being determined by the pressure difference.

Since it soon became apparent that, aside from a small quantity of polymer, hydrogen cyanide was the only product formed in any substantial amount, the analytical procedure was designed to determine hydrogen and hydrogen cyanide. In order to determine hydrogen the cyanogen and hydrogen cyanide were condensed by surrounding the analysis bulb with liquid air and the hydrogen rapidly pumped off. The difference in pressure when the contents of the bulb had been allowed to return to room temperature was a measure of the hydrogen present since several experiments showed that no appreciable quantity of hydrogen dissolves in the condensed phase.

The determination of hydrogen cyanide in the presence of cyanogen was based on the method of Rhodes[3] and involves the rapid and quantitative reaction of hydrogen cyanide with a slightly acidified solution of silver nitrate with no interference by cyanogen. The analysis bulb was removed from the apparatus and inverted in a beaker containing a measured quantity of 0.025 *N* solution of silver nitrate to which one drop of dilute nitric acid per 5 cc. of solution had been added. By momentarily opening a stopcock a portion of this solution was allowed to flow up into the analysis bulb containing the cyanogen and hydrogen cyanide. The bulb was then shaken vigorously, opened, and the contents, consisting of precipitated silver cyanide and unreacted solution, washed out into the beaker with distilled water. The solution was then filtered and the remaining silver nitrate determined by titration with standard potassium thiocyanate using an indicator solution of ferric ammonium sulfate. From the silver nitrate neutralized by the hydrogen cyanide it was possible to calculate the pressure of hydrogen cyanide in the reaction vessel. Analysis of known mixtures and the consistent checks with the analysis for hydrogen showed this method to be accurate to 1%.

Results

The reaction was studied over the temperature range 550–675°; however, it proceeds at a very convenient rate at 625°, and the kinetic results were obtained at this temperature.

In order to show experimentally that equilibrium in the system

$$H_2 + (CN)_2 \rightleftarrows 2HCN$$

is far to the right, 0.5 atmosphere of hydrogen cyanide was allowed to stand for forty-eight hours at 625°. No decomposition could be detected on analysis although polymerization amounted to about 3%. It was concluded that the reaction as written is at least 98% complete.

About thirty runs were made in the silica vessel at temperatures of 500–600° before any attempt at accurate kinetic measurements. In view of the tendency of both cyanogen and hydrogen cyanide to polymerize in this region, it is probable that some polymer accumulated on the surface of the bulb. In a single run at any temperature above 600°, however, the pressure decrease was only of the order of magnitude of 0.5%. About sixty runs were made in this "aged" bulb, each series being bracketed by standard runs of 215 mm. of each reactant for a sixty-minute period at 625°. Typical kinetic results at this temperature are summarized in Table I-A.

The most prominent feature of the reaction is the emphasis upon the concentration of hydrogen. Constants for a three halves order and for a "Bodenstein–Lind" expression were calculated and are given in the table. The temperature coefficient in this bulb was determined over the range 575–675° (Table I-C) and corresponded to an over-all activation energy of 72 kcal. (Fig. 1).

Although the reaction appeared to be of low order as far as total pressure is concerned, the rate decreased rather rapidly with time, which suggested an inhibiting action by the product, hydrogen cyanide. To test this, pure hydrogen cyanide was added at the beginning of several runs with results recorded in Table I-B. Not

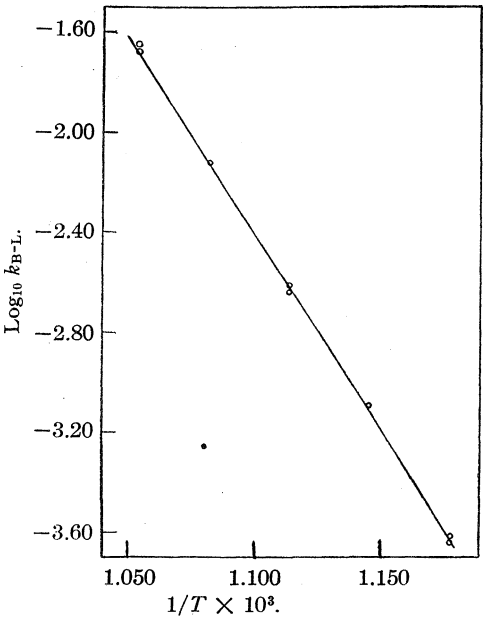

Fig. 1.—Activation energy in aged bulb.

only was the inhibiting action confirmed, but it was shown to be significantly greater when the ratio of the initial concentration of hydrogen to that of cyanogen was high.

[a] k's are expressed in the units millimeters and minutes.

In several experiments 1–2 mm. of oxygen was added to the reaction mixture, in which instance the rate was observed to increase by about 75%; however, no evidence for catalysis by minute traces of oxygen, such as characterizes the vapor phase reactions of many organic substances, was obtained.

An early observation that the rate in Pyrex at 550° is some 50% higher than in clean silica indicated a qualitative effect of surface. In order to study the quantitative influence, the reaction vessel was removed, treated with concentrated nitric acid to cleanse the surface of any film of polymer, washed with distilled water and packed with clear silica tubing of 10-mm. diameter which had been cleaned by prolonged treatment with hot nitric acid. This packing increased the surface–volume ratio by a factor of 3.5–4, and its surface was considered to be the best obtainable duplication of that of the blown silica vessel. Since it developed that cleaning the surface causes some alteration in the rate and temperature coefficient of the

process, a series of runs was made in the acid-cleaned unpacked bulb for purposes of comparison.

Although preliminary results in the packed bulb were erratic and somewhat high, the rates quickly settled down and became reproducible. A puzzling complication was encountered in that after raising the temperature from 550 to 625° or higher, it was necessary to make several runs followed by periods of extended pumping before the rate at the higher temperatures rose to a consistent value. On account of the greater pressure decrease during low temperature runs, it may be possible to attribute this to the formation of paracyanogen on the walls since this is said to occur in the range 500–600°. The consistent rates are given in Table II-A for standard runs at several temperatures in comparison with runs in the empty vessel after the packing had been removed. It is apparent that packing increases the rate at low temperatures somewhat, while causing no appreciable change at 650 or 675°. This makes it highly improbable that the reaction is entirely a surface process; however, it would seem to indicate either that at the lower temperatures there is a concurrent reaction proceeding on the surface or that the wall participates in some step of a gas phase process.

Since the nature of the surface is obviously of considerable importance to the kinetics, a means of treating it so that its function could be studied to better advantage was sought. It had been observed that treating the aged bulb with oxygen caused no substantial change in the rate; however, when the packed bulb was treated at 675° for two hours with an atmosphere of pure oxygen and then thoroughly evacuated, the rate was very decisively decreased at all temperatures, as may be seen from Table II-B. When the packing was removed, this procedure had no effect on the rates in the empty bulb. This seeming anomaly may be due to a qualitative difference between the surface of the packing and that of the bulb itself, but the fact that the rate in the packed bulb after oxygen treatment is less than in the unpacked bulb is considered most significant. It is plausible that oxygen at such high temperatures would strip any adsorbed film from the surface although this may not be its sole action.

A few runs with varying initial pressures of reactants were made in the unpacked bulb following oxygen treatment. The kinetics at 625° (Table II-C), although not markedly different from those in the aged bulb seem to require a somewhat lower power of the cyanogen concentration (see Discussion). The fact that the temperature coefficient is lower than in the aged bulb may be taken to indicate increased participation by the surface in some phase of the reaction.

[a] k's are expressed in the units millimeters and minutes.
[b] After nitric acid treatment.

Discussion of Results

With regard to the reaction kinetics, the following facts are outstanding: the existence of a brief period of rapid reaction when the gases are first introduced, the greater dependence upon the hydrogen concentration during the further course of the reaction, the inhibiting effect of the product, and the low order of the reaction with respect to total pressure.

A second-order expression of the hydrogen–iodine type was implausible on account of the low order of the reaction and the necessary dominance of the hydrogen concentration in any kinetic expression.

Constants for a three halves order equation involving the square root of the cyanogen concentration (Table I-A, Column 6) fall sharply with time when the ratio of hydrogen to cyanogen is high. This, together with the inhibition by hy-

drogen cyanide, pointed to the well-known Bodenstein–Lind[4] type of expression developed for the reaction of hydrogen and bromine

$$\frac{d[HCN]/2}{dt} = \frac{k_{B\text{-}L}\,[H_2][(CN)_2]^{1/2}}{1 + m\,\frac{([HCN]/2)}{[(CN)_2]}}$$

The constants, calculated for $m = 0.25$ and expressed in millimeters and minutes, are listed in column 7 of Table I-A, the values of the constants for some fifty runs falling within the range shown. This expression is the simplest one which fits the kinetics in the aged bulb reasonably well. Aside from its neglect of the period of initial acceleration, it is deficient only in the high values of the constants for runs with low total pressures. Quite possibly this may be attributed to a surface reaction of very low order; for, if 5–10 mm. of product per hour were formed by a zero-order reaction, the constants for runs with 100 mm. of each reactant would become compatible with those for higher pressures. For runs at low pressures or for high ratios of one reactant to the other the integrated expression is extremely sensitive, and this accounts for most of the observed fluctuations.

Since the packing experiments showed that the reaction is not heterogeneous, the applicability of the Bodenstein–Lind equation, the inhibition by product, and the strong inhibition by the packing in the oxygen-treated bulb are cogent arguments for a reaction involving chains propagated by free radicals and atoms. The acceleration by a small concentration of oxygen is also a type of phenomenon frequently encountered when chain processes are involved.

The most elementary mechanism, by analogy with the hydrogen–bromine reaction, is

$$(CN)_2 \longrightarrow 2CN \qquad (1)$$
$$CN + H_2 \longrightarrow HCN + H \qquad (2)$$
$$H + (CN)_2 \longrightarrow HCN + CN \qquad (3)$$
$$H + HCN \longrightarrow H_2 + CN \qquad (4)$$
$$CN + CN \longrightarrow (CN)_2 \qquad (5)$$

which leads by the familiar steady state solution to the equation

$$\frac{d[HCN]/2}{dt} = \frac{2k_2\sqrt{k_1/k_5}\,[H_2][(CN)_2]^{1/2}}{1 + \frac{k_4}{k_3}\,\frac{[HCN]}{[(CN)_2]}}$$

The propagation of the chains almost certainly centers around reactions 2, 3 and 4, and the necessity for introducing the one-half power of the cyanogen concentration is good evidence for chain ending by a recombination of two CN radicals. The feasibility of chain initiation by the dissociation of cyanogen molecules into free radicals as in equation 1, however, must be determined by other considerations; for, if this is the case, the maximum concentration of cyanide radicals is that attained when the reversible dissociation of cyanogen has reached equilibrium. In order to determine whether this equilibrium concentration is sufficient to give the observed absolute rate of reaction the simple collision theory treatment used by Morris and Pease[5] in considering the thermal hydrogen–chlorine reaction may be employed. The rate of formation of hydrogen cyanide, neglecting the inhibiting action by the product through reaction 4, is calculated as

$$dn_{HCN}/dt = 2k_2\sqrt{K_{eq.}}\,\sqrt{n_{(CN)_2}}\,n_{H_2}$$

where the n's are the numbers of hydrogen and cyanogen molecules, k_2 is the rate of the reaction

$$CN + H_2 \longrightarrow HCN + H \qquad (2)$$

and $K_{eq.}$ is the equilibrium constant for the dissociation

$$(CN)_2 \rightleftarrows 2CN$$

According to collision theory k_2 is given by

$$k_2 = 2\left[2\pi R\,\frac{M_1 + M_2}{M_1 M_2}\right]^{1/2}\sigma_{12}^2\,T^{1/2}\,e^{-E/RT}$$

A value of 7 kcal. for E, the activation energy of reaction 2, has been reported by Hartel and Polanyi[6] from their studies of highly dilute flames. The radius of hydrogen is taken from viscosity data as 1.09 Å. and that of the CN radical as 1.50 Å. or slightly less than that of the nitrogen molecule[7] which should occasion no serious error. Substitution of these values gives $k_2 = 1.34 \times 10^{-11}$ in cc. per molecule per second at 900°K.

