Aleuritic Acid.—A suspension of 100 g. of crude zinc salt in a liter of hot (90°) 20% sulfuric acid was stirred mechanically for thirty minutes, filtered and cooled quickly with ice cubes and the precipitated acid removed by filtration. This was dissolved in ethanol, decolorized with Norit, repeated if necessary, precipitated with water, recrystallized from hot water and dried at 41°; m. p. 101–101.5°. *Anal.* Calcd. for $C_{16}H_{32}O_5$: C, 63.15; H, 10.53. Found: C, 63.09, 63.27; H, 10.98, 10.79.

Methyl Aleuritate.—A solution of 10 g. of aleuritic acid in 80 ml. of 5% hydrogen chloride in absolute methanol, was allowed to stand for three days, then was neutralized with a solution of sodium hydroxide in absolute methanol, the precipitated sodium chloride filtered off and the filtrate poured into a large excess of cold (10°) water. The solid was filtered, washed with 10% aqueous sodium carbonate, stirred for thirty minutes, filtered, the precipitate washed with water, dried on a porous plate, and recrystallized from alcohol, yield 86.5%; m. p. 73°. *Anal.* Calcd. for $C_{17}H_{34}O_5$: C, 64.15; H, 10.69. Found: C, 63.99, 64.07; H, 10.81, 10.90.

Aleurityl Hydrazide.—A solution of 10 g. of highly purified methyl aleuritate in 100 ml. of 30% hydrazine hydrate in methanol was refluxed for forty minutes on a water-bath and then filtered through fluted paper, while still hot, to remove any insoluble impurities. The solution, in cooling, deposited crystals of the hydrazide, which were removed by means of a Büchner funnel with the aid of partial vacuum. The filtrate was then concentrated under reduced pressure so as to yield more crude aleurityl hydrazide, which was recrystallized thrice from hot (90°) water, yield 98%; m. p. 139–139.5°. *Anal.* Calcd. for

$C_{16}H_{34}O_4N_2$: C, 60.38; H, 10.69; N, 8.81. Found: C, 60.16, 60.40; H, 10.95, 10.61; N, 8.81, 8.88.

Aleurityl Azide.—A solution of 3 g. of pure aleurityl hydrazide in 600 ml. of hot (90°) water was carefully and slowly cooled to below 5° to produce supercooling. Despite the low solubility of the hydrazide in water, no precipitate formed under these conditions.

51 ml. of an aqueous solution (2%) of sodium nitrite at 0° was cautiously added with gentle stirring, before acidification of the system with 12 ml. of an iced (0°) 25% solution of acetic acid. On stirring, the white flocculent azide separated spontaneously.

The azide was filtered with the aid of gentle suction, washed with water and, finally, dried in an evacuated vacuum desiccator containing solid sodium hydroxide which was maintained at 10°, by placing in a refrigerator, yield 90%; decomp. 52°. The azide was soluble in chloroform and ethyl alcohol, partially soluble in ether and benzene, and completely insoluble in water and petroleum ether. It reacted rapidly with hot water (60°) evolving nitrogen, while a similar decomposition occurred when it was heated on a porcelain spatula. It did not explode when struck sharply with a hammer, on an iron plate.

8,9,15-Trihydroxypentadecyl Isocyanate.—A suspension of 3 g. of the azide in 150 ml. of anhydrous benzene was heated slowly under a reflux condenser for one hour. When decomposition of the azide had been completed and a clear solution remained, the insolubles were removed by filtration and the solution allowed to come to room temperature in a desiccator. Sufficient anhydrous petroleum ether (b. p. 28–38°) was added to the cold filtrate to precipitate the isocyanate completely. The coagulated precipitate was filtered, washed, dried on an unglazed plate and recrystallized from anhydrous dioxane, yield 92%; m. p. 103.5–104.5°. *Anal.* Calcd. for $C_{16}H_{31}O_4N$: C, 63.78; H, 10.29; N, 4.65. Found: C, 63.65, 63.91; H, 10.37, 10.59; N, 4.30, 4.42. The pure isocyanate was soluble in alcohol and dioxane, but insoluble in ether, petroleum ether, and water.

N,N'-Bis-8,9,15-trihydroxypentadecyl Urea. Method I.—A suspension of 3 g. of pure aleurityl azide in 200 ml. of water was refluxed for three hours over a small flame. When cool, the urea was filtered from the solution, dried on an unglazed plate and recrystallized from ethyl alcohol; m. p. 122.5–123°. *Anal.* Calcd. for $C_{31}H_{64}O_7N_2$: C, 64.58; H, 11.11; N, 4.86. Found: C, 64.50, 64.38; H, 11.27, 11.19; N, 4.73, 4.79. **Method II.**—A suspension of 0.2 g. of pure 8,9,15-trihydroxypentadecylisocyanate in 100 ml. of water was refluxed, at 100° for three hours. The system was cooled, the precipitate filtered, dried on an unglazed plate and recrystallized from ethyl alcohol; m. p. 122.5–123°.

Mixtures of various proportions of this product with that obtained by Method I, showed no lowering of the melting point. It was only slightly soluble in cold ethyl alcohol, but dissolved easily at temperatures approaching the boiling point.

8,9,15-Trihydroxypentadecyurethane. Method I.—A solution of 3 g. of pure aleurityl azide in 60 ml. of absolute ethyl alcohol was refluxed for one hour on a water-bath. The resulting solution, when cold, was filtered, added to an excess of anhydrous diethyl ether and the solid filtered, dried and recrystallized thrice from hot anhydrous ethyl acetate; m. p. 78–79°. *Anal.* Calcd. for $C_{18}H_{37}O_5N$: C, 62.25; H, 10.66; N, 5.03. Found: C, 62.37, 62.39; H, 10.89, 10.79; N, 5.03, 5.06. The pure product melted sharply at 78–79°, while slightly contaminated products melted at 73–74°, as reported by Nagel.[9,10] **Method II.**—. 0.2 g. of the pure isocyanate was suspended in 100 ml. of water, and refluxed at 100° for three hours. The solution was then allowed to cool to room temperature, filtered and the crude urethan thus obtained was purified as above. Fractional crystallization from ethyl acetate yielded a product melting at 78–79°, which showed no lowering in melting point when mixed with different proportions of the urethan prepared from the azide.

8,9,15-Trihydroxypentadecyl Amine.—A suspension of one gram of the pure isocyanate in 100 ml. of a 50% aqueous sodium hydroxide solution was refluxed for four hours on a hot plate. The solution was then cooled to room temperature and filtered through a sintered glass funnel. The residue was washed free of all adhering alkali with water, dried on an unglazed plate and fractionally crystallized from hot ethyl alcohol, yield 65%; m. p. 146–147°. *Anal.* Calcd. for $C_{15}H_{33}O_3N$: C, 65.45; H, 12.00; N, 5.09. Found: C, 65.39, 65.20; H, 11.66, 11.68; N, 5.29, 5.21. The purified product was completely soluble in hydrochloric acid and ethyl alcohol, but was insoluble in ether, petroleum ether, ethyl acetate and water.

Picrate of 8,9,15-Trihydroxypentadecyl Amine.—A solution of 1 g. of the purified amine dissolved in a 10% alcoholic solution of picric acid was evaporated to dryness on a water-bath. The solid product was extracted with hot benzene until a test portion of the extract showed the absence of even traces of the acid. The picrate was then thrice crystallized from ethyl alcohol and the purified product found to melt with decomposition at 118–119°. *Anal.* Calcd. for $C_{21}H_{36}O_{10}N_4$: C, 50.00; H, 7.14; N, 11.11. Found: C, 49.74, 49.83; H, 7.32, 7.39; N, 10.98, 10.89.

Summary

1. This investigation has demonstrated that it is possible to prepare a polyhydroxyamine from a polyhydroxycarboxylic acid by means of the Naegeli–Curtius series of reactions. The method has many possibilities of use in the further study of the chemical structure of shellac acids.

2. 8,9,15-Trihydroxypentadecyl isocyanate and 8,9,15-trihydroxypentadecylamine were prepared for the first time. These compounds are colorless solids which melt at 103.5–104.5° and 146–147°, respectively.

3. The isocyanate reacts with water to produce N,N'-bis-8,9,15-trihydroxypentadecylurea, and with alcohol, 8,9,15-trihydroxypentadecylurethan. Both of these compounds were identical with those obtained by Nagel who prepared them from the azide. The pure urethan has a melting point of 78–79° instead of 73–74° as previously reported.

4. Aleurityl azide is relatively stable at room

temperature when obtained pure. It decomposes at 52° as compared with the crude product which explodes if heated rapidly to 50°. The pure azide does not readily detonate when attacked with a hammer.

A Method for Standardization of Chromatographic Analysis[1]

BY ARTHUR L. LEROSEN

The chromatographic method of Tswett has been applied to many problems of the chemist with great success, making possible separations which could not be attained satisfactorily by any other means. As the use of this method increases it is desirable to obtain quantitative data for the comparison of adsorbents and the behavior of the adsorbed substances on these materials. A quantitive treatment of chromatography should be helpful in determining the best conditions for a given operation and in standardizing the properties of adsorbents.

Good books on chromatography are now available (Zechmeister,[2] Strain[3]). Theories of chromatography have been developed by Wilson[4] and by Martin and Synge,[5] and measurements of a quantitative nature have been made by Cassidy.[6,7] Brockmann and Schodder[8] have suggested a method of standardizing the adsorption affinity of certain alumina samples, using azo dye mixtures.

The investigations herein recorded were undertaken primarily with the purpose of ascertaining how far it is possible to determine the relative position of carotenoids on the adsorbent column by separate measurements of the rate of movement for each pigment.

It was first necessary to investigate the flow of the developing solvent through the adsorbent. The velocity of flow was found to vary directly with the pressure difference between the ends of the column, inversely with the length of the column and to be essentially independent of the diameter of the tube (tubes of diameter 17, 43, and 70 mm. gave almost equal rates for columns of the same length). The exact nature of each of these dependencies has not been thoroughly studied.

The change of rate of flow with time was of more importance. Table I illustrates the behavior of calcium hydroxide columns. It is evident that the flow becomes constant after an initial decrease, a uniform rate being obtained soon after the solvent has reached the bottom of the column.

Three terms will now be introduced to simplify the following discussion: S = length of adsorbent column containing one unit volume of solvent/length of tube required to contain the same volume of solvent; V_c = rate of flow of developing solvent through the column when a state of constant flow has been reached (mm./min.); R = rate of movement of adsorbate zone (mm./min.)/rate of flow of developing solvent (V_c).

The ratio S may be of importance in characterizing the packing of the column, and, moreover, it gives the percentage of the tube volume occupied by the adsorbent (% volume adsorbent = $100(S-1)/S$). There is a variation in the degree of packing throughout the column; S was found to vary

TABLE I

RATE OF BENZENE FLOW THROUGH CALCIUM HYDROXIDE COLUMNS (17 MM. IN DIAMETER AND 150 ± 5 MM. LONG).

The data given indicate flow in mm. column length/min. Time was measured from the instant the solvent was poured on the column.[a]

Column no.	Time, min. 1	5	10	15	20	25	30	35	40
1	32.0	14.5	9.0	7.1	6.4	6.3	6.3	...	...
2	43.0	15.5	9.8	7.1	7.0	7.0	7.0	...	...
3	36.0	13.5	7.8	...	7.6	7.5	7.5	7.5	...
4	42.0	15.3	...	...	7.6	7.7	7.7	7.7	7.7
5	43.0	13.8	8.8	...	8.4	8.2	8.2	8.2	8.2
6	42.0	16.0	13.0	...	...	8.1	8.1	8.1	8.1

[a] The solvent reached the bottom of the column in about twelve minutes.

on the average from 1.97 for the top third to 1.79 for the bottom third of the calcium hydroxide columns used. No consistent relation has been observed between S and V_c, probably due to the greater importance of local variations in the column packing.

The rate of solvent flow, V_c, varies from column to column packed with the same adsorbent under similar conditions, but the variation is within reasonable limits; for example, in 14 of 15 cases considered, V_c was between 6.3 and 8.2, while in one instance it was much higher, 10.3.

V_c itself depends on such variables as particle size, shape, surface character, solvent, etc., but it is beyond the scope of this paper to discuss these factors.

The "strength" or adsorption affinity of a material may be best determined by measuring the adsorption isotherm, but this is not always practical, as Brockmann and Schodder have pointed out. The same end can be attained with somewhat less precision by measuring R, the relative rate of movement of an adsorbate zone with respect to the developing solvent. Table II gives the values of R for certain carotenoids. Table III shows the agreement of the relative positions of carotenoid zones, calculated from R, and positions observed when a mixture was separated chromatographically.

There should be a relation between the adsorption isotherm and R. Let us consider the element of volume of any adsorbent column which contains in its interstitial spaces one unit volume of solution of uniform concentration c/unit volume. The adsorbent in equilibrium with this unit volume contains $f(c) = A$ concentration units of the solute. The use of volume here rather than length or weight has an advantage in dealing with rates, because, after the relation is obtained for an adsorbent, it is independent of tube radius. In the case of lycopene, $C_{40}H_{56}$, the relation was approximately linear over the concentration range studied for the system lycopene–benzene–calcium hydroxide; the value $A = 8c$ was found for the calcium hydroxide columns studied.

Eight units of solution would have to pass through an element of column, as defined above, before it reached saturation; therefore, the front edge of the solvent moves through nine elements, while the pigment moves through one. R should, therefore, be equal to 0.111. The value observed for lycopene, 0.125, is in reasonably good agreement.

Martin and Synge,[5] in discussing the theory of a certain type of chromatogram, have used a term, R,[10] for the relative rate of movement of a chromatographic zone. Their definition differs slightly from that proposed above.

Dr. W. T. Stewart has suggested[11] an alternative procedure, namely, the measurement of rates of movement relative to some standard dye, for the determination of the relative positions of chromatographic zones.

From measurements of R certain inversions of the relative positions of pairs of carotenoids on different adsorbents were predicted. The first example was the case of kryptoxanthin–lycopene;

TABLE II

RATES OF MOVEMENT OF CHROMATOGRAPHIC ZONES RELATIVE TO THAT OF THE DEVELOPING SOLVENT, ON CALCIUM HYDROXIDE AND DEVELOPED WITH BENZENE. MEASUREMENTS APPLY TO BOTTOM EDGE OF ZONE

Substance	R	Substance	R
Capsanthin	0.007	Lycopene	0.125
Celaxanthin[a]	.150	Kryptoxanthin	.340
β-Carotenone	.030	Physalien	.590
Zeaxanthin	.040	γ-Carotene	.790

Lycopene	.125	1.00	1.00	1.00

[a] Obtained from the fruits of *Celastrus scandens*. [b] Not separated; rechromatographing on calcium carbonate showed the presence of both pigments in this zone. [c] Two readings were taken at different stages in the development of the chromatogram.

(9) L. Zechmeister, A. L. LeRosen, F. W. Went and L. Pauling, *Proc. Nat. Acad. Sci.*, **27**, 236 (1941).

(10) The use of a somewhat different R in this paper is not only due to a delay in receiving the journal containing the work of Martin and Synge (received May 12, 1942), but also for convenience in measurement.

(11) W. T. Stewart, Thesis, California Institute of Technology, 1941.

kryptoxanthin is adsorbed above lycopene on calcium carbonate or alumina but below it on calcium hydroxide. Several other cases of this type have been observed. This phenomenon has already been noticed, *e. g.* by Duschinsky and Lederer.[12]

It has been found in this Laboratory that measurements of V_c of adsorbents led to the acquirement of better materials than before its use. For ordinary laboratory work a range of from about 5 to 15 mm./min. is desirable; this seems to be associated with an average particle size of 5 to 15 microns. If the adsorption affinity of a material shows much variation, as in the case of alumina, measurements of R for the substances to be separated should allow standardization. The most suitable value for R seems to be between 0.2 and 0.3. The values given for R in the tables are subject to correction as the measurement technique is improved.

Experimental

Determination of V_c.—For all the experimental work, except that concerning the influence of diameter, chromatographic tubes 250 by 17 mm. were used (obtainable from Scientific Glass Apparatus Co., Bloomfield, N. J.). The adsorbent was "Shell" brand lime, chemical hydrate, 325 mesh, obtained from the Braun Chemical Company in Los Angeles.

For the determination, the tubes were filled with the absorbent while suction was applied (about 25 mm. vacuum) and the absorbent slowly poured into the tube, the sides of which were then vigorously tapped in order to allow the absorbent to settle. The top of the column was pressed down firmly with a stamper, and the absorbent was removed from the walls above the column. Three successive 5-cc. portions of solvent were then pipetted onto the top of the column. Just as each portion disappeared into the absorbent the next one was introduced. At the same time, the position of the bottom edge of the solvent was noted. In this manner it was possible to determine the number of mm. column length equivalent to 1 cc. of solution. Next a buret was attached to the top of the absorption tube by a stopper provided with an outlet which could be closed when the air space above the column was filled with solvent. The buret stopcock was then opened, the tube filled with solvent and the outlet closed. It was then possible to determine the velocity of solvent in the column from the flow in cc. per minute shown by the buret.

Determination of R.—The procedure was the same as described above except that the initial portion of solvent (ligroin or ligroin–benzene) contained the carotenoid pigment, while all succeeding portions were pure benzene. The pigment was poured on the column in a solution containing ligroin, from which it is more strongly absorbed than benzene, in order to obtain a concentrated zone. The ligroin is immediately washed through the column by the benzene and, consequently, does not interfere with the determination. The buret reading and carotenoid position on the column were recorded at ten-minute intervals by a stop watch. The values, recorded in Table II, were obtained when V_c was reached.

All measurements were made with fresh solutions of pure crystals since the rates of movement may be profoundly influenced by impurities. It remains to be seen how far, even in very crude solutions, the relative rates remain proportional to those found with pure materials.

Summary

1. Some terms of importance to quantitative chromatography have been suggested; these are S, which indicates the average packing of the column, V_c, the rate of solvent flow when the velocity has become constant, and R, the rate of movement of an absorbate zone relative to that of the developing solvent.

2. Evidence has been given to show that the above mentioned quantities are of value in characterizing and standardizing absorbents, as well as predicting the relative positions of chromatographic zones.

3. Inversion of the sequence of some carotenoid pairs on different absorbents has been predicted and observed.

Effect of Strong Electric Fields on the Radiochemical Decomposition of Gaseous Ammonia[1]

BY MICHAEL J. McGUINNESS, JR.,[2] AND HARRY ESSEX

A paper by Essex and Smith[3] presented the results of ion yields in the alpha ray decomposition of ammonia in electric fields. This work has been continued with measurements at lower pressure and at higher field strength. The effects of these changes on the ion yield are significant as regards the mechanism of the alpha ray decomposition and on the products of the reactions between electrons and ammonia molecules.

The ion yields were determined by the saturation current method, the rate of ion production being determined from the saturation current across the ionized gas and the rate of decomposition of the gas by the increase in pressure of the gases, nitrogen and hydrogen, uncondensed by liquid air. Previous papers from this Laboratory have shown that the saturation current method gives ion yields which, when account is taken of the effect of the difference in intensity of irradiation, agree with the ion yields determined by the more indirect methods of "homogeneous irradiation" and "central irradiation" used by others.

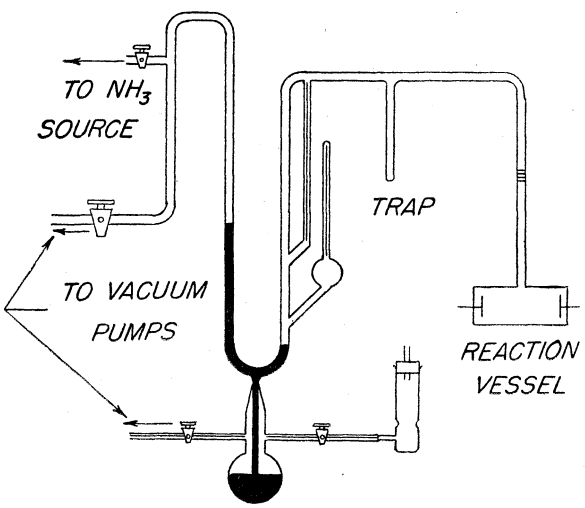

Fig. 1.

Experimental

The apparatus is shown in Fig. 1. The radioactive material, mesothorium, was placed in a small depression in the reaction vessel. The vessel was fitted with platinum electrodes as shown. Ammonia, guaranteed by the manufacturers to be not less than 99.95% NH_3, was dispensed from a solution in ammonium thiocyanate, dried over metallic sodium and purified by repeated condensation in the indicated trap at liquid-air temperature, followed each time by evacuation of uncondensed gases. The ammonia gas at about 20 cm. was finally enclosed by the mercury seal. The reaction vessel was surrounded by an air-bath maintained at $24.7 \pm 0.2°$.

Circular thin copper shields were cemented to the outside of each end of the reaction vessel with a nitrocellulose cement containing silver filings to improve electrical contact. The shield at the low potential end was electrically insulated from the lead to the electrode. Currents to electrode and shield were measured separately. At the highest potentials the current to the shield was about 2% of that to the plate and was included in the ion current since preliminary experiments showed the conductivity through and over this glass to be negligible. The shields prevented sparking between glass and electrode edges.

During a run the field strength was kept constant except that at intervals of about twenty-four hours the saturation current was measured and the residual pressure ($N_2 + 3H_2$) determined with the McLeod gage after freezing out ammonia in the trap. At the end of a run the ammonia was frozen out, the system evacuated, the mercury seal closed and a new run started at another field strength. In many of the runs the field strengths were far higher than necessary for saturation.

The results are presented in Table I and the ion yields (M/N) are plotted *vs.* field strength in Fig. 2. The experi-

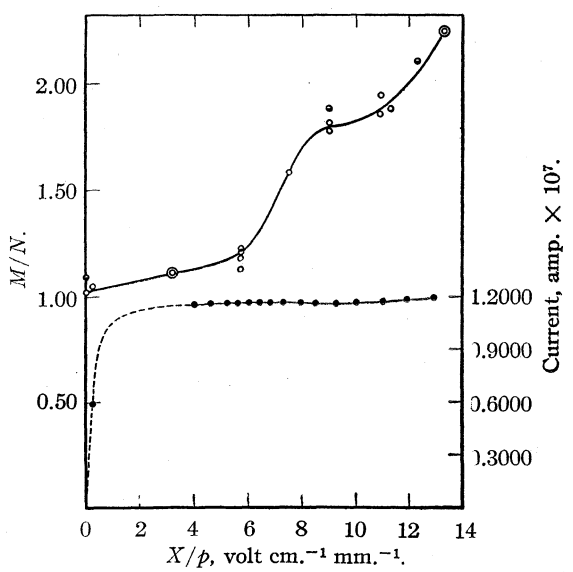

Fig. 2.—Comparison of ion yield with plate current: O, ion yield; ◒, short run; ●, plate current.

mental errors are naturally greater in the shorter runs. Figure 2 also shows a typical current *vs.* field strength curve. The ion yields reported here were obtained at intensities of ionization similar to those in the experiments carried out in this Laboratory[3] on ammonia at pressures in the neighborhood of one atmosphere. The nature of the method, depending upon saturation current measurements, precludes the use of higher intensities of irradiation where saturation is obtainable only at extremely high voltages, if at all. The ion yield 1.03 (weighted) obtained in the absence of a field at 20 cm. may be compared with the value 1.37 previously obtained[3] at 62 cm. and 30°. Luyckx[4] also observed a decrease in ion yield with decrease in pressure in the alpha ray decomposition of ammonia. He found that the effect was greater the lower the intensity of irradiation. Since the lowest intensity of irradiation he used was greater than that employed in these experiments, quantitative comparison is not possible.

(4) Luyckx, *Bull. soc. chim. belg.*, **43**, 117 (1934).

Discussion

Effect of Pressure.—It frequently has been assumed that alpha ray induced decompositions are entirely the result of recombination of ions. By measuring the ion yield at constant pressure and temperature as a function of field strength, it is possible to calculate the fraction of the decomposition which in the absence of a field is consequent on recombination of ions and the fraction of the decomposition due to other mechanisms. At field strengths sufficient for saturation, recombination cannot occur. But practical saturation is obtained only at such high fields that, as our previous work has shown, decomposition by a new mechanism, probably by electron collisions, has begun. However, half saturation is obtained

at field strengths only a small fraction, often about one-tenth of those necessary for saturation and the ion yield due to ion recombination should be twice the difference between the ion yield in no field and at half saturation. The ion yield due to other mechanisms is obtained by difference.

In this way Essex and Smith[3] calculated in the decomposition of ammonia at 30° and 62 cm. that 30% of the decomposition is consequent on ion recombination. But the data here presented show that at 24.7° and 20 cm. pressure and under very similar conditions as regards vessel size and intensity of irradiation, the ion yield at no field is 1.03 and at half saturation 1.05. These yields are identical within the experimental error and show that at this lower pressure, none of the alpha ray decomposition is consequent on ion recombination, *i. e.*, that the decomposition is entirely due to other mechanisms. It seems probable that at the lower pressure all of the ions reach the walls by diffusion and are there discharged. The only effect of low fields is to change the location of ion discharge from the walls to the electrodes. Assuming that recombination takes place entirely in alpha ray tracks which extend completely across the vessel at all pressures and that the diameter of the track and the rate of diffusion of ions show the pressure dependence to be expected, it is easily shown that the fraction of the ions recombining in the gas is proportional to the $^5/_2$ power of the pressure. Comparing the fraction of the ions which combine at 20 cm. and 62 cm. pressure

$$\frac{\text{fraction combining at 20 cm.}}{\text{fraction combining at 62 cm.}} = \frac{20^{5/2}}{62^{5/2}} = \frac{1}{17}$$

which makes plausible the implications of these experiments that at 20 cm. in a vessel of this shape and size, most of the ions are neutralized at the walls.

At 30° and 62 cm. pressure the total ion yield in the absence of a field was 1.37, the ion yield due to recombination of ions 0.40 and that due to other mechanisms 0.97. Comparing the latter figure with 1.03 it is seen that pressure has little or no effect on that portion of the reaction due to mechanisms other than ion combination.

Effect of Electric Field.—The first effect of increasing the field strength across ionized ammonia is to remove ions before they recombine, which often results in decomposition, or reach the walls by diffusion. The increase in ion yield at higher field strength is due to collisions of electrons with ammonia molecules as, at the pressures of these experiments, the energy of molecular ions is increased by the field but slightly above the thermal energy of the molecules. The ion yield curve (Fig. 2) is therefore an electron yield curve but with the electron yield scale undetermined since the ratio of electrons to molecular negative ions is unknown. High energy electrons are known to split the ammonia molecule with attachment of the electron to one or the other fragment.

Bradbury[5] passed electrons through ammonia at pressures from 3 to 97 mm. Negative molecular ions appeared at $X/p = 7.5$ at which value he estimated the average energy of the electrons to be 4 volts. A gas uncondensable by liquid air was formed upon the appearance of negative ions. Four volts is approximately the energy of dissociation of NH_3 either to NH_2 and H or NH and H_2. Bradbury postulated one or the other of the reactions

$$NH_3 \longrightarrow NH_2^- + H$$
$$NH_3 \longrightarrow NH^- + H_2$$

Mann, Hustrulid and Tate[6] analyzed with the mass spectrograph the ions formed in ammonia at very low pressures by electrons of controlled energies. The only negative ions found were NH_2^- and H^-. The onset of formation of both ions occurred at electron energies very close to the excitation potential, 6 e. v. The disagreement between Bradbury and Tate as to the minimum energy necessary for electron attachment (4 and 6 e. v., respectively) may be inherent in their methods of attack. Bradbury's method was excellent for detecting ions at small probability of formation due to the fact that he was using much higher pressures than are possible in mass spectrometric methods. His calculations provided the average energy of the electrons, but, regarding the actual energies of the individual electrons, little information is available since the distribution function has not been satisfactorily determined. Therefore, as Bradbury has stated,[7] his results do not show convincingly that electrons of energies less than 6 e. v. do become attached. Tate and his co-workers,[6] on the other hand, were operating at such low pressures that although the energy of the electrons could be known accurately, attachment would not be detectable if the probability of attachment were small.

The ion yield curve (Fig. 2) exhibits two poten-

(5) Bradbury, *J. Chem. Phys.*, **2**, 827 (1934).
(6) Mann, Hustrulid and Tate, *Phys. Rev.*, **58**, 340 (1940).

tial ranges in which the rise in ion yield is rapid, the first of which is followed by a potential range in which the ion yield increases more gradually. It seems plausible to assume that non-resonant splitting and resonant splitting occur successively with increasing field, *e. g.*

$$(1)\quad NH_3 + e \begin{cases} \nearrow NH_2^- + H \\ \searrow NH_2 + H + e \end{cases}$$

and

$$(2)\quad NH_3 + e \longrightarrow NH_3^* + e \begin{cases} \nearrow NH_2^- + H \\ \searrow NH_2 + H + e \end{cases}$$

in which are included the possibility of failure of a molecular fragment to capture the electron. After an electron is captured by either mechanism, no further decomposition is possible by the ion (thereafter molecular) in its progress toward the electrode, which may explain the nearly horizontal portion of the curve. That the first increase in ion yield occurs at a value of X/p less than that ($X/p = 7.5$) at which Bradbury first observed negative ions is probably due to the fact that in these experiments no special precautions were taken to maintain the field uniform. Under such conditions as obtained in these experiments the field strength is considerably above the average in the neighborhood of the electrodes, especially at the cathode and at low potentials.

That considerable splitting of ammonia molecules without electron attachment occurs is apparent from the magnitude of the increase in ion yield with increase in field strength, from 1.03 to 2.24. Splitting with attachment could only result in an increase in ion yield of 1 unit if all negative ions were initially electrons and if no ammonia resulted from the recombination of the fragments. The work of Melville and Birse[8] indicates that only 43% of ammonia molecules which are split into NH_2 and H finally result in nitrogen and hydrogen. It would therefore appear that in the collisions of electrons with ammonia molecules approximately 2 molecules are split without attachment for each split with attachment; more than 2 in so far as negative molecular ions are produced by the action of the alpha rays, less than 2 to the extent that resonance splitting occurs by the second Tate mechanism

$$NH_3 + e \longrightarrow NH_3^* + e \longrightarrow N + H_2 + H^-$$

That no positive ions are produced by accelerated electrons in our experiments is evidenced by the appearance of the current–field strength curve which remains flat above the saturation voltage. Maximum energy of the electrons is therefore less than 10.5 e. v., the ionization potential of ammonia.

The reactions occurring in a field are also operative in the ordinary radiochemical decomposition (in the absence of a field) where energetic electrons are also present. The direct splitting reaction postulated by Bradbury would account for little of the decomposition since Mann, Hustrulid and Tate have shown it to be an improbable one. That portion of the reaction not consequent on recombination of ions probably results, largely, from resonance splitting (*e. g.* (2)).

Acknowledgment.—The liquid air used in this investigation was provided by the General Electric Company of Schenectady, New York, through the courtesy of Dr. L. M. Willey, to whom the authors wish to express their gratitude.

Summary

Ion yields in the alpha ray decomposition of gaseous ammonia at 25° and a pressure of 20 cm. have been determined over a wide range of field strengths. In the absence of a field none of the reaction is consequent on ion recombination under these experimental conditions. The increase in ion yield at high field strengths has been attributed to electron collisions. The electron collisions have been assumed to result in direct and resonance splitting of the ammonia molecule. The splitting of an ammonia molecule on collision with an electron does not involve electron attachment in the majority of such collisions.

The Viscosity of *cis* and *trans* Decahydronaphthalene

BY WM. F. SEYER AND JOHN D. LESLIE[1]

Considerable work has been done in these Laboratories during the last few years on the properties of the cyclic and dicyclic naphthene hydrocarbons. The present paper deals with viscosity measurements on the *cis*- and *trans*-forms of decahydronaphthalene over a range of temperature from −30 to 180°.

Experimental Procedure

The materials used for this work had been specially purified. The *cis*-isomer after eight recrystallizations had a freezing point of −43.25°. In the case of the *trans*-compound the freezing point, −31.16°, obtained after twenty recrystallizations, was slightly higher than had previously been recorded, *viz.*, −31.47°.

The viscometers available were modifications of the Ostwald type. They were made in accordance with British Standards Specification No. 188–1937, and were specially designed to reduce deviations from Poiseuille's law to a minimum. For a given viscometer and constant volume of liquid where no external pressure is used the equation

$$\eta = \frac{\pi g H r^4 t}{8V(l+\lambda)} - \frac{mV\rho}{8\pi(l+\lambda)t}$$

is recommended by various authorities.[2] Here the symbols have the following meaning

- η = viscosity in absolute units
- r = radius of tube
- l = length of tube
- H = average acting hydrostatic head
- V = volume of fluid
- λ = a fictitious amount added to length of tube to correct for the extremities
- m = a constant which is here taken as 1.12
- ρ = density of fluid
- t = time of efflux

Where the tube is to be calibrated with liquids of known viscosity the above equation can be expressed in the simple form $\eta = C\rho t - c\rho/t$. The constants C and c can then be determined by experiment. It can be shown from the above equation that the second term is less than 2.5% of the first provided the efflux time is greater than one-hundred seconds. Hence it is clear that the kinetic energy correction can be kept small by selecting a viscometer which will give a sufficiently long efflux time.

Loading errors did not arise in this work since the same liquid was used throughout each series of measurements. Furthermore the liquid levels were kept constant at all temperatures, thus ensuring that the mean liquid head remained constant over the entire range. Again, the dimensions of the viscometer were such as to make errors due to drainage and surface tension differences negligible. Another possible source of error lies in the fact that the viscometer may not always be vertical. The error is proportional to $(1 - \cos\theta)$, where θ is the angular deviation from the vertical, and hence is about 0.1% for $\theta = 2.5°$. Such a deviation was easily detected by means of a small plum-bob.

A very important question is whether or not the constants of the instrument remain truly constant throughout the series of experiments. One possible effect is that of temperature. Although, as stated above, special pains were taken to ensure that the same apparent efflux volume, V, was used at all temperatures, there might still have been an error caused by expansion of the glass. Taking the mean coefficient of expansion of glass as 0.1×10^{-4}, and considering a range of 200°, we can show readily that C will increase by 0.2%, and c by 0.4%. The latter error will obviously have a negligible effect on the final results. Since the calibration covered the range from 20 to 100° the constants are probably correct near 60°, and hence the maximum error due to a variation in C would not likely exceed 0.1%. Some workers think that the constants may also vary because of continuous changes in the capillary bore owing to solvent action of the liquids and cleaning solutions used. In the present work it was considered very unlikely that the decalin would act on the glass, and care was taken not to leave strong cleaning solutions in the viscometer over long periods of time.

The viscometer was cleaned with concentrated dichromate solution, water, alcohol and ether in turn. Before each series of measurements the instrument was rinsed and left in contact with the test liquid for several hours.

The constant temperature bath consisted of a cylindrical Pyrex jar of about 11-liters capacity (45 cm. deep and 20

(2) E. C. Bingham, "Plasticity and Fluidity," McGraw-Hill Book Co., Inc., New York, N. Y., 1922.

cm. in diameter). It was lagged with asbestos and cotton batting, and was filled with a medium, clear petrolatum oil, which was circulated by a triple propeller. Some trouble resulted at high temperatures from the oil charring and becoming opaque; a lubricating oil, Marvelube 40, was tried but was found to be even less satisfactory. The bath was heated electrically by two Cenco immersion knives and a small nichrome coil (1 inch in diameter), the latter being hooked up to a precision thermo-regulator. A switchboard with suitable resistances enabled any temperature between 20 and 180° to be obtained. For the measurements below room temperature a double-walled, evacuated, Pyrex flask (25 cm. deep by 7 cm. in diameter) was found convenient. Acetone served as a bath liquid and the temperature was lowered and kept constant by dropping in small pieces of dry-ice. Except at the extremes, the temperature could be kept constant within ±0.02°, and even at the highest and lowest temperatures the variation was less than ±0.05°.

The temperature was measured with a Leeds and Northrup platinum resistance thermometer, No. 169,314, which had recently been checked by the Bureau of Standards in Washington and whose ice point had been determined several times in this Laboratory. Temperatures were calculated by means of Callendar's equations.

A Meylan stop watch, reading to 0.2 second, served as timing device. Checking against several reliable timepieces indicated a loss of 0.02 sec. per min., and while this is well within the limit of error required by Bingham,[2] a suitable correction was applied to all readings. Since the viscometer was designed for an efflux time of not less than one hundred seconds, and since the final results were always averages of from five to fifteen readings, the mean error in the stop watch reading was probably less than 0.1%. Care was taken always to run the stopwatch in a horizontal position.

Calibration.—To cover the viscosity range of the decalin isomers and to keep the efflux times greater than one hundred seconds, it was necessary to choose an uncalibrated viscometer. The instrument was calibrated by measuring the efflux times of pure water at several temperatures and from the resulting equations the constants of the viscometer were calculated by the method of least squares. The absolute viscosities of water were taken from the data of Bingham and Jackson[3] and the relative densities from the Smithsonian Tables. The calibration was later checked with a sample of oil, of which the kinematic viscosity had been accurately determined at 20, 40, and 100°, from the Bureau of Standards. The constants were redetermined, using the two sets of data together, and the final equation was

$$\nu = \eta/\rho = 0.004043t - 1.52/t$$

For the measurements below 0° another viscometer of larger bore was calibrated to avoid excessively long efflux times. *cis*-Decalin was used this time, as values for its viscosity above 0° were already known. The resulting equation for this instrument was

$$\nu = \eta/\rho = 0.05737t - 1.16/t$$

The final standard for all these measurements is the absolute viscosity of water (η = 1.005 at 20.00°), and this, according to Cannon and Fenske,[4] may be in error by ± 0.5%. Relative to this value, however, we believe our measurements to be correct within ± 0.3 %, except perhaps at the lower extreme of temperature where the error may be ± 0.5%.

Procedure.—The kinematic viscosities of first the *cis*- and then the *trans*-isomer were measured at 10° intervals between −30 and 180°, and from these data and the densities as given by Seyer and Davenport,[5] the absolute viscosities were calculated as explained above. Each temperature was maintained for at least two or three hours and in some cases from twelve to twenty-four hours. In all cases the averages of numerous readings were taken. At one time it was thought that the vibration from the stirring apparatus might affect the results, and a few runs were made with the motor turned off to see if any difference could be detected. No difference was found.

Then, for reasons given below, the measurements on *cis*-decalin were repeated between 110 and 180°. With both the *cis*- and the *trans*-decalin the measurements were repeated at intervals coming down the scale of temperature after the upper limit had been reached. In all cases these latter gave slightly higher results. The cause of this phenomenon has not yet been determined.

Discussion of Results

The curves obtained (Fig. 1) when log η is plotted against $1/T$ are not linear, but they are quite smooth and there appears to be no evidence to support the claims of discontinuities in various temperature ranges as suggested by Seyer and Davenport in the proceedings of the Petroleum Division of the A. C. S. (Boston Meeting, 1939). In the case of the *cis*-isomer, however, a considerable deviation begins to show itself at 110°. This deviation increased as the temperature went higher, and, furthermore, the longer the hydrocarbon was kept at any one temperature in this interval the greater its viscosity became. This is similiar to the results stated by the above authors who found an increase not only in the viscosity but also in the density, and surface tension. Additional measurements on these latter properties suggested an irreversible change in the *cis*-isomer possibly due to some chemical reaction or to the formation of a structural isomer. No definite

170.00	.479	.375
180.00	.439	.350

evidence of oxidation or of the formation of unsaturated compounds could be found. The surface tension measurements mentioned above, and more recently measurements on the specific heats and refractive indices indicate further irregularity in the behavior of the *cis*-isomer in the region 50–52° but, as can be seen, this is not supported by the present work.

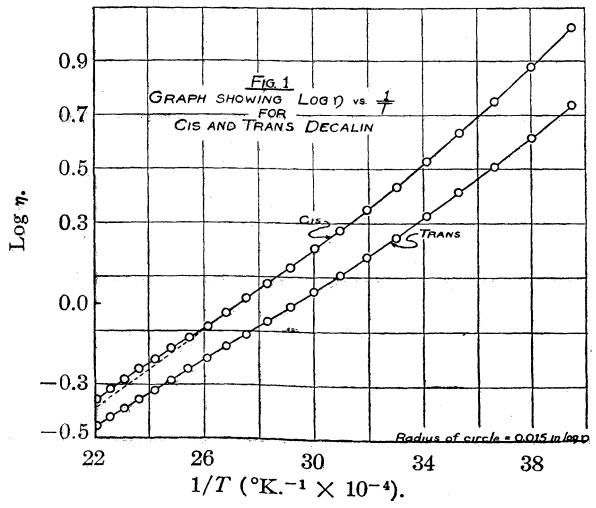

Fig. 1.

Many equations other than the simple exponential law, $\eta = Be^{A/T}$, have been proposed to express the temperature variation of viscosity, and several of these, including Batschinski's[6] relationship $\eta = B/(v-c)$ where v is the specific volume and B and c are constants, were tried on the present data. The results were, in general, the same, none gave linear curves and all indicated the abnormality discussed above.

The curves are sufficiently straight for their slopes to be of possible significance. If the assumed equation is $\eta = Be^{E_{vis}/RT}$, then the slopes, m, of our curves are given by $m = \frac{E_{vis}}{R} = \frac{\ln(\eta_2/\eta_1)}{1/T_2 - 1/T_1}$, where E_{vis} is the average molar activation energy for viscous flow. E_{vis} is given in the table below for the decalin isomers and also for a few other hydrocarbons of comparable size or structure. The data for these latter were taken from the work of E. B. Evans,[7] and from a compilation of physical data by The Texas Co.[8]

Hydrocarbon		η_0°(cp)	η_{100}°(cp)	m	E_{vis}, cal./mole
n-Hexane	C_6H_{14}	0.398	0.167	880	1750
n-Decane	$C_{10}H_{22}$	1.298	.357	1315	2615
Cyclohexane	C_6H_{12}	1.455	.572 (50°)	1650	3285
trans-Decalin	$C_{10}H_{18}$	3.233	.692	1570	3125
cis-Decalin	$C_{10}H_{18}$	5.620	.920	1845	3670
Cyclodecane	$C_{10}H_{20}$	4.48 (20°)	1.76 (60°)	2280	4535

It is apparent that for a given number of carbon atoms, cyclization increases both the viscosity and the activation energy. It is interesting, to note that although *trans*-decalin has a higher viscosity than cyclohexane E_{vis} is about the same for both, and again that although the single ringed compound, cyclodecane, has a higher viscosity than either *cis*- or *trans*-decalin at low temperatures, its E_{vis} is also much greater, which means that at more elevated temperatures the viscosity curves will cross. The same argument applies to the two decalin isomers themselves, and a rough calculation shows that if no structural changes took place the two would have the same viscosity at about 300°.

So far we have assumed that $dE_{vis}/dT = 0$. The curves show that this condition definitely does not hold for the decalin isomers, and this fact suggests the possibility that from the standpoint of viscosity they may be regarded as abnormal liquids. In a general discussion on liquids held by the Faraday Society,[9] A. G. Ward classifies the various types of liquids and then attempts to explain departures from the simple exponential equation for viscosity in terms of structure and forces. He states that E_{vis} will vary with the tem-

perature if the coördination of the molecules changes and further that a negative dE_{vis}/dT, as in the case of both *cis*- and *trans*-decalin, indicates increasing coördination, and hence directional forces. The same author goes on to say that high values of E_{vis} and of the viscosity at the freezing point characterize ionic liquids and those containing polar groups. In the latter he claims the high values indicate a possible bond rupture.

Eyring and his co-workers[10] show, also, that the above characteristics in a liquid may indicate association, by supposing that at the lower temperatures an extra "structure activation energy" is necessary to break the association bonds before the activated state for flow can be brought about. It should be pointed out[11] that even the simplest liquid must show a slightly decreasing activation energy with increasing temperature, if a sufficiently accurate analysis is made. This is because a liquid becomes more gas-like with increasing temperature and new equilibrium positions for the molecules to flow into become more plentiful. It can be shown, however, that this normal change in the activation energy, E_{vis}, is sufficiently small to make the simple exponential law quite accurate for most liquids. We may therefore conclude that the variations in E_{vis} for the decalin isomers indicate abnormality in structure.

Since decalin is a saturated dicyclic hydrocarbon we would not expect it to be markedly dipolar, and it certainly does not fall into the latter classes discussed by Ward. Hence, the present authors suggest that in such liquids as decalin there may be not single molecules, but molecular aggregates or macromolecules, these being naturally more plentiful at low temperatures, with a gradually increasing degree of dissociation as the temperature rises.

The differences between the viscosities and the activation energies of the decalin isomers themselves are not easy to explain because little is definitely known about the space configurations of these two compounds. A little enlightenment is to be had, however, from an examination of the data for several other naphthenic hydrocarbons which show *cis–trans* isomerism. These data are from the Texas Co. publication mentioned above, and are given in the following table along with the corresponding data for the decalin isomers.

In each compound the *cis*-isomer has a higher boiling point, a higher specific gravity, a higher viscosity and a higher E_{vis} than the *trans*. This would suggest that the differences in these properties are characteristic of the *cis–trans* isomerism itself and do not depend upon the number, sizes or complexity of the rings. The values are much higher for the decalin isomers but the ratio of the E_{vis} for the two isomers is about the same for all the hydrocarbons shown. In view of the discussion above a possible interpretation of these results is that directional forces are more pronounced in the *cis*-isomer and hence that there is closer packing of the molecules and a greater proportion of "macromolecules."

Eyring, *et al.*,[10] have developed a number of relationships between E_{vis}, $\Delta F^{\ddagger}$ and $\Delta E_{vap.}$ where $\Delta F^{\ddagger}$ is the molar free energy of activation for viscous flow and $\Delta E_{vap.}$ the molar energy of activation for evaporation. Lack of reliable vapor pressure data for decalin prevents us from making use of these relationships at the present time, but we hope to do so in a future paper.

Summary

1. The viscosities of *cis*- and *trans*-decahydro-

The Electromagnetic Mechanism of the Beta Phosphorescence of Fluorescein in Acid Solution

BY S. I. WEISSMAN[1] AND DAVID LIPKIN

Introduction

The peculiar nature of the beta phosphorescence of fluorescein in acid solution, investigated recently by Lewis, Lipkin and Magel,[2] suggested to us the desirability of studying the mechanism of this emission process. The peculiarities made themselves evident in several ways. Firstly, the luminescence is of unusually long duration. Secondly, no absorption band corresponding to a transition from the normal to the phosphorescent state has been found.[3] Thirdly, although the fluorescein molecules in the phosphorescent state have been found to be oriented when excited to that state by polarized light, the beta phosphorescence from such molecules is but little polarized.[2]

It is possible to describe the radiation processes from a source which is small compared with the wave length of the emitted waves in terms of the electric and magnetic multipole moments of the source. In the case of most of the familiar sources the only significant contribution to the radiation arises from an oscillating electric dipole. Indeed, most of the selection rules used in interpreting atomic and molecular spectra are not applicable in the case of transitions other than those involving electric dipoles. Thus, many spectral lines have been observed which appear to arise from processes which are forbidden by these selection rules. Two explanations may be advanced for the occurrence of these processes. In the first place, as we have just indicated, these seeming violations may occur because a given transition involves a multipole other than an electric dipole. Secondly, they may occur because of the invalidation of the rules by external perturbations of the emitting system. The $^2S_{1/2}$–$^2D_{3/2,\,5/2}$ doublet of potassium studied by Segrè and Bakker,[4] the $^1S_0$–$^3P_2$ and $^1D_2$–$^3P_0$ transitions of lead studied by Jenkins and Mrozowski,[5] and the $^1S_0$–$^1D_2$ transition of oxygen studied by Frerichs and Campbell[6] may be cited as examples of breakdowns of the first type. On the other hand, the 6^3P_2–7^3P_2 transition of mercury,[7] which is induced by external electric fields, may be cited as an example of a breakdown of the second type.

In the case of the transitions just mentioned, the investigators were able to determine the nature of the emission mechanism (magnetic dipole, electric dipole and electric quadrupole) by a study of the Zeeman effect. Obviously, this method cannot be used to study broad spectral bands such as those of large organic molecules. In this case it becomes necessary to use the wide-angle interference method of Selényi.[8] This method, the interpretation of which depends on characteristic differences in directional distribution of radiation about the various elementary multipoles,[9] involves the study of the coherence properties of rays issuing in widely diverging directions from small sources.

Experimental

In order to obtain interference between two beams of light issuing at a wide angle from a source, it must be of such dimensions that the interference patterns from different parts of the source do not obliterate each other. The most critical requirement as to the size of the source is that one dimension be not more than about one-twentieth of the wave length of the light. The other dimensions may be much larger and are determined by various optical characteristics of the interference apparatus. Selényi[8] has devised a simple experimental set-up which admirably fulfills the above requirements. We have used essentially

his set-up, but have adapted it so that the emitting source could be examined at liquid air temperatures.

A saturated solution of fluorescein in a phosphoric acid approximating metaphosphoric acid in composition was found satisfactory for preparing the small source necessary for the wide-angle interference study.[10] This source was obtained by placing a droplet (*ca.* 10^{-4} ml.) of the solution on the hypotenuse of a right angle prism and covering with a freshly split sheet of mica 0.005–0.010 mm. thick. The prism was maintained at a temperature of 110° until the film spread to the required thickness. The other dimensions of the source were determined by a pinhole in a sheet of black paper placed in contact with the mica (see Fig. 1B).

The experimental arrangement for the excitation and examination of the phosphorescence of the fluorescein film is depicted schematically in Fig. 1A. Light from a high-pressure mercury arc (1) was focused on the pinhole by means of a large aperture lens (2). The right angle prism (5)[11] was suspended in an unsilvered dewar (4) fitted with a balsa wood cover (7). The interfering beams of phosphorescent light from the film passed through a glass window in the cover (6). The fringe system was focused on the slit of the spectrograph (13) by means of a lens (9) and totally reflecting prism (11). The polarization of the fringe system was studied with the aid of a Polaroid disk (12) placed before the slit of the spectrograph.[12]

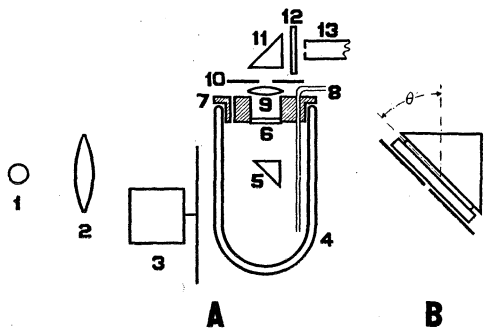

Fig. 1.—Schematic representation of the apparatus used for wide-angle interference studies at low temperatures.

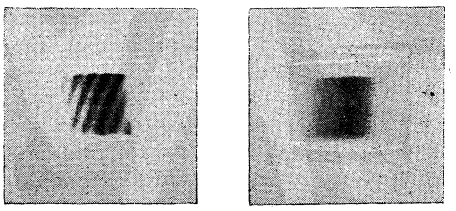
The fluorescein film which served as the source of phosphorescent light was maintained at the desired temperature (95°K.) by a stream of cold air produced by boiling the liquid air contained in the dewar. This method of cooling was found necessary in preference to the usual method of immersion in liquid air in order to prevent disturbance of the exciting and emitted light beams.

In order that only phosphorescent light might enter the spectrograph a phosphoroscope was used which consisted of two synchronized shutters A disk (3) with a 50° sector of an annulus cut out of it, rotating at the rate of one revolution per second, served as the shutter for the exciting beam. A Packard Ideal shutter (10) placed in the phosphorescent beam was operated in synchronism with the first shutter by means of electrical contacts placed at properly spaced intervals on the disk.

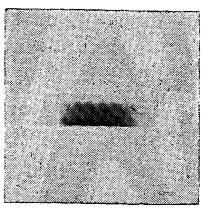
The fringes arising from the broad band of wave lengths contained in the phosphorescent light were separated and photographed in the spectrograph (13), which was a small Bausch and Lomb constant deviation spectrometer fitted with a camera.

The Nature of the Emission Process

Observations of the interference patterns formed by pairs of rays diverging at angles of 90° and 45° sufficed for an unambiguous assignment of the multipole nature of the source. At an angle of divergence $2\theta = 90°$ (see Fig. 1B) and with the Polaroid set to transmit light polarized with its electric vector perpendicular to the plane of the two interfering beams, we obtained a picture of the emission spectrum crossed by interference fringes of high visibility. The photograph showing these fringes is reproduced in Fig. 2(a). At the same angle of divergence, but with the Polaroid turned through 90° from its first position, interference fringes no longer appeared in the photograph of the emission spectrum (Fig. 2(b)). These results, when interpreted in the light of the theoretical



(a) (b)



(c)

Fig. 2.—Phosphorescence (5400–6200 Å.) of fluorescein in phosphoric acid at 95°K. (a) $2\theta = 90°$, electric vector perpendicular to plane of interfering beams. (b) $2\theta = 90°$, electric vector parallel to plane of interfering beams. (c) $2\theta = 45°$, electric vector perpendicular to plane of interfering beams. The photograph obtained with $2\theta = 45°$ and the electric vector parallel to plane of interfering beams is indistinguishable from this one.

(10) It was necessary to use such a concentrated solution of fluorescein in order to obtain phosphorescence of sufficient intensity. The low intensity of the phosphorescence as compared with the fluorescence is accounted for by the fact that the fluorescein molecules spend such a long time in the phosphorescent state.

(11) For observations at an angle of $2\theta = 90°$ (Fig. 1B) the 45° prism was used. At $2\theta = 45°$ a glass half cylinder was used such as the one described by Freed and Weissman [*Phys. Rev.*, **60**, 440 (1941)].

12) Since the only polarizations studied were perpendicular and parallel to the plane of incidence of the totally reflecting prism (11), it was permissible to place the Polaroid disk in this position.

investigations of Doermann and Halpern,[9] show that the emission process involved in the beta phosphorescence may be either an electric dipole or magnetic quadrupole transition. Furthermore, the theory definitely excluded transitions involving magnetic dipoles, electric quadrupoles, electric octopoles and magnetic octopoles. Detailed predictions of the interference properties of still higher multipoles have not as yet been made and, therefore, we cannot definitely exclude these on the basis of our photographs. However, these can be excluded on the basis of reasoning involving the lifetime of the phosphorescent state and the intensity of the emission.

In order to decide between the two alternatives allowed us by the results described above, *i. e.*, electric dipole and magnetic quadrupole, it was but necessary to observe the interference patterns at an angle of divergence $2\theta = 45°$. At this angle of divergence we again made observations with the Polaroid set to transmit light polarized with its electric vector perpendicular to, and parallel with, the plane of the two interfering beams. In each case we obtained photographs of the spectrum crossed with fringes of high visibility (Fig. 2(c)). These photographs definitely show the emission process to be electric dipole in nature.[13]

Had our wide-angle interference experiments shown that the transition giving rise to the beta phosphorescence involved a multipole of higher order than a dipole, there would have been no great difficulty in explaining the long lifetime and small polarization of this process.[14] However, the unambiguous results of these experiments confront us with this question: how can the long-lived beta dipole process occur with only slightly preferred directional properties in the same oriented molecule which gives rise to highly selective directional properties for the short-lived dipole fluorescence? Let us suppose that the two states involved in the beta transition resemble non-degenerate states of zero total electronic angular momentum encountered in atomic spectra. Transitions of any multipole order between such highly symmetrical states are forbidden. However, a perturbation possessing sufficiently low symmetry may induce an electric dipole transition between such states. In the case here being considered such a perturbation may arise from zero point fluctuations in the medium or the molecule, as suggested by Lewis, Lipkin and Magel.[2] The direction of the oscillating moment associated with such an induced transition would be determined principally by the direction of the perturbation and little by the molecular axes, giving rise to phosphorescence with little polarization. On the other hand, in the fluorescence the upper state may be thought of as arising from a degenerate electronic state. Presumably there would be no prohibition against an electric dipole transition between this state and the ground state, and the observed lifetime of the fluorescence[15] is actually found to be in good agreement with this presumption. Furthermore, such a state would partake of the symmetry of the molecule and the oscillating dipole moment associated with the transitions in which it is involved would be expected to be oriented with respect to the molecular axes. This would readily account for the high degree of polarization observed in the fluorescence and alpha phosphorescence.

We wish to thank Professor Gilbert N. Lewis for many helpful discussions of the results of this investigation.

Summary

A wide-angle interference study of the beta phosphorescence of fluorescein in phosphoric acid at 95°K. has shown that the process involves an electric dipole transition.

BERKELEY, CALIFORNIA RECEIVED MAY 26, 1942

(13) The results of Doermann and Halpern are applicable to isotropic sources. Our source fulfilled this requirement of isotropy for two reasons. In the first place, a highly convergent beam of exciting light was used. Second, almost complete saturation of the source was achieved and, therefore, even molecules whose axes approach parallelism with the axis of the exciting light beam are activated.

(14) It has been shown by means of electromagnetic theory that the lifetime of an oscillator increases markedly with increase in the order of the multipole. Thus, the ratio of the lifetimes of two successive multipoles, *i. e.*, dipole and quadrupole, is approximately equal to $(\lambda/a)^2$, where λ is equal to the wave length of the emitted radiation and a is equal to the amplitude of the oscillation.

Separation of *cis* and *trans* Stilbenes by Application of the Chromatographic Brush Method

BY L. ZECHMEISTER AND W. H. MCNEELY

In the stilbene series the *cis*-isomers are usually prepared either by irradiation of the stable *trans*-compound[1] or by direct synthesis.[2] The stereoisomers have been separated or differentiated by fractional crystallization, distillation and hydrogenation methods, and use has also been made of molecular addition compounds. For the determination of the *cis* and *trans* components in mixtures among other methods use has been made of spectrophotometric measurements and the study of melting point curves.[3]

We find that a convenient and rapid procedure for the detection, purification, separation and estimation of stereoisomeric stilbenes is to be found in the so-called chromatographic brush method.[4] After extrusion of the column, containing the invisible chromatogram, a narrow streak is made down the column with a brush which has been dipped into a 1% permanganate solution. Whenever the reagent crosses a zone containing *cis*- or *trans*-stilbenes it turns brown almost instantaneously. The zones thus located can be cut out and the isomers eluted after the streak has been shaved off.

In the present paper the application of this principle to stilbene, *p*-methylstilbene and *p*-methoxystilbene is described. In each case the *trans*-isomer possesses stronger adsorption affinity than the *cis*-form and is located near the top of the alumina column. After adequate development the two isomers are separated by a wide interzone. The procedure can be completed in ten to sixty minutes, with a total recovery of more than 90% when carried out with a quantity of starting material in a range of 10–500 mg. If the experiment is performed at room temperature no measurable isomerization of the *cis*-compound seems to take place.

By this method samples of *cis*- or *trans*-stilbenes can be tested for possible contamination by the other isomer. If 30–100 mg. of a mixture is analyzed the limit of detection is 1–2%. The method may also prove useful for the study of *cis–trans* shifts under the influence of light[5] and of other factors.

Finally, we may remark that the use of chromatography has revealed the presence of minor contaminants in commercial and in some recrystallized samples of stilbenes. These impurities are retained near the top of an activated alumina column where the adsorbate shows visible fluorescence in ultraviolet light. The main compound is easily washed into the filtrate by petroleum ether–benzene mixtures or by pure benzene. If the filtrate is sent through a fresh column, no fluorescing adsorbate appears. A great difference between the fluorescing power of non-chromatographed and chromatographed *p*-methyl- and *p*-methoxystilbene was observed when the crystals or 0.1% benzene solutions were inspected in ultraviolet light. The fluorescence of the purified samples was much weaker. No such difference was noticed in the case of stilbene except on the Tswett column. A preliminary chromatographic test of samples may be advisable if fluorescence spectra are to be studied.[6]

Acknowledgment.—The authors wish to thank Dr. G. Oppenheimer and Mr. G. Swinehart for microanalyses.

Experimental

The following adsorbents were used: for the purification of commercial *trans*-stilbene, activated alumina ("Alorco," 150–200 mesh or minus 80 mesh); for the purification of synthesized *p*-methoxy- and *p*-methylstilbene, Super Filtrol (Filtrol Corporation, Los Angeles) and activated alumina, and for the separation of *cis-trans* pairs, activated alumina. The petroleum ether had a boiling range 60–70°.

(6) B. Arends, *Ber.*, **64**, 1936 (1931), observed fluorescing contaminants in some of his *p*-methylstilbene samples. These were not removed by crystallization. No chromatographic treatment is mentioned.

All melting points are corrected and were taken in an electrically heated Berl block. The capillaries were introduced 10° below the melting point. The rise of temperature was 1–2° per minute.

For the inspection of chromatograms during development, a small portable ultraviolet lamp was used (light was excluded by covering the tube and the head of the observer with a black cloth), and for solutions or solids an Examalite Quartz Lamp, (Hanovia, Newark, N. J.). Irradiations were carried out by a mercury arc quartz lamp (4 amp. d. c., voltage drop 32 v.) in a hood cooled by ventilation. The distance between the lamp and the quartz test-tubes was 10 cm. Irradiations were discontinued at night.

cis- and *trans*-**Stilbene.**—The starting material was stilbene (Eastman Kodak Co.), m. p. 124–125°, from which a small quantity (<0.1%) of strongly fluorescent contaminants can be eliminated by filtering the benzene–petroleum ether (1:1) solution through activated alumina. The impurities are retained near the top while stilbene is washed into the filtrate. The melting point remained unchanged. The adsorbates[7] of *trans*- or *cis*-stilbene purified in this way showed no visible fluorescence in ultraviolet light.[8] For the preparation of the *cis*-compound 2.5 g. of stilbene in 35 ml. of benzene was irradiated for 200 hours. The pale yellow solution was kept in a cold room and samples were taken when needed.

A portion of this solution, containing 160 mg. of substance, was evaporated *in vacuo* at 35°, and in order to eliminate traces of benzene the evaporation was repeated twice after the addition of some petroleum ether. The residue (except for traces of yellow solids) was dissolved in 25 ml. of petroleum ether and poured onto an alumina column (17.5 × 1.7 cm.); the chromatogram was developed with 90 ml. of the solvent. Near the top a yellow by-product was retained, closely followed in some experiments by a minor fluorescent layer.[9] The main section of the column was colorless and did not fluoresce visibly in ultraviolet light. The permanganate brush located a *trans*-stilbene zone (42 mm. broad) and below it, separated by a 6-mm. empty section, the *cis*-zone (48 mm. broad). The streak turned light brown within two seconds where it crossed the zones while the nearly empty interzones began to react after several minutes.[10] Each isomer was eluted with dry ether and evaporated *in vacuo*.

The yield was 99.1 mg. of *trans*-stilbene (m. p. 123.5–124.5°, after one recrystallization from ethanol) and 51.8 mg. of *cis*-stilbene, the total recovery being 94% of the starting material. Before analysis the colorless, oily *cis*-compound (which can be crystallized at a lower temperature) was rechromatographed. Both samples were dried at 45° in high vacuum.

Anal. Calcd. for $C_{14}H_{12}$: C, 93.28; H, 6.72. Found (*cis*): C, 93.36; H, 6.65. Found (*trans*): C, 93.28; H, 6.78.

The *cis* compound was further identified by addition of a trace of iodine and exposure to sunshine for a few hours. By this treatment it crystallized almost completely. A chromatographic analysis showed only a minor zone of unchanged *cis*-isomer while pure *trans*-stilbene was isolated in a yield of 78%.

In order to establish the limits of detection by brushing, artificial mixtures of *cis*- and *trans*-stilbene were chromatographed. It is possible to detect 2 mg. of *cis* in 75 mg. of *trans* on alumina (17.5 × 1.7 cm.) or 0.5 mg. of *trans* in 30 mg. of *cis* by using a smaller column (10.5 × 0.9 cm.). If the quantity of one of the isomers is below these limits, its location may be established roughly from that of the other isomer. By elution of the proper region with ether and analytical recovery by evaporation, an extension of the limits of detection can be obtained. The procedure is applicable to *p*-methyl and *p*-methoxy stilbene.

cis- and *trans*-*p*-**Methylstilbene.**—The *trans*-compound was prepared according to Meerwein and his associates,[11] however, the crude product was purified by chromatography instead of by tedious sublimations in high vacuum. The hydrochloric acid solution of 13.4 g. of *p*-toluidine was added, after diazotization, to 18.5 g. of cinnamic acid in 150 ml. of acetone. After the addition of 27.5 g. of sodium acetate and a solution of 6.7 g. of crystallized cupric chloride, the liquid was stirred at 20° until the evolution of gases ceased (about five hours). The volatile components were then removed by steam distillation, and the dark residue was extracted with 150 ml. of benzene. After filtration and removal of unchanged cinnamic acid by extraction with ammonia containing ammonium chloride, the solution was dried with sodium sulfate. It was diluted with 400 ml. of petroleum ether and filtered through a Superfiltrol column (27 × 7 cm.) which was washed with about 1 liter of a benzene–petroleum ether mixture (1:1) until a pale blue fluorescing zone reached the filtrate. The column showed numerous intensely colored layers which were discarded. The evaporation residue of the filtrate yielded 6.0 g. of *trans*-*p*-methylstilbene, m. p. 118.5–119.5°, on crystallization from alcohol.

Such a sample may be used directly for the preparation of the *cis*-isomer by irradiation, or it can first be rechromatographed on activated alumina in order to remove the fluorescing contaminant mentioned which appears near the top on developing with benzene–petroleum ether. After this treatment practically no visible fluorescence of the *cis*- or *trans*-form was observed in petroleum ether on the column.

For the preparation of *cis*-*p*-methylstilbene 450 mg. of the *trans*-isomer in 90 ml. of petroleum ether was irradiated for seventy-five hours and then developed on alumina (22.5 × 4.3 cm.) with 700 ml. of the solvent. On inspection and brushing the presence of the following zones was revealed (the figures on the left denote the width of the zones in millimeters)

5 by-product (yellow before brushing)
12 empty interzone
30 *trans*-*p*-methylstilbene (located by permanganate)
55 empty interzone
50 *cis*-*p*-methylstilbene (located by permanganate)
73 empty bottom zone

(7) We suggest that the term "Adsorbate" should designate the substance-adsorbent complex and not the adsorbed substance alone. (This nomenclature is now accepted in the German literature.)

(9) On fluorescing of stilbenes *cf.* G. N. Lewis, *et al.*, footnote 1; H. Ley and H. Specker, *Z. wiss. Phot.*, **38**, 13 (1939).

(10) In blank experiments the column began to show a reaction with permanganate in several minutes.

(11) H. Meerwein, E. Büchner and K. van Emster, *J. prakt. Chem.*, **152**, 237 (1939).

The isomers were isolated by eluting with dry ether, evaporating and drying *in vacuo*. The yields were 160 mg. of *trans*- and 268 mg. of oily *cis*-*p*-methylstilbene, the total recovery being 95%. For analysis the *trans*-compound was recrystallized from alcohol (m. p. 119.5–120°) and the *cis*-isomer rechromatographed as described. The samples were dried in high vacuum at 20°.

Anal. Calcd. for $C_{15}H_{14}$: C, 92.73; H, 7.27. Found (*cis*): C, 92.98; H, 7.50. Found (*trans*): C, 93.06; H, 7.33.

Eighteen mg. of oily *cis*-*p*-methylstilbene was isomerized in the sunshine with iodine. Crystallization began after fifteen min. but the exposure was continued for a few hours. On brushing the column did not reveal any unchanged *cis*-isomer while 16.4 mg. of the *trans*-form was recovered (m. p. 119.5–120° after one recrystallization). The yield was 91%.

The solution of an artificial mixture of 70.3 mg. of *trans*- and 56.2 mg. of *cis*-*p*-methylstilbene in 10 ml. of petroleum ether was developed on alumina (17.5 × 1.7 cm.) with 60 ml. of the solvent. This washing was completed in twenty-five min. Ten mm. below the top the *trans*-zone appeared (55 mm. wide), and after an empty section (30 mm.) the *cis*-zone followed (50 mm. wide). Elution with 65 ml. of ether and evaporation yielded 68.6 mg. of the *trans*-isomer (m. p. 118–119°, without recrystallization) and 54.4 mg. of the *cis*-compound. The total recovery was 97%. The samples were chromatographically homogeneous.

On an alumina column (10.5 × 0.9 cm.) 0.3 mg. of *trans*-*p*-methylstilbene can easily be detected in admixture with 25.3 mg. of the *cis*-form or on a larger column (17.5 × 1.7 cm.) 1.8 mg. of the *cis*-form in 98.8 mg. of the *trans*-compound.

***cis*- and *trans*-*p*-Methoxystilbene.**—The synthesis of the *trans*-compound from diazotized *p*-anisidine and cinnamic acid was carried out according to Meerwein, *et al.*,[9] the product was purified chromatographically as described for *p*-methylstilbene. By filtering a benzene solution through activated alumina a by-product can be removed, the adsorbate of which fluoresces much stronger than that of the methoxystilbene. The pure compound melted at 135–136° after recrystallization from methanol. For the preparation of the *cis*-isomer a solution of 730 mg. in 35 ml. of benzene was irradiated for 160 hours (shorter irradiation is also satisfactory). A portion of the solution containing 161 mg. of substance was evaporated. The residue was taken up with 2.5 ml. of chloroform and, after the addition of an equal volume of petroleum ether, chromatographed on alumina (17.5 × 1.7 cm.). On developing with 70 ml. of a petroleum ether–benzene mixture (3:1) the following chromatogram appeared

0.5 brownish top layer (visible before brushing)
5 empty interzone
1 bright yellow by-product (visible before brushing)
6 empty interzone
40 *trans*-*p*-methoxystilbene (located by permanganate)
15 empty interzone
47 *cis*-*p*-methoxystilbene (located by permanganate)
60 empty bottom zone

Each main zone was eluted with 65 ml. of ether and treated as described for the *p*-methyl compound. The yield was 58.5 mg. of the *trans*-isomer (m. p. 135–136°, after recrystallization from methanol) and 79.1 mg. of the *cis*-form (colorless oil), the recovery being 86%. The oil was rechromatographed before analysis.

Anal. Calcd. for $C_{15}H_{14}O$: C, 85.67; H, 6.72. Found: (*cis*) C, 85.76; H, 6.66; (*trans*) C, 85.31; H, 7.07.

2.2 mg. of the *cis*-isomer was detected in the presence of 95.4 mg. of the *trans*-form on alumina (17.5 × 1.7 cm.), and 1.5 mg. of *trans* in admixture with 86.6 mg. of *cis*-*p*-methoxystilbene.

Summary

The chromatographic brush method, with permanganate, has been used for the detection, separation and estimation of the *cis*- and *trans*-forms of stilbene, *p*-methylstilbene and *p*-methoxystilbene. In a mixture composed of two stereoisomeric compounds 1–2% of either form can be detected. The method can be used for the study of the interconversion of stilbene *cis*- and *trans*-isomers. Fluorescing contaminants can be removed by chromatography in ultraviolet light.

Chromatography of *cis* and *trans* Benzoin and Anisoin Oximes with Application of the Brush Method

BY L. ZECHMEISTER, W. H. MCNEELY AND G. SÓLYOM

It was shown recently that the brushing of a chromatographic column with a suitable color reagent[1] can be used for the detection, separation and estimation of *cis*- and *trans*-stilbenes.[2] This was made possible by the differences in adsorption affinities of stereoisomers which have been observed in various classes of compounds.[3] The present paper describes the application of the same principle to an investigation of the chromatographic behavior of some *cis*- and *trans*-oximes. According to Feigl,[4] a solution of *trans*-benzoin oxime (α or *anti*), $C_6H_5CHOHC(:NOH)C_6H_5$, gives a stable deep-green complex when treated with ammoniacal copper sulfate, while, according to Meisenheimer and Theilacker,[5] the complex obtained with the *cis*-isomer (β, *syn*) is brown. It is this behavior which has been made a basis for the application of the brush method. If two stereoisomeric oximes capable of complex formation are present in a solution, chromatography on a Neutrol Filtrol column shows that the *trans*-form is adsorbed near the top and gives a green brush reaction while the *cis*-isomer is located in a lower section and turns brown where the brush crosses it. Between the two layers an interzone is found, free of substance or containing only very little; no such interzone appears on any other adsorbent tested, including Floridin.[6]

The behavior of the two anisoin oximes, $CH_3O\text{-}C_6H_4CHOHC(:NOH)C_6H_4OCH_3$ is analogous.

If 40–200 mg. of a mixture of two stereoisomers is analyzed by the procedure described, 1–2% of either form can be detected. This allows a study of their interconversion under the influence of different factors. It was known that *cis*-benzoin oxime is isomerized by refluxing an alcoholic solution,[7] but our chromatographic experiments demonstrate that the *trans*-compound also isomerizes to a slight extent.

The analytical applicability is somewhat limited by the catalytic action of Neutrol Filtrol on some *cis*-oximes. If the rate of the chromatographic filtration is low and the duration of the experiment too long, the interzone which separates the *cis*- and *trans*-fractions contains small amounts of the *trans*-isomer formed on the column itself. The latter appears during the slow migration of the *cis*-oxime and is retained near the place of the conversion. In such a case the brush streak does not remain blue where it crosses the interzone, but takes on a slightly greenish tint within several minutes. In contrast, the main portion of the *trans*-compound which was present in the original solution and is adsorbed near the top, instantaneously gives a well-defined dark green color on brushing. This difference allows quantitative experiments to be carried out.

Under the conditions applied, the "column isomerization" amounts to less than 5% of the original quantity of *cis*-benzoin oxime and less than 1% of *cis*-anisoin oxime.

Acknowledgment.—The authors are indebted to Dr. G. Oppenheimer and Mr. G. Swinehart for microanalyses.

Experimental

Neutrol Filtrol (Filtrol Corp., Los Angeles) was used as an adsorbent. A trace of oil was removed either by hot extractions with benzene and then acetone, or by numerous extractions with benzene and alcohol–ether (1:1) at room temperature, with mechanical shaking. The adsorbent was dried at 90° for four hours. These operations increase the adsorptive power, but decrease the rate of filtration. Therefore, 17% Celite (no. 535) or Hyflo Super-Cel (Johns–Manville Co.) was used as a filter aid.

The color reagent was prepared by diluting 0.15 mole of copper sulfate and 4 moles of ammonia to one liter. The

(6) A series of experiments with Floridin has been described by G. Sólyom in his Thesis (Univ. Pécs, 1940). This adsorbent has been now abandoned as the use of Neutrol Filtrol is far more satisfactory. The earlier experiments were carried out in collaboration with Dr. O. Frehden.

(7) A. Werner, *Ber.*, **23**, 2333 (1890).

melting points are corrected and were taken in an electrically heated Berl block.

***cis-* and *trans*-Benzoin Oxime.**—The oximes were prepared according to the data of Werner and Detscheff.[8] In repeated experiments, however, we were unable to obtain chromatographically homogeneous samples. Adsorption analysis revealed the presence of, for example, 1% of the *cis*-isomer in the *trans*-compound and 30% or more of the *trans*-isomer in the *cis*-compound. The latter when purified in this way showed the m. p. 99° as given by the authors mentioned. The *trans*-compound melted at 151°.

In order to purify *cis*-benzoin oxime, a solution of 1 g. in 100 ml. of a chloroform–benzene mixture (1:1) was poured on a column (19 × 3.2 cm.) and developed within thirty min. with 160 ml. of benzene containing 2% alcohol. After brushing with the reagent, the presence of the following zones was revealed (the colors given refer to the streak,[9] the figures on the left denote the width of the zones in millimeters)

5 sky blue (empty top section)
16 dark green (*trans*-benzoin oxime)
50 bluish green (small amounts of *trans*)
54 dark brown (*cis*-benzoin oxime)
65 sky blue (empty bottom section)

After cutting out the three zones and shaving off the streak, each of the two *trans*-fractions was eluted with 100 ml. of alcohol–ether (1:1) and the *cis*-fraction with the same volume of dry ether. The adsorbent was removed on a sintered glass funnel. Evaporation and analytical weighing indicated the presence of 181 mg. and 43 mg. of *trans*- and 722 mg. of *cis*-benzoin oxime, the total recovery being 95%. The melting point of the *trans*-compound was 147–148° after recrystallization from 2 ml. of ethanol. The oily *cis* fraction was dissolved in a few ml. of dry ether and evaporated in a carbon dioxide current at 25°. On scratching, it crystallized out (m. p. 99–99.5°).

Anal. Calcd. for $C_{14}H_{13}O_2N$: N, 6.17. Found: (*cis*) N, 6.38. Found: (*trans*) N, 6.15.

(a) An artificial mixture of equal parts (75 mg.) of *cis*- and *trans*-benzoin oxime was dissolved in 20 ml. of chloroform–benzene (2:1) and developed with 40 ml. of benzene containing 2% ethanol on a column (17.5 × 1.7 cm.) within twenty min.

2 sky blue (empty top section)
17 dark green (*trans*-benzoin oxime)
42 blue (trace of *trans*)
26 dark brown (*cis*-benzoin oxime)
88 sky blue (empty bottom section)

Fifty ml. of dry alcohol–ether (1:1) was used for the elution of the *trans*-zone, 40 ml. of the same mixture for the interzone and 40 ml. of ether for the *cis*-compound. The recovery was 74.5 mg. and 1.7 mg. of *trans*- and 70.1 mg. of *cis*-benzoin oxime; the melting points were correct.

(b) The limits of detection were established by experiments of the type (a). In the presence of 40 mg. of *trans*-benzoin oxime 0.4 mg. of the *cis*-isomer can be detected by washing with 12 ml. of benzene plus 2% ethanol (column: 10.5 × 0.9 cm.). In the presence of 100 mg. of *cis*-, 2 mg. of the *trans*-compound was detected on a larger column (17.5 × 1.7 cm.). Each experiment required twenty to twenty-five minutes.

(c) A solution of 50 mg. of chromatographed *cis*-benzoin oxime was refluxed in 25 ml. of alcohol for two hours, evaporated and taken up in 10 ml. of chloroform–benzene (1:1). The adsorption analysis showed two equally broad oxime zones from which 11.2 mg. of the *trans*- and 29.3 mg. of unchanged *cis*-compound were isolated in pure state. A similar experiment with *trans*-benzoin oxime showed only 1% isomerization.

(d) Two 125-mg. samples of chromatographically pure *cis*-benzoin oxime were dissolved in 10 ml. of chloroform–benzene (1:1). Each solution was developed on a column (17.5 × 1.7 cm.) with 50 ml. of benzene containing 2% alcohol. The development in one experiment was completed in twenty-two minutes using full suction. The development of the other column, carried out with very little suction, required three and one-fourth hours. In the first case the chromatogram showed a 66-mm. section (above the unchanged *cis* zone) which gave a very weak reaction for *trans* and contained 5.9 mg. of this isomer; 114.4 mg. of *cis*-compound was recovered.

In the slow experiment the 67-mm. upper zone gave a definite brush reaction for the *trans*-oxime and yielded 34.6 mg. of this compound formed by isomerization; 82.3 mg. of the starting material was recovered unchanged. The extent of isomerization during chromatography was 5 and 28%, respectively, in the rapid and slow experiment.

***cis-* and *trans*-Anisoin Oxime.**—Anisaldehyde (Eastman Kodak Co.) was fractioned *in vacuo;* it was then condensed to anisoin in the presence of potassium cyanide.[10] In spite of the correct melting point (112–113°) of the recrystallized product it proved to be chromatographically heterogeneous. For purification, 20 g. was dissolved in 0.8 liter of chloroform–benzene (1:1) and developed on a column (27 × 7 cm.) with 2.5 liters of benzene containing 0.5% ethanol. On brushing with 1% permanganate the anisoin was located in a 90-mm. zone near the top while a minor compound adsorbed below was discarded. The anisoin was eluted with 2 liters of alcohol–ether (10:1) and the solution concentrated in a carbon dioxide stream to 50 ml. The product was recrystallized from alcohol (17 g., m. p. 112–113°).

Anal. Calcd. for $C_{16}H_{16}O_4$: OCH_3, 22.79. Found: OCH_3, 22.68.

The oximation carried out as described by Werner and Detscheff[8] for benzoin oxime gave a mixture of both stereoisomers. For example, 2.3 g. of aqueous hydroxylamine hydrochloride (neutralized against litmus) was added to 4.5 g. of anisoin in 20 ml. of ethanol. After one and one-half hours of refluxing, the liquid was diluted with 150 ml. of water and allowed to stand overnight. The oil was dissolved in 300 ml. of benzene, dried with sodium sulfate, developed with 500 ml. of benzene containing 3% alcohol on a column (22.5 × 4.3 cm.) and brushed[9]

12 sky blue (empty top section)
73 dark green (*trans*-anisoin oxime)
56 bluish green (traces of *trans*)
1 pink without brushing (unknown)
35 dark brown (*cis*-anisoin oxime)
48 sky blue (empty bottom section)

(8) A. Werner and Th. Detscheff, *Ber.*, **38**, 69 (1905); *cf.* L. Malatesta, *Gazz. chim. ital.*, **68**, 319 (1938).

(9) In some cases the *cis*-zone showed a pale yellow color before brushing. This color darkens in air.

(10) M. Bösler, *Ber.*, **14**, 323 (1881); R. Stierlin, *ibid.*, **22**, 376 (1889).

The *trans*-compound was eluted with 450 ml. of anhydrous alcohol–ether (1:1) and the *cis*-isomer with 250 ml. of dry ether. The solvents were removed *in vacuo*.

The *trans*-oxime appeared as an oil and was crystallized by dissolving it in about 50 ml. of benzene at 25° and scratching. The yield was 1.9 g.; the colorless, short, quadrangular plates melted at 125.5°. The *cis*-compound came out in the form of crystals which contained ether. These were dissolved in 6 ml. of acetone at room temperature and rapidly evaporated with a carbon dioxide stream at 25°. The oily residue was evaporated with 2 ml. of benzene, dissolved in 10 ml. of cold benzene and scratched. Thin, elongated, colorless prisms appeared (1.2 g., m. p. 121–122°).

Anal. Calcd. for $C_{16}H_{17}O_4N$: N, 4.88. Found: (*cis*) N, 5.08; (*trans*) N, 4.99.

The difference in the melting points of the two isomers is remarkably small. The configurations, however, are given by the location on the column and by the color reactions. Chromatography showed the presence of less than 1% of the *cis*-compound in the *trans*-sample and *vice versa*.

(a) A mixture of 75 mg. of each isomer was dissolved in 35 ml. of benzene by slight warming, developed on a column (14 × 1.7 cm.) with 50 ml. of benzene containing 3% abs. alcohol, and brushed:

10 sky blue (empty top section)
21 dark green (*trans*-anisoin oxime)
37 blue (interzone)
7 dark brown (*cis*-anisoin oxime)
65 sky blue (bottom section containing a faint yellow line)

After elution with 55 ml. of the solvent mentioned, 69.2 mg. of *trans*-oxime (m. p. 125–125.5°, after crystallization from cold benzene) and 68.3 mg. of *cis*-oxime (m. p. 122.5–123.5°, after crystallization) were isolated, the total recovery being 92%. The interzone yielded 0.8 mg. of the *trans*-compound.

(b) It was found in similar adsorption experiments that 1.6 mg. of *cis*-anisoin oxime can be detected in the presence of 200 mg. of the *trans*-isomer or 1.2 mg. of *trans*- in the presence of 135 mg. of the *cis*-compound. The limit is 0.5–1%.

(c) A solution of 140 mg. of *cis*-anisoin oxime in 40 ml. of ethyl alcohol was refluxed for one and one-half hours. After removing the solvent and chromatographing as described in expt. (a), a 6-mm. zone was located above the main zone by brushing. This contained 11.5 mg. (8%) of the *trans*-compound, formed by isomerization. A parallel experiment carried out with *trans*-anisoin oxime yielded 2.5% of formed *cis*-isomer.

(d) A solution of 125 mg. of pure *cis*-anisoin oxime in 30 ml. of benzene was developed in three and one-fourth hours on a column (17.5 × 1 cm.) with 50 ml. of benzene containing 3% absolute alcohol. From the interzone 13.7 mg. of the *trans*-isomer was isolated. The extent of the "column isomerization" amounted to 11% in this case while the corresponding figure for a short experiment is about 1%.

Summary

The chromatographic brush method, with an ammoniacal copper solution as color reagent, has been used for the detection and separation of *cis*- and *trans*-benzoin and anisoin oximes on Neutrol Filtrol columns. In a mixture composed of two stereoisomers, 1–2% of either form can be rapidly detected in the presence of the other. Some data concerning the interconversion of stereoisomeric oximes are given, and the influence of the adsorbent on the *cis-trans* shift is discussed.

The Configuration of Organic Coördination Compounds of Nickel, with Especial Reference to Bis-formylcamphor-ethylenediamine-nickel

BY H. S. FRENCH, M. Z. MAGEE[1] AND E. SHEFFIELD[1]

Evidence is accumulating from various groups of investigators which may ultimately furnish an answer to the question implied in Pauling's[2] statement that "factors which determine whether the diamagnetic square or the paramagnetic tetrahedral configurations will be assumed by a nickel complex cannot be stated precisely." The present paper seeks to add to the evidence results of three different types: first, the magnetic susceptibilities of nine compounds; second, the absorption spectra of four of these compounds; and third, the *relation between* the adsorption spectrum and rotatory dispersion of a single one of the compounds.

Magnetic Susceptibility.—Determination of magnetic susceptibility is probably the most generally used method for the study of the configuration of the quadricovalent nickel complexes, since diamagnetism is associated with the square coplanar configuration and no unpaired electrons, while paramagnetism is associated with the tetrahedral configuration and two unpaired electrons. Pauling[3] has given the most satisfactory explanation for this change in the number

(1) Taken in part from the M.A. Thesis of M. Z. Magee and from the Honors Thesis of E. Sheffield.

(3) Pauling, *ibid.*, p. 111.

of unpaired electrons by his theory of the hybridization of bond orbitals. The nine compounds chosen for this study of magnetic susceptibility are the following

(I) bis-salicylaldehyde nickel $(C_6H_4(CHO)O)_2Ni$
(II) bis-*o*-hydroxyacetophenone nickel $(CH_3COC_6H_4O)_2Ni$
(III) bis-formylcamphor nickel $(C_{10}H_{14}(CHO)O)_2Ni$
(IV) bis-salicylaldimine nickel $(C_6H_4(CH{=}NH)O)_2Ni$
(V) bis-*o*-hydroxyacetophenoneimine nickel $(CH_3C{=}NHC_6H_4O)_2Ni$
(VI) bis-salicylaldehyde-propylenediamine nickel

$$C_6H_4(CH)\ O\ Ni\ O\ (CH)C_6H_4$$
$$\|\qquad\qquad\|$$
$$N{-}CH_2(CH_3)CH{-}N$$

(VII) bis-formyl camphor ethylenediamine nickel

$$C_{10}H_{14}(CH)O\quad Ni\quad O(CH)C_{10}H_{14}$$
$$\|\qquad\qquad\|$$
$$N{-}CH_2{-}CH_2{-}N$$

(VIII) bis-*o*-aminobenzalimine nickel $(C_6H_4(CH{=}NH)NH)_2Ni$
(IX) bis-*o*-aminobenzaldehyde phenylenediamine nickel

$$C_6H_4(CH)NHNiNH(CH)C_6H_4$$
$$\|\qquad\qquad\|$$
$$N{-}{-}C_6H_4{-}{-}N$$

Since no new methods of preparation were used for any of the compounds studied, we refer to the original directions by footnotes in Table I. We include also in Table I, the results of the analyses for nickel, and of the magnetic susceptibility determinations. Magnetic susceptibilities were measured by the Gouy[4] method and from these the magnetic moments in Bohr magnetons were calculated in the usual way.[5] The analyses for nickel were carried out on the micro-scale by igniting the compound to the oxides of nickel, and reducing the oxides to nickel in a stream of hydrogen.

1960	5000	5.10	25.00

We believe that it will be necessary in any final interpretation to subdivide these classes according to the chelate rings involved, as suggested by Diehl[8] or by Pfeiffer.[9] Our compounds I, II and III fall under Mellor and Craig's class A, in which nickel is joined to four oxygen atoms. Table I shows paramagnetic susceptibility for all three compounds, corresponding to two unpaired electrons and tetrahedral configuration. So far as we know, all class A compounds studied by other investigators are also paramagnetic. Class B includes compounds in which nickel is joined to two oxygen and two nitrogen atoms and it is in such compounds that previous investigators have failed to find any uniformity in magnetic susceptibility. Our compounds IV, V, VI and VII fall in this class. Table I shows diamagnetic susceptibility for all four compounds, corresponding to no unpaired electrons and square co-planar configuration. Compound VII offers the interesting peculiarity, however, that it is diamagnetic in the solid state, but paramagnetic in methyl alcohol solution. This peculiarity will be discussed later. Class C includes compounds in which nickel is joined to four nitrogen atoms. Table I shows our compounds VIII and IX in this

(8) Diehl, *Chem. Rev.*, **21**, 39–42 (1937).

(9) Pfeiffer, *Z. angew. Chem.*, **53**, 93–98 (1940).

class to be diamagnetic, and this fact is in accord with the results of other investigators for compounds in class C.

The absorption spectra studies have thus far been applied to too limited a number of compounds for reliable generalizations. In the four curves shown here it may be noted that the change of two oxygen atoms to two nitrogen atoms in otherwise similar nickel complexes has in each case (1) increased the number of absorption maxima, (2) moved the ultraviolet maxima to longer wave lengths, and (3) moved the visible maximum to shorter wave lengths. The last two effects result in the long-wave length bands approaching each other so closely that one may become merely a step-out in the nitrogen-containing complex. It must remain for further investigation to prove whether *many* absorption bands, including one poorly defined step-out, are always characteristic of diamagnetic, square co-planar nickel complexes, and whether such a phenomenon may serve as one criterion for configuration. Incidentally, it should be added that the substitution of nitrogen for oxygen in metallic coördination compounds frequently moves the visible absorption band characteristic of the metal to shorter wave lengths,[10] and also that the formation of a Schiff base from an ortho (or para) hydroxy aldehyde or ketone causes an additional band to appear in the absorption spectrum.[11] In general, the color in the solid state of the nitrogen-containing compounds of class B is reddish or yellowish, while that of the paramagnetic compounds of class A is green or blue.[7] The few exceptions to this statement thus far found emphasize the necessity for the complete absorption spectra investigations, which alone can show the responsibility for the apparent color being borne by the usual *two* nickel absorption bands.[12]

An earlier paper[d] from this Laboratory has already shown by the method of rotatory dispersion analysis that the nickel center in compound III (class A) has the tetrahedral configuration. The argument was there based on the fact that the rotatory dispersion of the molecule was governed almost entirely by the absorption band of the nickel center, and that only the tetrahedral nickel configuration could result in optical activity. The conclusion was confirmed by finding the compound strongly paramagnetic.