Unfortunately, reports of the heat of dissociation of cyanogen into radicals are contradictory. The value 77 kcal. was determined by Kistiakowsky and Gershinowitz.[8] More recently White[9] has assigned 137 kcal. as a minimum value with a probable value of 146 kcal. White has also calculated the entropy change in the dissociation as a function of temperature making use of the best available spectroscopic data; and from this the free energy change and equilibrium constant at

any temperature not far from 1200°K. may be evaluated if the heat of dissociation is known.

Using the value 77 kcal., which is almost certainly too low, and calculating the equilibrium constant by means of White's equation, dn_{HCN}/dt is 5.4×10^6 mm./min. for a reaction mixture of 215 mm. each of hydrogen and cyanogen at 900° K. With White's value of 137 kcal. the rate is calculated as 0.30 mm./min. These calculated rates, whose validity depends upon the 7 kcal. activation energy for reaction 2, bracket the observed "steady" rate, the rate after the period of initial acceleration, of 2 mm./min.

It is possible that White's value may be somewhat high. Hogness and T'sai[10] concluded from their studies on the photochemical polymerization of cyanogen that 2240 Å., corresponding to 127 kcal., is the longest wave length of a cyanogen absorption band and is sufficient to give dissociation into CN radicals. If this value is taken, the equilibrium rate of formation of hydrogen cyanide, assuming again that reaction 2 requires 7 kcal. activation energy, becomes 4.5 mm./min. in better agreement with experiment.

It is also noteworthy that on the assumption of chain starting by dissociation of cyanogen it should be possible to obtain the over-all activation energy as the sum of half the heat of dissociation plus the activation energy of step 2. With the values 127 kcal. and 7 kcal., respectively, the over-all activation energy should be 71 kcal., in good agreement with the observed value of 72 kcal. From another standpoint, however, this is most significant in that it shows the experimental activation energy to be consistent with the proposed mechanism. Thus if the activation energy for step 2 as observed by Hartel and Polanyi is too high by several kilocalories, a larger heat of dissociation could be admitted; if it is too low, a value of even less than 127 kcal. would be necessary to account for the observed over-all activation energy and rate.

If the heat of dissociation of cyanogen is very large, the question of why the reaction does not proceed by the initial dissociation of hydrogen, which requires only 103 kcal., arises. Using White's equation for the entropy change, the equilibrium concentration of CN radicals would be equal to that of hydrogen atoms only if the heat of dissociation of cyanogen were as low as 114 kcal. If the starting involved the dissociation of hydrogen, however, the rate of reaction 3 would determine the absolute rate of formation of hydrogen cyanide; and this, for an equilibrium concentration of hydrogen atoms, may be so low compared to that of reaction 2, for an equilibrium concentration of CN radicals, that the hydrogen dissociation would be of minor importance in the conversion. This would imply that the activation energy of reaction 3 is larger than that of reaction 2, which is reasonable when the large energy of the carbon–carbon bond in cyanogen is considered.

It must be emphasized that these considerations show only that chain initiation by the direct dissociation of cyanogen into cyanide radicals is well within the realm of possibility. The final decision must wait upon the clarification of the uncertainties already mentioned when new data become available.

If chains are initiated by the dissociation of cyanogen molecules, then they must certainly start on the walls of the vessel since an elementary collision theory calculation shows that the time required to attain an equilibrium concentration of CN radicals by gas phase dissociation is of the order of magnitude of several days; furthermore if the walls act as a catalyst for the dissociation, they must also catalyze the chain ending process of recombination.

In view of the complexity of the reaction, however, chain initiation by some process other than the direct dissociation of cyanogen, by means of which a concentration of radicals greater than the equilibrium concentration could be furnished, must not be ruled out. Such a process might be a reaction between cyanogen and adsorbed hydrogen similiar to a mechanism suggested by Morris and Pease for chain starting in the hydrogen–chlorine reaction in one of their Pyrex bulbs.

$$WH_2 + (CN)_2 \longrightarrow WHCN + H + CN$$

For strong adsorption of hydrogen this leads to a Bodenstein–Lind type of expression.

Too few runs in which there were wide variations in the initial pressures were made in the oxygen treated empty bulb to warrant broad generalizations with regard to the kinetics. The expression

$$\frac{d[HCN]/2}{dt} = \frac{k'[H_2]}{1 + m\dfrac{([HCN]/2)}{[(CN)_2]}}$$

seems to fit the data at 625°, the constants for $m = 0.25$ and again expressed in terms of milli-

(10) T. R. Hogness and Liu-Sheng T'sai, THIS JOURNAL, 54, 123 (1932).

meters and minutes appearing in column 7 of Table II-C. The low value for the one run with a 3–1 initial ratio of hydrogen to cyanogen is understandable since by the end of the run practically all the cyanogen has reacted. Bodenstein–Lind constants, however, fit the variation with respect to total pressure at 675°, and the fit would be better if a lower value of m were taken for this temperature; but they are totally unsatisfactory at 625°.

Since there is no reason to suppose that the steps in chain propagation are any different in the clean bulb, the increased rate at low temperatures along with the lower temperature coefficient argues for a different method of chain starting on the surface. The possibility

$$WH_2 + W(CN)_2 \longrightarrow WHCN + H + CN$$

which results in the foregoing kinetic expression suggests itself since Hadow and Hinshelwood[11] obtained evidence of strong adsorption of cyanogen on clean silica in their oxidation studies.

Hogness and T'sai[10] found that CN radicals disappear at room temperature by addition to cyanogen molecules to form a postulated $(CN)_3$ which acts as a nucleus for further polymerization with the ultimate formation of paracyanogen. White[9] concluded that the radicals formed during an electric discharge combine with complex ions simultaneously produced in the discharge as a first step in polymerization. In the present investigation at temperatures of 625° or higher such an addition reaction was not indicated by kinetic analysis of the results in the aged bulb, nor was any extensive polymerization observed. This must mean that the reactions

$$CN + H_2 \longrightarrow HCN + H$$

and

$$CN + CN + W \longrightarrow (CN)_2 + W$$

are much faster than the addition of radical to molecule. It may well be that the $(CN)_3$ complex is unstable at these temperatures since it is known that cyanogen does not polymerize at elevated temperatures and that paracyanogen begins to regenerate cyanogen in the region 700–800°.

Summary

The thermal reaction of hydrogen and cyanogen to yield hydrogen cyanide has been studied in a silica vessel over the temperature range 550–675°. The reaction proceeds without undue complications, but the nature of the surface of the reaction bulb has some influence on the rate. The product, hydrogen cyanide, inhibits the reaction. Packing increases the rate at low temperatures but has little effect above 625°.

The simplest expression which fits the kinetics at 625° reasonably well is that developed by Bodenstein and Lind for the combination of hydrogen and bromine. Evidence is presented which favors a radical chain mechanism involving gas phase propagation by hydrogen atoms and cyanide radicals with chains starting and breaking on the walls. The steps in this process would be analogous to those in the hydrogen–bromine reaction with the cyanogen assuming the role of bromine.

The Ternary Systems Involving Cyclohexane, Water, and Isopropyl and Normal Propyl Alcohols

BY E. ROGER WASHBURN, CHARLES E. BROCKWAY, C. LOREN GRAHAM AND PHILIP DEMING

The ternary systems[1] made up of cyclohexane, water, and[1a] methyl and[1b] ethyl alcohols have been described previously.

The systems[2] involving water, isopropyl alcohol and[2a] benzene,[2b] toluene and[2c] cyclohexene have been described.

This report adds normal propyl and isopropyl alcohols to the first group and cyclohexane to the second group.

Materials.—Cyclohexane from Eastman Kodak Company was carefully fractionated, dried with sodium and recrystallized several times. The alcohols were the best grades obtainable from the same company. They were dried with active lime and carefully fractionated. Some physical

constants for the materials used in this investigation are recorded in Table I.

TABLE I

Material	Specific gravity, d^{25}_4	Refractive index, $n^{25}D$	Freezing point, °C.
Cyclohexane	0.7746	1.4232	6.1[a]
n-Propyl alcohol	.8000	1.3838	..
Isopropyl alcohol	.7808	1.3749	..

[a] A small amount of cyclohexane resulting from many recrystallizations had a freezing point of 6.33° and a specific gravity, d^{25}_4 of 0.7744, and a refractive index not measurably different from that recorded above. This more highly purified material was employed in four solubility measurements with *n*-propyl alcohol and water at 35°. The differences in the results obtained with the 6.1° and the 6.33° cyclohexane, both for the solubility determinations and the refractive index–composition relationships, were well within the experimental errors.

Procedure and Results.—The experimental procedures were essentially the same as those which have been described.[1,2] The results are presented in the following tables and graphs. Since the concentrations are presented in weight per cent., it will be enlightening to state that in each solubility determination and in each distribution study the total weight of liquids employed was of the order of 13 to 15 g.

The earlier investigations[2] of ternary systems containing isopropyl alcohol, water and the hydrocarbons benzene, toluene and cyclohexene showed

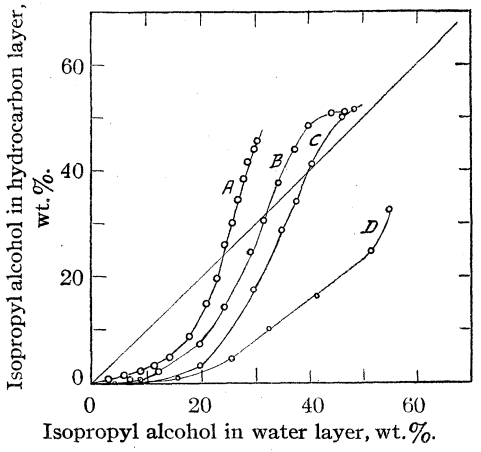

Fig. 1.—A, Benzene; B, toluene; C, cyclohexene; D, cyclohexane.

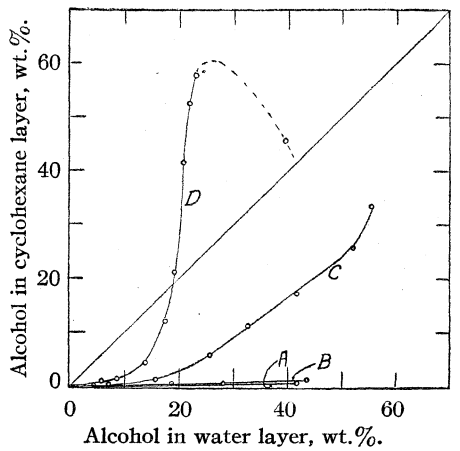

Fig. 2.—A, Methyl alcohol; B, ethyl alcohol; C, isopropyl alcohol; D, *n*-propyl alcohol.

that the greatly increasing proportions in which the alcohol entered the hydrocarbon layer as the total amount of alcohol in the system was increased caused a change in the direction of slope of the tie lines. It will be noted in the present study that, while the proportion of alcohol in the cyclohexane layer increases as the total amount of alcohol increases, it does not ever become equal to the proportion of alcohol in the conjugate layer which is rich in water. The tie lines never become horizontal and the plait point is some distance down on the cyclohexane branch of the binodal solubility curve. Experimental difficulties prevented a very close approach to the plait point and a study of the conjugation curves[3] did not greatly improve the situation. It is probably not far from 48% alcohol on the cyclohexane arm of the curve.

It should be mentioned that extensions of the tie lines for this system do not converge at a single point. Attention has been called to the fact that in several ternary systems such convergence is to be observed.[4] The system methyl alcohol–cyclohexane and water when studied at 25.0°[1a] not only shows such convergence but the point at which the tie lines converge is practically the cyclohexane vertex of the ternary diagram. The solubility of methyl alcohol in cyclohexane is not only limited but very small. As would be expected, ethyl alcohol[1b] is between methyl alcohol and the propyl alcohols in its distribution. It is not much different from methyl alcohol.