This method has now been applied to compound VII (class B). We find that a logical analysis of the rotatory dispersion (Fig. 3) is given by attributing a considerable degree of optical activity to the absorption band at 6250 Å., due to the nickel center of the molecule. Only by such an assumption is a curve of residual rotation obtained with no inflection within that absorption band. We have already noted that this compound is paramagnetic in methyl alcohol solution, and this fact confirms the conclusion from the rotational dispersion and absorption spectrum. Yet, in the solid state it is diamagnetic. Mellor and Craig[b] suggest two conditions for paramagnetism in class B: first, that the oxygen atom joined to the nickel was *not* previously an hydroxyl oxygen; second, that even if the oxygen atom was previously an hydroxyl oxygen (as in their bis-8-hydroxy-quinoline nickel and presumably in our tautomeric compound) steric effects function to force the bonds out of coplanar positions. Porter[13] similarly explains the unexpected paramagnetism of the nickel complex of 3,3′,5,5′-tetramethylpyrromethane-4,4′-dicarboxylate by steric interference of the substituted groups. Pfeiffer[9] states that only a slight displacement of the four bonds out of the plane is enough to give asymmetry of the metallic center. In our bis-formyl camphor ethylenediamine nickel the oxygen atoms joined to the nickel were at least in an enolic hydroxyl group, so that diamagnetism would be expected. The presence of the ethylenediamine ring would tend to preserve the coplanarity of the molecule rather than force the bonds toward the tetrahedral configuration. A determining factor working in the opposite direction, however, is the presence of asymmetric centers in the camphor rings. That such an asymmetric center induces asymmetry in the carbonyl group of camphor was shown by Kuhn and Gore[14] and is explained by Kuhn's[15] vicinal effect. Such induction might easily go further, after rendering the aldimine bonds asymmetric and cause sufficient strain at the nickel center for the slight "twist" necessary for asymmetry (and ionization ultimately). Such "twist" might not occur in the solid state (hence diamagnetism) but

might be made possible under the influence of the solvent methyl alcohol. The fact that the change is not complete but that an equilibrium exists in methyl alcohol is indicated both (1) by the low value of the magnetic susceptibility and (2) by the effect of dilution on the absorption spectrum, especially in the region governed by the nickel aldimine complex band (step-out) at about 4500 Å.

We might go further and suggest that this equilibrium in methyl alcohol solution consists of approximately one-third of the paramagnetic form and two-thirds of the diamagnetic form of the molecules, since the observed value of the magnetic susceptibility is approximately one-third as great as the value to be expected for a paramagnetic compound of this type.

Confirmation of the interpretation just given for our results comes from further consideration of the curve for residual rotatory dispersion. When the values of $1/M$ are plotted against λ^2 for this curve, the points do not yet lie on a straight line, showing that at least two other absorption bands are optically active. It is possible, but not advisable without further experimental data, to analyze further the residual curve into two others, one governed by the band at 4500, due probably to the nickel aldimine complex, and the second by the far distant band of the camphor radical itself.

Summary

New data are presented on the visible and ultraviolet absorption spectrum of the nickel complex of formylcamphor-ethylenediamine and on its magnetic susceptibility in the solid state and in methyl alcohol solution. From an analysis of the relation between its rotatory dispersion and its absorption spectrum, and from the magnetic susceptibilities, the conclusion is drawn that the configuration of the nickel complex is square coplanar in the solid state, but strained and twisted under the influence of the asymmetric camphor to such an extent that the nickel center in methyl alcohol solution also is asymmetric and tends toward the tetrahedral configuration. New data are also presented for the magnetic susceptibilities of five other organic coördination compounds of nickel: with *o*-hydroxyacetophenone, *o*-hydroxyacetophenone imine, salicylic aldehyde propylenediamine, *o*-amino-benzalimine, and *o*-aminobenzaldehyde phenylenediamine. New data are given for the absorption spectra in the visible and ultraviolet of bis-salicylaldehyde nickel and bis-salicylaldehyde-propylenediamine-nickel. Tentative conclusions are drawn concerning the difference in absorption spectra of paramagnetic and diamagnetic compounds of the types studied.

Rate and Mechanism in the Reactions of *t*-Butyl Nitrate and of Benzyl Nitrate with Water and with Hydroxyl Ion[1]

BY GLENNARD R. LUCAS AND LOUIS P. HAMMETT

We have investigated kinetically the reactions with water and hydroxyl ion of two alkyl nitrates which illustrate the two kinds of reactions other than hydrolysis which such substances undergo in the presence of water.[2]

In the case of tertiary butyl nitrate the only reactions are the two solvolytic ones producing alcohol (A) and olefin (B).

$$C_4H_9ONO_2 + 2H_2O \xrightarrow{k_1} C_4H_9OH + H_3O^+ + NO_3^- \quad (A)$$

$$C_4H_9ONO_2 + H_2O \xrightarrow{k_2} C_4H_8 + H_3O^+ + NO_3^- \quad (B)$$

In the case of benzyl nitrate no olefin is produced but the solvolysis to benzyl alcohol and nitric acid (C) is accompanied by a likewise first order formation of benzaldehyde and nitrous acid (D).

$$C_6H_5CH_2ONO_2 + 2H_2O \xrightarrow{k_3} C_6H_5CH_2OH + H_3O^+ + NO_3^- \quad (C)$$

$$C_6H_5CH_2ONO_2 \xrightarrow[(H_2O)]{k_4} C_6H_5CHO + HNO_2 \quad (D)$$

These first order reactions are accompanied by second order reactions with hydroxyl ion leading to the same products.

$$C_6H_5CH_2ONO_2 + OH^- \xrightarrow{k_5} C_6H_5CH_2OH + NO_3^- \quad (E)$$

$$C_6H_5CH_2ONO_2 + OH^- \xrightarrow{k_6} C_6H_5CHO + H_2O + NO_2^- \quad (F)$$

Experimental

Apparatus.—Only calibrated weights and volumetric apparatus were used. The temperatures were determined by thermometers calibrated by the Bureau of Standards. The thermostats used at 25 and 50° were of the conventional type; that employed at 0.3 and 10° was the one previously described.[3] The timing of the very fast runs was done with an A. R. & J. E. Meylan one-fifth second split timer.

Tertiary Butyl Nitrate.—Following the procedure of Michael and Carlson,[4] *t*-butyl nitrate was prepared from tertiary butyl alcohol (Eastman Kodak Co. best grade) and 98.6% nitric acid. The product was separated by distillation under vacuum through a 20-in. jacketed column with reflux ratio kept high by means of a cold-tip finger condenser; b. p. 22–23° at 4 mm. The last traces of methylene chloride and nitric acid were removed by repeated partial crystallization without solvent. The crystals were allowed to form slowly until approximately three-fourths was crystallized and the remaining liquid removed through a sintered glass filter. The degree of purity was tested in an air-jacketed test-tube cooled by solid carbon dioxide at a rate of one degree per minute. The material accepted as pure gave a constant freezing point out to half crystallization, was colorless and free from acid; m. p. −34 to −35°. Titration of the acid formed on complete hydrolysis indicated 99.9% purity. For further test 5.00 g. of the *t*-butyl nitrate was added to 8.0 g. of dimethylaniline and warmed. The nitrate salt which crystallized on cooling was washed free of dimethylaniline with dry ether, yielding 7.21 g.; calcd. 7.23; m. p. 82–83°.

In some preparations the ester was colorless but not free from acid after the above recrystallization procedure. Rate measurements on this ester agree within experimental error with those made on the pure material when allowance is made for the effect of electrolyte. The purified ester was sealed in amber ampoules and kept frozen in dry-ice until used.

Benzyl Nitrate.—Following the procedure of Nef,[5] benzyl nitrate was prepared from powdered silver nitrate and benzyl chloride (Mallinckrodt Analytical grade) in dry ether. For complete conversion it was found desirable to add fresh silver nitrate from time to time. After twenty hours at room temperature the ether was distilled off and the product held at 70–75° for five hours. After cooling, the liquid was decanted and the residue extracted with ether and dried over calcium chloride. Fresh silver nitrate was added to the filtered ether solution, the ether removed and the benzyl nitrate distilled directly from silver nitrate. The main fraction (b. p. 72.5–73.5° at 4–5 mm.) was found by refluxing with alcoholic silver nitrate to be chloride free, $n^{25}D$ 1.5180. Redistillation gave fractions with the same constant refractive index. *Anal.* Calcd. for $C_7H_7NO_3$: C, 54.9; H, 4.61. Found: C, 55.2; H, 4.63. The purified ester was kept in a dark bottle in a desiccator over phosphorus pentoxide.

Other Materials.—1,4-Dioxane (Carbide and Carbon Chemical Co.) was purified in 3–4 liter quantities as described by Beste and Hammett.[6]

Sodium perchlorate solution was prepared from Mallinckrodt A. C. S. grade perchloric acid 99.8% neutralized with carbon dioxide-free sodium hydroxide solution. Tests on this solution showed no detectable traces of chloride. The perchloric acid solution that was added to runs was made from the same stock acid.

The potassium bromide and potassium bromate used for the olefin determination and the potassium nitrate and lithium nitrate used in the runs were A. C. S. grade, recrystallized from water and dried over phosphorus pentoxide. Anhydrous lithium nitrate is so hygroscopic that the concentration was probably lower than that indicated because of water absorbed in the weighing process.

The primary standard for titration was Bureau of Standards acid potassium phthalate.

Method.—The solvent in all kinetic experiments was a mixture of dioxane and water in the proportions indicated; that is, in an experiment in "60% dioxane" the proportions of dioxane and water were 60 to 40 by weight. In the case of experiments containing sodium hydroxide, sodium perchlorate or perchloric acid, these solutes were introduced as solutions at the time the solvent was prepared, and correction was made for the amount of water displaced by these solutes. All other solutes were weighed out and added directly.

In starting experiments the reaction bottle with all solutes except the ester was placed in the thermostat to reach temperature equilibrium. In the case of *t*-butyl nitrate, the ester was then removed from the dewar where it was stored, allowed to melt and the approximate amount transferred by means of a graduated pipet, the bottle was shaken and the initial time taken. The exact initial ester concentration was determined by delivering duplicate samples into 40% dioxane at room temperature. The hydrolysis in this medium is complete in a few minutes and the total ester concentration was found by titration of the acid produced. Samples for analysis were withdrawn at convenient intervals using a 5-ml. pipet and delivered into cold dioxane of such volume that in the following titration the dioxane composition always exceeded 80%. In the runs at 0 and 10° the pipet was kept in a well in the thermostat between samples.

In the case of benzyl nitrate, after the mixture had reached temperature equilibrium in the thermostat, the ester was weighed in and the initial time taken. At convenient intervals 10-ml. samples were withdrawn for analysis. In the runs at 50° the dried pipet, initially at room temperature, delivered reproducible volumes of the reaction solution if the sampling was done rapidly. The water reaction was arrested by pipetting the samples into dioxane at room temperature. The hydroxide reaction was stopped by pipetting the samples into an excess of standard nitric acid and dioxane. To reduce further reaction to a negligible level and to prevent the unreacted benzyl nitrate from separating, the dioxane was kept above 50% in the titrating flask. In the solvolytic runs where the percentage benzaldehyde was determined the solvent containing all solutes except the ester was cooled to ice temperature, the ester added and portions of this reaction mixture were placed in 10-ml. ampoules. After freezing solid in a dry-ice bath the ampoules were evacuated and sealed. The initial time was taken when the ampoules were placed in the thermostat.

Isobutene was determined by a modification of the method of Lucas and Eberz[7] using a standard bromide-bromate solution to liberate bromine and back-titrating with thiosulfate after conversion to iodine. The sample was delivered into glass-stoppered iodine flasks containing a five-fold excess of the neutral bromide-bromate solution; 5 ml. of 6 *N* sulfuric acid was quickly added and the walls washed down with 15 ml. of water. After tightly stoppering, the flask was kept in the dark and shaken frequently for five minutes. The flask was then chilled under running water and saturated, freshly-prepared potassium iodide solution was allowed to be sucked in by carefully lifting the stopper slightly. When a few cc. had been admitted, the stopper was replaced and the flask thoroughly shaken. The stopper was washed free of iodine and removed, and the excess iodine was titrated with thiosulfate. The blank depends slightly on the volume of dioxane in the sample and is reproducible. A correction must be made for the olefin produced by the nearly instantaneous hydrolysis of the unreacted *t*-butyl nitrate. Using the above procedure with *t*-butyl nitrate in 100% dioxane, four blank experiments showed that 2.99 ± 0.01% of the ester was converted to isobutene durings its rapid hydrolysis.

Benzaldehyde was determined by the method of Eitel and Lock,[8] by producing the 2,4-dinitrophenylhydrazone of benzaldehyde and determining it gravimetrically. For small samples drying to constant weight in a vacuum desiccator over phosphorus pentoxide was found more satisfactory than heating in the oven. To prevent the separation of unreacted benzyl nitrate the samples of solution tested had to be kept small. Somewhat larger samples could be added where the precipitating medium for the hydrazone was 50% cold alcohol. The two methods gave consistent results when used in the runs or with standard solutions of benzaldehyde to which benzyl nitrate had been added.

In following the acid production, phenolphthalein is unsatisfactory where much dioxane is present. Brom cresol purple gave a sharp end-point in media containing about 50% dioxane and was consequently used in titrations of the benzyl nitrate runs. Brom phenol blue gave a very sharp end-point in 80–90% dioxane and was used in the *t*-butyl nitrate runs.

Rate Calculations.—The following abbreviations will be used in this section: a is the initial concentration of tertiary butyl nitrate, b initial concentration of hydroxide, c initial concentration of benzyl nitrate, x concentration of acid produced at time t, t time in seconds. The *t*-butyl group will be written Bu, the benzyl group Bz and the phenyl group Ph.

Data for the water reactions (A) and (B) were calculated according to the equation $\ln a/(a - x) = kt$ where $k = k_1 + k_2$; $a = [H^+]_\infty$ or $\{[H]^+_\infty - [H^+]_t\}_0$ in the cases where $[H^+]_0 \neq 0$ and $(a - x) = [H^+]_\infty - [H^+]_t$. The slope of the plot of $\ln (a - x)$ against t increases slightly during the course of a given experiment. For purposes of comparison the initial value of k was obtained from the empirical equation $-\ln (a - x) = -\ln a + (k)_0 t + Kt^2$; the coefficients of this equation were calculated by the method of averages,[9] whereby adjacent experimental points were used to obtain each of the three simultaneous equations. The values of k_1 and k_2 were established by determination of the per cent. olefin produced.

In the runs in the presence of sodium chloride and sodium toluenesulfonate the curve follows too complicated a course to be satisfied by this three constant equation. This is probably because the nitrate ester is gradually being replaced by chloride or toluenesulfonate ester which have slower rates of hydrolysis. Here the initial rates were determined by means of graphical differentiation.

Data for the water reactions of benzyl nitrate (C) and (D) were calculated according to the equation $\ln c/(c - x) = k't$ where $k' = k_3 + k_4$. Here again the plot of $ln\ (c - x)$ against time gave an increasing slope and the initial value was found by the method of averages. The respective values of k_3 and k_4 were established by determination of the per cent. benzaldehyde produced.

In the presence of hydroxyl ion we are concerned with reactions (C), (D), (E) and (F). The rate of disappearance of nitrate ester is given by

$$-\mathrm{d}[BzNO_3]/dt = k_3[BzNO_3] + k_4[BzNO_3] + k_5[BzNO_3][OH^-] + k_6[BzNO_3][OH^-] \quad (1)$$

which may be written

$$-\mathrm{d}[BzNO_3]/dt = k'[BzNO_3] + k''[BzNO_3][OH^-] \quad (2)$$

where

$$k' = k_3 + k_4 \text{ and} \quad (3)$$

$$k'' = k_5 + k_6 \quad (4)$$

The above equation is best solved by writing in the form

$$-\mathrm{d}[BzNO_3]/dt = k'''[BzNO_3][OH^-] \quad (5)$$

where

$$k''' = k'' + (k'/[OH^-]) \quad (6)$$

The value of k''' may be obtained by a plot of $\frac{1}{c - b} \ln \frac{c - x}{b - x}$ against time. The method of averages is again used to determine the initial value of the slope. The value of $(k'')_0$ may then be evaluated from equation (6) using the $(k')_0$ independently determined from hydrolysis measurements. Some uncertainty exists concerning the value of $(k')_0$ to be used. Those independently

(7) Lucas and Eberz, *ibid.*, **56**, 461 (1934).

(8) Eitel and Lock, *Monatsh.*, **72**, 385 (1939).

(9) Daniels, "Mathematical Preparation for Physical Chemistry," McGraw Hill Book Co., Inc., New York, N. Y., 1928, p. 235.

measured were of necessity obtained in the absence of hydroxyl ion. The data on *t*-butyl nitrate indicated that a solvolysis reaction may proceed more slowly in the presence of hydroxyl ion than in the solvent alone and at a much slower rate than in the presence of a corresponding concentration of sodium perchlorate. The rate constants were therefore evaluated on the assumption that $(k')_0$ is not changed by the addition of sodium hydroxide.

Examination of these four equations shows that the rate of benzaldehyde production is given by

$$d[PhCHO]/dt = k_4[BzNO_3] + k_6[BzNO_3][OH^-] \quad (7)$$

and combining equations (5) and (7), we obtain

$$\text{Fraction PhCHO formed in reaction} = \frac{k_4[BzNO_3] + k_6[BzNO_3][OH^-]}{k'''[BzNO_3][OH^-]} \quad (8)$$

Solving for k_6

$$k_6 = k''' x \text{ (fraction PhCHO)} - (k_4/[OH^-]) \quad (9)$$

and using this value of k_6 we obtain k_5

$$k_5 = k'' - k_6 \quad (10)$$

Errors.—Since the results of this research are based on the determination of initial slopes of curves, it is difficult to estimate the precision with which specific rates are known. In general it involves a consideration of duplicate experiments and of the deviation of the individual points of the run from the empirical equation which best fits the data. Careful examination of the data indicates a probable error of 1.5% in $(k)_0$ and $(k')_0$ each of which is the sum of two solvolytic reactions. The percentage of olefin produced is the average of two or three independent determinations and the precision varies from 1 part in 50 to 1 part in 400 as the proportion of olefin increases. Consequently the precision of the constant k_2 varies in the same way. The error in k_1 will be about the same as that in k. The reported percentage of benzaldehyde is also the average of two or more determinations and the precision varies from 1 part in 5 to 1 part in 60 according to the proportion of benzaldehyde. The initial specific rate constants $(k''')_0$ in the hydroxide reaction have a probable error of 2.0 to 2.5% but the lack of precision in the benzaldehyde determination increases the probable error of $(k_5)_0$ and $(k_6)_0$ to 3–5%.

Sample Data.—For the sake of uniformity the constants reported in the tables of results are those at the initial time. It is, however, of some importance to indicate how the specific rate changes during the course of a reaction; a skeleton record is therefore given for a typical experiment on each of the reactions studied (Tables I, II and III).

In Table I the values of k were calculated from the empirical equation

$$-\ln(a - x) = 2.3497 + (3.33_5 \times 10^{-5})t + (8.92 \times 10^{-11})t^2$$

This equation was obtained from the experimental points of Table I by grouping the first three, the second three and the last three to obtain three simultaneous equations according to the method of averages mentioned above. For the olefin determination the ester concentration was found by solving the above equation for $(a - x)$ at the given time. Applying the correction for the olefin produced by the unreacted butyl nitrate, the percentage of x, or moles reacted, going to olefin is determined. The isobutene concentration given in quotation marks is the indicated olefin concentration from the thiosulfate titer, before the correction is made.

In Table II the values of (k') were calculated from the empirical equation

$$-\ln(c - x) = 2.2562 + (1.57_1 \times 10^{-6})t + (2.16 \times 10^{-13})t^2.$$

This equation was obtained like the one for Table I by grouping the points in threes to make three simultaneous equations. The amount of benzal-

dehyde was determined gravimetrically in the way indicated and converted to molar concentration of aldehyde.

TABLE II

TYPICAL EXPERIMENTAL RECORD FOR THE WATER REACTION OF BENZYL NITRATE, TIME IN SECONDS

Expt. 151: 60% dioxane at 50°; initial concn. $BzNO_3$ = 0.10530.

t, sec.	Acid titer[a]	$[H_3O^+]$	$-\ln[BzNO_3]$	$(k') \times 10^6$

t, sec.	x	2,4-Dinitrophenylhydrazone,[b] g.	[PhCHO]	% PhCHO
400068	0.05131	0.0098	0.003351	6.5
582912	.06633	.0116	.003966	6.0
			Av.	6.25

[a] In ml. of 0.02652 N NaOH per 10.047 ml. sample.
[b] From 10.222 ml. sample.

In Table III the values of (k''') were calculated from the empirical equation

$$\frac{1}{b-c}\ln\frac{b-x}{c-x} = 10.959 + (4.69_3 \times 10^{-4})t + (3.97 \times 10^{-9})t^2$$

This equation was obtained from the experimental points by grouping as before. The value of x was obtained from this equation for the calculation of the per cent. benzaldehyde produced. While in this experiment the percentage converted to benzaldehyde appears to increase slightly during the course of the reaction, this effect was not reproducible and in calculation of (k_5) and (k_6) by equations (9) and (10) the average value was used.

Results

Data for tertiary butyl nitrate solvolysis in the presence and in the absence of various salts are given in Tables IV and V, the data being subdivided according to the medium and temperature indicated. In the experiments listed in Table IV only the total rate constant $(k)_0$ was determined, while in those in Table V $(k)_0$ is divided into $(k_1)_0$ and $(k_2)_0$ and the percentage olefin produced is indicated. By comparison of Table I and Table IV it may be seen that the values of k in a given reaction mixture drift upward as the reaction proceeds approximately as one would predict from the changing ester concentration and the increasing concentration of nitrate ion.

Data for benzyl nitrate solvolysis in 60% dioxane at two temperatures are given in Table VI, the constants listed being $(k')_0$ the sum in each case of $(k_3)_0$ and $(k_4)_0$; in Table VII experiments where the percentage benzaldehyde produced was determined are listed and the corresponding values of $(k_3)_0$ and $(k_4)_0$ are indicated. In Table VIII are listed data showing $(k_5)_0$ and $(k_6)_0$ for the benzyl nitrate–hydroxyl ion reaction.

In Table IX are listed the energies of activation of the various reactions.

TABLE III

thoroughly studied reactions of tertiary butyl halides, which likewise lead partly to alcohol and partly to olefin.[11]

Like benzyl chloride in a similar medium[6] benzyl nitrate shows a solvolytic reaction which predominates in neutral or acid media and a hydroxyl ion displacement which predominates in alkaline media. These reactions are accompanied by an oxidation–reduction reaction producing benzaldehyde which is both solvolytic and hydroxyl ion catalyzed.

Our data show that none of these reactions are catalyzed by acids in dilute solution.

Salt and Medium Effects.—As has been observed previously with other esters,[6,12] the specific rates of the solvolytic reactions (A) and (C) decrease with increasing concentration of ester. Table IV shows the sensitivity of such reactions to the composition of the medium, the rate increasing somewhat more than a thousand-fold in going from 95% to 60% dioxane, the temperature remaining constant. Table X shows for a 0.1 *M* solution of ester the percentage changes in specific rate produced by the addition of various solutes in the same concentration.

Similar but even larger effects are observed in the second order displacement reaction of benzyl nitrate with hydroxyl ion. At 25° $(k_6)_0$ is essentially unaffected by variations in concentration of ester and of hydroxyl ion. However, at 50°

Discussion

General.—Like other *t*-butyl esters[10] the nitrate ester shows no acceleration of hydrolysis by hydroxyl ion except at high concentration of dioxane (see Table IV, hydroxide–perchlorate solute in 75% dioxane). In 60% dioxane a small retardation is produced by sodium hydroxide, the occasion for which will be discussed later. In all important respects the reaction behaves like the $(k_6)_0$ increases with decreasing concentration of either reactant, increasing by 57.0% in going from the largest ester and hydroxyl ion concentration to the lowest in each. At both temperatures $(k_5)_0$ shows an increase with decreasing ester concentration and a decrease with decreasing hydroxyl ion concentration. Since the ionic strength is maintained constant by the introduction of sodium perchlorate, the change in rate

Energies of Activation.—The Arrhenius energies of activation appear in Table IX. Those for *t*-butyl nitrate are in excellent agreement with those observed in the unimolecular reactions of alkyl halides[10b] which all lie within the range 22 ± 2 kcal. The difference between k_1 and k_2 is consistent with those observed for unimolecular solvolytic reactions of secondary and tertiary halides and for alkyl sulfonium ions where the increases in the proportion of olefin produced with rise of temperature correspond to activation energies which are larger by about 2–5 kcal. for the elimination than for the substitution.[13]

The energy of activation for the solvolytic reaction $(k_3)_0$ of benzyl nitrate is appreciably larger than that for benzyl chloride,[14] being 24,170 as compared to 20,600. The energy of activation for the hydroxyl ion displacement $(k_5)_0$ is even more strikingly higher than for the corresponding displacement reactions of benzyl chloride; 23,970 compared with 18,400 for the hydroxyl ion dis-

placement of benzyl chloride in 50% acetone[14a] and with 18,300 for the iodide ion displacement of benzyl chloride in acetone.[14b] The significance of these differences will be discussed under the mechanism of the solvolytic reaction.

Kinetics of the Elimination Reaction.—Table V gives the proportions of olefin formed in the solvolysis of tertiary butyl nitrate in various media at various temperatures. These correspond in every way with those observed for tertiary butyl halides in water–alcohol media.[13] In agreement with the *t*-butyl halides the ratio of elimination to the over-all reaction decreases as the ionizing power of the medium increases and increases with increasing temperature. The rate constant $(k_2)_0$ is unchanged by the basicity of the reagent (comparison of hydroxyl ion and perchlorate ion runs) and has a positive salt effect. The latter feature has not heretofore been reported for such reactions and is probably, although not certainly, beyond experimental error. As indicated in Table IX the increase in per cent. olefin with rising temperature leads to a difference in the energies of activation of the two competing solvolytic reactions of approximately two kilo-calories.

Mechanism of the Solvolytic Reaction.—The reaction of an alkyl nitrate with water may be (1) a displacement of nitrate ion by a water molecule; (2) a true solvolysis, *i. e.*, an incipient solvation of the anion leading to a rupture of the carbon–oxygen bond with more or less transient formation of a carbonium ion; (3) a rupture of the oxygen–nitrogen bond by a mechanism analogous to the hydrolysis of a carboxylic ester.

The great similarity of the solvolysis of *t*-butyl chloride and of *t*-butyl nitrate, notably the near identity of energy of activation and of the ratio of olefin to alcohol in the reaction product, strongly supports the conclusion of an identity of mechanism. This is, no doubt, the mechanism (2) above, the true solvolysis.

On the other hand, the marked difference in energies of activation of the reactions of benzyl chloride and benzyl nitrate suggests the idea of a materially different mechanism. There is much reason for expecting the reaction of the chloride to partake of both mechanisms (1) and (2), in particular the fact that a strong hydroxyl ion displacement is observed. Since the rates of reaction of nitrate and chloride are nearly the same the entropy of activation must be much greater in the nitrate case than in the chloride.

There is evidence that solvolytic reactions of halides which show marked hydroxyl ion displacement reactions and which may therefore be expected to react significantly by mechanism (1) are likely to show smaller entropies of activation than the reactions of halides which go by mechanism (2). Thus benzylidene chloride which shows no measurable hydroxyl ion reaction has an entropy of activation for the solvolytic reaction greater by 11.2 cal./dg. than that of benzyl chloride.[14a]

It is probably also significant that the entropies of activation of substituted benzyl halides may differ considerably: thus *p*-methylbenzyl chloride has an entropy of activation 6.8 cal./dg. greater than benzyl chloride while *p*-nitrobenzyl chloride has an entropy of activation 1.8 cal./dg. lower.[15]

Kinetics of *t*-Butyl Nitrate Solvolysis.—The large dependence of rate on solvent composition

(15) Oliver, *Rec. trav. chim.*, **56**, 247 (1937).

and the characteristic salt effects shown, clearly indicate that tertiary butyl nitrate reacts with water by a true solvolysis. The striking difference between the effects of sodium perchlorate or perchloric acid on one hand and of potassium nitrate, sodium chloride or sodium toluenesulfonate on the other parallels those observed in the hydrolysis of tertiary butyl halides, various benzhydryl halides[16] and benzyl chloride.[6] If the rate determining step is the ionization

$$R - X \longrightarrow R^+ + X^-$$

then the rate of reaction will be increased by the presence of electrolyte. This effect is observed in the case of perchlorate ion. The decrease from this rate produced by nitrate, chloride, azide or acetate ion has then been interpreted to mean that some of the carbonium ion was diverted to form either the original ester ("common ion" effect) or a more stable ester.

$$R^+ + X^- \longrightarrow RX$$
$$R^+ + OAc^- \longrightarrow ROAc$$

The marked reduction in rate by hydroxyl ion which we have observed cannot however be explained by any such diversion of the carbonium ion, because attack by hydroxyl ion produces alcohol and would not decrease the rate as measured by acid production. Such an effect is understandable only in terms of a decreased activity on the part of one of the reactants, either water or butyl nitrate. That the effect is through the water, *i. e.*, by way of a varying affinity of the different anions for water molecules, is suggested by the fact that the order of the various ions is approximately that of the Hofmeister series.[17]

In an effort to establish their effect on the activity of the water, the freezing points of 60% dioxane containing 0.108 *M* concentration of various solutes were measured in a standard Beckmann freezing point apparatus, the temperature indicated being that of disappearance of sharply defined crystals of dioxane. That the crystallizing phase was dioxane was shown in the case of solvent alone and for the hydroxyl solution by cooling 2–3° below the temperature of first crystals and removing the remaining liquid through a sintered-glass filter under suction. The crystals were melted and distilled free of traces of electrolyte, and the composition measured by refractive index. In both cases the liquid contained more than 80% dioxane. The temperatures in Table XI are average values of four determinations and are probably reliable to ±0.05, that for 60% solvent being consistent with data by Hovorka, Schaefer and Dreisbach, for that medium.[18]

TABLE XI

FREEZING TEMPERATURE DATA FOR 60% DIOXANE CONTAINING 0.108 *M* CONCENTRATIONS OF ELECTROLYTE

NaOH	−2.70	KNO_3	−3.92
NaAc	−3.08	Solvent	−4.65
NaCl	−3.35	$NaClO_4$	−4.80

For this three-component system at equilibrium the Gibbs–Duhem relationship must hold

$$N_1 d\mu_1 + N_2 d\mu_2 + N_3 d\mu_3 = 0$$

subscript 1 referring to water, 2 to dioxane and 3 to the electrolyte to be added, and for constant ratio N_1/N_2 we may write it in the form

$$N_1 \left(\frac{d\mu_1}{dN_3}\right)_{N_1/N_2} + N_2 \left(\frac{d\mu_2}{dN_3}\right)_{N_1/N_2} + N_3 \left(\frac{d\mu_3}{dN_3}\right)_{N_1/N_2} = 0$$

Since $(d\mu_3/dN_3)$ is positive both $(d\mu_1/dN_3)$ and $(d\mu_2/dN_3)$ might be negative, *i. e.*, both μ_1 and μ_2 might decrease with increasing electrolyte concentration. If, however, one bracketed term can be shown to be positive the other bracketed term must be sufficiently negative to maintain the condition that the sum of the three terms is zero. Since the freezing temperature of the solution with respect to dioxane is raised then the activity of the dioxane in the solution must also be raised, the elevation of the freezing point being a measure of the relative positive value of $(d\mu_2/dN_3)$. In comparing various electrolytes $(d\mu_3/dN_3)$ is approximately a constant and $(d\mu_1/dN_3)$ must vary inversely with $(d\mu_2/dN_3)$. Therefore when the added electrolyte tends to raise the activity of the dioxane component strongly it must act to lower the activity of the water to a corresponding extent.

If the decrease in rate in the presence of hydroxide must be interpreted in terms of such a decrease in the water activity, then the effect of chloride, acetate and nitrate on the freezing point strongly suggests an analogous explanation of their action on the rate of the solvolytic reaction. The data therefore weaken materially the argument of Ingold and Hughes and of Beste and Hammett that direct kinetic evidence exists for a carbonium ion intermediate in the solvolytic reaction.

Kinetics of the Oxidation–Reduction Reaction.—Table VII gives the proportion of benzaldehyde formed in the solvolysis of benzyl nitrate, and Table VIII gives the proportion formed in the hydroxyl ion reaction.

The two oxidation–reduction reactions which lead to benzaldehyde and nitrate appear to have the same order as the two hydrolytic ones, although the proportion of benzaldehyde does show some small dependence upon the concentration of hydroxyl ion. In view of the importance recently ascribed to a radical chain mechanism in the Cannizzaro reaction[19] the experiments using "aged" solvent containing large proportions of peroxides are of interest. In the first order reaction the total rate of reaction of benzyl nitrate was unchanged, but the proportion of benzaldehyde produced was approximately doubled. In the reaction with hydroxyl ion the total rate of reaction was materially increased, while the proportion of benzaldehyde decreased slightly if at all.

As was to be expected from the well-known behavior of nitroglycerine and nitrocellulose with alkaline reducing agents, hydroquinone completely suppressed the formation of benzaldehyde in alkaline medium. A similar suppression of aldehyde formation appeared in neutral and acid solutions also. In alkaline media hydroquinone materially increased the total rate of reaction of benzyl nitrate. This suggests some direct attack of hydroquinone or of its ions upon the benzyl nitrate. No such change in the total rate of reaction was observed in neutral or acid solutions.

At the present stage of our knowledge it would seem to be premature to offer any mechanism for the oxidation–reduction reaction.

(19) Weiss, *Trans. Faraday Soc.*, 782 (1941).

Summary

The reactions with water and with sodium hydroxide of *t*-butyl nitrate and of benzyl nitrate have been studied kinetically in various dioxane–water mixtures.

The reaction of *t*-butyl nitrate produces alcohol and olefin in proportions similar to those in which they are formed from *t*-butyl halides. Since, further, the energies of activation of nitrate and halide reactions are nearly identical, an identity of mechanism is strongly indicated. No appreciable reaction with hydroxyl ion or catalysis by acids has been observed.

Although perchlorate ion accelerates, hydroxyl ion retards and other anions have intermediate effects which parallel their effects upon the activity of water in the medium. This materially weakens the direct kinetic argument of Ingold and Hughes and of Beste and Hammett for a free carbonium ion intermediate in solvolytic reactions.

The solvolysis of benzyl nitrate to benzyl alcohol has a much higher energy and entropy of activation than the analogous reactions of benzyl chloride. This suggests that the reaction of the nitrate partakes more largely of a true solvolysis rather than a displacement of anion by water molecule than does that of the halide. There is a pronounced acceleration by hydroxyl ion but acids have no effect.

The conversion of benzyl nitrate to benzaldehyde and nitrite also shows both a kinetically first order reaction of benzyl nitrate and a second order reaction with hydroxyl ion. Both are completely suppressed by the addition of hydroquinone.

The Hydration of Isobutene in Dilute Nitric Acid

BY GLENNARD R. LUCAS AND LOUIS P. HAMMETT

While the rate of hydration of isobutene in dilute nitric acid at constant ionic strength is strictly first order with respect to isobutene and oxonium ion, the specific rate constant divided by oxonium ion concentration varies with ionic strength by a factor of 2.64 between ionic strengths of 0.1 and 2.[1] The effect is approximately linear so that the expression for the rate constant can be written in the form

$$k = k' [H_3O^+](1 + k''\mu)$$

and the effect is of unexpected magnitude according to the Brönsted theory of salt effects.[2] Since the ionic strength was varied by the addition of potassium nitrate it is interesting to consider whether the effect can be accounted for in terms of the formation of *t*-butyl nitrate as a transient intermediate. We have investigated this possibility in connection with a recent study of *t*-butyl nitrate hydrolysis in water–dioxane mixtures.[3]

The reaction of an alkyl chloride and mercuric nitrate has been thoroughly investigated and the lack of correspondence between effects on rate and product composition clearly indicates that the reaction occurs by way of a carbonium ion intermediate.[4] We have therefore examined the reaction between *t*-butyl chloride and mercuric nitrate in various dioxane–water mixtures. We have also investigated the effect of the partial substitution of dioxane for water on the rate of reaction of isobutene in dilute nitric acid solutions and established under what conditions *t*-butyl nitrate is found in the reaction product.

Experimental

Materials.—*t*-Butyl chloride (Eastman Kodak Co. best grade) was fractionated, the middle half being taken; b. p. 50.9°. C. P. mercuric nitrate was used directly. The isobutene was prepared by refluxing *t*-butyl alcohol (Eastman best grade) with crystallized oxalic acid[5] and passed through wash bottles containing water and stored over water. When used it was passed from the storage bottle through a long drying tube containing soda lime and calcium chloride. Reagent grade concentrated nitric acid was used in preparing the solutions containing nitric acid. The lithium nitrate was A. C. S. grade recrystallized from water and dried over phosphorus pentoxide.

(4) Roberts and Hammett, *ibid.*, **59**, 1063 (1937).
(5) Hurd and Spence, *ibid.*, **51**, 2561 (1929).

Method.—The method of preparing solutions was that followed in the solvolytic studies of *t*-butyl nitrate.[3] The *t*-butyl chloride was sealed and weighed in tared thin glass bulbs blown from 6-mm. tubing. The procedure was to deliver the approximate amount of the cooled ester into the tared bulb through the 6-mm. neck which was 3–4 inches long; bulb and contents were cooled to dry-ice temperature and the neck sealed quickly in an oxygen flame, preserving the portion of the neck which had been sealed off to be weighed with the sealed bulb. In starting an experiment the reaction bottle containing all the solutes except the ester was placed in the thermostat and brought to temperature equilibrium. The bulb containing the ester was then broken beneath the surface and the initial time taken.

With *t*-butyl chloride Roberts' method of determination of the product ratio by determination of both chloride ion concentration and acidity[4] is unsatisfactory since the hydrolysis of *t*-butyl chloride is appreciable under the conditions of the chloride determination. It was found, however, that the primary reaction between the *t*-butyl chloride and mercuric nitrate producing *t*-butyl alcohol, *t*-butyl nitrate and isobutene is complete within a small fraction of the time required for the subsequent hydrolysis of the *t*-butyl nitrate formed in the reaction. Hence after the preliminary experiments no effort was made to determine the initial slopes, samples being taken at the frequencies previously found satisfactory in the hydrolysis of *t*-butyl nitrate. The reaction was stopped by running a sample into a cold solution of 50% alcohol and 50% dioxane, in which medium lithium chloride was sufficiently soluble to remove the excess mercuric ion, and the titration of acidity was carried out with standard sodium hydroxide using brom phenol blue indicator.

The experiments on the hydration of isobutene were of a semi-quantitative nature since we were interested in the order of magnitude of the rates of reaction in the various media. Into the proper dioxane–water mixture a known volume of dry isobutene gas was bubbled, the acid was added by pipet and the initial time was noted. The sampling was done by a crude modification of the method of Lucas and Ebertz.[1] The end of a pipet similar to the one they used was passed through a two-hole rubber stopper, the other hole containing a short piece of tubing attached to an air bulb. At the time of sampling this rubber stopper was quickly inserted in place of the ground glass stopper of the reaction flask so that the flask was never open for any appreciable time. Pumping the bulb forced the liquid into the pipet until it overflowed and the isobutene concentration was then determined as previously described.[3]

The determination of the amount of *t*-butyl nitrate produced in the hydration reaction offered some difficulty, because the errors in sampling and titration were of the order of the difference between the initial acid titer and that at the time of measurement. The method finally adopted consisted of running the sample into approximately 100 ml. of cold dioxane, adding the approximate amount of 0.1 *N* sodium hydroxide and completing the titration to a

TABLE I

PRODUCT COMPOSITION IN THE REACTION OF *t*-BUTYL CHLORIDE AND MERCURIC NITRATE IN DIOXANE–WATER MIXTURES

t, °C.	% Dioxane in solvent	Molar concentration of BuCl	$Hg(NO_3)_2$	HNO_3	$LiNO_3$	% Nitrate ester	% Olefin

25	95	.0248	.0274	.0138	.0977	58.5	

brom phenol blue end-point with 0.025 *N* sodium hydroxide. The flask was then allowed to warm up and to stand for twenty-four to thirty-six hours. During this period the *t*-butyl nitrate hydrolyzes and titration to a new end-point gives the amount of nitrate ester.

Rate Calculations.—The specific rate constant for the disappearance of isobutene was calculated from the first order equation $\ln a/(a - x) = kt$ where a is the initial concentration of the isobutene and $(a - x)$ is the concentration at time t, t in seconds.

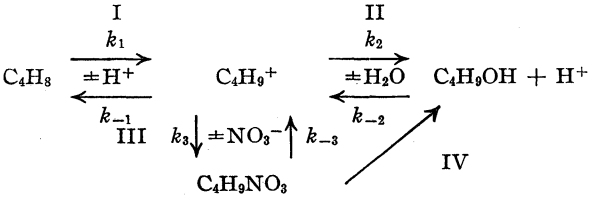
The fraction of the mercuric nitrate–*t*-butyl chloride reaction product which is *t*-butyl nitrate was determined by a plot of $\ln (b - x)$ against time, where b is the initial concentration of *t*-butyl chloride and x is the number of moles reacted as determined by titration at time t. That this is actually the plot of the hydrolysis of the *t*-butyl nitrate formed in the reaction was established by comparing the slope of the curve with curves independently determined for *t*-butyl nitrate. The slopes agree within the experimental error. The intercept of the plot at zero time, converted to molar concentration, was used in calculating the per cent. nitrate ester produced. The percentage of olefin formed in the primary reaction between the *t*-butyl chloride and mercuric nitrate was estimated from determinations of the isobutene concentration at several different times early in the run, effort being made not to include any resulting from the hydrolysis of the *t*-butyl nitrate.

Results

Data for the *t*-butyl chloride–mercuric nitrate reaction are given in Table I. The rates of disappearance of isobutene are given in Table II, together with the amounts of *t*-butyl nitrate appearing in the reaction product.

Discussion

If we consider the hydration of olefins in dilute nitric acid under conditions where *t*-butyl nitrate is formed, the simplest picture we could give would be



In order that the increase in rate of hydration of olefin upon the addition of nitrate ion be explained by the formation of the unstable intermediate, *t*-butyl nitrate, the following conditions must hold

1. Reaction I cannot be the rate determining step $-k_{-1} \gg k_2$.
2. To show first order kinetics in respect to isobutene an equilibrium concentration of $C_4H_9^+$ must be maintained $-k_{-1} \gg k_2$.
3. Step IV, another route between *t*-butyl nitrate and alcohol, must be postulated.

The rate of reaction in the absence of nitrate ion would then be the relatively slow addition of a water molecule; when nitrate ion is present an alternate path is possible. The linearity of the salt effect on the rate would simply require that k_2 be unaffected by the addition of nitrate ion. Hence

$$k_{H_3O^+} = k_{obs.}/[H_3O^+] = k_2 + k_3[NO_3^-]$$

from which $k_{H_3O^+}$ would be a linear function of the nitrate ion concentration.

Such a theory though plausible is in conflict

TABLE II

EFFECT OF DIOXANE ON THE RATE OF DISAPPEARANCE OF ISOBUTENE FROM 0.1 *M* HNO_3 AT 25° (TIME IN SECONDS)

Medium	$k \times 10^6$	% Nitrate ester found in product
Water	39	None
50% Dioxane	3.3	None
95% Dioxane	0.14	25–30[a]

[a] In 0.288 *N* HNO_3.

with certain experimental facts. The reaction of *t*-butyl chloride with mercuric nitrate, by analogy with the corresponding benzyl chloride system, must occur by way of a carbonium ion. If $k_{-1} \gg k_2$ then the ratio of olefin to alcohol should be very large. Actually in 75% dioxane the respective percentages of olefin, nitrate and alcohol are shown in Table I to be approximately 5:15:80 where the nitrate ion concentration is 0.014 and 5:25:70 where the nitrate ion concentration is 0.130.

Furthermore the effect of dioxane on the rate of disappearance of olefin seems to be inconsistent with any mechanism involving the combination of isobutene, oxonium ion and nitrate ion to give *t*-butyl nitrate since the rate of such a reaction should be affected by a change in the medium in the same way as is the equilibrium constant of the formation of acetic acid from its ions, which increases markedly with increasing dioxane content.[6]

The amount of *t*-butyl nitrate found in the hydration reaction in 95% dioxane appears to be of the order expected from the product ratio observed in the mercuric nitrate–*t*-butyl chloride reaction and the specific rate constant of hydrolysis of the *t*-butyl nitrate in that medium.[3] If the butyl nitrate did not hydrolyze, upward of 60% of the ester should be produced from the reaction of isobutene as it is in the mercuric nitrate–*t*-butyl chloride reaction. The hydrolysis constant (*i. e.*, the rate of disappearance of *t*-butyl nitrate at unit butyl nitrate concentration) must be at least seventy times as large as the rate at which the substance is formed from isobutene under the prevailing conditions the uncertainty arising from the unknown salt effect. Consequently the value of 25 to 30% nitrate ester observed is of the order expected.

Finally the hydrolysis of *t*-butyl nitrate by its resemblance to that of *t*-butyl chloride appears to be a true solvolytic reaction involving a carbonium ion intermediate[3] and step IV which necessarily by-passes this intermediate is questionable. Reaction III will therefore ordinarily be significant only under special conditions, *e. g.*, 95% dioxane medium for the hydration reaction, or very rapid formation of carbonium ion as in the *t*-butyl chloride–mercuric nitrate reaction. Hydration of isobutene in water as well as the reaction of mercuric nitrate with *t*-butyl chloride in water would not be expected to produce any nitrate ester because the ratio $k_2[H_2O]/k_3[NO_3^-]$ clearly increases rapidly with increasing water concentration.

It therefore seems unlikely that the effect of added nitrate ion is due to the formation of *t*-butyl nitrate. In terms of the Brönsted theory of salt effects

$$v = k_0 f_{H_3O^+} f_{C_4H_8}/f_{X^+}$$

the activity coefficient of the positively charged transition state complex decreases more rapidly than does the product of activity coefficients of the oxonium ion and isobutene. Like effects have been observed in the acid-catalyzed hydration reactions of various ethylene oxides,[7] the acid-catalyzed decomposition of diazoacetic ester[8] and the acid-catalyzed hydrolysis of various acetals,[9] and the effect seems to be general for such reactions.

Summary

The distribution of products in the reaction of mercuric nitrate with *t*-butyl chloride has been studied in various dioxane–water mixtures. Semi-quantitative results show that the rate of disappearance of isobutene in dilute nitric acid decreases rapidly with increasing proportion of dioxane.

The experimental facts indicate that *t*-butyl nitrate is not an intermediate in the hydration of isobutene in dilute nitric acid, and H. J. Lucas' conclusion that the pronounced acceleration produced by nitrate ion is a salt effect is therefore verified.

The Dipole Moments of Some Bile Acids

BY W. D. KUMLER AND I. F. HALVERSTADT[1]

The cyclopentanoperhydrophenanthrene nucleus or one of its modifications occurs in over eight types of physiologically active compounds including the bile acids, sex hormones, antirachitic vitamins, sterols, etc. A knowledge of the structure of this nucleus is of much importance both from a theoretical and practical standpoint.

At present the points of attachment of the rings are known but the evidence is conflicting in regard to whether some of the rings are linked *cis* or *trans* and very little, if anything, is known in regard to whether the individual rings are *cis* or *trans*.

A dipole moment study appeared to offer a new and rather fruitful method of attack on the problem. This nucleus is particularly suited to a dipole moment study for two reasons. First, it is saturated so that complicated resonance effects will not obscure the interpretation of the data. Second, the groups with appreciable dipoles are usually widely separated so steric or inductive effects will not interfere.

The bile acids were used to start the study because a number of these compounds were available and there is considerable evidence that the nuclei in the various bile acids studied have the same configuration. In this paper the dipole moments of ten bile acids have been measured and such factors as association, choleic acids and possible nonrotation of the molecules in the field are considered. In a later paper a detailed analysis of the moments of these compounds will be given in terms of their stereostructure.

Results

The symbols used in the equations and tables are the same as those given previously.[2] The equations used in calculating the moments are[2]

$$p_{2_0} = \frac{3\alpha v_1}{(\epsilon_1 + 2)^2} + (v_1 + \beta)\frac{(\epsilon_1 - 1)}{(\epsilon_1 + 2)}$$

$$P_{2_0} = p_{2_0} M_2$$

$$\mu = 0.0127\sqrt{(P_{2_0} - P_{E_2})T}$$

The P_{2_0} values are obtained by a method described previously[2] which is more accurate than the usual method. P_{E_2} values were calculated from the molar refractivities of the atoms present in the molecules.

Discussion

The bile acids are comparatively large molecules with molecular weights around 400, hence it is possible that they might not orient in the field at the frequency used, which was 680 kilocycles. There is no evidence, however, that such is the case. The moments obtained are of the magnitude expected for compounds having the groups present in these acids.

The bile acids are carboxylic acids and much evidence has accumulated which indicates that carboxylic acids are associated through hydrogen bonds to form dimers both in solvents such as hexane and in the vapor state. If such an association occurs in our solutions, it will make the interpretation extremely difficult. A good criterion for lack of association[2] is the linearity of the dielectric constant–concentration, ϵ_{12}–ω_2 curves, plus evidence that the extrapolated ϵ_1 value is approximately equal to ϵ_1 measured. We have plotted these curves for the ten acids in Fig. 1.

The curves are all linear, showing that the bile acids are not associated in dioxane at concentrations less than weight fraction 0.017.

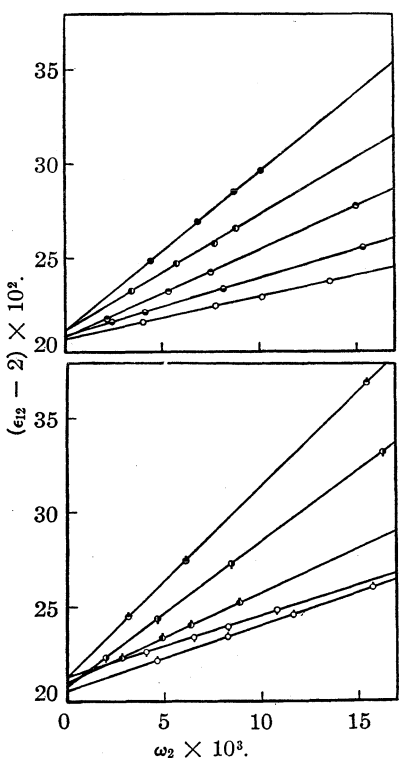

Fig. 1.—O, Lithocholic; ◒, apocholic; ◓, cholic; ◐, 3-hydroxy-12-keto-cholanic; ●, reductodehydrocholic.

Fig. 1a.—◔, Desoxycholic; ♀, hyodesoxycholic; ◐, dehydrolithocholic; ◕, dehydrodesoxycholic; ◓, dehydrocholic.

Another point of interest is whether this study gives any evidence of the presence of choleic acids in these solutions. Choleic acids are "molecular compounds" formed between desoxycholic acid and a wide variety of other types of compounds. A logical procedure would be to dissolve a choleic acid in some non-polar solvent and then determine the resulting dipole moment. Such a procedure does not seem feasible because the only solvent in which choleic acids appear to be soluble is dioxane, and dioxane itself forms a choleic acid. However, this permits some evidence to be obtained from the measurement of desoxycholic acid in dioxane, for if the choleic acid structure persists in the solution then the observed dipole moment of desoxycholic acid should be abnormal with respect to the other bile acids that do not form these molecular complexes. This would be the case if the complex either did or did not orient in the field. If the complex did not orient the apparent moment would be low, if it did orient the apparent moment would be expected to be different from that of a "free" molecule of desoxycholic acid.

An examination of the observed moments in Table II indicates that desoxycholic acid with two hydroxyl groups has a moment of 3.22 about midway between the moment 2.50 of lithocholic acid with one hydroxyl group and the moment of cholic acid 3.84 with three hydroxyl groups; thus the moment of desoxycholic acid is normal with respect to the moments of lithocholic and cholic acids.

The desoxycholic acid moment is also consistent with the moments of hyodesoxycholic and apocholic acids. Hyodesoxycholic acid is an isomer of desoxycholic acid with hydroxyl groups in the 3,6 positions instead of the 3,12 positions. One would thus expect not much difference in their moments and such is the case, hyodesoxycholic having a moment of 3.12 and desoxycholic a moment of 3.22. Apocholic acid differs from desoxycholic acid by having a double bond, which would be expected to alter the moment by only a small amount. The moment of apocholic, 2.98, is 0.24 less than that of desoxycholic acid. Since the moment of desoxy-

cholic acid which forms choleic acids with a large number of substances and the moment of apocholic which also shows this same property to a certain extent are normal with respect to the moment of cholic, lithocholic and hyodesoxycholic acids, which do not form choleic acids, we conclude that the dipole moment data give no evidence for the existence of the choleic acids in our solutions.

It is interesting to see what effect the introduction of an additional hydroxyl group and of an additional ketone group has on the moment. The difference between the moment of the compounds differing by one hydroxyl group and by one ketone group are as follows.

DIFFERENCE—ONE HYDROXYL	
Desoxycholic–Lithocholic	3.22 − 2.50 = 0.72
Hyodesoxycholic–Lithocholic	3.12 − 2.50 = 0.62
Cholic–Desoxycholic	3.84 − 3.22 = 0.62
Cholic–Hyodesoxycholic	3.84 − 3.12 = 0.72
3-Hydroxy-12-keto-cholanic–Dehydrolithocholic	4.26 − 3.72 = 0.54
Reductodehydrocholic–Dehydrodesoxycholic	5.16 − 4.82 = 0.34
DIFFERENCE—ONE KETONE	
3-Hydroxy-12-ketocholanic–Lithocholic	4.26 − 2.50 = 1.76
Dehydrodesoxycholic–Dehydrolithocholic	4.82 − 3.72 = 1.10
Reductodehydrocholic–3-Hydroxy-12-ketocholanic	5.16 − 4.26 = 0.90
Dehydrocholic–Dehydrodesoxycholic	5.63 − 4.82 = 0.81

The introduction of a hydroxyl group into desoxycholic or hyodesoxycholic acid has about the same effect as its introduction into lithocholic acid. In all the other cases, however, as a polar group (either hydroxyl or ketone) is introduced, its increment to the resultant dipole moment of the molecule decreases as the number of polar groups and moment of the compounds into which it is introduced become larger. This effect can be accounted for on the basis of the vector addition of the dipoles and does not demand the contribution of saturation effects.

Experimental

The measurements were carried out as described in the previous paper.[3]

Materials

The purification and constants of the dioxane were as described previously.[3]

Lithocholic Acid.—This sample was obtained from Dr. H. L. Mason of the Mayo Foundation; m. p. 187–188° $[\alpha]^{25}_{5461}$ +40.6°; equivalent weight by titration 378.

Desoxycholic Acid.—The Riedel–de Haen product was converted to the dioxane–choleic acid which was decomposed by boiling with water, then dried; m. p. 174–175°; equivalent weight 391.

Apocholic Acid.—The Riedel–de Haen product was crystallized from dioxane; m. p. 172–173°; equivalent weight 392.

Cholic Acid.—The Riedel–de Haen product was dried in a pistol over phosphorus pentoxide; m. p. 197–198°; equivalent weight 407.

Dehydrodesoxycholic Acid.—The Riedel–de Haen product was used without further purification; m. p. 185–186°; equivalent weight 387.

Dehydrocholic Acid.—The Riedel–de Haen product was used without further purification; m. p. 234–235°; equivalent weight 399.

Hyodesoxycholic Acid, Dehydrolithocholic Acid, Reductodehydrocholic Acid, and 3-Hydroxy-12-keto-cholanic Acid.—These four compounds were obtained from Dr. Willard M. Hoehn of the George A. Breon Co. The constants of the acids are:

Hyodesoxycholic acid; m. p. 192–194°
Dehydrolithocholic acid; m. p. 138–139°
Reductodehydrocholic acid, m. p. 186–187°
3-Hydroxy-12-keto-cholanic acid; m. p. 156–157°

Acknowledgment.—We wish to thank Dr. Willard M. Hoehn for supplying us with the four above mentioned bile acids, Dr. H. L. Mason for the lithocholic acid, and Dr. C. L. A. Schmidt for the samples of the Riedel–de Haen products.

Summary

The dipole moments of ten bile acids have been measured in dioxane. The values are lithocholic 2.50, desoxycholic 3.22, hyodesoxycholic 3.12, apocholic 2.98, dehydrolithocholic 3.72, cholic 3.84, 3-hydroxy-12-keto-cholanic 4.26, dehydrodesoxycholic 4.82, reductodehydrocholic 5.16, dehydrocholic 5.63.

These bile acids are not associated in dioxane in concentrations up to a weight fraction of 0.017. The ϵ_{12}–ω_2 curves are linear in this range.

The dipole moment evidence points to the nonexistence of choleic acids in our solutions. The dipole moment of desoxycholic acid is normal with respect to the moment of other bile acids that do not form choleic acids.

The Dipole Moment and Structure of Urea and Thiourea[1]

BY W. D. KUMLER AND GEORGE M. FOHLEN

The only work in the literature on the dipole moment of urea is that of Bergmann and Weizmann,[2] who obtained a value of 8.6 in dioxane. A redetermination of the moment of this very important compound seems desirable for several reasons. First, the previous value is based on only one measurement at very high dilution; second, the value seems extraordinarily large compared with the dipole moments of other amides and substituted ureas; third, a recent study by Halverstadt and Kumler[3] shows that measurements in very dilute solutions are apt to give results that are too high due to solvent polarization (water) error unless rigid precautions are taken to exclude moisture; fourth, the previous authors filtered the solutions, thus giving ample opportunity for absorption of water.

The measurement of the dipole moment of urea in a non-polar solvent is complicated by the insolubility of the compound in all non-polar solvents. The only available solvent in which it is appreciably soluble is dioxane and here its solubility is only about 35 mg. per 100 cc. The low solubility of urea makes any solvent polarization error of great importance in the resultant value for the dipole moment. Errors in the dielectric constant will have a larger effect on the moment than usual, due to the small difference between the dielectric constant of the solvent and the various solutions.

The dipole moment of thiourea has also been redetermined. The value[2] 7.6 in the literature appears likewise to be high.

Thiourea has a somewhat greater solubility in dioxane than urea but it still is necessary to measure the compound in comparatively dilute solutions.

Results

The results are given in Table I.

The symbols have the same significance as in the previous papers.[3] The moments have been calculated by a method described previously,[3]

TABLE I

MEASUREMENTS IN DIOXANE AT 25°

Urea

ω_2	ϵ_{12}
0.0001225	2.2175
.0001655	2.2196
.0001847	2.2201
.0002751	2.2243

Thiourea

ω_2	ϵ_{12}	v_{12}
0.0002715	2.2239	0.97362
.0005179	2.2334	.97355
.0006755	2.2403	.97350
.0008978	2.2488	.97342

	ϵ_1	v_1	α	$-\beta$	P_{2_0}	P_{E_2}	μ
Urea	2.2120	0.97371	44.44	0.3	456	16	4.56
Thiourea	2.2130	.97371	40.43	.322	521	24	4.89

employing the graphic modification, and using the equations

$$p_{2_0} = \frac{3v_1\alpha}{(\epsilon_1 + 2)^2} + (v_1 + \beta)\frac{(\epsilon_1 - 1)}{(\epsilon_1 + 2)}$$

$$P_{2_0} = p_{2_0}M_2$$

$$\mu = 0.0127\sqrt{(P_{2_0} - P_{E_2})T}$$

This method of calculating P_{2_0} is more accurate than the usual method and is particularly advantageous in dilute solutions where solvent polarization error may have a large effect on the moment.

In the case of urea the difference in density between the solutions and the pure solvent was within the experimental error, hence, the value of β could not be determined directly. We have taken a value of -0.3, which seems reasonable compared with the value of -0.322 for thiourea. In any event β does not have a very large effect on the moment. If β is taken as zero the value of the moment is raised by only 0.04.

The ϵ_{12}–ω_2 curves are linear in both cases showing that the molecules are not associated in these solutions.

Discussion

The values for the dipole moments of urea, 4.56, and thiourea, 4.89, are much smaller than the values in the literature 8.6 and 7.6, respectively. This is the most striking example we have found to date of the large amount of error that can be

(1) We are indebted to Professor John T. Edsall for suggesting this problem.

(2) Bergmann and Weizmann, *Trans. Faraday Soc.*, **34**, 783 (1938).

(3) Halverstadt and Kumler, "A Critical Study of Dielectric Polarization Concentration Curves," in publication.

introduced in dipole moment values by solvent polarization errors.

The new values are in general consistent with the dipole moment values of substituted ureas that appear in the literature. The substituted ureas are sufficiently soluble so that a solvent polarization error would not have an enormous effect on their moment. It is perhaps also significant that none of the solutions of these substituted ureas were filtered, thus they did not have the same opportunity to pick up water as did the solutions of urea and thiourea. In some cases when determinations have been made by different workers they check reasonably well. Thus values of 4.85[4] and 4.9[2] are given for diphenylthiourea and values of 4.8[4] and 5.1[5] for *sym*-dimethylurea.

Let us examine the moment of urea and thiourea in the light of the published values for the substituted ureas which are listed in Table II.

TABLE II

Urea	4.56
Propylurea[5]	4.1
Phenylurea[2]	3.6
sym-Dimethylurea[4]	4.8
sym-Diethylurea[4]	4.9
sym-Diphenylurea[4]	4.6
unsym-Diphenylure [2]	2.7
N,N-Diethyl-N′-phenylurea[2]	3.2
sym-Dimethyl-diphenylurea[2]	3.6
Tetraethylurea[5]	3.3
Thiourea	4.89
Methylthiourea[2]	4.2
sym-Diethylthiourea[4]	4.9
sym-Diphenylthiourea[4]	4.85
Allyl-piperylthiourea[6]	4.61

Urea and thiourea have moments about 1 unit higher than those of the simple amides whose moments are in the range 3.7–3.9.[7] A calculation similar to that made previously with acetamide[7] where the contribution of the excited form was of the order of 6–15%, gives a contribution of 20–30% for the excited form in urea and thiourea. This is in qualitative agreement with the greater resonance energy[8] of these compounds and the fact that they have two equivalent forms with a separation of charge that can contribute to their structure.

Thiourea and the substituted thioureas have slightly higher moments (0.1–0.3) than the corresponding ureas. The introduction of an alkyl group into urea or thiourea lowers the moment by 0.5–0.7. The introduction of one phenyl group reduces the moment by 1.0. Two phenyl groups, if placed on the same nitrogen, reduces the moment by 1.9. In contrast with these reductions in moments is the fact that when two alkyl or two phenyl groups are placed symmetrically in the molecule the moment remains virtually the same. Thus urea, *sym*-dimethylurea, *sym*-diethylurea and *sym*-diphenylurea have moments differing by 0.3, while thiourea, *sym*-diethylthiourea and *sym*-diphenylthiourea have moments that differ by only 0.05.

These moments can be interpreted on the basis of the number and contribution of the resonating forms.[8] Thus in compounds of the type  or  the two forms with a separation of charge,  ,  etc., do not have the same energy and consequently do not contribute much to the structure, hence the moments of these compounds are less than those of the unsubstituted molecules. If R is a phenyl group the resonance between the phenyl group and the  group,  etc., will further decrease the contribution of the form  due to cross conjugation. Furthermore, this resonance between the ring and the  group introduces forms with a separation of charge which can oppose the resultant moment in the molecule and hence reduce the moment. When two phenyl groups are substituted on the same nitrogen these combined effects are sufficient to bring the moment down to 2.7 which is one unit less than the moment of simple amides.

When two like groups are substituted on different nitrogen atoms so the molecules are symmetrical the forms with a separation of charge are again equivalent and these forms, as in the case of the unsubstituted compounds, make a comparatively larger contribution to the structure.

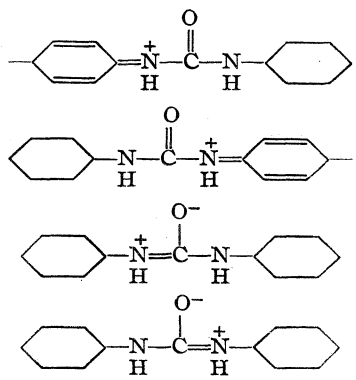
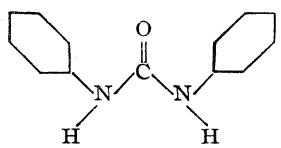
Hence, the moments of the symmetrical disubstituted compounds are approximately the same as those of the parent compounds, urea and thiourea.

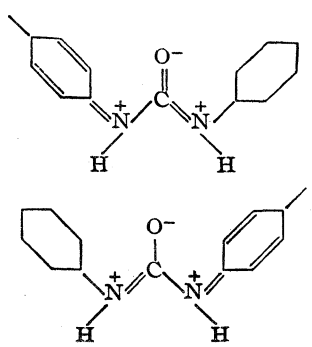
The cases of *sym*-diphenylurea and *sym*-diphenylthiourea are very interesting. It might be thought that these compounds would have lower moments than the parent compounds due to the cross conjugation between the main resonance and the ring resonance plus the possible opposition of the moment from the main resonance and the ring resonance. However, for all four forms to contribute, the molecule must be co-planar. A



study of the Fisher–Hirschfelder models reveals that the only way the molecule can get in a co-planar form is for the molecule to be arranged with the phenyl groups on the same side as the oxygen thus



in which case the moment from the ring— $\overset{}{\underset{H}{N}}$— resonance would be in a direction to augment the moment from the main resonance. Furthermore with a phenyl group on both nitrogens a new powerful resonance is possible between the following forms.



Here the ring resonance now supports the urea resonance in the other part of the molecule due to the conjugation, and the negative charge can oscillate from one phenyl group to the other while both nitrogens remain positively and the oxygen negatively charged. The contribution of these equivalent forms with separation of charges will raise the moment. Two symmetrically placed phenyl groups thus introduce factors which lower the moment and others which raise it and the factors balance one another so the moments of *sym*-diphenylurea and *sym*-diphenylthiourea are about the same as the moments of the parent compounds.

Although tetraethylurea and *sym*-dimethyldiphenylurea are both symmetrical molecules, and therefore might be expected to have moments of about 4.6 these values are considerably less, 3.3 and 3.6, respectively. It is likely that steric hindrance in these tetrasubstituted compounds prevents their atoms from getting in a suitable position for the forms with a separation of charge to make an appreciable contribution. Examination of the models supports this view.

The new dipole moment values throw some light on the old controversy in regard to whether urea and thiourea are zwitterions. The use of the term "zwitterion" applied to these compounds was first taken to mean the structure $H_3\overset{+}{N}—\overset{O^-}{\overset{|}{C}}=NH$. This structure has two things in common with a typical zwitterion, it has a separation of charge, and a shift of a proton is necessary to form it from the normal form. This structure, however, is very untenable and has been discarded in favor of the structure $H_2\overset{+}{N}=\overset{O^-}{\overset{|}{C}}—NH_2$ which also has a separation of charge but a shift of a proton is not necessary for its formation. The term "zwitterion" was carried over to this structure although it is a resonance hybrid and not a typical zwitterion. When we use the term "zwitterion" in the rest of this discussion we refer to a molecule with a complete separation of charge regardless of how it comes about. The dipole moments indicate very definitely that in dioxane these compounds are not chiefly in the zwitterion forms. The evidence for and against[9] the zwitterion structure has been summarized in "Sidgwick's Organic Chemistry of Nitrogen." One argument is that since amino

(9) Taylor and Baker, "Sidgwick's Organic Chemistry of Nitrogen," Clarendon Press, Oxford, 1937, p. 280.

acids are zwitterions and have high melting points, the high melting points of urea and thiourea suggest they are also zwitterions. The high melting points of urea and thiourea, however, can be accounted for on the basis of the number and strength of the hydrogen bonds that are formed between molecules in the solids. In fact, it is likely that with amino acids themselves the hydrogen bonds formed between molecules may be more responsible for the high melting points than is the zwitterion structure. The compound oxamide has a higher melting or decomposition point, 420°, than any of the amino acids and oxamide is most certainly not a typical zwitterion. However, each molecule in the solid has the possibility of being attached to the surrounding molecules by eight hydrogen bonds.

Another argument is that the short carbon–nitrogen distance of 1.37 Å. suggests a zwitterion structure. Pauling[8] has pointed out that this value for the carbon–nitrogen distance amounts to about 20% double bond character, hence the normal form makes a greater contribution to the structure than do the forms with a separation of charge.

Evidence considered most convincing for the zwitterion structure of urea and thiourea is the fact that these compounds and the aliphatic aminoacids raise the dielectric constant of water (have a positive dielectric increment) while most amides and other nitrogen compounds lower it. However amides in which a major portion of the molecule consists of the amide group such as formamide, malonamide and malamide have positive dielectric increments.[9a,10] The dipole moment of formamide[11] 3.68 is quite normal with respect to the moment of the other amides 3.7–3.9 and the moment value gives no evidence of formamide being a zwitterion.

Whether a compound raises or lowers the dielectric constant of water depends essentially on the number and size of the dipoles per unit volume compared with water. Or stated a bit differently it depends on whether the value of $\mu\bar{\mu}/v$ for the compound is greater or less than its value for water where μ is the dipole moment of a single molecule in the liquid, $\bar{\mu}$ a related dipole moment[12] and v the molal volume. The value of this function for water is about 0.7 taking Kirkwood's value for $\mu\bar{\mu}$ as 3.55 μ_0^2 where μ_0 is 1.88 the dipole moment of water in the vapor. The value of μ_0^2/v for water is about 0.2. Using 44.3 cc.[13] for the apparent molal volume of urea and our value for the moment, the value of μ^2/v for urea is about 0.48 considerably higher than the value of μ_0^2/v for water. The larger value of $\mu\bar{\mu}$ compared with μ_0^2 for water arises mainly from the hydrogen bonds that are formed between the water molecules in the liquid,[12] four such bonds being possible for each water molecule. An analogous effect would take place between urea and water with six possible hydrogen bonds for each urea molecule. Furthermore it is likely that some of these bonds are stronger than those in water due to the greater plus charge on the nitrogen resulting from the resonance.[14,15] The net effect would be to make the value of $\mu\bar{\mu}/v$ for urea considerably larger than the corresponding value for water. Consequently these factors alone are sufficient to account for the positive dielectric increment of urea in water without making the assumption that the molecule is a zwitterion.

Evidence of a chemical nature pointing to structures of the type $HN{=}\overset{\overset{H}{|}}{\underset{|}{S}}{-}C{-}NH_2$ can be accounted for just as well on a basis of a 20–30% contribution of forms $H_2\overset{+}{N}{=}\overset{S^-}{\underset{|}{C}}{-}NH_2$, $H_2\overset{+}{N}{-}\overset{S^-}{\underset{|}{C}}{=}\overset{+}{N}H_2$.

Convincing evidence against the zwitterion structure for urea is that of Cohn, McMeekin, Edsall and Blanchard,[13] who found that the ratio of the solubility of urea in alcohol to its solubility in water is much higher for urea than for a typical amino-acid zwitterion. This points rather strongly to urea not being a zwitterion in alcohol. Our dipole moment data are definite evidence that urea and thiourea are not zwitterions in dioxane. The evidence in the solid state and in water solution does not demand the existence of urea as a zwitterion, but the facts can adequately be accounted for on the basis of factors such as the number and strength of dipoles per unit volume, hydrogen bonds, etc.

A consideration of all the available evidence thus leads to the conclusion that urea and thiourea are resonance hybrids with 20–30% contribution of the forms with a separation of charge and that this structure adequately accounts for their behavior whether in the solid state or in dioxane,

alcohol or water solutions. Their structure is essentially the same as that of the simple amides except for a higher contribution of the forms with a separation of charge.

Experimental

The measurements were carried out as was described in a previous paper.[16]

Materials

Dioxane.—The purification and constants of dioxane were as described previously.[16]

Urea.—A C. P. grade of urea was recrystallized twice from methyl alcohol, heated with pure dioxane to remove any alcohol; m. p. 132.6°.

Thiourea.—Eastman Kodak Co. best grade thiourea was recrystallized from methyl alcohol, heated with pure dioxane. The product gave no test for thiocyanate.

Summary

The dipole moments of urea 4.56 and thiourea 4.89 have been measured in dioxane at 25°. Plots of the dielectric constants against weight fractions were linear, showing the molecules were not associated in these solutions.

The dipole moment values indicate that urea and thiourea are resonance hybrids with a 20–30% contribution from the forms with a separation of charge.

The magnitude of our values for these compounds together with those for substituted ureas appearing in the literature are correlated from the standpoint of resonance. Urea and thiourea have nearly the same moments as the corresponding symmetrical disubstituted compounds. All of these compounds have two equivalent forms with a separation of charge. The moments of the monosubstituted compounds in which the two forms with a separation of charge are not equivalent are smaller, and those of the unsymmetrical disubstituted compounds still less. The low moments of the symmetrical tetrasubstituted compounds are attributed to steric hindrance.

The evidence of the existence of urea and thiourea as zwitterions is examined and it is shown that all the evidence can be adequately accounted for by the resonance hybrid structure whether urea is in the solid state or in dioxane, alcohol, or water solutions.

The structure of urea and thiourea is not essentially different from that of the simple amides except for a somewhat larger contribution of the forms with a separation of charge.

The Dissociation Constant, Dipole Moment and Structure of α-Nitrotetronic Acid

BY W. D. KUMLER

α-Nitrotetronic acid was originally assigned the isonitro form.[1] The structure of this compound is reconsidered here in the light of present day viewpoints. The dissociation constant and dipole moment have been measured and the results interpreted.

Results

TABLE I

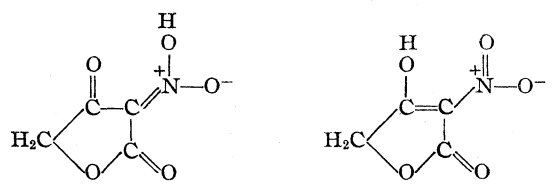
(1) Wolff and Lüttringhaus, *Ann.*, **312**, 133 (1900).

Discussion

The possibilities for the structure are the isonitro and the enol.



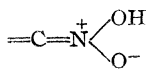
The structure of analogous compounds suggests that the enol is by far the more stable structure. Thus tetronic acid and α-halogen substituted tetronic acids are largely in the enol form[2] while no stable isonitro compound of any kind has been isolated. The isonitro compounds that have been obtained[3] change into the nitro form on standing. These facts in themselves suggest that the enol form is the more probable.

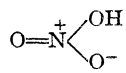
The structure of an isonitro compound is ana-

(2) Kumler, THIS JOURNAL, **60**, 857, 859 (1938).

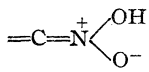
(3) Hantzsch and Schultze, *Ber.*, **29**, 699, 2253 (1896).

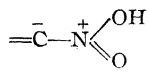
logous to that of nitric acid, which is of course a strong acid.





The fact that the two forms with a separation of charge are not equivalent





as they are in the case of nitric acid would cause the isonitro compound to be somewhat weaker than nitric acid. However, the compound would be much stronger than nitrous acid $Ka = 4 \times 10^{-4}$ and would probably have a Ka greater than 10^{-2}. The observed Ka of 2.1×10^{-2} therefore, does not exclude the isonitro structure.

Some of the factors likely to affect the dissociation constant of the enol form of α-nitrotetronic acid are illustrated by the ratios in Table II.

TABLE II

$\frac{Ka\ \alpha\text{-Nitrotetronic acid}}{Ka\ \alpha\text{-Chlorotetronic acid}}$	$= \frac{21 \times 10^{-3}}{7.4 \times 10^{-3}}$	$= 2.8$
$\frac{Ka\ o\text{-Nitrophenol}}{Ka\ o\text{-Chlorophenol}}$	$= \frac{6.8 \times 10^{-8}}{7.97 \times 10^{-10}}$	$= 86$
$\frac{Ka\ p\text{-Nitrophenol}}{Ka\ p\text{-Chlorophenol}}$	$= \frac{7.0 \times 10^{-8}}{1.46 \times 10^{-10}}$	$= 478$
$\frac{Ka\ o\text{-Nitrobenzoic acid}}{Ka\ o\text{-Chlorobenzoic acid}}$	$= \frac{6.71 \times 10^{-3}}{1.14 \times 10^{-3}}$	$= 5.9$
$\frac{Ka\ p\text{-Nitrobenzoic acid}}{Ka\ p\text{-Chlorobenzoic acid}}$	$= \frac{3.76 \times 10^{-4}}{1.05 \times 10^{-4}}$	$= 3.7$

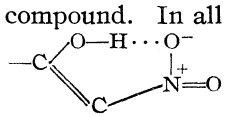
The fact that the ratios for the phenols are considerably greater than those for the benzoic acids is due to two effects. Acid strengthening groups have a greater relative effect on weak acids than on strong ones and with the phenols the nitro group is in a position to exert its rather large acid strengthening resonance effect. The nitro group cannot do this in the benzoic acids and here the major factor is the inductive effect, which is greater the nearer the groups are to the dissociating hydrogen. The ratio for the *ortho* benzoic acids is thus greater than for the *para* acids.

If a hydrogen bond is formed by the dissociating hydrogen it would weaken the acid because the hydrogen would be held by an additional force. As Branch and Yabroff pointed out,[4] this factor is reponsible for the anomalously small second dissociation constant of salicylic acid. In the *ortho* chloro and nitro benzoic acids, however, if any hydrogen bonds are present they are quite weak and do not have a major effect on the acid strength. It is known that only weak hydrogen bonds are formed to chlorine atoms and in the case of the ortho nitro compound apparently unfavorable angles and distances cause the bond to be weak. If a strong hydrogen bond were present in this compound, the ratio for the ortho acids would be much smaller.

The acid weakening effect of a hydrogen bond formed by a dissociating hydrogen is shown very strikingly by the ratios for the phenols. Thus while the ratio Ka *o*-nitrophenol/Ka *o*-chlorophenol would be expected to be about twice that of the para compounds, or about 900, it is actually 86 or about one-tenth the expected value. The strong hydrogen bond in *o*-nitrophenol thus reduces the dissociation constant of the compound by a factor of more than ten.

Tetronic acids are of about the same strength as the ortho benzoic acids, so a comparison of the Ka's of the two series will not be invalidated by a great difference in acid strength. In α-nitrotetronic acid, however, the nitro group, as in the case of the ortho and para nitrophenols, is in a position to increase the acid strength due to resonance. As a result one would expect the ratio of the Ka's for the nitro and chloro compounds to be greater for the tetronic acids than for the ortho nitro benzoic acids. The fact that it is considerably less is evidence that a strong hydrogen bond is present in α-nitrotetronic acid.

In α-nitrotetronic acid the same possibilities are present for hydrogen bond formation that are present in *o*-nitrophenol and nitroacetophenone. The last two compounds are known to contain strong hydrogen bonds so by analogy one would expect such a bond in the first compound. In all these compounds the structure



is present.

The fact that α-nitrotetronic acid does not give a color with ferric chloride is evidence that a strong hydrogen bond is present in the molecule. Ordinary enols and isonitro compounds give colors with ferric chloride. Thus the α-halogen tetronic acids and the isonitro form of *p*-bromophenylnitromethane[5] show this reaction but compounds with strong hydrogen bonds like *o*-nitrophenol do not.

(4) Branch and Yabroff, THIS JOURNAL, **56**, 2568 (1934).

(5) Sidgwick, "Organic Chemistry of Nitrogen," Oxford University Press, London, 1937, p. 232.

When the moment of 6.10 for α-nitrotetronic acid is compared with that of tetronic acid 4.80, and that of α-chlorotetronic acid 5.83, it is apparent that there is a factor present in the nitro compound that is not present in the other two. The carbon–chlorine moment is about 1.5–1.8. The moment of α-chlorotetronic acid is 1.03 units higher than that of tetronic acid which seems reasonable in that the carbon–chlorine moment most probably is not directly in line with the resultant moment of the rest of the molecule. The large moment of the nitro group, 3–4, is directed along the carbon–nitrogen bond in the same direction in the nitro compound as the carbon–chlorine moment is directed in the corresponding chloro compound. This means that the moment of the nitro compound should be 1.5–2 units greater than that of the chloro compound. Actually it is only 0.27 unit greater which suggests some factor being present in the nitro compound which changes the direction and(or) magnitude of the moment of the nitro group. The formation of a hydrogen bond to one of the oxygens of the nitro group would have such an effect. Thus the dipole moment as well as the dissociation constant is consistent with the presence of a hydrogen bond in the enol form.

Experimental

The *p*H values of the solutions were measured with a glass electrode in connection with the *p*H meter of Goyan, Barnes and Hind.[6]

The dielectric constant measurements were carried out as described previously,[7] as was the purification of the dioxane.

The α-nitrotetronic acid had an equivalent weight of 145.5 and a melting point of 183–184° with decomposition.

The moment also was calculated by a method described previously[8] using the equations

$$p_{2_0} = \frac{3\alpha v_1}{(\epsilon_1 + 2)^2} + (v_1 + \beta)\frac{(\epsilon_1 - 1)}{(\epsilon_1 + 2)}$$

$$P_{2_0} = p_{2_0} M_2$$

$$\mu = 0.0127\sqrt{(P_{2_0} - P_{E2_0})T}$$

The dielectric constants were linear with the weight fractions indicating no association effects in the solutions.

Summary

α-Nitrotetronic acid has a *pKa* of 1.68 and a dipole moment of 6.10. From considerations of general stability the enol form is more probable than the isonitro structure. Both the dissociation constant and the dipole moment are consistent with the presence of a strong hydrogen bond in the enol form.

The Absorption Spectra and the X-Ray Examination of the Isomeric Glucononitriles[1]

BY PHILIPPOS E. PAPADAKIS

Two forms of glucononitriles are known[1a,2,3] melting at 120.5 and 145°, and obtained by crystallization from absolute alcohol and glacial acetic acid, respectively.[3] Aqueous solutions of the two forms have initially practically the same specific rotation, but whereas that of the high melting form, to be now referred to as the A form, remains unchanged with time, that of the low melting B form shows a complex time-dependence. The present report describes investigations on the X-ray diffraction and absorption spectra of the two modifications, in an attempt to discover the reason for this contrast in behavior. Three samples of the B form,[3] checked as to melting point and microcombustion analysis, served as material.

X-Ray Examination.—Specimens of the two forms A and B were subjected to X-ray powder analysis using focusing cameras of the Bohlin type as modified by Phragmen. Possible atmospheric action was prevented by enclosing the samples in sheaths of regenerated cellulose which themselves gave no diffraction pattern. Twenty-seven lines were observed between θ values of 15 and 45° on the photograms of both specimens, corresponding in the two cases in position and intensity. These experiments within their limits of resolution did not help much in answering the problem.

Ultraviolet Absorption Spectra.—The absorption spectra of aqueous solutions of the A and B forms were examined by means of a small Hilger quartz spectrograph and a continuous hydrogen source. The molar extinctions were evaluated, with a precision of some 3 or 4% in the value of ϵ, by the method of Stücklen,[4] with the use of potassium nitrate as standard. Microdensitometer tracings were made of the plates by means of the Moll microdensitometer, and wave lengths were measured on these tracings.[5]

The B form in aqueous solution showed an absorption band with a maximum at 2780 Å. and log $\epsilon_{max.}$ of 0.9, besides a region of short wave absorption extending into the Schumann region. The band at 2780 Å. was present at full intensity in spectra taken as soon as possible after addition of the solid to water and persisted on standing for ten months. The characteristic band of the B form gradually disappeared on crystallization from pure acetic acid, which favors the A form, and returned on recrystallization from alcohol. The A form had no band near 2780 Å. Its spectrum was like that of β-hydroxypropionitrile and the substance was assumed to have a straight chain structure. The absorption spectra of boiled aqueous solutions of the A form showed considerable change, with a shift of the beginning of the further ultraviolet absorption toward the longer wave lengths. No such change was observed with unboiled solutions.

Although all specimens of the B form showed a band in the neighborhood of 2780 Å., irrespective of the time elapsed since the preparation of the solution, there were, nevertheless, changes in the details of the band with time. Approximately 0.113 *M* solutions of the B form were examined at various thicknesses and with an exposure of ten seconds. The plot of log ϵ molar against λ (Fig. 1) shows the curves 1, 2, 3 and 4 as a function of time. Four preparations gave similar curves. The characteristic band broadened with time, especially on the short wave side, and the beginning of the further ultraviolet band shifted first to longer wave lengths and then reverted to shorter. The absorption maxima[6] of the characteristic band in curves 1, 2, 3 and 4 as measured are 2780, 2775, 2770, 2750 and the absorption minima 2510, 2535, 2525 and 2530, respectively.

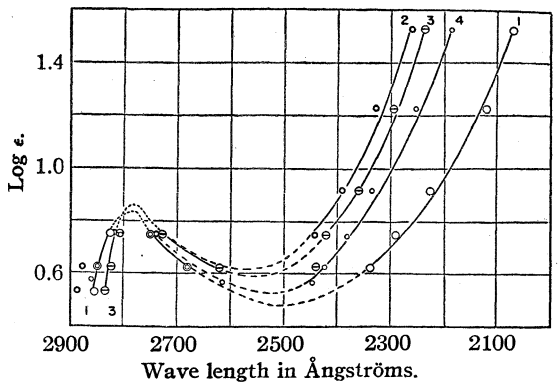

Fig. 1.—Time from mixing glucononitrile and water. Spectra photographed for Curve 1, first one-half hour; Curve 2, after twenty-five hours; Curve 3 after seventy-three hours; and Curve 4 after 672 hours.

Curves 1 and 2 of Fig. 2 are for a more dilute solution, 0.056 *M* in a cell 3.5 cm. long, photographed, respectively, one and 233 minutes from the time of mixing with water. These solutions showed evidence of discrete band structure, with bands at about 2730, 2678, (2608) (2530) for curve 1 and 2723, 2662, 2608 and 2530 Å. for curve 2, which became more distinct with time. Other preparations in similar conditions showed a hint of these bands, but not so distinctly as in the plate for which the curves of Fig. 2 were obtained. These bands caused the apparent maximum of the general band to shift toward the shorter wave lengths.

Scission of Hydrogen Cyanide from Gluconononitrile.—In explanation of the change in rotation of aqueous solutions of gluconononitrile with time, Dr. M. L. Wolfrom of the Ohio State University has suggested the possibility of the formation of *d*-arabinose, which has a negative rotation, by the loss of hydrogen cyanide. Pure nitrogen was bubbled for four and one-half hours through 10 cc. of an aqueous solution containing 0.4 g. of the gluconononitrile and the gas evolved was passed through silver nitrate solution. A precipitate shown to be silver cyanide was collected and found to weigh 0.028715 g. The corresponding amount of *d*-arabinose was calculated to be 0.03216 g. This amount, dissolved in 10 ml. of water and examined in a 1-dm. tube, would have contributed rotations of −0.17, −0.57 and −0.34°, respectively, if present in the α,β or mutarotated form.[7]

(4) Stücklen, *J. Opt. Soc. Am.*, **29**, 37 (1939).

(5) The apparent extinction coefficients in Fig. 1 were computed on the assumption that the absorbing material was a pure substance at the stoichiometric concentration of gluconononitrile.

(6) The absorption maxima and minima were determined from microphotometer tracings of respective spectra of the plates representing solutions of smaller depth. The extinction due to the band in these spectra was not complete and the microphotometric tracings afforded well-defined maxima and minima.

(7) The calculations were based upon the values for the specific rotations found by Hudson and Yanowski, THIS JOURNAL, **39**, 1013 (1917).

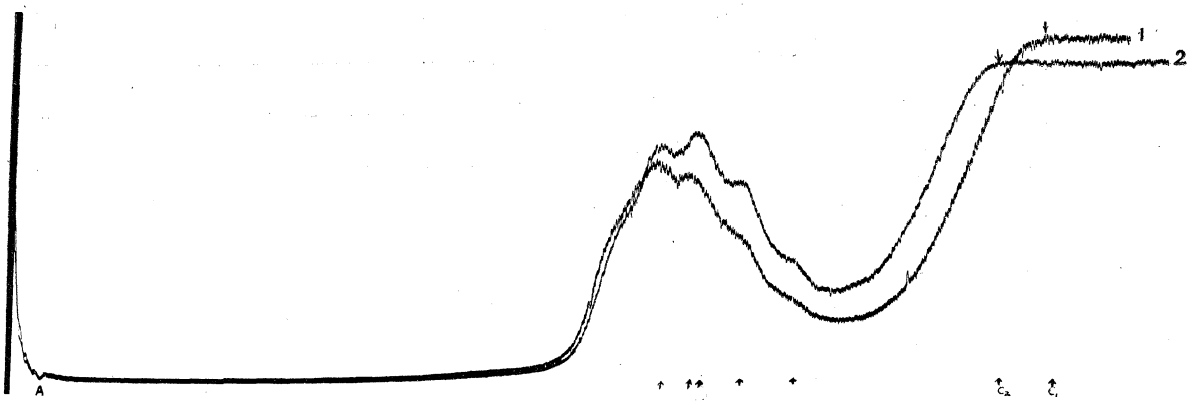

Fig. 2.—Microphotometric curves 1 and 2: A = H_B = 4861·327 Å.; C_1 and C_2 are beginnings of continuous absorption respectively.

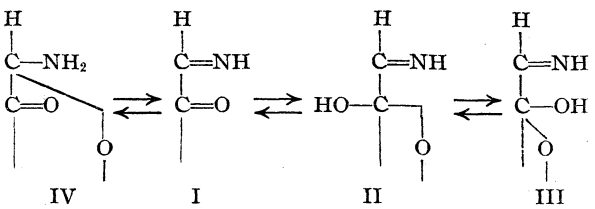
Since the calculated drop in the rotation of the 4% solution of glucononitrile was approximately 1.40° (l = 1), the scission of hydrogen cyanide, even when favored by the passage of nitrogen, was not sufficient to account for all the change.