The systems in which the tie lines change direction of slope represent extreme cases of non-convergence. In one of the earlier studies the distribution of isopropyl alcohol between water and cyclohexene[2c] was investigated at three different temperatures, 15, 25 and 35°. The slopes of the tie lines and the positions of the plait points changed to a marked extent with the change in temperature. Larger proportions of the alcohol entered the hydrocarbon layer at the higher temperatures. If the present system behaves in a similar manner it might be expected that a change in direction of slope of the tie lines would be observed at a temperature somewhat higher than 25°.

The other system, described in this report, involving *n*-propyl alcohol shows such a change in the direction of slope of the tie lines at 25 and 35°. The change causes the plait point to appear on the opposite branch of the binodal curve from that which would be predicted by the tie lines obtained with the smaller total proportions of the alcohol. It was possible to determine the plait point quite accurately with this system; it appeared at about 42% alcohol on the water branch at 25°. The change of temperature to 35° did not cause as large a change in plait point as was observed in the former system.

The proportions in which these alcohols are distributed between the water and the hydrocarbon layers for these and related systems are clearly shown in Figs. 1 and 2.

Summary

The solubility relationships for the ternary system containing water, cyclohexane and isopropyl alcohol have been determined at 25°. The system containing water, cyclohexane and *n*-propyl alcohol has been studied at 25 and 35°.

The Chemistry of Allergens. VI. Chemical Composition and Properties of an Active Carbohydrate-free Protein from Cottonseed*,[1]

BY JOSEPH R. SPIES AND ERNEST J. UMBERGER

The importance of the role of carbohydrates in immunological specificity has increased since Heidelberger and Avery[2] first showed that polysaccharides determine the specificity of the pneumococcus organism. The possible analogous relationship of polysaccharides to allergenic specificity has made it seem worth while to record properties characterizing a carbohydrate-free allergenic protein fraction from cottonseed.[3]

Allergenic protein-polysaccharidic fractions containing less than 1% carbohydrate were described in a previous paper.[4] Some of these fractions which contained 0.9 to 3.0% carbohydrate were subjected to further electrophoresis to remove the carbohydrate. The material which migrated toward the cathode was used as starting product in three successive electrophoretic fractionations. The final cathodic fraction, CS-60C, was essentially free from carbohydrate as shown by chemical tests.[5]

Experimental

Apparatus.—Electrophoresis apparatus similar to that described and illustrated (Fig. 1) in the fourth article of this series[4] was employed, except that 125, 50 or 25 ml. cells were used, depending on the quantity of material to be fractionated. Side tubes were 10 mm. in outside diameter. Connection between cells was made with gum rubber tubing having 3 mm. wall thickness. *Danger of the current becoming grounded between the glass side-arm and the rubber connection was eliminated by coating the glass with petrolatum before sliding on the rubber tubing.*

Preparation of CS-60C.—Preliminary electrophoresis of previously described fractions[4] consisting of 1.0 g. of CS-51R, 1.5 g. CS-52R and 7.0 g. of CS-53R, which contained 0.9, 0.9, and 3.0 per cent. carbohydrate, respectively, was made in a 7-cell apparatus. The allergenic solution was placed in the center cell and an equal volume of distilled water was placed in each of the other cells. Electrophoresis was conducted with voltages ranging from 2500 to 5000 for six days. A general technique similar to that previously detailed[4] was used. The final *p*H in the cells ranged from 2.8 at the anode to 11.0 at the cathode. The substance which collected in cathodic cells having *p*H values higher than 6.5 was separated and isolated, as previously described, by alcohol precipitation. A combined total of 2.68 g. of solid was obtained in the first run. This solid was dissolved in 25 ml. of water and the solution was filtered from a slight amount of insoluble precipitate. The solution was placed in cell 2+ (25-ml. vol.) of a 6-cell apparatus and subjected to a second electrophoresis, using from 2500 to 5000 v. for five days. The *p*H in the cells ranged from 5.28 at the anode to 11.2 at the cathode. The substance which collected in cathodic cells having *p*H values from 7.69 to 11.0 was isolated by alcohol precipitation. The 563 mg. of solid thus obtained was dissolved in 25 ml. of distilled water and the solution (*p*H 9.4) was placed in cell 2+ of the 6-cell (25-ml. vol.) apparatus. After electrophoresis at 2500 v. for one day the solution in cell − was replaced with 25 ml. of distilled water. Electrophoresis was continued at 5000 v. for three days. The *p*H in the cells ranged from 4.49 at the anode to 10.6 at the cathode. Solutions in cells −, 1−, and 2− (*p*H, 7.52, 8.81 and 10.6, respectively) were combined and concentrated to 30 ml. in a vacuum desiccator over phosphorus

(5) A Molisch test made on a 1% solution of CS-60C was negative. A control test using an equal volume of a 0.002% solution of galactose was distinctly positive by comparison. Using the orcinol method [Heidelberger and Kendall, *J. Immunol.*, **30**, 267 (1936)] 0.2% carbohydrate was indicated in CS-60C. This value is so near the lower limit of the method that it is indecisive and may be due to "blank."

pentoxide. The clear solution was then filtered through a porous platinum filter to avoid contamination with filter paper hairs. The colorless solution was then frozen in a 250-ml. conical centrifuge cup. After freezing the ice was dissolved by addition of 120 ml. of absolute ethanol and the suspension was stirred gently. This procedure eliminated the *p*H adjustment required to effect precipitation of the protein when its solution was poured into alcohol. The suspension was then centrifuged and the solid was washed with two 25-ml. portions of cold 80% ethanol. The white solid, designated as CS-60C, was dried in a vacuum over phosphorus pentoxide. A yield of 204 mg. was obtained. CS-60C was ground to a powder and equilibrated with air before analysis. CS-60C was completely soluble in water and gave protein color tests like those described in previous publications for the precursor fractions.

Discussion

The chemical composition and some properties of CS-60C are shown in Table I. Carbon and hydrogen content were of the usual order of magnitude encountered in proteins. The nitrogen content of CS-60C was higher than that found in most proteins, owing to the relatively large proportion of arginine present in cottonseed allergenic fractions.[1] Fraction CS-60C had a levo optical rotation of 140.

Substantiating evidence for the absence of carbohydrate in fraction CS-60C is contained in Fig. 1 where carbohydrate contents of the previously described[4] electrophoretic fractions CS-51R, CS-52R, CS-53R, CS-54R, CS-55R, and CS-56R are plotted as abscissas against their nitrogen contents as ordinates. A straight line starting on the abscissa at 100% carbohydrate passed through these points and intersected the ordinate representing zero per cent. carbohydrate at 20.4 which is the percentage of nitrogen actually found in CS-60C.

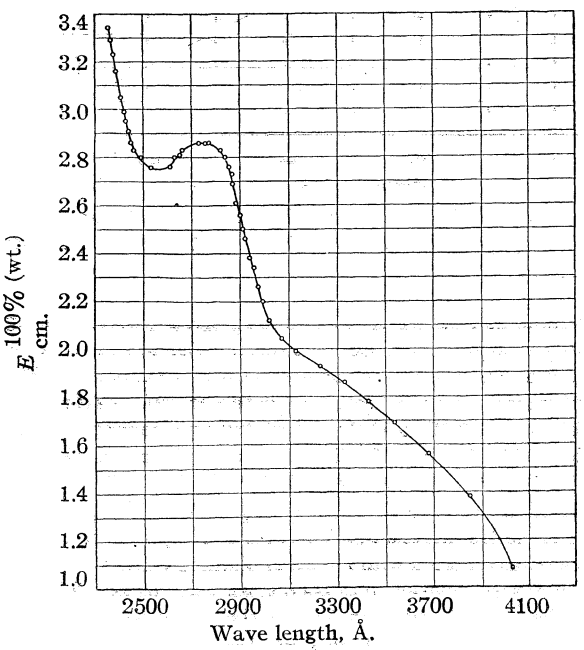

Fig. 2.—Ultraviolet absorption curve of CS-60C in water (concentration 0.413%).

TABLE I

CHEMICAL COMPOSITION AND PROPERTIES OF CS-60C[a]

Nitrogen	20.4
Nitrogen pptd. by 5% trichloroacetic acid [20 ± 0.1°][b]	86.6
Carbon	48.2
Hydrogen	6.58
Sulfur	2.35
$[\alpha]^{20}D$ 1% water solution	−140[c]
$[\alpha]^{20}D$ 2% water solution	−135

[a] All analyses are expressed on an ash and water-free percentage basis. CS-60C contained 0.58% ash and 7.94% water. Analyses were made by the micro methods of Pregl. [b] *Cf.* Paper IV, of this series, Table I.[4] [c] Optical rotation was kindly determined by Dr. E. Yanovsky of the Bureau of Agricultural Chemistry and Engineering.

CS-60C was further characterized by determination of the ultraviolet absorption curve,[6] Fig. 2. An absorption maximum occurred at 2750 Å. which coincides with that found for tyrosine.[7] The fractions from which CS-60C was obtained contained approximately 5% tyrosine.[1] No absorption maximum corresponding to that of phenylalanine was found.[7] The ultraviolet absorption of CS-60C corresponds in general to that which would be predicted from its composition.[1,8]

The solubility curve of CS-60C, Fig. 3, indicated that it was a solid solution.[9]

Whether this protein fraction was a mixture of allergenic components, closely related structurally, or consisted of a single active constituent associated with inactive contaminant cannot be decided from present evidence. However, in view of the variety and drastic nature of the processes used to isolate CS-60C, it seemed unlikely that a small proportion of active substance could have persistently remained associated with a preponderance of inactive material. It seemed more probable that CS-60C represented a mixture of proteins whose structural variations were too slight to permit effective chemical fractionation

(6) The authors are indebted to Dr. P. A. Cole of the National Institute of Health for determination of the ultraviolet absorption curve.

or perhaps too slight to impart immunological identity even if they could be separated.

Fraction CS-60C was antigenic as demonstrated by the property of producing anaphylactic sensitivity and shock in guinea pigs.[10]

The threshold quantity of CS-60C required to incite passive transfer reactions is shown in Table II. These results show that 1×10^{-9} g. of CS-60C was capable of producing positive reactions using a serum of moderate potency.[11]

TABLE II

THRESHOLD QUANTITY OF CS-60C REQUIRED TO PRODUCE POSITIVE PASSIVE TRANSFER REACTIONS WITH SERUM FROM A COTTONSEED SENSITIVE PATIENT[a]

CS-60C Injected,[b] micrograms	Recipients[c] T.W.	N.W.	H.B.
1	19 × 17		
0.1	15 × 15	15 × 13	12 × 15
.01	12 × 14	11 × 11	9 × 11
.001	6 × 7	10 × 10	0
.0001	0	±	0
.00001	..	0	..

[a] This serum (E.S.) gave positive passive transfer reactions to cottonseed allergen when diluted 1:10 and in one case 1:10². *Cf.* Coca and Grove, *J. Immunol.*, **10**, 445 (1925); also Levine and Coca, *ibid.*, **11**, 411, 435 and 449 (1926). [b] Quantity of CS-60C (contained in 0.025 ml. of sterile physiological salt solution) injected into each sensitive site. [c] Recipients were uniformly sensitized on the upper arms with 0.05 ml. of serum in each of five sites. The tests of each series were conducted simultaneously. The numbers refer to the diameter (in mm.) of the wheals which formed within fifteen to thirty minutes. CS-60C produced no non-specific reactions in normal skin. Qualitatively similar results were obtained using serum from another cottonseed sensitive patient (G.W.).

(10) The authors are indebted to Dr. E. J. Coulson for immunological tests: *cf.* Coulson, Spies and Stevens, *J. Immunol.*, **41**, 375 (1941).

(11) The authors wish to acknowledge their indebtedness to Dr. Harry S. Bernton for clinical facilities and to Dorris C. Chambers for assistance in conducting the tests. The clinical evidence showing that CS-1A and fractions derived from it are immunologically distinct from other allergens present in cottonseed has been described by Bernton, Spies and Stevens, *J. Allergy*, **13**, 289 (1942).

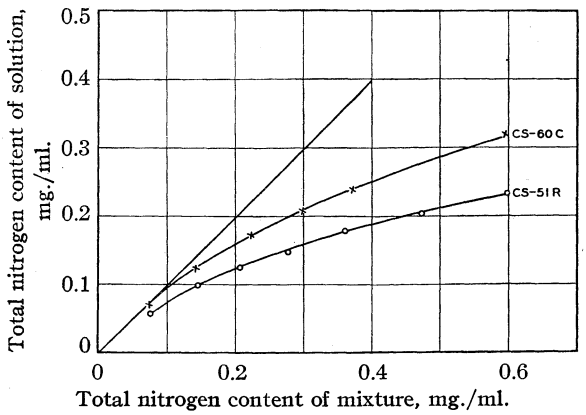

Fig. 3.—Solubility curves of CS-51R and CS-60C: weighed quantities of the protein fractions were placed in glass-stoppered tubes and then dissolved in 1.5 ml. of 0.05 *M* acid potassium phthalate solution buffered at *p*H 5.0. One ml. of absolute ethanol was added to the solution. The suspension was equilibrated by slowly rotating the tubes at 5 ± 0.1° for at least eighteen hours. The excess solid collected on the walls of the tubes during equilibration, leaving a clear supernatant solution which was analyzed for total nitrogen.

Summary

1. A carbohydrate-free allergenic protein, CS-60C, has been isolated from previously described protein-polysaccharidic fractions from cottonseed. Its chemical composition, optical rotation and ultraviolet absorption curve were determined. Solubility data indicated that CS-60C was not homogeneous but probably represented a mixture of active proteins whose structural variations were too slight to permit effective chemical separation.

2. Fraction CS-60C was antigenic as shown by tests on guinea pigs. Positive passive transfer reactions were produced with 1×10^{-9} g. of CS-60C.

Erythrina Alkaloids. XII. Chromatographic Analyses of Erysodine, Erysovine and "Erysocine" and Technique for Preparative Isolation[1]

BY KARL FOLKERS AND JOHN SHAVEL, JR.

The isolation and characterization of erysopine, erysodine, erysovine[2] and erysonine[3] from various species of *Erythrina* have been described. These four alkaloids were obtained by appropriate techniques subsequent to their liberation by the acid hydrolysis of their aqueous solutions after complete removal of the free alkaloids. Difficulties in isolating homogeneous alkaloids from species of *Erythrina* have been observed frequently in published[4] and unpublished studies. It is to be emphasized again that special care should be given to establishing the homogeneity of any new free *Erythrina* alkaloid. Chromatographic analyses have been applied to alkaloids,[5] and preliminary experiments on erysonine[3] confirmed the purity of samples obtained by crystallization technique. This paper describes the results of further chromatographic analyses on pure eryso- alkaloids as a further check on purity and application of such adsorption methods for actual preparative separation of *Erythrina* alkaloidal mixtures.

The melting point and specific rotation of standard samples of erysodine and erysovine were not altered by chromatographic analyses over aluminum oxide. Pure erysopine was not sufficiently soluble in the ordinary solvents to make this analysis feasible. It was soluble in morpholine, as was erysonine,[3] but it was unstable in this solvent, the solution becoming dark green in color, probably because of oxidation due to its two ortho phenolic hydroxyl groups.[2] It was strongly adsorbed and was badly decomposed after elution. However, it is not so essential to confirm the purity of erysopine or isolate it by this technique, since the normal solvent isolation and purification is dependable because of the low solubility of this alkaloid.

"Erysocine" was described[2] as an alkaloid of apparently constant melting point, specific rotation and elementary analyses as isolated from four species of *Erythrina*, and from six other species of *Erythrina* listed in Table II. Gentile and Labriola recently isolated[6] "erysocine," besides erysodine and erysopine, from *E. falcata* Benth. in Argentina. A standard sample of "erysocine" was found to be separated into approximately equal parts of erysodine and erysovine by analysis over alumina. Since these two substances have identical empirical formulas, $C_{18}H_{21}NO_3$, elementary analyses were not significant. "Erysocine," from *E. sandwicensis* Deg.,[2] *E. flabelliformis* Kearney,[2] and *E. costaricensis* Micheli,[3] and from the six species in Table II of this paper, was separated into the two components. Only erysovine was obtained from the "erysocine" of *E. Poeppigiana* (Walp.) O. F. Cook[2] because of the paucity of the sample. Thus, sufficient samples of "erysocine" have been resolved into erysodine and erysovine to show that it is not a single alkaloidal entity.

"Erysocine" might be a molecular complex of erysodine and erysovine obtainable from ether or ethanol, the solvents used for crystallization. Erysodine and erysovine have similar solubilities in ether and it would be expected that their separation in this solvent would be difficult. Conclusive proof as to whether "erysocine" is just a mixture of erysodine and erysovine, mixed crystals or a complex of the two, remains to be settled.[7] Alkaloidal complexes are not unknown; for example, the ergot alkaloidal product, erygoclavine, was shown[8] to be an equimolecular mixture of ergosine and ergosinine. Stoll[9] found sensibamine to be a similar complex of ergotamine and ergotaminine.

Because of the curare-like action of so many species of *Erythrina*,[10] it was of interest to charac-

(7) Preliminary determination of an equilibrium diagram, based on melting points in a capillary, indicated such a complex. Molecular weight determination of "erysocine" by the freezing point depression of dioxane showed negligible association in this solvent. Determination of freezing points of molten erysovine and "erysocine" for plotting cooling curves was not satisfactory because of the decomposition of the molten alkaloids.

terize the liberated alkaloidal fraction of certain other species of the genus for possible isolation of new physiologically active alkaloids. The data on seven such species are in the Experimental Part and the alkaloids isolated are indicated in Table I by positive signs. Widespread occurrence of the liberated alkaloids, erysodine, erysovine and erysopine, is observed[2,3] and is in contrast to the more limited range of occurrence of the free *Erythrina* alkaloids such as erythraline or erythramine.

The ether extraction technique previously described[2] for the isolation and separation of erysovine and erysodine, which also resulted in "erysocine" for some species, has been abandoned in favor of the chromatographic technique. Actually, the isolation of pure erysovine in quantity was quite unsatisfactory, and the chromatographic method described herein has been a desirable improvement.

Experimental Part

Isolation of Alkaloids.—The data on the generalized part of the procedures have been recorded in Table II, Parts A and B. The details of the procedures were analogous to those of the isolations described in paper IX.[2] Reference to the General Remarks to the Experimental Part of Paper IX[2] and X[3] should also be made for additional information which is not repeated here. Those details which cannot be tabulated satisfactorily, concern the fractional crystallizations of the liberated alkaloids and their identification. These data are described briefly as expanded notes to Part B of Table II. For the hydrolyses, after removal of the free alkaloidal fraction, the aqueous solutions were acidified as described in note *c*. For exploratory work, successive hydrolyses have proved helpful for examination of the alkaloids because of the different rates of hydrolysis of the combined alkaloids, but for subsequent preparative work, single prolonged hydrolyses have been used. The numbers of the specimens were assigned by Mr. B. A. Krukoff to the botanical specimens taken from the same plants as the seeds.[11] These specimens are deposited with the New York Botanical Garden.

General Procedure for the Chromatographic Analyses.—For 100–300 mg. of alkaloid, a 15 × 1 cm. column of aluminum oxide Merck (according to Brockmann) was found to be satisfactory. For 1 g. of alkaloid, a 30 × 1.9 cm. column was used.

For chromatographing erysovine and "erysocine," chloroform was preferred as the initial solvent and developing agent. For erysodine, chloroform was preferred for the solution, but ethanol was a better developing solvent.

It was found that when ethanol, morpholine or water solutions were passed over alumina, fine particles of alumina were dispersed which were not removed from the eluate by filter paper. The solutions were cloudy and, on standing, slowly deposited a fine sediment of alumina. Consequently, such eluates were concentrated *in vacuo*, and the residue was dissolved in chloroform and passed through a 2–3 cm. column of alumina. A sufficient amount of chloroform was used to elute the alkaloids.

During development, the column was examined under ultraviolet light, and occasional fluorescent bands were marked with a crayon and followed. Erysodine exhibited a weak yellow–green fluorescence, whereas erysovine seemed to exhibit even less fluorescence. In general, these weak bands were of little help. At the top of the column, there was always a light to dark brown band of decomposition products which had a vivid green fluorescence under ultraviolet light. These top bands remained there during the development and were discarded when the alumina was taken out for elution.

When the amount of alkaloid being eluted by washing the column decreased to a small value it was desirable to elute the remaining material by other means. The method used has been to put the alumina in a glass thimble of a continuous extractor shown in Fig. 1, and extract for several hours with chloroform. This procedure consistently gave almost quantitative recovery of the residual alkaloid. When alkaloid samples were adsorbed so strongly that only very small eluated residues were obtained, the column of adsorbant was divided into several parts, each of which was eluted in the continuous extractor.[12]

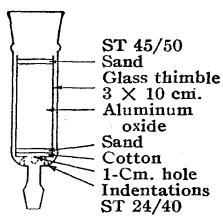

Fig. 1.[12]

Chromatographic Analysis of Erysodine.—The erysodine used was from *E. flabelliformis* Kearney (Jones 9485) and showed m. p. 200–201°, $[\alpha]^{25}D$ +251°, 75.8 mg./10 ml. ethanol, $l = 1$. The 3.66 g. was dissolved in 100 ml. of chloroform and passed into a 45 × 2.3 cm. column. There was a 5-mm. light brown top band which represented decomposition products. The tube under ultraviolet light showed a 5-mm. band of a light yellow–green fluorescence located 10 cm. from the top. The column was then developed with absolute ethanol. After collection of five fractions of the filtrate, the alumina was eluted with chloroform in the continuous extractor. The data are in Table III. Rotations were taken in ethanol at 30–60 mg./10 ml. concentration.

(11) Krukoff, *Brittonia*, **3**, 205 (1939); *Am. J. Botany*, **28**, 683 (1941).

(12) The sand at the bottom of the thimble prevented passage of the alumina, and the sand at the top prevented splattering of the adsorbent and its being washed down into the flask, causing "bumping." This extractor was used for a 30 × 1.9 cm. column of alumina.

[a] Methanol was used. [b] The free alkaloidal fraction was removed by the preferred procedure as described in paper IX. [c] The hydrolyses were made on aqueous solutions acidified with hydrochloric acid to about *p*H 2–2.3 except in a few cases where the solutions were acidified to *p*H 1 as indicated. T. = time in minutes, Y. = % yield of crude liberated bases after removal of the chloroform solvent. [d] The total yield of chloroform residues. [e] The hypaphorine was removed by the alternative procedure as described in paper IX. Further remarks on the isolation of hypaphorine are found in paper III. [f] Examination for hypaphorine was not made. [g] Hydrolysis was made at *p*H 1.