Discussion

The foregoing work showed that the essential difference between the absorption spectra of aqueous solutions of the A and B forms of glucononitrile is that the former has the type of spectrum to be expected of a hydroxy nitrile while the latter has a characteristic band at about 2780 Å., which may be due to some group not present in the A form. Hydrolysis products of the nitrile, as ammonium gluconate, gluconamide, glucono-γ or δ lactone or gluconic acid are not responsible for the characteristic band, since these substances,[8a] as has been verified in the course of this work, have no band near 2780 Å. Arabinose (see previous paragraph) is also without characteristic absorption in this region.[9] It seems necessary to seek for some chromophoric group which might result from internal changes in the glucononitrile molecule as the origin of the 2780 Å. band. Aliphatic aldehydes or ketones are known to have a band in this region, regarded as characteristic of aldehydic or ketonic carbonyl. The practical identity in the spectra of benzophenone and benzophenonimine[10] suggests that the C=NH group absorbs like carbonyl, and the iminolactone forms of imino-gluco-ascorbic[11] and imino-galacto-ascorbic acid have a strong band with a maximum at 2750 Å. A 1-imino-glucosone structure previously suggested[3] (formula I), on mutarotation might give II and III, while mutarotation involving the imino group might give the ketone derivative IV. Compound I by analogy



to glucosone[8b,12] may show selective absorption at a wave length somewhat higher than 2780 Å. Compounds II, III and IV may absorb at or near 2780 Å., by analogy with the behavior of aldehydes and ketones, and their interconversion might cause both the optical rotational changes and the changes in the characteristic band. The changes with time of the long wave side of the far ultraviolet band may be due to such interconversion products. Although the formation of hydrolysis products[8,9] could not account for the absorption band at 2780 Å., the possibility of slow hydrolysis may have an effect on the changes observed in the short wave spectrum. Analysis of aged sirups of form B evaporated at room temperature and dried at 80° and *in vacuo* showed that loss of nitrogen had occurred which could not be explained by assuming a loss of hydrogen cyanide. The changes observed in the short wave spectrum curves 1, 2, 3, and 4, Fig. 1, are compatible with the relative position of the spectrophotometric curves from glucononitrile, gluconyl-*d*-lactone, gluconamide and ammonium gluconate. In addition, the shift of the beginning

of the further ultraviolet absorption of boiled aqueous solutions of form A may suggest hydrolysis. On account of the inconclusive evidence concerning the question of the slow hydrolysis of the B form, it is not possible at present to associate the spectral observations with the details of the chemical changes and the problem requires further investigation.

Finally a suggestion may be made on the origin of the different melting points of the two forms. Glucononitrile may resonate between the structures RC:::N: and $RC^+{:}\ {:}\ddot{N}{:}^-$ as the alkyl cyanides are supposed to do.[13] The rather ionic character of the CN group might then lead to the formation of hydrogen bonds between the highly electro-negative hydroxyl oxygen and the nitrogen atoms. According to Thompson's infrared investigations[14] intermolecular bonding is more prominent in liquid hydroxy nitriles. As the presence of intermolecular hydrogen bridges is associated with higher melting points than their absence,[13] it seems plausible to associate the high melting point of the A form with the presence of intermolecular hydrogen bonds, while in the B form the bonds are either weaker or of the intramolecular type. More direct information on this question might be gained from a study of the infrared spectra of appropriate glucononitrile derivatives in which all but one hydroxyl group is blocked.

The author wishes to express his thanks to Dr. Wm. F. Ehret for the X-ray work, to Dr. Wm. West for the use of the spectrograph, to Dr. Raymond L. Garman and Dr. Marcel E. Droz for the microphotometer curves, and to Mr. D. Rigakos for the micro-analyses.

Summary

The two forms of glucononitrile, A and B, melting at 145 and 120.5°, respectively, shown by earlier work to differ in their optical activity, exhibited, within the accuracy of the measurements, the same X-ray powder diffraction spectra, but different ultraviolet absorption spectra. Aqueous solutions of the B form displayed an absorption band at 2780 Å. and an extinction coefficient given by log $\epsilon_{molar} = 0.9$, approximately. The (ultraviolet) spectrum also underwent complex changes with time. The A form gave a spectrum resembling that of β-hydroxypropionitrile and showing no absorption maximum at λ 2780 Å. Several cyclic compounds containing carbonyl or imino groups, derivable from the nitrile, are regarded as causing the band at 2780 Å. Interconversion of these compounds may be responsible for the changes with time in the details of the characteristic band, and for the changes in optical rotation as well as for other spectral changes in the short wave ultraviolet. A gradual hydrolysis of the B form would not account for some facts and degradation by loss of hydrogen cyanide was shown to be inconsiderable. Consideration was given to the possibility that the two crystalline forms A and B differed in the nature of the hydrogen bonding.

Hydration of Unsaturated Compounds. XI. Acrolein and Acrylic Acid[1]

BY D. PRESSMAN AND H. J. LUCAS

Kinetics.—The hydration of acrolein[2] is shown by Eq. 1. That of acrylic acid[3] is similar.

$$H_2C{=}CHCHO + H_2O \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} HOCH_2{-}CH_2CHO \quad (1)$$

At a given hydronium ion concentration in dilute aqueous solution, the hydration is first order with respect to the unsaturated compound and the dehydration is first order with respect to the hydrated compound, as shown by the straight line character of the plots of $\log_{10} \epsilon/(\epsilon - x)$ against t (Fig. 1), which is the case of two first order reac-

(1) Previous communication, X, THIS JOURNAL, **64**, 1122 (1942).

(2) J. U. Nef has shown that acrolein undergoes hydration in hot aqueous solution to form hydracrolein, *Ann.*, **335**, 219 (1904). Hydration of acrolein in aqueous sulfuric acid can explain the results of Lobry de Bruyn, who isolated a colorless syrup, probably hydracrolein, from a dilute aqueous sulfuric acid solution of acrolein, *Rec. trav. chim.*, **4**, 232 (1885).

(3) Acrylic acid undergoes hydration in aqueous sodium hydroxide, E. Lennemann, *Ber.*, **8**, 1095 (1875); E. Erlenmeyer, *Ann.*, **191**, 281 (1878). Hydracrylic acid undergoes dehydration in 50% sulfuric acid, W. Moldenhauer, *ibid.*, **131**, 335 (1864); J. Wislicenus, *ibid.*, **166**, 23 (1873).

tions coming to an equilibrium, according to the integrated Eq. 2

$$\log_{10} \epsilon/(\epsilon - x) = t(k_1 + k_{-1})/2.303 \qquad (2)$$

Here x is the fraction of the original unsaturated compound hydrated at time, t, ϵ is the fraction hydrated at equilibrium and k_1 and k_{-1} are the specific first order rate constants of hydration and dehydration, respectively, at a given hydronium ion concentration.

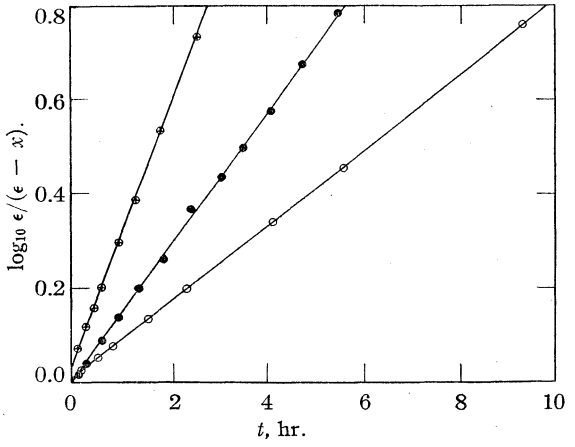

Fig. 1.—Hydration of acrolein and acrylic acid, dehydration of hydracrylic acid:

	Starting compound	Temp., °C.	(H_3O^+), N	μ, N
○	Acrolein	29.20	0.493	0.493
●	Acrylic acid	119.8	1.01	2.00
⊕	Hydracrylic acid	119.8	1.92	2.00

The individual values of k_1 and k_{-1} were calculated from the values of $(k_1 + k_{-1})/2.303$, the slope of the curves of the type of those of Fig. 1, and the equilibrium constant, Eq. 3.

$$K = k_1/k_{-1} = \epsilon/(1 - \epsilon) \qquad (3)$$

All of the values of ϵ are experimental except the one for acrylic acid at 119.8°, which is calculated from the values at 110.6 and 134.8 by the use of the Arrhenius equation. In Table I are listed the values of k_1, k_{-1}, ϵ and K for acrolein and acrylic acid.

The reversibility of the hydration–dehydration system was demonstrated in each case by lowering the temperature after the system had already reached equilibrium and then returning the system to the original temperature after equilibrium had been established at the lower temperature. The system returned to the original equilibrium. In each case the extent of hydration was greater at the lower temperature, thus showing that the equilibrium could be approached from both sides and demonstrating the exothermic character of the hydration reaction.

The reversibility in the case of acrylic acid was confirmed by observing the rate of dehydration of hydracrylic acid at 119.8°. The values thus obtained for k_1, k_{-1}, ϵ and K agree well with values from the hydration experiments. The two systems are remarkable in the stability of the equilibrium. Evidently the β-hydroxy compound is the only reaction product in these two cases.

The effect of replacing sodium ion by hydronium ion is evident from the slight decrease in the values of $k_1/(H_3O^+)$ and $k_{-1}/(H_3O^+)$, (Table I), and of the equilibrium constants K. Undoubtedly these effects are due primarily to the presence of oxonium complexes, as was demonstrated previously in the case of the mesityl oxide-diacetone alcohol system.[1] The decreases in $k_1/(H_3O^+)$ and $k_{-1}/(H_3O^+)$ probably are due to the fact that each oxonium complex is less reactive than the uncomplexed compound. The decreases in the equilibrium constants probably are due to the fact that each hydrated compound is a weaker base than the respective unsaturated compound. The roles of the oxonium complexes were not investigated further.

Thermochemistry.—The heats of activation of the hydration and dehydration reactions were calculated by means of the Arrhenius equation. The heats of activation in the temperature range 19.98 to 29.70° are: for the hydration of acrolein, 18.0 kcal. in 0.249 N perchloric acid and 17.5 kcal. in 0.493 N acid; for the dehydration of hydracrolein, 24.0 kcal. in 0.249 N acid and 24.5 kcal. in 0.493 N acid. The heats of activation, 110.6 to 119.8°, are: for the hydration of acrylic acid, 20.4 kcal. in 1.01 N acid and 20.2 kcal. in 2.00 N acid; for the dehydration of hydracrylic acid, 27.0 kcal. in 1.01 N acid and 26.8 kcal. in 2.00 N acid.

It is probable that the heat of activation of the complexed form approximates that of the uncomplexed form, since the heat of activation is essentially constant even though the hydrogen ion concentration changes.

Values of ΔH for the hydration reactions were obtained from plots of log K against $1/T$. For the hydration of acrolein in 0.249 N acid three points fell on a straight line, giving for ΔH the value of −5.8 kcal. and at 0.493 N acid two points gave −5.8 kcal., while the third point, at 19.98°, was inconsistent. For the hydration of acrylic acid in 1.01 N and 2.00 N acid, ΔH is −6.5 and −6.7 kcal., respectively.

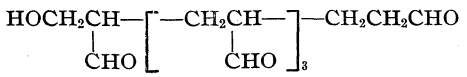
[a] Calculated by interpolation. [b] Reaction started with hydracrylic acid.

The replacement of hydronium ion by sodium ion appears to have no effect on the heat of hydration. This would be expected if the uncomplexed and complexed forms of the unsaturated compound have identical heats of hydration, as was noted in the case of mesityl oxide.[1]

The Hydration of Acrolein in Water.—Nef[2] observed that hydracrolein was formed when a 25% solution of acrolein was heated in a sealed tube at 100°, and that the yield decreased, due to polymerization, if the heating was continued longer than seventy hours. Recently Rodebush[4] and co-workers have measured the absorption spectra of aged aqueous acrolein solution, and have found that they are quite similar to the absorption spectrum of aqueous aldol. They claim that the material responsible for the characteristic absorption is a polycondensation product similar in nature to the hydrated pentamer which Gilbert and Donleavy[5] consider to be the product resulting from the polycondensation of acrolein in dilute aqueous alkaline solutions and to which they assign the structure



The arguments advanced by Rodebush, *et al.*, in substantiation of their claim are: (1) similarity in absorption spectra of aqueous aldol and aged acrolein solutions; (2) structural resemblance between aldol and the pentamer of Gilbert and Donleavy, in that both are β-hydroxyaldehydes; (3) absence of absorption due to a conjugated double bond, as would be the case if acrolein underwent the aldol condensation, which it is not known to do anyway. They completely overlook the possibility of a simple hydration of acrolein to hydracrolein, which explains in a highly satisfactory manner the effects they observed. On this account it became desirable to investigate the hydration of acrolein in water, in the absence of a catalyst.

Experiment showed that 0.03 M aqueous acrolein solution after heating at about 100° gave, at successive intervals, the following fractions of unchanged acrolein: 0.6 hr., 0.88; 1.3 hr., 0.715; 3.3 hr., 0.433; 7.5 hr., 0.395; 23 hr., 0.391. The equilibrium value 0.39 is close to 0.411 and 0.416, the values obtained when aliquots of a solution 0.02 M in acrolein and 0.5 N in perchloric acid were heated in boiling water for five and thirteen minutes, respectively, before quenching.[6] It appears from these results that in water at 100° the acrolein comes to a fairly stable equilibrium with hydracrolein, which is known to be formed in this solution.[2]

At 29.70 and 19.98° it was possible to follow the reaction more closely than at 100°. From the nature of the curves obtained by plotting x and log x against t, Fig. 2, it is evident that the reaction is essentially first order with respect to acrolein. The nature of the curves seems to indicate

20	0.0316	●	■

that the rate constant increases as the reaction proceeds. This is due to cumulative evaporation losses into the free space above the solution. As this space becomes larger the percentage loss by evaporation increases, thus giving the effect of a continually accelerating reaction. This effect was not observed in the acid-catalyzed studies because the loss due to evaporation was negligible in comparison to decrease of acrolein through hydration.

Non-reproducibility of the hydration data in water points to an extreme sensitivity to catalysis as, for example, slight daily variations in the *p*H of the water. In any event, the rate of hydration in water is negligible, when compared to the rate in acid solution.

Experimental

Acrolein.—Eastman Kodak Co. acrolein was distilled immediately before use. Determination of unsaturation by bromine absorption showed 1:000 double bond per mole. The analysis was carried out with an acetic acid solution, since acrolein is miscible with this solvent. Thus it is possible to make up a solution quantitatively by weight.

Acrylic Acid.—This was prepared by the action of metallic zinc upon a refluxing aqueous solution of α,β-dibromopropionic acid.[7] The fraction of acrylic acid which distilled at 138–140° and melted at 8° was purified by freezing about half way and decanting the liquid. After four such treatments the acid melted at 10.3°. When debromination was carried out without external heating, the boiling point of the acrylic acid was 140.0–0.3°, and the melting point of the distilled acid was 11.0°. This higher melting point when debromination is carried out at the lower temperature is due to the fact that there is less propionic acid present. The presence of propionic acid is indicated by the fact that whereas the neutralization equivalent as determined by titration with standard base was low by 2% (probably due to evaporation losses) bromine absorption was low by 5%.

Calcium Hydracrylate.—Hydracrylic acid was prepared by Mr. Frank Dickey from ethylene cyanohydrin.[8] After purification by ether extraction from the aqueous solution, it was shaken with a paste of calcium hydroxide and water. The resulting liquid was made neutral to phenolphthalein with carbon dioxide. Following removal of insoluble material by filtration, the solution of calcium hydracrylate was concentrated to a viscous mass in a vacuum desiccator. This was dried at 75° in an Abderhalden dryer. The resulting white deliquescent powder gave negative tests for chloride and sulfate ions with silver and barium nitrate solutions, respectively. *Anal.* Calcd. for $C_6H_{10}O_6Ca$: Ca, 18.4. Found: Ca (by ashing), 18.98, 19.02.

Analysis.—Acrolein was determined by the bromine absorption technique described previously in connection with crotonic acid.[9] Bromine was absorbed as rapidly as it was liberated from the bromate–bromide mixture. There was no interference from any hydracrolein present.

Acrylic acid reacted so slowly that after ten minutes, with 150% excess of bromide, only 90% of the theoretical amount of bromine was absorbed. On the addition of aqueous mercuric sulfate (so that the ratio of the concentration of mercuric ion[10] to the final concentration of bromide ion was about 1.3), absorption of bromine was quantitative after two minutes, with 50% excess bromine. Substitution was negligible. Actually this was only 4% in twenty-five minutes, even when the excess of bromine was 400%. Hydracrylic acid did not interfere. Substitution here was comparable to that in the dibromo acid.

Procedure.—For runs at 100° or above, the organic material was added to the acid or water, aliquots were sealed in ampoules and then placed in the thermostat at the required temperature. Ampoules were removed from time to time, quenched in cold water and analyzed. For runs at 40° or lower, acrolein was added to water or aqueous acid solution in a flask at the proper temperature. Immediately after thorough mixing an aliquot was analyzed. Other aliquots were removed at various intervals of time.

Correction was made for the change in hydrogen ion concentration when calcium hydracrylate was added.

No correction was made for the change in volume when the organic material was dissolved in the aqueous solution, usually about 1 ml. per liter, since any error is so small (about 0.1%) that it can be neglected. No account was taken of the change in concentration with temperature since the equilibria and, hence, the heats of hydration are not affected.

Summary

The equilibria in aqueous perchloric acid solutions in the systems, acrolein–hydracrolein, and acrylic acid–hydracrylic acid, have been studied.

The rates of hydration and dehydration are first order with respect to hydronium ion and to the organic compound involved.

In each case the drop in the values of the specific reaction rate constants of hydration and dehydration when hydronium ion replaces sodium ion is ascribed to the formation of an oxonium complex which is less reactive than the uncomplexed compound.

In each case the decrease in the value of the equilibrium constant with the above change is ascribed to the fact that the unsaturated compound probably is a stronger base than the corresponding hydrated compound.

Acrolein hydrates at 100° in pure water and in 0.5 *N* perchloric acid to the same extent.

The values for ΔH of hydration are: −5.8 kcal. in the case of acrolein, and −6.6 kcal. in the case of acrylic acid.

Studies on Reactions Relating to Carbohydrates and Polysaccharides. LXV. An Improved Technique for the Fractionation of Partially Methylated Glucosides[1]

BY IRVING LEVI, W. LINCOLN HAWKINS AND HAROLD HIBBERT

The quantitative separation of mixtures of partially methylated glucosides obtained on hydrolysis of methylated polysaccharides has been attempted by three general methods.[2,3,4] Several of the techniques described during recent years have been complicated, requiring large amounts of the methylated polysaccharide, and no procedure has been reported by which a complete quantitative separation of mixtures of tetra-, tri- and dimethylmethyl glucosides can be effected.

A description is now given of an improved procedure based on the fractionation principles and technique described by Podbielniak.[5] Several control fractionations carried out with mixtures of synthetic 2,3,4,6-tetramethyl-, 2,3,4-trimethyl- and 2,3-dimethylmethyl glucosides yielded excellent separations of the glucosides with a total recovery of 95–97%. The fractionation results on a typical mixture of these glucosides are shown in Table I. With this apparatus the 2,3,4-trimethylmethyl glucosides could be readily fractionated into the pure solid β and the liquid α isomer. In no case was there any appreciable decomposition.

In a recent investigation[6] on the structure of dextran, the present procedure gave very satisfactory results; an excellent separation was obtained using only three to four grams of the mixed glucosides. Intermediate fractions were very small and there was *practically no non-volatile residue* (not more than 1% and in some cases not detectable). The application of this fractionation technique is thus of particular significance in the field of structural carbohydrate chemistry, especially where the amount of material is limited and more than one distillation undesirable.

TABLE I

FRACTIONATION OF SYNTHETIC MIXTURES OF METHYL GLUCOSIDES

Fraction	Fraction, g.	OCH_3, %	"Tetra," g.	"Tri," g.	"Di," g.
1	0.746	60.5	0.746		
2	.151	59.6	.113	0.038	
3	.387	52.5		.387	
4	.665	52.3		.665	
5	.257	52.4		.257	
6	.300	50.8		.249	0.051
7	.451	42.1			.451
Total wt.	2.957		.859	1.596	.502
Starting wt.			.872	1.660	.516

The theoretical methoxyl values for tetra-, tri- and dimethylmethyl glucosides are 62.0, 52.6 and 41.9%, respectively. The amounts of each present in the small intermediate fractions (2 and 6) were calculated on this basis.

The fractionating column used is shown in Fig. 1. It is packed with a gold-plated wire (20 gage) spiral with $^1/_8$″ pitch. The vacuum-jacket, column head and delivery tube of the small condenser were wound with a heating element (nichrome ribbon) and the small condenser adapted for the passage of cold water or steam, depending on the nature of the distillate.

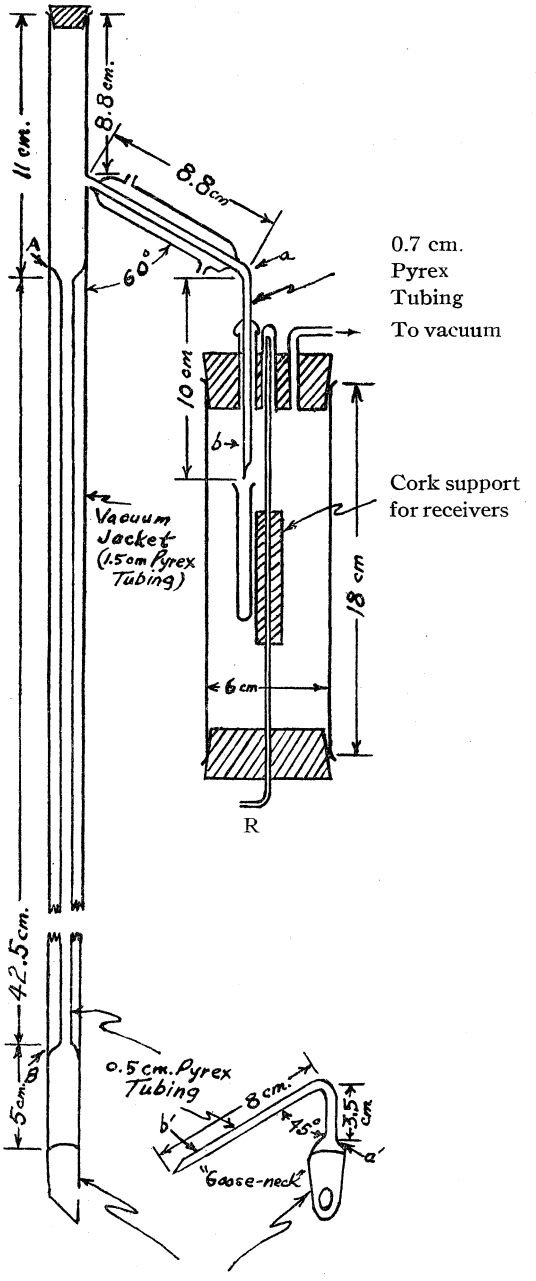

Fig. 1. No. 12/18 Pyrex ground bevelled to 45° angle and with hole in bottom as shown.

Fractionation Technique

The glucoside mixture is placed in a pear-shaped flask (25-cc. capacity) loosely packed with glass wool to maintain smooth boiling, and fitted to the bottom of the fractionating column by means of a ground-glass joint. After evacuation of the system to a constant pressure (regulated by a "bleeder" stopcock), the bath temperature is slowly increased until the maximum height of the reflux level is attained (about one-third up the column). Heat is then applied very gradually to the column (but not to the condenser top), while the bath temperature is kept constant, until the liquid refluxes to within 2.5 cm. of the top of the column. These conditions are then maintained for several hours to establish equilibrium, the gold-plated wire becoming, meanwhile, completely wet with the liquid.

The column temperature is raised slightly (3–4°) and the tetramethylmethyl glucoside collected at the rate of 150 to 200 mg. per hour, cold water being passed through the condenser during this operation. Due to the slow rate at which the column is operated at reduced pressure, the true boiling points cannot be determined, but the thermometer installed in the column head, with its bulb opposite the condenser side arm, gives the approximate values. The approximate column temperatures are read on a thermometer placed within the column air-jacket.

After a certain number of hours (dependent on the amount of tetramethylmethyl glucoside in the mixture) of constant distillation under these conditions, a dry spot on the previously completely wet gold-plated spiral wire becomes clearly visible, usually at about one-fifth the distance from the base, and during the next one to two hours the column dries completely with the exception of several cm. at the bottom. The receiver is now changed by turning the glass rod (R), the vacuum being maintained constant. The first fraction is pure tetramethylmethyl glucoside.

The bath temperature is slowly increased and also that of the column, until the spiral wire is again wet, and equilibrium conditions maintained for four hours. The column temperature is raised a further 2–3°, thus assuring the same uniform rate of distillation. The first four or five drops of distillate suffice to remove any residual "tetra" and are retained as an intermediate fraction of "tetra" and "tri." The third fraction is pure trimethylmethyl glucoside. It was necessary at this point to insert the condenser tip (a-b, Fig. 1) into the heating system, and to pass steam instead of cold water through the condenser to prevent solidification of the β-isomer of 2,3,4-trimethylmethyl glucoside.

After complete distillation of the trimethylmethyl glucoside, the column again becomes "dry," only the lowest 5 cm. being wet with dimethylmethyl glucoside. The column is now allowed to cool to room temperature and the vacuum released.

The pear-shaped distilling cup is removed and the column and condenser washed by distilling through them a small amount of chloroform. The chloroform distillate and washings from the column are combined and taken to dryness, this residue constituting the fraction intermediate between tri- and dimethylmethyl glucosides.

The dimethylmethyl glucoside should not be removed through the column because of its high boiling point but is distilled out of the flask through a short "goose-neck" (Fig. 1). This has a glass joint ground to fit the distilling flask and is wound with nichrome ribbon. This heating element is inserted in series with the heating unit of the column, thus permitting temperature control. The temperature of the "goose-neck" is kept at 100° during the distillation and the pressure reduced to 0.010 mm.

The authors are indebted to Dr. L. M. Cooke for designing the column described.

Summary

An improved apparatus is described and pro-

cedure outlined for the separation of small quantities of partially methylated glucosides whereby an almost quantitative recovery (95–97%) can be effected.

The glucosides can be separated in a high degree of purity and with accompaniment of only very small intermediate fractions.

The amount of non-volatile residue formed was never more than one per cent.

Studies on Reactions Relating to Carbohydrates and Polysaccharides. LXVI. Structure of the Dextran Synthesized by the Action of *Leuconostoc Mesenteroides* on Sucrose[1]

BY IRVING LEVI, W. LINCOLN HAWKINS AND HAROLD HIBBERT

In a previous communication[2] an investigation of the structure of dextran synthesized by the action of *L. mesenteroides* on sucrose was described. Hydrolysis of the trimethyl dextran by the action of methanolic hydrogen chloride yielded dimethyl, trimethyl and tetramethyl methyl glucosides in the approximate ratio of 1:3:1. The products of hydrolysis were identified as 2,3-dimethyl methyl glucoside, 2,3,4-trimethyl methyl glucoside and 2,3,4,6-tetramethyl methyl glucoside. Based on these results a branched chain structure for the dextran was proposed.

These results were subsequently criticized by Brauns[3] on the following grounds: (a) the dextran was incompletely methylated; (b) the ratio of tetra- to tri- to dimethyl methyl glucosides of 1:3:1 was not conclusive because of the inefficient fractional distillation employed; and (c) the large percentage (18.4%) of material lost during fractionation. A re-investigation of this dextran was therefore made in order definitely to establish its structure.

Discussion of Results

Most complex polysaccharides such as mannan,[4,5] glycogen,[6,7,8] and araban[9] contain intricately branched chains, every branching position of which yields a dimethyl methyl glycoside in the case of hexosans and a monomethyl methyl glycoside in the case of pentosans. In methylation studies of such polysaccharides a final methoxyl value of one or two per cent. lower than the theoretical can render the results worthless with respect to the extent of branching and so preclude an accurate structural assignment. The great importance of complete methylation of polysaccharide products prior to structural determination by hydrolysis cannot be over-stressed and has been all too frequently neglected[10,11] with the result that conclusions drawn have only a restricted value.

Throughout this investigation every precaution was taken to obtain yields of material as nearly quantitative as possible in order that the results obtained could be based on a very high percentage of the starting material and therefore be of true significance. With dextran and its derivatives this involved reducing experimental manipulations and transfers to a minimum since these compounds are very difficult to handle because of their physical properties.

Dimethyl sulfate and alkali yielded a partially methylated dextran (40–41% OCH_3) which was further methylated to the theoretical value of 45.6% OCH_3 (calcd. for $C_6H_7O_2(OCH_3)_3$) in 71.4% over-all yield by a modified Muskat technique.[12] Hydrolysis of the completely methylated dextran was carried out with methanol–hydrogen chloride, in sealed glass bombs, heated to 140–142° for sixty to sixty-five hours in a tilting electric oven. The resulting glucosidic mixture, obtained in 95% yield, was fractionated by the new technique described in the preceding communication[13] using the modified Podbielniak column,[14] and an excellent separation of the glucosides effected with an over-all recovery of 97%. Of the 5% lost during

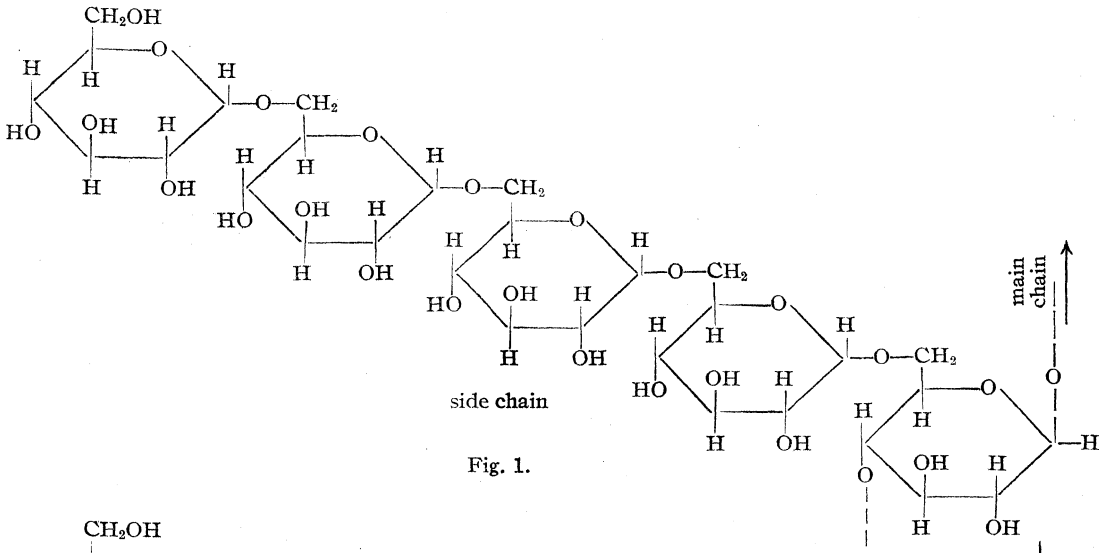

Fig. 1.

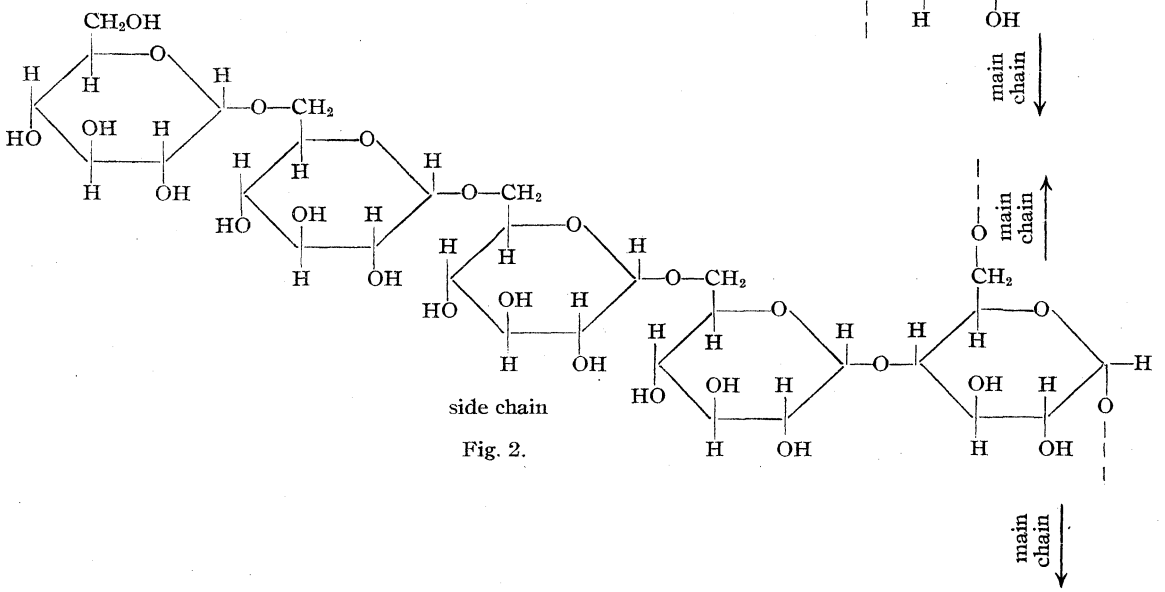

Fig. 2.

hydrolysis, 4% could be accounted for as methyl levulinate. It was shown by control experiments that the three partially methylated monosaccharides obtained from the hydrolysis of methylated dextran were all decomposed in this manner and to the same extent (1.5%) so that this side reaction does not affect the final ratio. By this procedure the ratio of tetra- to tri- to dimethyl methyl glucoside was established as exactly 1:3:1, thus verifying the earlier results of Hibbert and co-workers.[2]

The tetramethyl methyl glucoside and trimethyl methyl glucoside were identified as 2,3,4,6-tetramethyl methyl glucoside and 2,3,4-trimethyl methyl glucoside, respectively.

The dimethyl methyl glucoside was identified as the 2,3-derivative by oxidation of the dimethyl glucose to the corresponding dimethyl gluconic acid (84% yield) by the method of Hudson and Isbell.[15]

The dimethyl gluconic acid was characterized as the crystalline 2,3-dimethyl gluconophenylhydrazide (81% yield).

Based on the above evidence, two tentative formulas for dextran (Figs. 1 and 2), differing only in the position of attachment of the side chain, are suggested. These, however, do not exhaust all the possibilities and it is conceivable that the side chain may consist of three, two or even one unit with a corresponding lengthening of the primary chains.

Three of the linkages between the building units are of the 1,6 type while the remaining two are

(15) Hudson and Isbell, THIS JOURNAL, **51**, 2225 (1929).

either 1,4 or 1,6. No decision can be reached at present as to whether the linkages are α or β.

Experimental

Methylation of Dextran.—Thirty grams of dextran was suspended in 300 cc. of water, made alkaline by the addition of 25 cc. of 30% sodium hydroxide and methylated by the Haworth method in an atmosphere of nitrogen, using ten successive portions of 100 cc. of sodium hydroxide and 40 cc. of dimethyl sulfate. The alkali and the dimethyl sulfate were added to the reaction mixture concurrently. The complete reaction was carried out at room temperature.

The sodium sulfate formed during the methylation was removed by dialysis through a cellophane membrane. Three such methylations were carried out; yield, 34.0 g.; OCH_3, 40.5%.

Further methylations were effected using an original modification of Muskat's method.[12] The apparatus consisted of a cylindrical Pyrex container (7.5 × 22.5 cm.) with a side arm for the passage of ammonia. A condenser and mercury-sealed stirrer were attached to the flask by ground glass joints.

Thirty-four grams of dextran (OCH_3, 40.5%) was suspended in anhydrous anisole (340 cc.) in the reaction flask and 40 cc. of anisole distilled off under reduced pressure (20 mm.) to remove the last traces of water. The remaining dextran–anisole suspension (300 cc.) was stirred overnight. The anisole was then frozen by means of a chloroform–solid carbon dioxide-bath, and metallic sodium (0.9 g.) added to dry the ammonia (200 cc.), which was condensed on the solid anisole (time three to four hours). Metallic sodium (4 g.) was added, the anisole allowed to melt, and the mixture stirred for three to four hours. The ammonia was allowed to evaporate spontaneously. Twenty cc. of anisole was distilled off under vacuum and in an atmosphere of nitrogen, to remove the last traces of ammonia, methyl iodide (100 g.) added and the mixture refluxed overnight at 60° on the water-bath. Additions of both sodium and methyl iodide were made through the side-arm by temporarily removing the condenser.

The methyl iodide was removed by distillation under reduced pressure through a distilling head which fitted the reaction flask (ground glass joints throughout). Twenty cc. of anisole was added and then removed by vacuum distillation in order to expel traces of moisture.

This procedure was repeated twice more without removing the product from the flask (trial experiments had shown that the inorganic impurities did not interfere with the methylation).

After the third methylation there was considerable inorganic material present which was removed at this stage as follows. The reaction mixture was taken to dryness (20 mm.) in an atmosphere of nitrogen, water (300 cc.) added, the mixture heated, with occasional stirring, to the boiling point and kept at this temperature for ten minutes. The dextran was removed by centrifuging the cooled solution, then dried in the vacuum oven overnight at 55–60°. The well-dried, partially-methylated dextran dissolved readily in cold chloroform (10 cc. of chloroform per gram of methylated dextran) and any appreciable residue was removed by centrifuging the chloroform solution, followed by filtration. One to two volumes of 30–50° petroleum ether was added until an appreciable turbidity was apparent. This initial slight precipitate contained much of the residual ash. The clear filtrate was precipitated into 30–50° petroleum ether (total volume twenty times that of chloroform used), and the resulting precipitate washed twice with fresh 30–50° petroleum ether and dried [55° (20 mm.)] for thirty hours; yield, 29.8 g.; OCH_3: 1st Muskat methylation 41.5%; 2nd, 42.3%; 3rd, 44.0%. (The methoxyl values were obtained by removing and purifying a small representative sample.) The dextran was then methylated three more times as above and purified in the same manner; yield, 27.6 g.; OCH_3: 4th Muskat methylation 44.9%; 5th, 45.3%; 6th, 45.6%. Calcd. for: $C_6H_7O_2(OCH_3)_3$: C, 52.94; H, 7.84; OCH_3, 45.6. Found: C, 52.70; H, 7.92; OCH_3, 45.6.

Hydrolysis of Methylated Dextran.—Fully methylated dextran (7.100 g.) was hydrolyzed in three separate portions of 3.060, 1.520 and 2.520 g., respectively.

In a typical hydrolysis 3.060 g. of methylated dextran was suspended in anhydrous methanol (60 cc.) containing 2% hydrogen chloride, sealed in a glass bomb-tube and heated at 140–142° in a tilting electric oven for 60–65 hours. After this time the dextran had dissolved completely and the solution changed from a pale yellow to a clear reddish brown color.

The bomb was cooled to 0°, opened, and the excess hydrogen chloride gas allowed to escape while the solution attained room temperature. The open end of the bomb was fitted, during this period, with a Kjeldahl trap as a precaution in case of a too vigorous effervescence.

The solution was transferred to a centrifuge cup and neutralized (litmus) with silver carbonate, the insoluble silver salts removed by centrifugence and filtration and washed with three portions (15 cc. each) of anhydrous methanol, the washings being added to the original filtrate. At this point the methanolic solutions from the three separate hydrolyses were combined and the solvent removed under reduced pressure [20 mm. (50°)].

The resulting sirup was dissolved in 142 cc. of water so that a 10-cc. aliquot contained the glucosides originating from 0.5 g. of methylated dextran. To 10 cc. of this solution was added 50 cc. of 2,4-dinitrophenylhydrazine (containing 0.2 g. of reagent). After twenty minutes the precipitate (A) was filtered, dried under suction and finally in a vacuum desiccator; yield, 0.030 g. representing 4.2% decomposition of the dextran; recrystallized from methanol; melting point, 138–139°. A mixed melting point with an authentic sample of 2,4-dinitrophenylhydrazone of methyl levulinate showed no depression.

To the filtrate (B) an additional 50 cc. of reagent was added and the solution allowed to stand at room temperature for two and one-half hours. No further precipitate formed.

Removal of Methyl Levulinate.—To the remainder of the aqueous solution containing the glucosides from 6.6 g. of methylated dextran was added a barium hydroxide solution (20 cc.), saturated at 92–93°, and the mixture kept at 60–62° on the water-bath for two hours. It was then taken to dryness [20 mm. (50–60°)], and the residue extracted by hand shaking with the following successive portions of hot chloroform: 100, 50, 50, 50, 50, 25, 25, 25 cc.

TABLE I

FRACTIONATION OF GLUCOSIDIC MIXTURE OBTAINED FROM HYDROLYSIS OF FULLY-METHYLATED DEXTRAN

Fraction	Physical state	Fraction, g.	OCH_3, %	"Tetra," g.	"Tri," g.	"Di" g.
1	Colorless sirup	1.204	61.0	1.204		
2	Colorless sirup and white crystals	0.207	57.8	0.113	0.094	
3	White crystals (pure 2,3,4-trimethyl methyl glucoside)	0.605	52.8		0.605	
4	White crystals and colorless sirup (α and β mixture)	2.811	52.4		2.811	
5	Colorless sirup	0.397	46.5		0.172	0.225
6	Light yellow sirup	1.013	42.0			1.013
Total				1.317	3.682	1.238
Ratio				1.01	3.00	1.07

The theoretical methoxyl values for tetra-, tri-, and dimethyl methyl glucosides are 62.0, 52.6, and 41.9%, respectively. The amounts of each present in the small intermediate fractions (2 and 5, Table I) were calculated on this basis.

The combined extracts were evaporated at 40° and 20 mm. pressure, and the residue distilled under high vacuum (0.005 mm.) to give a clear sirup; yield, 7.245 g. (95%). Calcd. for $C_6H_8O_2(OCH_3)_4$: OCH_3, 52.6%; found, OCH_3, 52.3%.

Fractionation of the Glucosides.—The glucosidic mixture (6.43 g.) was fractionated using the same conditions and technique as described in the preceding paper.[13] The results of the fractionation, methoxyl analyses and allocation of the two intermediate fractions among the glucosides are summarized in Table I.

Identification of the Glucosides

(a) Tetramethyl Methyl Glucoside.—A portion (0.70 g.) of Fraction 1 was hydrolyzed with 15 cc. of 5% sulfuric acid at 100° for eighteen hours, after which time the rotation was constant.

The acid solution was neutralized to litmus with solid barium carbonate, filtered, and the filtrate taken to dryness [55° (20 mm.)], in an atmosphere of nitrogen. The residue was extracted with four 25-cc. portions of hot anhydrous acetone, the combined acetone solutions filtered, and the solvent removed at 20° leaving a pale yellow sirup, to which 10 cc. of anhydrous ether was added. On standing a precipitate of fine white needles was obtained as the ether evaporated; weight 0.50 g. (75% of theoretical). The product was recrystallized from low-boiling (30–50°) petroleum ether containing 5% diethyl ether; m. p. 90–91°. A mixed melting point with an authentic sample of 2,3,4,6-tetramethyl glucose showed no depression.

(b) Trimethyl Methyl Glucoside.—A portion (0.58 g.) of Fraction 3 was recrystallized from low boiling (30–50°) petroleum ether containing 5% diethyl ether. A mass of fine white needles was obtained (0.42 g.), m. p. 93–94°, which showed no mixed melting point depression with an authentic sample of 2,3,4-trimethyl-β-methyl glucoside.

(c) Dimethyl Methyl Glucoside.—A portion (0.60 g.) of Fraction 6 was hydrolyzed to the corresponding dimethyl glucose (0.538 g.) using the procedure outlined above for the hydrolysis of the tetramethyl methyl glucoside. Calcd. for $C_6H_{10}O_4(OCH_3)_2$: OCH_3, 29.9. Found: OCH_3, 30.2.

The dimethylglucose (0.538 g.) was oxidized to the corresponding dimethylgluconic acid by use of the method of Hudson and Isbell;[15] weight of dimethylgluconic acid, 0.487 g. (84%).

The dimethylgluconic acid (0.487 g.) was characterized as the crystalline 2,3-dimethylgluconophenylhydrazide.[16] The weight of recrystallized product (from ethanol) was 0.556 g. (81.4%), (of fine white needles); m. p. 166.5–167.5° (uncor.); mixed melting point with authentic 2,3-dimethylgluconophenylhydrazide showed no depression. Calcd. for $C_{14}H_{22}O_6N_2$: C, 53.5; H, 7.0; N, 8.9; OCH_3, 19.7. Found: C, 53.5; H, 7.1; N, 9.0; OCH_3, 19.5.

Summary

1. The complete methylation of the dextran, synthesized by *Leuconostoc mesenteroides*, has been accomplished in an over-all yield of 71.4%.

2. Hydrolysis of trimethyl dextran and fractionation of the resulting glucoside mixture, employing quantitative technique, have established the ratio of tetra- to tri- to dimethyl methyl glucoside as 1:3:1.

3. The three glucosides have been identified, and based on these results a tentative formula for the structure of dextran has been proposed.

The Preparation and Properties of Certain Polyethoxyethanes and their Bromo Derivatives

BY S. M. MCELVAIN AND PHILIP M. WALTERS

The original object of most of the work that is described in this paper was the preparation of triethoxyethylene (ethoxyketene diethylacetal) in order that its properties might be recorded with those of the other ketene acetals recently reported[1] from this Laboratory. To date, however, all attempts to prepare this particular ketene acetal have been consistently unsuccessful, but the preparation and properties of the various ethoxyethanes and their bromo derivatives that have been used in these attempts seem to be of sufficient interest to record.

The unsymmetrical diethoxyethane, acetal (I), in the presence of pyridine is brominated readily (at 10–15°) and in fair yields (25–30%) to the mono- and dibromo derivatives II and III.[2] The unsymmetrical triethoxyethane, ethyl orthoacetate (IV), brominates in good yields (55–75%) in the presence of pyridine, but at slightly higher temperatures (10–35°) to the bromo derivatives V and VI, thus

Py = pyridine

$$CH_3CH(OEt)_2 \xrightarrow[\text{at } 10^\circ]{Br_2 + Py} BrCH_2CH(OEt)_2 \xrightarrow[\text{at } 15^\circ]{Br_2 + Py} Br_2CHCH(OEt)_2$$

I II III

$$CH_3C(OEt)_3 \xrightarrow[\text{at } 10^\circ]{Br_2 + Py} BrCH_2C(OEt)_3 \xrightarrow[\text{at } 35^\circ]{Br_2 + Py} Br_2CHC(OEt)_3$$

IV V VI

However, the corresponding symmetrically substituted compounds, ethylene glycoldiethyl ether and ethoxyacetal, $EtOCH_2CH(OEt)_2$, not only require a decidedly higher reaction temperature (65°) to cause one equivalent of bromine and pyridine to react with each of them, but yield a variety of cleavage products instead of monobromo derivatives. In all of the above mentioned brominations higher reaction temperatures are required if pyridine is not used, and under these conditions the bromination is not smooth but is accompanied by cleavage of ethoxyl groups by the hydrogen bromide produced in the reaction.

The differences in the behavior of the bromo compounds II, III, V and VI toward sodium or potassium alkoxides are interesting. As previously reported[3] bromoacetal (II) yields mainly ethoxyacetal when treated with an alcoholic solution of sodium ethoxide, but with potassium *t*-butoxide in *t*-butyl alcohol it is converted into ketene acetal.[4] Dibromoacetal (III) reacts readily with one equivalent of potassium ethoxide but is very resistant to further action of this reagent. It was first thought[5] that the product of the reaction of one equivalent of potassium ethoxide with III was bromoethoxyacetal, $EtOCHBrCH(OEt)_2$, together with a small amount of bromoketene acetal (VII), which added a molecule of alcohol to give the orthobromoester (V) that was always isolated as one of the reaction products. With potassium *t*-butoxide in *t*-butyl alcohol the dibromoacetal (III) was smoothly transformed with the loss of hydrogen bromide, into VII.

$$III \xrightarrow{-HBr} BrCH{=}C(OEt)_2 \xrightarrow{EtOH} V$$

VII

It is now found that the earlier observation was in error and that the reaction of III with potassium ethoxide in ethyl alcohol solution does not yield any detectable quantities of the bromoethoxyacetal by direct replacement of a bromine by ethoxy but instead gives bromoketene acetal (VII) by the elimination of hydrogen bromide from III. Indeed, if the reaction mixture is worked up within a few hours after the reaction is finished, yields of VII as high as those obtained in *t*-butyl alcohol may be isolated. As previously reported[5] ethyl orthobromoacetate (V) is always present as a reaction product; in fact, it is the only product if the reaction mixture is allowed to stand too long before working up. It appears from these results that bromoketene acetal reacts sufficiently slowly with alkaline alcohol to allow

(1) McElvain and Walters, THIS JOURNAL, **64**, 1059 (1942).

(2) This method of preparation, however, is not as satisfactory for II as is the bromination of vinyl acetate [Filachione, *ibid.*, **61**, 1705 (1939)] nor for III as is the bromination of II in the presence of calcium carbonate [Beyerstedt and McElvain, *ibid.*, **59**, 2267 (1937)].

(3) Beyerstedt and McElvain, *ibid.*, **58**, 529 (1936).

(4) Johnson, Barnes and McElvain, *ibid.*, **62**, 968 (1940).

(5) Beyerstedt and McElvain, *ibid.*, **59**, 2266 (1937).

it to be formed in and isolated from this medium.[6] This behavior is in a marked contrast to the instantaneous reaction of this ketene acetal with alcohol, containing a trace of acid, to produce the ortho-ester V.

Since it was not possible to obtain the bromoethoxyacetal $EtOCHBrCH(OEt)_2$ from III due to the ease with which this latter compound lost hydrogen bromide, the preparation of ethyl orthobromoethoxyacetate, $EtOCHBrC(OEt)_3$, from the orthodibromoester (VI) was undertaken. If this bromoethoxyorthoester were available it should be readily convertible into the desired triethoxyethylene by the action of sodium.[7] Although the dibromo-orthoester (VI) cannot lose hydrogen bromide it failed to give the expected bromoethoxyorthoester when treated with one equivalent of potassium ethoxide in alcohol solution. Instead the monobromo-orthoester (V) was the reaction product. This latter orthoester was found to react similarly with alcoholic potassium ethoxide with the formation of ethyl orthoacetate, thus

$$VI \xrightarrow[EtOH]{KOEt} V \xrightarrow[EtOH]{KOEt} CH_3C(OEt)_3$$

The positive character of the bromine in the orthoesters V and VI is striking. It is well known[8] that an increase in the number of negative (electron attracting) groups on a carbon carrying a halogen increases the tendency of that halogen to be replaced, through hydrolytic cleavage, by hydrogen (instead of hydroxyl) as, for example, in the hydrolysis of carbon tetrabromide to bromoform and bromomalonic ester to malonic ester. In the cases of the orthoesters, V and VI, however, it is seen that the effect of the three ethoxy groups is sufficiently great to render positive in its reaction a bromine one carbon removed from the carbon carrying the ethoxy groups.

The failure of the dibromo-orthoester VI to yield the bromoethoxyorthoester led to the attempt to prepare this latter compound by the bromination of ethyl orthoethoxyacetate (VIII). This latter ester was obtained through the following sequence of reactions

$$ClCH_2COOH \longrightarrow EtOCH_2COOH \longrightarrow EtOCH_2COOEt \longrightarrow EtOCH_2CONH_2$$
$$EtOCH_2CN \longrightarrow EtOCH_2C(OEt)=NH\cdot HCl \longrightarrow EtOCH_2C(OEt)_3$$
VIII

The orthoester VIII shows a resistance to bromination similar to that of ethylene glycol diethyl ether and ethoxyacetal mentioned above. It did react with bromine in the presence of pyridine at 80° to yield pyridine hydrobromide, but the ester was transformed in the process into a tar from which nothing could be distilled.

Experimental

Ethyl Orthobromoacetate.—This bromo-orthoester was prepared by the bromination of ethyl orthoacetate in pyridine employing the method of Beyerstedt and McElvain.[9]

Ethyl Orthodibromoacetate.—To a stirred mixture of 162 g. (1 mole) of ethyl orthoacetate and 158 g. (2 moles) of pyridine was added dropwise 320 g. (2 moles) of bromine over a period of two hours. The reaction mixture was cooled to about 30° until one-half of the bromine had been added, whereupon the temperature was allowed to rise to 60–70° for the remainder of the bromine addition. The reaction mixture was stirred for an additional two hours. The brominated ester then was separated from the precipitated pyridine hydrobromide and this salt thoroughly washed with anhydrous ether. These washings were combined with the dibromoester and distilled. The yield of ethyl orthodibromoacetate was 170 g. (53%); b. p. 102–104° (8 mm.); $n^{25}D$ 1.4691; d^{25}_{25} 1.5272.

This compound has been previously isolated and identified as a by-product of the monobromination of ethyl orthoacetate.[9]

Bromination of Acetal in Pyridine.—Diethyl acetal was brominated in pyridine by the above method at a somewhat lower temperature (10–15°) to monobromoacetal (23%) and dibromoacetal (29%).

Bromination of Ethoxyacetal and Ethylene Glycol Diethylether.—Bromination of ethoxyacetal[10] in pyridine at 65° failed to give the expected monobromination product, bromoethoxyacetal, but resulted in a variety of cleavage products. The only clean-cut fraction obtained on fractionation was a 15% yield of a material boiling at 79° (12 mm.); $n^{25}D$ 1.4175. This material gave a positive Fehling test and yielded a sodium bisulfite addition product, reactions which the original ethoxyacetal failed to show. These two tests and the ethoxyl analysis would indicate this fraction to be diethoxyacetaldehyde.

Anal. Calcd. for $C_6H_{12}O_3$: C_2H_5O, 68.1. Found: C_2H_5O, 68.3.

This compound has been reported previously by Fischer

(6) Dichloroacetal shows a similar behavior with alcoholic potassium ethoxide and yields 60% of the theoretical amount of chloroketene acetal even after the reaction mixture is allowed to stand overnight before it is worked up. In this connection it is interesting to note that Pinner (*Ber.*, **5**, 151 (1872)) reported the preparation of the symmetrical tetraethoxyethane, glyoxaltetraethylacetal, from the reaction of sodium ethoxide with dichloroacetal. He reported no yields or analyses, but did remark that he could not obtain a completely chlorine-free product. In the light of the present work it would seem that Pinner did not have the glyoxal-acetal but ethyl orthochloroacetate (from the addition of alcohol to chloroketene acetal) probably mixed with ethyl orthoacetate (from the reaction of sodium ethoxide with the orthochloroester).

and Baer[11] who prepared it by the lead tetraacetate oxidation of glyceraldehyde acetal. However, they reported a considerably lower boiling point for their product than was obtained in the present work.

Bromination of ethoxyacetal in the absence of a solvent at 80° yielded a number of cleavage products. From one mole of acetal, there was obtained 0.48 mole of ethyl bromide, b. p. 38–40°; 0.97 mole of water, b. p. 98–100°; 0.75 mole of ethyl alcohol, b. p. 76–80°; and 0.275 mole of dibromoacetal, b. p. 95–97° (12 mm.); $n^{25}D$ 1.4788; C_2H_5O, 32.6% (calcd. 32.6%).

Bromination of ethylene glycol diethylether in pyridine at 65° and bromination in the absence of a solvent at a somewhat higher temperature (80°), resulted in a variety of cleavage products instead of monobromo derivatives.

The Reaction of Alcoholic Potassium Ethoxide with Ethyl Orthobromoacetate and with Ethyl Orthodibromoacetate.—To a stirred solution of 30 g. (0.77 atom) of potassium in 400 ml. of absolute alcohol was added 80 g. (0.25 mole) of ethyl orthodibromoacetate and the resulting mixture gently refluxed for thirty-six hours. The excess alcohol then was removed carefully by atmospheric distillation, and the orthoesters separated from the precipitated potassium bromide by extracting the residue several times with anhydrous ether. The ether extracts were combined and distilled. Twenty-one grams (52%) of ethyl orthoacetate, b. p. 68–70° (50 mm.), and 25 g. (42%) of ethyl orthobromoacetate, b. p. 78–80° (10 mm.), were obtained.

In a similar experiment employing equimolar quantities of potassium ethoxide and dibromo ester, there was obtained 30 g. (50%) of ethyl orthobromoacetate and 12 g. (15%) of unchanged ethyl orthodibromoacetate. Repetition of this experiment with ethyl orthobromoacetate as the starting material gave ethyl orthoacetate as the reaction product.

Reaction of Dibromo- and Dichloroacetal with Alcoholic Potassium Ethoxide.—To a stirred mixture of 138 g. (0.5 mole) of dibromoacetal and 100 ml. of absolute alcohol in a 1-liter three-necked flask, fitted with a dropping funnel and reflux condenser was added slowly a solution of 20 g. (0.5 atom) of potassium in 300 ml. of absolute alcohol. The flask was heated on a steam-bath during the addition and for two hours after the last of the alcoholic alkali had been added. The condenser then was set for downward distillation and 300 ml. of alcohol removed from the reaction mixture, after which the precipitated potassium bromide was filtered off. The filtered salt was washed thoroughly with anhydrous ether and the washings combined with the filtrate, and distilled. The yield of bromoketene acetal was 61 g. (62.5%); b. p. 72–3° (11 mm.); $n^{25}D$ 1.4610; d^{25}_4 1.319; C_2H_5O, 45.7% (calcd. 46.1%).

In a similar experiment employing dichloroacetal instead of dibromoacetal there was obtained 45 g. (60%) of chloroketene acetal, b. p. 57–58° (10 mm.); $n^{25}D$ 1.4378; d^{25}_4 1.052; C_2H_5O, 59.4% (calcd. 59.8%).

In each of the above preparations the product should be worked up as rapidly as possible to ensure the optimum yields of the respective ketene acetals.

(11) Fischer and Baer, *Helv. Chim. Acta*, **18**, 514 (1935).

Ethoxyacetonitrile.—Ethoxyacetamide, b. p. 225–230°, m. p. 82–83°, was obtained in 85% yields by the action of aqueous ammonia on ethyl ethoxyacetate.[12] A mixture of 103 g. of this amide and 142 g. of phosphorus pentoxide in a 1-l. distilling flask was heated in an oil-bath at 150–180° as long as the ethoxyacetonitrile distilled over. The crude distillate was redistilled from 5 g. of fresh phosphorus pentoxide. The yield of nitrile boiling at 133–134°, $n^{25}D$ 1.3888,[13] amounted to 51 g. (60%).

Ethyl Orthoethoxyacetate.—This orthoester was prepared by the method of McElvain and Nelson.[14] The iminoester hydrochloride precipitated in 88% yield when the procedure described for the preparation of the hydrochloride from chloroacetonitrile was followed. A 47% yield of the orthoester was obtained when 1 mole of the hydrochloride was alcoholysed in a refluxing mixture of 290 ml. of absolute alcohol and 340 ml. of absolute ether over a period of three hours. Ethyl orthoethoxyacetate boils at 69–70° (10 mm.) or 180–181° (740 mm.); $n^{25}D$ 1.4055; d^{25}_{25} 0.921.

Anal. Calcd. for $C_{10}H_{22}O_4$: C, 58.2; H, 10.8; C_2H_5O, 87.4. Found: C, 58.4; H, 10.7; C_2H_5O, 86.5.

Bromination of Ethyl Orthoethoxyacetate.—To a stirred mixture of 20.6 g. (0.1 mole) of ethyl orthoethoxyacetate and 7.7 g. (0.098 mole) of pyridine was added dropwise 16.0 g. (0.1 mole) of bromine over a period of thirty minutes. The reaction mixture was heated at a temperature of 80° during the bromine addition with no apparent reaction occurring until the bromine addition was practically completed. Then a vigorous reaction occurred which had to be controlled by the application of a cold water-bath. After the initial reaction had subsided, the reaction flask was heated for an additional hour at 80°. The precipitated pyridine hydrobromide (88%) was removed by filtration and thoroughly extracted with anhydrous ether. These washings were combined with the filtrate and distilled.

From none of the several brominations carried out could any bromination product be isolated and identified. The products obtained were mainly low-boiling liquids and a non-distillable, carbonaceous residue.

Summary

The behavior of acetal, ethyl orthoacetate, ethylene glycol diethyl ether, ethoxyacetal, and ethyl orthoethoxyacetate toward bromination is compared.

Dibromoacetal is shown to give only bromoketene acetal with alcoholic potassium ethoxide, and not bromoethoxyacetal as was reported previously. Both ethyl orthobromoacetate and ethyl orthodibromoacetate have their bromine replaced by hydrogen instead of ethoxyl with this reagent.

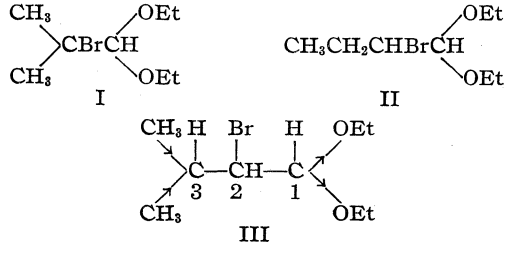
Ketene Acetals. X. The Elimination of Hydrogen Bromide from the Acetals of α-Bromoaldehydes. Isopropyl- and *n*-Propylketene Diethylacetal

By S. M. McElvain, Robert L. Clarke[1] and Giffin D. Jones

The preparation of ketene diethylacetal by the elimination of a molecule of halogen acid from the iodo- or bromo-acetal[2] raised the question as to the applicability of this reaction to the α-bromo-acetals of the higher homologs of acetaldehyde. From a purely statistical consideration, such an acetal as α-bromoisobutyraldehyde acetal (I) with six β-hydrogens would seem much more likely to lose hydrogen bromide between the α- and one of the β-carbon atoms and yield the acetal of the unsaturated aldehyde. Similarly, the acetal of α-bromo-*n*-butyraldehyde (II) contains two β-hydrogens to compete with the single hydrogen of the acetal carbon atom. In the case of the acetal of α-bromoisovaleraldehyde (III), however, the single hydrogen in the β-position would indicate an even statistical chance that some of the ketene acetal as well as the unsaturated acetal would be formed. A consideration of the electronic nature of the groups of III would seem to lead more surely to the prediction that the ketene acetal rather than the unsaturated aldehyde acetal would be produced by the elimination of hydrogen bromide. If the mechanism of the elimination reaction involves, as is generally believed, first the removal of a proton[3] from the molecule by the base, followed by the emission of the bromide ion, then the inductive effects of the groups attached to carbons 1 and 3 of III should make the hydrogen on carbon 1 much more labile and consequently more likely to be removed with the bromine than the hydrogen on carbon 3.



As a matter of fact, each of the bromo-acetals, I, II and III is converted by both sodium ethoxide in alcohol and potassium *t*-butoxide in *t*-butyl alcohol into the corresponding unsaturated acetals. There is no indication that a ketene acetal is produced in any of these reactions. An explanation of these results led to a consideration of (a) the validity of the proton-removal mechanism of the elimination reaction, (b) the possibility that the ketene acetal really was initially formed from III and then rearranged under the reaction conditions into the acetal of the α,β-unsaturated aldehyde.

Relative to the mechanism of the elimination reaction, Hughes, Ingold, Masterman and McNulty[4] in a recent paper have pointed out that there are two mechanisms by which hydrogen bromide may be eliminated from such a compound as III. The first of these involves the emission (or ionization) of the bromide ion from the molecule as the rate controlling step which is then followed by the rapid loss of a proton. Such a mechanism requires that the elimination be a first order reaction. The other alternative is the generally accepted proton-removal mechanism which postulates that the rate controlling step is the removal of a proton by the base followed by the rapid emission of the bromide ion. This mechanism requires that the reaction be second order. A third possibility that might be considered involves the intermediate formation of a β-alkoxy acetal with the subsequent loss of an alcohol molecule to form the unsaturated aldehyde acetal. It would be predicted that the *t*-butoxide ion should, due to steric effects, react more slowly than the ethoxide ion to form this intermediate were this the correct mechanism. This mechanism also requires that the reaction be second order unless the loss of the alcohol molecule be the controlling step.

In the hope of gaining some information as to which of these mechanisms is followed in the process of elimination of hydrogen bromide from III, three series of reaction rate determinations between this bromo-acetal and 0.75 *N* and 2.0 *N* sodium ethoxide in absolute alcohol and 0.75 *N* potassium *t*-butoxide in *t*-butyl alcohol were

carried out. Plots of the reciprocal of the concentration against time are shown in Fig. 1. It is seen that these curves approximate the straight lines characteristic of a second order reaction in each case. It may also be seen from these plots that potassium *t*-butoxide causes a more rapid elimination of hydrogen bromide from III than does sodium ethoxide, a fact which eliminates the third possible reaction mechanism mentioned above. These facts lead to the rather contradictory conclusions that the elimination of hydrogen bromide from III follows the proton-removal mechanism and that the least labile proton is removed, unless it be that the proton of carbon 1 of III is really removed and the resulting ketene acetal, by a prototropic change, rearranges into the acetal of the unsaturated aldehyde which actually was isolated from the reaction.

In order to test this latter possibility it was necessary to prepare the ketene acetal in question. Both the isopropyl- and *n*-propylketene diethyl-acetals (V, R is isopropyl and *n*-propyl) were prepared by the action of sodium on the corresponding α-bromo-orthoesters,[5] thus

$$\underset{\text{IV}}{RCHBrC(OEt)_3} + Na \longrightarrow \underset{\text{V}}{RCH{=}C(OEt)_2} + NaOEt + NaBr$$

Both of these ketene acetals add water readily to give the corresponding esters and show no tendency to rearrange into the unsaturated acetals when refluxed in a *t*-butyl alcohol solution of potassium *t*-butoxide. In these respects their behavior is similar to that of methylketene diethyl acetal.[5,6]

It is seen from the results outlined above that the hydrogen on carbon 3 rather than the one on carbon 1 of α-bromoisovaleraldehyde acetal (III) is the more active and that electronic factors other than simple inductive effects are operative in the basic elimination of hydrogen bromide from this acetal. In this connection it might be noted that a halogen on a carbon carrying an ethoxyl group, *i. e.*, an α-chloro-ether, is very reactive, presumably on account of an electromeric polarization, $EtO\overset{\curvearrowright}{-}\underset{|}{\overset{|}{C}}\overset{\curvearrowright}{-}Cl$, that facilitates the removal of the chloride ion. If the ethoxy group is thus able to facilitate the removal of an anion from a carbon to which it is attached, it would seem reasonable to believe that it would impede the separation of a positive proton. That is to say, the failure of the acetal (III) to lose hydrogen bromide between carbons 1 and 2 is another case of the more potent electromeric (E) effect of an alkoxy group overshadowing an inductive (I) effect of opposite direction.[7] It must be admitted, however, that an illustration of the electromeric hindrance of the ethoxy groups of III to the loss of a proton from carbon 1 is difficult to imagine without some increase in this carbon's octet of electrons.

Experimental

Acetals.—The diethyl acetals of isobutyraldehyde, *n*-butyraldehyde and isovaleraldehyde were prepared by the Tschitschibabin reaction from ethyl orthoformate and the appropriate Grignard reagent according to the procedure for the preparation of the acetal of hexaldehyde.[8] The following modifications were found to give considerable improvements in yield. After the addition of the ethyl orthoformate and a refluxing period of sixteen hours, crushed ice was added to decompose the excess of Grignard reagent. The ether layer was decanted and washed with water. The aqueous layer was covered with ether, cooled and treated slowly and with stirring with a 10% solution of acetic acid that contained 80% of the acetic acid required for the neutralization of the basic magnesium bromide produced in the reaction. Since all of the solids did not dissolve, the supernatant liquids were decanted, the ether layer separated, washed with water and a 10% sodium carbonate solution. The aqueous layer was extracted twice with ether and, after washing, the ether layers were combined, dried over potassium carbonate and fraction-

ated. Using these modifications of procedure and two-mole quantities of reactants isobutyraldehyde diethylacetal, b. p. 133–136°, *n*-butyraldehyde diethylacetal, b. p. 143–144°, and isovaleraldehyde diethylacetal, b. p. 156–158°, were obtained in yields of 83, 80 and 90% of the theoretical, respectively.

α-Bromo-acetals.—The three acetals mentioned above were brominated by the procedure of Hartung and Adkins.[9] The yields of α-bromoisobutyraldehyde diethylacetal, b. p. 63–64° (7 mm.), α-bromo-*n*-butyraldehyde diethylacetal, b. p. 82–84° (12 mm.), and α-bromoisovaleraldehyde diethylacetal, b. p. 87–88° (14 mm.), were 36, 20 and 40% of the theoretical, respectively.

Since the α-bromoisovaleraldehyde acetal was to be used for kinetic studies it was further purified, particularly since it was found that the product obtained from the bromination reaction gave low ethoxyl values as well as about 8% immediate reaction with an alcoholic solution of sodium ethoxide. In an attempt to hydrolyze the bromo-acetal to the corresponding bromo-aldehyde, it was accidentally discovered that the unchanged bromo-acetal recovered from the incomplete hydrolysis showed the correct ethoxyl content and gave a quite low (2%) zero-time reaction with sodium ethoxide. Apparently the lower boiling bromo-aldehyde had carried with it, as an azeotropic mixture, the unknown contaminants of the bromo-acetal leaving the unhydrolyzed acetal quite pure. Since as high a purity as possible for the acetal was desired, the following rather wasteful purification procedure was adopted: a mixture of 25 g. of the bromo-acetal from the bromination reaction and 7 ml. of dilute (1:10) sulfuric acid was heated on a steam-bath with occasional shaking for ten minutes. Then 10 ml. of ether was added, the layers separated and the ether layer washed with 7 ml. of a 10% potassium carbonate solution. After drying over anhydrous potassium carbonate, the ether layer was fractionated. After removal of the ether and the lower boiling fractions, 12 g. of α-bromoisovaleraldehyde diethyl acetal, b. p. 55–56° (3 mm.), or 92–93° (14 mm.); $n^{25}D$ 1.4438; d^{25}_4 1.163 was obtained.

Anal. Calcd. for $C_9H_{19}O_2Br$: C_2H_5O, 37.7; Br, 33.5. Found: C_2H_5O, 37.5; Br, 33.2.

α-Bromoisovaleraldehyde diethylacetal has been prepared by Fischer, Ertel and Löwenberg,[10] who reported it to have the following properties: b. p. 88–89° (13 mm.); $n^{20}D$ 1.4489; d^{20}_4 1.177.

Preparation of Isobutenal-, *n*-Butenal- and Isopentenal-diethylacetal.—Each of these unsaturated acetals was obtained when the corresponding bromo-acetal was heated with an equivalent amount of 1.4 *N* potassium *t*-butoxide in *t*-butyl alcohol solution in the manner described[2b] for the preparation of ketene acetal from bromo-acetal. When the reactions were carried out in 0.2-mole quantities the yields of the isobutenal acetal,[11] b. p. 136–137°, *n*-butenal acetal,[12] b. p. 48–49° (21 mm.), and isopentenal acetal,[9,10] b. p. 59–60° (16 mm.), were 64, 41 and 62% of the theoretical, respectively.

None of these unsaturated acetals showed the warming characteristic of a ketene acetal when treated with water containing a trace of hydrochloric acid. The isobutenal acetal yielded a resinous solid when hydrolyzed, but the *n*-butenal acetal and isopentenal acetal gave the corresponding unsaturated aldehydes which were identified as the known semicarbazones.

Rate of Reaction of α-Bromoisovaleraldehyde Diethyl Acetal with Alkali Alkoxides.—The determination of the reaction rates between the bromoacetal and sodium ethoxide was attempted at 55°, but the rate was so low (11% reaction in thirteen hours) at this temperature that 80° was used as the reaction temperature. Determinations were made with 0.771 *N* and with 2.040 *N* sodium ethoxide in absolute ethyl alcohol and 0.760 *N* potassium *t*-butoxide in *t*-butyl alcohol.

The alkali solutions were prepared by dissolving the metal in the alcohol and titrating the resulting solutions against standard hydrochloric acid solution.

For each rate determination a series of 10 reaction tubes 7 cm. in length and 1.5 cm. in diameter and constricted at the open end for sealing, was prepared from Pyrex test-tubes. Approximately a 0.5-g. sample of the bromo-acetal was accurately weighed into each of these reaction tubes. Then the volume of the alcoholic alkali solution containing alkoxide equivalent to the bromo-acetal in each tube was rapidly calculated and added to the reaction tube from a buret. Each tube was sealed and immersed in an ice-bath immediately after the addition of the alkali.

At zero time all of the tubes except nos. 1 and 10 (in order of filling) were placed in a constant temperature bath at 80 ± 2°. Tubes 1 and 10 were then opened in bottles containing 50 ml. of water and 25 ml. of ether. After thorough mixing 1.5 ml. of concentrated nitric acid was added to the mixture, and the bromide ion determined by adding an excess of standard silver nitrate solution and back titrating with potassium thiocyanate. The apparent per cent. reaction at zero time thus obtained was subtracted from the per cent. reaction at each subsequent time interval. The concentration of the reactants at zero time was calculated by multiplying the original concentration in moles per liter after mixing by the per cent. reaction at zero time and subtracting this value from the original concentration.

Plots against time of $1/(a - x)$, in which a represents the original concentration of the reactants in moles per liter and x represents the moles reacted in time t, are shown in Fig. 1.

Isovaleronitrile.—In a distilling flask of such size that the reactants occupied not more than 0.4 of the volume of the flask were placed 190 g. (1.88 moles) of isovaleramide[13] (which had been dried at 110°) and 230 g. (1.62 moles) of phosphorus pentoxide. The two solids were mixed very thoroughly by shaking and the flask was connected to a condenser for distillation. The solid mixture was heated slowly in an oil-bath to 90° and allowed to stand at this temperature overnight. The bath temperature was then raised to 130° and held there for two hours. The product was then distilled under reduced pressure (200 mm.). The resulting distillate was redistilled from 5 g. of phosphorus pentoxide. A yield of 125 g. (80% of the theoretical) of the isovaleronitrile, b. p. 127–129°,[14] was obtained.

Ethyl Ortho-α-bromoisovalerate.—This ester was prepared from ethyl orthoisovalerate[15] by the following procedure. A mixture of 33 g. (0.162 mole) of ethyl orthoisovalerate and 13 g. (0.164 mole) of pyridine was introduced into a three neck flask fitted with a stirrer, condenser and dropping funnel. To this mixture was added 26 g. (0.162 mole) of bromine over a period of one hour, after which time the mixture was stirred overnight. Approximately 50 ml. of dry ether was then added and, after mixing and allowing the precipitate to settle, the ether solution was decanted. The solid remaining in the flask was washed by decantation with three 30-ml. portions of dry ether and the combined washings washed once with 25 ml. of 10% potassium carbonate. The ether solution was dried over anhydrous potassium carbonate and after the ether was removed, the product was distilled under reduced pressure. It boiled at 63–64° (1.3 mm.); $n^{25}D$ 1.4408; d^{25}_4 1.150. The yield amounted to 31 g. (67% of the theoretical). Although this ester possessed a very constant boiling point it showed an unexpectedly high bromine content and low ethoxyl values. The carbon and hydrogen analyses were fairly good.

Anal. Calcd. for $C_{11}H_{23}O_3Br$: C_2H_5O, 47.7; Br, 28.2; C, 46.65; H, 8.19. Found: C_2H_5O, 45.9; Br, 32.0; C, 46.33; H, 7.86.

Ethyl Ortho-α-bromovalerate.—This compound was prepared from ethyl orthovalerate[15] by the procedure described above for the preparation of ethyl ortho-α-bromoisovalerate. The yield amounted to 80% of the theoretical and the product boiled at 69–70° (2 mm.); $n^{25}D$ 1.4390.

Anal. Calcd. for $C_{11}H_{23}O_3Br$: C_2H_5O, 47.7. Found: C_2H_5O, 47.4.

Isopropylketene Diethylacetal.—This ketene acetal was prepared from ethyl ortho-α-bromoisovalerate and sodium by the procedure of Walters and McElvain.[5] It boiled at 96–97° (100 mm.) or 156–157° (745 mm.); $n^{25}D$ 1.4158; d^{25}_4 0.8385. The yield from 25.4 g. of the bromo-ortho-ester was 9.4 g. (65%).

Anal. Calcd. for $C_9H_{18}O_2$: C, 68.31; H, 11.46; C_2H_5O, 56.96. Found: C, 68.33; H, 11.64; C_2H_5O, 54.59.

A 1.7-g. sample of isopropylketene diethylacetal was treated with the theoretical amount of water containing a trace of hydrochloric acid. The reaction mixture underwent almost spontaneous reaction, the temperature rose rapidly to 60–65° and the ketene acetal was converted quantitatively into ethyl isovalerate. The reaction mixture was dried over anhydrous potassium carbonate and distilled under atmospheric pressure. The ethyl isovalerate thus obtained boiled at 134°; $n^{25}D$ 1.3947; sap. equiv., 128 (calcd. 130); m. p. of the toluidide of the acid, 107°.

n-Propylketene Diethylacetal.—This ketene acetal was prepared as was the isopropylketene diethylacetal. The yield of product boiling at 107–108° (100 mm.) or 167–168° (737 mm.); $n^{25}D$ 1.4204; d^{25}_4 0.850, amounted to 71% of the theoretical.

Anal. Calcd. for $C_9H_{18}O_2$: C, 68.31; H, 11.46; C_2H_5O, 56.96. Found: C, 67.89; H, 11.37; C_2H_5O, 54.58.

A 1.8-g. sample of *n*-propylketene diethylacetal was treated with the theoretical amount of water and converted quantitatively to ethyl valerate. This reaction was strongly exothermic as was the case with the isopropylketene diethylacetal. The ester so obtained boiled at 144°; $n^{25}D$ 1.3991; sap. equiv., 133 (calcd. 130); m. p. of the toluidide of the acid, 69.5°.

Each of the above described ketene acetals was recovered unchanged when it was refluxed in a 1.4 *N* solution of potassium *t*-butoxide in *t*-butyl alcohol for three hours.

Summary

The acetals of α-bromoisobutyraldehyde, α-bromo-*n*-butyraldehyde and α-bromoisovaleraldehyde are converted by potassium *t*-butoxide in *t*-butyl alcohol into the corresponding unsaturated acetals rather than into the ketene acetals.

The reactions between α-bromoisovaleraldehyde diethylacetal and both sodium ethoxide and potassium *t*-butoxide are shown to be second order and the implications of this fact are discussed.

Isopropylketene diethylacetal and *n*-propylketene diethylacetal have been prepared from the corresponding α-bromo-orthoesters and show no tendency to rearrange into unsaturated aldehyde acetals.

The Reduction of Iodate and Bromate at the Dropping Mercury Electrode in Neutral and Basic Media and the Effects of Salts upon the Current–Voltage Curves

BY E. F. ORLEMANN[1,2] AND I. M. KOLTHOFF

Rylich[3] found that the decomposition potentials of iodate and bromate ions observed in neutral or alkaline medium at the dropping mercury electrode are affected by the kind and concentration of indifferent salts in the solution. The decomposition potential becomes more positive with increasing valence of the cation and with increasing concentration of the salt. Rylich's data were not sufficiently extensive to allow a satisfactory interpretation of his results. In the present study we have made a systematic investigation of the effect of salts on the current–voltage (c. v.) curves of iodate and bromate in neutral or alkaline media, and an attempt has been made to devise a mechanism for the electroreduction of these ions which accounts for the experimental results. In a previous paper[4] the c. v. curves of iodate and bromate in buffered solutions at *p*H values smaller than 8 have been reported.

Experimental

The manual apparatus was used as described in previous papers,[4] and all the experiments were performed in a thermostat at 25.00 ± 0.05°. The potentials were measured against the saturated calomel electrode (S. C. E.) at 25°. Two different capillaries of marine barometer tubing with the following characteristics were used: Capillary 2, pressure = 90 cm. of mercury; m = 1.93 mg. sec.$^{-1}$ at −0.6 v.; t = 3.60 sec. at −0.6 v.; $m^{2/3}t^{1/6}$ = 1.92 at −0.6 v.; −capillary 3, pressure = 80 cm. of mercury; m = 1.80 mg. sec.$^{-1}$ at −0.6 v.; t = 3.52 sec. at −0.6 v.; $m^{2/3}t^{1/6}$ = 1.79 at 0.6 v. Changes of $m^{2/3}t^{1/6}$ with the potential of the dropping electrode were calculated with the aid of a table given in a previous communication.[5] Current–voltage curves shown in the figures have been plotted without making correction for the residual current. The plots have been made using an exaggerated potential axis in order to avoid crowding of the waves and to bring out small differences in the effect of the salt concentration. Values of the current used in the analysis of the waves and of the diffusion current reported in the tables have been properly corrected for the residual current of the particular medium used.

Effect of Alkali Salts and of Tetramethylammonium Bromide on the c. v. Curves of Iodate.—Salts were found to affect the relation between current and potential, the half wave potential, the value of K in the relation $i_d = Kc$, in which i_d is the diffusion current at a given potential and c the concentration of iodate. In addition, the change of the diffusion current with increasing negative potential was affected by the salt concentration. All the essential data are collected in a concise way in Table I. In all cases—with the exception of tetramethylammonium bromide—the equation of the wave was found to be given by the expression

$$\pi = \pi_{1/2} + a \log (i_d - i)/i \qquad (1)$$

in which π is the potential and i the current at any potential on the wave. The value of a was obtained from the slope of the linear relation between log $(i_d - i)/i$ and the potential. Examples of the linear relations found are given in Fig. 1. In this figure the plots obtained in 3.60, 0.91 and 0.09 M lithium chloride are shown. Values of a in the different salt solutions are listed in Table I.

In all cases—with the exception of tetramethylammonium bromide—the half wave potential (see equation 1) was found to be independent of the iodate concentration in a given salt solution. Values of $\pi_{1/2}$ are reported in Table I. The apparent diffusion current and the value of the potential at which it was obtained are listed in the column i_d at π. From the diffusion current and the concentration of iodate, also found in the table, the quantity $K_{ob} = i_d/c$ was obtained. The calculated value $K_{calcd.}$ was obtained from the Ilkovic equation

$$K_{calcd.} = i_d/c = 605nD^{1/2}m^{2/3}t^{1/6} \qquad (2)$$

in which n is taken equal to six and D = 1.09 × 10^{-5} cm.^{2} sec.$^{-1}$ at 25°.

The effect of the salt concentration on the change of the diffusion current with increasing

[X] In tetramethylammonium bromide the equation of the wave is: $\pi = \text{Const.} - a \log (i_d - i)/i^2$.

negative potential is shown qualitatively in the column "i_d change with π." According to the Ilkovic equation the ratio $i_d/m^{2/3}t^{1/6}$ in a given solution should be constant and independent of the potential. When this relation was found to hold the notation "Norm." is used in the column "i_d change with π." At high salt concentrations the ratio $i_d/m^{2/3}t^{1/6}$ was found to decrease markedly with increasing negative potential. In such cases the notation "abn." is used in the table. As a demonstration of the normal and abnormal effects we give in Fig. 2 the c. v. curves obtained in different concentrations of potassium chloride.

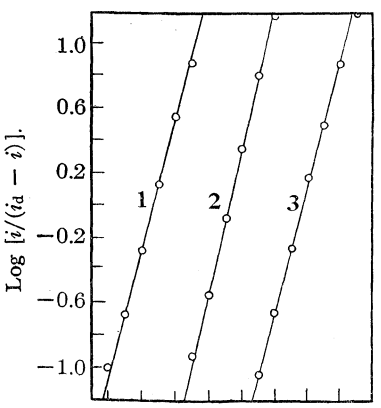

Fig. 1.—Analysis of the waves of iodate in lithium chloride solutions: Curves 1, 2 and 3 correspond to 3.6, 0.91 and 0.090 M lithium chloride, respectively.

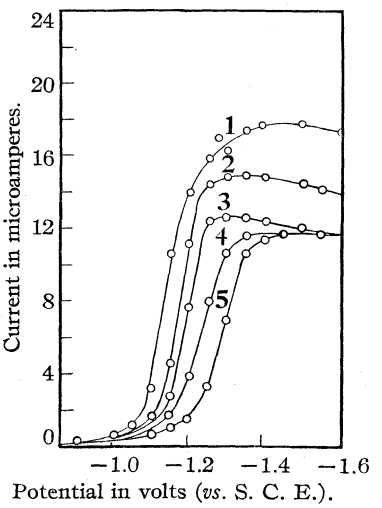

Fig. 2.—Current-voltage curves of 5×10^{-4} M potassium iodate in potassium chloride solutions of the following concentrations, using capillary 2: Curve 1, 4.0 M; curve 2, 1.0 M; curve 3, 0.5 M; curve 4, 0.2 M; curve 5, 0.05 M.

The cause of the abnormal change was found to be the occurrence of a "water current" at high salt concentrations. In a previous paper[6] the conditions have been described under which such a "water current" occurs at high salt concentrations. In the present study it happens that this water wave overlaps with the iodate wave. Hence, the diffusion current observed is not the true diffusion current of iodate, but the sum of the latter and the water wave. That this interpretation is correct is demonstrated by the following figures. It has been shown[6] that gelatin eliminates the water wave. Working with a 0.500×10^{-3} M iodate solution in 4 M potassium chloride, we found a diffusion current of 14.6 microamp., which was reduced to 10 microamp. in the presence of 0.01% of gelatin. Similarly, in 4 M lithium chloride we measured a diffusion current of 9.7 microamp. which was reduced to 7.2 microamp. in the presence of 0.01% of gelatin.

From the data given in the paper on the water wave[6] it was possible to calculate the magnitude of the water wave in the various salt solutions at a given potential. For the sake of brevity we will omit the various values and refer to the thesis of the junior author.[1] Only the final result is given in Table I in the column $K_{cor.}/K_{calcd.}$, in which $K_{cor.}$ is the experimental value of $K_{obs.}$ corrected for the water current. From the value of $K_{cor.}$ the diffusion coefficient of the iodate ion D_{IO_3} in the particular salt solution was calculated with the aid of equation (2), and is reported in Table I.

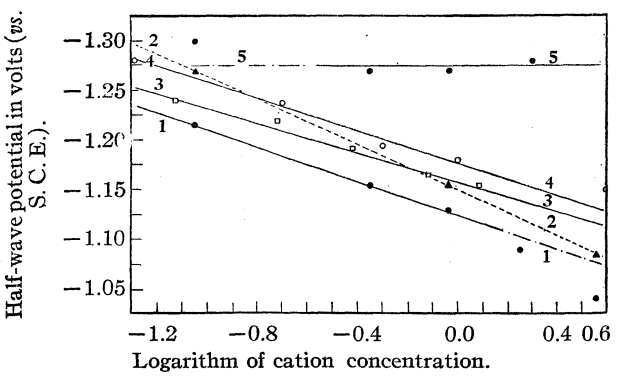

Fig. 3.—The relation between the half-wave potential of iodate and the concentration of cations in neutral or basic solutions at 25°: Curve 1, lithium ion; curve 2 sodium ion; curve 3, cesium ion; curve 4, potassium ion; curve 5, tetramethylammonium ion.

From the results reported in Table I the following conclusions are drawn: The observed and the corrected diffusion currents are proportional to the iodate concentration in a given salt solution. When the salt concentration is smaller than 0.2 M the water current is negligibly small. Under such circumstances $i_d/m^{2/3}t^{1/6}$ becomes constant and independent of the potential or the "i_d change with π" becomes normal, while the calculated value of D_{IO_3} (equation 2) agrees exactly with the value of 1.09×10^{-5} cm.^{2} sec.$^{-1}$ calculated from the mobility of the iodate ion at infinite dilution. It is of interest to notice that the diffusion coefficient of the iodate ion is not affected by the potassium chloride concentration. Even in 4 M potassium chloride it was found equal to the value at infinite dilution. On the other hand, the diffusion coefficient decreases markedly with increasing concentration of the other salts, the effect being LiCl > NaCl > Me_4NBr.

The relation between the half wave potential and the concentration of various univalent cations is shown in Fig. 3. Evidently, there is an approximately linear relation between the half wave potential and the logarithm of the concentration of the cation in the solution. The half wave potentials are necessarily somewhat uncertain as their measurement involves a liquid junction potential which cannot be corrected for in a satisfactory way. From Fig. 3 and the data in Table I the equations of the iodate waves and the characteristics of the waves were found. The corresponding data are summarized in Table II.

Effect of Divalent Cations on the c. v. Curves of Iodate.—The effects of barium and calcium chloride have been studied and the results are summarized in Table III. When the salt concentration is equal to or smaller than 0.1 M, the normal value of the diffusion coefficient of the iodate ion is found. The latter decreases rapidly when the barium or calcium chloride concentration becomes greater than 0.1 M. The equations and characteristics of the waves obtained upon graphical analysis are found in Table II. Again, there is a linear relation between the half wave potential and the logarithm of the barium or calcium concentration. We have tried to study the effect of trivalent cations on the iodate waves, but it was difficult to find ions which allowed an unambiguous interpretation of the c. v. curves. Salts of most trivalent cations are hydrolyzed and cause an acid reaction in the solution. In such cases the c. v. curves correspond to the "acid mechanism" of the iodate reduction[4] or the re-

(6) THIS JOURNAL., 64, 833 (1942).

TABLE II

CHARACTERISTICS AND EQUATION OF IODATE WAVES IN UNIVALENT AND DIVALENT CATION SOLUTIONS (25°)

Salt	$\pi_{1/2}$ in 1 M salt	$\Delta\pi_{1/2}/\Delta$ log M, m. v.	Empirical equation of wave

[a] The iodate concentration in the barium chloride solutions was 0.91×10^{-3} M. The diffusion current was measured at −1.4 v. [b] The iodate concentration was 1.00×10^{-3} M.

duction takes place according to both the acid and neutral mechanism. Lanthanum salts of strong acids are practically unhydrolyzed. However, in this case a complication arises due to a film formation of lanthanum hydroxide on the mercury drop during the reduction and to the slight solubility of lanthanum iodate. Lanthanum salts shift the half wave potential markedly to more positive potentials. Examples of the striking lanthanum effect upon iodate waves in unbuffered solutions are shown in Fig. 4.