[h] **Erysovine, Erysodine and Erysopine from E. cubensis Wright.**—The 830 mg. of chloroform residue obtained from the first hydrolysis did not give a green color test with ferric chloride, showing the absence of erysopine. When treated with 1 ml. of ethanol, crystallization took place and 548 mg. of crystals, m. p. 154–157°, was obtained. Ether fractionation and recrystallization gave 223 mg. of "erysocine," m. p. 160–161°. A 162-mg. quantity of this fraction was dissolved in 5 ml. of chloroform and passed into a 1.5 × 1 cm. column. On developing with 40 ml. of chloroform, the first eluate gave 56 mg. of erysovine, which after crystallization from ether, showed m. p. 178–178.5°, $[\alpha]^{25}D$ +230°. Elution of the alumina in the extractor gave 108 mg. of alkaloid which gave 12 mg. of erysodine, after one recrystallization from ethanol, m. p. 200–201°, $[\alpha]^{25}D$ +248°. The second hydrolysis yielded 2.175 g. of alkaloids which gave a green color test with ferric chloride, showing the presence of erysopine. Treatment with 4 ml. of ethanol and refrigeration yielded 1.154 g. of m. p. 168–172°. When this material was heated with about 12 ml. of hot ethanol and filtered, 423 mg. of insoluble bases (A) of m. p. 197–198° was obtained. After refrigeration of the filtrate, 431 mg. of crystals (B) of m. p. 198–199° was obtained, which yielded 351 mg. of pure erysodine, m. p. 201–202°, $[\alpha]^{25}D$ +248°, after recrystallization from ethanol. When the crystals (A) were heated with about 4 ml. of hot ethanol and filtered, 51 mg. of crystals (C) of m. p. 214° was obtained. These were recrystallized twice from ethanol to yield 25 mg. of pure erysopine, m. p. 242–243°, $[\alpha]^{25}D$ +265.5° in 40% glycerol and 60% ethanol.

[i] **Erysovine and Erysodine from E. pallida Britton and Rose.**—The 3.271 g. of residue (negative green color test with ferric chloride) from the first hydrolysis was extracted with 300 ml. of boiling ether. There was 96 mg. of insoluble material of m. p. 143–146°. The ether solution yielded 2.245 g. of crystals of m. p. 146–150°. Three recrystallizations of this crop yielded 810 mg. of "erysocine," m. p. 161–162°. A 544-mg. quantity of "erysocine" was dissolved in 50 ml. of chloroform and passed into a 30 × 1.9 cm. column. On developing with 100 ml. of chloroform, the first eluate yielded 431 mg. of gum which, after two recrystallizations from ether, gave 123 mg. of pure erysovine showing m. p. 178–179°, $[\alpha]^{25}D$ +234°. The remaining erysodine adsorbed on the alumina was not sought. The 11.237 g. of residue from the second hydrolysis was combined with the 5.186 g. of residue from the third hydrolysis. Only the latter material gave a slight green color test with ferric chloride for erysopine. The com-

bined bases were extracted with 800 ml. of boiling ether. There was 3.206 g. of insoluble bases of m. p. 193–195°, and the ether extract yielded 4.476 g. of m. p. 157–159°, which corresponded to the material chromatographed before. The insoluble bases were recrystallized twice from ethanol to give 1.5916 g. of erysodine of m. p. 198–199° and $[\alpha]^{25}D$ +250°.

[j] **Erysopine from E. pallida Britton and Rose.**—A fourth hydrolysis of sixty minutes yielded 309 mg. of solid bases, which gave a positive color test with ferric chloride for erysopine. Treatment with 1 ml. of ethanol yielded 131 mg. of crystals of m. p. 186–188°. Five recrystallizations from ethanol gave 8 mg. of erysopine, m. p. 242–243°, $[\alpha]^{25}D$ +262.5°, in 40% glycerol and 60% ethanol. A fifth hydrolysis for sixty minutes at *p*H 1 yielded only 259 mg. of brown semi-crystalline residue which gave a positive color test for erysopine.

[k] **Erysovine, Erysodine, and Erysopine from E. arborescens Roxb.**—The 2.227 g. of bases from the first hydrolysis was triturated with 3 ml. of ethanol at 25° and the insoluble portion, 994 mg., m. p. 160–178°, was extracted with 50 ml. of boiling ether. The insoluble portion (A) was 311 mg., m. p. 164–190°, and the filtrate was concentrated to give a second crop (B), 413 mg., m. p. 163–164°. The portion (B) was recrystallized from ether to give 335 mg. of "erysocine," m. p. 162–163°. A quantity of 327 mg. of this fraction was then dissolved in 5 ml. of chloroform and passed into a 15 × 1 cm. column. On developing with 15 ml. of chloroform, the first eluate gave 139 mg. of erysovine, which after one recrystallization from ether showed m. p. 178–178.5°, $[\alpha]^{25}D$ +235°. The second eluate was added to the extract from the continuous elution of the adsorbent and, after distillation, it gave 184 mg. of residue which after one recrystallization from ethanol gave 35 mg. of pure erysodine, m. p. 199–200°, $[\alpha]^{25}D$ +250°. The portion (A) was triturated twice on the filter with ethanol and the insoluble portion left was 197 mg., m. p. 164–195–197°. This crop was recrystallized from ethanol to give 116 mg. of erysodine, m. p. 199–200°, $[\alpha]^{25}D$ +249°.

The second hydrolysis gave 3.429 g. of bases, which, after trituration with 5 ml. of ethanol, gave 1.367 g. of erysodine, m. p. (and mixed) 201–203°. The second crop was fairly pure erysodine, m. p. 197–200°. During the chloroform extraction after the third hydrolysis, 1.466 g. of erysopine separated from the aqueous solution and was filtered, m. p. (and mixed) 240–242°. Recrystallization from ethanol gave pure erysopine, m. p. 240–242°, $[\alpha]^{25}D$ +264°. The chloroform extraction residue amounted to 2.948 g. and yielded 1.105 g. of erysodine by crystallization.

[l] **Erysovine and Erysodine from E. Folkersii Kruk. and Mold.**—The 1.412 g. of bases from the first hydrolysis did not give a green color test with ferric chloride. It was triturated with 1 ml. of ethanol and the insoluble portion was 684 mg. (A). The filtrate was combined with the similar filtrate from the second hydrolysis, and after concentration the 811 mg. of residue was dissolved in aqueous sodium hydroxide solution and extracted six times with chloroform. The 402 mg. of solvent residue was triturated with 0.4 ml. of ethanol to give 127 mg. of insoluble material, m. p. 159–161° (B). The mother liquor on standing yielded large crystals which were fairly pure erysovine, m. p. 173.5–175°. The insoluble portion (B) was recrystallized once from ethanol and once from ether to give 23 mg. of "erysocine," m. p. 161–162°. A 15-mg. portion of this complex was dissolved in 1 ml. of chloroform and passed into a 3 × 1 cm. column to give 3 mg. of base, m. p. 160–161°. The second development gave 5 mg., m. p. 161–162° (clear at 178°) and on recrystallization from ether yielded 2 mg. of erysovine, m. p. 175–176° (clear, 180°, indicating presence of some erysodine). Elution of the alumina gave 5 mg. of base, m. p. 170–174° (clear at 190°). On recrystallization from ethanol, it yielded 2 mg. of erysodine, m. p. 197–198°, $[\alpha]^{25}D$ +244°. The insoluble portion (A) was recrystallized from ethanol to give 438 mg. of pure erysodine, m. p. (and mixed) 202–203°. The second hydrolysis gave 395 mg. of bases which was triturated with 0.4 ml. of ethanol to give 103 mg. of solid of m. p. 199–201°. After two recrystallizations from ethanol, pure erysodine was obtained, 10 mg., m. p. 200–201°, $[\alpha]^{25}D$ +249°.

[m] **Erysovine and Erysodine from E. velutina Willd.**—The 6.039 g. of bases from the first hydrolysis gave a negative green color test with ferric chloride. Trituration with ethanol, and subsequent recrystallization from ether of the solvent insoluble residue yielded 1.991 g. of "erysocine," m. p. 162–163°. A 1.108-g. quantity of this substance was dissolved in 25 ml. of chloroform and passed into a 30 × 1.9 cm. column. On developing with 400 ml. of chloroform, the first eluate yielded 377 mg. of gum which on recrystallization from ether gave 277 mg. of pure erysovine, m. p. 178–178.5°, $[\alpha]^{25}D$ +230°. Elution of the adsorbent in the extractor yielded 716 mg. of residue which after one recrystallization from ethanol gave pure erysodine, m. p. 200–201°, $[\alpha]^{25}D$ +247°.

The second hydrolysis gave 1.152 g. and the third gave 1.295 g. of bases. Neither product gave the green color test with ferric chloride. Both gave crude erysodine on trituration with ethanol, which, on combination and recrystallization, gave 564 mg. of pure erysodine, m. p. 200–201°, $[\alpha]^{25}D$ +249°.

[n] **Erysodine from the Free Alkaloidal Fraction of E. excelsa Baker.**—The 1.184 g. of the free alkaloidal fraction gave 474 mg. of crude erysodine, m. p. 196–200°, after trituration with 1 ml. of ethanol. Three recrystallizations gave pure erysodine, m. p. 201–202°, $[\alpha]^{25}D$ +245°.

[o] **Erysodine and Erysovine from E. excelsa Baker.**—The 2.033 g. of bases, m. p. 148–150°, from the first hydrolysis was extracted with 50 ml. of boiling ether. There was 460 mg. of insoluble bases (A), m. p. 174–194°, and the filtrate yielded 569 mg. of bases (B), m. p. 158–175°, after concentration. Three recrystallizations of (A) from ethanol yielded 161 mg. of pure erysodine, m. p. 201–202.5°, $[\alpha]^{25}D$ +246°. Recrystallization of (B) from ether gave 403 mg. of "erysocine," m. p. 161–162°. This was dissolved in 5 ml. of chloroform and passed into a 15 × 1 cm. column. It was developed with 25 ml. of chloroform. There was obtained 43 mg. of erysovine, m. p. 178–178.5°, $[\alpha]^{25}D$ +235°, after one recrystallization from ether of the 94 mg. of residue. Elution of the alumina in the extractor yielded 67 mg. of erysodine which showed, after one recrystallization from ethanol, m. p. 200–201°, $[\alpha]^{25}D$ +250°.

The 1.760 g. of bases from the second hydrolysis was triturated with 2 ml. of ethanol, and the 785 mg. of insoluble bases, m. p. 197–200°, showed the presence of erysopine by the ferric chloride color test. Two recrystal-

lizations from ethanol gave pure erysodine, m. p. 201–202°, $[\alpha]^{25}D$ +246°. The third hydrolysis gave 1.084 g. of liquid bases which was deeply fluorescent in chloroform solution.

TABLE III

DATA ON ERYSODINE

Filtrate	Vol., ml.	Residue, g.	M. p., °C.	$[\alpha]^{25}D$
1	200	None		
2	100	1.119	199–200	+247
3	100	0.290	200–201	+243
4	200	.458	197–198	+252
5	200	.323	200–201	+245
Continuous eluate	(*ca.* 6 hr.)	.906	197–198	+245

The residues were not recrystallized before taking the constants. The eluates were slightly cloudy and on standing slowly deposited a slight, fine sediment of alumina; this might account for the slight variations in the constants of the fractions. This chromatographic analysis did not yield erysodine of significantly altered constants when compared to the starting material.

Chromatographic Analysis of Erysovine.—The specific rotation of erysovine has been redetermined on larger and purer samples and found to be $[\alpha]^{25}D$ +232–234° as compared to the original value, $[\alpha]^{25}D$ +252°.[2] The erysovine used was from *E. glauca* Willd.[2] (Wortley 9242) and showed m. p. 177–178°, $[\alpha]^{25}D$ +232°, 49.0 mg./10 ml. ethanol, $l = 1$. A quantity of 1.045 g. was dissolved in 20 ml. of chloroform and passed into a 30 × 1.9 cm. column. Fresh solvent was added and 50-ml. fractions of filtrate were collected. The data are in Table IV. The specific rotations were in ethanol at 10 to 28 mg./2 ml. concentration.

TABLE IV

DATA ON ERYSOVINE

Filtrate	Residue, mg.	M. p., °C.	$[\alpha]^{25}D$
1	None		
2	None		
3	83	177–178	+235
4	192	178–179	+232
5	142	178–179	
6	77	178–179	
7	55	176–177	
8	67	175–176	
Continuous eluate	423	178–179	+233

None of the fractions showed significantly different constants.

Chromatographic Resolution of "Erysocine" into Erysodine and Erysovine.—When a chloroform solution of erysocine was passed into a column of alumina and developed with chloroform, the first eluate was found to contain pure erysovine. An intermediate eluate containing erysovine and erysodine followed, after which the erysodine was slowly eluted. To effect almost quantitative removal of erysodine, the alumina was extracted continuously with chloroform. After removal of the solvent recrystallization of the residue from ethanol gave pure erysodine.

When a solution of erysovine in chloroform was quickly concentrated to dryness *in vacuo* at 50–60°, the residue was an amorphous fluff which was easily soluble in ether. The addition of a little ether followed by warming, quickly dissolved the fluff, and pure erysovine started to crystallize after a minute or two. This procedure was found to be the most efficient for giving pure erysovine with the minimum amount of recrystallizations.

The details on the obtaining of erysodine and erysovine from "erysocine" are described in the footnotes to Table II.

Preparative Isolation of Erysovine by Chromatographic Technique.—The crude alkaloids obtained from the first hydrolysis of an extract from *E. Berteroana* Urb. (Armstrong 9304) on several recrystallizations from ethanol yielded "erysocine," m. p. 159–161°, indicating the presence of erysovine and erysodine. Mr. Frank Koniuszy found that another similar extract yielded on hydrolysis two crops of alkaloidal mixtures. The first crop of 43 g., m. p. 169–172°, was dissolved in 150 ml. of chloroform and passed through a 92 × 4 cm. column, and was developed with chloroform. The data are in Table V. The weight of crystals represents the yield obtained after the gum remaining, after distillation of the chloroform eluant, was recrystallized from ether. The second crop of 24 g., m. p. 177–178°, was treated similarly and pure erysovine obtained.

TABLE V

ISOLATION OF ERYSOVINE

Filtrate	Volume, ml.	Crystals, g.	M. p., °C.	$[\alpha]^{25}D$
1	500	14	178	+236.9
2	1000	12	178	+236.7
3	2000	4.5	178	

Acknowledgment.—We wish to express our gratitude to Mr. B. A. Krukoff of the New York Botanical Garden for obtaining the plant materials and for his coöperation on botanical matters. We are indebted to the many people who aided in the collection of plant material. The technical assistance of Messrs. Michael Kasha and W. B. Wright was very valuable.

Summary

Chromatographic analyses of standard samples did not significantly alter the constants of erysodine and erysovine. All samples of "erysocine" were chromatographically resolved into approximately equal parts of erysodine and erysovine. The chromatographic technique is more satisfactory for the isolation and separation of pure erysovine from erysodine than the previously used ether extraction process.

Erysodine and erysovine have been isolated for the first time from *E. cubensis* Wright, *E. pallida* Britton and Rose, *E. arborescens* Roxb., *E. Folkersii* Kruk. and Mold., *E. velutina* Willd. and *E. excelsa* Baker. Erysopine was isolated anew from the first three mentioned species, and erysodine was isolated from *E. Berteroana* Urb. These three eryso- alkaloids have a very wide distribution in the seeds of species of the genus *Erythrina*.

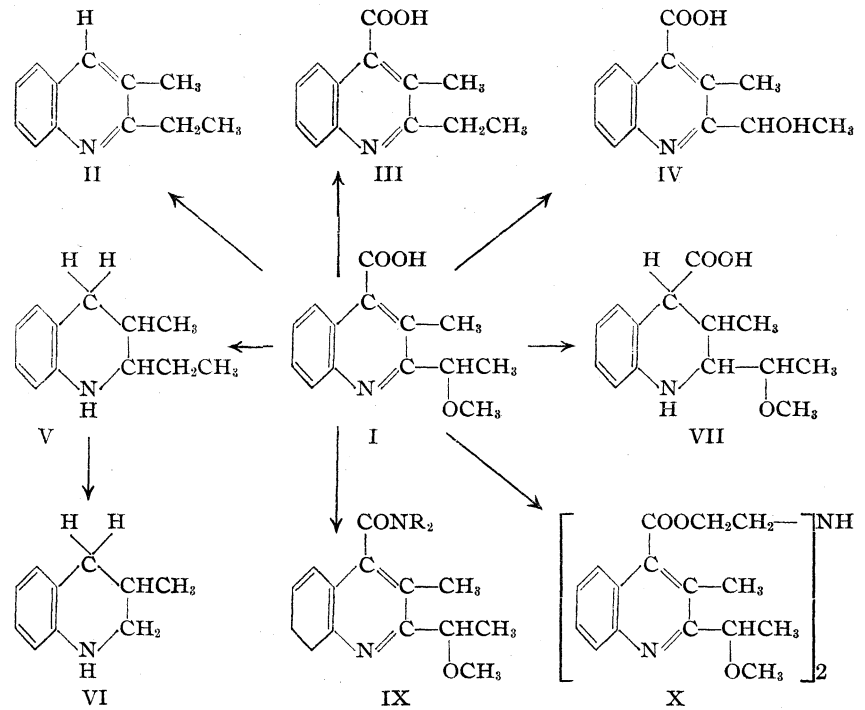
Utilization of Alkoxy Ketones in the Synthesis of Quinolines by the Pfitzinger Reaction. II[1]

BY SHERMAN D. LESESNE[2,3] WITH HENRY R. HENZE

It has been shown recently in this Laboratory that keto ethers[4] can be employed in the synthesis of quinoline derivatives by the Pfitzinger reaction. Thus,[4b] ethoxyacetone and ethoxymethyl ethyl ketone, respectively, were condensed with isatin to produce the corresponding 2-methyl- (or 2-ethyl)-3-ethoxycinchoninic acid. A survey of the literature revealed no record of the preparation of any 2-alkoxyalkylcinchoninic acids.

In the present investigation the Pfitzinger reaction has been extended to include the utilization of alkoxy ketones in the synthesis of 2-alkoxyalkyl and 2-alkoxyalkyl-3-alkylcinchoninic acids. For example, isatin and 1-methoxydiethyl ketone were condensed in potassium hydroxide solution to form 2-(1-methoxyethyl)-3-methylcinchoninic acid (I). Proof of the structure of I was obtained by conversion into 2-ethyl-3-methylquinoline (II)[5] by heating at the melting point of the acid. The decarboxylation which occurred thus was anticipated but the cleavage of the ether linkage and reduction of the carbinol to alkyl was unexpected. Cleavage and reduction without decarboxylation of I to form III was accomplished by heating with hydriodic acid and red phosphorus for six hours. In contrast, when I was heated with concentrated hydrochloric acid only the ether grouping underwent fission and 2-(1-hydroxyethyl)-3-methylcinchoninic acid (IV) resulted. However, by heating for seven days with hydriodic acid and red phosphorus, I was converted into 2-ethyl-1,2,3,4-tetrahydro-3-methylquinoline (V). In turn, V, by action of hydrochloric acid and tin, yielded 1,2,3,4-tetrahydro-3-methylquinoline (VI).[6] Reduction without cleavage was effected by catalytic hydrogenation of I in the preparation of 2-(1-methoxyethyl)-1,2,3,4-tetrahydro-3-methylcinchoninic acid (VII).

By treatment of I with thionyl chloride and subsequent interaction with appropriate secondary amines, three substituted amides (IX) were produced; diethanolamine reacted with the acid chloride of I to form the dicarbethoxyamine (X) rather than an hydroxyethyl amide. 2-(1-Methoxyethyl)-cinchoninic acid (XV) reacted in an analogous manner with the same amines.



In view of the fact that some 2-substituted-cinchoninic acid derivatives are useful as antimalarials,[7] it was thought desirable to include, in this study, the synthesis of bis-2-cinchoninic acid (XI) and 2-phenyl-3-ethylcinchoninic acid (XIII).

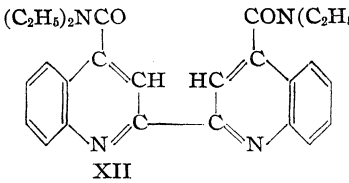
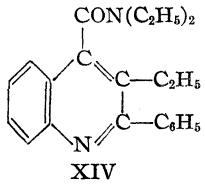
Finally, XI and XIII were converted into the corresponding diethylamides, XII and XIV, respectively.



XII



XIV

Through the courtesy of Parke, Davis and Company, preliminary pharmacological testing of ten of the new derivatives of cinchoninic acid has been made. The study was made by daily oral treatment for three days of canaries infested with *Plasmodium cathemerium* and led to negative results as far as the antimalarial activity of I, III, XI, XIII, XIV and XVI are concerned. Likewise, against avian malaria compounds XIII and the diethylamides of I and III are inactive. Finally, the diethylamide of bis-2-cinchoninic acid (XII) was found to have no action orally on *Streptococcus viridans* in mice.

Experimental

2-(1-Methoxyethyl)-3-methylcinchoninic Acid (I).—Sixty grams (0.41 mole) of isatin was dissolved in 300 g. of 33% potassium hydroxide solution; 42 g. (0.42 mole) of 1-methoxydiethyl ketone[8] was added and the mixture was heated under a reflux condenser on a steam cone for twenty-four hours. The reaction mixture was diluted with water to a volume of 750 cc., partially decolorized with Norite and filtered while hot. The filtrate was cooled and acidified by addition of 250 cc. of 50% acetic acid solution. After standing in an ice-bath a light cream-colored solid separated. The acid was recrystallized from water in colorless needles melting at 234° (cor.) with decomposition; yield 74 g. (74%). This cinchoninic acid is soluble in alcohol, moderately soluble in acetone, and insoluble in ether and benzene. It readily formed a picrate which melts at 201° (cor.).

Anal. Calcd. for $C_{14}H_{15}NO_3$: neut. equiv., 245.3; C, 68.55; H, 6.16; N, 5.71. Found: neut. equiv., 244.0; C, 68.92; H, 6.17; N, 5.77.

Effect of Heating I.—Fifteen grams of I was heated in a distilling flask in an oil-bath at 250°; the solid first melted, then carbon dioxide was evolved. At the end of twenty minutes gas evolution had ceased and the residual, black liquid was distilled under diminished pressure. There was obtained about 1.5 g. (14% yield) of a clear yellow oil (II) which readily yielded a bright yellow picrate. The latter, after recrystallization from diluted alcohol, melted at 191° (cor.)[9].

Anal. Calcd. for picrate, $C_{18}H_{16}N_4O_7$: C, 54.00; H, 4.03; N, 14.00. Found: C, 53.98; H, 4.03; N, 13.48.

Action of Hydrochloric Acid on I.—Five grams of I was heated with 10 cc. of concentrated hydrochloric acid for forty-eight hours at 100°. Upon neutralization with sodium hydroxide a light cream-colored precipitate formed, which was purified through resolution in alkaline solution and reprecipitation with acetic acid. Thus was obtained 2.7 g. (55% yield) of the mono-hydrate of **2-(1-hydroxyethyl)-3-methylcinchoninic acid** (IV) melting at 265° (cor.). The picrate of this compound has a melting point (explosive!) above 310°.

Anal. Calcd. for $C_{13}H_{13}NO_3 \cdot H_2O$: C, 62.61; H, 6.06; N, 5.62. Found: C, 62.76; H, 5.94; N, 5.50.

Action of Hydriodic Acid on I.—(A) Twelve grams of I, 50 cc. of hydriodic acid (57% strength), and 5 g. of red phosphorus were heated together under a reflux condenser for six hours at 150°. The mixture was made basic with sodium hydroxide and filtered to remove phosphorus. The filtrate was acidified with acetic acid causing precipitation of a white solid, which was filtered, washed with cold water, and after drying weighed 8 g. (78% yield). **2-Ethyl-3-methylcinchoninic acid** (III) melts at 279° (cor.) and is soluble in alcohol, moderately soluble in acetone, and insoluble in ether and benzene. It readily forms a picrate melting at 198° (cor.).

Anal. Calcd. for $C_{13}H_{13}NO_2$: neut. equiv., 215.2; C, 72.54; H, 6.09; N, 6.51. Found: neut. equiv., 213.3; C, 72.52; H, 6.04; N, 6.66.