The solutions were 0.1 M in potassium chloride and 5×10^{-4} M in iodate. In the presence of 0.1 to 0.01 M lanthanum chloride identical and steep waves were obtained (curves 1 and 2) with a half wave potential of −0.38 v. An equally steep wave was obtained in 0.001 M lanthanum salt (curve 3), but the half wave potential was shifted to −0.49 v. In 0.0001 M lanthanum solution (curve 4) the wave started at −0.6 v. and became poorly defined, probably as a result of precipitation of most of the lanthanum as hydroxide during the reduction of iodate. That the film of lanthanum hydroxide has some effect upon the shape and location of the wave is evident from a comparison of curves 2 and 5. Both solutions were identical in composition except that the solution corresponding to curve 5 contained 0.01% of gelatin. The "decomposition potential" of the iodate

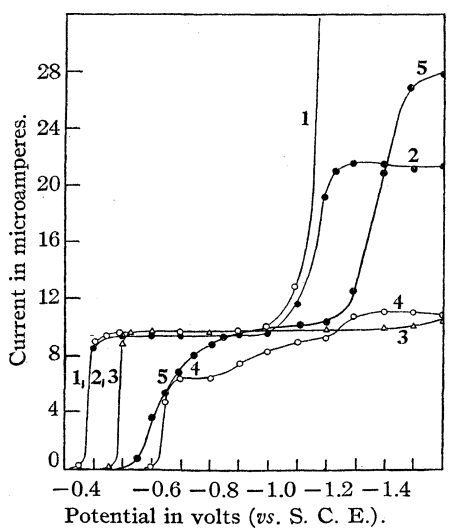

Fig. 4.—Current–voltage curves (using capillary 3) of 5×10^{-4} M potassium iodate, 0.1 M potassium chloride solutions (unbuffered) in the presence of lanthanum chloride: The concentrations of lanthanum chloride are, curve 1, 0.1 M; curve 2, 0.01 M; curve 3, 0.001 M; curve 4, 0.0001 M; curve 5, 0.01 M lanthanum chloride with 0.01% gelatin present.

was shifted from −0.4 to −0.6 v. by the addition of gelatin. The drops of mercury falling in the diffusion current region in the absence of gelatin did not coalesce readily, presumably as a consequence of the presence of a film of lanthanum hydroxide, whereas they did coalesce in buffered iodate solutions containing lanthanum. In addition in buffered solutions (pH 7) of lanthanum the iodate wave is found at a potential of the order of −0.8 instead of −0.4 v., indicating that the iodate reduction is catalyzed by the precipitation of lanthanum at the electrode.

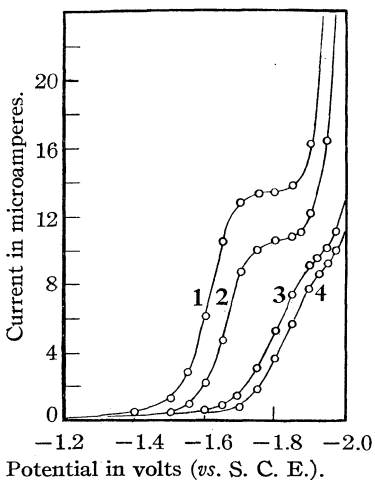

Fig. 5.—Current–voltage curves (using capillary 2) of 4×10^{-4} M potassium bromate in potassium chloride solutions of the following concentrations: Curve 1, 4.0 M; curve 2, 1.0 M; curve 3, 0.10 M; curve 4, 0.05 M.

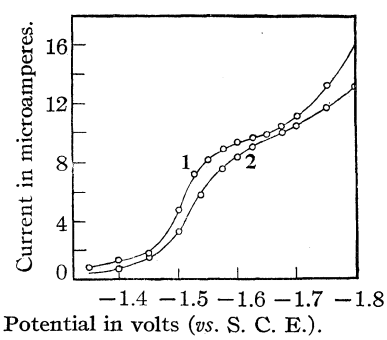

Fig. 6.—Current–voltage curves (using capillary 2) of 4×10^{-4} M potassium bromate in barium chloride solutions of the following concentrations: Curve 1, 0.165 M; curve 2, 0.05 M.

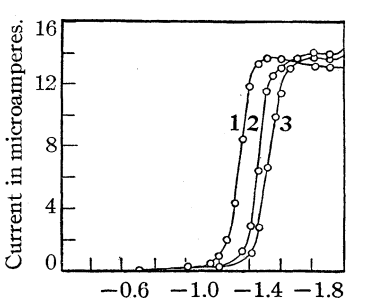

Fig. 7.—Current–voltage curves (using capillary 3) of 6×10^{-4} M potassium bromate in calcium chloride solutions of the following concentrations: Curve 1, 2.0 M; curve 2, 0.4 M; curve 3, 0.1 M.

Effect of Salts on the c. v. Curves of Bromate.—Bromate is reduced at a much more negative potential than is iodate. Consequently, it is hardly possible to find well-defined diffusion currents in dilute solutions of alkali or barium salts, as the reduction of the alkali or barium ion sets in before the diffusion current is attained. In concentrated solutions of alkali salts, well-defined diffusion currents are found. Their values, however, are affected by the water current. For analytical purposes, therefore, it is not to be recommended to use concentrated solutions of alkali or barium salts as supporting electrolytes. Current–voltage curves obtained in solutions of potassium, barium and calcium chlorides are shown in Figs. 5, 6, and 7.

From Fig. 7 it is seen that, from the analytical viewpoint, dilute solutions of calcium chloride (0.025 to 0.2 M) are most suitable as supporting medium for the polarographic determination of bromate. Calculating from the mobility of the bromate ion at infinite dilution a coefficient of diffusion of 1.44×10^{-5} cm.^{2} sec.$^{-1}$ at 25°, it was found that the values of i_d calculated with the aid of the Ilkovic equation (equation 2) agreed within 1 to 2% with the experimental data. The diffusion current was found proportional to the bromate concentration. For the sake of brevity we omit a complete account of all experimental data[1] and summarize the most important characteristics of the waves in Table IV.

TABLE IV

CHARACTERISTICS OF BROMATE WAVES IN SOME SALT SOLUTIONS

Salt	$\pi_{1/2}$ in 0.1 M salt	$\Delta\pi_{1/2}/\Delta$ log cation in m. v.	Value of a in eq. (1) in m. v.
KCl	−1.780	115	60
$CaCl_2$	−1.510	(150)	(90)
$BaCl_2$	−1.555	(70)	100

Lanthanum chloride shifted the bromate waves to much more positive potentials. This is shown in Fig. 8. The solutions were 0.1 M in potassium chloride and 6×10^{-4} M in bromate. In the presence of 0.1 to 0.001 M lanthanum chloride identical and steep waves were obtained (curves 1, 2 and 3) at a potential of −0.82 v. The wave

in 0.0001 *M* lanthanum solution (curve 4) was irregular probably as a result of exhaustion of lanthanum around the drop by precipitation as hydroxide. The solutions corresponding to curves 2 and 5 were identical (0.01 *M* lanthanum), except that the solution of curve 5 contained 0.01% of gelatin. The gelatin shifted the wave from −0.82 to −1.1 v.

Discussion

The linear relation between the half-wave potential and the logarithm of the concentration of cations noted in Fig. 3 and Tables II and IV shows that cations play a very definite part in the potential determining step involved in the reduction of iodate and bromate ions. A mechanism which accounts for this regular shift in half-wave potential with a change in concentration of cations has been developed by extending the ideas described in connection with the reduction of iodate and bromate ions in acid media.[4] Considering only iodate, for convenience, the general mechanism proposed may be represented by the scheme

$$yM + IO_3^- = M_yIO_3^{z+} \quad \text{(fast)} \qquad (3)$$

(in which M is the cation, y an integer, and z an integer depending upon y and the valence of M)

$$M_yIO_3^{z+} + e = M_yIO_3^{(z-1)+} \quad \text{(slow)} \qquad (4)$$

$$M_yIO_3^{(z-1)+} + 5e + 3H_2O = yM + I^- + 6OH^- \quad \text{(fast)} \qquad (5)$$

(this process probably occurs in several steps).

The above mechanism is identical with that proposed in connection with the studies in acid media if the cation M is taken as an hydrogen ion and the substance $M_yIO_3^{z+}$ is iodic acid. In the discussion of the acid mechanism for the iodate and bromate reductions it was shown that if both iodate ions and a species such as $M_yIO_3^{z+}$ coexist in a solution, it is easier to transfer an electron from the electrode into the species which has the lowest vacant electron level. If we make the reasonable assumption that the vacant electron level in $M_yIO_3^{z+}$ is lower than it is in an iodate ion, then there will be a reduction of the former substance instead of a direct reduction of iodate ions. The reason for assuming that the slow step in the reduction is the transfer of one electron from the electrode to the iodate is discussed in the thesis of the junior author.

A quantitative formulation of the above mechanism readily can be made using the method of derivation given in the previous communication.[4]

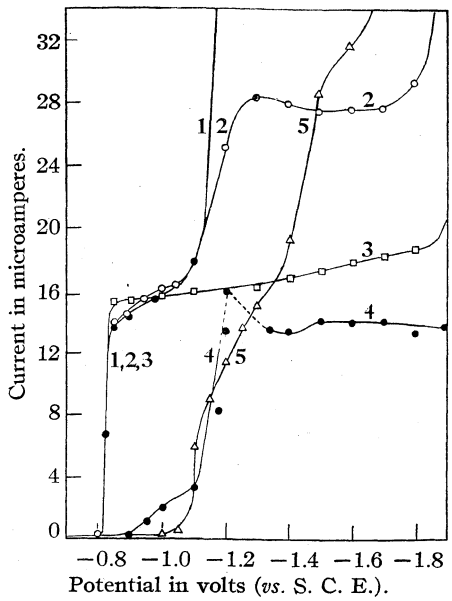

Fig. 8.—Current–voltage curves (using capillary 3) of 6×10^{-4} *M* potassium bromate, 0.1 *M* potassium chloride solutions (unbuffered) in the presence of lanthanum chloride. The lanthanum chloride concentrations are: Curve 1, 0.1 *M;* curve 2, 0.01 *M;* curve 3, 0.001 *M;* curve 4, 0.0001 *M;* and curve 5, 0.01 *M* lanthanum chloride with 0.01% gelatin present.

The equation for the c. v. curves found in this way is

$$\pi = \pi_{1/2} + \frac{RT}{\alpha F} \ln \frac{(i_d - i)}{i} \qquad (6)$$

$$\pi_{1/2} = \text{const.} + \frac{RT}{2\alpha F} \ln \frac{t}{D} + \frac{RT}{\alpha F} \ln \frac{f_M^y f_{IO_3^-}}{f_{M_yIO_3^{z+}}} + \frac{yRT}{\alpha F} \ln [M] \qquad (7)$$

In the above equations, α is the fraction of the total potential difference between the electrode and the bulk of the solution which acts in the reduction, t is the drop time, D is the diffusion coefficient of iodate ions, and f is the activity coefficient of the species indicated by the subscript used. The true definition of α is given in the previous communication,[4] where it is shown that if the reduction occurs at a negatively charged surface the value of α would be expected to lie close to one. There was a variation of less than 5% in the drop time over the range of salt concentrations used in the experiments described. The diffusion coefficient of iodate ions varies with the salt concentration as shown by Table I. In the most extreme case shown in Table I, that of lithium chloride, the diffusion coefficient decreased approximately by a factor of two when the concentration of lithium chloride was increased from 0.1 to 4 *M*. In the concentration range from 0.1

to 4 M it is difficult to find reliable data on the activity coefficients of the species involved and this factor will be neglected. To some extent the decrease in the diffusion coefficient tends to offset the decrease in activity coefficients in equation (7). The experiments reported were carried out at 25° and with the above considerations in mind equations (6) and (7) may be applied to the experimental data in the following approximate form:

$$\pi = \pi_{1/2} + \frac{0.060}{\alpha} \log \frac{(i_d - i)}{i} \quad (8)$$

$$\pi_{1/2} \cong \text{const.} + \frac{0.06y}{\alpha} \log [M] \quad (9)$$

From the experimentally determined slopes of the linear log $(i_d - i)/i$ *versus* potential plots values of α were found with the aid of equation (8). Using the values of α determined in this way and the experimentally observed slopes of the linear relation between half-wave potential and the logarithm of the concentration of cations values of y were obtained with the aid of equation (9). Values of α and y determined in this way are shown in Table V. Since the reductions occur at a negatively charged mercury surface (see Fig. 3) the expected value of α is approximately one. With the exception of tetramethylammonium bromide this prediction is borne out. In the presence of tetramethylammonium salt the potential is not a linear function of log $(i_d - i)/i$ but was found to be a linear function of log $(i_d - i)/i^2$. We have not been able to find any reasonable explanations for this relation. In Table V values of 0.75 and 1 are listed for α in potassium chloride solutions. When the solution around the drop was suitably observed with a microscope during electrolysis in potassium chloride solution it was found that there was a stirring of the solution until the diffusion current was reached in those cases where the apparent value of α was 0.75. Addition of 2×10^{-3} per cent. tropeoline 00 to these solutions completely eliminated this stirring and under these conditions the observed value of α was 1. In view of the approximate nature of equation (9) the values of y in Table V would be expected to deviate from unity. Taking this fact into consideration the values of y in Table V are reasonably close to an integral with the exception of those in lithium chloride solutions. In this case a better approximation of y was found by plotting the quantity

$$\pi_{1/2} + 0.03 \log D - 0.06 \log \frac{f_{Li^+} f_{IO_3^-}}{f_{Li_2IO_3^+}}$$

(see equation (7)) against the logarithm of the lithium chloride concentration. Values of the diffusion coefficient of iodate at the concentrations of lithium chloride used were found in Table I. It was assumed that $f^2_{Li} f_{IO_3^-}/f_{Li_2IO_3^+}$ was equal to the mean activity coefficient of lithium chloride. The plot was found to be linear and the observed slope of 110 millivolts leads to a value of 1.8 for y which is reasonably close to an integral value of 2. To account for the observed values of y it is necessary to assume that the species being reduced in each case are those listed in the last column in Table V. The species $BaIO_3^+$, $CaIO_3^+$, KIO_3 and $CsIO_3$ listed in Table V appear reasonable but those listed with lithium and sodium do not.

TABLE V

VALUES OF α AND y IN EQUATION (7) IN THE IODATE REDUCTION

Salt	$\Delta\pi_{1/2}/\Delta \log (i_d - i)/i$ mv.	α	$\Delta\pi_{1/2}/\Delta \log M$, mv.	y	Species reduced
LiCl	60	1	85	1.8[a]	$Li_2IO_3^+$
NaCl	60	1	115	2	$Na_2IO_3^+$
KCl	60 (to 80[b])	1	80	1	KIO_3
CsCl	65	1	75	1	$CsIO_3$
$BaCl_2$	60	1	60	1	$BaIO_3^+$
$CaCl_2$	60	1	50	1 (0.85)	$CaIO_3^+$

[a,b] See text.

The shift in half-wave potential with a change in drop time predicted by equation (7) was checked. At a drop time of 2.05 sec. the half-wave potential in 0.05 M potassium chloride was −1.256 v. and became −1.250 v. at a drop time of 4.10 sec. in the same solution. Therefore, the observed shift in half-wave potential with the above increase in drop time was 0.006 v. The shift calculated from equation (9) is 0.009 v., in reasonable agreement with the observed value.

The bromate reduction has been treated in the same manner as described above for the reduction of iodate and the results found are presented in Table VI. Qualitatively, the results in Table VI are in agreement with the mechanism proposed

TABLE VI

VALUES OF α AND OF y IN EQUATION (7) IN THE BROMATE REDUCTION

Salt	$\Delta\pi_{1/2}/\Delta \log (i_d - i)/i$ mv.	α	$\Delta\pi_{1/2}/\Delta \log M$, mv.	y	Species reduced
KCl	60	1	115	2	$K_2BrO_3^+$
$CaCl_2$	80–100	0.75–0.6	(150)		$(CaBrO_3^+)$
$BaCl_2$	100	0.6	(70)	0.7	$BaBrO_3^+$
$LaCl_3$[a]	100–140	0.6–0.4	90	0.6–0.9	$LaBrO_3^{++}$

[a] Buffered solution.

but quantitatively they are not. The conclusion that there is a reduction of $K_2BrO_3^+$ is not reasonable although the other species indicated by the data in Table VI are acceptable. We are unable to give a reasonable quantitative explanation for these results on the basis of our present knowledge of the mechanism of electrolysis phenomena in general. In view of the qualitative and partial quantitative success of the proposed mechanism it seems reasonable to conclude that the mechanism is essentially correct but must be modified in some way to include secondary effects of cations, such as their effect on the detailed structure of the double layer.

Some experiments were done in 50% acetone solution to see whether the expected increase in association of the ions in this medium would result in a change in the species which were apparently reduced. The relations observed between the half-wave potentials and the salt concentration in these cases are shown in Fig. 9. It is evident from Fig. 9 that the relation between these quantities is quite complex, but it is interesting to note that the half-wave potential is shifted with a change in concentration of tetramethylammonium bromide in this medium whereas it was practically unaffected by the concentration of tetramethylammonium bromide in aqueous medium. No attempt was made to extend these data or attempt an interpretation since too little is known about the behavior of concentrated salt solutions in 50% acetone.

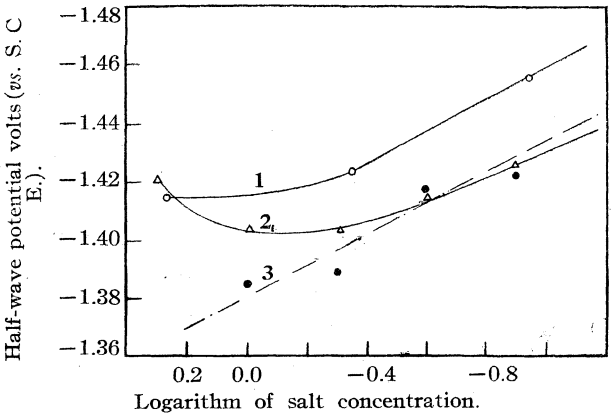

Fig. 9.—The half-wave potential of iodate as a function of the concentration of salt in 50% acetone solution. Curves 1, 2 and 3 correspond to solutions of tetramethylammonium bromide, potassium bromide and sodium chloride, respectively.

Summary

1. In the reduction of iodate and bromate at the dropping mercury electrode in neutral or alkaline media, the following relation exists between the potential on the one hand and $(i_d - i)/i$ and the concentration of the indifferent cation M on the other

$$\pi = \pi_{1/2} + a \log(i_d - i)/i + b \log M$$

The relation does not hold in solutions of tetramethylammonium bromide. Values of a and b in the iodate reduction have been determined in solutions of varying concentrations of potassium, sodium, lithium, cesium, calcium and barium.

2. There is a linear relation between the shift of the half-wave potential and the concentration of the different cation in the solution (with the exception of tetramethylammonium ion).

3. The half wave potential is slightly dependent upon the drop time.

4. A mechanism has been proposed for the reduction of iodate and bromate in salt solutions. It has been postulated that in the case of iodate the following species are reduced: KIO_3, $CsIO_3$, $Na_2IO_3^+$, $Li_2IO_3^+$, $BaIO_3^+$, $CaIO_3^+$.

NOTES

Identification of Alcohols and Alkyl Hydrogen Sulfates with S-Benzylthiuronium Chloride

By Robert K. Bair and C. M. Suter

The sodium salts of many acids including sulfonic acids[1] react with S-benzylthiuronium chloride to form derivatives which are of value in the identification of the original materials. The reagent is produced in nearly quantitative yield by the action of benzyl chloride with thiourea.[1,2] It has now been found that most alcohols are easily identified by this same reagent through first converting them to the corresponding alkyl hydrogen sulfates by warming in dioxane solution with chlorosulfonic acid. The benzylthiuronium salts of

$$ROH + ClSO_3H \longrightarrow ROSO_3H + HCl$$

$$ROSO_3H + C_6H_5CH_2SC(NH_2)_2Cl \longrightarrow ROSO_3(NH_2)_2CSCH_2C_6H_5 + HCl$$

methyl and ethyl hydrogen sulfate are too soluble in water to be isolated readily and the *n*-octyl compound showed an anomalous melting point behavior although the analysis was satisfactory. Ethylene glycol was identified as the bis-(hydrogen sulfate) but the behavior of other glycols was not studied.

Table I

S-Benzylthiuronium Derivatives

Alcohol	M. p., °C. (cor.)	Nitrogen,[a] % Calcd.	Found
n-Propyl	111.5–112.5	9.15	9.16
i-Propyl	142–143	9.15	9.07

[a] Nitrogen analyses by Dr. T. S. Ma, University of Chicago.

[b] Chlorosulfonic acid added to solid alcohols dissolved in dioxane.

[c] Thiuronium derivatives made from alkyl hydrogen sulfates.

[d] We are indebted to Dr. Sydney Archer for purifying samples of the last four compounds.

[e] Mixed melting points were taken: *n*-amyl and *n*-hexyl, 77–82°; *n*-heptyl and *n*-decyl, 53–71°.

Obviously this method of identification is applicable to sodium alkyl sulfates as such and this is of considerable interest because of the varied commercial uses of these compounds. However, the difference in melting point for the decyl and lauryl compounds is small.

Procedure.—About 5 drops of the alcohol is added to a mixture of 4 drops of chlorosulfonic acid and 5 drops of dioxane. If hydrogen chloride is not immediately evolved, the resulting mixture is warmed with shaking and allowed to stand for five or ten minutes. Then after the addition of 1 ml. of water, 1 ml. of a saturated aqueous solution (or 15% alcohol solution) of S-benzylthiuronium chloride is added. If crystals do not form in a few minutes the solution is chilled in an ice-bath. The derivatives of the lower molecular weight alcohols (to *n*-hexyl inclusive) can be recrystallized from 10% ethyl alcohol, and derivatives of higher alcohols from 50% alcohol. In preparing samples for analyses the quantities used in this procedure were multiplied by five.

The corresponding *p*-chlorobenzylthiuronium derivatives were also made from about eight alcohols; however, several of these were waxy, difficult to filter and to obtain in a pure state. Also five of them melted between 80 and 90°. No derivatives of methanol and ethanol were obtained by using either the *p*-chloro-S-benzyl- or S-benzylthiuronium chloride.

The Dehydration of 1,5-Hexadiene-3-ol to 1,3,5-Hexatriene and 1,3-Cyclohexadiene[1]

By Lewis W. Butz

That the dehydration of 1,5-hexadiene-3-ol under the conditions recently described[2] yields about 70% of 1,3,5-hexatriene was demonstrated by conversion of part of the products to 1-vinylanthraquinone. At the same time it appeared that 1,3-cyclohexadiene was formed in about 30% yield, since reaction of the hydrocarbon products with 1,4-naphthoquinone gave a 1,4-ethano adduct. The alternative explanation would be that hexatriene is converted to cyclohexadiene when

(1) Not subject to copyright.

(2) L. Butz, E. Butz and Gaddis, *J. Org. Chem.*, **5**, 178 (1940).

heated with naphthoquinone at 50°, a result hardly to be expected.

In contact with maleic anhydride at 30°, the hydrocarbon products gave a crystalline compound which was different from the adduct obtained by Farmer and Warren[3] from hexatriene and maleic anhydride at 100°. Since Farmer and Warren considered their compound to be an ethylidenetetrahydrophthalic anhydride, it appeared likely that the new isomer was the vinyltetrahydrophthalic anhydride, the normal adduct, and this view was expressed publicly.[4]

This has now been shown not to be the case. The substance, m. p. 147°, does not depress the m. p. of the ethanotetrahydrophthalic anhydride prepared[5] from cyclohexadiene and maleic anhydride. This is further evidence that the hydrocarbon obtained by the dehydration of the hexadienol contained cyclohexadiene. While the possibility of a direct hexatriene → cyclohexadiene transformation is still not excluded, it must be supposed that it occurs, if at all, during the dehydration of the hexadienol rather than during the reaction with naphthoquinone or maleic anhydride at 50 or 30°. However, it appears that the hexatriene prepared by this method is not always contaminated with so much cyclohexadiene, and the formation of the latter must depend on small variations in procedure, because the hydrocarbon has been found[6] not to yield, upon reaction with 5-acetoxy-1,4-toluquinone, any of the adducts obtained from cyclohexadiene and this quinone.

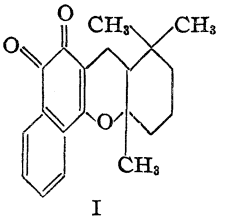
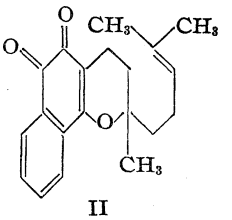
The Condensation of β-Cyclogeraniol with Leucoisonaphthazarin

BY MARSHALL D. GATES AND FERNANDA MISANI

In a recent paper Fieser and Gates[1] described the preparation of β-geranolapachone, a member of the β-lapachone series, by cyclization of 2-hydroxy-3-geranyl-1,4-naphthoquinone with concentrated sulfuric acid. The high melting point of this compound (234°) suggests that further cyclization of the side chain may have taken place to give structure I rather than the supposed structure II.

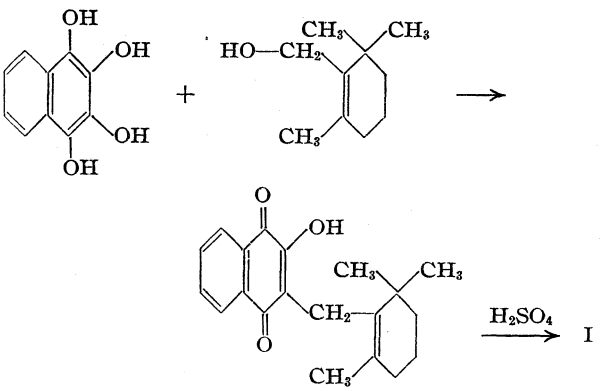


I



II

A choice between these two structures was readily made by synthesizing structure I by application of the general scheme employed by Fieser and Gates.[1]



The β-cyclogeraniol employed (m. p. 44°) was prepared by Meerwein–Ponndorf reduction of β-cyclocitral according to Kuhn and Hoffer.[2] Condensation with leucoisonaphthazarin gave the desired 2-hydroxy-3-(β-cyclogeranyl)-1,4-naphthoquinone in rather poor yield, but in easily isolated form. On cyclization with sulfuric acid, β-cyclogeranolapachone (I) was obtained. It proved to be identical with β-geranolapachone prepared according to Fieser and Gates, and their β-geranolapachone must therefore be regarded as β-cyclogeranolapachone (I).

The conditions used in the condensation of allylic alcohols with hydroxyhydroquinones in these syntheses are not sufficiently acidic (oxalic acid) to bring about cyclization of the geranyl group during the condensation. This is shown by the non-identity of the products obtained by the condensation of geraniol and β-cyclogeraniol with leucoisonaphthazarin.

Experimental Part[3]

Isonaphthazarin.—The following procedure represents an improvement over that reported by Fieser and Gates.[1] A solution of 8.9 g. of 2-hydroxy-1,4-naphthoquinone

(1) Fieser and Gates, THIS JOURNAL, **63**, 2948 (1941).
(2) Kuhn and Hoffer, *Ber.*, **67**, 357 (1934).
(3) All melting points are corrected.

(purified through the methoxy compound) in 500 cc. of water containing 4.3 g. of sodium bicarbonate was treated with 20 cc. of 30% hydrogen peroxide (superoxol). The solution rapidly darkened and, after standing for thirty-four hours, a crop of dull red large leaves had separated, 3.2 g. (43% based on 2-hydroxy-1,4-naphthoquinone utilized). One crystallization from dioxane gave pure isonaphthazarin. Acidification of the aqueous filtrate yielded 2.1 g. of orange precipitate which consisted of unchanged 2-hydroxy-1,4-naphthoquinone plus a small amount of isonaphthazarin. On several occasions, use of less pure 2-hydroxy-1,4-naphthoquinone as starting material led to much lower yields.

2-Hydroxy-3-(β-cyclogeranyl)-1,4-naphthoquinone.—Isonaphthazarin (2.0 g.) was reduced as described by Fieser and Gates[1] and the leuco compound heated in the dark under nitrogen for forty-eight hours at 65–70° with 1.0 g. of β-cyclogeraniol[2] (m. p. 44°),, 0.6 g. of anhydrous oxalic acid and 20 cc. of dioxane. The processing of the reaction mixture included the following steps: extraction of the unchanged leucoisonaphthazarin with aqueous hydrosulfite, reduction with concentrated aqueous hydrosulfite, and extraction from ether–petroleum ether with Claisen's alkali. The crude phenolic portion thus obtained was chromatographed after air oxidation on freshly ignited magnesium sulfate. On development with petroleum ether, a weakly adsorbed bright yellow band readily passed into the filtrate. Similar filtrates from systematic readsorptions of the column eluate were combined and on concentration to dryness under reduced pressure afforded 99 mg. of solid residue which after three crystallizations from ether–petroleum ether gave 36 mg. of golden yellow rectangular plates, m. p. 135–135.5°. It is quite soluble in the ordinary organic solvents, fairly soluble in warm petroleum ether, much less soluble cold, and dissolves in dilute alcoholic alkali to give the beautiful scarlet characteristic of alkali salts of 2-hydroxy-1,4-naphthoquinones. It dissolves in concentrated sulfuric acid to give a deep orange-red solution. Two further crystallizations to obtain a sample for analysis did not alter the melting point.

Anal. Calcd. for $C_{20}H_{22}O_3$: C, 77.38; H, 7.15. Found: C, 77.50; H, 7.23.

β-Cyclogeranolapachone (I).—A solution of 11 mg. of 2-hydroxy-3-(β-cyclogeranyl)-1,4-naphthoquinone in ice-cold concentrated sulfuric acid (0.3 cc.) was allowed to stand several minutes, then diluted with ice water. The precipitated dark orange-brown material was taken into ether, washed with water, bicarbonate and brine, and concentrated to dryness. The residue was taken into benzene–hexane and chromatographed on freshly ignited magnesium sulfate. Development with 50% benzene–hexane left a broad salmon-pink band in the middle of the column which was sectioned out and eluted with ether. After evaporation of the ether, the solid residue was crystallized twice from pure acetone to give 3.5 mg. of orange-red prismatic blades, m. p. 232–233.3°. A mixed melting point with β-geranolapachone prepared according to Fieser and Gates[1] showed no depression.

Riboflavin Estimation in Fruits and Vegetables

BY G. MACKINNEY AND J. M. SUGIHARA

As part of a collaborative project,[1] it was recently necessary to make a series of chemical determinations of thiamin and riboflavin in certain fruits and vegetables, and the Conner–Straub procedure[2] was followed. Unfortunately, at the beginning, Supersorb,[3] the specific adsorbent for riboflavin was unavailable. An empirical method was, therefore, evolved, and we hoped, later, to correlate results into the series by concurrent assays on additional samples on arrival of the adsorbent. This comparison may now be made and, subject to certain provisos, we believe the modification accurately reflects differences in riboflavin content within a series. With respect to absolute values, it is in accord with microbiological assay by means of *Lactobacillus casei.* It has, further, certain advantages: increased light stability, no adsorbent is needed and the riboflavin in the aqueous buffer exhibits approximately twice the fluorescence found in pyridine–acetic solution, with consequent decrease in the percentage reading error.

The Conner–Straub procedure is followed in detail in extraction and preparation of the sample, except that, in the case of fruits, 10 ml. of pectinol (1 g. in 25 ml.) is added per 50-ml. of sample, in addition to the clarase. The whole is then incubated at 45° for two hours. The pectinol is absolutely necessary for prunes, apricots, dates, etc., to produce a satisfactory solution. A 10–20 ml. aliquot is then heated to boiling with 5 ml. of 2% acetic, as in (1), made to volume, 50 ml., with buffer, and a 15-ml. aliquot treated for a minimum of three minutes with 1 ml. of potassium permanganate, and decolorized with 3 ml. of 3% hydrogen peroxide. The solution is then filtered and compared with buffered standards at *p*H 6.0 in a Coleman fluorophotometer. The B_2 filter for the exciting light (Hg arc) cuts out completely above 4900 Å. and for the fluorescent light, below 5100 Å. The cut-out is sharp, and, for the latter filter, the transmission rises from zero at 5100 to over 90% at 5400 Å. Quinine sulfate and thiochrome have no effect on the galvanometer with these filters, at least in the concentrations used. In the majority of plant extracts treated as above, there appear to be no other water-soluble fluorescent compounds in sufficient quantities to interfere, though trouble might be anticipated in those botanical families where anthraquinone glucosides occur. However, since we do not know the behavior of these compounds on Decalso or Supersorb, similar difficulties might arise with either method.

(1) With the Department of Home Economics.

(2) Conner and Straub, *Ind. Eng. Chem., Anal. Ed.*, **13**, 385 (1941).

(3) Supersorb, Florisil or Floridin is a Fuller's Earth; Decalso, a synthetic zeolite, obtainable through supply houses, Clarase (Takamine Laboratories, N. Y.) and Pectinol (Röhm and Haas, Philadelphia) are commercial enzyme preparations.

Grass, dehydrated	8.23	7.80	11.5	4.78		5.28

[a] It should be understood that the estimates on the materials assayed are valid only for these samples, purchased for the most part on the local market, without consideration of variety, maturity or possible abnormal local conditions caused by climate, Jan.–March, 1942. [b] We thank Miss M. B. Smith of the Department of Home Economics for these values.

Riboflavin estimates are given, Table I, in column 2 by the above procedure, and in column 4 after passage over Decalso and Supersorb, where the Conner–Straub procedure for both B_1 and B_2 is followed. The same samples measured twenty hours later, columns 3 and 5, after standing in the laboratory away from direct lighting, clearly show the higher light stability of our extract. We are greatly indebted to Professor Agnes Fay Morgan for permission to include, in column 6, certain microbiological assays on the same samples with *Lactobacillus casei*. They indicate very satisfactory agreement with the chemical method over the range 1 to 20 μg. per gram of sample. We include thiamin values in column 7. The rice bran concentrate, a trade product, is of interest because the thiamin value is approximately 10% higher than the minimum stated on the label, the riboflavin roughly 8 or 35% lower, depending upon whether we take the value of column 2 or 4. The thiamin content of the sulfured apricot is low, as might have been predicted.

With two reproducible exceptions, grass and peas *after* dehydration, our simpler procedure yields consistently higher results. In the case of the dehydrated peas there is definitely interference, possibly from a compound which forms a discrete yellow zone on the Supersorb, not found in the fresh peas, removed with the riboflavin by the eluting solvent. The values listed in Table I for a given vegetable are from different samples, variously treated. In general, at levels of 20 μg. per g., the results are reproducible within 5–10%, and 5–20% at 1.0 μg. per g.

The effect of diffuse light on the standards is shown in Table II. The concentration used at zero time is approximately 0.1 μg. per ml.

Our simpler procedure is certainly worth consideration where the adsorbent is unavailable, because comparative variations are reflected with accuracy in the figures. It is necessary to be more cautious in considering absolute values. Discussing specifically the vitamin A potency of foods, Booth[4] suggests that physiological responses should be expressed in International Units, and that only chemical results should be based on the gram and the liter. We may also note that it does not follow *a priori* that either of the above procedures has been absolutely (as distinct from comparatively) calibrated against *Lactobacillus* or any other bio-assay. In other words, the true chemical concentration may not represent the real biological potency. This may be illustrated in the case of carrots and spinach, where the former may have 2 to 4 times the carotene content, but where there is still doubt concerning the relative biological potencies, in terms of vitamin A bio-assay.

TABLE II

EFFECT OF LIGHT ON PERCENTAGE RETENTION OF RIBOFLAVIN IN STANDARDS

Time in hours	0	3	6	24

The Dipole Moments of Cyclohexanol and Cyclohexanone in Dioxane

BY I. F. HALVERSTADT[1] AND W. D. KUMLER

In the course of an investigation on the structure of the bile acids it was desirable to know the dipole moments of cyclohexanol and cyclohexanone in dioxane. These compounds have been measured in benzene by Williams,[2] the moments being cyclohexanol, 1.9, and cyclohexanone 2.9.[3]

$$P_{2_0} = p_{2_0} M_2$$

$$\mu = 0.0127 \sqrt{(P_{2_0} - P_{E_2})T}$$

P_{E_2} values were calculated from the molar refractivities of the electron groups present in the molecules.

The ϵ_{12}–ω_2 curves were linear for both compounds and the extrapolated value of ϵ_1 was approximately equal to the observed value, indicating that the compounds are not associated in these solutions.

TABLE I

MEASUREMENTS IN DIOXANE AT 25°

Cyclohexanol			Cyclohexanone		
ω_2	v_{12}	ϵ_{12}	ω_2	v_{12}	ϵ_{12}
0.002696	0.97424	2.2237	0.002580	0.97422	2.2395
.005279	.97447	2.2337	.004785	.97448	2.2631
.007566	.97476	2.2432	.008013	.97472	2.2972
.010630	.97508	2.2554	.009462	.97491	2.3128
.012633	.97524	2.2639	.011496	.97512	2.3342
.014741	.97549	2.2723	.014441	.97546	2.3657

	ϵ_1 measured	ϵ_1 extrapolated	v_1 extrapolated	α	β	P_{2_0}	P_{E_2}	μ
Cyclohexanol	2.2123	2.2126	0.97395	4.05	0.104	97.8	29.2	1.82
Cyclohexanone	2.2128	2.2121	0.97395	10.63	0.102	202.2	27.7	2.90

The symbols in the equations and tables are the same as those given previously.[4] The equations used in calculating the moments are[4]

$$p_{2_0} = \frac{3\alpha v_1}{(\epsilon_1 + 2)^2} + (v_1 + \beta)\frac{(\epsilon_1 - 1)}{(\epsilon_1 + 2)}$$

Eastman Kodak Co. practical cyclohexanol was dried over "Drierite" and twice fractionally distilled through a Widmer column, b. p. 160.9–161.3° cor. at 759 mm.

Eastman Kodak Co. practical cyclohexanone was twice fractionally distilled through a Widmer column, b. p. 157.0–157.5° cor. at 759 mm.

NEW BOOKS

The Tools of the Chemist. Their Ancestry and American Evolution. By ERNEST CHILD. Reinhold Publishing Corporation, New York, N. Y., 1940. 220 pp. Price, $3.50.

"Tools of the Chemist," by Ernest Child is an historical account of the development of laboratory apparatus and ware with special emphasis on American enterprise. The book is divided into three parts. Part I, "People and Events in American Chemistry," is entirely historical and biographical and reviews the accomplishments of the pioneers of our science in this country. This part of the book is particularly valuable to the student of the history of chemistry and makes interesting and fascinating reading.

The major portion of the book, Part II, describes the "Ancestry and Development of American Chemical Laboratory Apparatus." In turn, the following appliances, ware and other materials are taken up: balances, glass, porcelain and silica ware, filter paper, heating apparatus, metal laboratory ware, platinum, alundum, rubber ware and optical apparatus. The section on balances is by far the best presented and is given in greatest detail, the illustrations being particularly well chosen to show the earlier forms. One is forcibly reminded throughout the reading of this section of the important and vital role the American chemist has had in developing and perfecting our modern chemical tools. More illustrations of present types of apparatus would have added interest to the book.

The book closes with a short historical account of the leading supply houses and distributors of laboratory apparatus.

The book is profusely and attractively illustrated with over one hundred illustrations. It is an admirable and valuable addition to our growing libraries on historical chemistry. Every chemist will delight and profit in perusing it.

CARL J. ENGELDER

Fluorescent Chemicals and their Applications. By JACK DE MENT, Research Chemist, The Mineralogist Laboratories; Associate Editor, the Mineralogist Magazine. With a Special Chapter on Ultraviolet Radiation Sources by H. C. Dake, Editor, the Mineralogist Magazine. Chemical Publishing Company, Inc., 232 King Street, Brooklyn, N. Y., 1942. xiii + 240 pp. Illustrated. 14 × 22 cm. Price, $4.25.

During the last few years, fluorescence phenomena have been arousing scientific scrutiny because of the remarkable results obtained from them in fluorescent lighting and in cathode ray tubes. Such successful application has stimulated attempts to develop still other commercial uses. The author of the present book has evidently been diligent in conversing with many who are engaged in these developments, and he records some novel applications, though not all, which are quite up to the minute. Furthermore, he has examined a large number of chemical compounds and listed the color of their fluorescence.

It is in these two respects that interest in the book lies. Its discussion of the theory is inadequate to the needs of the scientist, and there is not to be found the critical viewpoint that characterizes some older books on the subject.

The information given on the fluorescence of chemical compounds is no doubt helpful in chemical analysis as a guide, but the real value of fluorescence in this field can best be determined by the individual chemist for those specific cases with which he is confronted. The colors involved are generally subtle and, particularly at low intensities, are influenced by the low visible transmission of the ultraviolet lamp filter employed. Consequently, the chemist must ultimately depend on judgments formed from his own observations.

While it is true that the book contains some information that may be interesting or helpful to the chemist, yet it is necessary to point out some serious deficiencies. Its style gives evidence of haste and carelessness in composition. The treatment is superficial and too often pseudo-scientific. Its discussions, which are sometimes poorly balanced, indicate a lack of comprehension and understanding of present scientific viewpoints. The price for such a small book seems inexcusably high.

G. R. FONDA

The Polarographic Method of Analysis. By OTTO H. MÜLLER, Department of Anatomy, Cornell University Medical College, New York City. Journal of Chemical Education, Easton, Pennsylvania, 1941. vi + 114 pp. 30 figs. 13 × 20.5 cm. Price, $1.00.

Dr. Müller's stated intention in writing this little monograph on polarographic analysis has been "to present a simple account of polarography in a form which can be used by teachers and students in courses of physical chemistry as well as in advanced courses of analytical chemistry." The tone of the book is thus that of an elementary text, and the discussion is limited mainly to fundamental principles with only cursory mention of practical applications.

The book comprises five chapters, the first of which is well described by its title, "Review of Electro-Analytical Methods." The second chapter, entitled "Apparatus," is devoted practically entirely to the description of simple home-made equipment that should be very useful for instructional purposes. The third chapter, "Fundamentals of Quantitative Analysis," contains a discussion of the factors that govern the limiting current. The analysis of polarographic waves and the significance of the half-wave potential are treated in the fourth chapter under the title, "Fundamentals of Qualitative Analysis." The last chapter contains a good résumé of the types of analyses to which the polarographic method can be applied, and a discussion of various points that must be considered in practical work.

The following misstatements and errors have been noticed. Opposite sign conventions are given on p. 21 and p. 39 for cathodic and anodic currents. The discussion on p. 52 of the relation between diffusion current and diffusion coefficient, and the comparison of observed and theoretical diffusion current ratios, lacks conviction because no mention is made of the source of the diffusion coefficient data. It is unfortunate in this connection that the author did not make use of recent data in the literature that demonstrate conclusively the validity of the Ilkovic equation. In the statement at the top of p. 55 the author implies that the use of a "capillary constant" P/m is less laborious than the use of m itself for characterizing and checking the behavior of a capillary, which is misleading. On p. 74, and again on p. 81, it is stated incorrectly that the cathodic and anodic half-wave potentials of a reversible oxidation–reduction system will only be identical if the diffusion coefficients of the reduced and oxidized forms are identical. Actually the cathodic and anodic half-wave potentials will be identical regardless of any difference in the diffusion coefficients. In stating on p. 79 that the theory regarding the shift of the half-wave potential of a metal ion by complex formation "has not yet been subjected to critical tests" the author has apparently overlooked recent work in this field.

On p. 84 the author discusses anodic waves that involve the oxidation of the mercury itself under the general heading "Irreversible Reactions," and he states that "The curves are not the usual S-shape and the half-wave potentials are not independent of concentration." It is thus implied that such reactions are always irreversible, whereas certain waves of this type have actually been shown to correspond to reversible reactions. On p. 98 it is stated incorrectly that a polarogram of a mixture of thallous and cadmium salts in a potassium cyanide supporting electrolyte would only show the cadmium wave. Actually such a polarogram does show a wave and diffusion current for the thallium preceding the cadmium wave, but the position of the thallium wave corresponds to the potential at which cyanide ion depolarizes the dropping electrode rather than the true reduction potential of the thallous ion. In the discussion on p. 111 of amperometric titrations in which the current changes sign, it is stated incorrectly that the end-

point is indicated by zero current. Actually the end-point is reached when the current has become equal to the residual current of the medium.

The author's style is clear and easy to follow and the arrangement of topics is good. An outstanding feature of the book is the inclusion at numerous points throughout the text of directions for well-chosen experiments that illustrate important theoretical points. This feature, combined with a laudable emphasis on simplicity of apparatus, should make this little monograph quite useful as an elementary text of the subject.

JAMES J. LINGANE

Organic Reagents in Inorganic Analysis. By PAUL VON STEIN, Director of Analytical Developments, Cadmium Residue and Pigment Department, Harshaw Chemical Company, Elyria, Ohio. Chemical Publishing Co., Inc., Brooklyn, N. Y., 1942. viii+ 242 pp. 22 × 14.5 cm. Price, $4.50.

In this book forty-seven elements and radicals are arranged in alphabetical order, and brief abstracts of the more pertinent methods of detection, using organic reagents, are given. Each abstract is accompanied by an average of only one or two references to the literature.

Although a majority of the more useful of the methods given can be found in brief form in the larger reference books of qualitative analysis and in Lange's "Handbook of Chemistry," such a compilation as the one under consideration should be useful to the analytical chemist. Unfortunately, the book is so replete with errors of omission and commission that its value is considerably lowered. Certainly in a book that the author states is intended to be "a complete reference work of organic compounds which yield indicative reactions with inorganic materials," the omission of dimethylglyoxime as a precipitant for nickel is surprising, to say the least. The scantiness of the bibliography is also disappointing.

Typographical errors begin at the second line of the text and continue with alarming frequency throughout the book, including the appendix and index. On page 56, where the author sees fit to take time out to show us how to oxidize chromic ions to chromate, he makes two glaring grammatical errors in as many sentences.

The reviewer questions the implication that dimethylglyoxime precipitates so many metals from acid solution that its use as a precipitant for palladium is of little importance. But he is completely baffled to learn that the test for gold with dimethylaminobenzylidene rhodamine is specific only in the absence of *gold*, mercury and palladium. A great many other errors could be listed if space permitted. The above merely serve as examples.

Most of the material in the appendix is either repetitious or could well be incorporated in the text. The index is incomplete.

Altogether, the impression the book gives is that it was too hastily compiled and even more hastily printed.

[CONTRIBUTION FROM THE CHEMICAL LABORATORY OF HARVARD UNIVERSITY]

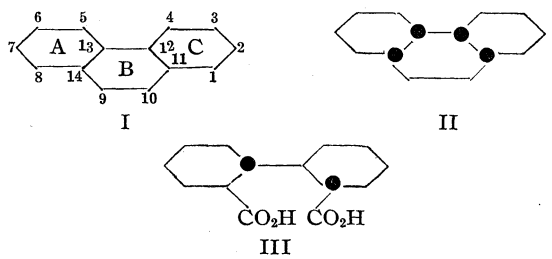
The Stereochemistry of Catalytic Hydrogenation. I. The Stereochemistry of the Hydrogenation of Aromatic Rings

BY R. P. LINSTEAD, W. E. DOERING, SELBY B. DAVIS, PHILIP LEVINE AND RICHARD R. WHETSTONE

This paper and the six that follow it give an account of the main results which have been obtained from a stereochemical study of the catalytic hydrogenation of a number of aromatic compounds. We have examined derivatives of phenanthrene substituted in the central ring and the hydro-diphenic acids which can be obtained from them by oxidation. The key substances in the elucidation of the configuration were the perhydrodiphenic acids. The six possible isomeric forms of these have been prepared and oriented. The information so obtained has been used to orientate the hydrogenation products of the phenanthrene derivatives.

The experimental results and the determination of configuration are given in Parts II to VII. The present paper summarizes the data, and analyzes their bearing on the phenomena of catalytic hydrogenation.

The system of nomenclature for these compounds is the following.[1] When phenanthrene is completely hydrogenated, four (potential) asymmetric carbon atoms appear. These are numbered 11, 12, 13 and 14 in formula I. The configurations of the ring fusions AB and BC are designated *cis* or *trans* in the usual manner, according to whether the pair of hydrogen atoms on C_{13} and C_{14} (or C_{11} and C_{12}) are on the same side of the molecule. The configuration of the backbone (the C_{12}–C_{13} bond) is designated *syn* if the two hydrogens on



C_{12} and C_{13} are on the same side of the molecule and *anti* if they are on opposite sides. The positions of the hydrogen atoms are represented in the formulas by black dots, a dot indicating that a hydrogen atom is above the molecule. A dot is always placed on C_{13}. On this convention, formula II represents *cis-syn-cis* (*c. s. c.*) perhydrophenanthrene. The related perhydrodiphenic acids are similarly named and represented, the molecule being written in the coiled state with the carboxyl groups together. Formula III thus represents *trans-anti-trans* (*t. a. t.*) perhydrodiphenic acid.

The catalytic hydrogenations were carried out over Adams platinum oxide in acetic acid unless otherwise stated. The following compounds were hydrogenated to the corresponding perhydro products: diphenic acid[2] (in alcohol as well as in acetic acid), diphenic ester,[2] diphenic anhydride,[2] *cis*-hexahydrodiphenic acid,[3] *trans*-hexahydrodiphenic acid,[3] 9-phenanthrol,[4] *cis-as*-octahydro-9-

phenanthrol[4] (in alcohol as well), *cis*-9-keto-octahydrophenanthrene[4] (in alcohol), and 9,10-phenanthrenequinone.[5]

There is a remarkable regularity in these results. *All the hydrogenations studied have given largely cis- and syn-material.* The only compound which gives a main per-hydrogenation product containing a *trans*-linkage is the *trans*-hexahydrodiphenic acid which already contains such a linkage. The results refer to the *main* stereoisomer formed, which constitutes 75% or more of the total perhydro product. Diphenic acid both in alcohol and in acetic acid gives a small amount of the *cis-syn-trans* and *cis-anti-cis* perhydro acids. Diphenic ester gives some *anti*-material. The remaining compounds mentioned probably yield small quantities of stereoisomers containing different skeletal configurations, but these have not as yet been isolated in the pure state.

The regularity in these experiments invites a theoretical analysis. We propose three hypotheses to account for the results: (1) that when one or more aromatic rings are hydrogenated during a single period of adsorption, the hydrogen atoms add to one side of the molecule; (2) that the orientation of the adsorption of the aromatic molecule on the catalyst is affected by hindrance between the catalyst and the substrate ("catalyst hindrance"); (3) that the derivatives of diphenic acid which have been studied are hydrogenated in the coiled phase. These will now be considered in turn.

(1) **One-Sided Addition.**—Willstätter in 1908[6] made the basic discovery that aromatic compounds could be hydrogenated at room temperatures over a platinum catalyst. It was some years before it was observed, mainly owing to the work of Skita[7] and von Auwers,[8] that, when two or more nuclear substituents were present, the products obtained by the use of platinum were isomeric but not identical with those obtained by Sabatier hydrogenations of the same compounds over nickel at high temperatures. As is well known, it was generally accepted that the products were geometrical isomers of the von Baeyer type, the compounds prepared over platinum being *cis*, and those by the Sabatier method being *trans*. Moreover, Skita,[7] in particular, noted that in hydrogenations over platinum a *cis*-orientation was favored in acid media, a *trans*-orientation in neutral or basic media.

Most of the configurations of the hydrogenation products in the early work were assigned on the basis of von Auwers' generalization that, of a pair of stereoisomers of this type, the *cis*-compound has the higher density and refractive index but the lower molecular refractivity. This rule has been of considerable service, although the differences in the physical constants become slight among the more complicated molecules. For our present purpose, however, we wish to emphasize those results in which the configurations have been determined by absolute methods, depending (ultimately) on optical resolution. A number of examples of this kind are collected in Table I, which is not exhaustive. The evidence for the configuration of the product is outlined at the foot of the table, and is, in all cases, conclusive. The substances all owe their isomerism to the presence of carboxyl groups, fatty acid residues or fused rings. Compounds in which one (or more) of the orientating groups is a hydroxyl, amino or similar group have deliberately been excluded, because of the danger of stereochemical inversions in these cases.

TABLE I

CATALYTIC HYDROGENATIONS OVER PLATINUM IN ACETIC ACID

	Substance	Catalyst	Configuration of product	References
1	(*o*-) Phthalic acid	Willstätter Pt	*cis*	9
2	Phthalic anhydride	Willstätter Pt	*cis*	9
3	Phthalimide	Willstätter Pt	*cis*	9
4	Isophthalic acid	Willstätter Pt Adams Pt	mainly *cis*	9, 10
5	Terephthalic acid	Willstätter Pt Adams Pt	*cis* + *trans*	9, 10
6	Benzene-1-acetic-2β-propionic acid	Willstätter Pt	*cis*	11
7	β-Naphthol	Skita Pt	*cis*	11
8	*ar*-β-Tetralol	Willstätter Pt Skita Pt	*cis*	11
9	*ac*-β-Tetralol	Willstätter Pt Skita Pt	*cis*	11
10	*ac*-α-Tetralol	Willstätter Pt	*cis*	11, 12
11	*ar*-α-Tetralol	Willstätter Pt	*cis*	11, 12
12	5-Hydroxy-hydrindene	Adams Pt	*cis*	13

The configuration of the products is proved by the following evidence: nos. 1–3: From the resolution of *trans*-hexahydrophthalic acid (Werner

and Conrad[14]). No. 4: From the resolution of *trans*-hexahydro-isophthalic acid (Böeseken and Peek[15]). No. 5: From the work of Mills and Keats.[16] Nos. 6–11: From the resolution of *trans*-cyclohexane-1,2-diacetic acid (Hückel and collaborators[17]; Barrett and Linstead[18]). No. 12: From the resolution of *trans*-cyclopentane-1,2-diacetic acid (Barrett and Linstead[18]).

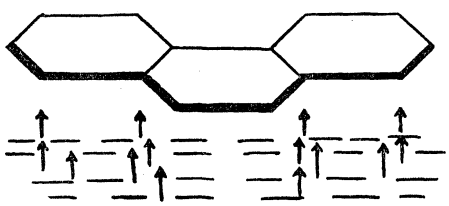
Of the twelve compounds given in Table I, all except terephthalic acid hydrogenate nearly exclusively *cis*- under these experimental conditions. It would be possible to bolster up the case by including a great deal of confirmatory evidence from hydrogenations in which the configuration of the product was known with a high degree of probability but not with certainty. However, the clear-cut evidence obtained from our studies and that presented in Table I is sufficient to demonstrate that aromatic compounds hydrogenate predominantly *cis*-, under the stated conditions. The new work summarized above is the most rigorous test of this generalization, because four asymmetric centers instead of two are involved. The generalization is restricted to the mildest type of catalytic hydrogenation, namely, that which occurs over platinum at room temperature, and in the solvent, acetic acid, which gives the most rapid addition.

This preferential addition can be explained by an application of the ideas of Farkas and Farkas.[19] They have shown that the catalytic hydrogenation of benzene and the exchange of hydrogen and deuterium proceed by different mechanisms. The hydrogenation involves the simultaneous addition of pairs of hydrogen atoms, whereas the exchange involves a radical or atomic reaction. Farkas and Farkas[20] have shown that these views can satisfactorily explain the preferential formation of *cis*-ethylenes in the half-hydrogenation of acetylenes over catalysts. It has been shown, notably by Bourguel,[21] that such hydrogenations yield initially *cis*-compounds but that *trans*-compounds may be formed if the hydrogenations are protracted.

In applying these conceptions to the aromatic series, we shall assume that the hydrogenation of a compound containing one aromatic ring proceeds to completion during one period of adsorption of the molecule on the catalyst surface. This assumption simplifies the argument and is in harmony with the experimental fact that benzene derivatives, except phenols, normally hydrogenate without yielding intermediates (see, for example, Vavon[22]). This is further connected with the fact that the hydrogenations of cyclohexene and the cyclohexadienes are exothermic.

There is an increasing body of evidence that the adsorption of an organic molecule on a catalyst, and hence the ease of hydrogenation, is affected by stereochemical considerations. The recent work of Beeck, Smith and Wheeler[23] has shown the importance of the orientation of the metallic atoms in the lattice of the catalyst on its activity. It is possible that the catalytic hydrogenation of large aromatic molecules, which are planar and comparatively rigid, will be determined largely by the ability of the molecule to find an area in the catalyst which has sufficient size, suitable spacing of the metallic atoms, and sufficient flatness.

We suggest that the stages in the hydrogenation which determine that the product shall have a *cis*-configuration are: (1) the adsorption of the aromatic molecule upon a suitable part of the catalyst; and (2) the addition of the hydrogen to the molecule from the underside so that all the atoms appear on the same side of the asymmetric carbon atoms. This is illustrated diagrammatically below for the case of a phenanthrene nucleus. The arrows represent the approach of the hydrogen atoms from the catalyst.



In the case of polynuclear compounds, there is little doubt that this is an oversimplification. These substances may give rise to incompletely hydrogenated compounds which are comparatively stable, of the type of tetralin. In several of the hydrogenations studied in the present work such intermediate hydrogenation products were isolated from the reaction products; for example,

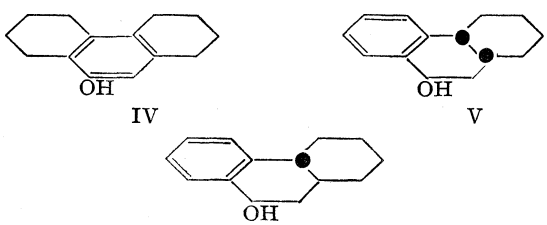
diphenic acid yields some *cis*-hexahydrodiphenic acid and 9-phenanthrol gives the *sym*-octahydro derivative. There is no doubt, therefore, that desorption of the organic molecule from the catalyst can occur at an intermediate state of hydrogenation, and it is reasonable to suppose that some of the perhydrogenated material is formed as a result of two (or even more) separate periods of adsorption.

Consider the final stage of the hydrogenation of the *sym*-octahydrophenanthrol (IV). Simple one-sided addition of hydrogen to the remaining benzene ring would determine the configuration of all four asymmetric carbon atoms, and a *cis-syn-cis* product would be expected. The isomeric *as*-octahydro compounds (V and VI), however, do not present such a simple case. We should expect



IV V VI

the final hydrogenation to go *cis*- to both the *cis*-alcohol (V) and the *trans*-alcohol (VI), but the principle of one-sided addition does not enable us to predict the backbone configuration of the perhydro product. It appears equally possible for V to give a *cis-syn-cis* or a *cis-anti-cis* perhydro alcohol. The same is true of the diphenic acids, where the stable intermediate is a hexahydro acid with an unsymmetrical arrangement of hydrogen atoms. It is only possible to account for completely *cis*- and *syn*-perhydrogenation of a phenanthrene or diphenic acid derivative on the basis of the principle of one-sided addition by making the following subsidiary postulates: (1) no desorption of the molecule occurs at an intermediate stage, or (2) the intermediate which is hydrogenated in the stage which determines the configuration has double bonds at all the potential asymmetric carbon atoms. These are highly arbitrary and improbable assumptions, and a more reasonable suggestion is that a second determining factor, that of catalyst hindrance, comes into play. This is discussed later.

It has already been stated that Skita observed many cases in which *cis*-hydrogenation occurs in an acid, and *trans*- in a neutral or basic medium. It is true that the configurations of his products were often not conclusively proved, but there is no doubt of the variability of the orientation of addition to the compounds which he studied. We have so far confined ourselves to one main set of hydrogenation conditions and have little experimental evidence to offer in this connection. A few comments may, however, be made. (1) In most of our experiments either the solvent or the molecule undergoing hydrogenation was an acid. However, *cis-as*-octahydro-9-phenanthrol and the corresponding ketone both hydrogenate *cis*- and *syn*- in a neutral (alcoholic) medium, and in the case of the phenanthrol the orientation was shown by direct comparison to be the same as that obtained in acetic acid solution. This is contrary to Skita's generalization. (2) Many of the examples studied by Skita involved the hydrogenation of phenols and aromatic amines. We think this evidence of doubtful value in relation to the stereochemistry of hydrogenation of the aromatic ring because of the possibility of the formation of hydroaromatic ketones (as has often been demonstrated experimentally) or of ketimines. These substances are capable of stereochemical inversion by enolization or an analogous process, so that the final orientation, for example, of the hydroxyl group to the methyl in a perhydrocresol, has no necessary bearing on the course of the hydrogenation of the aromatic ring.[23a] (3) In spite of these reservations there are a number of examples in which the acidity of the medium appears to affect the orientation of aromatic hydrogenation, and in which the orienting groups are alkyls or other groups incapable of inversion. Under suitable experimental conditions *trans*-hydrogenation can occur. It appears probable that in these reactions (and, indeed, in other cases of *trans*-hydrogenation) the mechanism of hydrogenation is different from the molecular addition involved in *cis*-hydrogenation. Atoms of hydrogen and organic radicals may well be involved, as in the exchange reactions studied by Farkas and Farkas.[19] The intervention of radicals is indeed strongly indicated in some of the hydrogenations of aromatic bases studied by Skita which readily yield compounds of the dicyclohexylamine type.[24]

Particular reference may be made to Skita's studies[25] of the hydrogenation of the xylenols and

(23a) With the hydrogenation of hydroaromatic ketones, which has been thoroughly studied by Vavon, Skita, Hückel and others, we are not concerned in this paper.

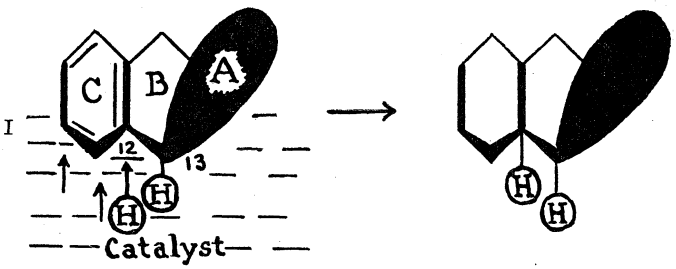
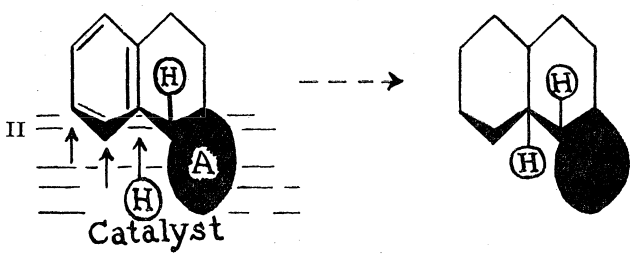
xylidines, especially of *vic-m*-xylenol (2,6-dimethylphenol). In this case good evidence was obtained that the methyl groups in the product were oriented *trans* to each other whether the hydrogenation was carried out in a neutral or an acid medium. This not only conflicts with the run of Skita's own observations but also is opposed to the evidence summarized above and in Table I. We propose to undertake a further study of the hydrogenation of the xylenols when conditions permit. In the meantime it would seem that this is an example of the abnormal (atomic) mechanism already mentioned.

The abnormal mechanism is much more evident in hydrogenation over nickel, and may be presumed to account for the formation of predominantly *trans*-products in Sabatier hydrogenations. In the somewhat milder hydrogenations over Raney nickel the orientations are irregular, and it appears certain that both mechanisms may function. Thus we find that phenanthraquinone hydrogenates *cis-syn-cis* over platinum at 25° and almost exclusively *cis-syn-cis* over nickel at 160°. A very small amount of a *cis-syn-trans* glycol is formed under the latter conditions. On the other hand, diphenic ester can yield considerable quantities of *anti*-perhydro material over nickel,[26] under very similar conditions, but here the results of a number of recent experiments show considerable variations and *syn*-perhydro ester has frequently been almost the sole product.

(2) **Catalyst Hindrance.**—As was pointed out above *cis-as*-octahydro-9-phenanthrol (V), the corresponding ketone and the related *cis*-hexahydrodiphenic acid all yield *cis-syn-cis* perhydro-products. *Trans*-hexahydrodiphenic acid also undergoes *cis*- and *syn*-perhydrogenation. The simple hypothesis of one-sided addition is quite unable to account for these results, and also, as has already been pointed out, cannot explain the *cis-syn-cis* perhydrogenation of phenanthrene derivatives except on the basis of two unlikely postulates. The crux of the problem is this: Why should the position of the hydrogen on C_{13} determine the position taken up by that which enters on C_{12}? No explanation based on a disproportionation or a migration of the hydrogens already in position can be accepted, because the integrity of the configuration already established is preserved. In our view the determining factor is one of *catalyst hindrance, i. e.*, a steric hindrance between the catalyst and the substrate. This is illustrated for the case of a *cis-as*-octahydrophenanthrene derivative in the diagrams given below:



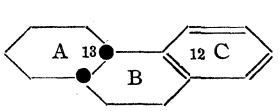
Preferred adsorption; Ring A clear of catalyst; *syn*-hydrogenation occurs.



Hindrance between catalyst and ring A; adsorption inhibited; little or no *anti*-hydrogenation.

It may be taken that it is the aromatic part of the molecule which anchors it to the catalyst. Two arrangements are then possible, in which ring A is either inclined away from or toward the catalyst. In diagram I the A ring is away from the catalyst and the hydrogen atom on C_{13} toward it. The hydrogens adding to the molecule from the underside will therefore come from the same side as the hydrogen on C_{13}. The hydrogen atom which attaches itself to C_{12} and determines the backbone configuration thus takes up a *syn* arrangement with respect to C_{13}. In diagram II, the opposite state of affairs holds; ring A will be on the same side as the catalyst and any hydrogen which becomes attached to C_{12} (by the normal mechanism) will take up the *anti*-configuration. It appears reasonable to suppose that the adsorption corresponding to I will be greatly preferred to that represented by II and therefore that *syn*-hydrogenation will preponderate. This is what is found experimentally.

The same argument can be applied to the diphenic acid derivatives, providing these sub-

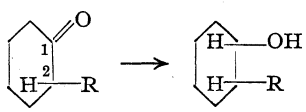


(26) Vocke, *Ann.*, **508**, 1 (1934); Linstead and Walpole, *J. Chem. Soc.*, 850 (1939).

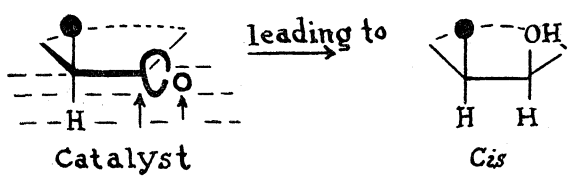
stances are considered as reacting in a coiled or "pseudo-tricyclic" state. This question is dealt with in the next section.

To the best of our knowledge, the proposal that there can be a steric hindrance between a metallic catalyst and its substrate is novel. There appears to be no other reasonable way of accounting for the regular occurrence of *syn*-hydrogenation over platinum. There is a philosophical connection with Bergmann's explanation[27] of the selective action of proteolytic enzymes (peptidases) on polypeptides made from natural and unnatural amino acids, respectively.

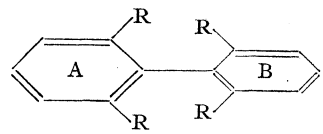
It seems probable that catalyst hindrance is a determining factor in many other reactions. Vavon has proposed[28] that the production of a *cis*-alcohol in the catalytic hydrogenation of substituted hydroaromatic ketones, particularly those of the ortho series, is due to a steric hindrance between the substituent group R and the entering hydrogen. This, he suggests, makes the hydrogen



attack the carbonyl double bond from the side removed from the group R, so that the hydroxyl group which is formed takes up the *cis*-position with respect to this. We agree with Vavon that steric hindrance of the group R is the operative factor but regard it as acting at an earlier stage, namely, that of adsorption. The adsorption can most readily occur with the group R inclined away from the catalyst so that the entering hydrogen on C_1 takes up the *cis*-position with respect to that on C_2. The preferred reaction is illustrated below:

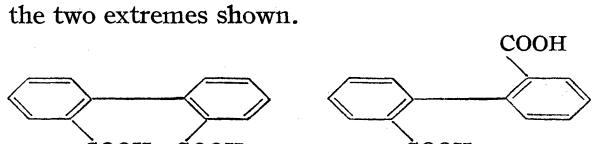


Catalyst hindrance can also account in a simple way for a remarkable discovery made by Adkins and his co-workers in 1933.[29] They studied the hydrogenation of various substituted diphenyls in which the rotation about the internuclear bond was restricted so that optical activity of the well-known type was possible. It was found to be quite *impossible to hydrogenate* these compounds over Raney nickel even under remarkably drastic conditions, in contrast to the comparatively easy hydrogenation of diphenyl derivatives in which free rotation was possible. We suggest that this reluctance to react originates with the fact that these restricted molecules cannot lie in one plane.



Hence if one ring lies flat on the catalyst, the other will interfere with it. Adsorption, and hence hydrogenation, is therefore inhibited. It appears that the forces which would be involved in the complete adsorption of the molecule on the catalyst are too weak to overcome the repulsion between the substituent groups R. Adkins commented upon his results in the following words: "It is possible that the same factors which prevent the rotation of the rings . . . in resolvable derivatives of diphenyl, also prevent the reaction (adsorption) of the benzenoid ring by the catalyst, and so inhibit the first step in the catalytic hydrogenation of the former." Our proposal in this connection is therefore an extension of Adkins' suggestion.

(3) **Coiling.**—A remarkable feature of the new results is that diphenic acid and its ester hydrogenate in the same stereochemical manner as do its anhydride and the phenanthrene derivatives to which it is related. The hexahydro acids also simulate their tricyclic counterparts. It is to be presumed that diphenic acid can exist in all the possible phases intermediate between the two extremes shown.



On the basis of the hypotheses already advanced, the coiled form would yield a *cis-syn-cis* perhydroproduct and the zigzag form one with a *cis-anti-cis* configuration. We indeed anticipated that diphenic acid would yield a stereochemically different perhydro product from its anhydride, but this was found not to be true. Unfortunately, we have so far been unable to bring about catalytic hydrogenation of the diphenate anion in water

over platinum. The anion would be expected to exist preferentially in the zigzag form and to yield *anti*-material on hydrogenation.

As it is unlikely that the agreement of the results is purely due to coincidence, it appears that the "open-chain" derivatives of diphenic acid (the acid itself, its ester and its two hexahydrides) *all hydrogenate in the coiled or pseudo-tricyclic phase.* This would mean that this phase is the one which is most readily adsorbed on the catalyst. We can see no particular reason for this preference. Hydrogen bonding between the carboxyl groups could be invoked for the acid but not for its ester.

The hypotheses which are advanced in this paper are tentative and require additional experimental investigation from many points of view. This we hope to provide in due course. One aspect which has not yet been mentioned will have to be considered before these hypotheses could be applied generally. The present work has been almost completely confined to the ortho-substituted compounds. (This is to some extent inevitable in the study of polycyclic aromatic structures). It may be found that the behavior of compounds in which the orienting groups are further apart may be much less regular than those studied in the present work. There are several indications in the literature that this may be true, for example, the considerable degree of *trans*-hydrogenation of terephthalic acid, as mentioned in Table I.

Summary

The stereochemistry of the hydrogenation of a number of derivatives of diphenic acid and of phenanthrene over a platinum catalyst is discussed. The nine compounds studied all hydrogenate *cis* and *syn*.

The results are explained on the basis of three hypotheses.

1. When one or more aromatic rings are hydrogenated during a single period of adsorption, the hydrogen atoms add to one side of the molecule.
2. The orientation of the adsorption of the aromatic molecule on the catalyst is affected by hindrance between the catalyst and the substrate.
3. The open-chain derivatives of diphenic acid are hydrogenated in the coiled phase.

Earlier work is discussed in the light of these views, and certain applications to related fields are indicated.

The Stereochemistry of Catalytic Hydrogenation. II. The Preparation of the Six Inactive Perhydrodiphenic[1] Acids

BY R. P. LINSTEAD AND W. E. DOERING

Earlier work by Linstead and A. L. Walpole[2] on the hydrogenation of diphenic acid had revealed the following facts: (1) Catalytic hydrogenation of the free acid in acetic acid solution over platinum gave a perhydro acid of m. p. 273°. (2) Similar hydrogenation of dimethyl diphenate gave a solid perhydro ester, m. p. 73°, which on alkaline hydrolysis gave a perhydro acid of m. p. 220°. (3) Hydrogenation of dimethyl diphenate over Raney nickel by Adkins' procedure gave a mixture of the ester of m. p. 73° and a liquid ester which on alkaline hydrolysis gave a third perhydro acid of m. p. 244°. Other early work on the perhydro acids is reviewed later in the present paper.

We have now made a fuller study of the hydrogenation of diphenic acid and its derivatives over platinum, and of the stereochemical inversion of the products. This has led to the isolation of eleven distinct optically inactive hydrodiphenic acids. Six of these are dodecahydro- (perhydro-) derivatives; three are decahydro-, containing one double bond; and the remaining two are hexahydro-, and contain one intact benzene ring. This paper is concerned only with the perhydro acids.

As pointed out by Linstead and Walpole,[2] perhydrodiphenic acid can exist in six inactive modifications, four of which are resolvable. All the possible forms have therefore been obtained. Experiments on their resolution are described in the following paper.

(1) The common 2,2'-diphenic acid is referred to as diphenic acid for the sake of brevity throughout these papers. Its hydrogenated derivatives are correspondingly named without prefix.

(2) Linstead and Walpole, *J. Chem. Soc.*, 850 (1939).

The *syn*-Series

When diphenic acid is exhaustively hydrogenated in acetic acid solution over Adams catalyst, one main product and three by-products are obtained. The main product is a perhydro-acid, $C_{12}H_{20}(CO_2H)_2$, m. p. 289°. This is easily isolated and purified owing to its low solubility. Accompanying this, in low amounts, are two isomeric perhydro-acids melting at 198 and 200°, respectively. Usually also there is a certain amount of a hexahydro-acid $C_{12}H_{14}(CO_2H)_2$ of m. p. 242°, which occurs even when the uptake of hydrogen appears to have ceased completely. The proportions of the products appear to vary slightly with variations in the experimental procedure and in the catalyst, but the acid of m. p. 289° always constitutes the bulk of the product.

The acid of m. p. 289° is a slightly purer form of the material of m. p. 273° already reported by Linstead and Walpole[2] and by Hückel.[3] The m. p. varies with the rate of heating, and this fact may contribute to the lower m. p.'s previously recorded.

The same compound (accompanied by the same impurities) is formed when the hydrogenation of the acid is carried out in acetic acid containing 2% of hydrochloric acid. The hydrogenation also takes the same course in alcohol but in this case the reaction is much slower. When diphenic anhydride is hydrogenated over platinum and the product hydrolyzed, the perhydro acid of m. p. 289° is also obtained. Sodium diphenate resisted catalytic hydrogenation in aqueous solution. Dimethyl diphenate, however, was exhaustively hydrogenated over platinum without difficulty, and, in agreement with Linstead and Walpole,[2] the main product was a perhydro ester, m. p. 73°. It is proved below that this is the dimethyl ester of the 289° acid and that its alkaline hydrolysis is anomalous. There is, therefore, a general tendency for the diphenic acid system to be hydrogenated over platinum to the perhydro form corresponding with the acid of m. p. 289°.

Because of the complicated inversions which can occur in the chemistry of the 289° acid and its derivatives, it was necessary to establish conclusively its relationship with its anhydride and esters. This was done as follows.

The perhydrodiphenic acid of m. p. 289° on treatment with acetic anhydride yielded a mixed anhydride, $CH_3COOOCC_{12}H_{20}COOOCCH_3$, which on sublimation gave the simple perhydrodiphenic anhydride, $C_{12}H_{20}(CO)_2O$, m. p. 146–147°. From this the parent acid could be regenerated. These results confirm those already reported.[2] Treatment of the anhydride with sodium methoxide yielded a monomethyl ester, m. p. 129°. When either the 289° acid or its monomethyl ester was treated with diazomethane, there was obtained a dimethyl ester of m. p. 73–74°. This was identical with the perhydro ester prepared by the direct hydrogenation of dimethyl diphenate. Fischer-Speier esterification of the 289° acid or of the 129° acid ester also yielded the 73° dimethyl ester, but the reaction was slow. The best preparative method for the esterification of the acid is to boil it for several days with methanol containing 2% of fuming sulfuric acid. Treatment of the anhydride with methanol and a trace of oleum gave a mixture of the 129° acid ester and the 73° dimethyl ester. When the 289° acid was treated with one equivalent of diazomethane, the main reaction was the formation of the dimethyl ester, an approximately equivalent amount of the acid remaining unchanged. A small amount (10%) of the 129° acid ester was also formed. It therefore appears that the acid ester reacts more readily with diazomethane than does the dicarboxylic acid. Acid hydrolysis of the 73° ester yielded a mixture of the 289° acid and the 129° acid ester. Acid hydrolysis of the 129° acid ester gave the 289° acid.

It was shown by Linstead and Walpole[2] that hydrolysis of the 73° dimethyl ester with alcoholic potash yielded an acid of m. p. 220°, identical with that formed by heating the 289° (273°) acid with hydrochloric acid at 200°. In the present work, this result was confirmed and the perhydro-acid produced was found to melt, in the pure state, at 223°. This hydrolysis involved an inversion of configuration at one or both of the carboxyl groups. It has frequently been observed[4] that esters, in which the carbalkoxyl group is directly attached to a cyclic carbon atom which carried a hydrogen, can be inverted in configuration by treatment with sodium alkoxide. (This inversion normally proceeds in the direction *cis→trans;* however, it is the existence rather than the direction of the inversion which we wish to stress at the moment.) We therefore attempted to invert the 73° ester without hydrolysis by

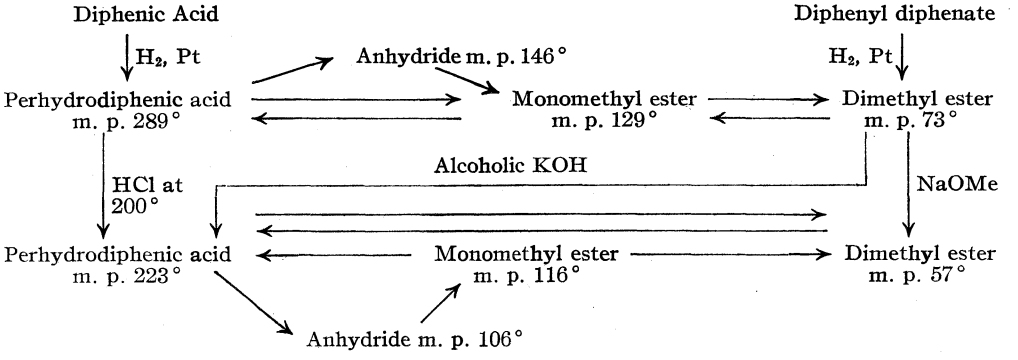
(3) Hückel, note in Vocke's paper, *Ann.*, **508**, 1 (1934).

(4) Hückel and Goth, *Ber.*, **58**, 447 (1925); Cook and Linstead, *J. Chem. Soc.*, 946 (1934).

heating it with sodium methoxide. This was successful; the ester was converted almost completely into an isomeride of m. p. 57°. A small amount of another isomeride, m. p. about 10°, also was formed. This is discussed later.

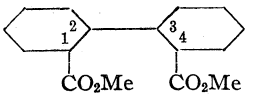
Acid hydrolysis of the 57° ester yielded the perhydrodiphenic acid of m. p. 223°. Esterification of the 223° acid with diazomethane yielded the ester, m. p. 57°. The acid was also characterized by conversion into the anhydride, m. p. 106° (in agreement with Linstead and Walpole[2]) and thence the monomethyl ester, m. p. 116°. Acid hydrolysis of the latter regenerated the 223° acid, while treatment with diazomethane formed the dimethyl ester, m. p. 57°.

The inter-relationships between the substances so far mentioned are summarized.



A curious anomaly in the literature should be mentioned at this point. Hückel[3] reported that his acid, m. p. 273°, on esterification with diazomethane gave an ester, m. p. *57°*. There can be little doubt that Hückel's acid was substantially our 289° acid. We have performed this esterification many times with diazomethane, as well as by the other methods already mentioned. Our product has always melted at 73° and we are convinced that this material is the authentic dimethyl ester. It would appear most probable that Hückel's note contains a misprint. This is supported by the fact that our 73° ester crystallizes in beautiful long needles, and this is the form described by Hückel for his "57°" ester. On the other hand, our 57° ester has never crystallized in this form. From the agreement of the m. p. with that of the invert ester, an alternative explanation for Hückel's result is that an inversion due to some contamination by alkali may have occurred in his work.

The question now arises, what is the nature of the inversion of configuration which occurs when the ester of m. p. 73° is converted into its isomeride of m. p. 57°? We are concerned only with the stereochemistry at carbons 1 and 4 (in the formula given below).



The configuration at C_2 and C_3—the "backbone configuration"[4a]—is fixed in the catalytic hydrogenation and will not be affected by the experimental conditions of our inversions. As regards C_1 and C_4, there are three possibilities. (1) Either these both have the same configuration in the 289° acid (and 73° ester) and both centers are inverted (*e. g., cis–cis-* → *trans–trans-*); or (2) both have the same initial configuration and only one center is inverted, because the *cis–trans* is the alkali-stable form, (*e. g., cis–cis* → *cis–trans*); or (3) they have different initial configurations and one center is inverted (*e. g., cis–trans-* → *trans–trans-*). It is proved below that the first of these possibilities is correct.

It was first shown by direct experiment that the 289° acid was stable to hot aqueous alkali. The inversion of the ester during treatment with alcoholic alkali therefore occurs in the unhydrolyzed ester, and cannot be brought about at the carbon atom carrying the ionized carboxyl. (This is of course due to the difference in the ease of enolization of the two groups.) The half-ester of the 289° acid therefore contains *one* group which is capable of effecting an inversion. If possibility (1) is correct, treatment with alkali should yield either a new acid (inversion + hydrolysis) or a new half-ester (inversion) according to the experimental conditions. If possibility (2) is correct, then either there will be no inversion

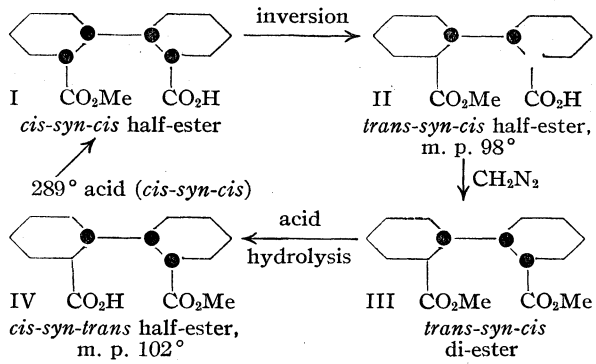
(4a) See Linstead and Walpole[2] and the preceding paper for a general outline of the stereochemistry.

or inversion to the 223° acid series will occur; the same is true of possibility (3).

The monomethyl ester of the 289° acid (m. p. 129°) was accordingly refluxed first with sodium methoxide, and the solution was then diluted somewhat with water and the heating continued. The product was a new perhydrodiphenic acid, m. p. 200°. (When the same acid ester was hydrolyzed with boiling aqueous alkali it gave the parent acid, m. p. 289°. The small amount of alcohol formed in this hydrolysis was clearly insufficient to effect any appreciable inversion.) When the 129° monomethyl ester was refluxed with sodium methoxide in the absence of water, it was converted into an isomeride of m. p. 98°. Acid hydrolysis of the new monomethyl ester yielded the new acid, m. p. 200°. Esterification of both the 98° monomethyl ester and the 200° acid with diazomethane yielded a dimethyl perhydrodiphenate, m. p. 14°. This material was identical with the by-product obtained in the inversion of the 73° dimethyl ester into the 57° isomeride.

An interesting observation which shows the ease of inversion in alkaline medium is the following. The anhydride of the 289° acid was boiled with some methanol which had been freshly distilled from baryta. It yielded mainly the corresponding monomethyl ester, m. p. 129°, but also, in 14% yield, the acid ester (m. p. 98°) of the half-invert acid. The partial inversion was traced to the presence of a small amount of barium methoxide in the methanol.

When the dimethyl ester (m. p. 14°) of the new acid was hydrolyzed for a comparatively short time with hydrochloric and acetic acids, it gave a mixture of the parent acid (m. p. 200°) and an acid ester. The latter melted at 102° and was not identical with that (m. p. 98°) described above; it depressed its m. p. and behaved differently on alkaline hydrolysis. It is clear therefore that this is the second acid ester which is theoretically possible for the half-invert acid, owing to the non-equivalence of the two carboxyl groups. The carbomethoxyl group preferentially hydrolyzed by acid is that on the *inverted* side of the molecule. To make this clearer we shall anticipate the assignment of the configuration to the acids. The 200° acid has been conclusively proved to have the *cis-syn-trans* configuration (see Part III). To distinguish between its two acid esters we shall refer to the configuration *on the ester side* first. Thus, in the *trans-syn-cis* half-ester, the hydrogen atom on the carbon which carries the carbomethoxyl group is orientated *trans-* to that on the neighboring backbone carbon; whereas that on the carbon which carries the free carboxyl group is orientated *cis-* (II). The preparation and naming of the two acid esters is shown in the following scheme.



The *cis-syn-trans* acid with acetic anhydride yields a distinct anhydride, m. p. 104°, from which it can be regenerated. The anhydride is not inverted by prolonged boiling with acetic anhydride.

It was pointed out above that the *trans-syn-cis* half-ester (II) was prevented from inverting further because its configurationally unstable (*cis*) ring carried the carboxyl group which was unable to provide a path for the inversion under the experimental conditions used. This is not true of the second half-ester (IV), for this carries the carbomethoxyl group on the unstable ring. It was accordingly expected that this would invert on hydrolysis with alcoholic alkali and this was realized. The 102° half-ester yielded the fully inverted acid of m. p. 223°. This series of reactions makes it certain that the 200° acid is intermediate in configuration between its isomers of m. p. 289° and 223°. We can now answer the question raised at the beginning of this section explicitly by saying that the inversion of the 73° to the 57° ester is a *double inversion.* We are not concerned at the moment with the proof of the direction of this but it is shown in later papers that it is *cis* → *trans*.

The acids of m. p. 289, 200 and 223° form one of the "backbone" series (*syn-* and *anti-*). It is proved later that this is the *syn*-series of perhydrodiphenic acids.

The *anti*-Series

The acids of this group are less accessible than their *syn*-isomers. This is particularly true of the

two members which contain configurationally unstable (*cis*-) arrangements.

It has already been stated that the catalytic hydrogenation of diphenic acid yields, besides the 289° acid, minor quantities of other hydrogenation products. The separation of these was laborious and difficult. Little or no benefit was achieved by converting the acids into their esters and carefully fractionating these. Direct fractional crystallization was useless in the early stages except for the isolation of the 289° acid. The following technique was of considerable assistance. The mixed acids were dissolved in sodium carbonate and the solution acidified in stages at the boiling point with dilute hydrochloric acid. Successive small crops of acids were so obtained. The method depends upon differences in acidity as well as in solubility. By its use the perhydro acids separate first and incompletely hydrogenated acids, which are aromatic and hence stronger, come down later. It was also possible by this means to separate a resinous ψ-acidic material (probably a lactone) which was sometimes present.

As an example, when the product of the hydrogenation of diphenic acid over platinum in alcohol was fractionated in the above manner, a succession of fractions were obtained, of which the principal components were

Crops 1–4:	Perhydro acid, m. p. 289° (*cis-syn-cis*)
Crop 5:	Perhydro acids, m. p. 289° and m. p. 198° (*cis-anti-cis*)
Crop 6:	Perhydro acid, m. p. 198°
Crop 7:	Perhydro acids, m. p. 198° and m. p. 200° (*cis-syn-trans*)
Crop 8:	Perhydro acid, m. p. 200°, and hexahydro acid, m. p. 242° (*cis*)
Crops 9–10:	Mainly diphenic acid

The various fractions could subsequently be further purified by direct crystallization. This enabled an estimate to be made of the relative amounts of the various products. In the above mixture these were approximately

Perhydro acids:	*cis-syn-cis*, 53%; *cis-anti-cis*, 10%; *cis-syn-trans*, 7%
Hexahydro acid:	10%
Diphenic acid:	20%

The method was found superior to that used by Vocke[5] for the separation of perhydro and hexahydro diphenic acids, which involves the use of barium salts.

In material exhaustively hydrogenated over platinum in acetic acid solution, the amount of unchanged or incompletely reduced acid was much lower. The proportion of *cis-syn-cis* material expressed as a percentage of the total perhydro acids was about the same, 70–80%, and the by-products were the same, namely, the *cis-anti-cis* acid, m. p. 198°, and the *cis-syn-trans* acid m. p. 200°. The isolation of these products is described in detail in the experimental section. The two acids were quite distinct and gave different series of derivatives. The *cis-syn-trans* (200°) acid was identical with that obtained by the half-inversion of the *cis-syn-cis* (289°) acid as described above. The final purification of the new acid (m. p. 198°) was conveniently achieved through the anhydride (m. p. 100°). The acid yielded crystalline di- and mono-methyl esters, melting at 44 and 99°, respectively. Acid hydrolysis of both these esters regenerated the parent acid.

It seemed reasonable to suppose that the new acid would have two configurationally unstable centers and would therefore be capable of half-inversion and of double inversion, as in the case of the 289° acid and its derivatives. The methods used in the *syn*-series were therefore applied to the new *anti*-acid. The monomethyl ester on hydrolysis with alcoholic potash yielded a new acid, m. p. 206°, which gave a distinct anhydride, m. p. 93°. The dimethyl ester (m. p. 44°) on similar hydrolysis gave the known acid m. p. 244° of Vocke[5] and of Walpole and Linstead.[2] This is now found to melt at 246–248° and to yield a dimethyl ester, m. p. 86°. The fact that this acid has previously been obtained by the hydrolysis of perhydro esters with alcoholic alkali is understandable. It represents the final alkali-stable form of all the *anti*-material originally present in the ester.

The above results make it clear that the *anti*-series consists of the three acids of m. p. 198, 206 and 248°, and that the acid of m. p. 206° is intermediate in configuration between the other two.

The melting points (in round numbers) of the six inactive perhydrodiphenic acids and of their derivatives are summarized in the table. Un-

Acid, probable (or certain) configuration	Melting points, °C.			
		Anhydride	Mono-methyl ester(s)	Di-methyl ester
cis-syn-cis	289	147	126	73
cis-syn-trans	200 (and 174)	104	98 and 102	14
trans-syn-trans	223	106	117	57

(5) Vocke, *Ann.*, **508**, 1 (1934).

stable dimorphous modifications are given in parentheses.