(B) Twenty grams of I, 100 cc. of hydriodic acid (57% strength), and 5 g. of red phosphorus were heated together for *seven days* at 140–150°. The reaction mixture was made alkaline and subjected to steam distillation. The colorless oil in the distillate was extracted with ether, dried over sodium sulfate and fractionated. Ten grams (70% yield) of **2-ethyl-1,2,3,4-tetrahydro-3-methylquinoline** (V) was obtained; b. p. 253° (716 mm.); $n^{20}D$ 1.5902; d^{20}_4 1.0423; *MR* calcd. 56.51; *MR* found 56.78; picrate (from alcohol) m. p. 188° (cor.).

Anal. Calcd. for $C_{12}H_{17}N$: C, 82.23; H, 9.78; N, 7.99. Found: C, 82.10; H, 9.45; N, 8.03.

Action of Tin and Hydrochloric Acid on V.—Seven grams of V, 40 g. of granulated tin, and 150 cc. of concentrated hydrochloric acid were heated on a steam-bath for twelve hours. At intervals, 50-cc. portions of acid were added to maintain reaction. The reaction mixture was made alkaline and steam-distilled; the distillate was ether extracted, the extract dried and fractionated; 4 g. (68% yield) of **1,2,3,4-tetrahydro-3-methylquinoline** (VI) was collected; b. p. 117° (15 mm.);[10] $n^{20}D$ 1.5536; d^{20}_4 0.9931; *MR* calcd. 47.27; *MR* found 47.50; picrate (from ether) m. p. 159° (cor.).[11]

Catalytic Reduction of I.—Two grams of I in 30 cc. of ethanol was shaken for two hours with 0.05 g. of the Adams catalyst and hydrogen at atmospheric pressure. After filtration from the catalyst, spontaneous evaporation of the filtrate of the solvent yielded **2-(1-methoxyethyl)-1,2,3,4-tetrahydro-3-methylcinchoninic acid** (VII) melting with

(8) (a) Gauthier [*Ann. chim. phys.*, (8) **16**, 322 (1909)] reported only b. p. 133° (729 mm.); (b) Wallace [M.A. thesis, University of Texas, 1936] reported b. p. 154–155° (746 mm.); $n^{20}D$ 0.8913; semicarbazone m. p. 120.5° (cor.).

Methyl Ester of I.—Five grams of I was heated with 10 cc. of dimethyl sulfate for eight hours at 100°. Upon neutralization of the reaction mixture with sodium hydroxide, a viscous liquid separated and was extracted with petroleum ether. Upon evaporation of the solvent at 0°, **methyl 2-(1-methoxyethyl)-3-methylcinchoninate** crystallized (4.5 g. or 85% yield); m. p. 57° (cor.); picrate (from alcohol) m. p. 179° (cor.).

Anal. Calcd. for $C_{15}H_{17}NO_3$: C, 69.48; H, 6.61; N, 5.40. Found: C, 69.85; H, 6.49; N, 5.64.

Substituted Amides of I.—In general, 0.02–0.05 mole of I was dissolved in 0.12–0.18 mole of purified thionyl chloride, the mixture was allowed to stand at 0° for thirty minutes, then poured into a mixture of 0.025–0.07 mole of a secondary amine, 0.11–0.26 mole of potassium carbonate and 200–300 cc. of crushed ice. After reaction had ceased the mixture was placed in a separator with 200–300 cc. of ethyl ether and allowed to stand for six hours. The ether layer was removed and dried over sodium sulfate before being concentrated to a small volume by impact of a jet of dry air at 0°. Then 100–200 cc. of petroleum ether was added and evaporation continued until the amide crystallized. Amides were thus prepared from interaction of diethylamine, diisoamylamine and diallylamine, respectively. The compounds are moderately soluble in alcohol and acetone, but insoluble in benzene and water. The melting point of each of these amides, as well as that of the corresponding picrate, is listed in Table I.

In the same manner were prepared three analogous amides from 2-ethyl-3-methylcinchoninic acid (III) and the diethyl amide from bis-2-cinchoninic acid (XI) and 2-phenyl-3-ethylcinchoninic acid (XIII), respectively. Likewise, interaction of diethanolamine and the acid chloride of I and III, respectively, yielded the corresponding dicarbethoxyamines. The melting point data for these amides and ester amines are also included in Table I.

2-(1-Methoxyethyl)-cinchoninic Acid (XV).—This acid was prepared in a manner wholly similar to that of its 3-methyl homolog by interaction of 47 g. of isatin, 34 g. of 1-methoxyethyl methyl ketone,[12] and 200 g. of 33% potassium hydroxide solution. Forty-four grams (60% yield) of the acid was obtained; m. p. 186° (cor.) dec.; a picrate was not produced.

Anal. Calcd. for $C_{13}H_{13}NO_3$: neut. equiv., 231.2; C, 67.52; H, 5.67; N, 6.06. Found: neut. equiv., 229.1; C, 67.35; H, 5.70; N, 6.24.

Twelve grams of XV, 5 g. of red phosphorus and 50 cc. of hydriodic acid (sp. gr. 1.7) were heated at 150° for six hours. Using the procedure for preparation of III, there was obtained 8.2 g. (80% yield) of **2-ethylcinchoninic acid** (XVI) melting at 180° (cor.); a picrate of XII was not obtained.

Anal. Calcd. for $C_{12}H_{11}NO_2$: neut. equiv., 201.2; C, 71.61; H, 5.51; N, 6.96. Found: neut. equiv., 201.2; C, 71.68; H, 5.43; N, 7.13.

When 17 g. of XV was heated at 200° the solid first melted, then decomposed with evolution of carbon dioxide. After twenty minutes the residual black oil was fractionated yielding but 1.5 g. (13% yield) of liquid. The latter was converted into a picrate which melted at 148° (cor.). This temperature compares well with that of the anticipated product of decarboxylation, namely, **2-ethylquinoline.**[13]

Anal. Calcd. for picrate, $C_{17}H_{14}N_4O_7$: C, 52.85; H, 3.65; N, 14.50. Found: C, 52.30; H, 3.62; N, 14.02.

Bis-2-cinchoninic Acid (XI).—A mixture of 40 g. (0.27 mole) of isatin, 12.5 g. (0.14 mole) of acetoin, and 200 g. of 33% potassium hydroxide solution was heated for twenty-four hours at 100°. On cooling the sodium salt of the acid separated and was filtered, redissolved in hot water and acidified with acetic acid. When dry the crude material weighed 28 g. (58% yield) and was purified by dissolution in sodium hydroxide solution and reprecipitation with

(12) Gauthier, ref. 8a, reported only b. p. 114° (727 mm.); Wallace, ref. 8b, reported b. p. 115–116° (739 mm.); $n^{20}D$ 1.3936; d^{20}_4 0.9014; semicarbazone m. p. 141°.

(13) Reher [*Ber.*, **19**, 2997 (1886)] recorded m. p. 147° (cor.).

acetic acid; m. p. 367° (cor.). This acid is insoluble in water and in the common organic solvents; attempts to form a picrate failed.

Anal. Calcd. for $C_{20}H_{12}N_2O_4$: neut. equiv., 172.16; C, 69.76; H, 3.51; N, 8.14. Found: neut. equiv., 174.4; C, 69.64; H, 3.61; N, 8.14.

2-Phenyl-3-ethylcinchoninic Acid (XIII).[14]—In a similar manner, from 40 g. (0.27 mole) of isatin, 43 g. (0.27 mole) of phenyl *n*-propyl ketone, and 200 g. of 33% potassium hydroxide solution, was obtained 40 g. (55% yield) of crude acid. After recrystallization from acetone this compound melts at 286° (cor.); the picrate melts at 147° (cor.).

Anal. Calcd. for $C_{18}H_{15}NO_2$: C, 77.96; H, 5.45; N, 5.05. Found: C, 77.41; H, 5.59; N, 5.04.

Summary

1. The Pfitzinger reaction has been extended to include the production of two cinchoninic acid derivatives containing an alkoxyalkyl substituent at the 2-position through utilization of alkoxyalkyl ketones of type $CH_3OCH(CH_3)COR$.

2. These acids suffer cleavage of their ether linkage by action of concentrated hydriodic acid and red phosphorus, yet resist reduction.

3. The acids are decarboxylated by heating above their melting points, and, by action of tin with hydrochloric acid, undergo reduction of the pyridine nucleus and dealkylation of the ether group.

4. Bis-2-cinchoninic acid and 2-phenyl-3-ethylcinchoninic acid have been prepared and converted into their diethylamides.

5. Several substituted amides of these cinchoninic acids have been prepared and shown elsewhere not to possess antimalarial activity.

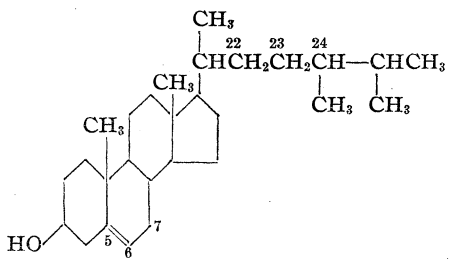
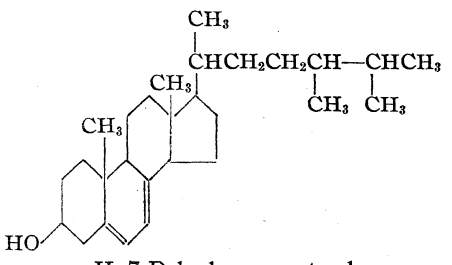
7-Dehydrocampesterol, a New Provitamin D

BY WILLIAM L. RUIGH

The relationship between the structure of the side chain of the D vitamins and their antirachitic activity has been the subject of a number of investigations. The isolation[1] of a new phytosterol, campesterol (I), and the determination of its structure[2] as the C-24 epimer of Δ^5-ergostenol, suggested a new approach to the problem.



I, Campesterol



II, 7-Dehydrocampesterol

Campesteryl acetate was converted by the conventional method[3] via the 7-keto compound into 7(α)-benzoxycampesteryl benzoate. The usual method of preparing 7-dehydrosterols was modified at this point by selectively hydrolyzing the dibenzoate to the 7-monobenzoate and cleaving the latter into benzoic acid and free 7-dehydrocampesterol[4] II. Irradiation of this compound with ultraviolet light gave a resin, the antirachitic activity of which determined by the line test on rats was 725,000 international units per gram. The product obtained from ergosterol under identical conditions assayed at 7,000,000 I. U. per gram corresponding to a yield of 17.5% vitamin D_2 (40,000,000 I. U. per gram). Assuming the same extent of conversion in both cases the potency of the vitamin from 7-dehydrocampesterol is estimated to be 4,100,000 I. U. per gram, which is thus only 10% of the potency of vitamin D_2. Due to lack of sufficient material no attempt was made to isolate the new vitamin in crystalline form.

Vitamin D_4, prepared from 22,23-dihydroergosterol by Windaus and Trautmann,[5] was reported to have from 20,000,000 to 30,000,000

international units per gram. On the basis of the comparative data available, the antirachitic substance from 7-dehydrocampesterol has only one-sixth the activity of vitamin D_4. The two vitamins are stereoisomers differing only in the configuration of carbon atom twenty-four in the side-chain. It is thus apparent that the difference in antirachitic activity due to stereoisomerism on C-24 is considerably greater than the comparatively slight difference (25–50%) caused by the presence or absence of the side chain double bond in vitamins D_2 and D_4, respectively.