There is no doubt that these six isomers are distinct individuals. The three acids with very similar melting points (200°, 198°, 206°) depress each others' melting points, and have distinctive crystalline forms. Their derivatives are also different. All the six inactive forms, which are theoretically possible, have therefore been made and interrelated.

There were on record in the literature, however, two other substances to which the perhydrodiphenic acid structure has been assigned. These are the acid of m. p. 213°, described by Vocke,[5] and that of m. p. 203°, prepared by Linstead and Walpole.[2] After the present work had been completed, Marvel and White[6] described what appeared to be a further isomer, m. p. 174–175°. It became necessary, therefore, to consider the nature of these compounds.

Vocke Acid, m. p. 213°.—This acid was obtained by Vocke[5] by alkaline hydrolysis of the product of the hydrogenation of dimethyl diphenate over nickel. It was separated from the *trans-anti-trans* (247°) acid, which was Vocke's main perhydro-product, by a tedious fractional crystallization. We have never obtained a substance with these properties. It seems most probable that Vocke's acid was an impure form of our *trans-syn-trans* acid (m. p. 223°). This would tally with the method of preparation, for all the *syn*-material would be expected to assume the *trans-trans* configuration during the alkaline hydrolysis. Moreover, there is no doubt that *syn*-material is formed in hydrogenations over nickel, because the solid *cis-syn-cis*-dimethyl ester can be isolated in quantity from the unhydrolyzed reaction product.[2] The m. p. of Vocke's anhydride (80°) does not agree with ours (106°) but his compound was not analyzed and it is possible that it was a mixed anhydride with acetic acid, similar to that which Linstead and Walpole isolated from the *cis-syn-cis* acid.[2] The other discrepancy lies in the ease of ketonization. Linstead and Walpole[2] were able to form a pyroketone from the 223° acid, whereas Vocke observed that his acid and anhydride sublimed practically undecomposed. An alternative possibility is that Vocke's 213° acid may have contained one double bond, *i. e.*, it may have been a decahydrodiphenic acid. We have isolated a decahydrodiphenic acid of m. p. 212° as a by-product in certain hydrogenations. Vocke's analytical figures, however, correspond with a perhydro product.

Linstead and Walpole Acid, m. p. 203°.—This differs from the six isomerides described above. The position with regard to it is more complicated. It was prepared[2] by the nitric acid oxidation of a ketone, m. p. 51°, itself obtained[7] by the hydrogenation of two unsaturated ketones of m. p. 39 and 94°. These two unsaturated ketones were first prepared by Marvel and co-workers[8] by cyclization of di-Δ^1-cyclohexenylacetylene with formic acid, and were considered by them to have a hydrophenanthrene structure. Linstead and Walpole[7] reduced the two unsaturated ketones to hydrocarbons which were dehydrogenated to phenanthrene. Moreover, treatment of the saturated ketone with methylmagnesium iodide followed by dehydrogenation yielded 9-methylphenanthrene.[7] This provided definite evidence in support of Marvel's proposed skeletal structure. Further supporting evidence by the same method of attack has been reported by Marvel, Pearson and White.[9] It appeared to follow that the saturated ketone was 9-keto-perhydrophenanthrene and the acid obtained from it by oxidation was a perhydrodiphenic acid.

Marvel[8] was originally led to assign the hydrophenanthrene structure to his ketones from the behavior of a hydrocarbon obtained from one of them. This yielded on selenium dehydrogenation a product very similar in properties to what was at the time believed to be *trans-as*-octahydrophenanthrene. Levitz, Perlman and Bogert[10] have conclusively proved that this substance is a spirane. They therefore suggested that Marvel's ketones are also spiranes, a possibility earlier rejected by Marvel.[11]

The evidence summarized above on the structure of Marvel's ketones is inconclusive. However, now that six distinct perhydrodiphenic acids have been prepared and interrelated, there are only two possibilities for the 203° acid. Either it has a different skeletal structure, or the perhydrodiphenic acid series contains more isomeric forms than are demanded by classical

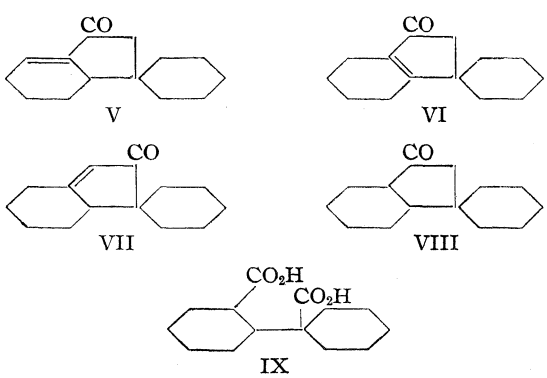
stereochemical theory. In the latter connection, the least unreasonable suggestion would be that there was a restriction of free rotation about the inter-nuclear bond, as in the case of various substituted diphenic acids. Many arguments could be raised against this possibility. It will be sufficient to quote the following direct experimental evidence. We find that *all* the authentic perhydrodiphenic acids yield pyroketones, whereas the 203° acid does not. It is inconceivable that the delicate isomerism due to restricted rotation could survive the high temperatures (300°) involved in this reaction.

It is, therefore, concluded that the 203° acid cannot be a perhydrodiphenic acid. Hence the 51° ketone is not a perhydrophenanthrene derivative and the unsaturated ketones of Marvel cannot have a phenanthrene skeleton.

We, therefore, accept as probable the spirane skeleton proposed by Levitz, Perlmán and Bogert,[10] which is most easily reconciled with the dehydrogenation results. The following further suggestions as to the structure are made. It was shown by Linstead and Walpole[7] that both the unsaturated ketones have $\alpha\beta$-double bonds and give the same pair of saturated ketones on hydrogenation. The carbonyl group is now placed in the five-membered ring because of the consistent formation of 9-alkyl phenanthrenes after Grignard reaction and dehydrogenation, as noted above.[7,9] Moreover, this offers a simple explanation for the fact that the 203° acid forms an anhydride but no pyroketone.[2] The three possible structures for the two unsaturated ketones which came up for consideration are (V), (VI) and (VII)



The structure corresponding to (VII) in the hydrophenanthrene series was eliminated by a stereochemical argument (Linstead and Walpole[7]), which is not valid in the spirane series. However, (VII) can be ruled out because it cannot possibly give the same ketones on hydrogenation as either (V) or (VI). Structures (V) and (VI), therefore, are the most acceptable for the two unsaturated ketones. Woodward[12] has given spectrographic evidence which indicates that (VI) is to be preferred for the ketone of m. p. 94°, and (V) for the more common isomeride, m. p. 39°. Essentially the same spectrochemical deduction has independently been drawn by Evans and Gillam[13] from Woodward's generalization. They placed the bonds in the equivalent positions in ketodecahydrophenanthrene molecules.

The two saturated ketones of Linstead and Walpole now become the *cis*- and *trans*-forms of (VIII). It is probable that the more stable modification (m. p. 51°) is the *cis*-form, judging from the relative stabilities of the α-hydrindanones. The acid of m. p. 203°, must have structure (IX) if the spirane skeleton is correct. It is therefore dicyclohexyl-1,2′-dicarboxylic acid.

Marvel and White Acid, m. p. 174°.—A sample of this material was kindly sent us by Professor Marvel. It was found to be essentially a dimorphic modification of the *cis-syn-trans* acid (m. p. 200°). When crystallized from dilute acetic acid it separated in the high melting form and was then identical with our material. Moreover, the melt of the 174° form soon solidified and then remelted at 198–200°.

Before the present work was completed, two "perhydrodiphenic acids" were known which apparently broke the Blanc rule regarding the pyrolysis of adipic acids. These were the 203 and 213° acids, which have been discussed above. It is now plain that the 203° acid is not a perhydrodiphenic acid at all, and the validity of the work on the 213° acid is doubtful. We propose to reserve further discussion on this general topic until our investigation of the pyrolysis of the new perhydrodiphenic acids is complete.

The optical resolution of the perhydrodiphenic acids is described in Part III, and the evidence for the assignment of configuration is given in Parts III and V. The bearing of the new result on the stereochemistry of perhydrophenanthrene derivatives is discussed in Parts VI and VII.

Experimental[14]

Intermediates

The following procedures, based on those of Oyster and Adkins[15] and Linstead and Walpole,[2] respectively, were found satisfactory for the routine preparation of pure diphenic acid from crude phenanthrene.

Potassium dichromate (300 g.) was dissolved in a mixture of 500 cc. of concentrated sulfuric acid and 1500 cc. of water contained in a 4-l. beaker. Without cooling, 100 g. of crude phenanthrene was added with vigorous stirring. This operation requires caution as much heat is evolved. After the reaction had quieted, a further 300 g. of potassium dichromate was added. The mixture was allowed to stand for one hour, and was then diluted with water (2 l.) and allowed to cool. The granular product was filtered off, washed thoroughly with water and dried; yield of crude phenanthraquinone, 89 to 94 g. (76–80%), m. p. 190–194°.

The quinone was oxidized in 100-g. lots in a 2-l. flask, fitted with stirrer and condenser, by means of a mixture of 120 cc. of 30% (100 vol.) hydrogen peroxide, 900 g. of 3% hydrogen peroxide and 300 cc. of glacial acetic acid. The mixture was boiled *very gently* for three hours. The product was filtered hot (steam funnel) from a little unreacted anthraquinone, and allowed to crystallize overnight in the ice-box. The crude diphenic acid was filtered off and dried (45 to 48.5 g.). To obtain material capable of being readily hydrogenated, the following procedure was used: 12 g. of the crude acid was dissolved in 1.5 l. of boiling water, the solution filtered and boiled for one-half hour with 2 g. of Norit. The solution was then filtered and the treatment repeated twice, using thirty minutes of boiling with 2 g. and 1 g. of Norit, respectively. The final filtrate deposited on cooling 6–7 g. of glistening plates of diphenic acid, m. p. 232–233°. The over-all yield from the crude phenanthrene varied between 18 and 21%.

The acid (25 g.) was esterified by five days of refluxing with 250 cc. of absolute methanol (freshly distilled from magnesium methoxide) containing 14 g. of dry hydrogen chloride. The product was separated by means of sodium carbonate into neutral and acid fractions. The neutral product was crystallized once from methanol which yielded 25.4 g. (91%) of pure dimethyl diphenate, m. p. 73–74°. Acidification of the sodium carbonate extract yielded a small quantity of *the monomethyl ester* of diphenic acid, which does not appear to have been described previously. It crystallizes from dilute alcohol in delicate plates, m. p. 110–111°.

Anal. (material dried at 80° *in vacuo*). Calcd. for $C_{15}H_{12}O_4$: C, 70.30; H, 4.72. Found: C, 70.45, 70.34; H, 4.80, 4.64.

syn-Series

289° Acid (*cis-syn-cis*[16]).—All the hydrogenations described in this paper were carried out in a Parr apparatus using an initial gage pressure of hydrogen of about 60 lb./sq. in. The glacial acetic acid was refluxed over, and then distilled from potassium permanganate. The Adams catalyst was prepared following Bruce.[17]

A solution of 20 g. of diphenic acid in 250 cc. of acetic acid was shaken under hydrogen with 1 g. of catalyst. Most hydrogenations went to completion in from one to four days without the addition of more catalyst. Occasionally a further gram of platinum oxide had to be added to complete the reduction. The bulk of the perhydro-acid separated from the solution during the reaction.

The catalyst and precipitate were filtered off from the product on a sintered-glass funnel and washed with 100 cc. of glacial acetic acid. The investigation of the filtrate (A) is described later. The solid acid was extracted from the catalyst by means of 5% aqueous alkali and was precipitated by dilute hydrochloric acid. The crude product weighed 11.2–12.7 g. (56–63%) and melted at 282–284°. Recrystallization from 500 cc. of glacial acetic acid yielded the pure *cis-syn-cis*-perhydrodiphenic acid, m. p. 287–289°.

The m. p. of this acid varies with the rate of heating owing to the formation of anhydride and to stereochemical inversion. For these reasons, also, very sharp values cannot be obtained. The above constant was obtained by immersing the capillary at 280° and raising the temperature 1° every six seconds. A mixture with a sample of the acid of Linstead and Walpole[2] (recorded m. p. 273–274°) melted under the same conditions at 285–287°.

Anal. (material dried at 110° *in vacuo*). Calcd. for $C_{14}H_{22}O_4$: C, 66.13; H, 8.72. Found: C, 66.21, 66.43; H, 8.83, 8.88.

The hydrogenation in alcohol solution was much slower and required frequent addition of fresh catalyst. The main product was the 289° acid. The separation of the products is more conveniently considered later under the 198° (*cis-anti-cis*) acid. The *cis-syn-cis* acid can also be prepared by catalytic hydrogenation of *cis*-hexahydrodiphenic acid. This is described in Part IV.

Derivatives of the 289° Acid

Anhydride.—Following Linstead and Walpole,[2] the acid (6 g.) was refluxed for twenty hours with 100 cc. of acetic anhydride. The excess of reagent was removed *in vacuo* and the solid residue sublimed onto a cold "finger" at 130° and 2 mm. After three sublimations, the acetic anhydride had been practically all eliminated and 4.0 g. (72%) of a crude anhydride m. p. 137–142° remained. Crystallization of this (1.6 g.) from 100 cc. of ligroin (b. p. 60–90°) gave 1.15 g. of the pure anhydride, shining plates, m. p. 146–147°; 1.5 g. of unsublimable material, probably polymeric anhydride, was also obtained.

Dimethyl Ester.—(1) The acid (5 g.) was refluxed for four days with 100 cc. of absolute methanol and 2 cc. of fuming sulfuric acid, containing 15% SO_3. The alcohol was boiled off and the residue was stirred with 100 cc. of hot 10% sodium carbonate solution. On cooling the ester crystallized, and was filtered off (m. p. 67–72°, yield, 5.3 g., 95%). One crystallization from dilute methanol gave 4.7 g. (85%) of long needles of pure *cis-syn-cis* dimethyl perhydrodiphenate, m. p. 73–74°. This material was identical with that prepared by Linstead and Walpole[2] by hydrogenation of dimethyl diphenate. Acidification of the sodium carbonate solution gave 0.13 g. (2.5%) of the

(14) All melting points are corrected.

(16) The configurations assigned are discussed more fully in the following papers. They have been added for convenience in reference.

(17) Bruce, THIS JOURNAL, **58**, 687 (1936).

monomethyl ester, m. p. 124–126°, which is described more fully below.

(2) The acid (5.08 g.) dissolved in 150 cc. of dioxane was added to an ethereal solution of diazomethane, prepared from 10.3 g. of nitroso-methyl urethan. After two days at room temperature the product was treated with acetic acid, the solvent removed and the residue crystallized from methanol, yield 89%, m. p. and mixed m. p. 73–74°.

Monomethyl Ester.—The anhydride, m. p. 147° (3.22 g.) was treated with a solution of sodium methoxide from 1.26 g. (4 moles) of sodium in 60 cc. of methanol. After three hours at room temperature, the solvent was removed, the residue taken up in water and the solution filtered and acidified. The crude half-ester which separated was dried and recrystallized from ligroin, b. p. 60–90° (*ca.* 250 cc.). This yielded 2.80 g., 76.5%, of the pure *monomethyl ester* of *cis-syn-cis*-perhydrodiphenic acid, small plates, m. p. 128.5–129.5°.

Anal. (material dried *in vacuo* at 110°). Calcd. for $C_{15}H_{24}O_4$: C, 67.14; H, 9.02. Found: C, 67.32, 67.12; H, 9.09, 9.08.

An alcoholic solution of 2.54 g. of the 289° acid was treated with one equivalent of diazomethane (from 2.11 cc. of nitrosomethyl urethan). The solution was immediately decolorized. It was extracted with 5% aqueous sodium hydroxide. The ethereal layer yielded 1.07 g. (38%) of the dimethyl ester, m. p. 72–74°. The alkaline extract was acidified and the crystalline precipitate so obtained was extracted with boiling ligroin (b. p. 60–90°). The residue (1.12 g., 44%) was the unchanged acid (m. p. 270–277°). The ligroin extract yielded the acid ester (0.28 g., 11%) which melted at 127–129° after one crystallization from ligroin.

When the monomethyl ester (150 mg., m. p. 129°) was treated with diazomethane in ether, it yielded the dimethyl ester (150 mg., m. p. and mixed m. p. 73°).

The anhydride, m. p. 147° (470 mg.), was refluxed for sixty-four hours with 20 cc. of methanol containing a drop of fuming sulfuric acid (15% SO_3), moisture being excluded. The methanol was removed and the residue extracted with boiling ligroin (b. p. 70–90°). Fractional crystallization of the ligroin solution yielded 160 mg. (30%) of the acid ester (less soluble) and 280 mg. (50%) of the dimethyl ester, identical with material already described.

Hydrolyses.—The dimethyl ester, m. p. 74° (500 mg.), was refluxed for twenty hours with 5 cc. of glacial acetic acid and 2 cc. of concentrated hydrochloric acid. The product was diluted with water and the precipitate so obtained was extracted with aqueous sodium carbonate. The insoluble portion (170 mg.) was the unchanged dimethyl ester. The carbonate solution was heated to the boiling point and treated with hydrochloric acid in drops until crystals began to appear. The acid ester (150 mg., m. p. 126–127.5°) then separated. Completion of the acidification yielded the slightly impure dicarboxylic acid, m. p. 270–272°, mixed m. p. 275–285° (140 mg.).

A similar acid hydrolysis of the monomethyl ester also yielded the *cis-syn-cis* acid (m. p. 282–285°, mixed m. p. 284–287°). The acid ester (10.3 mg.) was refluxed for fifty-two hours in a soft-glass apparatus with 2 cc. of 20% aqueous sodium hydroxide. The acidic product, crystallized from acetic acid, yielded 6.5 mg. (67%) of pure *cis-syn-cis* acid, m. p. and mixed m. p. 287–290°. No appreciable inversion had therefore occurred. On the other hand, hydrolyses of both the dimethyl and monomethyl esters with alcoholic potash led to inversions. These are described below under the headings of the appropriate acids.

200° Acid (*cis-syn-trans*)

The monomethyl ester of *cis-syn-cis*-perhydrodiphenic acid (1 g., m. p. 129°) was refluxed for seventeen hours with a solution of 2.0 g. of sodium in 20 cc. of absolute methanol. Water (2.5 cc.) was then added and the refluxing continued for a further fifty-seven hours. The solution was diluted, acidified and extracted with ether. Removal of the ether left a solid residue which was extracted with three 20-cc. portions of boiling benzene. The united extracts, on cooling, deposited a crust of *cis-syn-trans* acid. One crystallization from dilute alcohol gave 430 mg. (46%) of the pure *acid* in small needles, m. p. 198–200°. A second crop (420 mg.) of less pure acid was isolated from the benzene mother liquors. For analysis the acid was crystallized from acetic acid containing a trace of water, and was dried *in vacuo* at 110°, m. p. 199–200°.

Anal. Calcd. for $C_{14}H_{24}O_4$: C, 66.13; H, 8.72. Found: C, 66.26, 66.22; H, 8.79, 8.72. Equivalent (dibasic): Calcd., 127.2. Found, 124.6.

The isolation of the same acid as a by-product in the hydrogenation of diphenic acid is described below under the *cis-anti-cis* (198°) acid. The acid has also been prepared by catalytic hydrogenation of *trans*-hexahydrodiphenic acid (see Part IV).

A sample of the material of Marvel and White[6] was supplied by Dr. Marvel. It was a white powder, melting at 173–175° alone and at 198–200° in admixture with the *cis-syn-trans* acid, m. p. 199–200°. This material (3 mg.) was dissolved in 0.2 cc. of acetic acid and the solution was diluted to 0.5 cc. with water. The acid then separated in needles, m. p. 197–199°, identical with our *cis-syn-trans* acid. We have had occasional examples of the separation of this low-melting dimorphous modification. When this material has melted (at about 174°) it will resolidify and then melt at 198–200°.

Derivatives of the 200° Acid

trans-syn-cis **Monomethyl Ester.**—The acid ester of the *cis-syn-cis* acid (m. p. 129°, 540 mg.) was treated with sodium methoxide made from 460 mg. of sodium and 20 cc. of freshly dried methanol. The solution was refluxed for sixteen hours in a soft-glass apparatus. Some of the methanol was removed and the product acidified, diluted and extracted with ether. Evaporation of the ether left an oil which was taken up in 5 cc. of ligroin (b. p. 70–90°) and the solution left to crystallize. A mixture of *trans-syn-cis* and unchanged *cis-syn-cis* half esters crystallized, the former in large prisms, the latter in small plates. They were separated partly manually, and partly by fractional crystallization.

Yield of crude *cis-syn-cis* half-ester: 230 mg., (44%), m. p. 118–125°

Yield of purified *cis-syn-cis* half-ester: 140 mg., m. p. 125–127.5°

Yield of crude *trans-syn-cis* half-ester: 180 mg., (33%), m. p. 90–93°

Yield of purified *trans-syn-cis* half-ester: 130 mg., m. p. 97–99°

For analysis, the *trans-syn-cis*-monomethyl perhydrodiphenate was dried *in vacuo* at 56°. Calcd. for $C_{15}H_{24}O_4$: C, 6.14; H, 9.02. Found: C, 67.37, 67.21; H, 9.14, 9.02.

The following experiment illustrates the ease of inversion of the *cis-syn-cis* configuration. The *cis-syn-cis* anhydride, m. p. 145° (5 g.) was refluxed for seventy hours with 200 cc. of methanol which had been freshly distilled from barium oxide. (Subsequent examination showed that this methanol contained a trace of barium methoxide.) Removal of the solvent gave a residue, which on one crystallization from dilute alcohol gave 2.87 g. of the *cis-syn-cis*-monomethyl ester (m. p. 127–129°). The mother liquors were freed from solvent and the residue crystallized from ligroin in the manner described above. In this way there was separated 220 mg. more of the *cis-syn-cis* half-ester and 810 mg. of the *trans-syn-cis* half-ester. The latter after two more crystallizations from dilute alcohol melted at 97–99°, alone, or in admixture with that described above.

Acid hydrolysis of the 98° half-ester (13.3 mg.) with hydrochloric and acetic acids (1:2) yielded the *cis-syn-trans* acid (6 mg.) identified by m. p. and mixed m. p.

Dimethyl Ester.—Esterification of the acid (360 mg., m. p. 196–198°) was carried out with an excess of diazomethane in the usual way. The neutral product, an oil, was dissolved in a little petroleum ether and left at −70° to crystallize. After two days, prismatic clumps of the dimethyl ester separated. These melted at 12.5–14.5° alone and below 5° in admixture with the dimethyl ester (m. p. 57°) of the *trans-syn-trans* acid (see below). The same material was formed by diazomethane esterification of the *trans-syn-cis*-monomethyl ester, yield 86%; m. p. 12.5–14.5°. This dimethyl ester was also obtained as a by-product in the inversion of the *cis-syn-cis* dimethyl ester (*q. v.*).

***cis-syn-trans*-Monomethyl Ester.**—The dimethyl ester (250 mg., m. p. 12–14°) was refluxed for eleven hours with 2 cc. of concentrated hydrochloric acid and 3 cc. of glacial acetic acid. The product was evaporated to dryness and the acidic material extracted with hot 10% aqueous sodium carbonate solution. The extract was filtered through a layer of Norit, diluted to 30 cc. with water, and heated to boiling. The solution was then treated at the b. p. with 10% hydrochloric acid, 2 drops at a time. The solution was cooled after each addition and any precipitate was filtered off. The first material to separate in this way was a new acid ester (60 mg.) which melted at 100–102.5° alone and at 80–90° in admixture with the acid ester (*trans-syn-cis-*), m. p. 98°, described above. Three further crops separated on further acidification. These were united and separated into fractions soluble and insoluble in boiling hexane. The hexane-soluble fraction gave a further 80 mg. of the new acid ester. The hexane-insoluble fraction was essentially the *cis-syn-trans* acid. After two crystallizations from dilute acetic acid, 40 mg. was obtained which melted at 194–196° alone and at 195–198° in admixture with a pure sample.

The pure ***cis-syn-trans*-monomethyl ester** formed small prismatic crystals from ligroin, m. p. 101.5–102.5°. The analytical sample was dried at 80° *in vacuo*. Calcd. for $C_{15}H_{24}O_4$: C, 67.14; H, 9.02. Found: C, 67.30, 67.20; H, 9.20, 9.08.

The *cis-syn-trans* acid (300 mg., m. p. 196–198°) was refluxed for an hour with 3 cc. of acetic anhydride. The **anhydride,** obtained by removal of the reagent, crystallized from petroleum ether (b. p. 35–60°) in glistening prisms, m. p. 104–104.5°.

Anal. Calcd. for $C_{14}H_{20}O_3$: C, 71.16; H, 8.53. Found: C, 71.44; H, 8.29.

An oily product, probably a polymeric anhydride, was also formed. Both the crystalline anhydride and the oil, when boiled with aqueous alkali, regenerated the parent acid, m. p. and mixed m. p. 198.5–199.5°.

The crystalline *cis-syn-trans* anhydride was refluxed for twenty-four hours with 30 parts of acetic anhydride. The reagent was removed, the product treated with alkali and the acid fractionally precipitated by careful addition of dilute hydrochloric acid. Only *cis-syn-trans* acid was isolated. The absence of *cis-syn-cis* and *trans-syn-trans* acid was confirmed by the fact that neither of these could be obtained by seeding the mother liquor with authentic samples. (Experiments by Mr. Selby Davis; analysis by Miss E. Werble.)

Marvel and White[6] had described an anhydride, m. p. 104°, made from their acid of m. p. 174°. This was undoubtedly identical with our anhydride, although we were unable to make a direct comparison as a sample provided by Dr. Marvel had already largely hydrated back to the acid.

223° Acid (*trans-syn-trans*)

(1) **Double inversion and hydrolysis of *cis-syn-cis* ester.**—*cis-syn-cis*-Dimethyl perhydrodiphenate, m. p. 73–74°, (1 g.) was refluxed for fifty hours with a solution of 7 g. of potassium hydroxide in 20 cc. of commercial methanol. The product was diluted, freed from neutral material with ether, acidified and again extracted with ether. The second extract was freed from solvent and the sticky residue dissolved in benzene. On standing, the solution deposited three successive crops (0.43 g., 48%) of almost pure *trans-syn-trans*-perhydrodiphenic acid, m. p. 221–223° (Linstead and Walpole,[2] give 220°).

Derivatives.—Esterification of this acid with an excess of diazomethane in the usual way gave, in practically quantitative yield, the **dimethyl ester.** This crystallized from light petroleum in small opaque rosets, m. p. 56–57.5°. For analysis the material was dried *in vacuo* at 25°.

Anal. Calcd. for $C_{16}H_{26}O_4$: C, 68.05; H, 9.28. Found: C, 68.28, 68.36; H, 9.26, 9.35.

Acid hydrolysis of this ester (300 mg.) was carried out in the usual way (2 cc. acetic acid, 1 cc. hydrochloric acid, nineteen hours of refluxing). The product was evaporated to dryness and the residue dissolved in aqueous sodium carbonate. The solution was boiled with charcoal, filtered and fractionally acidified at the boiling point by the method already described. The first product to separate was an oil from which no crystalline material was isolated. Further acidification yielded 3 crops of crystalline *trans-syn-trans* acid, a total of 190 mg. (70%) melting above 216°. One recrystallization of this gave the pure acid, m. p. and mixed m. p. 220–222°.

The anhydride, prepared by means of acetic anhydride, crystallized from ligroin (b. p. 70–90°) in flat rhombic prisms, m. p. 105–106.5°, in agreement with Linstead and Walpole.[2] The anhydride (250 mg.) was refluxed for nineteen hours with 5 cc. of pure methanol, moisture being excluded. The product was evaporated to dryness, the residual oil taken up in ligroin and the solution filtered through a layer of charcoal. Removal of the solvent left an oil, which was dissolved in 4 cc. of petroleum ether (b. p. 20–40°) and the solution allowed to crystallize at 4°. Two types of crystals were obtained, which were separated by hand. The rarer type (20 mg., 7%) melted at 105–107° and was identified as unchanged anhydride. The common type (200 mg., 70%) melted at 109–114° and after three crystallizations from ligroin, formed hard prisms, m. p. 115.5–117.5°, of the pure **monomethyl ester** of the *trans-syn-trans* acid. For analysis it was dried at 80° *in vacuo*.

Anal. Calcd. for $C_{15}H_{24}O_4$: C, 67.14; H, 9.02. Found: C, 67.26, 67.17; H, 9.04, 9.14.

Acid hydrolysis of this material (10 mg.) gave in 84% yield the parent acid, m. p. and mixed m. p. 221–223°. The same result was obtained by alkaline hydrolysis but the reaction was more difficult and the purity low.

Esterification of the acid ester (13.4 mg.) with diazomethane yielded the dimethyl ester (11.6 mg., 82%). This crystallized from petroleum ether at −70° in white rosets, m. p. and mixed m. p. 55.5–57°.

(2) **Inversion without Hydrolysis of *cis-syn-cis* Ester.**—*cis-syn-cis*-Perhydrodiphenic dimethyl ester (m. p. 74°, 1 g.) was refluxed for one hour with a solution of 0.1 g. of sodium in 4 cc. of dry methanol. The product was diluted and extracted twice with ether. The united extracts were washed with water, dried and evaporated to dryness. The oily residue was dissolved in 8 cc. of petroleum ether and the solution allowed to crystallize at −70°. The first two crops weighed 480 mg. (m. p. 51–56°) and 110 mg. (m. p. 47–51°), respectively. Recrystallization yielded 400 mg. of pure *trans-syn-trans* dimethyl ester, m. p. and mixed m. p. 56–57.5°. The mother liquor from the second crop was cooled to −70° and seeded with the dimethyl ester (m. p. 14°) of the *cis-syn-trans* acid. The solution then deposited 70 mg. of this ester, separating in the characteristic clumps, m. p. 8–11°.

(3) **Half-inversion and Hydrolysis of *cis-syn-trans* Half-ester.**—A solution of 10.6 mg. of *cis-syn-trans*-monomethyl ester (m. p. 102°) and 400 mg. of potassium hydroxide in 2 cc. of methanol was refluxed in soft glass for four days. The product was acidified, filtered from inorganic matter and the solvent removed. The residue was dissolved in ether and the solution washed with water. Removal of the ether left a crystalline solid which was crystallized from dilute acetic acid (charcoal). After the separation of a little oil, the solution deposited 3.6 mg. (36%) of *trans-syn-trans* acid crystallizing in prismatic needles, m. p. and mixed m. p. 220–223°.

anti Series—198° Acid (*cis-anti-cis*)

By-products in the Hydrogenation of Diphenic Acid.—(a) Diphenic acid (5 g.) was catalytically hydrogenated in absolute alcohol (200 cc.) at 60 lb. pressure. In all, 7.6 g. of Adams catalyst, added in 7 portions, was required. The precipitated acid was dissolved by heating and the catalyst was then filtered off. The first four crops which separated on concentrating the solution were the *cis-syn-cis* acid, m. p. 289° (see later), and no further crystalline material separated. The mother liquor on concentration gave a glass, which was dissolved in aqueous sodium carbonate and treated with charcoal. The filtrate was treated at the boiling point with 10% hydrochloric acid in drops until a faint permanent cloudiness could be seen. It was then left for fourteen days and the fifth crop of crystals was removed. The process of "fractional acidification" was then continued and five further crops were obtained. It was necessary to allow the solution to stand for several days after each acidification. The amounts, melting points and main components of the various fractions are summarized.

Crop	Wt., mg.	M. p., °C.	Main components
1	500	282–286	*c.s.c.* perhydro
2	850	274–284	*c.s.c.* perhydro
3	450	258–278	*c.s.c.* perhydro
4	400	250–270	*c.s.c.* perhydro
5	320	200–240	*c.s.c.* and *c.a.c.* perhydro
6	160	180–185	*c.a.c.* perhydro
7	240	90–130	*c.a.c.* and *c.s.t.* perhydro
8	600	165–205	*c.s.t.* perhydro and *cis*-hexahydro
9	320	185–222	Diphenic acid
10	520	188–210	Diphenic acid

The total recovery of acid was 4.36 g. or 87%, by weight. Fraction 5 was separated by benzene into a soluble and insoluble portion. The insoluble portion (100 mg.), together with fractions 1–4, on crystallization from acetic acid yielded 1.35 g. of pure *cis-syn-cis*-perhydro acid, m. p. 287–289° (26%). The benzene-soluble portion of fraction 5, together with fraction 6 and a small sample, obtained from fraction 7 by crystallization, were fractionally crystallized from dilute acetic acid. Eventually there was isolated a new perhydrodiphenic acid of m. p. 196–198° (120 mg., 2.3%). The mode of crystallization was characteristic. On rapid separation from dilute acetic acid the acid came out in fine feathery needles. After three weeks of standing in contact with the mother liquor these changed into a stable dimorphic form, which was also obtained by slow crystallization. The stable variety formed small clear prismatic parallelepipeds, m. p. 197–198.5°. A mixture with the *cis-syn-trans* acid m. p. 200°, melted at 162–182°. The analytical sample was dried at 110° *in vacuo*.

Anal. Calcd. for $C_{14}H_{22}O_4$: C, 66.13; H, 8.72. Found: C, 66.21, 66.36; H, 8.74, 9.03.

The derivatives of this acid and another method of preparation are described later.

Fractional crystallizations of the remainder of fraction 7 and of fraction 8, yielded 110 mg. (2.1%) of *cis-syn-trans*-perhydrodiphenic acid, m. p. 197–199°, which was identified by a mixed melting point determination.

Fraction 8 gave as its main component 400 mg. (7.8%) of an acid, m. p. 241–242° (bath initially at 235°). Analysis showed that this was a **hexahydrodiphenic acid.** It was identical with material prepared by Mr. Selby Davis and described more fully in a later paper (Part IV), and is

presumably identical with Vocke's hexahydro acid of the same m. p.[5] The analytical sample was crystallized from acetic acid and dried *in vacuo* at 110°.

Anal. Calcd. for $C_{14}H_{16}O_4$: C, 67.72; H, 6.50. Found: C, 67.43, 67.68; H, 6.63, 6.65.

Fractions 9 and 10 yielded mainly impure starting material, melting at 222–227° alone and at 223–230° in admixture with diphenic acid (m. p. 232–233°). Even after a tedious series of crystallizations we were unable to separate the impurity which was obviously contaminating this.

Anal. Calcd. for $C_{14}H_{10}O_4$: C, 69.42; H, 4.16. Found: C, 69.24; H, 4.50.

(b) For preparative purposes the new (198°) acid was more easily obtained from the by-product of the catalytic hydrogenation of diphenic acid in acetic acid. Thus, 20 g. of diphenic acid was hydrogenated in the manner described under the *cis-syn-cis* acid; this substance (12 g.) was filtered off and the mother liquor was evaporated *in vacuo*. The colorless glass so obtained was dissolved in 15 cc. of acetic acid, and the sirup was allowed to crystallize. The first crop separated spontaneously, weighed 420 mg. and was essentially the perhydro acid of m. p. 289°. The mother liquor was then seeded twice with the 200° acid (*cis-syn-trans*) and two crops mainly composed of this acid were removed. These weighed 800 and 230 mg., and melted at 200–218° and 187–199°, respectively. The mother liquor was concentrated to 10 cc., seeded with the desired 198° acid (*cis-anti-cis*) and allowed to stand. A hard crust (3.25 g.) separated. An arduous series of fractional crystallizations from acetic acid yielded the acid in a state of moderate purity (prisms, m. p. about 190°), but it was found that final purification was best effected through the anhydride. In a typical experiment, 150 mg. of acid of m. p. 187–192° was refluxed with 2 cc. of acetic anhydride for thirty minutes. The excess of reagent was blown off in a stream of dry air and the residue crystallized from 2 cc. of ligroin (b. p. 60–90°), which yielded 57.3 mg. of the *cis-anti-cis* anhydride, m. p. 94.5–96°. Boiling 10% aqueous alkali regenerated the acid from this, m. p. 195–197°. In this manner a total quantity of 1.01 g. of the acid was prepared (4.8%).

Derivatives.—The pure acid, m. p. 198° (200.6 mg.), was refluxed for four hours with 3 cc. of acetic anhydride and the anhydride isolated and purified as described above, yield 156.1 mg., 83%. The **anhydride** is dimorphous; it separates in light needles, m. p. 95–96° and in prismatic needles, m. p. 99–100°. The melt of the lower melting form solidifies and the solid then remelts at 99–100°.

Anal. Calcd. for $C_{14}H_{20}O_3$: C, 71.16; H, 8.52. Found: C, 71.19; H, 8.77.

When boiled with methanol for forty-eight hours, the anhydride yielded the **monomethyl ester** in 87% yield. This first crystallized when its solution in petroleum ether was scratched and subsequently separated in heavy prisms, m. p. 97.5–99°. The analytical sample was dried *in vacuo* at 56°.

Anal. Calcd. for $C_{15}H_{24}O_4$: C, 67.14; H, 9.02. Found: C, 66.89; H, 9.09.

When the 198° acid (200 mg.) was esterified in the usual manner with diazomethane it gave an oil which soon crystallized. The pure **dimethyl ester** (94% yield) separated from dilute alcohol in prismatic plates, m. p. 43–44.5°. The same dimethyl ester was obtained by treating the monomethyl ester with diazomethane (m. p. and mixed m. p. 42–44°).

Anal. Calcd. for $C_{16}H_{26}O_4$: C, 68.05; H, 9.28. Found: C, 68.13; H, 9.30.

Hydrolysis both of the monomethyl ester, m. p. 98° and of the dimethyl ester, m. p. 44°, with hydrochloric and acetic acids, in the manner already described for isomeric compounds, yielded the parent *cis-anti-cis* acid, m. p. and mixed m. p. 196–198°.

206° Acid (*cis-anti-trans*)

This was prepared by a similar method to that used for the *cis-trans* acid of the *syn*-series, namely, by the half-inversion and hydrolysis of the acid-ester of the *cis-cis*-acid. 25.0 mg. of the monomethyl ester of *cis-anti-cis* perhydrodiphenate (m. p. 99°) was refluxed for 150 hours with 500 mg. of potassium hydroxide dissolved in 2.5 cc. of methanol. The product was acidified and evaporated to dryness. The residue was diluted with water and extracted with ether. Removal of the ether left a solid which was crystallized from dilute acetic acid, yield 14.2 mg., 60%, irregular prisms, m. p. 200–204°. Two recrystallizations from acetic acid gave 7.3 mg. of prisms, m. p. 205.5–206.5°. The *cis-anti-trans* **acid** was also obtained in the form of needles. For analysis it was dried *in vacuo* at 110°.

Anal. Calcd. for $C_{14}H_{22}O_4$: C, 66.13; H, 8.72. Found: C, 66.28, 66.26; H, 8.87, 8.94.

The **anhydride** was prepared in the usual way, by refluxing the acid (80 mg.) for two and one-half hours with 2 cc. of acetic anhydride. It separated from ligroin in heavy prisms, m. p. 91.5–93° (yield, 53.7 mg.). A mixture with the *cis-anti-cis* anhydride (m. p. 99–100°) melted between 70 and 87°. For analysis it was dried *in vacuo* at 56°.

Anal. Calcd. for $C_{14}H_{20}O_3$: C, 71.16; H, 8.52. Found: C, 71.16; H, 8.53.

The anhydride dissolved slowly in boiling 10% aqueous sodium hydroxide. Acidification of the solution regenerated the *cis-anti-trans* acid, m. p. and mixed m. p. 205.5–206.5°.

Acid, m. p. 247° (*trans-anti-trans*)

The racemic form of this acid has been described by Linstead and Walpole[2] and by Vocke.[5] It had been prepared by alkaline hydrolysis of a perhydro-ester obtained by hydrogenation of diphenic ester over Raney nickel, and also by the oxidation of a 9-keto-perhydrophenanthrene.[2] It has now been observed that the pure acid melts at 246–248° after a preliminary sintering at 237°. The following preparative method involves a double inversion and hydrolysis.

Dimethyl *cis-anti-cis*-perhydrodiphenate (50 mg., m. p. 42–44°) was refluxed for four days with a solution of 400 mg. of potassium hydroxide in 2 cc. of commercial methanol. The product was partly neutralized and evaporated to dryness. The solid was then shaken with dilute hydrochloric acid and ether. The ether layer was separated, washed, dried and evaporated to dryness. The residue was crystallized from dilute acetic acid. The first crop

was a partially inverted acid (24.6 mg., m. p. 192–234°). The mother liquor yielded 11.3 mg. of beautiful prismatic needles. This acid melted at 237–240° alone and in admixture with the authentic *trans-anti-trans* acid softened at 237° and finally melted at 246–248°.

The *dimethyl ester* of the *trans-anti-trans* acid was prepared by means of diazomethane in the usual way in 89% yield. It formed prisms, m. p. 84.5–86°.

Anal. Calcd. for $C_{16}H_{26}O_4$: C, 68.05; H, 9.28. Found: C, 67.85; H, 9.19.

Summary

All the six optically inactive forms of perhydrodiphenic acid, which are theoretically possible, have been prepared.

One of these, m. p. 289°, is the main product of the catalytic hydrogenation of diphenic acid over platinum, and its derivatives are similarly formed from the corresponding derivatives of diphenic acid. The monomethyl ester of the 289° acid is capable of half-inversion to an isomeric acid of m. p. 200°, or its derivatives. The dimethyl ester of the 289° acid is capable of double inversion to an isomeric acid of m. p. 223°, or its derivatives. The acid of m. p. 200° has two monomethyl esters. One of these can be inverted and hydrolyzed to the 223° acid. These three acids form the *syn*-stereoisomeric series. The 200° acid is intermediate in configuration between the 289 and 223° acids.

The catalytic hydrogenation of diphenic acid gives as by-products the 200° acid and a fourth isomer of m. p. 198°. The 198° acid can be converted by half-inversion into the fifth isomer of m. p. 206°, and by double inversion into the sixth isomer of m. p. 247°. The 198, 206 and 247° acids thus represent the second (*anti-*) stereoisomeric series, the 206° acid being intermediate in configuration between the other two.

The formation of esters by diazomethane or by the Fischer–Speier procedure, the formation of anhydrides and the acid hydrolysis of esters proceed normally. The hydrolysis of esters with alcoholic alkali proceeds with inversion.

The results are correlated with previous investigations in the field. It is shown that the tricyclic ketones of Marvel cannot belong to the hydrophenanthrene series.

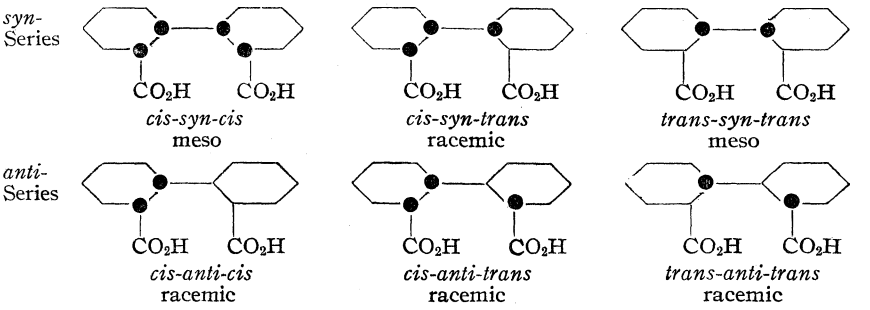
The Stereochemistry of Catalytic Hydrogenation. III. Optically Active Perhydrodiphenic Acids. A Proof of the Configuration of the Backbone

BY R. P. LINSTEAD AND W. E. DOERING

It has been shown in the preceding paper that the six perhydrodiphenic acids can be divided into two series of three members each. It has been found possible to interconvert the members within each series but not (as yet) to pass from one group to the other. These two series have the two possible backbone configurations, *syn-* and *anti-*. In order to assign the correct configuration to each of the six isomers, three questions must be answered: (1) Which series is *syn-* and which *anti-?* (2) In each series which member is the intermediate with the unlike (*cis-trans*) arrangement of the carboxyl groups? (3) In the terminal or symmetrical members of each series, which has the two *cis-* arrangements and which the two *trans-?* The first two of these questions are answered below. The third question is answered in Part V.

(1) **Backbone Configuration.**—As was pointed out by Linstead and Walpole,[1] of the six isomeric acids, four are capable of existence in optically active forms and two are internally compensated. This is shown below



The two symmetrical molecules are both in the *syn*-series. Two propositions therefore follow;

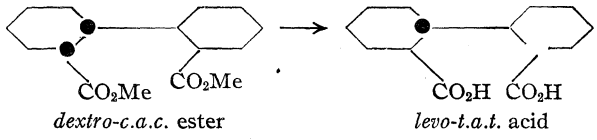
(1) Linstead and Walpole, *J. Chem. Soc.*, 850 (1939).

(1) That series which can be shown to contain *more than one* member capable of existing in optically active forms must have the *anti*-configuration of the backbone. (2) That series in which one (or more) member can be proved to have a meso configuration must be the *syn*-.

By both these tests it is proved below that the 289–200–223° acid series is *syn*-, and the 198–206–247° acid series is *anti*-.

The 247° (*trans-anti-trans*) acid was the first perhydrodiphenic acid to be resolved. The experimental work was carried out in 1939 by Dr. F. H. Slinger of the University of Sheffield, England. The resolution was effected by means of ephedrine. The *d*-acid[2] melted at 258° and had $[\alpha]_D$ +77.5°.

The 198° acid was resolved by means of cinchonidine into its enantiomorphs, which melted at 240° and had $[\alpha]_D$ ±44°. The *d*-enantiomorph was converted into the dimethyl ester by means of diazomethane. The ester had m. p. 27°, $[\alpha]_D$ +69°. When it was hydrolyzed by alcoholic potash it underwent a double inversion without racemization:



dextro-c.a.c. ester — *levo-t.a.t.* acid

The product was a levorotatory acid, m. p. 258°, $[\alpha]_D$ −79°. This was shown to be the enantiomorph corresponding to the *d*-acid obtained by the direct resolution of the 247° acid. A mixture of the two yielded the racemic *trans-anti-trans* acid, m. p. 247°.

This provides a refined confirmation of the corresponding experiment with the inactive materials, described in the previous paper.[3] The absence of racemization proves conclusively that the backbone carbon atoms are not involved in the reaction.

Attempts to resolve both the 289° and the 223° acids were fruitless. However, this does not prove the symmetry of their molecules, and to do this conclusively we made use of the principle used by Stoermer and Steinbeck[4] to prove the symmetry of the molecule of *cis*-hexahydrophthalic acid. According to this, an element of dissymmetry is first introduced by modifying one of the carboxyl groups, the compound is then resolved and the modifying group is removed by some mild reaction. If the resulting compound is inactive, then its molecule must be symmetrical.

The 289° acid was accordingly converted into its monomethyl ester. This was resolved by means of cinchonidine into two enantiomorphs of m. p. 134° and $[\alpha]_D$ ±10°. When the *l*-acid ester was hydrolyzed by acetic and hydrochloric acids it yielded the *inactive* parent acid, m. p. 289°. Even stronger evidence was provided by the fact that the *l*-acid ester on treatment with diazomethane yielded the *inactive* dimethyl ester, m. p. 73°, of the same acid. It will be recalled that the active form of the *cis-anti-cis* (198°) acid yielded the active ester on treatment with diazomethane. There is therefore nothing in the experimental conditions to cause racemization providing the molecule of the acid is unsymmetrical. These results prove that the 289° acid has a symmetrical structure. Hence the series to which it belongs has a *syn*-arrangement of the backbone.

We have also attempted to deduce the configuration of the backbone from a study of the formation of pyroketones from the acids. This work, which is still incomplete, will be the subject of a future communication.

(2) **Intermediate** (*cis-trans*) **Acids.**—In the preceding paper[3] it was shown by inversion experiments that the 200° acid was intermediate in configuration between the 289 and 223° acids. If this is so, it must be the *cis-syn-trans* acid, and be the only member of the *syn*-series capable of exhibiting optical activity. The following experiments confirm this view. The *l*-monomethyl ester of the 289° acid was inverted and hydrolyzed by treatment with sodium methoxide followed by the addition of a little water. This yielded a dextrorotatory acid, m. p. 173°, $[\alpha]_D$ +75°. A similar series of reactions performed with the *d*-monomethyl ester of the 289° acid gave the *levo*-enantiomorph, m. p. 173°, $[\alpha]_D$ −75°. A mixture of these acids gave the racemic acid of m. p. 200°, identical with that described in the preceding paper. This acid is thus conclusively proved to be *cis-syn-trans*-perhydrodiphenic acid. The existence of two acid esters[3] is in harmony with this conclusion.

We have not as yet had sufficient material to perform a similar partial asymmetric synthesis in the *anti*-series. As, however, the 206° acid has

(2) The prefixes *d*- and *l*- in this paper refer solely to the observed rotations and do not imply any relationships in configuration.

(3) Linstead and Doering, THIS JOURNAL, **64**, 1991 (1942).

(4) Stoermer and Steinbeck, *Ber.*, **65**, 413 (1932).

been shown to stand in precisely the same relation to the other *anti* acids as does the 200° acid in the *syn*-series, there can be no doubt that it has the *cis-anti-trans* configuration.

J. C. Speakman[5] has recently determined the first and second dissociation constants of two of the perhydrodiphenic acids (m. p.'s 222 and 247°), and has explored the possibility of estimating the inter-carboxyl distances from their ΔpK values, by the Bjerrum–Ingold method. This method has sometimes given significant results for cyclic dicarboxylic acids—a recent example is provided by Speakman's measurement of the *cis*- and *trans*-forms of tetralin 2,3-dicarboxylic acid.[5] However, each perhydrodiphenic acid has so many configurational possibilities that no safe deduction can be made from the results. It is nevertheless interesting that the 247° acid has a ΔpK of 1.1 and therefore behaves very like adipic acid, whereas the 222° acid has the high ΔpK of 1.7, which, from the usual calculation, would indicate that the mean intercarboxyl distance is unusually small.

The properties of the various forms of the acids are summarized in Table I.

TABLE I

OPTICALLY ISOMERIC PERHYDRODIPHENIC ACIDS

Configuration	dextro Form	levo Form	Inactive form, m. p., °C.
cis-syn-cis	Not possible		288–289 (meso)
cis-syn-trans	m. p. 170–174°, [α] +75°	m. p. 171–174°, [α] −75°	199–200 (rac.)
trans-syn-trans	Not possible		222–223 (meso)
cis-anti-cis	m. p. 238–240°, [α] +43°	m. p. 238–240°, [α] −45°	198–199 (rac.)
cis-anti-trans	Not yet prepared		206–207 (rac.)
trans-anti-trans	m. p. 257–259°, [α] +77.5°	m. p. 257–258.5°, [α] −79°	246–247 (rac.)

Experimental Part[6]

syn-Series

cis-syn-cis **Acid (289°).**—The cinchonidine, brucine, quinine, ephedrine and ψ-ephedrine salts were also crystalline but no resolution was observed. (Experiments by Dr. F. H. Slinger.)

The monomethyl ester,[7] m. p. 130° (3.80 g.), and 4.17 g. of cinchonidine were dissolved in 160 cc. of methanol and the solution diluted with 100 cc. of distilled water at the boiling point. On cooling the solution deposited long fine needles, which were filtered and washed with 50 cc. of 60% aqueous methanol. The dry salt weighed 3.55 g. (45% of the theoretical yield from both enantiomorphs) and melted at 186–188°. The acid ester was regenerated from it by means of 5% hydrochloric acid and crystallized from ligroin (b. p. 70–90°). The heavy prismatic needles so obtained weighed 1.35 g. (36%) and had m. p. 134° and $[\alpha]^{27}D$ −9.1°. This *levo* **acid ester** after one more crystallization from ligroin had m. p. 133.5–134.5°, $[\alpha]^{27}D$ −10.7 ± 0.3° (1% solution in alcohol containing 5% water). Subsequent recrystallization failed to change the specific rotation.

The aqueous alcoholic mother liquor from the original precipitate, containing 190 cc. of methanol and 120 cc. of water, was diluted at the b. p. with 70 cc. of water. The solution then deposited 2.64 g. (33%) of heavy needles, m. p. 172–174°. From this there was regenerated 1.34 g. of *d*-acid ester, m. p. 134°. The alcoholic mother liquor when boiled free from alcohol yielded a further 230 mg. of the *d*-acid ester and 270 mg. of the original racemate. The total *dextro* **acid ester** was crystallized to constant rotation from ligroin. It had m. p. 133.5–134.5°, $[\alpha]^{27}D$ +10.3 ± 0.3° (1% solution in 95% alcohol). The *d*-acid ester was dried at 80° *in vacuo* and analyzed.

Anal. Calcd. for $C_{15}H_{24}O_4$: C, 67.14; H, 9.02. Found: C, 67.27, 67.21; H, 9.09, 9.03.

Esterification of the *levo*-monomethyl ester (160 mg.) with diazomethane in the usual manner gave 102 mg. of long prismatic needles of the meso dimethyl ester, m. p. and mixed m. p. 73–74°. A solution in alcohol showed no activity.

The *levo*-monomethyl ester (450 mg.) was boiled with 3 cc. of concentrated hydrochloric acid and 10 cc. of glacial acetic acid for twenty hours. The acid product was isolated by dilution and freed from starting material (160 mg.) by extraction with hot ligroin. The insoluble residue (220 mg.) on crystallization from 15 cc. of 95% alcohol yielded 170 mg. of inactive *cis-syn-cis* acid, m. p. 286–288.5°. The m. p. was not depressed by admixture with the authentic inactive acid and the solution showed no optical activity.

cis-syn-trans **Acid (200°).**—The *l*-acid ester of the *cis-syn-cis* acid (1.11 g., m. p. 134°, $[\alpha]^{27}D$ −10.5°) was refluxed with sodium methoxide from 2 g. of sodium and 20 cc. of absolute methanol. After forty-eight, seventy-two and ninety-six hours 1 cc. of water was added. After five days the solvent was evaporated, and the residue acidified and extracted with ether. Evaporation of the ether left an oil which solidified when boiled with 40 cc. of ligroin. Recrystallization of the powder (980 mg.) from acetic acid failed to remove a small amount of the *cis-syn-cis* acid which was present. The impure acid was accordingly extracted with several small quantities of boiling benzene. This removed the *cis-syn-trans* acid and left the *cis-syn-cis*. After several further crystallizations from dilute acetic acid and from alcohol the pure *dextro-cis-syn-trans* **acid** crystallized in needles, m. p. 170–174°, $[\alpha]^{29}D$ +75° (1% in alcohol).

A similar inversion and hydrolysis was carried out on the *dextro*-acid ester of the *cis-syn-cis* acid (780 mg.). The crude acid product weighed 760 mg. Extraction with hot benzene removed 530 mg. of *levo-cis-syn-trans* **acid** which was crystallized to constant rotation, m. p. 171–174°, $[\alpha]^{28}D$ −75° (1% in 95% alcohol).

trans-syn-trans **Acid (223°).**—The cinchonidine, quinine, ephedrine, ψ-ephedrine and strychnine salts could not be obtained crystalline. The brucine salt crystallized well from alcohol but showed no sign of resolution (experiment by Dr. Slinger).

(5) J. C. Speakman, *J. Chem. Soc.*, 490 (1941).

(6) All melting points are corrected.

(7) Linstead and Doering, THIS JOURNAL, **64**, 1991 (1942).

The half methyl ester of this acid should be capable of resolution but we have been unable as yet to find a suitable salt. The cinchonidine, cinchonine, ephedrine, brucine, quinine and strychnine salts could not be obtained crystalline (experiments by Miss E. J. Cook, Radcliffe College).

anti-Series

cis-anti-cis **Acid (198°).**—To a solution of 454.1 mg. of the acid and 1.051 g. of cinchonidine in 10 cc. of methanol there was added at the boiling point, 2.5 cc. of water. The solution deposited 1.03 g. of light needles, m. p. 194–200°, on cooling (A). The mother liquor was evaporated to dryness, the residue treated with acid and extracted with ether. The residue from the ether was crystallized from acetic acid. This yielded 100 mg. of the *dextro*-**acid** in heavy prisms, m. p. 235–239°. Recrystallization to constant rotation yielded material with m. p. 238.5–240.5°, $[\alpha]^{27}D$ +43 ± 1° (1% in 95% alcohol).

The salt (A) was recrystallized from 15 cc. of methanol and 2 cc. of water. This yielded 670 mg. of well-formed needles, m. p. 204.5–205.5°. Regeneration of the acid in the usual way gave the *levo*-**acid** which after two crystallizations from acetic acid formed prisms, m. p. 239–241° (132.8 mg.). This material was submitted to a second treatment with cinchonidine but its properties were unaltered (m. p. 238.5–240.5°). The specific rotation $[\alpha]^{26}D$ of a 1% solution in 95% alcohol was −45 ± 1°.

The *dextro-cis-anti-cis* **acid** was esterified in the usual manner with diazomethane, yield 75.1 mg. from 84.5 mg. The *d*-dimethyl ester crystallizes from light petroleum at −70° in large prisms, m. p. 26–28°. $[\alpha]^{25}D$ +69 ± 1° (1% in 95% alcohol).

trans-anti-trans **Acid (247°).**—The above *d*-dimethyl ester (140 mg.) of the *cis-anti-cis* acid was refluxed for 112 hours with 0.5 g. of potassium hydroxide in 2 cc. of methanol. A little water was added from time to time. The acidic product was isolated by means of ether in the usual way. After two crystallizations from dilute acetic acid, the *levo-trans-anti-trans* **acid** was isolated with m. p. 257–258.5°, $[\alpha]^{26}D$ −79.5 ± 5° (1% in 95% alcohol).

Resolution of the 247° Acid (Experiments by Dr. Slinger).—The acid (3.0 g.) and ephedrine (1.98 g.) were dissolved in 60 cc. of alcohol, 90 cc. of water was added and the mixture heated to effect solution. Slow cooling precipitated needles of a salt from which 950 mg. of a crude dextrorotatory acid was regenerated. This material was submitted to a second resolution with ephedrine. The product melted at 257.5–259° and had $[\alpha]^{20}D$ +77.5° (1% in alcohol). A further resolution failed to alter the m. p. or specific rotation.

An equal mixture of the *d*- and *l*-acids (4 mg. of each) was dissolved in dilute acetic acid. The solution deposited needles, m. p. 237–239°, of the *dl-trans-anti-trans* acid. After resolidifying, these melted at 245–247° and did not depress a sample of authentic *dl*-acid, m. p. 245–247°.

Summary

The perhydrodiphenic acid of m. p. 289° gives an acid methyl ester which can be resolved into *d*- and *l*-forms. Conversion of these into the acid or the dimethyl ester gives inactive material. The acid therefore has a symmetrical molecule and must belong to the *syn*-series.

The perhydrodiphenic acid of m. p. 198° (*cis-anti-cis*) can be resolved by means of cinchonidine. The dimethyl ester of the active ester on hydrolysis and double inversion with alcoholic alkali gives the *levo*-enantiomorph of the *trans-anti-trans* acid (m. p. 247°). The latter acid has been resolved to give the other enantiomorph. As two acids in this series can be resolved, it must be the *anti*-series.

The three acids of m. p.'s 289, 200 and 223°, therefore, constitute the *syn*-series and the acids of m. p.'s 198, 206 and 247°, the *anti*-series.

The acids of m. p.'s 200 and 206° are proved to be *cis-syn-trans* and *cis-anti-trans*, respectively.

The Stereochemistry of Catalytic Hydrogenation. IV. Hexahydrodiphenic Acids

BY R. P. LINSTEAD AND SELBY B. DAVIS

Vocke[1] reported that the hydrogenation of diphenic ester over Raney nickel yielded a mixture of perhydro- and hexahydro-diphenic esters. From the hydrolysis product of this he isolated two hexahydrodiphenic acids of m. p. 242 and 220°. It was shown that the 242° acid could be converted into the 220° isomer, and the acids were assigned the structures of *cis*- and *trans*- modifications of the hexahydrodiphenic acid with one intact aromatic ring.

We have investigated the partial hydrogenation of diphenic acid in acetic acid solution over a platinum catalyst. If hydrogenation is stopped arbitrarily at the half-way stage, there is obtained a mixture consisting substantially of *cis-syn-cis*-perhydrodiphenic acid, m. p. 289°,[2] a hexahydrodiphenic acid and unchanged diphenic acid. The hexahydro acid melts at 242° and has other properties which show its identity with Vocke's acid of similar m. p. The presence of an

(1) Vocke, *Ann.*, **508**, 1 (1934).

(2) Linstead and Doering, THIS JOURNAL, **64**, 1991 (1942).

aromatic ring is shown by the absence of reactivity with potassium permanganate and by the formation of a mono-nitro derivative, m. p. 219°. The latter can be reduced to an amine which can be diazotized and coupled with β-naphthol.

The proportions of the three compounds in the hydrogenation product are approximately: *c.s.c.*-perhydro acid, 25%; hexahydro acid, 25%; unchanged diphenic acid, 40%. The indications are therefore that the half hydrogenated compound is hydrogenated rather more readily than the original diphenic acid. When the hexahydrodiphenic acid, m. p. 242°, is further hydrogenated over platinum it yields *cis-syn-cis*-perhydrodiphenic acid, m. p. 289°. The yield of the pure *cis-syn-cis* acid is 77% and no isomers have as yet been isolated. Both the first and the second stages of the hydrogenation of diphenic acid under these conditions thus follow a substantially homogeneous steric course.

It is shown in the next paper that the 242° acid has the *cis*-configuration.

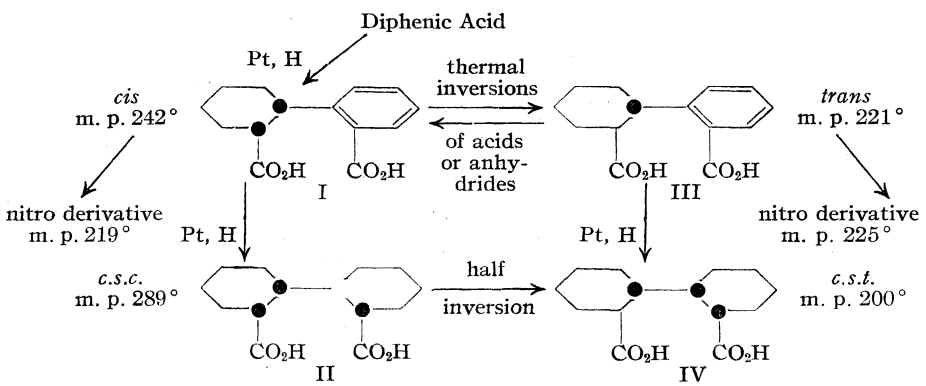
Treatment of the *cis*-hexahydro acid with acetic anhydride yielded a liquid anhydride from which the parent acid could be regenerated. If the *cis*-acid was kept at its melting point for an hour, it was converted into an isomeric acid which melts at 221°. The conversion is reversible with an equilibrium well on the side of the new acid. Catalytic hydrogenation of the new acid over platinum gave rise to *cis-syn-trans*-perhydrodiphenic acid (IV), m. p. 200°, identical with the material described in Part II.[2] The orientation of this perhydro acid has been completely proved.[3] The yield of the perhydro acid was at least 84% and a careful search failed to show the presence of any of the *cis-anti-trans*-isomer. A small amount of a decahydrodiphenic acid, m. p. 212°, was, however, isolated. It follows from these results that the new hexahydro acid, m. p. 221°, is the *trans*-isomer (III) of the 242° acid.

The presence of an intact aromatic ring in the *trans*-acid was shown by its nitration to a mono-nitro derivative, not identical with that obtained from the *cis*-isomer.

When the *cis*-hexahydro acid was inverted by heat and the crude *trans*-acid treated with acetic anhydride, there was formed the beautifully crystalline *trans*-anhydride, which on hydrolysis yielded the parent acid, m. p. 221°. There can be no doubt that our *trans*-acid is identical with Vocke's second hexahydro acid of m. p. 220° which he obtained by heating the 242° acid to about 300°.[1] He reported the anhydride as melting at 120°, whereas the m. p. of our material could not be raised above 116°. When the *trans*-anhydride was heated for some time, and the product hydrolyzed, a mixture of *cis*- and *trans*-hexahydro acids was obtained, which contained about 70% of the *trans*-isomer.

An important general result from this work is that in the further hydrogenation of our hexahydro acids over platinum at room temperature, the integrity of the configuration already established is preserved, and the further hydrogenation goes almost entirely *cis*- and *syn*-. This presents an instructive contrast to Vocke's observation on the perhydrogenation of the same acids over nickel at high temperatures. He observed the formation of two perhydro acids (*trans-anti-trans* and probably *trans-syn-trans*) from *each* of the hexahydro acids. Clearly, the use of nickel at high temperatures may lead to inversions of configuration.

The results are summarized in the scheme



Experimental[4]

cis-**Hexahydrodiphenic Acid.**—A solution of 10 g. of diphenic acid in 200 cc. of glacial acetic acid was hydrogenated in a Parr apparatus by means of 1 g. of Adams catalyst. After six and one-half hours, hydrogen equivalent to 3.0 moles had been taken up. The solution was then

(3) Linstead and Doering, THIS JOURNAL, **64**, 2003 (1942).

(4) All melting points corrected. Analyses by Miss Eleanor Werble.

filtered. Extraction of the catalyst and insoluble material with alkali and reprecipitation with hydrochloric acid yielded 1.24 g. of *cis-syn-cis*-perhydrodiphenic acid, m. p. 275–280°, identified by mixed m. p. The acetic acid filtrate was freed from solvent by vacuum evaporation and the solid residue dissolved in 100 cc. of 10% aqueous sodium carbonate. A second run on the same amount of material required eight and one-half hours for the absorption of 3.0 moles of hydrogen and yielded 1.48 g. of the *cis-syn-cis* acid, m. p. 278–286°. The filtrate was treated as above. The combined carbonate solution was then submitted to the process of fractional acidification with 10% hydrochloric acid which has been described in Part II.[2] The hydrochloric acid was added to the boiling solution to incipient cloudiness. No precipitate appeared on cooling. After this successive 10-cc. portions of 10% hydrochloric acid were added to the boiling solution, and the solution allowed to stand for twelve to twenty-four hours after each addition, with the following results:

Fraction	HCl added, cc.	Acid pptd., g.	M. p. (crude), °C.	Main component
1	10.0	2.08	204–262	*c.s.c.* perhydro
2	10.0	0.70	80–95	....
3	10.0	5.39	212–227	*cis*-hexahydro
4	10.0	3.30	199–214	Diphenic acid
5	10.0	3.98	211–216	Diphenic acid

The total amount of acid isolated at this stage, including the *cis-syn-cis* acid which separated from the solution originally, was 18.17 g. Evaporation of the final mother liquor gave no useful material.

Recrystallization of fraction 3 from acetic acid containing about 20% water at the boiling point, yielded 3.90 g. of practically pure *cis*-hexahydrodiphenic acid, m. p. 238–240°. Another crystallization gave the pure acid, m. p. 241–242° (bath preheated to 235°). The acid was identical with that obtained as a by-product in perhydrogenations (see Part II[2]). Fractions 4 and 5, after crystallization from acetic acid, yielded diphenic acid, m. p. and mixed m. p. 229–231°.

The subsequent preparations were done in a similar manner. In some cases the *cis*-hexahydro acid appeared in the second fraction. Completion of the precipitation of perhydro acid was marked by a drop in the *p*H of the solution from 8 to 5. In one run a very small amount of material identified as the *trans*-hexahydro acid was obtained after the diphenic acid had been precipitated. The average yield of crude material from 20 g. of diphenic acid was *cis-syn-cis*-perhydrodiphenic acid, 4.8 g.; *cis*-hexahydrodiphenic acid, 5.0 g.; recovered diphenic acid, 7.7 g.

***cis*-Anhydride.**—The *cis*-acid (400 mg.) was refluxed for five hours with 4 cc. of acetic anhydride. The anhydride failed to solidify on standing *in vacuo* at 3° or on attempted crystallization from hexane. The oily anhydride on boiling with dilute hydrochloric acid regenerated the *cis*-acid, m. p. and mixed m. p. 238–240°.

Mono-nitro Derivative.—The *cis*-acid (100 mg.) was stirred into a mixture of 1 cc. of concentrated sulfuric acid with 1 cc. of concentrated nitric acid. The solution was heated to 60°, allowed to stand for thirty minutes, and then poured into 10 cc. of ice and water to give 104 mg. of crude nitro compound, m. p. 184–190°. From 90 mg. there was obtained 56 mg. of irregular prisms, m. p. 201–202°, after two recrystallizations from acetone–benzene. Recrystallization from water, under such conditions that the substance separated as an oil and subsequently crystallized, gave identical material. By slow crystallization of a dilute aqueous solution the nitro compound is obtained in a stable higher melting form, needles, m. p. 218–219°. The mixed m. p. with the low-melting material was 218–219°.

Anal. Calcd. for $C_{14}H_{15}O_6N$: C, 57.34; H, 5.16. Found: C, 57.53; H, 5.02.

The high-melting form of the nitro derivative (5 mg.) was dissolved in 15 cc. of distilled water and shaken with hydrogen in the presence of 5 mg. of Adams catalyst. The theoretical amount of hydrogen for reduction to the amine was absorbed in fifteen minutes. Removal of the catalyst and solvent left the product as a clear, glassy film. On diazotization and coupling with alkaline β-naphthol in the usual manner, an immediate orange color was produced and a brown precipitate separated on standing.

Hydrogenation.—The *cis*-acid (2 g.) was hydrogenated in 200 cc. of acetic acid over 750 mg. of Adams catalyst. The theoretical quantity (3 moles) of hydrogen was taken up in thirty-five minutes and no further absorption was observed in another half hour. This is a remarkably quick hydrogenation of an aromatic ring. The reaction product was worked up in the usual manner. The precipitate yielded 1.32 g. (64%) of pure *cis-syn-cis*-perhydrodiphenic acid, m. p. 286–288°. Evaporation of the mother liquor yielded a solid residue, melting above 245°. Fractional crystallization of the latter yielded two successive crops of the *cis-syn-cis* acid and brought the total yield of this up to 77%. The small residue was not further examined.

***trans*-Hexahydrodiphenic Acid.**—The *cis*-acid (4 g.) was heated at 242 ± 3° for one hour. The residue set to a pale yellow glass. Crystallization from glacial acetic acid yielded 2.48 g. of nearly pure *trans*-acid, m. p. 215–218°. This substance was more easily purified through the anhydride. The *cis*-acid (1.5 g.) was heated as before and the residue was refluxed with 5 cc. of acetic anhydride for four hours. The reagent was removed and the sirup stirred with a few cc. of light petroleum in which it was practically insoluble. The solid *trans*-anhydride (1.2 g.) was so obtained. The yield corresponds with one of 87% of *trans*-acid in the thermal inversion. After three crystallizations from benzene the beautifully crystalline anhydride of the *trans*-acid was obtained, m. p. 115–116°. The m. p. could not be raised by further crystallization (compare Vocke[1]).

Anal. Calcd. for $C_{14}H_{14}O_3$: C, 73.02; H, 6.13. Found: C, 73.28; H, 6.19.

A small portion of the anhydride was converted into the corresponding acid by means of alkali. The *trans*-acid so obtained melted at 220–221.5° and failed to depress the m. p. (218–220°) of that isolated by crystallization. The mixed m. p. with the *cis*-isomer was 197–210°. This is a good method for the final purification of the *trans*-acid, for repeated crystallization of the acid, which had not been taken through the anhydride, failed to raise the m. p. above 220°.

Anal.[5] Calcd. for $C_{14}H_{16}O_4$: C, 67.72; H, 6.50. Found: C, 67.89; H, 6.65.

(5) Analysis by W. E. Doering.

Mono-nitro Derivative.—The *trans*-acid (96 mg.) was nitrated in the same manner as the *cis*- (*vide supra*) to obtain 116 mg. of the crude product, m. p. 212–217°. Two recrystallizations from acetone–benzene gave 65 mg. of irregular prisms, m. p. 218–219°. Further recrystallization from water, under such conditions that the substance separated as an oil and subsequently crystallized, gave material of similar appearance and m. p. Crystallization of 40 mg. from water, with slow cooling, gave 32 mg. of needles, m. p. 224–225°. The mixed m. p. with the low-melting material was 224–225°. The mixed m. p.'s of both forms with either form of the nitro derivative from the *cis*-acid showed depressions to about 185°.

Anal. Calcd. for $C_{14}H_{15}O_6N$: C, 57.34; H, 5.16. Found: C, 57.43; H, 5.12.

Hydrogenation.—The *trans*-acid (2 g.) in 200 cc. of acetic acid was hydrogenated over 550 mg. of Adams catalyst. The theoretical uptake of hydrogen (3 moles) occurred in one hundred minutes, after which there was no appreciable reaction. No precipitate separated. The catalyst was filtered and the solvent removed. The granular residue was crystallized from acetic acid, a seed of *cis-syn-trans*-perhydrodiphenic acid being introduced. The first crop, 1.60 g. (78%), melted at 190–194° alone, at 192–197° in admixture with *cis-syn-trans*-perhydrodiphenic acid (m. p. 198–200°) and at 192–196° after a further crystallization. As the m. p. of the *cis-syn-trans* acid is sensitive to traces of impurities, this material may be taken to be the nearly pure isomer. The mother liquor from this acid was submitted to an exhaustive fractional crystallization. It yielded three products: (a) more of the *cis-syn-trans* perhydro acid, bringing the total yield up to 84%; (b) about 10 mg. of an unsaturated acid, m. p. 210–211.5°, identical with material already isolated by Mr. Doering; (c) about 3 mg. of what was apparently another unsaturated acid. This formed soft needles of m. p. 261–264°, depressed the m. p. of the *cis-syn-cis* perhydro acid and readily reduced 0.5% potassium permanganate in aqueous sodium bicarbonate solution. (Under the same conditions the hexahydro- and perhydrodiphenic acids require from eight to twenty-four hours for a discharge of the color of one drop of 0.5% permanganate.) During this fractional crystallization, the solution was frequently seeded with *cis-anti-trans* perhydrodiphenic acid (m. p. 206°[2]), but none of this substance separated, and it can safely be concluded that it is either wholly or almost completely absent.

The pure *trans*-anhydride (150 mg.) was heated for one hour at 243 ± 3°. A little carbon dioxide was evolved, indicating the formation of some pyroketone. The acidic portion of the product was isolated by means of alkali and was crystallized from acetic acid. Seeding with the *cis*-hexahydro acid yielded three crops of this material (total, 20 mg.) and further seeding gave no more of it. The solution was accordingly seeded with the *trans*-hexahydro acid, which yielded five crops of *trans*-acid, totalling 45 mg. The acids were identified by m. p. and mixed m. p.

Summary

Half-hydrogenation of diphenic acid over platinum yields *cis*-hexahydrodiphenic acid. Thermal inversion of this acid yields the *trans*-isomer. Both the acids and their anhydrides yield mixtures rich in the *trans*-isomer when heated. The two acids yield distinct mono-nitro derivatives.

Further catalytic hydrogenation of the *cis*-hexahydro acid yields *cis-syn-cis*-perhydrodiphenic acid, and hydrogenation of the *trans*-hexahydro acid yields *cis-syn-trans*-perhydrodiphenic acid. The integrity of the configuration already established is therefore preserved, and further hydrogenation goes *cis*- and *syn*-.

The Stereochemistry of Catalytic Hydrogenation. V. The Assignment of *cis*- and *trans*-Configurations

BY R. P. LINSTEAD, SELBY B. DAVIS AND RICHARD R. WHETSTONE

The stereochemical problem connected with the perhydrodiphenic acids which is left unsolved in the preceding papers is the allocation of *cis*- and *trans*-configurations to the terminal acids.[1] It has been shown that the 289 and 223° acids between them constitute the *cis-syn-cis* and *trans-syn-trans* acids, and the 198 and 247° acids share the *cis-anti-cis* and *trans-anti-trans*-configurations. There are many indications that the 289° and the 198° acids are the *cis*-members of the two series. The work described in the present paper proves this to be true.

The 289° perhydro acid has two similar arrangements of the carboxyl groups with respect to the backbone. It is made by the hydrogenation of the hexahydro acid of m. p. 242° by a method not involving an inversion.[2] Hence the configuration of the 242° acid is repeated twice in the 289° acid.

We therefore examined the configuration of

(1) Linstead and Doering, THIS JOURNAL, **64**, 2003 (1942).

(2) Linstead and Davis, *ibid.*, **64**, 2006 (1942).

this hexahydro acid by oxidizing away the aromatic ring and leaving a cyclohexane derivative of known configuration. Treatment of the acid with a mixture of concentrated and fuming nitric acids gave only nitration in the aromatic ring and permanganate oxidation also yielded no useful products. Ozonization, however, gave the desired information.

The acid was treated in acetic acid solution with ozonized oxygen and subsequently with hydrogen peroxide. The acidic product was separated by means of the fractional acidification technique which has already been described.[3] This effected a simple separation of the starting material and another acid which after one crystallization melted at 185–188° and was nearly pure *cis*-hexahydrophthalic acid (I). It was identified by direct comparison of the free acid with authentic material and by conversion into the known *cis*-dianilide, m. p. 238°.[4b] The *cis*-configuration of the latter was confirmed by the fact that it readily yielded the phenylimide (II) when boiled with acetic acid. The dianilide of *trans*-hexahydrophthalic acid, which was separately made for comparison, melted at 317–318° and failed to yield a phenylimide under the same conditions.

The *cis*-configuration of this form of hexahydrophthalic acid is known with certainty.[4] In the present work *cis*-hexahydrophthalic acid was formed in a yield of 44% by a mild series of operations in which there is no possibility of an inversion. Moreover, it must be borne in mind that the *cis*- is the *unstable* configuration and that any inversion would tend to yield a *trans*-product.

This evidence conclusively proves that the acid of m. p. 242° is *cis*-hexahydrodiphenic acid (III). Hence the acid of m. p. 289° is *cis-syn-cis*-perhydrodiphenic acid (IV) and the double invert acid, m. p. 223°, has the *trans-syn-trans*-configuration. It follows that among the diphenic acids, catalytic hydrogenation over platinum yields *cis*-products which can be inverted by chemical means into the *trans*-isomers. The usual rule-of-thumb generalizations are therefore correct in this series.

It is shown in the following paper[5] that the 289° acid is related to a 9-ketoperhydrophenanthrene of m. p. 44° (V). This ketone is easily inverted by the action of heat or bases into an isomer of m. p. 57°, which yields *cis-syn-trans*-perhydrodiphenic acid on oxidation. There is a complete analogy with Hückel's related experiments with dicyclic compounds and the rearrangement of the ketone corresponds precisely with the conversion of *cis*-α-decalone to its *trans*-isomer.

The chemical inversions of the *syn*-keto-hydrophenanthrenes and of the *syn*-hydrodiphenic acids accordingly fall into line with those of related substances of simpler structure. We may therefore make the corresponding deductions in the *anti*-series with confidence, thus: (1) Among the *anti* compounds the perhydro acid of m. p. 198° is the direct hydrogenation product and yields the isomer of m. p. 247° by double inversion. Hence these substances are *cis-anti-cis* (VIII) and *trans-anti-trans* (IX), respectively.

(2) The 247° acid has been prepared[6] by the oxidation of a 9-keto-perhydrophenanthrene of m. p. 49° which was stable to heat and alkali.[7] Hence the ketone will have a *trans*-fusion of the rings next to the keto group. Hence the 247° acid contains at least one *trans*-carboxyl; but as it is a terminal acid, it must have two such arrangements and be the *trans-anti-trans*-isomer. The 49° ketone must have the same configuration (X) and this is supported by the physical properties of the related perhydrophenanthrene.[7]

We have obtained independent evidence supporting these configurations from the following experiments. The 49° ketone is made by the catalytic hydrogenation of an olefinic ketone, m. p. 89°, originally prepared by Rapson and Robinson.[8] (The method of preparation of the unsaturated ketone itself supports a *trans*-configuration for its one-ring fusion.) We find that ozonization of the unsaturated ketone gives a δ-keto acid, $C_{13}H_{20}O_3$, isolated as a crystalline oxime. This is assigned the formula XII. Its formation shows the correctness of the Δ^{10}-9-keto-dodecahydrophenanthrene structure (XI) assigned to the unsaturated ketone by Rapson and Robinson. On acetylation and subsequent pyrolysis by the general method of Thiele[9] the keto acid was converted into an unsaturated lactone. This was not obtained as a homogeneous substance but contained some of the isomer (XIII) with the double bond adjacent to the backbone.

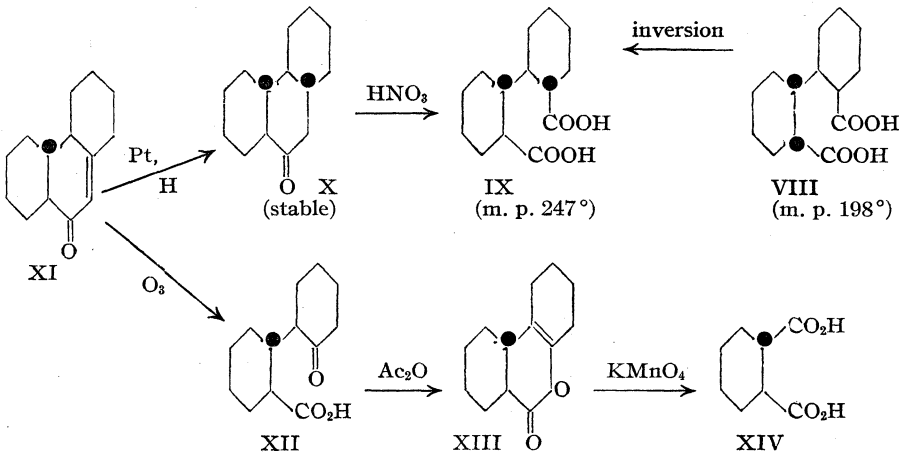
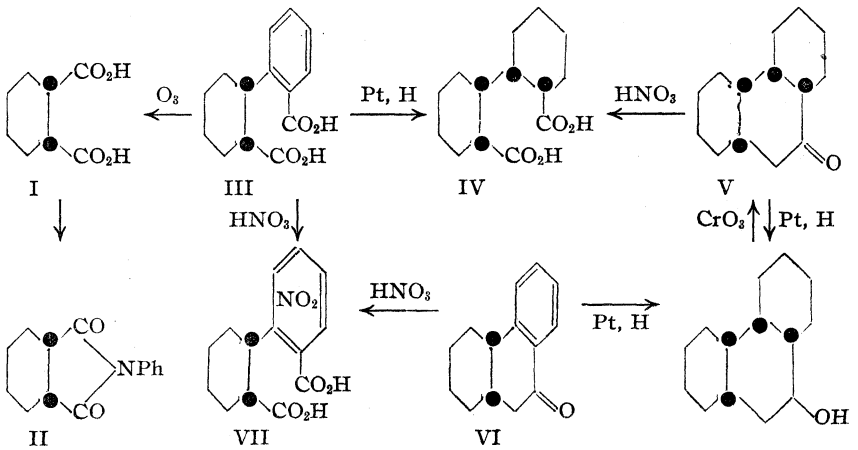
On oxidation with permanganate the lactone gave *trans*-hexahydrophthalic acid (XIV), in poor yield. Hence all the substances mentioned above have a *trans*-configuration. Some of the reactions used in this degradation were comparatively vigorous and the final product has the stable configuration. Hence, we do not regard this evidence as so unequivocal as that given above for the oxidation of *cis*-hexahydrodiphenic acid.

The most important configurational evidence in the *anti*-series is summarized in the following scheme



Finally, we have been able to establish two other stereochemical connections between the tricyclic compounds and the hydrodiphenic acids. It has already been pointed out that the 289 and 200° acids are related to the 44 and 57° perhydro ketones, respectively. In the next paper it is shown that the 44° ketone can be formed (through the corresponding perhydro alcohol) by the hydrogenation of a 9-keto-*as*-octahydrophenanthrene (VI). When the octahydro ketone was treated with nitric acid it yielded the mono-nitro derivative of *cis*-hexahydrodiphenic acid (VII). Hence it must have the *cis*-configuration. Its *trans*-isomer has been similarly oxidized and nitrated to the nitro- derivative of *trans*-hexahydrodiphenic acid. (A number of nitro-ketones are obtained as by-products in these oxidations. They are described in the experimental section.)

The stereochemical relationships between the tricyclic and dicyclic compounds are therefore firmly established by a number of independent links. The more important connections in the *syn*-series are indicated in the scheme



Experimental[10]

Ozonization of *cis*-Hexahydrodiphenic Acid.—The acid, m. p. 240–241°,[2] (1.00 g.) was dissolved in 20 cc. of warm glacial acetic acid and ozonized for four hours. The product was allowed to stand overnight with 50 cc. of 3% hydrogen peroxide and evaporated almost to dryness on the

(10) All melting points corrected. Analyses by Miss Eleanor Werble.

steam-bath in a current of air. The residue was then heated on the steam-bath for two hours with a further 25 cc. of 3% hydrogen peroxide and evaporated to dryness. The mainly crystalline residue was dissolved in 15 cc. of 10% aqueous sodium carbonate, a trace of insoluble material filtered off and the solution washed with ether. The alkaline solution was heated to boiling and concentrated hydrochloric acid added in drops to incipient crystallization. The subsequent fractional acidification by the method described in earlier papers[2,3] gave the following results

Fraction	Approx. vol. of concd. HCl, cc.	Weight, mg.	M. p., °C.	Identity
1	2.5	260	234–237	*cis*-Hexahydrodiphenic acid
2	0.5	240	237–239	
3	0.5	...	...	Trace of tar
4	0.5	9.1	174–181	*cis*-Hexahydrophthalic acid
5	1.0	82.2	177–184	
6	1.0	36.5	181–186	

A further 0.5 cc. of hydrochloric acid was added to the final mother liquor and the solution extracted with ether to give 0.11 g. of semi-crystalline residue.

Fractions 1 and 2 were identified as unchanged starting material by mixed m. p. Fractions 4, 5 and 6 in admixture with authentic *cis*-hexahydrophthalic acid (m. p. 191.5–192.5°) melted at about 185°. After one recrystallization from 80% acetic acid, nearly pure *cis*-hexahydrophthalic acid was obtained, m. p. 185–188°, mixed m. p. 186–189°. Recrystallization of the residue from the ether extract yielded 23 mg. of additional *cis*-hexahydrophthalic acid, m. p. 183–188°, mixed m. p. 185–189°.

The crystallized acid (53 mg.) was converted into the acid chloride by means of phosphorus pentachloride (130 mg.) in dry ether (3 cc.). After twenty minutes the solvent was removed and the residue evacuated at the water pump for half an hour. The residue was dissolved in 2 cc. of ether and treated with 120 mg. (2 mols) of aniline in 2 cc. of ether. The mixture was freed from solvent, the residue taken up in the minimum quantity of 95% alcohol (*ca.* 4 cc.), the solution filtered and allowed to cool. The dianilide of *cis*-hexahydrophthalic acid (43 mg.), so obtained, melted at 227–229° and after one crystallization from alcohol formed colorless needles, m. p. 237.5–238°.

Anal. Calcd. for $C_{20}H_{22}O_2N_2$: C, 74.50; H, 6.88. Found: C, 74.75; H, 6.70.

The dianilide was further identified by refluxing it for eighteen hours with 80% acetic acid which yielded the phenylimide (II), flat prisms from methanol, m. p. 131–132°. The m. p.'s of the dianilide and phenylimide prepared from authentic *cis*-hexahydrophthalic acid were the same and were not depressed by admixture with the above samples. For these substances Stoermer and Steinbeck[4b] give m. p.'s 234° (dianilide) and 132° (phenylimide).

Attempted oxidation of *cis*-hexahydrodiphenic acid with a mixture of fuming and concentrated nitric acids gave an acidic product, from which the only homogeneous substance which could be isolated was nitro-*cis*-hexahydrodiphenic acid, m. p. 219–220°. This was identical with the material described in Part IV.[2] Treatment of *cis*-hexahydrodiphenic acid with alkaline permanganate at 60–80°, left it largely unchanged and no useful products were isolated.

Oxidation of *trans*-Δ^{10}-9-Keto-dodecahydrophenanthrene (XI).—The unsaturated ketone was prepared from acetylcyclohexene by the method of Rapson and Robinson.[8] Preliminary experiments on the oxidation with nitric acid, permanganate, hypobromite and ozone indicated that the last-named reagent was the most suitable.

The ketone (8.9 g.) dissolved in 15 cc. of glacial acetic acid was treated with a current of ozonized oxygen for three hours. The product was refluxed for forty minutes with 45 cc. of water and 0.5 cc. of concentrated hydrochloric acid and then separated into neutral and acid fractions. The neutral fraction yielded 5.36 g. which was again ozonized and the product separated as before. The combined acid product from the two ozonizations was treated with 50 cc. of alcohol, 50 cc. of 10% aqueous sodium hydroxide and 4.6 g. of hydroxylamine hydrochloride. The mixture was refluxed for two hours, cooled, acidified with acetic acid and left overnight at 5°. An oxime separated, 3.07 g., m. p. 160–161°. Evaporation of the filtrate yielded material which separated as an oil and subsequently solidified in brown lumps, m. p. *ca.* 100–130°, 3.15 g. Crystallization of the first fraction from alcohol gave the pure oxime of ***trans*-2-keto-1,1'-dicyclohexyl-2'-carboxylic acid** (XII), m. p. 162–163°.

Anal. Calcd. for $C_{13}H_{21}O_3N$: C, 65.24; H, 8.85. Found: C, 65.64, 65.61; H, 8.92, 8.99.

When the oxime (3.07 g.) was refluxed with 10% hydrochloric acid (100 cc.) for two hours it regenerated the keto-acid as a pale yellow liquid which failed to solidify (yield: 2.45 g.). The keto-acid (1.31 g.) was refluxed for five hours with acetic anhydride (6 cc.), and the excess of reagent was then removed at about 65°, under reduced pressure. The residue was dissolved in ether, freed from acids by means of sodium bicarbonate solution, and isolated by removal of the ether, 1.12 g. of an orange oil being obtained. This lactone (partly XIII) was insoluble in aqueous sodium hydroxide in the cold but dissolved slowly on warming. Dissolved in acetone it decolorized alkaline permanganate. The equivalent was determined by warming the lactone for an hour with an excess of 0.1 *N* alkali and back-titration. *Anal.* Calcd. for $C_{13}H_{18}O_3$: equiv., 206.3. Found: equiv., 203.

The unsaturated lactone (1.1 g.) was suspended in a mixture of 100 cc. of acetone and 50 cc. of 5% sodium bicarbonate solution. To the solution, mechanically stirred at 0°, 100 cc. of 0.5% potassium permanganate solution was added during one-half hour, followed by 100 cc. of 1% permanganate solution during one hour and, finally, 60 cc. of 3% permanganate solution during one hour. Reduction of the permanganate was slow after the addition of the 1% solution. The mixture was finally allowed to come to room temperature and, after standing for two hours, was freed from manganese dioxide by filtration, and the filtrate and washings evaporated nearly to dryness. This residual solution was filtered, acidified with acetic acid and freed from carbon dioxide by boiling. A solution of barium acetate was then added which precipitated a mixture of barium salts, including that of *trans*-hexahydrophthalic acid. After various attempts by other methods

this acid was isolated as follows. The free acids were obtained as a glassy solid (1.02 g.) by treatment of the precipitate and filtrate with hydrochloric acid and extraction with ether. The glassy solid (0.70 g.) was dissolved in 10 ml. of boiling 10% sodium carbonate solution and the insoluble portion discarded. The solution was then fractionally acidified by the standard procedure. The early fractions were glassy solids, but the final fraction consisted of 9 mg. of a light brown, microcrystalline powder melting at 203–213° in the crude state and 216–223° after crystallization from water. The mixed m. p. of the crude material with authentic *trans*-hexahydrophthalic acid (m. p. 227–229°) was 212–217°, but the m. p. of *cis*-hexahydrophthalic acid was considerably depressed. The identity was confirmed by conversion to the anhydride with acetyl chloride, m. p. and mixed m. p. 142–144°. Extraction of the mother liquor from the fractional precipitation with ether gave a semi-crystalline residue from which 21 mg. of additional *trans*-hexahydrophthalic acid, m. p. 219–223°, was obtained by crystallization from aqueous acetic acid. This was treated with phosphorus pentachloride and aniline, as previously described for the preparation of the *cis*-compound, and the product crystallized from glacial acetic acid to give 10 mg. of the dianilide, colorless needles, m. p. (block preheated to 260°) 317–318°. The mixed m. p. with the dianilide of similar m. p. prepared from authentic *trans*-hexahydrophthalic acid showed no depression.

Anal. Calcd. for $C_{20}H_{22}O_2N_2$: C, 74.50; H, 6.88. Found: C, 74.27; H, 6.78.

It may be observed in passing that the m. p.'s of *trans*-hexahydrophthalic acid given in the literature are in the range 215–220° (see *e. g.*, reference 4). We find that by repeated crystallization from water it is possible to isolate the acid as prisms, m. p. 227–229°. The m. p. of the impure acid is considerably affected by the rate of heating, that of the pure acid less so. The above m. p. was obtained by introducing the acid into a bath at 200°. The pure acid of m. p. 227–229° yields the anhydride with the m. p. (142.5–144°) recorded in the literature.

Action of Nitric Acid on *cis*- and *trans*-9-Keto-*as*-octahydrophenanthrenes.—The two stereoisomeric 9-keto-*as*-octahydrophenanthrenes were prepared essentially by the methods of Cook and his co-workers[11] as described in the following paper.[5] The liquid ketone (*cis*-) (0.4 g.) was heated on the steam-bath for fifteen minutes with 5 cc. of concentrated nitric acid and 3 cc. of fuming nitric acid. The product was poured on ice and separated into neutral and acidic fractions by means of sodium carbonate solution. Acidification of the sodium carbonate solution yielded 20 mg. of *cis*-nitro-hexahydrodiphenic acid (VII) as a yellow solid, which was isolated by means of ether. It melted at 200–208° in the crude state, at 208–210° after one crystallization from acetone–benzene and at 217–219° in admixture with an authentic sample of the high-melting form (m. p. 218–219°) prepared as described in the preceding paper.[2] The neutral fraction from this reaction yielded 0.1 g. of a crystalline **trinitro-ketone,** which formed clear plates, m. p. 151.5–152° from hexane.

Anal. Calcd. for $C_{14}H_{13}N_3O_7$: C, 50.15; H, 3.91. Found: C, 50.57; H, 4.18.

(11) Cook, Hewett and Lawrence, *J. Chem. Soc.*, 71 (1936); Cook, Hewett and Robinson, *ibid.*, 168 (1939).

This substance agrees in m. p. but not in analysis with the mononitro ketone reported by Cook, *et al.*[11] When the *cis*-octahydro ketone (500 mg.) was heated for thirty minutes on the steam-bath with 1 cc. of concentrated and 1 cc. of fuming nitric acid in 10 cc. of acetic acid, it gave 300 mg. of a neutral solid. After recrystallization from acetic acid and then from benzene–hexane, this formed colorless plates, m. p. 95–96.5°, and analysis showed it to be a **dinitro-ketone.** Its m. p. was depressed by admixture with the nitro-ketone of m. p. 152°.

Anal. Calcd. for $C_{14}H_{14}N_2O_5$: C, 57.93; H, 4.86. Found: C, 57.87; H, 4.55.

Further treatment of the dinitro-ketone with nitric acid on the steam-bath yielded the trinitro-ketone of m. p. 152°.

The dinitro-ketone very probably contains the nitro-groups ortho- and para- to the backbone. The introduction of a third nitro-group is abnormal and it is probable that it corresponds with an attack on the alicyclic portion of the molecule.

Oxidation of *cis*-9-keto-*as*-octahydrophenanthrene with hot chromic acid in acetic acid, or with alkaline permanganate, gave no useful products.

trans-9-Keto-*as*-octahydrophenanthrene (350 mg., m. p. 95°) was heated for fifteen minutes with 4 cc. of concentrated and 4 cc. of fuming nitric acid. The product was separated as before. Crystallization of the acid fraction from acetic acid yielded *trans*-nitro-hexahydrodiphenic acid (100 mg.). This melted crude at 211–221° and from dilute acetic acid gave thin yellowish plates, m. p. 224–225° alone or in admixture with the authentic *trans*-nitro acid. The neutral fraction from this reaction (100 mg.) crystallized in bold needles from acetic acid, m. p. 182–184°, and in thin plates from hexane, m. p. 182.5–183.5°. Analysis showed it to be a **trinitro-ketone.** It was not identical with either of the nitro-ketones derived from the *cis*-ketone.

Anal. Calcd. for $C_{14}H_{13}N_3O_7$: C, 50.15; H, 3.91. Found: C, 50.30; H, 3.67.

Summary

Ozonization of the hexahydrodiphenic acid of m. p. 242° yields *cis*-hexahydrophthalic acid. Ozonization of *trans*-Δ^{10}-9-keto-dodecahydrophenanthrene yields a keto-acid which can be converted into an unsaturated lactone. The latter on oxidation with permanganate gives *trans*-hexahydrophthalic acid.

Taken in conjunction with work described in the preceding papers, these facts establish the *cis*-configurations for the following substances: hexahydrodiphenic acid, m. p. 242°; perhydrodiphenic acids, m. p. 289° (*syn*) and 198° (*anti*); and the *trans*-configurations for the following: hexahydrodiphenic acid, m. p. 221°; perhydrodiphenic acids, m. p. 223° (*syn*) and 247° (*anti*).

Two additional stereochemical links between the hydrodiphenic acids and the hydrophenanthrenes have been established by the conversion

of the *cis*- and *trans*-forms of 9-keto-*as*-octahydrophenanthrene into the corresponding nitro-hexahydrodiphenic acids.

The stereochemical implications of these results are discussed and it is shown that they are in agreement with other, less exact, evidence.

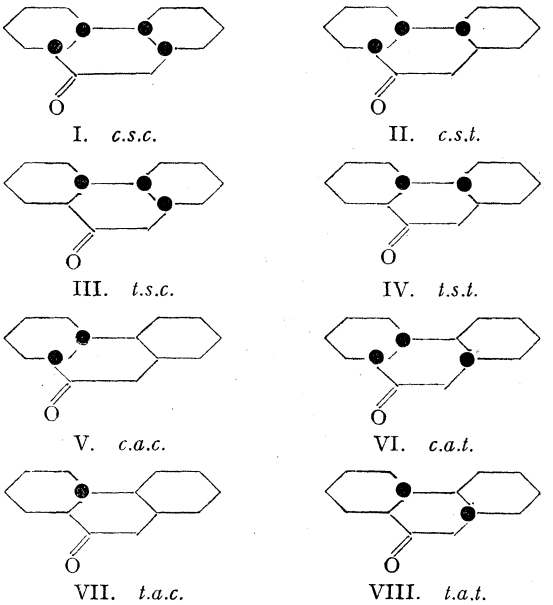
The Stereochemistry of Catalytic Hydrogenation. VI. The Hydrogenation of 9-Phenanthrol and Related Substances and the Identification of Three of the Possible Stereoisomeric Forms of the Perhydrophenanthrene Ring

BY R. P. LINSTEAD, RICHARD R. WHETSTONE AND PHILIP LEVINE

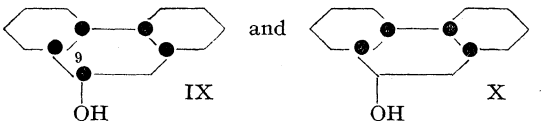
Perhydrophenanthrene can theoretically exist in six (inactive) stereoisomeric modifications.[1] Corresponding to each of four of these hydrocarbons (the *cis-syn-cis*, *trans-syn-trans*, *cis-anti-cis* and *trans-anti-trans* forms), there will be one ketone with the carbonyl group at C_9. Corresponding to each of the other two hydrocarbons (the *cis-syn-trans* and *cis-anti-trans* forms), there will be a pair of C_9 ketones, the additional forms being possible because the carbonyl can lie next to either a *cis*- or a *trans*-junction. All the ketones, and all the hydrocarbons except the *cis-syn-cis* and *trans-syn-trans* isomers, are capable of existence in enantiomorphic forms. Furthermore, each ketone can give rise to a pair of epimeric alcohols, so that eight inactive ketones and sixteen inactive alcohols become possible. The possibilities for the ketones are shown.



(1) Linstead and Walpole, *J. Chem. Soc.*, 842 (1939).

This is parallel to the half esters of the perhydrodiphenic acids[2] and we use a similar convention for the nomenclature of the *cis–trans* forms, the configuration on the side of the ketone group being named first.

It is also convenient for the sake of clarity to use dotted formulas[3] to designate the configuration of the alcohols. Thus of the two possible *cis-syn-*



cis alcohols the compound IX has the hydrogen atom on carbon 9 on the same side of the central ring as the four hydrogen atoms at the points of ring fusion.

The first perhydrophenanthrene derivatives of definite configuration to be discovered were the 9-ketone, m. p. 49°, and the related secondary alcohol, m. p. 119°, prepared by Linstead and Walpole.[1] This ketone, a stable crystalline solid, m. p. 49°, was oxidized to a perhydrodiphenic acid of m. p. 244°. This has now been proved to have the *trans-anti-trans* configuration.[4] Hence the ketone has the same configuration (VIII). Two other compounds which were believed[1] to be 9-keto-perhydrophenanthrenes have now been shown[2] to have a different skeleton structure.

In the present paper we describe the preparation of two new stereoisomeric modifications (*cis-syn-cis* and *trans-syn-cis*) of 9-keto-perhydrophenanthrene. Half of the possible stereoisomeric forms of the perhydrophenanthrene ring have therefore been prepared and orientated.

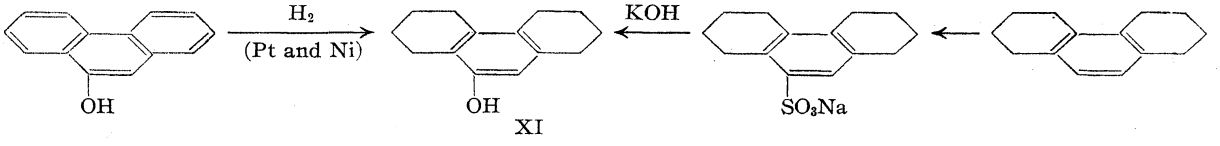
(4) Linstead and Doering, *ibid.*, **64**, 2003 (1942); Linstead, Davis and Whetstone, *ibid.*, **64**, 2009 (1942).

The new isomers were obtained in a study of the catalytic hydrogenation over platinum of 9-phenanthrol and of the *as*-octahydro-9-phenanthrols. Marvel and collaborators[5a,5b] have recently made some observations on the perhydrogenation of 9-phenanthrol over nickel. We shall discuss their results later in this paper.

When 9-phenanthrol was hydrogenated over platinum in acetic acid, there were formed (1) *sym*-octahydro-9-phenanthrol (XI), m. p. 135°, (2) a *cis-syn-cis*-perhydro-9-phenanthrol (IX or X), m. p. 111°, and (3) a hydrocarbon fraction. The *sym*-octahydro compound (which was isolated in very small amount) was identical with material prepared by hydrogenating 9-phenanthrol over Raney nickel. The hydrogenation over a different nickel catalyst has already been carried out by von Braun and Bayer[6] who had obtained the same compound. The structure of *sym*-octahydro-9-phenanthrol was proved by its synthesis from Schroeter's *sym*-octahydrophenanthrene[7] by sulfonation and fusion with alkali. The hydrogenation of 9-phenanthrol over Raney nickel is the best preparative method.



XI

The main oxygen-containing product of the platinum hydrogenation of 9-phenanthrol was a perhydro alcohol, m. p. 110–111°. This was easily separated from the octahydro-compound as it was lower boiling and more soluble. On oxidation with nitric acid it yielded *cis-syn-cis* perhydrodiphenic acid, m. p. 289°. This at once proved both its structure and its configuration (apart from the orientation of the hydroxyl group at C_9). We discuss the chemistry of this alcohol more fully below.

It was observed by Linstead and Davis[8] that in the perhydrogenation of *cis*- and *trans*-hexahydrodiphenic acids over platinum the integrity of the already established configuration was preserved, and the subsequent hydrogenation went *syn*- and *cis*-. It was of great interest to see if the same principle held in the tricyclic series. The *cis*- and *trans*-9-keto-*as*-octahydrophenanthrenes recently investigated by J. W. Cook and his collaborators[9] were suitable intermediates for such an investigation. These substances were accordingly prepared essentially by Cook's methods. In confirmation of the earlier results,[9a] we found that the dehydration of 2-phenylcyclohexanol-1-acetic ester, followed by hydrolysis, yielded the β,γ-unsaturated acid, m. p. 93° (probably XII), and that catalytic hydrogenation of this gave almost exclusively a 2-phenylcyclohexane-1-acetic acid of m. p. 170°. The evidence which we present below proves the correctness of Cook's view[9b] that this saturated acid has the *cis*-configuration (XIII). 2-Phenylcyclohexane-1-acetic acid can exist in a second geometrical form, and various reports of this have been made. Cook, Hewett and Lawrence[9a] obtained it in an impure form (m. p. 65–85°) from the mother liquors of the *cis*-acid. They also reported an acid of m. p. 84–85° which was obtained in poor yield by a malonic ester synthesis. Ghose[10] has described an acid of m. p. 69–70°, made by a different method. Cook, Hewett and Robinson[9b] reported that 2-phenylcyclohexylideneacetic acid (XIV, made by dehydrating the hydroxy acid with acetic anhydride) on hydrogenation failed to give the second (*trans*-) saturated acid in useful amount. We can confirm that the α,β-acid (XIV) hydrogenates *cis*- under most conditions. When, however, the hydrogenation is carried out over palladium in benzene solution there is obtained a mixture of saturated acids from which 57% of the *cis*-acid (m. p. 170°) and 33% of an isomer, m. p. 114°,[10a] can be separated without difficulty. The latter is undoubtedly the pure *trans*-2-phenylcyclohexane-1-acetic acid (XV). On cyclization with sulfuric acid, it gives the (*trans*-) 9-keto-*as*-octahydrophenanthrene, m. p. 96°, which Cook[9a] had obtained from his impure acid, m. p. 65–85°. The latter material must therefore have contained the *trans*-acid; the structure of the other low-melting acids described in the literature is doubt-

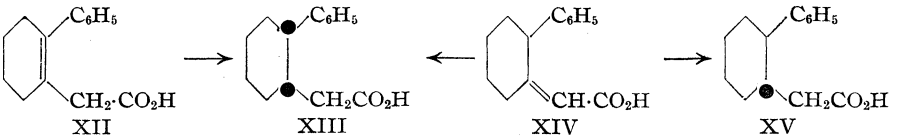
(10) Ghose, *Science and Culture*, **1**, 299 (1935).

(10a) It has just come to our attention that G. Blumenfeld, *Ber.*, **74B**, 524 (1941), recently prepared this acid by a different series of reactions. His acid melts at 112° and gave the same *as*-octahydrophenanthrone, m. p. 96°.

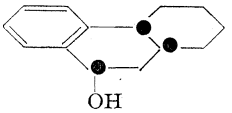
ful. The position of the double bond in the α,β-acid (XIV) was proved by its oxidation by means of alkaline permanganate to 2-phenylcyclohexanone.



XII m. p. 93° XIII m. p. 170° XIV m. p. 169° XV m. p. 114°

The route through phenylcyclohexylideneacetic acid (XIV) provides the best preparative method for the *trans*-acid (XV) but is still unsatisfactory owing to the difficulty of obtaining the α,β-acid. The yield of the latter from the acetic anhydride dehydration of the corresponding β-hydroxy acid, following Wallach, is low. A somewhat better yield is obtained by the use of *n*-butyric anhydride. If the β,γ-acid is equilibrated with alkali the amount of the α,β-isomer formed is very small. This is to be expected, because not only is cyclohexylideneacetic acid unstable with respect to its β,γ-isomer[11] but the γ-phenyl group further stabilizes the β,γ-form.[12]

Cyclization of the two saturated acids (XIII and XV) by means of sulfuric acid gave the two 9-keto-*as*-octahydrophenanthrenes reported by Cook.[9,12a] Catalytic hydrogenation of each of the two ketones yielded the corresponding pair of secondary alcohols. The *cis*-ketone gave almost completely a 9-hydroxy-*as*-octahydrophenanthrene, m. p. 115–116°, evidently identical with the alcohol described by Cook, Hewett and Lawrence.[9a] An epimeric *cis*-octahydro alcohol, m. p. 133°, was isolated from the products of the perhydrogenation of the *cis*-ketone. On the hypothesis of "catalyst hindrance" discussed in Part I,[13] it seems probable that the more easily prepared epimer has the three hydrogen atoms on the asymmetric carbon atoms, located on the same side of the central ring (XVI). The *trans*-ketone gives two epimeric alcohols, m. p.'s 91° and 101°, the proportion of which appears to vary with the method of hydrogenation. Reduction of the *cis*-ketone by means of sodium and alcohol gave a mixture of secondary alcohols from which the 116° epimer was isolated. Reduction with aluminum isopropoxide gave an epimeric mixture.



XVI

The perhydrogenation of the octahydro-ketones and alcohols was difficult because of the ease with which oxygen was eliminated over the active catalysts required to effect the reaction. This is true in particular of hydrogenation using palladium, and using platinum in acetic acid. The use of platinum in alcohol, however, gave a slow hydrogenation with little elimination of oxygen. In this way *cis*-9-keto-*as*-octahydrophenanthrene yielded a complex mixture from which four products were separated. These melted at 110, 114, 133 and 86°, severally. The first of these was identical with the perhydro-alcohol already obtained by the exhaustive hydrogenation of 9-phenanthrol. It is undoubtedly a *cis-syn-cis*-perhydro-9-phenanthrol and has the configuration represented by IX or X, probably the former. The second product was identical with the *cis-as*-octahydro-9-phenanthrol, m. p. 115–116°, described above (XVI). The product of m. p. 133° was the epimer of this. It has almost the same m. p. as *sym*-octahydro-9-phenanthrol (XI), but is not identical with this substance and depresses its melting point by some 35°. The fourth substance, m. p. 86°, crystallized well but was not homogeneous. Analysis indicated that it was a mixture of perhydro- and octahydro- compounds, and the absorption spectrum also showed the presence of aromatic material. After repeated crystallizations had failed to effect a purification, a method was devised (see experimental part) whereby the substance was separated into the three homogeneous products of the reaction, namely, the perhydro alcohol, m. p. 110° (10%), and the two octahydro-alcohols, m. p. 116° (10%) and m. p. 133° (30%).

Catalytic hydrogenation of the *cis-as*-octahydro-9-phenanthrol, m. p. 116°, over Adams catalyst in alcohol gave mainly the same *cis-syn-cis*-perhydrophenanthrol, m. p. 110°, and a little of the mixture, m. p. 86°.

Very interesting results were obtained from a study of the oxidation of the *cis-syn-cis*-perhydro-alcohol. When this compound was treated with a mixture of chromic and acetic acids at room temperature, it yielded a 9-keto-perhydrophenan-

(11) Linstead, *J. Chem. Soc.*, 355 (1927).

(12) Linstead and Williams, *ibid.*, 2735 (1926).

(12a) The assignment of the *cis*- and *trans*-configuration to these is proved by the evidence reported in the preceding paper (Part V).

(13) Linstead, Doering, Davis, Levine and Whetstone, THIS JOURNAL, **64**, 1985 (1942).

threne, m. p. 44°. This ketone formed a rather unstable oxime, m. p. 150°. It is undoubtedly *cis-syn-cis*-9-keto-perhydrophenanthrene (I) because on catalytic hydrogenation with platinum in ethyl alcohol it reformed the parent alcohol, m. p. 110°, and on oxidation with nitric acid it yielded *cis-syn-cis*-perhydrodiphenic acid, m. p. 289°. On the other hand, when the same alcohol was oxidized with chromic and acetic acids on the steam-bath a stereoisomeric ketone was obtained. This melted at 57°, depressed the m. p. of the 44° ketone and gave an oxime, m. p. 225°, from which it could be regenerated. Catalytic hydrogenation of the ketone yielded a perhydro-alcohol of m. p. 88–89° and oxidation with nitric acid gave *cis-syn-trans*-perhydrodiphenic acid, m. p. 199°. The new ketone has therefore been formed by inversion of the configuration of one asymmetric carbon atom, and clearly this must be the one adjacent to the carbonyl group. It must therefore have the *trans-syn-cis* configuration (III), and so must the derived alcohol, m. p. 88–89°.

These two ketones are precisely analogous to the α-decalones, studied by Hückel and his collaborators.[14] The *cis-syn-cis* ketone is easily inverted by heat, alkali, and to some extent in the formation of the usual carbonyl derivatives. The fact that the inversion only proceeds at one ring fusion, *i. e.*, to *trans-syn-cis* and not to *trans-syn-trans*, provides clear evidence that it proceeds through an enolization of the carbonyl group from the hydrogen atom on the neighboring bridgehead. The below summarizes the properties of the *cis-syn-cis* ketone in comparison with those of *cis* α-decalone.

	cis-syn-cis-9-Keto-perhydrophenanthrene	*cis*-α-Decalone[14]
Preparation	Cold CrO_3 on secondary alcohol	Same
Catalytic hydrogenation	Reforms the alcohol without inversion	Same
Nitric acid	Oxidizes without inversion	Same
Vacuum distillation	Unchanged	Same
High temperatures	Inverted at 200°	Inverted at 227°
Oxime	Gives (unstable) *cis-syn-cis*-derivative, m. p. 150°	Gives *trans*-derivative
2,4-Dinitrophenylhydrazone	Gives *trans-syn-cis*-derivative, m. p. 236°	...
Alcoholic alkali	Inverted	Inverted

(14) Hückel and Brinkmann, *Ann.*, **441**, 21 (1925); Hückel, Danneel, Gross and Naab, *ibid.*, **502**, 99 (1933).

The formation of *cis-syn-cis*-perhydrodiphenic acid by the nitric acid oxidation of the *cis-syn-cis* ketone (and alcohol) shows the reliability of this method in the determination of configuration. There could have been no reversible enolization and inversion under the experimental conditions and the ketone, in spite of the instability of its configuration, yielded the corresponding acid.

We are now in a position to review the results of Marvel and White[5a] on the hydrogenation of 9-phenanthrol over nickel. They obtained a perhydro-alcohol as a waxy solid, m. p. 67°. This on oxidation with chromic acid, finally on the steam-bath, yielded a ketone of m. p. 57° which was later prepared by another method.[5b] The ketone yielded an oxime, m. p. 219–220°, and a dinitrophenylhydrazone, m. p. 232–233°. On oxidation it gave an acid of m. p. 174°, which Linstead and Doering[2] have shown to be a dimorphous form of *cis-syn-trans*-perhydrodiphenic acid. It is therefore very probable that the ketone of Marvel and White is identical with our *trans-syn-cis* ketone which has the same m. p., and very similar m. p.'s for the derivatives. The configuration of the original hydrogenation product, m. p. 67°, of Marvel and White is, however, uncertain. It may be a *cis-syn-cis*, or a *trans-syn-cis* alcohol, because the conditions of oxidation were such that an inversion was possible. It is obviously not identical with any of our alcohols but there are vacancies for one epimer in each series.

Some preliminary work has been carried out on the perhydrogenation of *trans-as*-octahydrophenanthrene derivatives, but it has not yet reached a stage suitable for report.

The present state of knowledge of the 9-substituted hydrophenanthrenes of known structure is summarized.

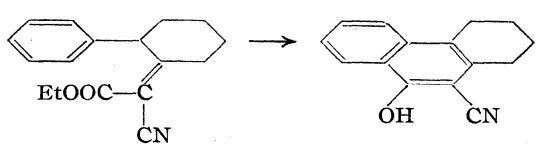
An interesting incidental observation was made during attempts to find a better method for the preparation of *trans*-2-phenylcyclohexaneacetic acid. 2-Phenylcyclohexanone was condensed with cyanoacetic ester and the 2-phenylcyclohexylidenecyanoacetic ester (XVII) so formed was reduced, both by aluminum amalgam and catalytically, and subsequently hydrolyzed. The acid isolated in this way was the common (*cis*) 2-phenylcyclohexaneacetic acid, m. p. 169–170° (XIII). The method therefore was of no preparative value as the yield was worse than that obtained by the Reformatsky procedure. The feature of interest was that the initial product of the cyanoacetic ester condensation always deposited a small amount of a crystalline solid on standing and that its analytical values were high both in carbon and hydrogen. It was found that the same solid could be formed by heating the unsaturated cyano ester at 210°. The solid gave figures corresponding to the formula $C_{15}H_{13}ON$, *i. e.*, to those required for the unsaturated cyano ester less the elements of ethyl alcohol. It yielded a sodium salt with sodium carbonate, a mono-benzoate and a picrate. It is accordingly assigned the structure 1,2,3,4-tetrahydro-10-cyano-9-phenanthrol (XVIII)



XVII XVIII

Analogous ring-closures have been observed by McRae and Marion,[15] and by Cope and his collaborators.[16]

Experimental[17]

1. Hydrogenation of 9-Phenanthrol.[18]—9-Phenanthrol was prepared essentially by the method of Fieser, Jacobsen and Price.[19] It was found that very poor yields were obtained unless the sodium (or potassium) acetate was omitted from the reaction mixture. The phenanthrol (9.5 g.) in 200 cc. of glacial acetic acid was hydrogenated in a Parr apparatus using 1.74 g. of Adams catalyst. The theoretical uptake of hydrogen was reached after 188 hours. The product was evaporated to small bulk under reduced pressure in a stream of nitrogen, the residual acid was neutralized and the oil isolated by means of ether. Vacuum distillation separated the product into 4.54 g. of a low fraction (b. p. 120–125° (3 mm.)), 3.22 g. boiling between 150–160° (3 mm.) and 0.54 g. of a residue. Careful fractional distillation of the low fraction yielded a liquid with b. p. 121° (3 mm.), $d^{26.5}_4$ 0.9587, $n^{26.5}D$ 1.5088. This material, which is undoubtedly a highly hydrogenated phenanthrene, awaits further investigation.

The high-boiling fractions from the above slowly deposited crystals. Fractional crystallization from hexane yielded *cis-syn-cis*-**perhydro-9-phenanthrol** (IX or X), white needles, m. p. 110.5–111°. The yield of this material from a total of 14.4 g. of 9-phenanthrol was 1.26 g.

Anal. Calcd. for $C_{14}H_{24}O$: C, 80,71; H, 11.61. Found: C, 80.82; H, 11.61.

The alcohol (125 mg.) was added to a mixture of 0.75 cc. of fuming nitric acid and 2.2 cc. of concentrated nitric acid. The mixture was at first warmed gently and then heated on the steam-bath for five minutes. The product was poured into water (15 cc.) and extracted with benzene. The benzene layer was then extracted with sodium carbonate solution. Acidification of the sodium carbonate gave a solid which was purified by a second extraction with sodium carbonate and was then crystallized from acetic acid. The white crystals melted at 278–283° alone, and at 282–285° in admixture with *cis-syn-cis*-perhydrodiphenic acid.

The further investigation of the *cis-syn-cis*-alcohol is described later.

The highest boiling fraction of the original hydrogenation, and the residue, on crystallization from hexane (charcoal) yielded *sym*-**octahydro-9-phenanthrol** (XI). This crystallized from hexane in needles and melted at 134.5–135° (von Braun and Bayer[6] give 133°).

Anal. Calcd. for $C_{14}H_{18}O$: C, 83.12; H, 8.97. Found: C, 83.22; H, 9.19.

9-Phenanthrol (5 g.) was hydrogenated with 2 cc. of Raney nickel made up to 20 cc. with alcohol, at 120° and an initial pressure of 123 atmospheres. The hydrogen uptake was about 20% above the theoretical for the formation of the octahydro compound. The alcoholic solution of the product turned dull red on exposure to the air. From it there was isolated *sym*-octahydro-9-phenanthrol, m. p. 132–134°, which did not depress the m. p. of the product obtained in the hydrogenation over platinum.

sym-Octahydrophenanthrene was prepared from tetralin by Schroeter's method,[7] and converted into the sodium salt of the 9-sulfonic acid.[7] The salt was fused with potassium hydroxide at 290–300° in the usual manner. The efficiency of the reaction was greatly reduced by secondary decomposition and the escape of organic vapors (possibly the desired product). At the end, the alkali was dissolved in water neutralized with acid, and the product was extracted with chloroform. The solution was clarified with charcoal, dried and freed from solvent. The residue was crystallized from hexane containing a little activated clay and then deposited *sym*-octahydro-9-phenanthrol, m. p. 133.5–135°. An attempt to carry out the same fusion in an autoclave failed. The phenol is very difficult to free from colored impurities. It separates from pale solutions in shades ranging from light brown to black. The best method of removing the color is to boil a solution in ligroin (b. p. 90–120°) with activated clay.

2. 2-Phenylcyclohexaneacetic Acids.—2-Phenylcyclohexanone was condensed with bromoacetic ester following Cook, Hewett and Lawrence.[9a] The hydroxy ester, obtained in 80% yield, was dehydrated by refluxing it (90 g.) for three and a half hours with 60 g. of phosphorus pentoxide and 300 cc. of benzene. A 77% yield of unsaturated ester, b. p. 146–153° (3 mm.), was obtained. This was hydrolyzed with alkali to the β,γ-acid (XII), yield 93%; b. p. 180–190° (3 mm.); m. p. 80–85° (crude); 92–93° after one crystallization from light petroleum (lit., 93°).[9a] The crude unsaturated acid (18 g.) in 75 cc. of glacial acetic acid was hydrogenated with 0.5 g. of palladium catalyst.[20] After eighteen hours at atmospheric pressure, the uptake of hydrogen corresponded to 1.12 mols. The solution was filtered, heated to boiling and diluted with water. The average yield was 63% of the pure *cis*-2-phenylcyclohexaneacetic acid (XIII), m. p. 168–170° (lit., 169–170°).[9a] The mother liquors from this acid, containing the *trans*-isomer, were used in the crude state for the preparation of *trans*-9-keto-*as*-octahydrophenanthrene.

2-Phenylcyclohexanol-1-acetic ester was hydrolyzed with boiling alkali. The corresponding hydroxy acid, obtained in 75% yield, melted at 128–129°. The acid was converted into 2-phenylcyclohexylidene-acetic acid (XIV) following Cook, Hewett and Robinson.[9b] The yield of the pure α,β-acid, m. p. 168–170°, was only 17%. The by-products of this reaction are still under investigation. When the hydroxy acid was refluxed with *n*-butyric anhydride for one and one-quarter hours, the α,β-acid was obtained in 35% yield. Both the β,γ- and α,β-acids readily decolorized permanganate in sodium carbonate solution. When the carbonate solutions of the acids were treated with iodine in potassium iodide,[21] the β,γ-acid reacted immediately but the α,β-acid showed no sign of reaction. This difference is in keeping with the structures assigned by Cook.[9] The structure of the α,β-acid was proved by oxidizing 450 mg. of it in sodium carbonate solution with potassium permanganate. The product yielded 220 mg. of 2-phenylcyclohexanone, identified by m. p. and mixed m. p.

The α,β-acid (210 mg.) in 10 cc. of benzene was hydrogenated over 120 mg. of palladium catalyst. In four hours 1.1 mols of hydrogen was taken up. The product was fractionally crystallized from benzene–hexane. It yielded 120 mg. of the *cis*-acid (XIII), m. p. 158–164°; followed by 70 mg. (33%) of a solid melting at 110–114°. Three crystallizations of the latter from hexane gave ***trans*-2-phenylcyclohexaneacetic acid** (XV) as thin plates, m. p. 113.5–114.5°.

Anal. Calcd. for $C_{14}H_{18}O_2$: C, 77.03; H, 8.31. Found: C, 77.33; H, 8.38.

Cyanoacetic Ester Condensations.—Following the general technique of Cope,[22] a mixture of 3.0 g. of 2-phenylcyclohexanone, 2.5 g. of cyanoacetic ester, 0.5 g. of ammonium acetate, 0.75 g. of acetic acid and 5 cc. of benzene was heated in a bath at 140–160° for six hours, the benzene being continually replaced. The product was taken up in ether, washed with water and 5% aqueous sodium hydroxide. The solvent was removed and the residue distilled, yield 2.4 g. (52%) of a colorless viscous oil, b. p. 167–174° (3 mm.). The product did not decolorize bromine in carbon tetrachloride but reduced permanganate in acetone. The redistilled product boiled at 174° (4 mm.) and analysis showed that it was mainly **2-phenylcyclohexylidenecyanoacetic ester** (XVII).

Anal. Calcd. for $C_{17}H_{19}O_2N$: C, 75.81; H, 7.11. Found: C, 76.46; H, 7.37.

The last drops obtained in the distillation of the above ester solidified to a mass of crystals of **1,2,3,4-tetrahydro-10-cyano-9-phenanthrol** (XVIII), and some of the same solid slowly separated when the original reaction mixture was allowed to stand in the cold. It was also obtained by acidifying the alkaline extracts from the cyano ester. The total yield of the by-product was 8%. It could be prepared by heating the unsaturated cyano ester (XVII) for one and three-quarters hours at 200–220°. It crystallized from benzene in fine white needles, m. p. 230–231°. It was sparingly soluble in alcohol, ether and benzene, and insoluble in sodium bicarbonate solution. With 5% aqueous sodium carbonate it gave an insoluble sodium salt. It gave no color with ferric chloride. Sundry attempts to hydrolyze it failed.

Anal. Calcd. for $C_{15}H_{13}ON$: C, 80.72; H, 5.83; N, 6.28. Found: C, 81.16; H, 5.79; N, 6.19.

Anal. Calcd. for $C_{22}H_{17}O_2N$: C, 80.71; H, 5.24. Found: C, 80.61; H, 5.23.

When warmed with alcoholic picric acid, the cyanophenol yielded a **picrate,** which separated in yellow crystals, m. p. 185–190°, with decomp.

Anal. Calcd. for $C_{21}H_{16}O_8N_4$: C, 55.75; H, 3.56. Found: C, 55.77; H, 3.37.

The picrate regenerated its components when heated with alcohol.

The unsaturated cyano ester (XVII, 1.68 g.) was hydrogenated in alcohol over Adams catalyst, the uptake of hydrogen being 1.03 mols in seven hours. The product was refluxed with 20 cc. of concentrated hydrochloric acid and 5 cc. of water for thirty-six hours. The bulk of the

ester survived hydrolysis; the acid formed melted at 165–168° and was identified as *cis*-2-phenylcyclohexaneacetic acid. Another portion of the unsaturated cyano ester was reduced with aluminum amalgam in moist ether for three days. Hydrolysis as before gave the *cis*-acid, again in poor yield.

3. Derivatives of the *as*-Octahydrophenanthrenes.—*cis*-2-Phenylcyclohexane-1-acetic acid (12.0 g.) was cyclized by means of sulfuric acid following Cook.[9] *cis*-9-Keto-*as*-octahydrophenanthrene (average yield 96%) was obtained as a colorless liquid, b. p. 162–163° (5 mm.).

The ketone (3.5 g.) in 25 cc. of alcohol was treated with 1 mol of hydrogen over Adams catalyst. The product yielded 3.3 g. (93%) of soft, feathery crystals which dried to a chalky mass, m. p. 112–114°. Two recrystallizations from cyclohexane raised the melting point of the ***cis*-octahydro-9-phenanthrol** to 115–116° (lit., 114–115°).[9] The ultraviolet absorption spectrum was measured in alcohol by Mr. J. J. Leavitt. It had two bands of equal intensity at 266 and 273 mμ with log $\epsilon_{max.}$ 2.54.

Anal. Calcd. for $C_{14}H_{18}O$: C, 83.12; H, 8.97. Found: C, 83.10; H, 8.90.

Reduction of the ketone with sodium in alcohol yielded a product melting initially at 60–69°. After a number of crystallizations from cyclohexane this gave some of the same octahydro-alcohol, m. p. 115–116°. Reduction of the ketone with aluminum isopropoxide in isopropyl alcohol gave a solid melting at about room temperature, from which no pure alcohol could be isolated. The ketone (6.0 g.) was hydrogenated over 0.62 g. of palladium catalyst in alcohol, 1.95 mols of hydrogen being taken up in three hours. A small amount (200 mg.) of the 115° alcohol was isolated from the product, but the bulk was a hydrocarbon (4 cc.) which distilled at 121–122° (4–5 mm.) and was presumably *cis-as*-octahydrophenanthrene. The reported boiling point of the latter is 129° (6 mm.).[23]

The isolation of the second epimeric form of the *cis*-alcohol is described below under the perhydrogenations.

***trans*-9-Keto-*as*-octahydrophenanthrene.**—The combined mother liquors from the crystallization of *cis*-2-phenylcyclohexylacetic acid were evaporated to a red sirup (25 cc.). This was treated with sulfuric acid as before and the neutral product was crystallized first from light petroleum and then several times from alcohol. The yield of *trans*-ketone was 4.3 g.; m. p. 95–96°, in agreement with Cook, Hewett and Lawrence.[9a] The same ketone was obtained in 74% yield by cyclization of the pure *trans*-acid, m. p. 114°.

The *trans*-ketone (610 mg.) in alcohol, over 120 mg. of Adams catalyst took up 1.0 mole of hydrogen in nineteen hours at atmospheric pressure. Crystallization of the product from hexane and cyclohexane yielded 400 mg. (63%) of a *trans-as*-**octahydro-9-phenanthrol,** sturdy needles melting at 90–91°, and a few milligrams of an *epimer* which formed cotton-like fibers, m. p. 100–101°. A mixture of the two alcohols melted at 84–88°. When a larger preparation was carried out over the same catalyst under a pressure of 3 atmospheres for four days, the proportions of the two alcohols were reversed, the ratio of 101° to 91° form being about 2:1.

Anal. Calcd. for $C_{14}H_{18}O$: C, 83.12; H, 8.97. Found (m. p. 90–91°): C, 83.29; H, 9.19; (m. p. 100–101°): C, 83.06; H, 9.12.

4. Derivatives of Perhydrophenanthrene.—Hydrogenation of the aromatic ring in the *cis*-octahydro compounds was carried out by means of Adams catalyst in alcoholic solution. The use of acetic acid as a solvent led to elimination of the oxygen atoms. This occurred even when very little acetic acid was present, as is shown by the following experiment. The *cis*-octahydro-9-phenanthrol, m. p. 116°, (2.1 g.) in 15 cc. of acetic acid and 185 cc. of alcohol took up 2.9 mols of hydrogen in five days under an initial pressure of 50 lb. The product was mainly a liquid hydrocarbon but yielded a little solid which on crystallization from hexane gave needles of *cis-syn-cis*-perhydro-9-phenanthrol (100 mg.). This melted at 110–111° alone or in admixture with that prepared from 9-phenanthrol.

Anal. Calcd. for $C_{14}H_{24}O$: C, 80.71; H, 11.61. Found: C, 80.63; H, 11.54.

The hydrocarbon boiled at 109–111° (4 mm.), failed to solidify, and was insoluble in cold concentrated sulfuric acid. Hence it was presumably a perhydrophenanthrene.

cis-9-Keto-*as*-octahydrophenanthrene (10.7 g.) in alcohol was hydrogenated over 0.9 g. of catalyst added in three portions. The uptake of hydrogen was 3.4 mols in eight days. Removal of the solvent and catalyst, followed by crystallization from hexane, yielded 7 g. of solid melting at about 70–85°. On fractional crystallization from cyclohexane, 2.9 g. of the *cis*-octahydro alcohol, m. p. 112–114°, was obtained. The residue was crystallized from ether, which yielded 2.4 g. of the *cis-syn-cis*-perhydro alcohol, m. p. 108–110°. These substances were identified by mixed m. p. determinations. The ethereal mother liquors deposited 0.2 g. of the epimeric *cis-as*-**octahydro-9-phenanthrol,** m. p. 126–128°, which after repeated crystallization from hexane gave fine needles, m. p. 132.5–133.5°. A mixture of this with the *cis-as*-octahydro alcohol (m. p. 115–116°) melted at 95–100°. A mixture with *sym*-octahydro-9-phenanthrol (m. p. 133°) melted at 95–105°. The new *cis-as*-octahydro alcohol differs from the isomeric *sym*-octahydro phenol of the same m. p. in that it is readily obtained and kept in a pure white crystalline form. The *sym*-octahydro phenol discolors very readily, as already noted.

Anal. Calcd. for $C_{14}H_{18}O$ (alcohol, m. p. 132.5–133.5°): C, 83.12; H, 8.97. Found: C, 82.94; H, 8.82.

The mother liquor from the original 7 g. of solid slowly deposited a further 1.4 g. of solid, which crystallized in rosets of thick spikes, m. p. 85–87°. Repeated crystallization from alcohol, ether and hydrocarbon solvents failed to alter this. This substance, however, gave analytical figures (C, 81.08; H, 10.41) intermediate between those required for an octahydro and a perhydro alcohol. The ultraviolet absorption spectrum (for which we are indebted to Mr. J. J. Leavitt) showed the two equal bands, with maxima at 266 and 273 mμ which are present in the spectrum of *cis-as*-octahydro-9-phenanthrol. The intensity (log $\epsilon_{max.}$ 2.2) corresponded to the presence of about 50% of this compound. The solid, m. p. 85–87°, was dissolved in acetic acid and the solution diluted with small portions of water. Crude *cis-syn-cis* perhydro alcohol

(10% of solid) then separated, and, after crystallization from ether, melted at 108–110°. Further dilution of the acetic acid gave the common *cis-as*-octahydro alcohol (10%), which melted at 115–116° after crystallization from cyclohexane. Removal of the acetic acid left an oil which was hydrolyzed with cold 10% alcoholic potash for forty-eight hours. Acidification and crystallization of the solid product yielded the epimeric *cis-as*-octahydro alcohol, m. p. 133°, (30%). The three components were identified by mixed m. p. determinations.

The *cis-as*-octahydro-9-phenanthrol of m. p. 112–114° was hydrogenated over platinum in alcohol in the same way. It yielded 47% of *cis-syn-cis*-perhydro-9-phenanthrol, m. p. 108–110°, and 10% of the mixture of m. p. 85–87°.

cis-syn-cis-**9-Keto-perhydrophenanthrene.**—Chromic acid (1.0 g.), dissolved in 5 cc. of 80% acetic acid, was added to an ice-cooled solution of 2.3 g. of *cis-syn-cis*-perhydro-9-phenanthrol, m. p. 110–111°, in 30 cc. of glacial acetic acid. The mixture was left overnight at room temperature, poured into water and extracted with ether. The ether was washed with water and sodium carbonate solution. Evaporation of the dried ether solution *in vacuo* left 2.0 g. (87%) of an oil which crystallized to a solid, m. p. 35–38°. The material could be distilled unchanged at about 130° (3 mm.). Six crystallizations from cold petroleum ether gave short needles of the *cis-syn-cis*-perhydro ketone, m. p. 43–44°.

Anal. Calcd. for $C_{14}H_{22}O$: C, 81.50; H, 10.75. Found: C, 81.69; H, 10.42.

The **oxime** was obtained by leaving the ketone in cold aqueous alcoholic solution with hydroxylamine hydrochloride and sodium acetate for four hours. The crystals so obtained melted at 150–151° and were rendered less pure by crystallization, presumably owing to the occurrence of inversion. For analysis the first precipitated crystals were washed with water and petroleum ether and dried.

Anal. Calcd. for $C_{14}H_{23}ON$: C, 75.97; H, 10.47. Found: C, 76.24; H, 10.28.

Recrystallization from hot alcohol lowered the m. p. to 143–146°. When an alcoholic solution was boiled for three hours, the crystals which separated melted at 135–141°.

The 2,4-dinitrophenylhydrazone formed orange plates from hot alcohol, m. p. 236–238°, decomp. The semicarbazone melted at 195–205° without crystallization, at 205–220° after one crystallization from hot alcohol, and at 210–218° after four hours of boiling with alcohol.

The ketone (200 mg.) was heated for fifteen minutes on the steam-bath with 3 cc. of a mixture of 5 cc. concentrated and 3 cc. fuming nitric acid. The product was poured on ice, the yellow resin taken up in ether. The ethereal solution was extracted four times with saturated aqueous sodium bicarbonate. The extract was acidified, the acid isolated by means of ether, boiled with charcoal in acetone and crystallized from benzene. *cis-syn-cis*-Perhydrodiphenic acid (10 mg.) separated, m. p. 275–280°, mixed m. p. 279–284°. The identity was confirmed by converting the acid (3 mg.) into the dimethyl ester, which melted at 66–69° alone and at 71–73° in admixture with authentic material.

Catalytic hydrogenation of the ketone over Adams catalyst in alcohol yielded the *cis-syn-cis*-perhydro-9-phenanthrol of m. p. 110°.

trans-syn-cis-**9-Keto-perhydrophenanthrene.**—*cis-syn-cis*-Perhydro-9-phenanthrol, m. p. 110°, was oxidized with chromic and acetic acids in the manner described above with the difference that after the initial reaction, the mixture was heated on the steam-bath for fifteen minutes. The *trans-syn-cis*-ketone, isolated in the same way as its isomer, crystallized from petroleum ether in needles, m. p. 56.5–57.5°. A mixture of the two ketones was liquid at room temperature.

Anal. Calcd. for $C_{14}H_{22}O$: C, 81.50; H, 10.75. Found: C, 81.65; H, 10.80.

The same perhydro alcohol (1.9 g.) was oxidized following Oppenauer's method by refluxing it for eight hours with 1.4 g. of aluminum *t*-butoxide in a mixture of acetone and benzene. The product was a mixture of the two ketones melting at about 25° and not easily separable by crystallization. It was accordingly heated in an atmosphere of nitrogen at 200° for one and three-quarters hours. The product was the nearly homogeneous *trans-syn-cis* ketone, m. p. 48–52°, identified by a mixed m. p. determination. The same inversion was achieved by refluxing the mixed ketone, m. p. 25°, with alcoholic sodium ethoxide for one and one-half hours.

The **oxime** of the *trans-syn-cis* ketone formed immediately at room temperature and crystallized in fine needles, m. p. 224–225°. A mixture with the *cis-syn-cis* oxime (m. p. 150–151°) melted over the range 143–180°.

Anal. Calcd. for $C_{14}H_{23}ON$: C, 75.97; H, 10.47. Found: C, 76.25; H, 10.38.

When the oxime was boiled for six hours with 5% sulfuric acid, it regenerated the *trans-syn-cis* ketone, m. p. 57°.

The 2,4-dinitrophenylhydrazone formed red plates from hot alcohol, m. p. 236–237°, decomp. The color was more intense than that of the corresponding derivative made from the *cis-syn-cis* ketone but the mixed m. p. was the same (236–237° decomp.) and it is probable that both ketones give the same derivative.

The ketone (200 mg.) was oxidized with nitric acid as described for the *cis-syn-cis*-isomer. The product yielded 30 mg. of *cis-syn-trans*-perhydrodiphenic acid, m. p. 196–198° alone, and 197–198° in admixture with an authentic sample (m. p. 198–199°). Hydrogenation of the ketone (130 mg.) over Adams catalyst in alcohol led to a theoretical uptake of hydrogen. The *trans-syn-cis*-**perhydro-9-phenanthrol** so obtained was crystallized first from hexane and then from ether, from which it separated in rosets of long prisms, m. p. 88–89°.

Anal. Calcd. for $C_{14}H_{24}O$: C, 80.71; H, 11.61. Found: C, 80.19, 80.21; H, 11.38, 11.33.

Summary

Catalytic hydrogenation of 9-phenanthrol over platinum yields *cis-syn-cis*-perhydro-9-phenanthrol, m. p. 111°, together with a small amount of *sym*-octahydro-9-phenanthrol. The latter substance was also obtained over nickel at 120°. Its structure was proved by its synthesis from *sym*-octahydrophenanthrene.

cis-9-Keto-*as*-octahydrophenanthrene yields two secondary alcohols, m. ps. 116° and 133°. The isomeric *trans*-ketone also yields two epimeric alcohols, m. ps. 91° and 101°.

Hydrogenation of *cis*-9-keto-*as*-octahydrophenanthrene over platinum in alcohol gives *cis-syn-cis*-perhydro-9-phenanthrol and the two octahydro alcohols. Hydrogenation of *cis-as*-octahydro-9-phenanthrol gave the same *cis-syn-cis*-perhydro alcohol. When the *cis-syn-cis*-perhydro alcohol was oxidized by chromic acid at 0–25° it yielded *cis-syn-cis*-9-keto-perhydrophenanthrene. However, when the same oxidation was completed at 100° the product was the isomeric ketone with the *trans-syn-cis* configuration, presumably identical with a ketone isolated by Marvel and coworkers. The inversion of the *cis-syn-cis* ketone has been studied and is correlated with that of *cis*-α-decalone.

The *cis-syn-cis*-perhydro alcohol and ketone were oxidized by nitric acid to *cis-syn-cis*-perhydrodiphenic acid. The *trans-syn-cis* ketone yielded *cis-syn-trans*-perhydrodiphenic acid on nitric acid oxidation and a new perhydro alcohol on catalytic hydrogenation.

Three forms of the perhydrophenanthrene ring have therefore been made and oriented.

Pure *trans*-2-phenylcyclohexaneacetic acid has been obtained, m. p. 114°. When heated to 200°, 2-phenylcyclohexylidenecyanoacetic ester spontaneously cyclizes to tetrahydro-10-cyano-9-phenanthrol.

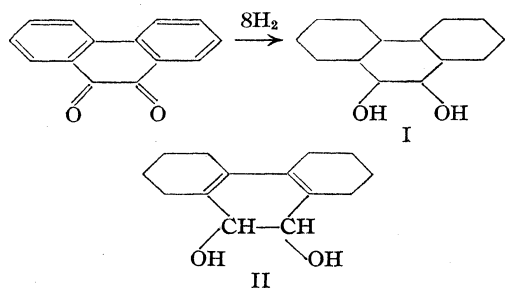
The Stereochemistry of Catalytic Hydrogenation. VII. The Complete Hydrogenation of Phenanthraquinone

BY R. P. LINSTEAD AND PHILIP LEVINE

The catalytic hydrogenation of 9,10-phenanthraquinone has already been investigated by von Braun and Bayer[1] and by Skita,[2] but they did not succeed in bringing about the complete hydrogenation of the molecule. Skita observed a reduction over colloidal platinum to *sym*-decahydro-9,10-dihydroxyphenanthrene (II). von Braun and Bayer, working with a nickel catalyst at high temperatures, also observed a preferential hydrogenation of the lateral rings, but their products suffered a partial or complete removal of the oxygen atoms.



We find that phenanthraquinone can be completely hydrogenated both over platinum at room temperature and over Raney nickel at 160° without loss of oxygen. Eight molecular proportions of hydrogen are taken up and the products are perhydro-9,10-dihydroxyphenanthrenes (I). Four beautifully crystalline stereoisomers of this structure have been obtained.

When the hydrogenation was carried out under about 4 atmospheres pressure over Adams platinum oxide in acetic acid solution, a homogeneous glycol, m. p. 174°, was obtained. Over Raney nickel in ethanol at 160° and about 170 atmospheres the reaction yielded principally two isomeric glycols, melting at 174 and 155°, respectively, together with a very small amount of a fourth isomer of m. p. 184°. The glycol of m. p. 174° obtained over nickel differed in crystalline form from that of the same m. p. obtained by the use of platinum, depressed its melting point, and gave a different dibenzoate. All the four products gave analyses corresponding to the perhydroglycol structure, $C_{14}H_{24}O_2$, and yielded distinct dibenzoates. They gave positive Criegee tests for 1,2-glycols.[3]

Corresponding to the six inactive stereoisomeric forms of the fundamental perhydrophenanthrene skeleton[4] there are twenty inactive 9,10-glycols. Each of the *cis-cis* and *trans-trans*

forms (*i. e.*, the *cis-syn-cis*, *cis-anti-cis*, *trans-syn-trans* and *trans-anti-trans* configurations) can give rise to *three* glycols (see III below). The remaining two perhydrophenanthrene structures (*cis-syn-trans* and *cis-anti-trans*) can give rise to four glycols each. The extra isomer comes from the fact that both when the two hydroxyl groups are *cis* and when they are *trans*, two forms are possible (see IV below). These possibilities are outlined below for the cases of the *cis-syn-cis* and *cis-syn-trans* series. Only the central ring is shown, for brevity.

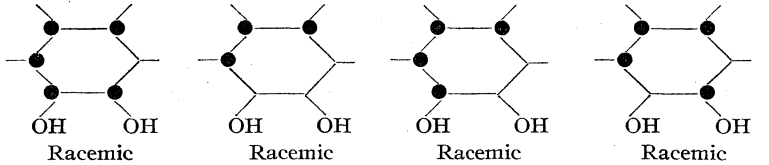
(a) Meso (b) Meso (c) Racemic

IV *c.s.t.* series



Racemic Racemic Racemic Racemic

[The dots represent hydrogen atoms *above* the plane of the ring.[4]]

To determine the configuration of the perhydrophenanthrene skeleton, the oxidation of the four glycols to the corresponding perhydrodiphenic acids was studied. The configurations of the latter are known.[5] The following reagents were successful for this purpose: lead tetraacetate, potassium periodate, Beckmann's mixture, chromic and acetic acids, and peracetic acid. The following reagents failed: potassium permanganate, nitric acid and potassium hypobromite. In no case was the yield particularly good. The same product was obtained from the three easily obtained glycols (Pt 174°, Ni 174°, Ni 155°). This was the *cis-syn-cis*-perhydrodiphenic acid, m. p. 289°,[6] and in each case was identified by direct comparison and by conversion into the dimethyl ester, m. p. 73°.

It is thus established that these three glycols have the same skeletal configuration and differ only in the orientation of the hydroxyl groups. They therefore correspond with the three formulas III (a), (b), and (c) given above, and all the possible members of this series (*c.s.c.*) have been prepared.

The rare glycol, m. p. 184°, obtained in small amount from the hydrogenation over nickel, was oxidized by chromic and acetic acids to *cis-syn-trans*-perhydrodiphenic acid,[5,6] m. p. 198–200° This was further identified by conversion into the anhydride,[6] m. p. 104°.

As far as the evidence from the isolated products is concerned, therefore, it may be deduced that phenanthraquinone is hydrogenated *cis-syn-cis* over platinum, and almost completely *cis-syn-cis* over nickel. A small amount of *cis-syn-trans* hydrogenation occurs under the conditions of our experiments over the latter catalyst.

In view of the work of Tiffeneau[7] (compare Bartlett[8]) on cyclohexane-1,2-diols, it appeared that it might be possible to dehydrate the glycols obtained from phenanthraquinone into 9-ketoperhydrophenanthrenes. For example, Tiffeneau has shown that *cis*-cyclohexane-1,2-diol yields cyclohexanone when its vapor is passed over alumina at 250–300°. Attempts were therefore made to carry out a parallel dehydration of the reduction products of phenanthraquinone, using both activated alumina and a precipitated alumina catalyst prepared according to Adkins and Krause.[9] In all cases the yield of carbonyl compound was very low. A positive test was obtained by means of Brady's reagent but no oxime or semicarbazone could be isolated. Neither could a ketone be obtained by dehydration with potassium bisulfate, and further experiments in this direction were abandoned.

When the hydrogenation of phenanthraquinone over Raney nickel was carried out at a temperature of 120°, the main product was an incompletely hydrogenated glycol, apparently identical with that of Skita,[2] to which he assigns the decahydro-9,10-dihydroxyphenanthrene structure (II).

Experimental[10]

Phenanthraquinone.—For the purpose of hydrogenation, the quinone was prepared and purified as follows.[11] To a

hot mixture of 500 cc. of concentrated sulfuric acid and 1500 cc. of water in a 4-l. beaker, 100 g. of crude phenanthrene was added. Potassium dichromate (300 g.) was then added slowly with mechanical stirring and the mixture subsequently stirred for one hour. The product was diluted to *ca.* 4 l. and the crude quinone collected and washed. The products from two such reactions were united and re-oxidized using 1300 cc. of water, 500 cc. of sulfuric acid and 350 g. of potassium dichromate. The final product was worked up as before and dried, yield 185 g. from 200 g. of crude phenanthrene.

This crude quinone was purified through the bisulfite addition product, by heating 75 g. with 1500 cc. of saturated sodium bisulfite solution. The product was filtered and decomposed with an excess of a concentrated aqueous solution of sodium hydroxide. This regenerated phenanthraquinone (58 g.) which was filtered, washed and crystallized from acetic acid (charcoal), yield 47 g., m. p. 205–207°. As a further precaution, in the case of the hydrogenation over platinum, the quinone was again recrystallized from xylene–acetic acid, and from acetic acid before hydrogenation.

Hydrogenation over Platinum.—The quinone (7.5 g.) in 190 cc. of acetic acid was shaken with 1 g. of Adams platinum oxide under about 4 atmospheres of hydrogen. At first the pressure fell very rapidly, and the orange color changed to a blue fluorescence. The reaction later became slower and an additional gram of catalyst was added on the second day. The theoretical amount of hydrogen was taken up on the fifth day. On exposure to air the resulting solution turned yellow and then a deep red. Removal of the solvent left an intensely red residue, which on crystallization from either benzene or toluene gave colorless crystals (2.3 g.). After several crystallizations from toluene *α-cis-syn-cis*-**perhydro-9,10-dihydroxyphenanthrene** was obtained as bold colorless needles, m. p. 173.9–174.4°.

Anal. Calcd. for $C_{14}H_{26}O_2$: C, 74.93; H, 10.80. Found: C, 74.92; H, 10.79.

A mixture of 0.3 g. of the α-glycol, 4 cc. of dry pyridine and 0.6 cc. of benzoyl chloride was heated at 50° for one week. The mixture was poured into dilute acid and extracted with chloroform. The extract was washed with aqueous sodium carbonate and with water, warmed with charcoal, and dried with sodium sulfate. The solvent was removed and the residue crystallized from hexane. The yield of the α-**dibenzoate** was 0.5 g., m. p. 153.5–154°.

Anal. Calcd. for $C_{28}H_{32}O_4$: C, 77.71; H, 7.46. Found: C, 77.40; H, 7.53.

Hydrogenation over Nickel.—A preliminary experiment indicated that at 110° and 80 atmospheres, the hydrogenation of phenanthraquinone over Raney nickel came to a stop after about two hours when about 60% of the theoretical amount of hydrogen had reacted. This would correspond approximately to the formation of Skita's compound (II) which involves the reaction of 6 of the total 8 mols of hydrogen (75%). On raising the temperature to 160° the reaction was resumed and the full amount of hydrogeu was taken up in just under two days.

The preparation was accordingly carried out as follows. A steel bomb of 1-l. capacity was charged with a mixture of 26 g. of pure phenanthraquinone, 150 cc. of absolute alcohol and 6 cc. of Raney nickel. The hydrogenation was allowed to proceed at 160° and 170 atmospheres and took nearly thirty-six hours. The resulting solution turned dark brown on exposure to air. It was diluted to about 200 cc. with alcohol and filtered hot through a column of charcoal and alumina. This removed almost all the color. The filtrate deposited 3.75 g. of crystals, m. p. 170–172°. Two crystallizations of this material from benzene yielded pure *β-cis-syn-cis*-**perhydro-9,10-dihydroxyphenanthrene,** m. p. 173.9–174.4°. The crystals are denser and more massive than those of the α-isomer. A mixture of the two compounds melts at 142–150°.

The filtrate from the above material was evaporated to 100 cc. and seeded with the β-glycol. This yielded a further 2.5 g. of nearly pure β-glycol. On further evaporation a little more β-glycol separated together with a second product which crystallized in large, clear prisms. These were separated partly mechanically and partly by taking advantage of the fact that the β-glycol dissolved faster in warm alcohol. The prisms melted at 148–152° and after three recrystallizations from benzene yielded the pure *γ-cis-syn-cis*-**perhydro-9,10-dihydroxyphenanthrene,** m. p. 154.5–155°.

The final residue from the fractional crystallizations was submitted to vacuum distillation. After removal of a viscous liquid boiling up to 180° (8 mm.) (which is probably partially de-oxygenated), the main portion distilled at 198–200° and set to a glassy solid. Crystallization of this from benzene with suitable seeding yielded more of the β- and γ-glycols.

The fraction boiling between 180 and 198° was mixed with hexane and allowed to stand. A crystalline solid was slowly deposited. The first crop was recrystallized from benzene. The crystals so obtained (60 mg.) melted at 179–183° and after two further crystallizations from benzene gave pure *α-cis-syn-trans*-**perhydro-9,10-dihydroxyphenanthrene,** long clear prisms, m. p. 184–184.5°. Further fractional crystallization of the remainder of the material led to the separation of more of all three forms (*β-* and *γ-cis-syn-cis,* m. p.'s 174 and 155°, and *α-cis-syn-trans,* m. p. 184°).

The total yield of crystalline glycols was 7.54 g. of the β-form, m. p. 174°, 3.96 g. of the γ-form, m. p. 155°, and 138 mg. of the *cis-syn-trans* form, m. p. 184°.

Anal. Calcd. for $C_{14}H_{24}O_2$: C, 74.93; H, 10.80. Found—for the β-glycol: C, 74.86; H, 10.94; for the γ-glycol: C, 75.05; H, 10.91; for the *cis-syn-trans*-glycol[12]: C, 74.81; H, 10.56.

By the method described above for the α-glycol, the β- and γ-glycols were converted into their dibenzoates. These melted at 115.5–116° (β), and 114.2–115° (γ), respectively. A mixture melted at 102–106°.

Anal. Calcd. for $C_{28}H_{32}O_4$: C, 77.71; H, 7.46. Found— for the β-dibenzoate: C, 77.46; H, 7.55; for the γ-dibenzoate: C, 77.50; H, 7.53.

Oxidation of the Glycols. (a) *α-cis-syn-cis*-**Glycol (m. p. 174°).**—This glycol (500 mg.) and 1.20 g. of lead tetraacetate were added to 50 cc. of benzene. The solid gathered in a lump which was crushed. After a few minutes the product was filtered and the insoluble solid washed with benzene. The filtrate and washings were freed from

(12) Analysis by Miss Eleanor Werble.

solvent and the oily residue was allowed to stand for two days at 4° with 3 cc. of 33% hydrogen peroxide and 5 cc. of 10% aqueous sodium hydroxide. The product was extracted with ether and the aqueous layer acidified. This precipitated a gummy mass, which was boiled with benzene and the insoluble portion crystallized from alcohol. This yielded *cis-syn-cis*-perhydrodiphenic acid (10 mg.), m. p. 273–280°, mixed m. p. 280–285°. The acid was further identified by conversion into the dimethyl ester, m. p. 69–71°, mixed m. p. 71–73°.

An attempt at the oxidation of the same glycol with potassium permanganate in acetone and with nitric acid at 50° failed to yield a solid acid.

(b) *β-cis-syn-cis*-**Glycol (m. p. 174°).**—The glycol (500 mg.) was dissolved in 50 cc. of hot benzene and the solution treated at 34° with 1.25 g. of lead tetraacetate. A very small temperature rise occurred. The mixture was allowed to stand overnight, filtered and the filtrate treated with alkaline hydrogen peroxide as described above. *cis-syn-cis*-Perhydrodiphenic acid was isolated in the manner already described, yield 30 mg., m. p. 275°, mixed m. p. 280°. The dimethyl ester had m. p. 72–73°, mixed m. p. 73–74°.

The same glycol (250 mg.) was shaken with potassium periodate (230 mg.) and dilute methanol, and then left at 55° overnight. Most of the methanol was removed, a solution of bromine in potassium hydroxide was added, and the product was extracted with ether. Acidification of the alkaline solution gave 40 mg. of acid melting at about 250°, and after one crystallization at 260–267°.

The β-glycol (300 mg.) was dissolved in acetic acid (10 cc.) and a solution of 900 mg. of chromic acid in a little water was added slowly. The solution was divided in half. The first half was allowed to stand at 0° for two hours, and the second half was kept at 75° for the same time. On dilution with water both portions gave *cis-syn-cis*-perhydrodiphenic acid [m. p. (crude) 275–277°] but the yield from the cold oxidation (30 mg.) was twice that from the reaction at 75°.

A very small yield of the same acid was obtained by oxidizing the β-glycol with Beckmann's mixture. No solid acid could be isolated by oxidations from potassium hypobromite.

(c) *γ-cis-syn-cis*-**Glycol (m. p. 155°).**—The glycol (100 mg.) was suspended in 1 cc. of acetic acid and a solution of chromic acid (120 mg.) in 2 cc. of dilute acetic acid was added during one hour at room temperature. The product was warmed on the steam-bath for five minutes. Addition of 10 cc. of water precipitated 18 mg. of *cis-syn-cis*-perhydrodiphenic acid, m. p. 270–274°. The identity was confirmed by the preparation of the dimethyl ester, m. p. 67–70°, mixed m. p. 70–72°.

The same acid was obtained by the oxidation of the 152° glycol (109 mg.) with peracetic acid (1.5 g. of 11.2%) for two months at room temperature. Evaporation of the solvent left a gum and a small amount of crystalline solid. The gum was removed by washing with cold benzene. There remained 5 mg. of *cis-syn-cis*-perhydrodiphenic acid, which was identified by m. p. and mixed m. p. Oxidation of the γ-glycol with lead tetraacetate or with potassium periodate did not yield a crystalline acid.

(d) *α-cis-syn-trans*-**Glycol (m. p. 184°).**—The glycol (100 mg.) was dissolved in glacial acetic acid (4 cc.) and a solution of 130 mg. of chromic acid in 1 cc. of acetic acid and 1 cc. of water was added slowly. The solution was allowed to stand at 4° overnight, diluted to 20 cc. with water and extracted four times with 5-cc. portions of ether. The ether was extracted with aqueous sodium hydroxide and the alkaline extract acidified and again extracted with ether. The ether was removed and the residual acetic acid solution was diluted with water. This yielded 41 mg. of *cis-syn-trans*-perhydrodiphenic acid, m. p. 197.5–199.5°, either alone or in admixture with authentic material. The second crop of acid was identical and equally pure. The identity was confirmed by the preparation of the anhydride, m. p. and mixed m. p. 103–104°.

Dehydration of the Glycols.—The method used was essentially that of Tiffeneau.[7] None of the three *cis-syn-cis* glycols yielded a ketone in sufficient amount to permit of the isolation of an oxime or semicarbazone, although indications of a positive reaction with 2,4-dinitrophenylhydrazine were obtained.

The γ-glycol, m. p. 155°, (150 mg.) was heated with 600 mg. of fused potassium bisulfate for four hours at 150–160°. The product was partitioned between chloroform and water. Evaporation of the chloroform layer left a mixture of an oil and a crystalline solid, which was washed with cold methanol. The methanol solution gave a very small amount of an oxime in the cold; this melted at 190–200° without crystallization. The residual crystals were almost insoluble in boiling alcohol, but easily soluble in hexane and benzene. After three crystallizations from ethyl acetate a pure *compound* was isolated which analyzes to $C_{14}H_{22}O$, or a polymer of this. It melts at 202–203° and is not affected by bromine in chloroform. This last property and the high m. p. do not agree with the decahydro-9-phenanthrol structure suggested by the analysis. A bimolecular structure with two ethereal oxygen atoms is possible, but the solubility in hydrocarbons seems high for so large a molecule.

Anal.[12] Calcd. for $C_{14}H_{22}O$: C, 81.49; H, 10.75. Found: C, 81.53; H, 10.55.

sym-**Decahydro-9,10-dihydroxyphenanthrene.**—Phenanthraquinone (3 g.) and 0.8 cc. of Raney nickel were treated with 20 cc. of alcohol and hydrogenated at 120°. Nearly exactly 5 mols of hydrogen was taken up. The resulting solution turned brown and later red in air. The solvent was removed under reduced pressure and the product crystallized from hexane. Fine white needles of the decahydro-glycol separated, m. p. 135–136° (Skita[2] gives m. p. 136°), yield 1.5 g. A mixture with *sym*-octahydro-9-phenanthrol (m. p. 135°) melted at 110–125°. Acetylation with sodium acetate and acetic anhydride gave a product of m. p. 160–161°. Skita[2] describes the diacetate as melting at 160°. Attempts to convert the decahydro-glycol to *sym*-octahydro-9-phenanthrol by means of potassium bisulfate and *p*-toluenesulfonic acid were unsuccessful. Oxidation of the decahydro-glycol with peracetic acid by Böeseken's method failed to yield an octahydrodiphenic acid.

Summary

The possibilities of stereoisomerism among the perhydro-9,10-dihydroxyphenanthrenes are indicated.

Phenanthraquinone is per-hydrogenated over platinum at 25° to a perhydro-9,10-dihydroxyphenanthrene, m. p. 174°, and over nickel at 160° to a mixture of three stereoisomers of the above, with m. p.'s 174° (not identical with the platinum product), 155 and 184°, respectively. The first three products have the *cis-syn-cis* configuration and may be oxidized to *cis-syn-cis*-perhydrodiphenic acid. The glycol of m. p. 184°, which is obtained in very small yield, has a *cis-syn-trans* configuration as it gives the *cis-syn-trans*-perhydrodiphenic acid on oxidation. The three *cis-syn-cis* glycols differ in the orientation of their hydroxyl groups and represent all the forms with this skeletal configuration which are theoretically possible. Over nickel at 120°, phenanthraquinone yields mainly Skita's decahydro-9,10-dihydroxyphenanthrene.

O-Pentaacetyl-*d*-gluconates of Polyhydric Alcohols and Cellulose[1]

BY M. L. WOLFROM AND P. W. MORGAN[2]

To our knowledge, only the methyl[3] and ethyl[4] esters of *d*-gluconic acid pentaacetate have been reported. The object of the present investigation was to prepare and characterize the O-pentaacetyl-*d*-gluconates of polyhydric alcohols and cellulose. Such esters were prepared from ethylene glycol, propanediol-1,3 (trimethylene glycol), bis-(2-hydroxyethyl) ether (diethylene glycol), glycerol, (*dextro*)-sorbitol, *d*-mannitol, α-methyl-*d*-glucoside, mercerized cotton linters and a modified cellulose acetate by reaction of these substances with an excess of *d*-gluconyl chloride pentaacetate in pyridine solution.

Ethylene glycol, propanediol-1,3 and bis-(2-hydroxyethyl) ether formed crystalline di-esters. Glycerol, (*dextro*)-sorbitol, *d*-mannitol and α-methyl-*d*-glucoside yielded fully esterified products in the form of colorless, amorphous powders. This lack of crystallizing power is not surprising, as the molecular weights of these esters are very high. Thus the ethylene glycol derivative has a molecular weight of 839 and the hexitol derivative ($C_{102}H_{134}O_{72}$, shown below) has a molecular weight of 2512.

$$\begin{array}{l} H_2COCO(HCOCOCH_3)_4CH_2OCOCH_3 \\ | \\ (HCOCO(HCOCOCH_3)_4CH_2OCOCH_3)_4 \\ | \\ H_2COCO(HCOCOCH_3)_4CH_2OCOCH_3 \end{array}$$

In the case of mercerized cotton linters, pyridine was found unsatisfactory as a reaction medium because the intense coloration developed by the acid chloride and pyridine, even at room temperature, was very strongly adsorbed on the fibers. Of several other tertiary bases tried as a substitute for pyridine in the reaction with cellulose, triethylamine in an inert solvent was found most satisfactory for the elimination of color. Using triethylamine as the base, a cream-colored, fibrous cellulose O-pentaacetyl-*d*-gluconate was obtained containing 0.45 O-pentaacetyl-*d*-gluconyl group per anhydroglucose unit. In pyridine, a modified cellulose acetate (1.72 acetyl group per anhydroglucose unit) yielded a mixed ester containing 0.75 O-pentaacetyl-*d*-gluconyl group per anhydroglucose unit, while with triethylamine in chloroform a product with 0.33 O-pentaacetyl-*d*-gluconyl groups was produced. The former was obtained as a cream-colored powder that was acetone and chloroform soluble and formed brittle films. The latter product was colorless, was acetone and chloroform soluble, and formed strong, flexible, transparent films.

Experimental

Preparation of the O-Pentaacetyl-*d*-gluconates of Several Polyhydric Alcohols.—The anhydrous polyhydric alcohol (0.5 g.) was dissolved in dry pyridine (50 cc.). Gluconyl chloride pentaacetate[4b] (9 g.) was quickly ground and added in approximately 1-g. portions to the solution with shaking. The mixture became warm and slowly turned deep orange in color. A crystalline water-soluble pyridine-complex separated after a few minutes. After standing overnight, the reaction mixture was diluted to incipient turbidity with water and the material crystallized. More water was added gradually until the volume was about 1 liter. This procedure was followed for the

[a] From 0.5 g. of the polyhydric alcohol. [b] Method of A. Kunz and C. S. Hudson, THIS JOURNAL, **48**, 1982 (1926); recorded as cc. 0.1 *N* NaOH per 100 mg. of substance. [c] Softening point.

first three products of Table I, where the alcohols were ethylene glycol, trimethylene glycol (propanediol-1,3) and diethylene glycol (bis-(2-(hydroxyethyl) ether). Crystalline products were obtained in each case and were purified by recrystallization from ethanol (decolorizing charcoal) and methanol–water. It was found that the addition of ethylene glycol to a solution of gluconyl chloride pentaacetate in pyridine gave no water-insoluble product and the solution became nearly black in color.

For the last four products of Table I (esters of glycerol, *dextro*-sorbitol, *d*-mannitol and α-methyl-*d*-glucopyranoside), the final products were obtained in the form of white, amorphous powders that resisted crystallization but were of analytical purity. These substances were isolated by pouring the reaction mixture through a small orifice into 800 cc. of a rapidly stirred mixture of ice and water. Purification was effected by solution in acetone (decolorizing charcoal) and precipitation by the addition of water. Colloidal solutions sometimes formed which were easily broken by the addition of a small amount of electrolyte. Drying was carried out slowly and below 45°. The esters of mannitol and of α-methyl-glucoside were purified from methanol (decolorizing charcoal)–water. In the case of mannitol, the reaction mixture was heated initially to 50° for five minutes and was then kept at room temperature overnight. The α-methyl-glucoside reaction mixture was kept at room temperature for seven days. All of the esters were soluble in the common solvents except petroleum ether and water.

Cellulose O-Pentaacetyl-*d*-gluconate.—High viscosity cotton linters[5] (0.5 g.) were mercerized for one hour at 20° in 25 cc. of 18% sodium hydroxide solution. The fibers were washed with water until free of alkali and placed in 50 cc. of dry nitrobenzene after solvent interchange with acetone and nitrobenzene. Triethylamine (0.7 cc.) and gluconyl chloride pentaacetate (5.2 g.) were added and the mixture heated at 80° for sixteen hours. The fibers were well dispersed but undissolved at the end of this time. The liquor showed no turbidity when diluted with large amounts of ethanol. The fibrous product was collected, thoroughly washed with acetone, water and ethanol, and then dried; yield 0.70 g. It was cream colored and resembled the original linters in texture.

A saponification was made according to the procedure of Malm and Clarke[6] for cellulose acetate. A blank was run on the solvent and on gluconic acid pentaacetate and corrections were made for a small absorption of alkali by the cellulose. The material was prepared for analysis by drying at 100° for three hours. The saponification equivalents found were 124.3 and 125.0 (8.04 cc. and 8.00 cc. of 0.1 *N* NaOH per 100 mg.). These correspond to 0.45 and 0.44 O-pentaacetyl-*d*-gluconyl group per anhydroglucose unit.

Cellulose Acetate O-Pentaacetyl-*d*-gluconate. Procedure A.—Cellulose acetate[7] (1.72 acetyl groups per anhydroglucose unit, 1.0 g.) was dissolved in 50 cc. of dry pyridine with 6.0 g. of gluconyl chloride pentaacetate and then kept at room temperature for one hundred and twenty hours. Upon pouring the mixture into rapidly stirred, cold water, a flesh-colored precipitate was obtained. The product was purified by precipitation with water from acetone solution and from pyridine solution (decolorizing charcoal), giving a cream-colored, amorphous powder; yield 1.53 g., spec. rot. +2.5° (24°, D line, *c* 3, $CHCl_3$), spec. rot. −10° (21°, *c* 1.5, dry pyridine). The substance was soluble in acetone, pyridine, glacial acetic acid, chloroform and warm tetrachloroethane. It was incompletely soluble in warm 75% ethanol. It formed dark yellow, brittle films. The original cellulose acetate was insoluble in acetone and chloroform, but was easily soluble in pyridine and warm 75% ethanol, and its specific rotation was −13° (24°, D line, *c* 3, dry pyridine).

The saponification equivalents[6] determined in acetone were 84.1 and 84.0 (11.89 cc. and 11.91 cc. 0.1 *N* NaOH per 100 mg.). These values correspond to 0.75 O-pentaacetyl-*d*-gluconyl group per anhydroglucose unit.

Procedure B.—Another sample of the same cellulose acetate (1.0 g.) was placed in 60 cc. of absolute chloroform with 1.0 cc. of triethylamine and 5.2 g. of gluconyl chloride pentaacetate and heated for forty-two hours at 60°. The mixture became orange in a short time and the cellulose acetate slowly went into solution. The solution was filtered and poured into 300 cc. of absolute ethanol, giving a gelatinous precipitate, which, after thorough washing with ethanol and water, dried to a colorless, amorphous powder;

yield 1.22 g., spec. rot. +1° (24°, D line, *c* 3.5, $CHCl_3$) and −9° (23°, D line, *c* 3.5, dry pyridine).

The product was soluble in acetone, chloroform, glacial acetic acid, pyridine, warm dioxane and benzene. It dissolved somewhat in warm 75% ethanol accompanied by strong swelling. It formed strong, flexible, colorless films from acetone or chloroform solutions.

The saponification equivalents[6] determined in acetone were 99.1 and 99.7 (10.09 cc. and 10.03 cc. 0.1 *N* NaOH per 100 mg.). These values correspond to 0.33 and 0.29 O-pentaacetyl-*d*-gluconyl groups per anhydroglucose unit. Repeated esterification of cellulose acetate under conditions similar to those described above did not raise the substitution above 0.37 O-pentaacetyl-*d*-gluconyl group per anhydroglucose unit.

Summary

1. Crystalline di-(O-pentaacetyl-*d*-gluconates) of ethylene glycol, propanediol-1,3 and bis-(2-hydroxyethyl) ether have been prepared by the reaction of the corresponding glycol with *d*-gluconyl chloride pentaacetate in pyridine.

2. Under similar conditions glycerol, (*dextro*)-sorbitol, *d*-mannitol and α-methyl-*d*-glucoside formed fully esterified O-pentaacetyl-*d*-gluconates in the form of colorless, amorphous powders.

3. Mercerized cotton linters were esterified in the presence of triethylamine and nitrobenzene, forming a fibrous product containing 0.4 O-pentaacetyl-*d*-gluconyl group per anhydroglucose unit.

4. A modified cellulose acetate (1.72 acetyl groups per anhydroglucose unit) in pyridine gave a mixed ester containing 0.7 O-pentaacetyl-*d*-gluconyl group per anhydroglucose unit and in chloroform and triethylamine, a mixed ester containing 0.3 O-pentaacetyl-*d*-gluconyl group per anhydroglucose unit was formed.

The Glyoxalines. II. A Study of the Reaction between Benzamidine and Phenylglyoxal

BY RICHARD C. WAUGH,* JOHN B. EKELEY AND ANTHONY R. RONZIO

A reaction between benzamidine and phenylglyoxal was reported by Kunckell and Bauer[1] in which a compound described as "phenacal benzamidine" (m. p. 224°) was isolated. When repeated by us the reaction proceeded exactly as described by them. The product obtained, recrystallized from ethyl alcohol, melted at 225°. Nitrogen analyses, however, failed to check the value for "phenacal benzamidine." The value obtained (13.65%) was so close to the value for kyanphenin (13.60%) that a melting point of the mixture was taken. The melting point found was 228° (m. p. of pure kyanphenin 230–231°). The solubilities and physical appearance of "phenacal benzamidine" and kyanphenin were also identical. The experiment was repeated many times with the same result. Hence, the work of Kunckell and Bauer was considered to be in error and the reaction between benzamidine and phenylglyoxal was re-investigated.

The products obtained from the reaction between benzamidine and phenylglyoxal under different conditions are shown in Chart I. Compound I was formed when the two reactants were treated with base in cold alcohol solution. Recrystallized from ethyl acetate, the product gave analyses corresponding to the formula $C_{17}H_{18}O_3N_2$. Since the compound formed readily in cold solution, it appeared likely that it was a simple addition product. The compound contains one-half molecule of ethyl acetate of crystallization.

Compound I is converted to Compound II by dissolving in basic solution, heating for a short time, then carefully neutralizing with acid. Recrystallized from dioxane, the analyses correspond to a compound $C_{17}H_{16}O_2N_2$.[2] The compound contains one-half molecule of dioxane of crystallization as proved by a cryoscopic determination.

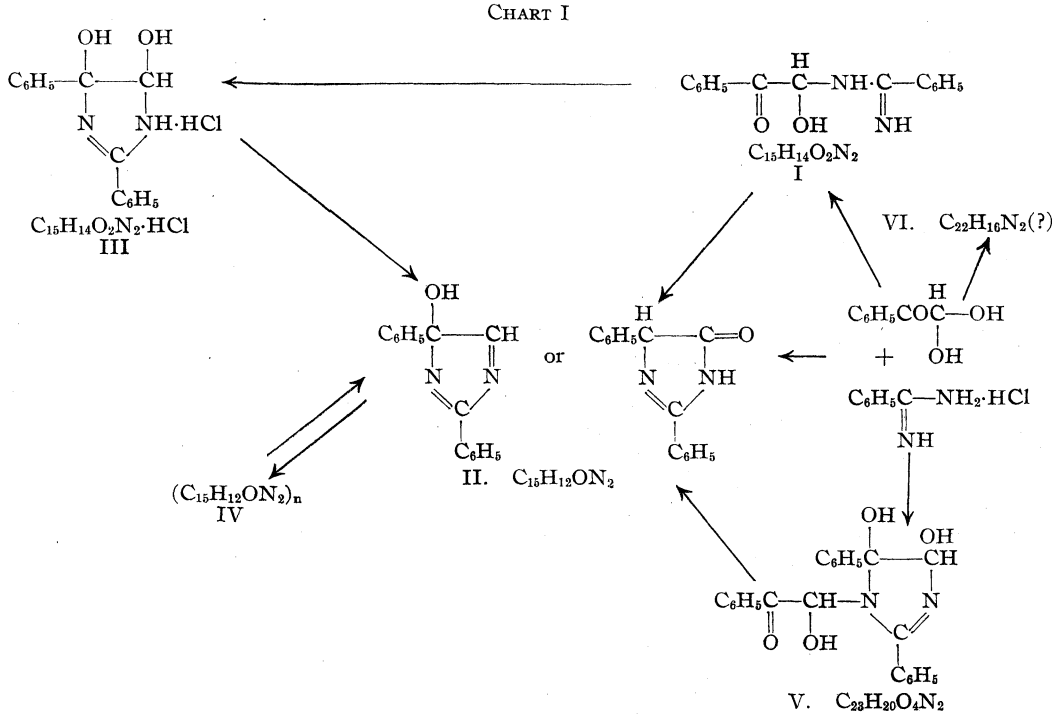
When a basic solution of either Compound I or II is treated with an excess of hydrochloric acid, a voluminous precipitate of the hydrochloride of Compound III is formed. This compound is very unstable in the absence of acids. Analyses gave results corresponding to the formula $C_{15}H_{14}O_2N_2 \cdot HCl$.

* Now with Eastman Kodak Co.

(1) Kunckell and Bauer, *Ber.*, **34**, 3029 (1901).

(2) In the first paper of this series [Fisher, Ekeley and Ronzio, THIS JOURNAL, **64**, 1434 (1942)] it has been shown that phenylglyoxal and urea react to form 4-phenyl-hydantoin. Should a similar reaction take place when benzamidine is used instead of urea, the formula for Compound II, would then be the second structure shown on Chart I.

CHART I



Upon standing in solvents containing traces of base, Compound II changes to Compound IV. This compound was insoluble in all the solvents tried. Analyses gave results corresponding to the empirical formula $C_{15}H_{12}ON_2$. It will be seen that this formula is identical to the formula for Compound II without any solvent of crystallization. The analyses and insolubility indicate that Compound IV is a polymer of Compound II.

Phenylglyoxal and benzamidine hydrochloride dissolved in a strong water solution of sodium acetate yields Compound V as an orange powder. When this powder is dissolved in hot alcohol, it almost instantly separates as yellow needles of Compound II. Analyses gave values which could not be formulated into any logical structure. The results were, however, close to those given by a reaction between two molecules of phenylglyoxal and one molecule of benzamidine. It is probable that the orange powder is Compound V mixed with a small amount of Compound II.

A compound of unknown structure (VI) giving analyses for $C_{22}H_{16}N_2$ was obtained by boiling benzamidine hydrochloride together with phenylglyoxal for several hours. Since a strong odor of ammonia was noted, it is probable that the product is formed from fragments of benzamidine and phenylglyoxal.

Experimental

Compound I. Hydroxyphenacylbenzamidine.—Concentrated potassium hydroxide was added to a cooled 95% alcohol solution containing 3 g. (0.02 mole) of phenylglyoxal hydrate and 3.8 g. (0.02 mole) of benzamidine hydrochloride until the solution was distinctly basic. The precipitated potassium chloride was filtered off and the filtrate was cooled in an ice–salt mixture.

Dropwise addition of water precipitated a colorless compound which was filtered off, dried and recrystallized from ethyl acetate containing just enough absolute ethyl alcohol to dissolve the compound. The compound must be dried *in air*. Either heat or a drying agent cause decomposition. The compound is soluble in acids, bases, alcohol, acetone and dioxane; insoluble in ether, hydrocarbons and chloroform; m. p. 112–115° with decomp., yield, 2.4 g. (40%).

Anal. Calcd. for $2(C_{15}H_{14}O_2N_2)\cdot CH_3\text{-}COO\text{-}C_2H_5$: C, 68.60; H, 6.05; N, 9.30. Found: C, 68.83; H, 5.99; N, 9.40.

Compound II. 2,4-Diphenyl-4-hydroxyglyoxaline (or 2,4-Diphenyl-5-ketodihydroglyoxaline).—Three grams of phenylglyoxal hydrate (0.02 mole) and 3.8 g. of benzamidine hydrochloride (0.02 mole) were dissolved in 200 ml. of warm water. The addition of 1 ml. of 50% potassium hydroxide and boiling caused a deep brown color to form. After fifteen minutes the solution was cooled and carefully neutralized, whereupon a flocculent yellow solid formed. Recrystallized from dioxane, the sparkling yellow needles melted at 251–252°; the yield was 64%.

Anal. Calcd. for $2(C_{15}H_{12}ON_2)\cdot C_4H_8O_2$: C, 72.90; H, 5.72; N, 10.00. Found: C, 72.80; H, 5.80; N, 10.03.

A molecular weight determination by the method of Smith and Young[3] gave a value of 189. Calcd. for $2(C_{15}$-

(3) J. Smith and W. Young, *J. Biol. Chem.*, **75**, 289 (1927).

$H_{12}ON_2)\cdot C_4H_5O_2$: mol. wt., 189. The compound is soluble in base, alcohol, dioxane and ethyl acetate; insoluble in ether, acetone and the hydrocarbons; soluble in acids but reprecipitates in a short time. A basic alcohol solution of the compound shows a blue fluorescence upon the addition of ether.

The same compound may be prepared by dissolving Compound I in hot base, followed by neutralization of the solution with acid.

A portion of this compound boiled with acetic anhydride yielded a gummy solid, which, recrystallized from a mixture of dioxane and water, yielded colorless plates of the monoacetyl derivative melting at 174°.

Anal. Calcd. for $C_{17}H_{14}O_2N_2$: C, 73.40; H, 5.05; N, 10.07. Found: C, 73.50; H, 5.00; N, 9.95.

Compound III. 2,4-Diphenyl-4,5-dihydroxydihydroglyoxaline.—A solution of 3 g. (0.02 mole) of phenylglyoxal hydrate and 3.8 g. (0.02 mole) of benzamidine hydrochloride in 50 ml. of glacial acetic acid was refluxed. Within ten minutes a white precipitate began to form. After being heated for an hour the mixture was cooled and filtered. The solid gave a positive chloride test. The product was recrystallized from glacial acetic acid containing enough concentrated hydrochloric acid to prevent the formation of a yellow color. The colorless needles obtained in this manner melted at 282° after darkening at 260°; the yield was 62%.