The demonstration that 7-dehydrocampesterol can function as a provitamin is also of interest in connection with the claim advanced by Wunderlich[6] and later by Bills[7] that 7-dehydrositosterol can be activated by ultraviolet light. The starting material employed by Wunderlich for the preparation of the 7-dehydrositosterol was the sterol fraction from soy-bean which remained after the removal of the stigmasterol as the tetrabromide. From a similar fraction 3% of pure campesterol was later isolated in this Laboratory[1] and has served as the starting material for the present work. It seems reasonable to assume that Wunderlich's sitosterol contained 3% or more campesterol and possibly other as yet unisolated C-28 sterols such as 22,23-dihydrobrassicasterol.[8] It is, therefore, probable that a part of the antirachitic activity possessed by Wunderlich's product from sitosterol was due to the presence of vitamin derived from campesterol. In view of the fact that irradiated 7-dehydrostigmasterol is practically devoid of vitamin D activity,[9,10,11] the possibility will now have to be considered that the same may be true of pure 7-dehydrositosterol and of C-29 sterols in general. It is clear that this question cannot be unequivocally answered until Wunderlich's work has been repeated with a sitosterol entirely free from C-28 sterols.

The author wishes to thank Dr. O. Wintersteiner for his interest and encouragement during the course of this work, Dr. A. Black of the Squibb Vitamin Research Laboratory for the biological assays and the benefit of his experience on the irradiation of 7-dehydrosterols, Dr. N. H. Coy of the same laboratory for absorption spectra and assays and Mr. Karl Reinhardt for his efficient technical assistance. All microanalyses were performed by Mr. J. F. Alicino, Fordham University.

Experimental

7-Ketocampesteryl Acetate.—Forty grams of campesterol, m. p. 156.5–158°, isolated from soy-bean oil[1] was converted to the acetate, m. p. 137–138°. The acetate was oxidized with chromic acid in glacial acetic acid following the method of Windaus, Lettré and Schenck[3] for the preparation of 7-ketocholesterol acetate. Fourteen grams of crude product, m. p. 168–80°, was obtained which on repeated recrystallization from alcohol yielded 7.4 g. of pure 7-ketocampesteryl acetate, needles, m. p. 177–178°; $[\alpha]^{24}D$ −88.6° (1.18% in chloroform).

Anal. Calcd. for $C_{30}H_{48}O_3$: C, 78.90; H, 10.59. Found: C, 78.72, 78.80; H, 10.47, 10.60.

7(α)-Benzoxycampesteryl Benzoate.—The reduction with aluminum isopropylate and isopropyl alcohol of 7 g. of 7-ketocampesteryl acetate yielded 4.7 g. of crude hexane-precipitable diol. Benzoylation in pyridine gave 3.8 g. of crude dibenzoate, m. p. 171–172°, from which was obtained pure benzoxycampesteryl benzoate by repeated recrystallization from acetone, needles, m. p. 176.5–177.5°; $[\alpha]^{23}D$ +96.6° (0.81% in chloroform).

Anal. Calcd. for $C_{42}H_{56}O_4$: C, 80.72; H, 9.03. Found: C, 80.90; H, 9.38.

7(α)-Benzoxycampesterol.—To 2 g. of the dibenzoate dissolved in 40 cc. of benzene a solution of 1.33 g. of sodium methylate in 66 cc. of dry methanol was added. The mixture was allowed to stand at room temperature for sixteen hours and worked up as described before[4] for the corresponding cholesterol derivative. The chromatographed product, 1.60 g., crystallized from benzene-hexane in filamentous needles. 7(α)-Benzoxycampesterol melts at 143–145° after sintering to a glassy solid at 126–130°; $[\alpha]^{26}D$ +115.0° (1.16% in chloroform). The analytical sample on drying for two hours at 108° in a high vacuum showed a loss in weight of 2.07%.

Anal. Calcd. for $C_{35}H_{52}O_3$: C, 80.72; H, 10.07. Found: C, 80.40, 80.38; H, 9.87, 9.94.

7-Dehydrocampesteryl Benzoate.—One gram of 7(α)-benzoxycampesterol was refluxed with dimethylaniline and worked up as previously described.[4] The digitonide on decomposition by pyridine–ether yielded 564 mg. of impure 7-dehydrocampesterol; leaflets from acetone, m. p. 148–149.5°[12] $[\alpha]^{23}D$ −91.0°, ϵ_{282} = 9350, corresponding to 81% of the absorption at 282 mμ given by ergosterol. The crude dehydrocampesterol (475 mg.) was benzoylated in pyridine and after seven recrystallizations from benzene–alcohol 229 mg. of 7-dehydrocampesteryl benzoate was obtained in the form of fine needles. The compound melted at 156–157° to a cloudy liquid which cleared sharply at 164°. This degree of purity was actually attained on the fourth crystallization and three further crystallizations did not change the melting point behavior. The compound gave positive Tortelli-Jaffé and Rosenheim trichloroacetic acid reactions, $[\alpha]^{23}D$ −50.2 (1.0% in chloroform).

(12) All melting points of dehydro derivatives were taken in sealed evacuated tubes after drying for half an hour under a high vacuum at 107°.

Anal. Calcd. for $C_{35}H_{50}O_2$: C, 83.61; H, 10.03. Found: C, 83.43; H, 10.02.

7-Dehydrocampesterol.—A solution of 150 mg. of dehydrocampesteryl benzoate in 5 cc. of benzene was added to 10 cc. of 5% methanolic potassium hydroxide. After boiling for two hours, the hydrolyzed product was obtained by ether extraction and crystallized from acetone–methanol. 7-Dehydrocampesterol formed shining irregular plates, m. p. 164–165°, $[\alpha]^{25}D$ −109.0° (0.96% in chloroform). The sample for analysis was dried for two and one-half hours at 107° in a high vacuum.

Anal. Calcd. for $C_{28}H_{46}O$: C, 84.35; H, 11.63. Found: C, 84.81; H, 11.58.

The absorption spectrum in ether exhibited the maxima at 272 mμ and 282 mμ characteristic of 7-dehydrosterols; $\epsilon_{282\ m\mu}$ = 10,600.

Irradiation with Ultraviolet Light.—The light source used in this work was a 125-watt air-cooled quartz mercury vapor lamp. For each run 63 cc. of a 0.1% solution of the sterol in peroxide-free ether was taken, and after displacing the dissolved air with a stream of carbon dioxide, irradiation commenced with the preheated lamp. After irradiation the solution was evaporated to dryness, taken up in a few drops of alcohol and then made up to 6.3 cc. with corn oil for assay. Preliminary experiments with ergosterol showed that four minutes was the optimal time for irradiation. Under these conditions ergosterol gave a product the activity of which assayed by the U. S. P. XI line test on rats was found to be 7,000,000 international units of vitamin D per gram of original ergosterol. This corresponds to a conversion of 17.5%. 7-Dehydrocampesterol irradiated under identical conditions assayed 725,000 international units per gram of original substance.[13]

Summary

The preparation and properties of 7-dehydrocampesterol are described. 7-Dehydrocampesterol on irradiation with ultraviolet light yields an antirachitically active product. By comparison with ergosterol irradiated under the same conditions the antirachitic potency of the vitamin derived from 7-dehydrocampesterol has been estimated as 4,100,000 international units per gram.

(13) Preliminary results indicated that the vitamin from 7-dehydrocampesterol resembles vitamin D_2 rather than vitamin D_3 in that it is relatively less active when assayed by the chick test.

Nature and Constitution of Shellac. XVI. Preparation of 8,9,15-Trihydroxypentadecylamine from Aleuritic Acid by the Naegeli–Curtius Series of Reactions[1]

BY ARTHUR L. DAVIS[2] AND WM. HOWLETT GARDNER

Introduction

Aliphatic polyhydroxyamines have many interesting properties.[3] They should be valuable intermediates in the synthesis of several new compounds which would be useful in the paint and other fields. Such hydroxyamines might be prepared from polyhydroxy acids which have been obtained from shellac.[4,5] The hydroxyl groups of such acids, however, have a tendency to react intermolecularly when subjected to elevated temperatures of 100° or higher, such as are employed in a number of common methods for obtaining amines from carboxylic acids. This was what apparently occurred in attempts to prepare the amide when using the Hofmann procedure.[5] The Lossen method involving the formation of a substituted hydroxamic acid also gives very poor results. The Curtius method[6] likewise has proved unsatisfactory. Nagel obtained only a mixture of partially chlorinated amines when he attempted to prepare 8,9,15-trihydroxypentadecylamine from aleuritic acid by this method. His failure can be traced to the use of concentrated hydrochloric acid in hydrolyzing the relatively stable trihydroxypentadecylurethan. Other strong mineral acids lead to like difficulties.[6] Naegeli[7] had similar trouble in attempting to synthesize the amine from chaulmoogric acid. Hence he was led to prepare the isocyanate from the azide instead of the urethan. Isocyanates generally can be hydrolyzed to the amines in the presence of aqueous solutions of alkali without affecting the hydroxyl groups. These series of reactions can be expressed as follows wherein the group $C_{15}H_{31}O_3$ may be rep-

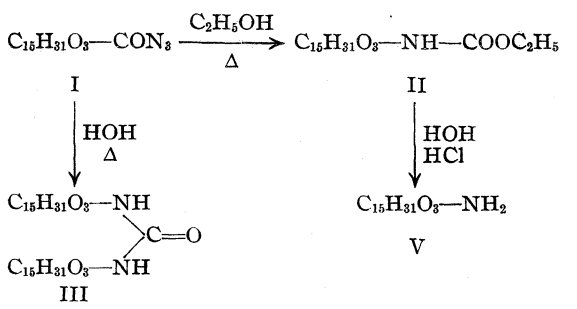
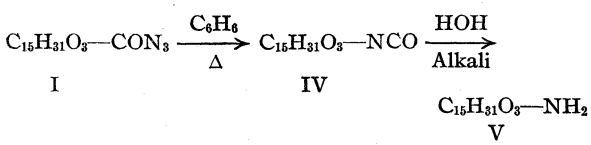
CURTIUS SERIES OF REACTIONS



NAEGELI MODIFICATION



This article describes how 8,9,15-trihydroxypentadecylamine was prepared from aleuritic acid by such a method. Kirk has already suggested how such a procedure might be employed in the study of shellac acids of unknown structure, such as shellolic acid.[4c,8] This study of shellolic acid will be described in a later communication.

In an attempt to prepare the amine corresponding to aleuritic acid (9,10,16-trihydroxypalmitic acid) with the aid of the Curtius series of degradation reactions, the acid was esterified directly with anhydrous methyl alcoholic hydrogen chloride. The product, methyl aleuritate, was converted to the acid hydrazide, by the action of hydrazine hydrate on an alcoholic solution of the ester. This conversion was practically quantitative when highly purified samples of the ester were used. Nitrosation, at temperatures approaching 0°, converted the hydrazide into aleurityl azide I, an unstable, hygroscopic solid. When I was heated in water for three hours, N,N′-bis-8,9,15-trihydroxypentadecyl urea III was formed, while when I was refluxed with anhydrous ethyl alcohol for one and one-half hours, 8,9,15-trihydroxypentadecylurethan II was the resulting product. Inasmuch as hydrolytic action failed to convert either II or III into the corresponding amine, the Naegeli modification was resorted to. When I was decomposed by heating in anhydrous benzene for one hour, the corresponding isocyanate was formed.

(8) P. M. Kirk, Doctor's dissertation, Polytechnic Institute of Brooklyn, Brooklyn, N. Y., June, 1939.

Pure 8,9,15-trihydroxypentadecyl isocyanate IV which was prepared for the first time, was a colorless, crystalline solid melting at 103.5–104.5°. It was soluble in alcohol and dioxane but practically insoluble in diethyl ether, petroleum ether and water. The isocyanate reacted with water and alcohol to produce N,N′-bis-8,9,15-trihydroxypentadecylurea III and 8,9,15-trihydroxypentadecylurethan II, respectively. These compounds were identical with those obtained previously by Nagel[9,10] from aleurityl azide except that the urethan was more highly purified.

Hydrolysis of the isocyanate IV with hot aqueous alkali produced 8,9,15-trihydroxypentadecylamine V which was obtained as minute colorless crystals melting at 146–147°. This product was soluble in aqueous solutions of mineral acids and gave the characteristic qualitative tests for primary aliphatic amines.[11] The picrate of the amine was a yellow powder melting at 118–119°.

Experimental Part