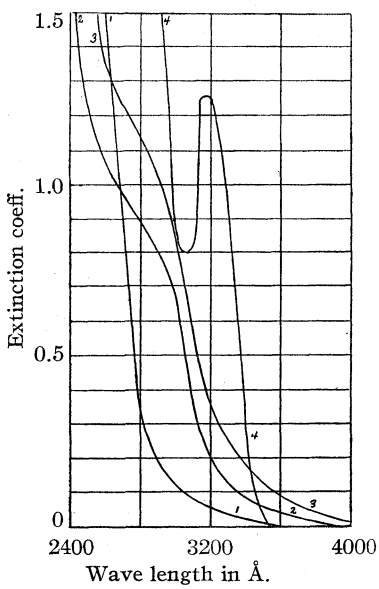


Fig. 1.

The compound was also prepared by adding a large excess of concentrated hydrochloric acid to a basic solution of either Compound I or Compound II. This method of preparation is less convenient.

In the absence of acid the compound quickly forms Compound II.

Anal. Calcd. for $C_{15}H_{14}O_2N_2\cdot HCl$: C, 62.00; H, 5.17; N, 9.65. Found: C, 61.90; H, 5.20; N, 9.50.

Compound III refluxed with acetic anhydride yielded a gummy product which, when recrystallized from dioxane–water mixture, yielded colorless plates of the diacetyl derivative which melted at 181° after three recrystallizations.

Anal. Calcd. for $C_{19}H_{18}O_3N_2$: C, 70.85; H, 5.95; N, 8.70. Found: C, 70.90; H, 5.65; N, 8.85.

Compound IV $(C_{15}H_{12}ON_2)_x$.—When an alcohol or dioxane solution of Compound II containing a trace of base was allowed to stand, it gradually lost its yellow color and a white powder was deposited. Insoluble in the solvents tried, the powder was washed successively with boiling alcohol, ethyl acetate, methyl alcohol, dioxane and acetone. After this treatment the compound darkened at 250° and melted at 262°.

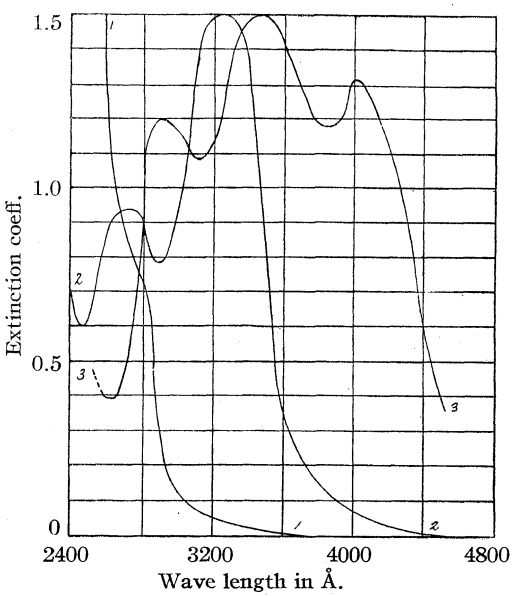

Fig. 2.

Attempts at acetylation produced an unrecrystallizable gum. Solution in hot base regenerated Compound II which was precipitated upon neutralization.

Anal. Calcd. for $(C_{15}H_{12}ON_2)_x$: C, 76.30; H, 5.08; N, 11.80. Found: C, 76.20; H, 4.73; N, 11.85.

Compound V. 2,4-Diphenyl-4,6-dihydroxy-3-(β-hydroxyphenacyl)-dihydroglyoxaline.—A water solution made by dissolving 3.8 g. (0.02 mole) of benzamidine hydrochloride, 3 g. (0.02 mole) of phenylglyoxal hydrate and 10 g. of sodium acetate in 200 ml. of water was allowed to stand for three days at room temperature. A brilliant orange powder was formed which defied all attempts at recrystallization; weight 3.3 g. (87%). The compound dissolved easily in alcohol, then, upon standing about one minute, yellow needles of Compound II precipitated out. The only purification that could be carried out was solution in benzene followed by precipitation of the compound by adding petroleum ether. The melting point of the product thus purified was 73–80°.

Anal. Calcd. for $C_{23}H_{20}O_4N_2$: C, 71.10; H, 5.16; N, 7.23. Found: C, 72.80; H, 5.14; N, 7.50.

Partial decomposition to Compound II is the only explanation which can, at present, be offered for these anomalous results.

Compound VI, $C_{22}H_{16}N_2$.—When 3 g. (0.02 mole) of phenylglyoxal hydrate and 3.8 g. (0.02 mole) of benzamidine hydrochloride in 300 ml. of water were boiled for three hours, a gummy substance formed which was filtered from the hot solution and recrystallized three times from ethyl alcohol. The colorless needles obtained melted at 170–172°. The yield was less than 1%.

Anal. Calcd. for $C_{22}H_{16}N_2$: C, 85.70; H, 5.19; N, 9.09. Found: C, 85.83; H, 5.38; N, 9.18.

No structure could be assigned to fit the formula and which would explain its formation. It would appear that the compound is the result of reaction between decomposition fragments.

TABLE I

ABSORPTION SPECTRA CURVES (1-CM. CELL)

Plate	Compound	Formula	Wt. used, g.	Solvent, ml.	Curve
I	IV	$(C_{15}H_{12}ON_2)_x$	0.00277	50 1% KOH	1
I	II	$2(C_{15}H_{12}ON_2)\cdot C_4H_8O_2$	.00250	50 1% KOH	2
I	III	$C_{15}H_{14}O_2N_2\cdot HCl$	.00266	50 1% KOH	3
I	VI	$C_{22}H_{16}N_2$	.00338	50 abs. EtOH	4
II	I	$2(C_{15}H_{14}O_2N_2)\cdot C_4H_8O_2$	.00250	50 abs. EtOH	1
II	III	$C_{15}H_{14}O_2N_2\cdot HCl$	.00112	50 EtOH contg. 5 ml. concd. HCl	2
II	II	$2(C_{15}H_{12}ON_2)\cdot C_4H_8O_2$	.00198	50 abs. EtOH	3

Absorption spectra data were obtained using a Hilger E3 spectrograph, Hilger Sector photometer and Eastman Wrattan and Wainwright Panchromatic plates. An under-water spark served as a light source.

It may be seen that Curves II and III, Plate I, and Curve I, Plate II are identical. This clearly demonstrates the formation of Compound II when base is added to a solution of either Compound I or Compound III.

Summary

1. The reaction between benzamidine and phenylglyoxal has been studied and found to yield a 2,4-diphenyl-4-hydroxyglyoxaline (or 2,4-diphenyl-5-keto-dihydroglyoxaline).

2. Intermediate, unstable compounds have been isolated and studied, and formulas proposed for them.

3. Absorption spectra curves in the ultraviolet and visible have been obtained for the compound studied.

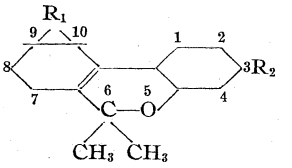
Some Analogs of Synthetic Tetrahydrocannabinol

BY GORDON A. ALLES, ROLAND N. ICKE AND GEORGE A. FEIGEN

The recent elucidation of the structure of cannabinol by Adams and co-workers,[1] and the discovery of marihuana activity in synthetic tetrahydrocannabinol[2a] and hexahydrocannabinol[2b] has opened the field for study of relationships between chemical constitution and this type of physiological action. The optically active tetrahydrocannabinols and hexahydrocannabinols derived by isomerization of cannabidiol[3] are of considerable interest in this connection, though their exact structure is in some doubt. Similarly, pulegone-5-*n*-alkylresorcinol products studied by Todd and co-workers,[4] and by Adams and co-workers[5] are of much interest, though the composition of such products is not yet certain.

Several series of compounds of known structure that are analogs or homologs of synthetic tetrahydrocannabinol and hexahydrocannabinol have been prepared by Adams and co-workers,[5,6] by Todd and co-workers[4,7] and by Bembry and Powell.[8] The object of the present work was to prepare and study the physiological activity of a series of analogs of synthetic tetrahydro*nor*cannabinol[5,7,8] (Series I) and of tetrahydrocannabinol (Series II) that lack a hydroxyl group in the 1-position.



Series I, $R_1 = H$
Series II, $R_1 = CH_3$

The series of compounds were prepared in which the R_2 group in the 3-position was amyl, methyl, hydroxy, butyloxy, butyroxy, ethoxy and acetoxy. Of these, the hydroxy and acetoxy com-

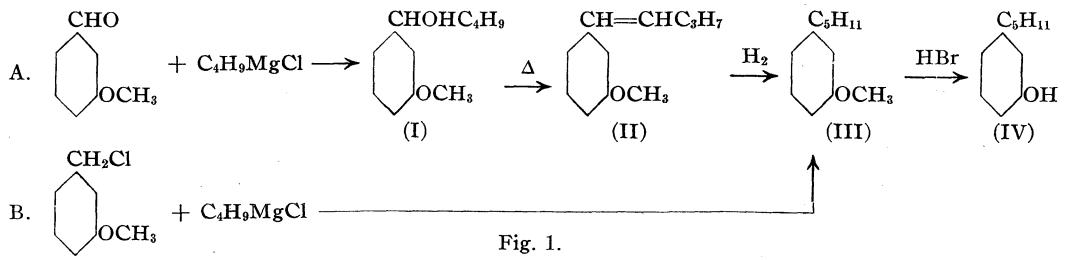

Fig. 1.

pounds had been previously prepared[7a] and reported to be inactive in the rabbit up to a dosage of 5 mg. per kg. intravenously, but were included in the present work for testing in dogs and extension of the rabbit testing. Synthetic tetrahydrocannabinol was prepared for use as a physiological test standard by making 1-hydroxy-3-*n*-amyl-9-methyl-7,8,9,10-tetrahydro-6-dibenzopyrone following the method of Adams and Baker,[1b] then converting this pyrone into the desired 6,6-dimethylpyran by the method of Ghosh, Todd and Wilkinson.[7a]

The synthesis of 3-*n*-amyl-6,6-dimethyl-7,8,9,-10-tetrahydro-6-dibenzo-pyran (VI) and 3-*n*-amyl-6,6,9-trimethyl-7,8,9,10-tetrahydro-6-dibenzopyran (VIII) required the previously unknown 3-*n*-amylphenol (IV), which was prepared by two different routes, as shown in Fig. 1.

The amyl pyrones were prepared by the condensation of 3-*n*-amylphenol (IV) with the properly substituted cyclohexanone-2-carboxylate in accord with Sen and Basu.[9]

The butyl ethers of the hydroxy pyrones were prepared by two different methods as outlined in Fig. 2. The corresponding butyloxy pyrans were prepared both from the butyloxy pyrones and by direct butylation of the hydroxy pyrans.

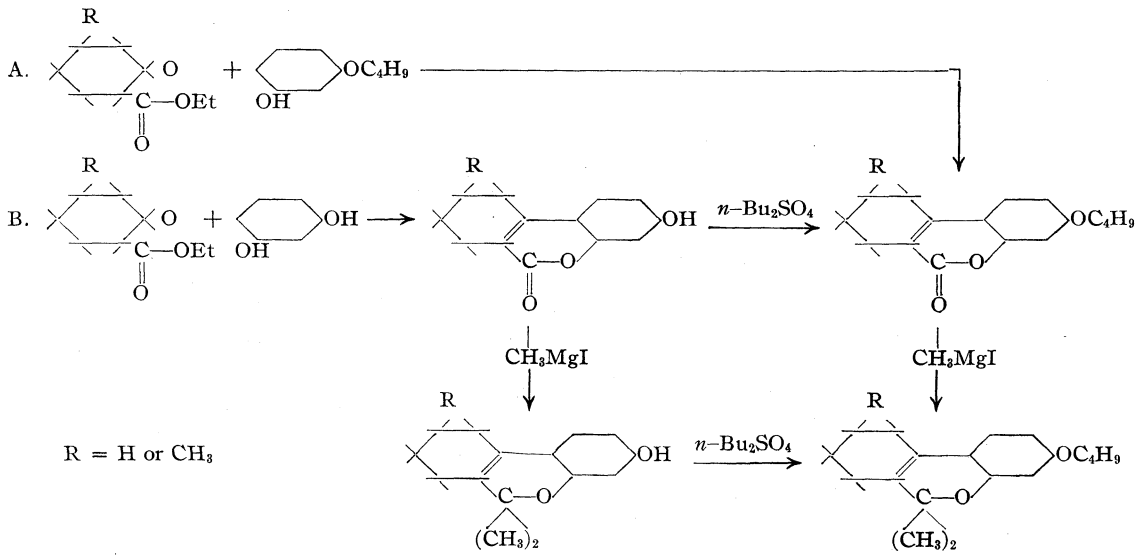

Fig. 2.

Experimental

3-Methoxyphenyl-*n*-butylcarbinol (I).—A solution of 69.5 g. of 3-methoxybenzaldehyde in 150 ml. of ether was added slowly to a Grignard reagent prepared from 25 g. of magnesium and 101.5 g. of *n*-butyl chloride in 300 ml. of ether. After refluxing for one-half hour, the solution was poured into an excess of ice–sulfuric acid. On distillation, there was obtained 90.8 g. (92% yield) of a viscous, colorless oil, b. p. 115–125° (1 mm.). Redistillation gave, with very little loss, the product b. p. 128.5–129° (5 mm.), d^{25}_4 1.009.

Anal. Calcd. for $C_{12}H_{18}O_2$: C, 74.16; H, 9.34. Found: C, 74.2; H, 9.50.

1-(3-Methoxyphenyl)-amylene-1 (II).—A mixture of 54 g. of I and 10 g. of finely powdered potassium bisulfate was heated in an oil-bath at 135–160° for one hour. After all the water, which readily split out during the heating, had been removed, the product was distilled without further treatment, yielding 33.7 g. of a colorless liquid, b. p. 92–99° (1 mm.), d^{25}_4 0.985.

3-Methoxy-*n*-amylbenzene (III).—A.—A solution of 29.3 g. of II in 100 ml. of ethanol with 100 mg. of palladium oxide catalyst was reduced at room temperature under 3 atmospheres pressure of hydrogen, absorbing nearly the theoretical quantity in twenty minutes. After filtering off

(9) Sen and Basu, *J. Indian Chem. Soc.*, **5**, 467 (1928).

the catalyst and distilling the ethanol, there was obtained 24.1 g. (81.5% yield) of a colorless liquid, b. p. 97–98° (3 mm.), d^{25}_4 0.947.

B.—3-Methoxybenzyl alcohol was prepared by Raney nickel and hydrogen reduction of the aldehyde at 90° under 90 atmospheres pressure. Treatment of 138 g. of the alcohol with 200 ml. of concentrated hydrochloric acid and 30 g. of anhydrous calcium chloride yielded 3-methoxybenzyl chloride, b. p. 75° (2 mm.), 78.3 g. of this in 100 ml. of dry benzene was added to a Grignard reagent prepared from 24.3 g. of magnesium, 92.5 g. of *n*-butyl chloride and 200 ml. of anhydrous ether. After distilling the ether and adding 200 ml. of dry benzene, the mixture was refluxed for thirty hours, then decomposed with ice–sulfuric acid. The benzene extract was separated, washed with dilute alkali, then water, and finally distilled to yield 15.2 g. of a colorless liquid, b. p. 96–99° (3 mm.), d^{25}_4 0.947.

Anal. Calcd. for $C_{12}H_{18}O$: C, 80.8; H, 10.17. Found: C, 79.6; H, 10.11.

Preparations A and B were demethylated separately and in each case the resultant phenol had the same properties.

3-*n*-Amylphenol (IV).—A mixture of 22 g. of III and 100 g. of 30% hydrobromic acid in glacial acetic acid was sealed in a bomb tube and heated for 3.5 hours in a boiling water-bath. The mixture became homogeneous during the heating period. After cooling, five volumes of water and about 5 g. of sodium bisulfite were added, then the solution was neutralized with sodium bicarbonate. Ether was added, the ether extract washed well with water, then the phenol extracted with excess 10% potassium hydroxide solution. Ether extraction of the alkali extract after acidification yielded 10 g. of a colorless viscous liquid, b. p. 103–108° (2 mm.). Upon redistillation this gave a main fraction, b. p. 99–100° (1 mm.), d^{25}_4 0.964. Yields by demethylating with constant boiling hydriodic acid were practically the same and the product identical.

Anal. Calcd. for $C_{11}H_{16}O$: C, 80.35; H, 9.81. Found: C, 79.94; H, 9.73.

The 3,5-dinitrobenzoate, recrystallized from isopropanol, melted at 70°.

Anal. Calcd. for $C_{18}H_{18}N_2O_6$: C, 60.5; H, 5.06. Found: C, 60.7; H, 5.12.

Excepting this dinitrobenzoate, all the preceding compounds proved to be difficult to analyze, since all had a tendency to explode during combustion.

3-*n*-Amyl-7,8,9,10-tetrahydro-6-dibenzopyrone (V).—To a mixture of 8.2 g. of IV and 8.7 g. of ethyl cyclohexanone-2-carboxylate cooled below 0°, was added slowly 40 ml. of concentrated sulfuric acid (also cooled to 0°), keeping the temperature below 25° by means of an ice-bath during the addition. The solution was allowed to stand for two hours in the cold-bath, poured onto crushed ice, and the salmon-colored viscous oil extracted with benzene. The benzene solution was washed with water, any unreacted phenol was extracted with 10% potassium hydroxide solution and washed again with water until the washings were neutral to litmus. After drying over magnesium sulfate, the benzene was removed, the unreacted ester (about 3 g.) was recovered under reduced pressure and, finally, the product was distilled under a mercury vapor pump vacuum (10 μ) with 180–185° oil-bath. A yield of 3.72 g. of pale yellow viscous liquid was obtained.

Anal. Calcd. for $C_{18}H_{22}O_2$: C, 79.96; H, 8.20. Found: C, 79.99; H, 8.20.

3-*n*-Amyl-6,6-dimethyl-7,8,9,10-tetrahydro-6-dibenzopyran (VI).—To a Grignard reagent prepared in the usual manner from 5.1 g. of magnesium and 30.2 g. of methyl iodide in anhydrous anisole was added a solution of 3.7 g. of V in 50 ml. of anisole. This solution was heated at 100° for eight hours with continuous mechanical stirring, cooled, poured onto ice containing 50 ml. of 12 *N* sulfuric acid and the anisole steam distilled. The residue was extracted with ether; the ether extract was washed with dilute sodium bicarbonate and then with water, dried over magnesium sulfate, and after removal of the solvent the product was distilled under 0.5 μ with a 140–145° bath, obtaining 3.5 g.(90% yield) of a pale yellow viscous liquid.

Anal. Calcd. for $C_{20}H_{28}O$: C, 84.45; H, 9.92. Found: C, 83.93; H, 9.86.

3-*n*-Amyl-9-methyl-7,8,9,10-tetrahydro-6-dibenzopyrone (VII).—This compound was prepared in the same manner as V from 10.8 g. of IV, 14.7 g. of ethyl 5-methyl-cyclohexanone-2-carboxylate, and 40 ml. of concentrated sulfuric acid. The yield was 5.9 g. of a viscous, pale yellow liquid, distilling at 3 μ with 200–205° bath.

Anal. Calcd. for $C_{19}H_{24}O_2$: C, 80.24; H, 8.51. Found: C, 80.28; H, 8.54.

3-*n*-Amyl-6,6,9-trimethyl-7,8,9,10-tetrahydro-6-dibenzopyran (VIII).—This compound was prepared by the same method as VI in 88% yield, distilling at 2 μ with a 155–160° bath.

Anal. Calcd. for $C_{21}H_{30}O$: C, 84.51; H, 10.13. Found: C, 84.50; H, 10.35.

3-Methyl-7,8,9,10-tetrahydro-6-dibenzopyrone (IX)[9] **and 3,9-dimethyl-7,8,9,10-tetrahydro-6-dibenzopyrone (X)** were prepared in the same manner as the amyl pyrones. Product X melted at 105–106°.

Anal. Calcd. for $C_{15}H_{16}O_2$: C, 78.93; H, 7.07. Found: C, 78.94; H, 7.60.

3,6,6-Trimethyl-7,8,9,10-tetrahydro-6-dibenzopyran (XI) and **3,6,6,9-tetramethyl-7,8,9,10-tetrahydro-6-dibenzopyran (XII)** were made by the same method as the amyl pyrans. XI distilled at 0.5 μ with a 100–105° bath.

Anal. Calcd. for $C_{16}H_{20}O$: C, 84.10; H, 8.83. Found: C, 83.80; H, 8.55.

XII distilled at 10 μ with 130–135° bath.

Anal. Calcd. for $C_{17}H_{22}O$: C, 84.24; H, 9.15. Found: C, 84.40; H, 9.11.

3-Hydroxy-7,8,9,10-tetrahydro-6-dibenzopyrone (XIII) and **3-hydroxy-9-methyl-7,8,9,10-tetrahydro-6-dibenzopyrone (XIV)** were made by Adams and Baker's[2a] modification of the method of Ahmad and Desai,[10] in yields of 86 and 80%, respectively.

3-Hydroxy-6,6-dimethyl-7,8,9,10-tetrahydro-6-dibenzopyran (XV) and **3-hydroxy-6,6,9-trimethyl-7,8,9,10-tetrahydro-6-dibenzopyran (XVI)** were made by the method of Todd and co-workers,[7a] except that the hydroxy pyrones, rather than the acetates, were converted into the pyrans.

(10) Ahmad and Desai, *J. Univ. Bombay*, **6**, Pt. II, 89 (1937).

3-*n*-Butyloxy-7,8,9,10-tetrahydro-6-dibenzopyrone (XVII)—A.—Ethyl cyclohexanone-2-carboxylate and resorcinol mono-*n*-butyl ether, obtained in 65% yield,[11] were condensed with phosphorus oxychloride in dry benzene.[2a] The product boiled at 240–243° under 3 mm. pressure and crystallized in the condenser. Crystallization from 95% ethanol gave fine white needles, m. p. 86–87°.

Anal. Calcd. for $C_{17}H_{20}O_3$: C, 75.02; H, 7.41. Found: C, 75.4; H, 7.31.

B.—Slightly more than 0.01 mole of di-*n*-butyl sulfate[12] was added to a mechanically stirred solution of 0.01 mole of XIII dissolved in 6 ml. of 2 *N* sodium hydroxide solution. After warming in an oil-bath at 90–110° for 1.5 hours, the mixture was allowed to cool slowly with continued rapid stirring. The excess sulfate was destroyed with concentrated ammonium hydroxide solution, and the precipitate was filtered off and crystallized from 95% ethanol in long, white, glistening needles. The yield was 2.2 g. of product, m. p. 87–88°. A mixture of this product with that from method **A**, m. p. 86–88°.

Anal. Calcd. (Same as **A**). Found: C, 74.4; H, 7.41.

3-*n*-Butyloxy-6,6-dimethyl-7,8,9,10-tetrahydro-6-dibenzopyran (XVIII).—To a Grignard reagent, prepared from 2.8 g. of magnesium and 16.5 g. of methyl iodide in 25 ml. of anisole, was added 4.5 g. of XVII. This solution was heated at 100° with continuous stirring for eight hours and then worked up in the same manner as VI. The yield was 3.4 g. of colorless viscous liquid distilling at 1 μ with a 133–134° bath.

Anal. Calcd. for $C_{19}H_{26}O_2$: C, 79.68; H, 9.15. Found: C, 79.52; H, 9.24.

3-*n*-Butyloxy-6,6,9-trimethyl-7,8,9,10-tetrahydro-6-dibenzopyran (XIX).—A solution of 2.44 g. of XVI in 10 ml. of 2 *N* sodium hydroxide solution was heated with 2.1 g. of di-*n*-butyl sulfate in an oil-bath at 90–110° for 1.5 hours with continuous mechanical stirring. The solution was cooled, extracted with ether, the extract washed well with water, and dried over magnesium sulfate. The yield was 2.9 g. of viscous yellow oil, distilling at 5 μ with 162–168° bath.

Anal. Calcd. for $C_{20}H_{28}O_2$: C, 79.96; H, 9.39. Found: C, 80.65; H, 9.15.

3-*n*-Butyroxy-6,6-dimethyl-7,8,9,10-tetrahydro-6-dibenzopyran (XX).—To 2.3 g. of XV was added 6.3 g. of *n*-butyric anhydride. Upon the addition of one drop of concentrated sulfuric acid, the hydroxypyran went into solution with a slight amount of spontaneous warming. After standing at room temperature for one hour the mixture was heated at 100° for 1.5 hours, cooled, considerable water added, and the organic layer separated. Any unreacted anhydride was hydrolyzed in accordance with Smith, Bryant and Mitchell's[13] pyridine–sodium iodide method. The resulting solution was cooled, diluted with 4 volumes of water and acidified with 4 *N* hydrochloric acid. The organic layer was separated with the aid of some ether, washed with water, and finally dried over magnesium sulfate. The yield was 2.1 g. of colorless, viscous liquid, distilling at 1 μ with 155–160° bath.

Anal. Calcd. for $C_{19}H_{24}O_3$: C, 75.97; H, 8.06. Found: C, 76.04; H, 8.49.

3-*n*-Butyroxy-6,6,9-trimethyl-7,8,9,10-tetrahydro-6-dibenzopyran (XXI).—This was prepared in the same way as XX from 2.44 g. of XVI and 6.33 g. of *n*-butyric anhydride. The yield was 2.6 g. of colorless, viscous liquid, distilling at 2 μ with 160–165° bath.

Anal. Calcd. for $C_{20}H_{26}O_3$: C, 76.40; H, 8.34. Found: C, 76.60; H, 8.56.

3-Ethoxy-6,6-dimethyl-7,8,9,10-tetrahydro-6-dibenzopyran (XXII).—This was prepared in the same manner as XIX, except that ethyl sulfate was used. The product, a pale yellow viscous liquid, was obtained in 91% yield, distilling at 5 μ with 120–125° bath.

Anal. Calcd. for $C_{17}H_{22}O_2$: C, 78.96; H, 8.56. Found: C, 78.32; H, 8.50.

3-Ethoxy-6,6,9-trimethyl-7,8,9,10-tetrahydro-7-dibenzopyran (XXIII).—This was also prepared by the same method as for XIX. The product, a viscous yellow liquid, was obtained in 78.6% yield, distilling at 10 μ with 145–150° bath.

Anal. Calcd. for $C_{18}H_{24}O_2$: C, 79.37; H, 8.88. Found: C, 78.70; H, 8.82.

3-Acetoxy-6,6-dimethyl-7,8,9,10-tetrahydro-6-dibenzopyran (XXIV) and **3-acetoxy-6,6,9-trimethyl-7,8,9,10-tetrahydro-6-dibenzopyran (XXV)** were prepared from XV and XVI by treatment with acetic anhydride and pyridine, yielding products corresponding to those of Todd and coworkers,[7a] which melted at 65–66° and 59–60°, respectively.

These pyrans that were synthesized in this work were tested for their marihuana activity in dogs by the method of Dixon.[14] Oral administration of each of the compounds of both Series I and II in doses of 50 and 100 mg. per kg. was tried, without the production of ataxia or the other symptoms of marihuana activity. In these same animals 8 mg. per kg. orally of synthetic tetrahydrocannabinol did produce notable ataxia.

The same pyrans were tested for their ability to produce corneal anesthesia in rabbits, following the method of Gayer[15] for testing of marihuana activity. Intravenous administration of each of the compounds of both Series I and II in 10% solution in acetone in doses of 10 and 20 mg. per kg. was tried, without the production of corneal anesthesia. These findings of inactivity in rabbits with regard to XV, XVI, XXIV and XXV extend the similar observations on these compounds made by Ghosh, Todd and Wilkinson.[7a] The testing of different preparations of synthetic tetrahydrocannabinol with doses of 1, 2, 4, 8, 16 and 32 mg. per kg. intravenously, each given to two different animals, did not cause any corneal anesthesia, though with the highest dosages there was some sluggishness of response. Ghosh, Todd and Wright[4] reported this compound to be active at 1 mg. per kg. intravenously in rabbits, and we are unable to explain the discrepancy between

these findings. Two different lots of synthetic tetrahydrocannabinol were prepared, and the rabbits used were shown to be responsive on subsequent days to fresh extracts of charas made with ethanol, evaporated, and taken up with acetone for testing.

We are indebted to Dr. C. E. Redemann for the analyses reported in this paper, and wish to thank him for many helpful suggestions made during the course of this work.

Summary

1. 3-*n*-Amylphenol has been prepared by two methods.

2. Derivatives of 6,6-dimethyl-7,8,9,10-tetrahydro-6-dibenzopyran substituted in the 3-position by *n*-amyl, methyl, hydroxy, butyloxy, butyroxy, ethoxy and acetoxy groups have been prepared.

3. Corresponding derivatives of 6,6,9-trimethyl-7,8,9,10-tetrahydro-6-dibenzopyran have also been prepared.

4. Neither of these two series of pyrans exhibits any significant degree of marihuana activity in dogs or rabbits.

The Optical Configuration of Glutamic Acid Isolated from Casein Hydrolyzates by Six Procedures[1]

BY JEANETTE C. OPSAHL AND L. EARLE ARNOW[2]

Kögl, *et al.*,[3,4,5] have claimed that the modification of the Foreman procedure employed by Chibnall, *et al.*,[6] isolates preferentially *l*(+)-glutamic acid, leaving much of the *d,l*-glutamic acid in the mother liquor. For example, they[5] isolated 2.472 g. of *l*(+)-glutamic acid from 23.4 g. of pig kidney protein by Chibnall's procedure. Two grams of *d,l*-glutamic acid then was added to the mother liquor, and the isolation was repeated. 1.290 g. of glutamic acid was isolated; the sample was found to contain 0.9335 g. of *l*(+)-glutamic acid and 0.3569 g. of *d*(−)-glutamic acid. The interpretation of this type of experiment is complicated by the possibility that the original isolation might not have been quantitative. In other words, the material recovered in the second isolation conceivably might have reflected more or less accurately the composition of the glutamic acid present in the mother liquor. Chibnall and his collaborators[6] isolated small amounts of *d,l*-glutamic acid from both normal and malignant tissue protein hydrolyzates by their procedure. However, they did not report experiments in which *d,l*-glutamic acid had been added to the hydrolyzate prior to isolation.

Graff, Rittenberg and Foster[7] added *d,l*-glutamic acid to protein hydrolyzates, and found that the material isolated by their modified Foreman procedure contained both optical forms of glutamic acid. However, they were investigating the optical composition of the glutamic acid in the hydrolyzates by means of an isotope (N^{15}) dilution method, and the percentages of *d*(−)-glutamic acid in the material actually isolated were not given in their paper.

It has been shown in several laboratories[8,9,10] that glutamic acid slowly racemizes in boiling hydrochloric acid solutions. Several reports describing the isolation of glutamic acid containing small percentages of *d*-isomer have been recorded.[6,11,12,13] This latter finding casts some doubt on the accuracy of the isotope dilution method as employed by Graff, *et al.*[7] If the figure reported by these workers for the *d*-isomer content of the glutamic acid of tissue protein hydrolyzates (not more than 0.5 ± 0.5%) is accepted, it then becomes necessary to assume that the methods

[a] Theoretical: C, 32.71%; H, 5.49%; N, 7.63%. Carbon and hydrogen analyses were done by the Organic Microanalytical Laboratory, University of Minnesota. [b] Theoretical: +31.6°, calculated for free *l*(+)-glutamic acid in 9% hydrochloric acid. [c] Grossly contaminated with barium chloride. [d] This sample accidentally lost prior to carbon and hydrogen analyses.

employed by others preferentially concentrate the *d*-isomer. Since the *d,l*-form is about twice as soluble as the *l*-form in the hydrochloric acid solution usually used for crystallization,[4,7] it seems unlikely that such a preferential concentration occurs, at least in cases in which seeding is not employed.

Experimental Plan and Results

In the first group of experiments, glutamic acid was isolated from aliquots of a single casein hydrolyzate by means of the 6 different procedures listed in Table I. The results indicate that casein hydrolyzates contain small percentages of *d*(−)-glutamic acid. The figures recorded for the *d*-isomer contents of the isolated samples cannot be explained by assuming a large experimental error in the determinations of specific optical rotations. The figures obtained by us for the specific optical rotation of pure *l*(+)-glutamic acid (in 9% hydrochloric acid) have ranged from +31.0 to +32.5°. The average figure obtained in a large number of determinations was +31.6°.

The possibility that drying the casein at 110° might have caused some racemization of the combined glutamic acid was investigated. A sample of casein was heated at 110° for one week. The glutamic acid subsequently isolated by the pyrrolidone-carboxylic acid method was found to contain only 2.5% of *d*-isomer. This is essentially the same figure as that obtained after a much shorter period of drying (Table I).

In calculating the yields listed in Table I (last column), it has been assumed that the hydrolyzate prepared from 100 g. of thoroughly dried casein contains 21.77 g. of glutamic acid. This figure was reported by Foreman[14]; and figures approximating this have been obtained also with the butyl alcohol extraction method[15] and by the pyrrolidone-carboxylic acid method.[16]

In this Laboratory, the pyrrolidone-carboxylic acid method has given the highest yields of pure material. Moreover, the initial crude material obtained with this procedure contains smaller amounts of contaminants than is the case for any of the other methods used. Since the pyrrolidone-carboxylic acid procedure involves prolonged heating in aqueous solution at 100°, it might be supposed that some racemization would occur. However, numerous experiments with solutions of *l*(+)-glutamic acid have demonstrated that no detectable racemization occurs. It has been found also that samples isolated from glutamic acid solutions by this method reflect accurately the optical composition of the original racemic mixture. For example, a sample composed of 25 parts of *l*(+)-glutamic acid hydrochloride and 75 parts of *d,l*-glutamic acid hydrochloride was partly neutralized with sodium hydroxide until the resulting solution was green to brom cresol green (approximately, *p*H 5). At this *p*H, as Wilson and Cannan[17] have shown, the conversion to pyrrolidone-carboxylic acid is not complete. After boiling for fifty hours, extraction with ethyl acetate, and isolation of the hydrochloride, the material obtained consisted of 26% *l*(+)-glutamic acid hydrochloride and 74% *d,l*-glutamic acid hydrochloride. Therefore, even though conditions purposely were adjusted so that recovery was far from complete (yield, 37%), nevertheless, within experimental error, the recovered glutamic acid hydrochloride had the same optical composition as the original sample.

[a] See Table I. [b] Isolated from "insoluble fraction."

The data recorded in Table II were obtained by isolating glutamic acid hydrochloride from a casein hydrolyzate to which had been added a known amount of *d,l*-glutamic acid. Since 12 g. of dry *d,l*-glutamic acid was added to hydrolyzate equivalent to 95 g. of dry casein, the theoretical *d*-isomer content of the glutamic acid in the mixture was 18.4%. This calculation involves the assumption that no *d*-isomer was formed during the hydrolysis. If it is assumed that the hydrolysis caused a racemization of 10% of the glutamic acid originally present, the theoretical content of *d*-isomer becomes 21.5%. Foreman's figure for the glutamic acid content of casein has been used for these calculations.

It appears justifiable, therefore, to assume that the *d*-isomer content of the glutamic acid in the casein hydrolyzate was something between 18.4 and 21.5%. The data recorded in Table II indicate that the methods yielding samples most closely approximating the theoretical value were the pyrrolidone-carboxylic acid method and the cuprous oxide (Abderhalden–Fuchs) method. The two variations of the Foreman procedure used in this investigation (methods 2 and 3) yielded samples containing, respectively, 76–89% and 82–96% of the calculated theoretical *d*-isomer content. The least efficient method was the zinc oxide procedure, which yielded a sample containing only 50–58% of the calculated amount of *d*-isomer.

Chibnall and his collaborators[6] have claimed that the cuprous oxide method preferentially isolates *d,l*-glutamic acid; *i. e.*, that the first fraction crystallizing from the clarified hydrolyzate contains a higher percentage of *d*-isomer than do subsequent fractions. The data in Table II appear to indicate that the initial material isolated by this method does contain a higher percentage of *d*-isomer than do the first samples isolated by the Foreman or pyrrolidone-carboxylic procedures. However, in our experience, invariably it has been found that the first purified fractions obtained from hydrolyzates clarified with cuprous oxide contain less *d*(−)-glutamic acid than do fractions isolated from the original mother liquor. For example, the first fraction isolated from the hydrolyzate to which had been added *d,l*-glutamic acid contained 14.1% *d*-isomer. A crystalline fraction isolated subsequently from the mother liquor had a much higher *d*-isomer content (52.2%). Seeding has not been employed in our isolations.

It is possible that the type of results obtained with casein would not have been obtained if crude tissue protein had been used. In other words, substances absent from casein, but present in tissue, may influence the yield of *d*-isomer. We plan to investigate this possibility.

Experimental

Preparation of Hydrolyzates.—A sample of casein (Hoffman–LaRoche) was dried for thirty-six hours in an oven (105°). Ninety-five grams of the dry protein was mixed with a liter of 20% hydrochloric acid, and the mixture was boiled gently under reflux for twenty hours. After the removal of the majority of the hydrochloric acid

by several distillations under reduced pressure, the hydrolyzate was diluted to a volume of 200 cc. Thirty cc. aliquots then were used for each of the procedures summarized in Table I.

A second sample of the dry casein (95 g.) was treated as just described, except that 12 g. of dry *d,l*-glutamic acid was added to the hydrolyzate before final dilution to a volume of 200 cc. Thirty-cc. aliquots of this hydrolyzate were employed in obtaining the results listed in Table II.

The *d,l*-glutamic acid was prepared from *l*(+)-glutamic acid by the method of Arnow and Opsahl.[18]

Isolation of Glutamic Acid Hydrochloride. Method 1.—The modification of the Abderhalden–Fuchs procedure[19] employed by Kögl, Erxleben and Akkerman[4] was used, except that crystallization was allowed to proceed without seeding.

Method 2.—The method used was that of Chibnall, *et al.*[6] No attempt was made to isolate aspartic acid.

Method 3.—Graff, *et al.*[7,20] did not publish the details of their procedure. The procedure used by us is illustrated by the following description of the isolation of glutamic acid hydrochloride from the hydrolyzate to which had been added *d,l*-glutamic acid.

Thirty cc. of hydrolyzate was added to 100 cc. of water. A slight excess of barium hydroxide was added with stirring, and the volume of the alkaline solution was made to 185 cc.; 925 cc. of 95% alcohol was added with stirring, and the mixture was placed in the refrigerator for four days. The insoluble material then was filtered off, and dissolved in warm water (volume now 310 cc.); 1550 cc. of 95% alcohol was added with stirring, and the mixture allowed to remain in the refrigerator for three days. The insoluble barium salts were filtered off and dissolved in warm water containing sufficient hydrochloric acid to cause complete solution. Barium then was removed with sulfuric acid. The precipitated sulfate was washed several times with hot water, and the washings were combined with the amino acid solution. The combined solutions were evaporated to a small volume (approximately 20 cc.) under reduced pressure. This concentrated solution was saturated with dry hydrogen chloride gas at ice-bath temperature, and was stored at 0° for several days. The precipitated glutamic acid hydrochloride was filtered off (sintered glass filter); washed successively with cold concentrated hydrochloric acid, absolute alcohol, and ether; and dried in a desiccator over calcium chloride and potassium hydroxide. After its weight had been recorded, it was recrystallized from a minimum quantity of 20% hydrochloric acid. The other fractions listed in Table II were isolated from the mother liquor filtrates.

Method 4.—Thirty cc. of hydrolyzate was diluted with 10 cc. of water, and solid calcium hydroxide was added until the *p*H of the solution reached 6.1, as indicated by the glass electrode. This solution was extracted in a continuous extractor with butyl alcohol for seventy-four hours. The butanol-insoluble fraction was filtered (*p*H of solution now 8.0), and was freed of calcium with oxalic acid solution. The calcium-free solution was concentrated under reduced pressure to a volume of approximately 20 cc., and was saturated with cold hydrogen chloride gas at ice-bath temperature. After the solution had remained for several days at 0°, glutamic acid hydrochloride was isolated and purified in the usual way.

Method 5.—The procedure will be illustrated by a brief description of the isolation of the material recorded in Table II.

Thirty cc. of hydrolyzate and 20 g. of zinc oxide were added to 100 cc. of water. The mixture was heated to boiling for a few minutes, after which it was allowed to remain at 0° for one week. The insoluble material was filtered off, and washed with hot water. (This precipitate was saved for further investigation.) Zinc was removed from the filtrate and washings with hydrogen sulfide, and the filtrate was evaporated under reduced pressure to a volume of approximately 20 cc. After the addition of 5 cc. of concentrated hydrochloric acid, the solution was heated under reflux for two hours (to convert any pyrrolidone-carboxylic acid present to glutamic acid). After saturation of the solution with dry hydrogen chloride gas at ice-bath temperature, and storage of the concentrated hydrochloric acid solution in the refrigerator for several days, glutamic acid hydrochloride was isolated in the usual manner.

The original insoluble material (see above) was dissolved in 10% acetic acid. After removal of the zinc with hydrogen sulfide, it was evaporated to dryness under reduced pressure (to remove acetic acid). The residue was dissolved in 20 cc. of 9% hydrochloric acid; 5 cc. of concentrated hydrochloric acid was added; and the solution was heated under reflux for two hours. The small fraction of glutamic acid indicated in Table II was isolated and purified as already described.

Method 6.—This procedure was based on the suggestive experiments of Wilson and Cannan[17] and of Pucher and Vickery.[21] It will be illustrated by a brief description of the isolation of the material listed in Table II.

Thirty cc. of hydrolyzate was diluted with 30 cc. of water. The *p*H of this solution was adjusted to 3.3 (glass electrode) with 15 *N* sodium hydroxide. This neutralized solution was boiled gently under reflux for fifty hours (to convert glutamic acid to pyrrolidone-carboxylic acid). After concentration to a volume of about 30 cc., insoluble material was filtered off and washed with a small amount of cold water. The combined filtrate and washings were adjusted to *p*H 2.5 (glass electrode) with hydrochloric acid, after which pyrrolidone-carboxylic acid was removed by extracting with ethyl acetate for fifty hours. Further extraction for fifty hours did not increase the yield. Ethyl acetate was removed from the crude pyrrolidone-carboxylic acid by evaporation on a water-bath. The crude material was dissolved in 40 cc. of 9% hydrochloric acid, and the solution was heated under reflux for two hours (to convert pyrrolidone-carboxylic acid to glutamic acid hydrochloride). The condenser was removed, and heating was continued until the volume of the solution was approximately 20 cc. After saturation with hydrogen chloride gas at ice-bath temperature and storage at 0°, glutamic acid hydrochloride was isolated and purified.

Nitrogen Analysis.—The nitrogen contents of the isolated samples were determined by the method of Cavett.[22] Each recorded nitrogen value represents the average of at least two independent determinations.

This investigation was financed in part by a grant from the Cancer Institute Fund, University of Minnesota.

Summary

1. Glutamic acid hydrochloride was isolated from hydrolyzed casein by six different procedures. The percentages of *d*-isomer in the isolated samples varied from 2.5 to 6.2%.

2. The isolations were repeated, using this time a casein hydrolyzate to which had been added a known amount of *d,l*-glutamic acid. The methods yielding samples having *d*-isomer contents closest to the theoretical content were the pyrrolidone-carboxylic acid procedure and the cuprous oxide procedure. Two modifications of the Foreman procedure yielded samples containing, respectively, 76–89 and 82–96% of the theoretical content of *d*-isomer. The poorest percentage yields of *d*-isomer were obtained with the zinc oxide procedure.

3. Methods for isolating glutamic acid by the pyrrolidone-carboxylic acid procedure and the zinc oxide clarification procedure, and modifications of the barium salt and butyl alcohol extraction procedures are described.

Products from the Wurtz Reaction and the Mechanism of their Formation[1]

BY ALFRED SAFFER AND T. W. DAVIS

The combination of methyl radicals with each other does not seem to occur under conditions where other combinations proceed readily.[2] The symmetrical approach of two methyl groups according to calculations of Kimball[3] and of Kassel[4] leads to a product of very short life. There is a possibility that methyl and ethyl radicals, being unlike, may combine more readily than like radicals, in which event the cross combination would result in a preponderant formation of propane, for example, in a Wurtz synthesis involving a methyl and an ethyl compound. The Wurtz reactions seem to offer a way to generate free radicals in any desired proportions so that one may study the relative probability of particular free radical combinations. The results of such a study are reported in this paper.

Von Hartel and Polanyi[5] found the reaction of methyl iodide with sodium vapor to proceed with zero energy of activation, and the reaction ought to go at every collision, therefore, regardless of the temperature. But below 300°, there is no measurable reaction because of the low vapor pressure of the metal. Above 300° with pressures of iodide in the neighborhood of 100 mm., the reaction with methyl or ethyl iodide proceeds at a convenient rate. Our experiments were conducted at 320° and in the absence of solvent because the compounds used as solvents in the ordinary Wurtz syntheses often enter into the reactions.[6] Consequently, in undertaking a study of mixed free radical reactions, we have found it convenient and desirable to depart markedly from the conventional details of the Wurtz synthesis.

Experimental

Method.—The apparatus for this study was used in the following way. About nine grams of sodium was placed in the large bulb of the addition tube, D, and the open end, E, was sealed off. The system was evacuated and the sodium melted by heating with a flame until it flowed into the lower and smaller bulb, where it was further melted and allowed to run into the reaction vessel, C.

During a run, the sodium was kept at 320° by means of the furnace, B. The reactant vapors were introduced by dropping liquid from the

dropping funnel, A, into the trap maintained above 100°. The vapors passed into the reaction vessel, spattering molten sodium over the walls. The alkyl iodide remained in contact with the sodium for ten minutes at a pressure of about 200 mm. Then on opening stopcock F, the products and unreacted iodide were drawn over into trap G, which was cooled in liquid nitrogen. This batch treatment was continued until enough halide had been sent through the apparatus in the course of several hours to produce on complete reaction an anticipated two liters of gaseous product, but under such circumstances reaction was only 10 to 40% complete as determined by Volhard titration of the sodium iodide formed.

The gaseous products volatile at liquid nitrogen temperatures were removed by a mercury piston and analyzed in a gas analysis apparatus of the Orsat type. The condensed material was warmed in turn to −131, −78 and −45° and the vapors released at the several temperatures were pumped off for analysis. The following table shows the products withdrawn from the condensate at the several temperatures.

TABLE I

FRACTIONATION OF PRODUCTS FROM REACTION MIXTURES

Refrigerating agent	Temp., °K.	Products released from mixture			
Liquid nitrogen	77	H_2	CH_4		
s-Butyl chloride mush	142	CH_4	C_2H_4	C_2H_6	(C_2H_2)
Dry-ice + toluene	195	C_2H_4	C_2H_6	C_3H_6	C_3H_8
Chlorobenzene mush	228	C_3H_6	C_3H_8	C_4H_8	C_4H_{10}

The gas analyses were carried out in the usual way. The unsaturated hydrocarbons were dissolved in fuming sulfuric acid. The hydrogen (which appeared only in the fraction uncondensed by liquid nitrogen) and saturated hydrocarbons were estimated by burning with excess oxygen. It was assumed in compiling the data that the unsaturated components in any sample of gas had the same average number of carbon atoms per molecule as the saturated gases in the same sample, for the boiling points of unsaturated hydrocarbons are fairly close to the boiling points of the corresponding alkanes. Complete identification of the alkenes could be accomplished by catalytic hydrogenation of the samples followed by combustion and carbon dioxide determination but, since the proportion of these products is so low, the more lengthy procedure was not adopted.

The results of the parallel analyses of gas from the reaction mixtures, as recorded in Table III, indicate the general consistency of the analytical results. To check further on the gas analysis methods, a mixture of tank gases was made up, mixed with about the quantity of methyl iodide used in our experiments and was fractionated in the usual manner. The tank gases were themselves analyzed before use. The results appear in Table II. There is clearly some uncertainty, amounting to about 15 to 30 ml. total, in the butane and propane figures. This arises largely from the solubility of these heavier gases in the methyl iodide, from which they cannot be completely recovered. The magnitude of the uncertainty, however, is not so large as to modify seriously the interpretation of the reaction.

TABLE II

ANALYSES OF KNOWN GAS MIXTURES

Gas	Mixture I		Mixture II	
	Taken, ml.	Found, ml.	Taken, ml.	Found, ml.
C_2H_4	6	6		
C_2H_6	191	192		
C_3H_6	18	16	9	9
C_3H_8	91	93	168	146
C_4H_8	1	5	2	9
C_4H_{10}	96	62	148	146
Total	403	374	327	310

The consistent trends in the values of n in successive samples of gas drawn from the various mixtures give basis for confidence in the combustion methods for analyzing the heavier hydrocarbons, where n is the average number of carbon atoms per molecule of alkane gas. With pure propane or pure butane, combustion gave the expected values of 3 and 4, respectively, for n.

Materials.—Methyl and ethyl iodides to be used in the experiments were prepared by treating the corresponding alcohols with red phosphorus and iodine. The crude products were dried over calcium chloride and fractionally distilled. Their final boiling points of 42.2–42.7° and 71.5–72.1° are in agreement with accepted values.

Results

The analyses of the products secured from typical reactions of sodium with methyl iodide and ethyl iodide, both singly and in equimolecular mixture, are shown in Table III.

The large amount of methane from the methyl iodide is relatively unexpected as is the appearance of hydrogen, methane and propane in the gases from the ethyl compound. We have noted the formation of carbon in all of these experiments.

[a] In this experiment acetylene was determined by absorption in ammoniacal silver nitrate solution. It made up 1.3% of the sample. This is included in the figure for % C_2H_4. [b] At S. T. P.

When all the volatile products had been distilled from the reaction vessel, methyl alcohol was added to the residual sodium iodide and excess sodium. The alcohol extract was always observed to contain much suspended material resembling carbon in appearance. This product was not introduced as an impurity in the sodium, for sodium melted into the apparatus, but not exposed to the halide vapors, yielded no carbon at all. Several of the black suspensions were filtered and the insoluble material was dried and weighed. The product had no observable solubility in ethyl alcohol, diethyl ether, tetralin, acetone or benzene and certainly is not to be confused with methylene polymer.

The carbon and hydrogen contents of some of the dried carbon samples were determined in a micro-combustion apparatus.[7] The ratio of the two elements varied fairly widely, not only from specimen to specimen, but different samples from a single specimen were sometimes in bad agreement with each other. The ratios varied from $C_{0.9}H_1$ to C_4H_1. Evidently the carbon had adsorbed fairly large and variable amounts of hydrocarbon gases.

While the color of iodine vapors was not observed in any of our experiments, a dark liquid, not easily volatile, condensed in the leads above the reaction vessel. This fluid probably consisted of polyiodide containing some dissolved iodine. The excess and unreacted halide collected with the reaction products was distilled after the hydrocarbon gases had been removed for analysis. While the material boiled at the temperature of the original reactants, there may have been present several per cent. of some higher iodide or hydrocarbon that would not be detected in our procedure.

In an effort to check on the completeness with which the chief reaction products were recovered, and to gain some idea of the nature of any missing products, a materials balance was set up for some of the runs. From the amount of sodium iodide formed, the quantities of carbon and hydrogen expected in the products may be computed, assuming further that in the mixture runs equimolecular amounts of the two halides enter into the original reaction. The detailed data for Experiments 15 and 24 appear in Table IV. The

TABLE IV

incomplete recovery of butane is sufficient to account for most of the hydrogen and carbon deficiencies, but possibly the formation of higher monohalides and hydrocarbons also contribute a little to the deficiency. Some of these products may arise from reactions like

$$CH_2I + C_2H_5I \longrightarrow C_3H_7I + I \qquad (1)$$

or by hydrogen exchange reactions.[8] These calculations are important in eliminating from the reaction scheme chain-producing reactions[9] of the type

$$CH_3 + CH_3I \longrightarrow CH_4 + CH_2I$$
$$CH_2I + CH_3I \longrightarrow CH_2I_2 + CH_3, \text{ etc.} \qquad (2)$$

Were such chain reactions a source of appreciable amounts of free radicals, the hydrogen and carbon content of the recovered products would be more than equivalent to the sodium iodide remaining in the reaction flask, for if the dihalide formed in reaction (2) contains a greater percentage of iodide than the original reactant, its appearance

(7) We are indebted to Dr. R. Bruce Van Order for these analyses.

(8) A. O. Allen [THIS JOURNAL, **63**, 708 (1941)] found these reactions to be of importance during the photolysis of acetone in the presence of propane.

(9) P. Fugasi and F. Daniels [*ibid.*, **60**, 771 (1938)] observed no chains in ethyl bromide decomposition at 395°,

in the products would correspond to additional amounts of both carbon and hydrogen brought into the reaction but not accompanied by an equivalent production of sodium iodide. Other experiments not reported here indicate that the dihalides react about as readily with sodium as the monohalides at 320°.

Mechanism

Methyl Iodide.—There is little doubt that the initial reaction involves the formation of sodium iodide and methyl radicals at the surface of the metal. Some of the radicals are doubtless held on the surface, but the instability of the sodium alkyls[10] makes unlikely the confining of the reaction to the sodium surface.

The most obvious second step in the reaction course is the union of the free radicals, but the multiplicity of products and their unexpected distribution indicates that such a picture is too simple, and a calculation of free radical concentrations shows that reactions between two alkyls are probably unimportant. Assuming the uniform production of the radicals and uniform distribution throughout the reaction vessel, and that the free radicals disappear in a chemical change with the alkyl iodide involving an energy of activation of 16 kcal., a steric factor of 0.1 and ordinary collision diameters, the partial pressure of the methyls will reach a steady state concentration of about 3×10^{-4} mm., when by contrast the pressure of halide is about 200 mm. If the bimolecular free radical reactions, either associations or disproportionations,[11] require an appreciable energy of activation, they will not contribute largely to the final products. On the other hand, the more probable free radical–molecule reactions lead to new free radicals which will meet halide molecules more frequently than any other species in the system. The occurrence of reaction chains of any considerable length, however, is not expected.[8] The chains must be interrupted either by unimolecular decomposition to give unreactive fragments or by two-radical reactions of some sort. It becomes a matter of some importance to observe not only whether the principal products can be accounted for in terms of reactions that are inherently probable, but also to find some reasonable way to account for the termination of the reaction chains.

On collision with methyl iodide, methyls can capture another methyl, an iodomethyl, a hydrogen atom or an iodine atom as shown by the equations

$$CH_3 + CH_3I \longrightarrow CH_3CH_3 + I \quad (3)$$
$$CH_3 + CH_3I \longrightarrow CH_3CH_2I + H \quad (4)$$
$$CH_3 + CH_3I \longrightarrow CH_4 + CH_2I \quad (5)$$
$$CH_3 + CH_3I \longrightarrow CH_3I + CH_3 \quad (6)$$

Probably all of these reactions proceed with an energy of activation around 16 kcal, with the exception of (4) which, because of its endothermal character, will require a greater activation energy. Reaction (5) should be favored over (3) on steric grounds in the ratio of 3 to 1 approximately, which is roughly the proportions of the stable products, CH_4 and C_2H_6. If hydrogen atoms are formed at all, they would probably yield molecular hydrogen in a combination on the walls. The iodine atoms for the most part end up as sodium iodide and the iodomethyls may either lose iodine at the surface of the sodium (the reaction going more easily than the original iodide–sodium reaction) or may unite to form ethylene and molecular iodine. If the CH_2I loses iodine at the sodium surface, the CH_2's apparently react there

$$\left.\begin{aligned} CH_2 + CH_2 &\longrightarrow CH_4 + C \\ CH_2 + CH_2 &\longrightarrow 2C + 2H_2 \end{aligned}\right\} \quad (7)$$

The carbon is almost certainly formed on the surface for, at the conclusion of the reactions, it is found intimately mixed with the sodium. The reacting vapors never appeared smoky as they would if the carbon was formed in the gas phase. Usually carbon is formed only at rather high temperatures and as a result of slow reactions; its appearance at such low temperatures is uncommon. Several investigators, however, have mentioned in passing the appearance of carbon from reactions of iodide near these temperatures[12] without discussing the manner of its formation.

Ordinarily methylene does not react to give free carbon[13] but at higher temperatures such reactions may be important, as in the decomposition of ketene at 530° as suggested by Williamson.[14] The general scheme proposed for the

(14) A. T. Williamson, *ibid.*, **56**, 2216 (1934).

reaction accounts for all the observed products by means of reasonable intermediate reactions.

Ethyl Iodide and Mixed Halides.—The possibilities in the ethyl iodide reaction are much more numerous than with methyl iodide alone. The ethyl radical on colliding with ethyl iodide may combine with hydrogen (from either of the two carbon atoms in ethyl iodide), with iodine, methyl, iodomethyl, iodoethyl, or ethyl groups. None of these reactions can be eliminated as completely impossible. The formation of propane and butane is indicated by the equations

$$C_2H_5 + CH_3CH_2I \longrightarrow C_3H_8 + CH_2I$$
$$C_2H_5 + C_2H_5I \longrightarrow C_4H_{10} + I$$

These reactions are expected to be about equally probable. Unsaturated products, including carbon, arise as before from CH_2I. The appearance of a little methane in the gases collected from the ethyl iodide reaction means either that the C–C chain is broken in the original reaction or, what is more likely, in a subsequent reaction of the type shown in equation (8) below.

$$C_2H_5 + C_2H_5I \longrightarrow C_2H_5CH_2I + CH_3 \quad (8)$$

That the propane is not formed by union of methyl and ethyl radicals is shown by the experiments with the mixed halides where the greatly increased concentration of methyls does not result in any appreciable increase in propane. That the propane production is not diminished by addition of methyl iodide to ethyl iodide means that methyls can enter into some propane-producing reaction with ethyl iodide, and ethyls can enter into a propane-producing reaction with methyl iodide, the most obvious suggestions being

$$CH_3 + C_2H_5I \longrightarrow C_3H_8 + I$$
$$C_2H_5 + CH_3I \longrightarrow C_3H_8 + I$$

There is no evidence for the union of either like or unlike alkyl radicals under the conditions of our experiments and it is possible in certain other reaction systems where saturated hydrocarbons have been attributed to this kind of process, that alternative sources are responsible.

Acknowledgment.—The authors express their thanks to Dr. Milton Burton for helpful discussion of many aspects of the work reported in this paper.

Conclusions and Summary

On the basis of a free radical mechanism, one would expect a gas phase Wurtz reaction to be very complicated, and this is found to be true experimentally. The reaction of methyl iodide or ethyl iodide or a mixture of the two at a pressure of about 200 mm. at 320° produces hydrogen, free carbon, saturated and unsaturated hydrocarbons and possibly smaller amounts of higher halides. The character of the products is in harmony with current views concerning free radical reactions.

Combinations of two alkyl radicals to give saturated molecules seem not to occur in this system. Most of the primarily formed free radicals disappear by reaction with excess halide molecules, and the secondary radicals containing iodine disappear either by reacting with each other or by reaction with sodium.

Alkylation of α-Naphthoquinones with Esters of Tetravalent Lead

BY LOUIS F. FIESER AND FREDERIC C. CHANG[1]

This investigation originated in a chance observation made by one of us in attempting to improve a known procedure[2,3] for converting butadiene-toluquinone (I) into 2-methyl-1,4-naphthoquinone. Treatment of the isomerization product II with silver oxide affords the highly sensitive quinone III, and powerful oxidizing agents lead to some destruction. With chromic anhydride, as in comparable cases,[4] II can be converted into IV in about 50% yield.

The use of lead tetraacetate was thought to offer a possibility for improvement, for the intermediate quinone III might undergo acetoxylation in one of the activated methylene groups or give a glycol diacetate by an addition to the double bond, and either intermediate should lose acetic acid readily with the formation of IV. When the hydroquinone II was warmed on the steam-bath

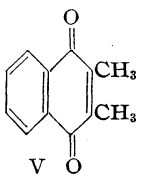
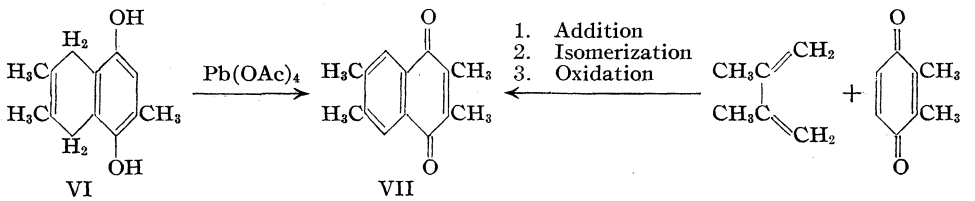
in acetic acid with just two moles of lead tetraacetate, there was obtained a crystalline product which melted slightly above the melting point of pure 2-methyl-1,4-naphthoquinone (m. p. 106–107°) and seemed reminiscent of the intermediate yellow products of unknown nature isolated on partial oxidation of other 5,8-dihydro-1,4-naphthohydroquinones with chromic acid.[4] Since these intermediates are convertible to the naphthoquinones by further oxidation, the experiment was repeated with three moles of lead tetraacetate, all of which was consumed. The reaction product melted at 126.5–127.5°, and analyses of the substance and of its sharply melting hydroquinone diacetate pointed to the formula $C_{12}H_{10}O_2$, whereas methylnaphthoquinone is $C_{11}H_8O_2$. The Craven test[5] was found to be completely negative, indicating the absence of a free position in the quinonoid ring, and the substance was identified by direct comparison as 2,3-dimethyl-1,4-naphthoquinone (V).



The action of excess lead tetraacetate on 2-methyl-5,8-dihydro-1,4-naphthohydroquinone thus involves a remarkable methylation reaction. It was ascertained that the result is the same when the hydroquinone II is first oxidized with silver oxide to the quinone III, and this is then treated with lead tetraacetate. When either II or III is employed as the starting material, the reaction with lead tetraacetate in acetic acid at the steam-bath temperature is characterized by a rapid evolution of gas containing carbon dioxide in amounts corresponding to approximately 1.4 moles per mole of hydroquinone II. When methylnaphthoquinone was submitted to similar treatment (thirty-six hours), there was no gas evolution or consumption of the reagent, and the starting material was recovered unchanged. It was observed also that when the quinone III is refluxed with lead tetraacetate in benzene solution it is converted in moderate yield into methylnaphthoquinone (IV), and affords none of the dimethyl compound V.

In a further investigation of the unusual reaction, the action of lead tetraacetate on 5,8-dihydro-1,4-naphthohydroquinone was found to give a small amount of 2,3-dimethyl-1,4-naphthoquinone. 2,6,7-Trimethyl-5,8-dihydro-1,4-naphthohydroquinone (VI) was prepared by the isomeri-



zation of the addition product from 2,3-dimethylbutadiene and toluquinone and treated with excess lead tetraacetate. The reaction product corresponded in melting point with 2,3,6,7-tetramethyl-1,4-naphthoquinone (VII), as described by Bergmann and Bergmann,[6] and its identity was established by comparison with a sample of this substance synthesized by adding 2,3-dimethylbutadiene to *o*-xyloquinone and oxidizing the isomerized product with chromic acid. The oxidation was also conducted with lead tetraacetate, and in this case the reaction proceeded normally and likewise yielded the tetramethylnaphthoquinone VII. The methylation of the trimethyl compound VI in the lead tetraacetate reaction bears some resemblance to the conversion of 2,6,7-trimethyl-1,4-naphthoquinone to the 2,3,6,7-tetramethyl compound VII by the action of diazomethane, observed by Bergmann and Berg-

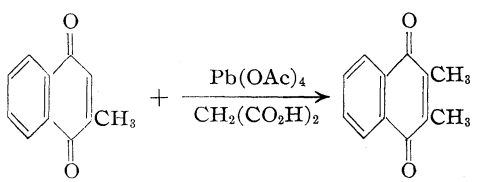
(5) Craven, *J. Chem. Soc.*, 1605 (1931).

(6) E. Bergmann and F. Bergmann, *J. Org. Chem.*, **3**, 125 (1938).

mann.[6,7] The resemblance is superficial, however, for the latter reaction very probably proceeds through the formation and decomposition of a pyrazoline, as in the example studied in this Laboratory.[8]

That the methyl group introduced in the course of the curious reaction comes from lead tetraacetate was initially discounted because of the observation that the reagent is without action on methylnaphthoquinone at the same temperature (steam-bath). That the 5,8-dihydride III under the same conditions enters into a brisk reaction, suggested that it may serve the dual rôle of providing the carbon substituent, through an allylic intermediate,[9] as well as acting as acceptor of the methyl group.

In an attempt to separate the two functions, malonic acid was selected as a component having an activated methylene group, and methylnaphthoquinone was employed as an acceptor which itself is not attacked under the conditions of the experiment. When an acetic acid solution of approximately equivalent amounts of methylnaphthoquinone and malonic acid was heated on the steam-bath and treated with successive portions of lead tetraacetate, a steady gas evolution ensued, nearly five moles of reagent were consumed, and the reaction product proved to be 2,3-dimethyl-1,4-naphthoquinone. Since the product is



easily isolated in a pure condition and the yield is 45–50% of the theoretical amount, this constitutes a practical method of methylation. The fact that no reaction occurred in the absence of malonic acid seemed to indicate that this substance had functioned as the methylating agent even though it is itself attacked by lead tetraacetate, probably in a reaction analogous to the conversion of malonic ester into acetylmalonic ester.[10,11]

Other active-hydrogen components were tried with varying results. Ethyl acetoacetate was found to function about as satisfactorily as malonic acid, but when diethyl malonate was employed the starting material was recovered unchanged. In experiments conducted under the same conditions (90–95°), triphenylmethane, cyclopentadiene, acenaphthene and dimethylmalonic acid proved ineffective in comparison with malonic acid, and at least a large part of the starting material was recovered. Methylmalonic acid was then tried and found to promote a characteristic gas evolution and to afford a transformation product in yield as high as that obtained with malonic acid. If the alkyl group introduced is derived from the malonic acid, methylmalonic acid should afford 2-methyl-3-ethyl-1,4-naphthoquinone. The product obtained, however, proved to be the 2,3-dimethyl compound (V). Therefore, although the active-hydrogen component promotes the alkylation, it is not the alkylating agent. This conclusion was confirmed by the observation that methylnaphthoquinone can be converted into the 2,3-dimethyl derivative by the action of lead tetraacetate in combination with C-ethyl ethyl acetoacetate as promoter.

A method of testing the possibility that lead tetraacetate functions as the methylating agent was to attempt the introduction of higher alkyl groups by means of appropriate esters of tetravalent lead. Thus lead tetrapropionate would be expected to afford an ethyl substituent. Since preformed lead tetraacetate is not required in typical oxidations with this reagent but can be replaced by a combination of red lead and acetic acid,[12] we adopted this method of operation both as a matter of convenience and in order to extend the scope of experimentation. Thus methylnaphthoquinone was dissolved in propionic acid, an equivalent amount of ethyl acetoacetate was added as a promoter, and red lead was added in portions, with heating and stirring. A smooth reaction ensued, affording in 49.5% yield a product melting at 72–72.6° and having the composition of the methylethyl compound. Karrer and Epprecht[13] observed the melting point 73° for a sample of 2-methyl-3-ethyl-1,4-naphthoquinone (VIII) synthesized from ar.-β-methyltetralin. As a possible means of obtaining a sample for direct comparison, we attempted the methylation of 2-ethyl-1,4-naphthoquinone (IX) with lead tetraacetate in the presence of malonic acid. The re-

(7) We do not agree with the interpretation which these authors advance of the nature of the product obtained from 2,6-dimethyl-1,4-naphthoquinone and diazomethane by Fieser and Seligman, THIS JOURNAL, **56**, 2690 (1934).

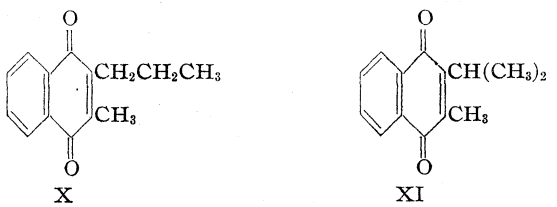
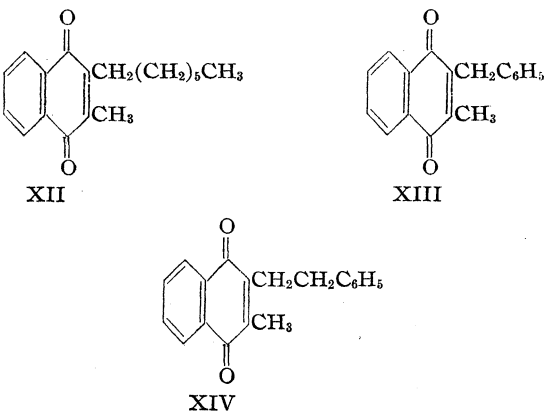
action proceeded satisfactorily and the product obtained proved to be identical with that resulting from the ethylation experiment. The organometallic ester is thereby identified as the alkylating agent.

The behavior of methylnaphthoquinone under the same conditions with red lead in combination with *n*-butyric acid and with isobutyric acid was then investigated. Each reaction yielded a different, fully substituted quinone (negative Craven test), and these melted at 65° and 112°, respectively, and had the expected composition of the methylpropyl compounds. It was established that these substances have the structures X and XI, respectively, corresponding to normal alkyla-



tions, and that the substituent does not suffer isomerization in the course of the reaction, by the above expedient of introducing the groups in the alternate order. 2-*n*-Propyl-1,4-naphthoquinone,[4] when treated with lead tetraacetate and malonic acid, afforded a product identical with the lower melting isomer, obtained in the propylation experiment employing *n*-butyric acid. One of the two routes to the disubstituted compound shows that it contains a normal propyl group in the quinonoid ring, and the other indicates the presence of a similarly situated methyl group; the structure X therefore is fully established. Evidence was likewise obtained in support of formula XI for the isomer. A small sample of β-isopropylnaphthalene was oxidized with chromic acid and the crude, oily quinone obtained was methylated with lead tetraacetate; this afforded a product identical with the higher melting methylpropyl compound. In the preparation of these comparison samples, it was observed that the methylation reaction proceeds less readily when the quinonoid ring carries an ethyl or propyl substituent than when a 2-methyl group is initially present. A higher temperature is required, and the yields are lower.

No comparable limitation was observed with respect to the introduction of higher alkyl groups into 2-methyl-1,4-naphthoquinone. The above ethylation and propylation reactions proceeded as smoothly as the methylation of this compound, giving yields as high as 59%, and alkylation of the same quinone with *n*-caprylic acid and red lead was conducted with success. When a stirred mixture of the quinone, the fatty acid and malonic ester was treated with red lead at 120–130°, the oxide dissolved steadily if slowly, and the reaction afforded in 34% yield a quinone of composition and properties consistent with the structure of 2-methyl-3-*n*-heptyl-1,4-naphthoquinone (XII). Quinones of this type heretofore have been obtainable only in a rather elaborate sequence of synthetic operations.[13,14] By a similar process,



phenylacetic acid afforded in 65% yield a product which was fully identified as the 2-methyl-3-benzyl compound XIII by direct comparison with a sample of the substance obtained previously in this Laboratory by another synthesis.[15] An alkylation utilizing hydrocinnamic acid yielded a new quinone which, in analogy with the other examples of the reaction, can be assigned the probable structure of 2-methyl-3-β-phenylethyl-1,4-naphthoquinone (XIV). Attempted alkylation

with γ-phenylbutyric acid thus far has been unsuccessful.

The alkylation of naphthoquinones with esters of tetravalent lead is at least a fairly general phenomenon, and it is evident that the alkyl group introduced is derived from an acyl radical of the ester. The carbon dioxide evolved evidently is derived from the same source, and it appears that under certain conditions lead tetraacetate suffers decomposition to lead acetate, carbon dioxide and either actual or potential methyl radicals. Of significance in this connection is the early observation by Dimroth and Schweizer[10] that when lead tetraacetate is heated with acetic acid and acetic anhydride at the reflux temperature a small amount of an inflammable gas is evolved, which presumably is ethane. A consideration of the mechanism of the breakdown of the lead tetraacetate molecule will be deferred to reports of further investigations being conducted by other workers in this Laboratory. An observation made by R. C. Clapp and W. H. Daudt suggested the possibility of initiating the alkylation reaction without the use of an active-hydrogen promoter, and it was found that, although methylnaphthoquinone is recovered unchanged after a prolonged period of warming with lead tetraacetate and acetic acid on the steam-bath, alkylation sets in, with evolution of carbon dioxide, if the temperature is raised to the point of refluxing. The 2,3-dimethyl compound is thus obtainable without the use of a promoter, although malonic acid or similar reagent definitely facilitates the reaction. Criegee[16] found that the velocity of the cleavage of glycols by lead tetraacetate in acetic acid solution is accelerated enormously by the addition of another solvent such as methanol or water. Following an observation by S. T. Putnam that the activating effect applies to still other reactions of lead tetraacetate, we discovered that methanol can be used to promote the alkylation reaction at 90–95°. When acetic acid is employed as the sole solvent, crystals of added lead tetraacetate remain colorless and undissolved until the reaction is initiated by adding a promoter or by raising the temperature to the boiling point. Although the alkylation appears to be subject to catalysis, it seems from the present results to require being maintained in progress, as well as being initiated.

It is now evident that, in the initial experiment which led to the discovery of the remarkable alkylating action of lead tetraacetate, the unsaturated compound II played the dual role of providing a source of methylnaphthoquinone and of functioning as a promoter of the methylation reaction.

(16) Criegee, *Ber.*, **73**, 563 (1940).

Experimental Part[17]

Action of Lead Tetraacetate on 2-Methyl-5,8-dihydro-1,4-naphthohydroquinone, II (L. F. F.).—In a first trial, 0.18 g. of II[2] (m. p. 173–174°) in 5 cc. of acetic acid was treated with 0.95 g. of lead tetraacetate, and the mixture was warmed until solution was complete and allowed to stand for two days, when the test for tetravalent lead was negative. The product, when crystallized from methanol, melted at 107–110.5° and showed a depression (*ca.* 90°) when mixed with 2-methyl-1,4-naphthoquinone. In another experiment a solution of 0.70 g. of II in 10 cc. of acetic acid was heated on the steam-bath and treated in the course of about four hours with a total of 5.54 (3.1 equivalents) of lead tetraacetate, added in portions. The reagent was all consumed, and on adding water there was precipitated a slightly sticky solid, m. p. 117–119°. One crystallization from methanol gave yellow needles, m. p. 124–125°, and after four more crystallizations the substance melted constantly at 126.5–127.5°; the Craven test was negative. In another experiment, 1.4 g. of II in 25 cc. of acetic acid took up a total of 13.9 g. (3.92 equivalents) of reagent under similar conditions and the once crystallized product (0.38 g.) melted at 124–126°. The fully purified material melted at 126.5–127.5° and gave no depression when mixed with **2,3-dimethyl-1,4-naphthoquinone.** Analyses of the two preparations were carried out with the following results.

Anal. Calcd. for $C_{12}H_{10}O_2$: C, 77.40; H, 5.41. Found: C, 77.37, 77.36; H, 5.66, 5.82.

The **hydroquinone diacetate,** prepared by reductive acetylation of the quinone with zinc dust, acetic anhydride and pyridine, melted initially at 189.5–190.5°. The substance crystallized from alcohol in the form of diamond-shaped, laminated plates, m. p. 190–190.5°.

Anal. Calcd. for $C_{16}H_{16}O_4$: C, 70.57; H, 5.92. Found: C, 70.70; H, 6.16.

The following experiments were run in parallel at the steam-bath temperature. In the first, 0.70 g. of II in 15 cc. of acetic acid was heated with 7.08 g. (4 equiv.) of lead tetraacetate. Carbon dioxide was evolved steadily and the starch–iodide test was negative only after four hours, when 0.5 g. more reagent was added. The test was negative after three hours, and the product was precipitated with water, extracted with ether and crystallized from methanol. The yield of 2,3-dimethyl-1,4-naphthoquinone, m. p. 124–125°, was 0.21 g. (28%). In the second experiment, 0.70 g. of II in 15 cc. of dry ether was shaken for one-half hour with 2 g. of silver oxide and magnesium sulfate, and the yellow solution was filtered and evaporated. The residue was a bright yellow, light-sensitive solid, m. p. 86–87°, consisting of the quinone III. This was dissolved in 15 cc. of acetic acid and treated as above with 5.32 g. (3

(17) Microanalyses by Lyon Southworth and E. Werble. All melting points are corrected.

equiv.) of lead tetraacetate. Gas was evolved at first and tetravalent lead was still present after heating for seven hours. After destroying the excess reagent by the addition of 3 drops of glycerol, the product was precipitated and worked up as above. The once crystallized product, m. p. 124.5–125.5°, was identified as the 2,3-dimethyl compound by mixed melting point determination; yield 0.16 g. (22%).

Another 0.70-g. lot of II was oxidized with silver oxide to the quinone and a solution of this in 15 cc. of benzene was refluxed with 5.32 g. of lead tetraacetate for fifteen hours. The mixture was filtered and the solution shaken with dilute hydrochloric acid until the precipitated lead dioxide was dissolved. The crude product (0.7 g.) obtained on evaporation afforded, on crystallization from methanol, 0.20 g. of yellow needles, m. p. 103–104°. The recrystallized material melted at 106–107° and did not depress the m. p. of 2-methyl-1,4-naphthoquinone. Treatment of 0.70 g. of II in acetic acid with a slight excess of chromic anhydride afforded 0.40 g. of methylnaphthoquinone, m. p. 102–103°. When pure methylnaphthoquinone (0.69 g.) was heated on the steam-bath in acetic acid with one equivalent of lead tetraacetate, there was no gas evolution, and unconsumed reagent was still present after thirty-six hours. The collected product proved to be unchanged starting material, m. p. 106–106.5°.

Extension of the Experiments.—Some improvements were made in the preparation of the starting material. The addition of butadiene (16 g.) to toluquinone (20 g., steam distilled) was conducted in the presence of benzene (20 cc.) in a capped bottle at 70° for six hours. The resulting solution was clarified with Norit, concentrated and diluted with ligroin (70–90°). The addition product I which crystallized was obtained after washing with ligroin as pale yellow crystals, m. p. 80–81°; yield 24.4 g. (84%). When this substance was heated with lead tetraacetate in acetic acid, there was no gas evolution, and no dimethylnaphthoquinone could be isolated. Isomerization to 2-methyl-5,8-dihydro-1,4-naphthohydroquinone was accomplished satisfactorily by the method reported[2] only when working with small quantities. With larger amounts it was found best to reflux the addition product for a few minutes in acetic acid containing about 1% of concentrated hydrochloric acid and a trace of stannous chloride; a colorless crystalline product invariably resulted, and either separated from the boiling medium or crystallized on dilution with water. A typical methylation experiment conducted with four equivalents of lead tetraacetate afforded 2,3-dimethyl-1,4-naphthoquinone in 28% yield; the hydroquinone diacetate melted at 190.5–191.5°.

Approximate determinations of the amount of carbon dioxide evolved in the course of the reaction were made. In one experiment with 3.1600 g. of II, the net weight of carbon dioxide evolved was 1.0910 g., whence the ratio moles CO_2/moles II = 1.38. In another run, 2.1397 g. of II gave rise to 0.7526 g. of carbon dioxide, corresponding to the molecular ratio 1.41:1.

Methylation of 5,8-Dihydro-1,4-naphthohydroquinone.—The starting material[18] was obtained by isomerization of the corresponding addition product with boiling acetic acid containing hydrochloric acid and stannous chloride; the substance crystallized on dilution in elongated prisms, m. p. 212–214°. A solution of 1.62 g. of the hydroquinone was treated with 16 g. (3.6 equivalents) of lead tetraacetate at 90°. Rapid gas evolution had ceased after one hour, although the test for oxidizing agent was negative only after four hours. The collected product was an oil which partially crystallized. Washing with methanol afforded 0.1 g. (5%) of brown crystals, m. p. 112–115°, and the recrystallized material melted at 122–124° and did not depress the melting point of 2,3-dimethyl-1,4-naphthoquinone.

2,3,6,7-Tetramethyl-1,4-naphthoquinone, VII. (a) **By the Methylation Reaction.**—For the preparation of the starting material, 8.6 g. of toluquinone was refluxed with 13.5 cc. of 2,3-dimethylbutadiene in 15 cc. of alcohol for four hours. The product[6] which separated on ice cooling was recrystallized once from alcohol and afforded 9.3 g. (67%) of material melting at 91–92°; this was isomerized by the method described above to **2,6,7-trimethyl-5,8-dihydro-1,4-naphthohydroquinone**[6] (VI), m. p. 214–215°. Methylation of 1.43 g. of VI was accomplished by treatment with lead tetraacetate as in the previous experiments. The sticky solid obtained as the crude reaction product on crystallization from methanol gave 0.32 g. (21%) of the tetramethyl compound VII in two crops (m. p. 164–165.5°). Recrystallization afforded well-formed yellow crystals melting at 167–168.5°. Bergmann and Bergmann[6] report the melting point 167–168°.

(b) **By Synthesis.**—*o*-Xyloquinone was prepared from *o*-xylidine by oxidation with manganese dioxide.[19] A mixture of 1.65 g. of the quinone, 4 cc. of 2,3-dimethylbutadiene, and 5 cc. of absolute alcohol was refluxed for eight hours. The addition product, **2,3,6,7-tetramethyl-5,8,9,10-tetrahydro-1,4-naphthoquinone,** separated on cooling as small, colorless needles, m. p. 105–106.5°; yield 2.22 g. (80%).

Anal. Calcd. for $C_{14}H_{18}O_2$: C, 77.03; H, 8.31. Found: C, 76.87; H, 8.24.

This was isomerized in the usual way to 2,3,6,7-tetramethyl-5,8-dihydro-1,4-naphthohydroquinone, which when purified from dioxane–ligroin melted at 269–270.5° (Bergmann and Bergmann[6] obtained in a different way a substance melting at 232° which they regarded as having this structure).

Oxidation of the hydroquinone with chromic acid in acetic acid gave a product which crystallized from methanol in yellow leaflets melting at 169.5–170°, and this did not depress the melting point of the quinone obtained by method (a). Oxidation of the hydroquinone with lead tetraacetate likewise afforded VII (m. p. 166–168°). Samples of the quinone prepared by methods (a) and (b) were submitted to reductive acetylation and in each case afforded a colorless **hydroquinone diacetate** melting at 216–217°; the samples when mixed showed no depression.

Anal. Calcd. for $C_{18}H_{20}O_4$: C, 71.98; H, 6.71. Found: C, 71.84; H, 6.54.

Action of Lead Tetraacetate on 2-Methyl-1,4-naphthoquinone, IV, (a) with Malonic Acid.—A solution of 0.86 g. (0.005 mole) of IV and 0.6 g. of malonic acid in 15 cc. of

(18) Diels and Alder, *Ber.*, **62**, 2361 (1929).

(19) Fieser, "Experiments in Organic Chemistry," D. C. Heath and Co., Boston, Mass., 1935, p. 228.

acetic acid was treated with 5 g. of lead tetraacetate and heated on a water-bath to 50–60°, when a brownish solid soon began to separate from the upper part of the solution and gas bubbles began to appear. After heating for about one hour, the precipitate had lightened in color and appeared as a curdy white solid which filled the entire solution. The same substance is formed in the absence of methylnaphthoquinone and probably is a lead salt of malonic acid. After heating for another hour at 75° the solid had all dissolved, no more gas was evolved, and the test with starch–iodide paper was negative. When an additional 2-g. portion of lead tetraacetate was added it was consumed rather rapidly, with further gas evolution. When the reaction slackened, another 2-g. portion was added. This process was repeated until, at the end of six and one-quarter hours (total), no more gas was evolved, the solution was of a clear, golden color, and excess reagent was present; a total of 10.5 g. (4.7 equivalents) of lead tetraacetate had been used. The excess reagent was destroyed with glycerol (6 drops) and the solution was poured into water. The crystalline yellow precipitate on one crystallization from methanol yielded 0.45 g. (49%) of yellow needles, m. p. 118–125°. On recrystallization, the sample melted at 122–124° and was identified by mixed melting point determination as 2,3-dimethyl-1,4-naphthoquinone. A trace of starting material (m. p. 102–104°) was recovered from the aqueous filtrate by extraction with ether and crystallization. In later experiments conducted at the steam-bath temperature, no starting material was detected and the yield of methylated product was better.

(b) **With Ethyl Acetoacetate.**—In an experiment with 0.86 g. of IV and 0.6 cc. of acetoacetic ester in 15 cc. of acetic acid, heated on the steam-bath, no solid intermediate appeared, but gas was evolved and a total of 4.16 equivalents of lead tetraacetate was consumed. The product was identified as the 2,3-dimethyl compound. Other experiments indicated that the results are better when a full molecular equivalent of the promoter is used than with 0.4 equivalent.

(c) **With C-Ethyl Ethyl Acetoacetate (L. F. F.).**—The following rapid procedure gave good results with this promoter but was less satisfactory when malonic acid or acetoacetic ester was used. A mixture of 0.86 g. of IV, 8.8 g. (3.7 equiv.) of lead tetraacetate, and 10 cc. of acetic acid was heated on the steam-bath and a solution of 1.03 g. (1.3 equiv.) of C-ethyl ethyl acetoacetate in 5 cc. of acetic acid was run in from a dropping funnel in the course of one-half hour, during which time gas was evolved steadily. A few remaining crystals of lead tetraacetate subsequently dissolved, but after heating for one and one-half hours excess reagent was still present. This was discharged with glycerol (4 drops) and the solution was diluted and extracted with ether. The ethereal extract was washed with dilute nitric acid and with sodium carbonate solution and shaken with aqueous sodium hydrosulfite solution to effect reduction of the quinone. The hydroquinone was then extracted with three portions of 5% potassium hydroxide containing 2% of sodium hydrosulfite and the yellow vat solutions were drawn off under ether, combined and acidified. [9] The hydroquinone was extracted with ether and the solution was washed with soda solution, dried, shaken with silver oxide and magnesium sulfate, filtered and evaporated. The residue was a bright yellow solid, m. p. 120–122° (recrystallized: 124–125°); yield 0.43 g. (46%).

(d) **With Diethyl Malonate.**—In an experiment conducted as in (a) except for the substitution of malonic ester in place of malonic acid, there was but little gas evolution at the steam-bath temperature and after heating for twelve hours a considerable part of the initial 5-g. lot of lead tetraacetate remained unconsumed and crystallized when the solution was cooled. The filtered solution afforded only starting material, m. p. 103–104°.

In another run performed in the same way but at the reflux temperature and with excess lead tetraacetate, methylation proceeded satisfactorily and the dimethyl compound was produced.

(e) **With Methylmalonic Acid.**—This reagent, when employed under the conditions defined for malonic acid (a), gave entirely comparable results and afforded 2,3-dimethyl-1,4-naphthoquinone in good yield. The only difference noticed was that no intermediate white salt precipitated, although at the beginning of the reaction the solution was slightly cloudy.

(f) **With Tartronic Acid.**—When tartronic acid[11] (m. p. 159°, dec.) was used, a curdy white solid at first separated and then dissolved on the addition of more reagent. Dimethylnaphthoquinone again was a product of the reaction.

(g) **With Dimethylmalonic Acid.**—With this reagent,[21] employed under the conditions of (a), about half the usual amount of lead tetraacetate was consumed, there was relatively little gas evolution, and the product after one crystallization melted at 95–100° and after a second at 99–102°. This, apparently, consisted largely of starting material, but on reëxamination it was found to afford after further crystallizations a small amount of material melting at 113–115°; a mixture with the dimethyl compound melted at 115–120°.

(h) **With Methanol.**—A solution of 0.86 g. of the quinone IV in 15 cc. of acetic acid and 5 cc. of methanol was treated at the steam-bath temperature with a total of 9 g. (4.1 equiv.) of lead tetraacetate, added in portions. At the end of the reaction the clear solution was decanted from a small amount of dark precipitate and processed as usual. After two crystallizations the product melted at 120–122° and was identified as the dimethyl compound VII.

(i) **Without a Promoter.**—When a mixture of 5.16 g. of methylnaphthoquinone, 30 cc. of acetic acid, and 25 g. of lead tetraacetate was heated to the reflux temperature, the reaction started promptly, with vigorous gas evolution. As the reagent was used up, further 5-g. portions were added until, when a total of 67 g. (5 equiv.) of lead tetraacetate had been added, the reaction subsided. Refluxing was continued for a total of five hours. The dark brown mixture was poured into water and the product extracted with ether and processed as usual. The solid material obtained from the residual oil when purified afforded 0.42 g. of 2,3-dimethyl-1,4-naphthoquinone, m. p. 123–125°; the mother liquor remained as an oil even on sublimation and yielded no additional product. Better results were

(20) Compare procedure for the isolation of vitamin K_1.[9]

(21) Bartlett, Fraser and Woodward, THIS JOURNAL, **63**, 495 (1941).

obtained in an earlier experiment employing less reagent (4 equiv.) and more acetic acid; the yield was not determined accurately but appeared to be comparable with those in the experiments with added malonic acid.

(j) **With Reactive Hydrocarbons.**—In trials with cyclopentadiene and with acenaphthene as possible promoters, the starting material was recovered unchanged. With triphenylmethane, the reaction seemed to proceed as in the successful methylations, but the only crystalline product isolated from the oily reaction mixture was a colorless solid, m. p. 88–90° (probably triphenylmethyl acetate, m. p. 87–88°).

2-Methyl-3-ethyl-1,4-naphthoquinone. (a) **By Ethylation.**—A solution of 3.44 g. (0.02 mole) of 2-methyl-1,4-naphthoquinone and 3.2 cc. (0.025 mole) of ethyl acetoacetate in 50 cc. of propionic acid was heated with stirring on the steam-bath and 60 g. (4.37 equiv.) of red lead was added in 5-g. portions. The reaction started on the addition of the first lot of oxide, as evidenced by the rapid evolution of gas. After a time the gas evolution noticeably lagged. The first 40 g. of red lead was consumed within forty-five minutes and the remainder had largely disappeared after a total time of about two hours, when the reaction appeared to be at an end. Heating and stirring were continued for a total of three hours. In this and similar alkylations it seems advisable to continue heating for about one hour after evident gas evolution ceases. The mixture, which gave a positive test for tetravalent lead, was cooled somewhat, with continued stirring, and ether was added to extract the product. The ethereal solution was decanted and the semisolid residue containing red lead and lead salts was extracted several times with fresh portions of ether. The combined ethereal solution was washed with saturated sodium bicarbonate solution until neutral, dried with calcium chloride, and evaporated. A voluminous white precipitate of a basic lead salt sometimes appears in the washing with sodium bicarbonate solution; in this case the ethereal solution is acidified, shaken thoroughly with 10% nitric acid, and then washed again with bicarbonate solution. The residual oil obtained from the ether crystallized when cooled and manipulated. The crystalline product was transferred to a Hirsch funnel and washed with methanol, giving 0.75 g. of yellow needles, m. p. 69–70.5°. Concentration of the mother liquor and washings afforded 0.87 g. of material melting at 66–70.5°. The total amount collected represents a yield of 40.5%; additional material is retained in the mother liquor. After two further crystallizations the quinone melted at 72–72.6° and sublimation of the sample produced no change (Karrer, *et al.*,[13] 73°).

Anal. Calcd. for $C_{13}H_{12}O_2$: C, 77.98; H, 6.04. Found: C, 78.36, 78.38; H, 6.48, 6.44.

The **hydroquinone diacetate** crystallized from dilute acetic acid in needles melting at 106–108°, and remelting at 116–117°.

Anal. Calcd. for $C_{17}H_{18}O_4$: C, 71.37; H, 6.34. Found: C, 71.69; H, 6.34.

(b) **By Methylation.**—2-Ethyl-1,4-naphthoquinone (1.86 g.) was methylated with lead tetraacetate in acetic acid in the presence of malonic acid (1.3 g.) by the procedure described above. The yield of once crystallized product, m. p. 65–68°, was 0.3 g. (15%). Sublimation, followed by crystallization from ether–petroleum ether raised the melting point to 71.4–72.4° and admixture of the sample with that described in (a) did not depress the melting point. The second crop of crystals from the mother liquor melted below 60° and contained a considerable amount of starting material.

2-Methyl-3-*n*-propyl-1,4-naphthoquinone. (a) **By Propylation.**—The reaction was conducted with 1.72 g. of methylnaphthoquinone, 1.5 g. of malonic acid (1.4 equiv.), 45 cc. of *n*-butyric acid, and 35.7 g. (5.2 equiv.) of red lead. The mixture was poured into water and the viscous oily layer which appeared was washed with water by decantation and extracted with ether. The crude reaction product was obtained as a yellow oil which crystallized on cooling. Crystallization from methanol afforded the following crops of material: 0.07 g. (m. p. 65–65.5°), 0.72 g. (64–64.5°), 0.21 g. (63–64.2°); combined yield 47%. Sublimation at 53–58° at 1 mm. gave quinone melting at 65–65.4°.

Anal. Calcd. for $C_{14}H_{14}O_2$: C, 78.48; H, 6.59. Found: C, 78.69; H, 6.90.

The **hydroquinone diacetate** was prepared by reductive acetylation of the quinone with acetic anhydride, zinc dust and a trace of pyridine. It separated from methanol in diamond-shaped crystals, m. p. 93.5–95°.

Anal. Calcd. for $C_{18}H_{20}O_4$: C, 71.98; H, 6.71. Found: C, 72.00; H, 7.11.

(b) **By Methylation.**—The 2-*n*-propyl-1,4-naphthoquinone required as starting material was prepared by hydrogenating a sample of the 2-allyl compound,[4] oxidizing the resulting hydroquinone, crystallizing the quinone from ether–petroleum ether, and finally subliming the sample slowly at 40° and 8 mm. This gave canary-yellow material melting at 40.5–41° (compare 39–39.5°[4]). Methylation with lead tetraacetate (and malonic acid) was first attempted at steam-bath temperature, but the starting material was recovered unchanged. The reaction proceeded successfully, however, when conducted at the boiling point of the acetic acid solution. The crude product melted at 50–55°, and recrystallization gave well formed needles, m. p. 58–60°. Slow sublimation afforded in the terminal fraction material melting at 61–63.5°, and a mixture of this with the sample (a) melted at 63.5–65°.

2-Methyl-3-isopropyl-1,4-naphthoquinone. (a) **By Propylation.**—The alkylation of methylnaphthoquinone (1.72 g.) with isobutyric acid and red lead afforded 1.27 g. (59%) of satisfactory product in two crops, m. p. 106–108° (0.95 g.) and 104–107° (0.32 g.). Recrystallization from methanol and sublimation at 80–85° and 1 mm. afforded canary-yellow material, m. p. 110–111.2°.

Anal. Calcd. for $C_{14}H_{14}O_2$: C, 78.48; H, 6.59. Found: C, 78.61; H, 6.77.

The **hydroquinone diacetate** crystallized from methanol in colorless, diamond-shaped needles, m. p. 115–116°.

Anal. Calcd. for $C_{18}H_{20}O_4$: C, 71.98; H, 6.71. Found: C, 72.20; H, 7.03.

(b) **By Methylation.**—The method first tried for the preparation of the required β-isopropylnaphthalene proved unsuccessful. **Dimethyl-β-naphthylcarbinol** was obtained by the reaction of β-acetonaphthalene (24.6 g.) with methylmagnesium iodide (from 3.5 g. of magnesium) in ether; the acid-hydrolyzed and washed ethereal layer was

neutralized with sodium bicarbonate solution, decolorized with Darco, concentrated to about 100 cc., and diluted with petroleum ether, which caused the separation of 19.7 g. (72%) of crystalline carbinol, m. p. 60–63°. Recrystallization from ligroin (70–90°) gave colorless leaflets, m. p. 65–65.5°.

Anal. Calcd. for $C_{13}H_{14}O$: C, 83.83; H, 7.58. Found: C, 84.08; H, 7.88.

Reduction was attempted by refluxing the carbinol in acetic acid and shaking the resulting solution with hydrogen and Adams catalyst,[22] but very little hydrogen was absorbed and the hydrocarbon appeared to have polymerized. Reduction with red phosphorus and potassium iodide[23] likewise gave a polymer.

β-Isopropylnaphthalene finally was prepared by the Friedel and Crafts reaction according to Haworth and coworkers,[24] although the reaction proceeded poorly and afforded a hydrocarbon fraction boiling at 120–135° (8 mm.) in only 14% yield. The crude hydrocarbon (4.5 g.) was oxidized with chromic anhydride[15] and the quinone extracted by the vatting procedure,[9] which afforded 1.5 g. of crude 2-isopropyl-1,4-naphthoquinone as a dark yellow, viscous oil. The entire product was methylated in boiling acetic acid solution with lead tetraacetate and malonic acid. The oily product partially crystallized when cooled, and the crystals when collected and washed with methanol melted at 95–110°. Fractional sublimation gave material melting progressively higher, and the best sample melted at 109–110°. A mixture with the 2-methyl-3-isopropyl-1,4-naphthoquinone described in (a) melted at 108.5–110°, while the substance strongly depressed the melting point both of 1,4-naphthoquinone and its 2-methyl derivative.

2-Methyl-3-*n*-heptyl-1,4-naphthoquinone.—The *n*-caprylic acid used was obtained by fractional distillation of commercial 90% acid; b. p. 120–126° (12 mm.). The alkylation of methylnaphthoquinone (1.72 g.) with *n*-caprylic acid (30 cc.), red lead (35 g.) and diethyl malonate (1.5 cc.) was conducted in an oil-bath maintained at 120–130°. The hot reaction mixture was poured into water and the nearly solid cake which separated was disintegrated by prolonged manipulation with ether and dilute nitric acid (see next section for a better method of processing the reaction mixture). The material recovered from the washed and dried ethereal solution afforded, on crystallization from methanol, 0.55 g. of product, m. p. 77–78°, and 0.36 g., m. p. 75–78°; total yield 34%. Sublimation at 70–76° (1 mm.) gave canary-yellow crystals, m. p. 80.4–80.8°. Malonic acid also was found satisfactory as the promoter.

Anal. Calcd. for $C_{18}H_{22}O_2$: C, 79.96; H, 8.20. Found: C, 80.22, 80.20; H, 8.55, 8.58.

The **hydroquinone diacetate** separated from methanol as colorless silken needles, m. p. 64–65°.

Anal. Calcd. for $C_{22}H_{28}O_4$: C, 74.13; H, 7.92. Found: C, 74.44; H, 8.25.

2-Methyl-3-benzyl-1,4-naphthoquinone.—The reaction was conducted with 1.72 g. of methylnaphthoquinone, 35 g. of phenylacetic acid, 1.7 cc. of ethyl acetoacetate, and excess red lead. The mixture was stirred in an oil-bath kept at 110–120° and toward the end of the reaction benzene was added to facilitate stirring of the otherwise pasty mixture. The addition of a diluent before the melt cools and solidifies also simplifies the processing of the reaction mixture. When benzene has been added as a thinning medium, the mixture can be cooled, with continued stirring, and enough ether added to dissolve the organic material. The solution is then filtered from oxides and salts of lead, washed with 10% nitric acid and then with sodium bicarbonate solution, dried and evaporated. In the present instance the crude product weighed 1.7 g. (65%), m. p. 98–104°. Crystallization from ethanol gave 1.13 g. of product melting at 107–108° but having the odor of phenylacetic acid. The odor was not removed entirely by sublimation at 80° (1 mm.), but two recrystallizations from ether–petroleum ether gave odorless, hexagonal, yellow prisms, m. p. 108–108.5°.

Anal. Calcd. for $C_{18}H_{14}O_2$: C, 82.41; H, 5.38. Found: C, 82.08; H, 5.60.

No depression in the melting point was observed when the material was mixed with a sample of the quinone (m. p. 107.5–108°) prepared by a different method.[15] The **hydroquinone diacetate** crystallized from methanol in clusters of colorless needles, m. p. 163–164.5°.

Anal. Calcd. for $C_{22}H_{20}O_4$: C, 75.84; H, 5.79. Found: C, 75.63; H, 5.50.

2-Methyl-3-β-phenylethyl-1,4-naphthoquinone.—The reaction was carried out with 1.7 g. of methylnaphthoquinone, 25 g. of hydrocinnamic acid, 1.7 cc. of ethyl acetoacetate, and excess red lead in a bath at 120–130° (four hours). The crude product when washed with methanol amounted to 0.40 g. (14.5%), m. p. 72–73° (additional material was retained in the mother liquor but was not recovered). After sublimation and crystallization from ether–petroleum ether, the substance was obtained as yellow crystals, m. p. 73–73.5°.

Anal. Calcd. for $C_{19}H_{16}O_2$: C, 82.58; H, 5.86. Found: C, 82.46; H, 5.90.

The hydroquinone diacetate formed microcrystals, 140.5–141.2°, from ether–petroleum ether.

Summary

Under certain experimental conditions lead tetraacetate is capable of functioning as a methylating agent. Thus 2-methyl-1,4-naphthoquinone can be converted into 2,3-dimethyl-1,4-naphthoquinone in yields as high as 50% by interaction with this reagent. The reaction can be caused to occur in acetic acid solution by operating at the reflux temperature, but proceeds more smoothly and at a lower temperature in the presence of a promoter such as malonic acid, methylmalonic acid acetoacetic ester or methanol. 2-Methyl-5,8-dihydro-1,4-naphthohydroquinone functions both as acceptor of the methyl group and as a promoter of the alkylative decomposition of lead tetraacetate.

Other alkyl groups can be introduced into the

naphthoquinone nucleus by treatment with an acid, a promoter and excess red lead. The 3-ethyl, 3-*n*-propyl and 3-isopropyl derivatives of 2-methylnaphthoquinone were synthesized with the use of propionic, *n*-butyric, and isobutyric acid, respectively, and the structures were established by the preparation of identical substances by the action of lead tetraacetate on 2-ethyl, 2-*n*-propyl, and 2-isopropyl-1,4-naphthoquinone. The 3-*n*-heptyl, 3-benzyl, and 3-β-phenylethyl derivatives of 2-methyl-1,4-naphthoquinone were synthesized by the new method.

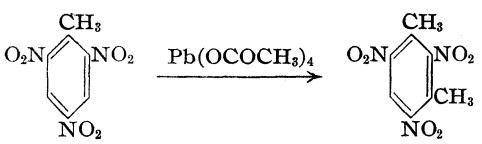
Methylation of Aromatic Nitro Compounds with Lead Tetraacetate

BY LOUIS F. FIESER, RICHARD C. CLAPP AND WILLIAM H. DAUDT

In an initial experiment, 2,4,6-trinitrotoluene was treated in acetic acid solution with lead tetraacetate in the expectation of introducing an acetoxyl group into the reactive methyl substituent. Much to our surprise, the only pure reaction product isolated proved to be trinitro-*m*-xylene. The reaction appears to constitute a second instance



of the methylating action of lead tetraacetate, observed in this Laboratory as applied to various α-naphthoquinones.[1] In further analogy with the naphthoquinone methylation, it was found that carbon dioxide is evolved copiously in the reaction with trinitrotoluene and that a large excess of lead tetraacetate is consumed. Since an efficient method of methylating nitrohydrocarbons might have practical applications of value in the production of high explosives, an exploratory survey was made to test the applicability and efficiency of the novel reaction.

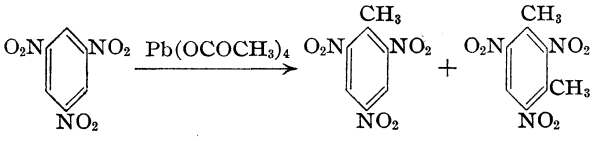
At the time the study was commenced, the parallel work in the quinone field was at a stage where it appeared that the methylating function of lead tetraacetate is evoked only in the presence of an active–hydrogen component such as malonic acid, which is itself attacked by the reagent. We thought at first that a part of the trinitrotoluene might be undergoing acetoxylation in the methyl group and thereby serving as the initiator of the methylation reaction. In the first applications of the reaction to *s*-trinitrobenzene and to *m*-dinitrobenzene, a suitable amount of malonic acid was incorporated in the reaction mixture comprising the nitro compound, lead tetraacetate and acetic acid. Although the reactions proceeded under these conditions, it was subsequently discovered that the malonic acid serves only as a promoter of reactions which can be realized in the absence of this or similar component. The methylation reaction, which becomes quite evident from the gas evolution as well as by a marked darkening of the solution, often can be initiated by brief refluxing of the mixture, or by local heating of the flask with a free flame. Once the reaction has been set in progress, it will proceed briskly at a temperature previously found insufficient to cause it to start promptly. No significant differences, in this respect, were observed between trinitrobenzene and trinitrotoluene. In one experiment with the latter compound which was conducted throughout at the steam-bath temperature, the reaction started only after an induction period of about five hours but then proceeded easily to completion. Malonic acid, added as a promoter, promptly induces reaction at the temperature of the steam-bath, and methanol has the same influence. These reagents, however, seem to have no advantages over the method of initiating the reaction by heat, and they merely consume an additional mount of lead tetraacetate. In several parallel experiments the yields were essentially the same whether or not a promoter was used.

The conversion of trinitrotoluene to trinitro-*m*-xylene constitutes a particularly favorable case for study because the product is much less soluble and higher-melting than the starting material. The dimethyl compound also appears to be an end-product, for lead tetraacetate was found to be without action on trinitro-*m*-xylene in refluxing acetic acid. On treating trinitrotoluene with varying amounts of lead tetraacetate in the ab-

(1) Fieser and Chang, THIS JOURNAL, 64, 2043 (1942).

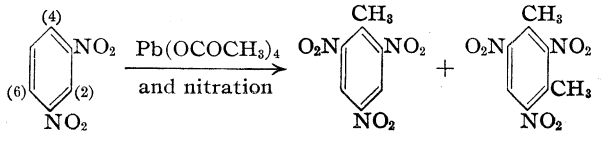
sence of a promoter, no evident stopping point was found and as much as 4.7 equivalents of the reagent was consumed readily. The yield of trinitro-*m*-xylene (19%) was not as high, however, as when a more moderate amount of reagent was used. In three experiments employing 2.5–3 equivalents of lead tetraacetate, yields of 28–32% were obtained, and this appears to be approximately the optimum proportion of reagent for the yield dropped to 20% when but one equivalent was used. The methylation was accomplished also by adding red lead to a warm solution of trinitrotoluene in acetic acid, and by prolonged refluxing of the nitro compound with lead dioxide in acetic acid, but the resulting mixtures were not as easily processed and these methods have no advantages over the use of lead tetraacetate.

The action of lead tetraacetate on 1,3,5-trinitrobenzene was found to result in the formation of both trinitrotoluene and trinitro-*m*-xylene. Be-



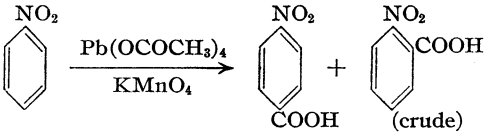
cause of the more complicated nature of the mixture and the less favorable solubility relationships, the yields are less easily determined; orienting experiments indicate merely that the reaction affords more of the monomethyl than of the dimethyl compound, and that the extent of total methylation is perhaps slightly less than found with trinitrotoluene.

In trials with *m*-dinitrobenzene, the reaction mixture was characterized after submitting it to nitration with mixed acid at 120°, for methylation products are thereby nitrated and converted to less soluble products, whereas any starting material is left unchanged. The crude products obtained by the action of lead tetraacetate on the dinitro compound, both with and without the use of a promoter, were nitrated and processed as follows. Crystallization from alcohol–acetone afforded trinitro-*m*-xylene, and addition of β-naphthylamine to the mother liquor gave an easily separated complex of this amine with trinitrotoluene, from which the nitro compound is recoverable by treatment with acid; unchanged *m*-dini-



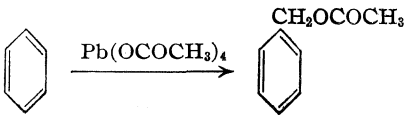
trobenzene was recovered from the acidified mother liquor. The results show that 1,3-dinitrobenzene is converted in part by lead tetraacetate into its 4-methyl and 2,4- or 4,6-dimethyl derivatives. The extent of total methylation appears to be of the same order of magnitude as with the trinitro compounds.

The reaction was found applicable also to nitrobenzene, although this substance is attacked somewhat less readily than the polynitro compounds. In the first trials, carried out both with lead tetraacetate (3 equivalents) and with red lead and acetic acid, the reaction product was characterized subsequent to nitration, and trinitrotoluene was isolated from the final mixture in 4.9% yield through the β-naphthylamine complex. In another experiment, conducted on a large scale with equivalent amounts of nitrobenzene and lead tetraacetate, the bulk of the unchanged starting material was eliminated by fractionation and the slightly higher-boiling terminal fraction was characterized by oxidation with permanganate. *p*-Nitrobenzoic acid was isolated in a pure condition and a second acidic product was characterized as crude *o*-nitrobenzoic acid; the ortho isomer ap-



pears to predominate but the para compound is more easily separated from the mixture. The extent of the reaction, as indicated by the amounts of the two nitrobenzoic acids isolated, represented 4.3% methylation.

We next ventured to try the new reaction on benzene. When a solution of benzene (10 g.) in acetic acid (60 cc.) was refluxed with lead tetraacetate there was little change at first but, after an induction period of four to five hours, a rapid reaction set in and a total of 2.4 equivalents of reagent was consumed. The reaction mixture contained little if any benzene but consisted almost entirely of high-boiling material. The main constituent of the mixture, isolated by a simple and inefficient distillation technique in 18% yield, proved to be essentially pure benzyl acetate. The reaction evidently involves the separate steps of



methylation and acetoxylation. The oxidative step has already been demonstrated, for Dimroth and Schweizer[2] found that toluene can be converted to benzyl acetate by the action of lead tetraacetate in refluxing acetic solution (four hours) under conditions very similar to those employed in the present work. Our yield of the product from benzene is even slightly better than theirs obtained starting with toluene (11.5%). The methylation step, therefore, must have proceeded with particular efficiency. Another point of interest is that Dimroth and Schweizer state that benzene is very stable to lead tetraacetate and cite in evidence an experiment in which a mixture of 15 cc. of benzene and 1 cc. of acetic acid was refluxed with the reagent for five and one-half hours with no more than 1% loss in the oxidation value. That they did not encounter the striking reaction observed in the present investigation, may have been because the refluxing was stopped somewhat short of the end of the induction period. Perhaps of greater importance is the difference in the relative amounts of benzene and acetic acid and the consequent difference in the reflux temperatures; the mixture containing an excess of acetic acid as the solvent would be more favorable for initiation of the reaction. It remains to be determined whether the nature of the solvent is of any consequence beyond controlling the boiling temperature. In past instances in which benzene has been employed as solvent for reactions conducted with lead tetraacetate, some attack of the solvent may well have occurred, only to remain undetected.

Chlorobenzene was found to react in a manner similar to benzene, giving a mixture probably consisting of isomeric chlorobenzyl acetates. After saponification, *p*-chlorobenzyl alcohol was isolated and identified, but no other component of the mixture was characterized. The behavior of naphthalene was different for, under the usual conditions of the methylation reaction, this hydrocarbon was converted in at least 26% yield into 1-acetoxynaphthalene. Thus naphthalene is sufficiently susceptible to oxidative attack to give this reaction precedence over methylation. Still more reactive hydrocarbons such as acenaphthene,[3] anthracene[4] and 3,4-benzpyrene[5] are known to undergo acetoxylation at temperatures well below that at which the methylative action of lead tetraacetate becomes operative.

In completion of this survey of the applicability of the reaction to available starting materials, we tested the action of lead tetraacetate on various mono-, di-, tri- and tetra-nitronaphthalenes, but with invariably unpromising results. The reactions proceeded rather destructively, and a product of methylation was isolated in only one case and in small amounts.

Although any interpretations of the unusual reaction are at present necessarily tentative, it may be noted that the substances which thus far have been found capable of being methylated by lead tetraacetate all conform to the general definition of unsaturated cyclic compounds which are rather resistant to ordinary aromatic substitutions and which do not appear to be susceptible to the acetoxylating action of the reagent. This roughly defined category includes such otherwise widely divergent types as 2-methyl-1,4-naphthoquinone, nitro- and chloro-benzene, the polynitro benzenes and even benzene itself. Toluene and naphthalene fall outside the category, for they are subject to acetoxylation in the side-chain and in the nucleus, respectively. 2-Methyl-1,4-naphthoquinone is associated in behavior with the polynitro compounds in the respect that the yields are favorable and that the methyl group introduced resists subsequent attack. The quinone resembles trinitrobenzene in that the nuclear position undergoing methylation is flanked by unsaturated groups, and a certain similarity is indicated by the fact that a hydroxyl group situated at this position is in each case endowed with pronounced acidic characteristics. The fact that in the series of benzene derivatives the substituting methyl group enters positions ortho and para to the nitro group and the halogen atom, indicates that the reaction is in a class entirely distinct from the usual aromatic substitution.

The reaction has certain other characteristic peculiarities, including the marked induction period frequently noted, and the promoting effect of active-hydrogen compounds and of heat. The evolution of carbon dioxide must be an index of the breakdown of the lead tetraacetate molecule or of some product derived from it, possibly with the direct liberation of methyl radicals. Once this breakdown is initiated, it appears to proceed autocatalytically and to an extent which is excessive in comparison with the amount of methylated

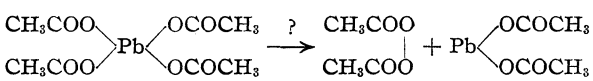
material formed, for the yield is not improved beyond a certain point by increasing the amount of lead tetraacetate, and starting material almost always is recovered. Certain substances of adequate stability, when present at the time of the decomposition, seem capable of acting as acceptors of a certain amount of the actual or potential methyl radicals.

There may be a certain analogy between the catalyzed decomposition of this lead salt of acetic acid to carbon dioxide and possible hydrocarbon radicals and the electrolytic decomposition of sodium acetate in the Kolbe synthesis, and from a consideration of this possible analogy we were led to investigate two other lines of experimentation. One of these was suggested by Dr. A. E. Oxford and has been applied by him in an extension of the parallel work in progress in this Laboratory in the quinone field. Since, according to one of the current views concerning the mechanism of the Kolbe synthesis,[6] the reaction may proceed through the intermediary formation of the acyl peroxide, it might be supposed that lead tetraacetate undergoes decomposition to the same intermediate. In



a trial made of the action of acetyl peroxide (3 equivalents) on trinitrotoluene in acetic acid solution, a reaction set in without delay at 85° and proceeded with steady gas evolution and darkening of the solution, in marked resemblance to the lead tetraacetate reaction. Processing of the reaction mixture afforded trinitro-*m*-xylene in 10.6% yield. The alkylation of quinones with acyl peroxides has been conducted with distinct success in several instances.

The second idea was that methylation might be realized by conducting the electrolytic decomposition of sodium acetate in the presence of a suitable acceptor. Initial trials were made with a solution of trinitrotoluene in acetic acid saturated with sodium acetate placed in a porcelain cell which constituted the anode chamber of the cell. On electrolysis over a period as long as twelve hours, some of the nitro compound was lost by diffusion, but there was little destruction of the material remaining in the anode chamber, and trinitro-*m*-xylene was isolated as a reaction product in yields up to 9%.

(6) Review papers: Fichter, *Trans. Electrochem. Soc.*, **75**, 309 (1939); Glasstone and Hickling, *ibid.*, **75**, 333 (1939).

These few exploratory experiments demonstrate that alkylations of a novel type may be accomplished by three different experimental methods which probably are interrelated and which may involve manifestations of the same general phenomenon. As for possible practical applications, the present survey indicates that methylation with either lead tetraacetate or acetyl peroxide is more likely to find uses in the synthesis of rare chemicals than in the quantity-production of polynitro alkylbenzenes. The electrolytic method of methylation has not been evaluated fully but does not appear promising for practical application.

Experimental Part[7]

Conversion of Trinitrotoluene into Trinitro-*m*-xylene

Identification of the Product.—In an initial experiment carried out by Dr. E. B. Hershberg, a mixture of 3 g. of 2,4,6-trinitrotoluene, 6.2 g. (1 equiv.) of lead tetraacetate and 20 cc. of glacial acetic acid was heated gently at first and then refluxed for one-half hour. The product precipitated with water (1.7 g.) on one crystallization from alcohol afforded 0.6 g. of material, m. p. 145–165°. After six further crystallizations from benzene–hexane, the purified substance melted at 182.7–183.2°, and a mixture with a sample of authentic trinitro-*m*-xylene (m. p. 180.5–182°) melted at 180.5–182°.

Anal. Calcd. for $C_8H_7O_6N_3$: C, 39.84; H, 2.93; N, 17.43. Found: C, 40.34; H, 3.06; N, 17.27.

With Red Lead and Acetic Acid.—Methylation also can be accomplished by the addition of red lead in portions to a stirred solution of trinitrotoluene in acetic acid at 95°, with subsequent gentle refluxing, and the formation of trinitro-*m*-xylene under these conditions was established. The reaction mixture is not as clean as when lead tetraacetate is used, and the processing is therefore less easily accomplished; the separation of lead dioxide from the acetic acid solution makes it difficult to follow the progress of the reaction. For these reasons, lead tetraacetate was employed in most of the exploratory experiments. Preliminary attempts to ethylate trinitrotoluene and trinitrobenzene with lead tetrapropionate or with propionic acid and red lead were unpromising.

With Lead Tetraacetate.—In trial runs made with 1.0, 2.5, and 4.7 equivalents of lead tetraacetate, which in each case was completely consumed, the yields of trinitro-*m*-xylene of comparable purity were 19.8, 28.2, and 18.8%, respectively. The product was more difficult to purify in the experiment utilizing the largest amount of reagent than in the other runs.

The most satisfactory of these experiments was carried out by adding 14.6 g. (0.033 mole) of lead tetraacetate to a solution of 3.0 g. (0.132 mole) of trinitrotoluene (m. p. 80.4–81.8°) in 40 cc. of acetic acid. The reaction was not initiated by heating the mixture on the steam-bath (90–95°), for no gas was evolved, and the originally undissolved lead tetraacetate remained colorless and showed no ten-

(7) Microanalyses by Lyon Southworth and E. Werble.

dency to go into solution. When the mixture was heated to the reflux temperature, however, a yellow coloration soon appeared at one spot in the lead tetraacetate crystals and soon spread over the entire mass, and there was a rapid evolution of gas containing carbon dioxide. After refluxing for about fifty minutes the evolution of gas had ceased and a test with moistened starch–iodide paper was negative. By this time the originally light yellow solution had acquired a rather deep red-orange color. The hot solution was diluted with water and cooled, when 1.4 g. of crude product separated; this melted at 135–165°. Two crystallizations from benzene–hexane (Norit) gave 0.90 g. (28.2%) of yellow needles of trinitro-*m*-xylene, m. p. 174–178°. A further crystallization from alcohol–acetone afforded 0.66 g. (20.7%) of long, light yellow needles, m. p. 178–180°, and the more fully purified material melted at 182.7–183.2° and did not depress the melting point of an authentic sample.

Effect of Promoters.—An experiment parallel to that just described was carried out with the same amounts of reagents (4.7 equiv. of lead tetraacetate) but with the addition of one equivalent of malonic acid. This functioned as a promoter, for the reaction started, as evidenced by the gas evolution, when the mixture was heated on the steam-bath. The reaction proceeded to completion at this temperature, and the test for lead tetraacetate was negative after one hour. The yield was practically the same as when no malonic acid was used. In other trials with varying proportions of lead tetraacetate, the yields tended to be slightly lower with malonic acid present than when no promoter was employed.

Methanol (1 cc. in 40 cc. of acetic acid, 3 equivalents of lead tetraacetate) also functioned as a promoter and induced a prompt reaction at the steam-bath temperature; the yield of trinitro-*m*-xylene, m. p. 177–179.5°, in this case was 28%. When an absolute methanol solution of trinitrotoluene and lead tetraacetate (3 equiv.) was refluxed, reaction set in immediately and was complete in about fifteen minutes. However, only starting material was recovered, indicating that the consumption of reagent was due to oxidation of the solvent.

Conversion at a Moderate Temperature.—A mixture of 1.0 g. of trinitrotoluene, 5.9 g. (3 equiv.) of lead tetraacetate, and 10 cc. of acetic acid was heated on the steam-bath without a promoter and without stirring. After an induction period of about five hours, gas evolution became discernible and the lead tetraacetate began to dissolve. After continued heating overnight on the steam-bath, the reaction was found to have gone to completion. The product which separated on adding water to the light red solution and cooling gave, on crystallization from acetone–alcohol (Norit), 0.37 g. of needles, m. p. 174–177°. Recrystallization afforded 0.34 g. (32%) of trinitro-*m*-xylene, m. p. 176–178.5°. The high yield and quality of the product may be due to the mild conditions of the reaction.

With Lead Dioxide and Acetic Acid.—A suspension of 10 g. (3.2 equiv.) of lead dioxide in a solution of 3 g. of trinitrotoluene in 50 cc. of acetic acid was heated under reflux, when a slow evolution of carbon dioxide was observed. After refluxing for twelve hours, all of the reagent had dissolved and the starch–iodide test was negative. The red-dish solution was filtered from a small amount of black residue and diluted with water. The precipitated material on crystallization afforded 0.54 g. (17%) of trinitro-*m*-xylene, m. p. 175–178°, and from the mother liquor there was recovered 0.64 g. of trinitrotoluene, isolated through the β-naphthylamine complex.

In another trial acetic anhydride was added to a similar reaction mixture. This caused the lead dioxide to dissolve rapidly, and the reaction was completed in a much shorter time; the yield, however, was distinctly lower. The yield was also lower when the above experiment was repeated with the use of a larger excess of lead dioxide.

Stability of Trinitro-*m*-xylene to Lead Tetraacetate.—A solution of 0.5 g. of trinitro-*m*-xylene and 0.92 g. (1 equiv.) of lead tetraacetate in acetic acid was refluxed for four and one-half hours, but there was no pronounced gas evolution, lead tetraacetate was still present at the end of the period of refluxing, and unchanged starting material crystallized from solution on cooling. In another trial an acetic acid solution of equimolecular amounts of trinitro-*m*-xylene and malonic acid was heated on the steam-bath and treated with lead tetraacetate until a total of 4.7 equivalents of the reagent had been consumed. Practically all of the starting material was recovered unchanged.

Methylation with Acetyl Peroxide.—The reagent was prepared essentially according to Gambarjan[8] by adding ice with shaking to a cooled mixture of acetic anhydride, sodium peroxide and petroleum ether, and separating and evaporating the hydrocarbon layer. A solution of 4 g. of trinitrotoluene and 6.2 g. (3 equiv.) of acetyl peroxide in 50 cc. of acetic acid was warmed gradually in a water-bath to a temperature of 85°, when a steady gas evolution was noted. After heating for one hour at 85–95°, and for one hour longer at 95–100°, the evolution of gas had become feeble, and after one hour more at 95–100° it had ceased completely. The orange-red solution was diluted well with water, and the semisolid material which precipitated was collected, dried, and leached with about 100 cc. of warm alcohol. This dissolved the bulk of the material and left 0.32 g. of powdery, light brown solid, m. p. 170–177°. Crystallization of this material from acetone–alcohol gave 0.28 g. of characteristic needles of trinitro-*m*-xylene, m. p. 177–180°, and 0.17 g. of product of the same melting point was recovered from the alcoholic mother liquor; total yield 10.6%. Only a very small amount of trinitrotoluene could be recovered from the mother liquors.

Methylation by Electrolysis.—The electrolysis was conducted in a 400-cc. beaker in which was suspended a 4-inch porcelain cell about 1.5 inches in diameter to contain the anode liquid. The anode and cathode were made of bright platinum foil. A solution of 1 g. of trinitrotoluene in acetic acid saturated with sodium acetate was placed in the anode chamber and the cathode chamber was filled with a concentrated solution of sodium acetate in 50% aqueous acetic acid. The electrolysis was conducted for twelve hours with an average current of about 0.9 ampere and at a temperature maintained with minor exceptions at 35–45° by thorough external cooling with salt-ice. Additional 7–8 cc. portions of acetic acid containing sodium acetate were added after four and nine hours. The anodic solution acquired a light orange-yellow color soon after the reaction

(8) Gambarjan, *Ber.*, **42**, 4003 (1909).

was initiated. The cathodic solution, after remaining essentially colorless for several hours, gradually turned light orange-red, indicating loss of material from the anode compartment.

On pouring the anodic solution into water, there separated rather slowly a solid precipitate weighing 0.24 g. and melting from 80 to 130°. Crystallization from alcohol–acetone afforded 95 mg. (9%) of characteristic needles of trinitro-*m*-xylene, m. p. 155–170°, representing 40% of the material collected. In another experiment, in which electrolysis was continued for only five and one-half hours, the yield was lower but there was less diffusion and considerable starting material was present in undamaged condition. When a lead anode was used there was no gas evolution in the anode chamber and only starting material was recovered.

Other Trials.—Hydrogen peroxide (1.5 cc. of Superoxol, 3.8 equiv.) proved to be without effect on trinitrotoluene (1 g.) in acetic acid solution (10 cc.) at the temperature of the steam-bath. Gas was evolved only very slowly and after six hours the starch–iodide test had become faint. On cooling, 0.8 g. of trinitrotoluene (m. p. 80–82°) crystallized.

Mercuric acetate was tried in place of lead tetraacetate in refluxing acetic acid (twelve hours), but no methylation was observed.

Solutions of trinitrotoluene in acetic acid containing 3 equivalents of tetraethyllead or tetramethyllead were heated on the steam-bath, but although there was some gas evolution and a darkening of the solutions, nearly all of the original trinitrotoluene was recovered unchanged in each case.

Methylation of 1,3,5-Trinitrobenzene

With a Promoter.—A mixture of 2.5 g. of trinitrobenzene (m. p. 122–123°), 1.25 g. of malonic acid, 26 g. (5 equiv.) of lead tetraacetate, and 60 cc. of acetic acid was heated on the steam-bath until all of the solids had dissolved, including a lead salt which formed at first, and until the evolution of carbon dioxide had ceased and the starch–iodide test was negative. On pouring the red solution into water and allowing the mixture to stand for several hours in the cold, 1.85 g. of material separated, m. p. 50–60°. One crystallization from benzene–hexane and two from alcohol (Norit) afforded 0.13 g. of trinitrobenzene as plates, m. p. 120–122° (no depression). Processing of the mother liquor gave a small amount of trinitro-*m*-xylene (needles, m. p. 173–178°, after several crystallizations from alcohol–acetone) and, after several crystallizations, 0.15 g. of trinitrotoluene, m. p. 76.5–78.5°. The mono and dimethyl derivatives were identified by mixed melting point determinations. Additional small amounts of trinitrobenzene were recovered from the mother liquors as the phenanthrene complex (yellow needles, m. p. 155–158°).

Without a Promoter.—A mixture of 2.5 g. of trinitrobenzene, 21.6 g. (4.15 equiv.) of lead tetraacetate, and 60 cc. of acetic acid was heated on the steam-bath for four hours without visible sign of reaction; the colorless crystals of lead tetraacetate remained largely undissolved and no gas was evolved. When the mixture was refluxed, a yellow color soon appeared in one part of the crystal mass and soon spread, the solution turned yellow and then red, and carbon dioxide was evolved. The gas evolution ceased in about one-half hour and the test for tetravalent lead was negative. Precipitation with water gave a total of 1.35 g. of material melting at about 80–130°. Systematic fractional crystallization afforded in all 0.11 g. of trinitro-*m*-xylene needles, m. p. 178–180°, and 0.26 g. of trinitrotoluene plates, m. p. 78–80°. No trinitrobenzene could be recovered, either as such or as the phenanthrene complex.

Methylation of *m*-Dinitrobenzene

In preliminary methylation experiments with twice recrystallized commercial *m*-dinitrobenzene, the reaction mixtures were found to contain small amounts of trinitro-*m*-xylene. Since this may well have arisen from a trace of trinitrobenzene present in the starting material as an impurity, the *m*-nitrobenzene employed in the final experiments was purified carefully by repeated crystallization, when it melted constantly at 89.8–90.5° and had the analysis: C, 42.90; H, 2.43 (calcd.: C, 42.86; H, 2.40). Since the preliminary trials had indicated that the separation of dinitrobenzene and dinitrotoluene presents considerable difficulty, the crude reaction mixtures (which with pure starting material afforded no trinitro-*m*-xylene) were, in subsequent experiments, submitted to nitration before being fractionated.

With a Promoter.—A stirred mixture of 3 g. of pure *m*-dinitrobenzene and 38 g. (4.8 equiv.) of lead tetraacetate in 40 cc. of acetic acid was maintained at 85–90° on the steam-cone and a portion of a solution of 1.9 g. (1 equiv.) of malonic acid in 40 cc. of acetic acid was added slowly by drops. When a little more than half of the solution had been added (in about thirty minutes), a marked deepening in the color of the liquid indicated that the reaction had started and no more malonic acid was added. After stirring at 95° for two and one-quarter hours the lead tetraacetate had all reacted and the solution was consequently poured into ice-water. The powdery precipitate was dissolved in ether and the cloudy aqueous solution was extracted three times with ether. The total ethereal solution was filtered from a trace of flocculent precipitate, washed well with water, dried over calcium chloride, and evaporated to a dark reddish brown, viscous oil. This was dissolved in 20 g. of concentrated sulfuric acid and treated dropwise at 75–95° with a mixture of 5 g. of fuming nitric acid and 30 g. of concentrated sulfuric acid. The temperature was raised to 110° in about twenty-five minutes and held at 110–120° for three and one-quarter hours. The crude, precipitated product (1.65 g.) was a brownish solid, m. p. 55–63°. The first crop from alcohol (0.18 g., m. p. 120–150°) afforded on further purification 80 mg. (1.9%) of crude trinitro-*m*-xylene, m. p. 168–175°. Treatment of the remaining mother liquor with 1.5 g. of β-naphthylamine afforded 0.78 g. of the trinitrotoluene–β-naphthylamine complex as red needles, m. p. 112–113°. Decomposition of the complex with dilute hydrochloric acid gave a total of 0.43 g. (10.6%) of trinitrotoluene, m. p. 77–79°. The mother liquor from the amine complex, after treatment with dilute hydrochloric acid, afforded 0.2 g. of *m*-dinitrobenzene, m. p. 90–92° (6.7% recovery).

Without a Promoter.—In this experiment a solution of 5 g. of analytically pure *m*-dinitrobenzene in 50 cc. of acetic acid was treated with 50 g. (3.9 equiv.) of lead tetraacetate in 5-g. portions, largely at the temperature of the steam-bath. It was discovered that the reaction can be initiated

either by refluxing the mixture for a short time at the outset or by application of localized heat. The reaction then proceeded at the temperature of the steam-bath (but not lower) at a moderate rate (about two bubbles of gas per second). The reaction product was collected and nitrated as described above, giving 2.35 g. of crude yellow solid, m. p. 75–85°. Systematic fractionation from alcohol–acetone afforded in all 0.7 g. of crude trinitro-*m*-xylene, m. p. 160–170°, which when recrystallized formed needles, m. p. 175–178° (no depression). The mother liquor material when processed as above gave 1.05 g. of red needles of trinitrotoluene–β-naphthylamine complex from which 0.53 g. of pure trinitrotoluene was obtained, m. p. 79–80° (no depression). The aqueous acid liquor was extracted with benzene and the solution was washed and concentrated and the residue taken up in alcohol, from which 150 mg. of *m*-dinitrobenzene (m. p. 89–91°) crystallized; a small amount of trinitrotoluene, m. p. 75–78°, was isolated from the mother liquor through the β-naphthylamine complex.

Methylation of Nitrobenzene

In one experiment a mixture of 5 g. of purified nitrobenzene (steam distilled and redistilled), 40 cc. of acetic acid, and 18 g. (1 equiv.) of lead tetraacetate was heated on the steam-cone and, when an attempt to initiate a reaction by local heating with a free flame failed, 0.1 g. of malonic acid was added. Heating on the steam-cone was continued for two hours, but gas was evolved only very slowly. When a second equivalent of reagent was added, however, a steady evolution of gas ensued and the color of the solution deepened to a red-orange. Four hours later, the addition of a third equivalent of lead tetraacetate further accelerated the reaction, and the reagent was all consumed in a total time of twelve hours. The crude product collected by dilution with water and extraction with ether was nitrated in the usual way, giving 2.67 g. of crude solid, m. p. 43–75°. This was treated in alcoholic solution with an equal weight of β-naphthylamine and yielded 0.79 g. of crude trinitrotoluene complex, m. p. 107–111°, which on cleavage with acid afforded 0.45 g. (4.9%) of trinitrotoluene, m. p. 79–81°. The mother liquor from the amine complex yielded, after acid treatment, a total of 1.88 g. (27.5%) of *m*-dinitrobenzene and a very small amount of high-melting material which probably is trinitro-*m*-xylene. The β-naphthylamine complex of trinitrotoluene was also isolated, after nitration, in a methylation experiment carried out with red lead, added in portions to a refluxing solution of nitrobenzene in acetic acid and acetic anhydride.

In another experiment designed to permit characterization of the methylated material as such, a total of 300 g. (0.68 mole) of lead tetraacetate was added in three portions, at intervals of about one hour, to a refluxing solution of 80 g. (0.65 mole) of purified nitrobenzene in 200 cc. of acetic acid. The reaction proceeded rapidly (gas evolution, darkening) at the reflux temperature, and each portion of reagent was consumed in about one hour. The very dark reddish brown solution was poured into water and the organic material extracted with ether and steam distilled (dark, tarry residue). The straw-colored distillate was washed in ether solution with water and with soda solution, and dried. The residual liquid (78 g.) was then fractionated in a 1-meter column packed with glass helices. The first fraction consisted chiefly of 55.7 g. of nitrobenzene, b. p. 102.8–106.3° at 25 mm. Further distillation gave 2.8 g. of material boiling at 106.3–109.5° (25 mm.) before exhaustion of liquid in the boiling flask. This was combined with the hold-up liquid recovered by washing the column, and distillation from a modified Claisen flask yielded 10.7 g. of straw yellow liquid, b. p. 105–112° (17.5 mm.).

Attempted characterization of the liquid by reduction of the nitro group and preparation of acyl derivatives proved unpromising, for mixtures were obtained which could not be separated satisfactorily by fractional crystallization. Oxidation with permanganate provided a more effective means of identification and of obtaining a measure of the extent of methylation. Following a procedure[9] which has been shown to afford *o*-nitrobenzoic acid from *o*-nitrotoluene in 90% yield, a mixture of 2.5 g. of the liquid product and 100 cc. of water containing 5.4 g. of potassium permanganate was stirred on the steam-cone for seven and one-half hours. The aqueous liquor was made alkaline with soda, the manganese dioxide was removed by filtration, and some unoxidized liquid was extracted with ether. Since no precipitate appeared on acidification of the alkaline solution, the product was collected by five extractions with ether. Evaporation of the ether left a white solid which, on crystallization from alcohol, gave in the first crop 0.3 g. of long, flat needles, m. p. 230–236°. Recrystallization raised the melting point to 238–239.5°, and a mixed melting point determination with authentic *p*-nitrobenzoic acid showed no depression. Further crops yielded a total of 0.79 g. of crude needles, m. p. 133–138°. The melting point of this material could not be raised above 138.5–142°, but a mixture of this sample with *o*-nitrobenzoic acid (m. p. 144–145.5°) showed no depression, whereas a mixture with *m*-nitrobenzoic acid (m. p. 138.5–140.5°) melted from 106 to 119°.

The unoxidized material recovered from the ethereal extract of the neutral fraction was reduced with stannous chloride and the crude amine treated with benzoyl chloride. This afforded 0.79 g. of solid which was identified after purification as benzanilide. The amount of this derivative collected corresponds to the presence of 23.7% of nitrobenzene in the product submitted to oxidation. The amounts of the two nitrobenzoic acids isolated indicate the presence in the product of 9.8% of *p*-nitrotoluene and 26.0% of *o*-nitrotoluene. On the basis of the oxidation experiment, the total yield of identified nitrotoluenes produced in the reaction with lead tetraacetate is 3.85 g., representing 4.3% methylation (compare 4.9%, found after nitration).

In view of the low yields in these experiments, it seemed desirable to examine the purified nitrobenzene employed as starting material for the possible presence of nitrotoluenes. For this purpose, 490 cc. of the nitrobenzene used was fractionated through the 1-m. column, when 465 cc. of material distilled at 97.9–98.1° at 20 mm. The tail fraction was recovered from the pot residue and the column by ether extraction. One 5-g. portion of the residual material was nitrated and gave 5.0 g. of crude *m*-dinitrobenzene, m. p. 75–83°; this when recrystallized afforded 2.72 g. of the dinitro compound, m. p. 89.5–90°, and on processing of the

(9) Ullmann and Uzbachian, *Ber.*, **36**, 1799 (1903).

mother liquor with β-naphthylamine no indication was obtained of the presence of trinitrotoluene. Another portion (5 cc.) of the tail fraction was oxidized with permanganate exactly as described above and the alkaline filtrate was acidified and extracted thoroughly with ether; there was no significant residue on evaporation of solution.

Other Actions of Lead Tetraacetate

Conversion of Benzene to Benzyl Acetate.—A mixture of 10 g. of thiophene-free benzene in 60 cc. of acetic acid with 57 g. (1 equiv.) of lead tetraacetate was refluxed for two and one-half hours with but little sign of reaction (light yellow solution), although toward the end of this period a slight evolution of carbon dioxide was noted. An additional 80-g. lot of lead tetraacetate (total = 2.42 equiv.) was added, together with 20 cc. more acetic acid. After a total time of about four hours of refluxing, the gas evolution became somewhat stronger and the color began to deepen. At about five hours, the solution was yellow-orange and the reaction began to proceed very rapidly. Within another half hour the solution had turned dark red-brown and all of the lead tetraacetate was found to have been consumed.

The mixture was drowned and extracted with ether, and the product collected, after washing with water and soda, was distilled at atmospheric pressure from a Claisen flask. Only 1.5 g. of distillate was obtained up to 190°, and the main fraction was taken at 190–250° and consisted of 7.0 g. of a slightly yellow liquid with a pleasant odor; a gummy residue of about 2 g. remained undistilled. The main fraction was redistilled and a cut taken of 3.45 g. (18%) of colorless liquid boiling at 95–110° (20 mm.); most of this distilled at 105–107°. Hydrolysis of this fraction with 10% sodium hydroxide gave a liquid which was identified as benzyl alcohol by the preparation of the α-naphthylurethan; this derivative melted at 131.4–132.0° and did not depress the melting point of an authentic sample. The alkaline solution from the hydrolysis was steam distilled for several hours and then acidified carefully with phosphoric acid and distilled. The Duclaux numbers found by the usual procedure[10] for three fractions were 7.04, 7.40, and 8.05, which demonstrates the presence of acetic acid. The reaction product is thereby identified completely as benzyl acetate.

A check run, in which all of the lead tetraacetate was added at the start, proceeded similarly and afforded benzyl acetate, b. p. 93–104° at 16 mm., in 16.2% yield (the bulk of the product distilled at 102–103°). The undistilled residues from the two runs were combined and hydrolyzed, but the only product recognized was a small additional amount of benzyl alcohol. It was noticed that the acidified aqueous solution obtained after hydrolysis of the main fraction has a phenolic odor, but no test for phenol could be obtained.

Action of Lead Tetraacetate on Chlorobenzene.—A mixture of 10 g. of chlorobenzene, 80 g. (2 equiv.) of lead tetraacetate, and 80 cc. of acetic acid was refluxed until the reagent was consumed; as with benzene, there was an induction period of three to four hours before the reaction became rapid. Distillation of the collected product gave 2.9 g. of material boiling at 115–140° at 12.5 mm., and redistillation of this fraction afforded 2.12 g. (12.9%) of clear, pleasant smelling liquid, b. p. 115–130° at 12.5 mm. (chiefly at 120–123°). Hydrolysis with dilute alcoholic alkali yielded 1.25 g. of material, b. p. 112–117° (11 mm.), which partially crystallized. Crystallization of the distillate from ligroin (70–90°) gave 0.45 g. (3.5%) of irregular plates, m. p. 60–63°, and the recrystallized sample formed flat needles, m. p. 69.4–70.4°. The melting point is close to that of *p*-chlorobenzyl alcohol (m. p. 71–72.5°[11]), but not far from that of the ortho isomer (m. p. 64–65°[11]), and consequently a sample of the alcohol melting at 60–63° was oxidized to the acid with refluxing permanganate solution. This afforded an acid which on recrystallization formed small plates melting at 238–240° and gave no depression when mixed with authentic *p*-chlorobenzoic acid. Since the yield of crystallized para acid was low (10–15%), it is quite possible that more soluble isomers may have been present. Oxidation of the crude product of hydrolysis gave evident mixtures of acids from which, however, only *p*-chlorobenzoic acid was isolated.

Acetoxylation of Naphthalene.—A mixture of 20 g. of naphthalene, 50 g. of lead tetraacetate and 100 cc. of acetic acid was heated with a flame adjusted so as to maintain a steady and moderate gas evolution. When the reagent had been consumed, another 50-g. portion was added (total, 2.9 equiv.) and heating was continued until it had all reacted (very dark solution). After collection of the product by drowning and extraction with ether, distillation at 10 mm. gave 7.8 g. of low-boiling material (to 140°), from which there was obtained 4.1 g. of naphthalene by crystallization. The next fraction taken (140–180° at 10 mm.) was redistilled and a middle fraction, b. p. 150–175° at 10 mm. (insoluble in alkali), was saponified with 10% sodium hydroxide and alcohol. Two distillations of the dark product of hydrolysis gave 4.0 g. of phenolic product, b. p. 140–150° (10 mm.). Crystallization from ether–hexane yielded 2.9 g. (26%) of crude α-naphthol, m. p. 91–94°, and two further crystallizations gave plates, m. p. 94–96°, which gave no depression when mixed with authentic α-naphthol.

Preliminary Trials with Nitronaphthalenes.—Trial experiments carried out essentially as described above with α-nitronaphthalene, 1,5- and 1,8-dinitronaphthalene, 1,3,8- and 1,4,5-trinitronaphthalene, and 1,3,6,8-tetranitronaphthalene gave unpromising results; oxides of nitrogen were evolved in some cases, the reaction mixtures were very dark, and brief processing afforded a pure transformation in only one instance. The reaction mixture from 1,8-dinitronaphthalene and lead tetraacetate yielded a very small amount of crystalline material melting at 207–210°. The substance corresponds in melting point and composition to 1,8-dinitro-2-methylnaphthalene.

Summary

Aromatic nitro compounds can be methylated in low or moderate yield by the action of lead tetraacetate in acetic acid solution. The reaction is akin to the recently observed alkylation of

methylnaphthoquinone by the same reagent and is similarly initiated by the use of active-hydrogen promoters or by heating. By this method trinitrotoluene has been converted in yields as high as 32% into trinitro-*m*-xylene, which appears to be an end product. Trinitrobenzene affords trinitrotoluene and trinitro-*m*-xylene as reaction products, and the same two substances were obtained from *m*-dinitrobenzene by treatment with lead tetraacetate, followed by nitration. Nitrobenzene is converted in low yield into *o*- and *p*-nitrotoluene, identified as the corresponding nitrobenzoic acids.

Under similar conditions, benzene is converted by lead tetraacetate in acetic acid into benzyl acetate in yields up to 18%. Chlorobenzene behaves similarly and yields a mixture which has been characterized as containing *p*-chlorobenzyl acetate. Naphthalene is converted into the 1-acetoxy derivative in 26% yield. The reaction does not appear promising as applied to nitro and polynitronaphthalenes.

Analogies to the electrolytic decomposition of metal salts of carboxylic acids in the Kolbe synthesis have led to the discovery of related methods of alkylation consisting in the treatment of the nitro compound in acetic acid solution with acetyl peroxide and the electrolysis of a solution of the nitro compound in acetic acid containing sodium acetate. Trinitrotoluene was converted by both methods into trinitro-*m*-xylene in low yields.

Alkylation of Para Quinones with Acyl Peroxides

BY LOUIS F. FIESER AND ALBERT E. OXFORD[1]

In continuation of previous work in this Laboratory on the alkylating action of esters of tetravalent lead,[2,3] a few exploratory experiments were made to see if the reaction of lead tetraacetate with 2-methyl-1,4-naphthoquinone in acetic acid solution to give 2,3-dimethyl-1,4-naphthoquinone can be promoted by the addition of substances other than active-hydrogen reagents and methanol.[2] It was found that a number of solvents, including some which do not themselves appear to be attacked, not only promote the methylation reaction but also, in the absence of a quinone or other methyl acceptor, exert a presumably catalytic effect and promote the decomposition of lead tetraacetate to carbon dioxide and an inflammable gas.

In experiments conducted with 0.005 mole of methylnaphthoquinone in 14 cc. of acetic acid at 90–100° with excess solid lead tetraacetate present throughout, no reaction occurred in the absence of a promoter, as previously observed,[2] but a usually vigorous gas evolution ensued, with darkening of the solution and ultimate production of the 2,3-dimethyl compound, on the addition of 1–3 g. of any one of the following substances: methanol,[2] water, isopropyl alcohol, *t*-butyl alcohol (thirty-minute lag, then gentle effervescence), isopropyl ether, benzene, toluene, cyclohexane (benzene-free), *n*-octane (synthetic). Under the same conditions but in the absence of methylnaphthoquinone, all of these substances except *t*-butyl alcohol brought about a steady if somewhat less vigorous decomposition of lead tetraacetate in the acetic acid solution. The gas evolution was particularly rapid and vigorous in the presence of added benzene, while with toluene as the promoter there was a prolonged induction period followed by a very slow gas evolution. Cyclohexane is a slightly less effective promoter for the decomposition than benzene, and *n*-octane produces, after a brief lag, a still more moderate gas evolution. The cyclohexane employed as a promoter was found to be largely recoverable unchanged after a reaction period of eight hours, in which time a considerable amount of lead tetraacetate had suffered decomposition before the reaction had come to a standstill. Although the action of the hydrocarbon somewhat resembles that of a true catalyst, it is noteworthy that the reaction slows down after a time and that a given quantity of cyclohexane brings about the decomposition of only a limited amount of lead tetraacetate. The

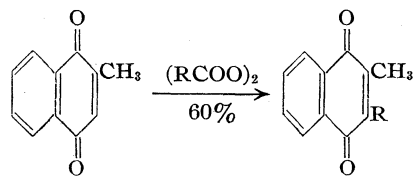
decomposition has been observed to come to a stop with a considerable amount of recoverable cyclohexane still present, and yet to be set in motion again by the addition of a fresh lot of this hydrocarbon. It was found further that the heating of lead tetraacetate with cyclohexane in the absence of acetic acid resulted in no evident decomposition and that methylnaphthoquinone could not be methylated under these conditions. The slowing down of the decomposition in acetic acid–cyclohexane may be due to some extent to the accumulation of lead diacetate, for the addition of this reagent to a mixture of methylnaphthoquinone, acetic acid, toluene and cyclohexane retarded the methylation reaction but did not prevent it.

The gas evolved in the course of the decomposition of lead tetraacetate in the presence or absence of an acceptor contains both carbon dioxide and an inflammable gas not absorbed in alkali. The amount of the neutral gas is often considerable (Table I, Experimental Part) and was found in one experiment conducted in the absence of an acceptor to be approximately 1/2.3 the volume of carbon dioxide, which is close to the ratio to be expected if the gas is pure ethane.

The decomposition therefore appears analogous to the Kolbe reaction. As noted in the second paper of this series,[3] the consideration that diacetyl peroxide is regarded by some as an intermediate in the electrolysis of potassium acetate, coupled with the possibility that lead tetraacetate may initially dissociate to give this substance and lead acetate, led us to attempt the alkylation of quinones with diacyl peroxides in place of esters of tetravalent lead. This indeed can be accomplished; 2-methyl-1,4-naphthoquinone and diacetyl peroxide, for example, afforded 2,3-dimethylnaphthoquinone when warmed together in acetic acid at about 90°. In this and many other instances the reaction proceeds readily and cleanly and under conditions of dilution, solvent and temperature similar to those found favorable for effecting analogous alkylations with the tetravalent lead derivatives. In the reaction with diacyl peroxides, however, no promoter is required, there is no induction period,[3] and one equivalent of the reagent gives better results than a 3–4 fold excess.[2,3] Inferences concerning the mechanisms of the two reactions and the question of a possible correlation between them can best await quantitative studies.

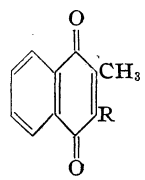
Many instances are on record of the thermal decomposition of diacyl peroxides in the presence of solvents which serve as acceptors of the hydrocarbon residue. This type of reaction has been investigated extensively, particularly as applied to diaroyl peroxides, by the Dutch workers Böeseken, Gelissen and Hermans, *et al.*, and by Wieland and collaborators, as summarized in an excellent review by Hey and Waters.[4] Recent applications to the peroxides of aliphatic acids are reported by Kharasch, Kane and Brown.[5] The present observations appear novel in that the reaction is applied to a type of acceptor so favorable for the reaction that the alkylation can be conducted with equivalent amounts of reactants in a solvent essentially inert to the peroxide.

The introduction of higher saturated alkyl radicals is illustrated by the smooth reaction of 2-methyl-1,4-naphthoquinone in ligroin solution with dipalmitoyl and distearoyl peroxide to give the 3-pentadecyl and 3-heptadecyl derivatives I and II. These quinones both melt about 4° lower than 2-methyl-3-octadecyl-1,4-naphthoquinone,



I, R = $C_{15}H_{31}$
II, R = $C_{17}H_{35}$

which has been prepared by a much longer synthesis.[6] As applied to the derivatives of the higher fatty acids, the present method is probably more convenient than the process of alkylation with a mixture of red lead and the fatty acid.[2] Furthermore, it can be employed for the introduction of at least certain types of unsaturated hydrocarbon residues. Thus the peroxides from erucic, chaulmoogric and undecenoic acids were employed successfully for the synthesis of the quinones III–V. 2-Methyl-3-norchaulmoogryl-1,4-naphthoquinone (IV) is of interest because of



III, R = $-(CH_2)_{11}CH{=}CH(CH_2)_7CH_3$
IV, R = $-(CH_2)_{12}-$

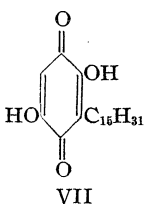
the presence in a structure related to that of the K vitamins of the hydrocarbon residue of an acid employed in the treatment of leprosy. The synthesis has the advantage of convenience and wide scope, since the diacyl peroxides required are obtainable by the action of sodium peroxide on a solution of the acid chloride in petroleum ether, and the examples cited show that a double bond remote from the carboxyl group does not interfere with either the formation or utilization of the peroxides. The α,β-unsaturated 2-heptadecenoic acid likewise afforded a peroxide which on interaction with methylnaphthoquinone gave a product, m. p. 72–73°, having the composition of 2-methyl-3-hexadecenyl(1′)-1,4-naphthoquinone (VI). The substance does not give the Dam–Karrer test[7] with alcoholic alkali and hence the double bond cannot have shifted to the β-position. The quinone is bright yellow, whereas compounds III–V, which are of comparable molecular weight but which do not possess a double bond in the α-position in the side-chain, are very pale yellow, and hence there is some analogy to the relationship between the 3-α-alkenyl (orange) and 3-β-alkenyl (yellow) derivatives of 2-hydroxy-1,4-naphthoquinone.[8]

Paralleling results obtained by the alternate method of alkylation,[2] it was found that a higher alkyl group present at the 2-position of a 1,4-naphthoquinone, in contrast to a methyl group, impedes the introduction of a second alkyl substituent. Thus, although α-naphthoquinone on treatment with diacetyl peroxide afforded only the 2,3-dimethyl derivative in low yield, the reaction of the quinone with dipalmitoyl peroxide provided a satisfactory method for the synthesis of 2-pentadecyl-1,4-naphthoquinone. The applicability of the diacyl peroxide method in the benzoquinone series was established by the conversion of cumoquinone into duroquinone and into 2,3,5-trimethyl-6-pentadecylquinone by interaction with diacetyl peroxide and with dipalmitoyl peroxide, respectively.

On extending the study to quinones having substituents other than alkyl groups, we were surprised to find that 2-methoxy-1,4-naphthoquinone could be recovered unchanged from the attempted reaction with diacetyl peroxide, whereas 2-hydroxy-1,4-naphthoquinone afforded phthiocol in good yield. Similarly 2,5-dihydroxybenzoquinone reacted satisfactorily with dipalmitoyl peroxide in acetic acid solution to give the mono substitution product VII, while under the same conditions the dimethyl ether was largely recovered unchanged. 2,5-Dihydroxy-3-pentadecylbenzoquinone (VII) is a higher homolog of the naturally occurring anthelmintic pigment embelin[9] (R = $C_{11}H_{23}$), to which the same synthesis may be applicable. 2,6-Dimethoxybenzoquinone gave at least a very small amount of the monomethyl derivative, but from the present observations it appears that methoxy quinones are definitely more inert to the products of the thermal decomposition of diacyl peroxides than hydroxy quinones and that the latter are perhaps somewhat more reactive than unsubstituted or alkylated quinones. The one bromoquinone investigated also reacted very readily in an appropriate solvent. Tribromoquinone was converted into tribromotoluquinone in acetic acid solution in about 68% yield but only in poor yield with the use of ligroin. This example of the reaction should offer a particularly favorable case for quantitative study because of the ease with which the high melting and sparingly soluble product can be separated from the reaction mixture. To test the possibility of using bromine to block temporarily nuclear positions and thus expand the scope of the synthetic method, we made a trial of the hydrogenation of tribromotoluquinone in acetic acid in the presence of palladium–barium sulfate and sodium acetate[10] and indeed isolated toluhydroquinone.



VII

Arylation with dibenzoyl peroxide was tried in a few instances with unpromising results. In experiments with methylnaphthoquinone conducted in both acetic acid and ligroin the starting material was consumed but no reaction product could be isolated. 2,5-Dihydroxybenzoquinone, however, afforded in very small yield a substance corresponding in properties to the fungus pigment polyporic acid[11] (VIII). Dicinnamoyl peroxide gave only negative results in attempted reaction with methylnaphthoquinone, while with 2,5-dihydroxybenzoquinone it gave only a trace of material forming lustrous plates and ex-

hibiting brilliant colors in ligroin (purple) and in sulfuric acid (green). The poor results may be due in part to the choice of unsuitable experimental conditions; it may also be significant that dibenzoyl and dicinnamoyl peroxide are notably prone to enter into decompositions leading to esters and diaryls.[12]

Experimental Part[13]

Gas Evolution Attending the Decomposition of Lead Tetraacetate.—In the exploratory experiments summarized in Table I the gases were swept from the reaction vessel to an azotometer with a stream of carbon dioxide and the volume of unabsorbed gas measured.

Another experiment (0.6 g. water, 10 g. lead tetraacetate, 7 cc. acetic acid) was carried out in a stream of dry oxygen and the gases collected over water (total, 92 cc.). The carbon dioxide (46 cc.) was then absorbed in strong caustic potash; the oxygen (26 cc.) was absorbed in alkaline pyrogallol and the residual hydrocarbon gas measured (20 cc.).

Preparation of the Peroxides.—The various diacyl peroxides were prepared for the most part by vigorously shaking a solution of the acid chloride (usually made by the phosphorus trichloride method) in petroleum ether (b. p. 20–40°) with a solution of sodium peroxide (large excess) in ice-water in a stoppered flask. The upper layer containing the peroxide was separated from the alkaline liquor or soap solution, dried, and allowed to evaporate. Usually the crude peroxide was found to evolve gas upon heating at 90–100° and to give no acid reaction when a cold solution in methanol was tested with moistened litmus paper. In this event, the crude material was regarded as satisfactory for use without further purification. The peroxides were stored and weighed out in the cold room (5°), where they could be safely scraped from a glass dish with a silver spatula.

The following procedure for the preparation of **dipalmitoyl peroxide** is typical. A solution of 3.3 g. of crude palmitoyl chloride in 10 cc. of petroleum ether was added with ice cooling to a solution of 1 g. of sodium peroxide in a few cc. of ice-water. After the addition of a little ice the flask was corked and shaken well for a minute or two. More solid sodium peroxide (1 g.) was added, together with more ice and petroleum ether, and the corked flask was shaken thoroughly for at least ten minutes with the introduction of small amounts of ice from time to time and with short periods of cooling in a freezing bath. The mixture was then transferred with about 100 cc. of added petroleum ether to a separatory funnel, and after shaking for a few minutes a little ether was added to facilitate separation of the layers. The top layer was separated as far as possible, dried over calcium chloride, filtered into a glass dish and allowed to evaporate spontaneously at room temperature. The residue consisted of 1 g. of colorless crystals, m. p. about 65°, and this was used directly for an alkylation. A sample of the peroxide recrystallized from methanol melted at 67–68°.

The crude **distearoyl peroxide** melted at 63–64° and a sample crystallized from methanol, in which it is not very soluble, melted at the same temperature. The crude peroxides from **erucic** and **2-heptadecenoic acid** melted at 30° and 45°, respectively, and that from **undecenoic acid** was liquid at room temperature and solidified in the cold room. An attempted conversion of **chaulmoogric acid** into the chloride with thionyl chloride gave a resin and it was found better to warm the acid with the calculated amount of phosphorus trichloride on the steam-bath, pour off the top layer from the phosphorous acid, and remove hydrogen chloride by evacuation at the water pump. The residue afforded a peroxide melting at 50–55°. **Dicinnamoyl peroxide** was prepared by the above procedure rather than in acetone solution[12]; 5 g. of acid chloride afforded 3.0 g. of peroxide, m. p. 127–130°.

Diacetyl peroxide was prepared best according to Gambarjan[14] from acetic anhydride in ether. With an initial reaction temperature of −5° instead of −15°, the yield was only 5.5 g. (G., 9 g.), and unless the evaporation was carried out in the cold room about half of the volatile peroxide was lost. The yield was much lower when the solvent ether was replaced by petroleum ether, in which acetic anhydride is only sparingly soluble.

Methylation of 2-Methyl-1,4-naphthoquinone.—In parallel experiments conducted to determine the optimum proportion of the reactants, tubes containing 1-g. samples of the quinone in 14 cc. of acetic acid were charged with 0.4 g. (0.6 equiv.), 0.75 g. (1.1 equiv.), and 1.4 g. (2 equiv.) of diacetyl peroxide, respectively, and heated together in the same bath at 90–95° until effervescence ceased. The solutions were cooled, poured into water and the products crystallized from methanol. The first experiment afforded much unchanged starting material and only 0.1 g. of impure 2,3-dimethyl-1,4-naphthoquinone, m. p. 112–118°, after several crystallizations. The second yielded 0.55 g. of the once crystallized dimethyl derivative, m. p. 118–123°, while the third gave a gummy product yielding only 0.1 g. of dimethylnaphthoquinone, m. p. 118–122°, after recrystallization. The ratio 1:1.1 therefore seems to be

[a] This may be a mixture of the *cis*- and *trans*- forms. The erucic acid used (Eastman Kodak Co.) was not purified but converted directly to the acid chloride by means of thionyl chloride. [b] Softening from 57°. [c] The acid was prepared according to Lauer, Gensler and Miller, THIS JOURNAL, **63,** 1153 (1941). [d] Graebe and Hess, *Ann.*, **340,** 237 (1905). [e] Anslow, Ashley and Raistrick, *J. Chem. Soc.*, 441 (1938), report the m. p. 125° (4,6-dimethoxytoluquinone). [f] Knoevenagel and Bückel, *Ber.*, **34,** 3995 (1901). [g] The quinone gives a light violet color in dilute alkali.

the best. The second experiment was duplicated except that half of the peroxide was added at the beginning and the rest when the first effervescence had ceased; the yield was the same (0.60 g., m. p. 115–119°). In another experiment *n*-propyl alcohol was employed successfully as the solvent.

Methylation of Tribromoquinone.—A mixture of 2.4 g. of tribromoquinone[15] (m. p. 147°), 0.85 g. of diacetyl peroxide and 24 cc. of acetic acid was warmed gently in a water-bath, when solution soon took place, and the temperature was slowly raised to 90° and kept there for one hour and at 100° for one-half hour longer, when effervescence had ceased. Pale yellow plates of tribromotoluquinone had begun to separate from the hot solution and, after cooling, the copious crystallizate was collected and amounted to 1.3 g., m. p. 230°, dec. The material precipitated from the mother liquor with water afforded after crystallization a further 0.4 g. of product, m. p. 210–220°; total yield 68%. A sample recrystallized from alcohol melted at 232–235°, dec. (lit., 235–236°).

Anal. Calcd. for $C_7H_3O_2Br_3$: C, 23.40; H, 0.84. Found: C, 23.85; H, 1.10.

When tribromoquinone (3 g.) was treated with diacetyl peroxide (1.1 g.) in purified ligroin[16] (40 cc., b. p. 95–100°) at 95–100° for one and one-half hours, the reaction mixture afforded only a trace of tribromotoluquinone and consisted largely of brown-red gums and a brown sandy product of indefinite melting point which could not be purified.

For **catalytic hydrogenation,** a solution of 0.65 g. of tribromotoluquinone and 0.65 g. of anhydrous sodium acetate was shaken with hydrogen in the presence of 8 g. of palladium–barium sulfate. The reaction stopped after the absorption of 200 cc. of gas in one-half hour. The solution was filtered and evaporated to dryness in vacuum and the residue extracted with ether in the presence of a little

(15) Sarauw, *Ann.*, **209,** 120 (1881); Datta and Bhoumik, THIS JOURNAL, **43,** 309 (1921).

(16) The solvent was shaken with a solution of potassium permanganate in dilute sulfuric acid and then with a mixture of concentrated sulfuric and nitric acids.

dilute sulfuric acid. Evaporation of the solvent left a dark gum which when dissolved in benzene and treated with petroleum ether afforded crystalline material, m. p. 120–121° (0.15 g.). Recrystallized from benzene–ligroin, the substance formed colorless plates, m. p. 124° (**toluhydroquinone,** m. p. 124–125°). The sample was free from bromine.

Anal. Calcd. for $C_7H_8O_2$: C, 67.69; H, 6.49. Found: C, 67.91; H, 6.56.

Other Alkylations.—The principal results of the synthetic experiments are summarized in Table II. The procedure generally employed for the introduction of higher alkyl and alkenyl groups may be illustrated by the following account of the preparation of **2-methyl-3-pentadecyl-1,4-naphthoquinone.** A solution of 1 g. of dipalmitoyl peroxide in 10 cc. of purified ligroin (95–100°) in a boiling tube was treated with 0.25 g. of methylnaphthoquinone, a chip of porous pot was added, and the mixture was warmed and stirred until the quinone had dissolved. The bath temperature was gradually raised until effervescence set in at 90°, and after one hour the temperature was raised to 100° during thirty minutes and then allowed to fall to 90°, when gas evolution had ceased.

The reaction products were isolated in one of the following ways.

A. Separation as a solid from the cooled solution was followed by recrystallization.

B. When no material crystallized on cooling, other than the fatty acid derived from the peroxide, the solution sometimes was evaporated to dryness and the residue fractionally crystallized (not recommended for quinones with long alkyl side chains).

C. As in B, but the residue was dissolved in alcohol and treated with aqueous sodium hydrosulfite solution according to the procedure of Fieser[17]; the reduced mixture was shaken with ligroin (b. p. 30–60°), when the substituted hydroquinone usually appeared as a white solid at the interface and could be collected by suction filtration. The solid was dried and oxidized with silver oxide in ethereal solution in the presence of sodium sulfate.

D. As in C, except that after reduction the hydroquinone did not separate from the water–ligroin mixture as a solid but remained in the hydrocarbon layer. In this case the ligroin solution was washed with aqueous alkali-hydrosulfite and extracted with Claisen's alkali, etc., exactly as in a procedure described for the isolation of vitamin K_1 from alfalfa concentrates.[17]

Each of the analytical samples of fully substituted quinones gave a negative test with Craven's reagent.[18]

Summary

Both the methylation of quinones by lead tetraacetate in acetic acid solution and the decomposition of the tetraacetate to carbon dioxide and hydrocarbon gas in the absence of an acceptor are promoted by a number of hydroxylic and hydrocarbon solvents.

Diacyl peroxides are excellent agents for the alkylation of *p*-benzo- and 1,4-naphthoquinones having a free position in the quinonoid ring, and a number of new or difficultly accessible quinones have been prepared with ease by this method.

Relative Acid Strengths of Formic, Acetic, and Propionic Acids in Alcohols and Dioxane–Water Mixtures

BY MARTIN KILPATRICK AND R. DEAN EANES

The determination, in various alcohols, of the acid strengths of substituted benzoic acids relative to benzoic acid, has shown that the logarithm of the acid strength varies linearly with the reciprocal of the dielectric constant of the medium over the range $D = 78.5$ to $D = 24.2$.[1] On the other hand, in dioxane–water mixtures, the logarithm of the acid strength does not vary linearly with the reciprocal of the dielectric constant. The present paper shows that these conclusions are also valid for certain aliphatic acids.

The acetic and propionic acids, free from homologs, were refluxed with the pure anhydrides and fractionally distilled. Formic acid was treated with boric anhydride to remove water and distilled under reduced pressure. The purification of methyl and ethyl alcohol, ethylene glycol, and dioxane and the preparation of the solutions have been described in the earlier papers as has the e. m. f. method by which the experiments were carried out.[2]

Table I gives the ratio of the dissociation constant of formic acid to that of acetic acid in the various solvents containing lithium chloride. The ratio of the dissociation constants is the equilibrium constant, $K_{A_xB_o}$, for the reaction

$$A_x + B_o \rightleftharpoons A_o + B_x \qquad (1)$$

where A_x is formic acid and B_o acetate ion.

TABLE I

RATIO OF THE DISSOCIATION CONSTANT OF FORMIC ACID TO THAT OF ACETIC

Solvent	Dielectric constant	Ionic strength	$K_{A_xB_o}$	Calculated $K_{A_xB_o}$ by eq. (2)
Water	78.5	0.00	10.1[a]	10.4
		.10	10.3[b]	
Ethylene glycol	37.7	.05	14.0	14.0
Methyl alcohol	31.5	.05	17.3	16.4
Ethyl alcohol	24.2	.05	19.6	20.5
Dioxane–water	25	.05	19.4	19.8

[a] From the thermodynamic dissociation constants of Harned and co-workers, ref. 4. [b] Solvent salt potassium chloride.

The logarithm of the ratio of the dissociation constants is plotted against the reciprocal of the dielectric constant in Fig. 1. The results for the pure solvents may be expressed by the equation

$$\log K_{A_xB_o} = 0.887 + \frac{10.3}{D}$$

Values thus calculated are given in column five of Table I. In agreement with our previous findings the relative acid strength in dioxane–water mixtures ($D = 25$) closely approximates that in ethyl alcohol.[2,3] Figure 1 also includes the values

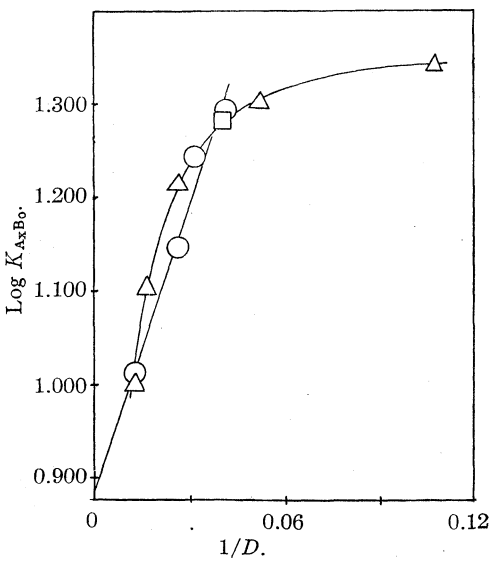

Fig. 1.—Formic acid *vs.* acetic acid: Δ, Harned and co-workers; O, pure solvents, this investigation; □, dioxane–water, this investigation.

of the constant, $K_{A_xB_o}$, calculated from the thermodynamic dissociation constants at 25° of formic and acetic acids in water and dioxane–water mixtures of dielectric constant 60.8, 38.5, 17.7 and 9.3.[4] It is evident that log $K_{A_xB_o}$ is not a linear function of the reciprocal of the dielectric constant, and that we are dealing with the same phenomenon observed in the case of the substituted benzoic acids.[5]

TABLE II

RATIO OF THE DISSOCIATION CONSTANT OF PROPIONIC ACID TO THAT OF ACETIC

Solvent	Dielectric constant	Ionic strength	$K_{A_xB_o}$	Calculated $K_{A_xB_o}$ by eq. (3)
Water	78.5	0.00	0.762[a]	0.773
Ethylene glycol	37.7	.05	.637	.617
Methyl alcohol	31.5	.05	.566	.566
Ethyl alcohol	24.2	.05	.477	.484
Dioxane–water	25	.05	.521	.495

[a] From the results of Harned and co-workers, refs. 4 and 5.

Table II and Fig. 2 present the corresponding results for the ratio of the dissociation constant of propionic acid to that of acetic.

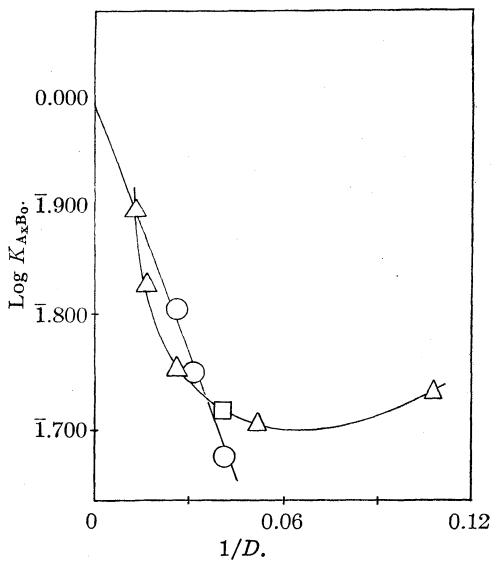

Fig. 2.—Propionic acid *vs.* acetic acid: Δ, Harned and co-workers; O, pure solvents, this investigation; □, dioxane–water, this investigation.

The result for the dioxane–water mixture of dielectric constant 25 lies above the value for the solvent ethyl alcohol, but fits nicely on the smooth curve through the values for the other dioxane–water mixtures calculated from the recent data on the thermodynamic dissociation constant of propionic acid,[6] and that of acetic acid.[4] In the

pure solvents, the results may be expressed by the equation

$$\log K_{A_xB_o} = -0.022 - \frac{7.1}{D}$$

and the values thus calculated are given in column five of Table II.

It should be emphasized that the values of $K_{A_xB_o}$ for the experiments reported in this paper are direct determinations of the equilibrium constant for the reaction

$$C_2H_5COOH + CH_3COO^- \rightleftharpoons CH_3COOH + C_2H_5COO^- \quad (4)$$

and the corresponding reaction for formic acid. The measurements were made in the presence of 0.045 mole per liter of lithium chloride with a 1.0 molar bridge solution of the same salt. For a reaction of the charge type of equation (4), the equilibrium constant would be expected to be independent of ionic strength, for the same solvent salt, and comparable to the thermodynamic equilibrium constant. This is borne out by the results at various ionic strengths given in the following table.

In addition, the value of $K_{A_xB_o}$ calculated from the thermodynamic constants in water given in Table I, agrees with the value in 0.095 molar potassium chloride.

TABLE III

THE EFFECT OF IONIC STRENGTH ON THE EQUILIBRIUM CONSTANT OF THE REACTION

$$HCOOH + CH_3COO^- \rightleftharpoons CH_3COOH + HCOO^-$$

Solvent	$K_{A_xB_o}$ μ = 0.05	0.10	0.20	0.50	1.00	2.00
Water	..	10.3	10.3	10.3	10.3	10.3
Methyl alcohol	17.3	17.8	17.6			
Ethyl alcohol	19.6	19.5	19.8			

The authors would like to take this opportunity to thank the Faculty Research Committee of the University for a grant.

Summary

In dioxane–water mixtures, the logarithm of the acid strength of formic acid relative to acetic, or of propionic relative to acetic, is not a linear function of the reciprocal of the dielectric constant of the medium. In the pure solvents studied—water, ethylene glycol, methyl alcohol and ethyl alcohol—a linear relationship holds. This same phenomenon has been observed in the case of the substituted benzoic acids.

Studies on High Molecular Weight Aliphatic Amines and their Salts. VIII. Soluble and Insoluble Films of the Amine Acetates. A. The Surface Tension of Aqueous Solutions of Dodecylamine Acetate

BY EVERETT J. HOFFMAN, G. E. BOYD AND A. W. RALSTON

Introduction

In the fifth paper of this series[1] we reported the results of an investigation of the surface properties of a simple, long chain cationic colloidal electrolyte, namely, dodecylamine hydrochloride. The present paper deals with a study of the surface properties of aqueous solutions of dodecylamine acetate. In this case the time effects of long duration which were observed for dilute solutions of dodecylamine hydrochloride were not found. In the case of 5×10^{-3} N solutions at 25°, constant values of the surface tension were obtained within thirty minutes. No time effects were observed at other temperatures for this same solution. With a solution of concentration 7.5×10^{-3} N (critical micelle concentration = 1.2×10^{-2} N) no time effects were observed at any temperature. In contrast to this behavior, in the case of dodecylamine hydrochloride a steady decrease was observed even after five hours.

The absence of aging effects with unbuffered *n*-alkylamine acetate solutions may not, however, reflect the behavior in general of solutions containing this type of colloidal electrolyte. Preliminary experiments on a 5×10^{-3} N solution of dodecylamine acetate in the presence of 10^{-2} N acetic acid–sodium acetate revealed an appreciable variation of surface tension with time. It is possible that the surface active species in our experiments consists of free amine in equilibrium with amine acetate in the interior of the solution.

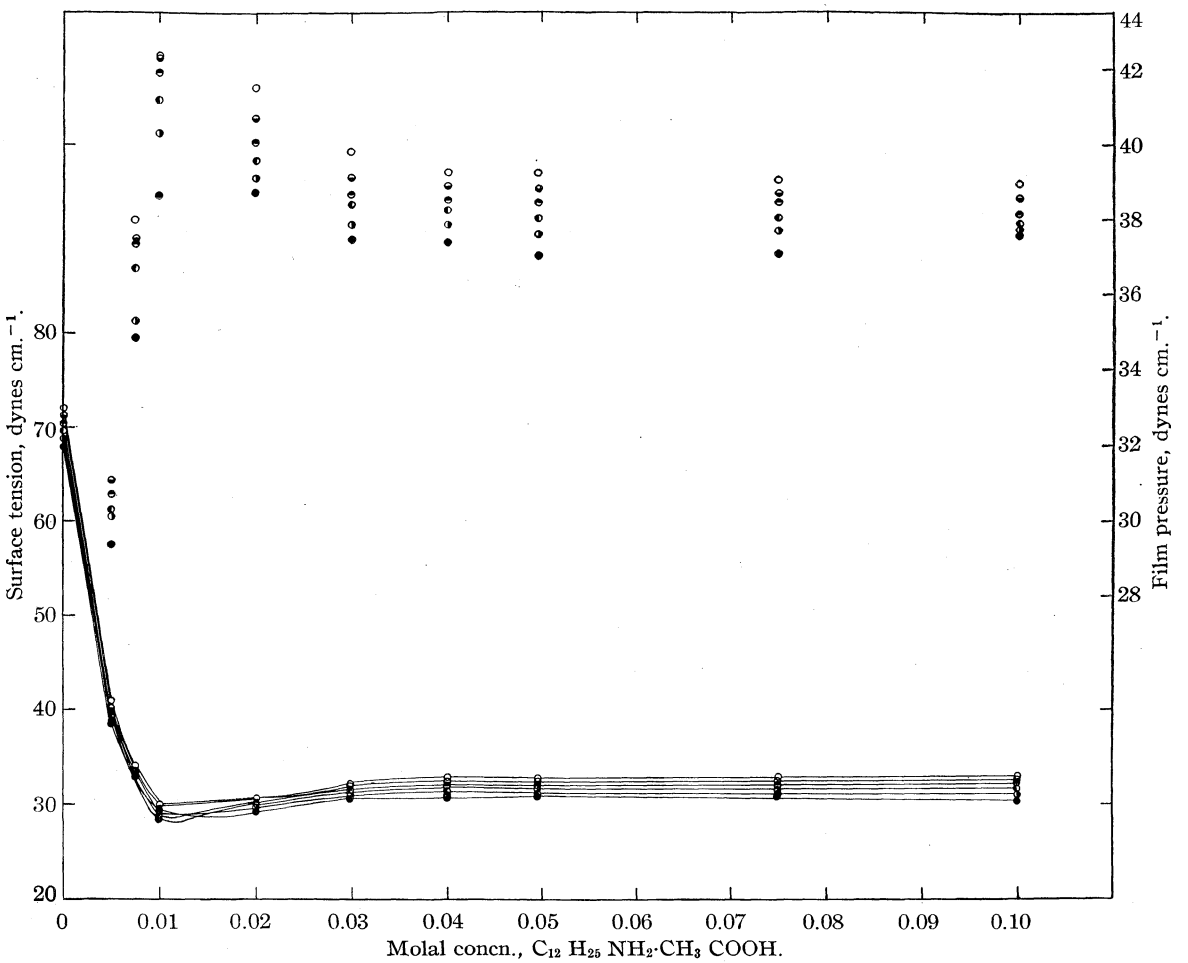

Fig. 1.—(a) Surface tension–concentration curves for aqueous solutions of dodecylamine acetate; (b) film pressure–concentration values for aqueous solutions of dodecylamine acetate: ○, 25°; ◒, 30°; ◓, 35°; ◐, 40°; ◑, 45°; ●, 50°.

Experimental Part

Preparation of Materials. Dodecylamine Acetate.—Dodecylamine acetate was prepared by the method previously described.[2] Solutions were made with triple distilled water as described in an earlier communication.[1] Densities of the solutions were determined by means of a 25-ml. pycnometer by C. W. Hoerr of the Armour Research Laboratories.

Apparatus and Procedure.—Surface tensions were determined at five degree intervals from 25 to 50° by the ring method with the apparatus used by Harkins and Jordan.[3] The ring used was made of platinum–iridium, and its mean radius was 0.6402 cm.; the value of R/r was 45.64, where R is the mean radius of the ring, and r is the mean radius of the wire.

(2) A. W. Ralston, C. W. Hoerr and E. J. Hoffman, THIS JOURNAL, **63**, 2576 (1941).

(3) W. D. Harkins and H. F. Jordan, *ibid.*, **52**, 1751 (1930).

Experimental Results

Surface tension–concentration curves at five-degree intervals from 25 to 50° are shown in Fig. 1. A plot of the film pressure, $\pi = -\Delta\gamma = \gamma_0 - \gamma$, where γ_0 is the surface tension of water and γ is the surface tension of the solution, against concentration is also shown. The latter plot has the advantage that the values are separated so that the effect of temperature is more clearly demonstrated.

Discussion

It is evident from an examination of the curves in Fig. 1 that the surface tension of solutions of dodecylamine acetate of concentrations above that exhibiting a minimum value decreases with increasing temperature. At lower concentrations this is true except for the surface tension at 40°. A slightly deeper minimum is obtained at 40° than at any other temperature investigated. A

similar behavior was observed in the study of the surface tension of aqueous solutions of dodecylamine hydrochloride.[1]

An examination of the values for the film pressure (Fig. 1) shows that at a given concentration it decreases with increasing temperature and that the value of $-\Delta\pi/\Delta T$ is fairly constant in the range 25 to 50°. The fact that, at a constant concentration, the film pressure decreases with increasing temperature shows that adsorption of dodecylamine acetate in the surface is less at higher temperatures. Between concentrations of approximately 3×10^{-2} and 10^{-1} N the film pressure does not change greatly with the concentration although this change is slightly greater at higher temperatures than at 25°.

The surface tension–concentration curves for aqueous solutions of dodecylamine acetate are similar to those obtained by us for dodecylamine hydrochloride[1] and by other investigators for anionic colloidal electrolytes.[4] A comparison of the concentration for minimum surface tension with that for the break in the conductance curve[5] shows that they are essentially the same. This is the so-called critical micelle concentration.

B. Pressure–Area Relations of Docosylamine Acetate Monolayers on Acetic Acid

Introduction

In a previous publication[1] we have reported a systematic study of the effect of inorganic anions on insoluble films of long-chain amines. In 1930, N. K. Adam[6] reported an extensive study of the variation of the character of amine films with *p*H in which the importance of the nature of the anion was noted. A portion of this investigation dealt with the use of an acetate buffer (*p*H 4.0) in which the total acetate concentration was 5×10^{-2} N. Adam reports that the insoluble films, even of eicosylamine, were gaseous and that that of hexadecylamine was one of the most perfect gaseous films ever found with insoluble substances. This last statement appears to be erroneous on the basis of our results since the film of octadecylamine acetate was so soluble that satisfactory pressure readings could not be obtained. Several trial runs were made by rapid compression of films of octadecylamine acetate to a constant area and observing the change in pressure with time. There was a continuous decline of pressure with time with an approximately constant final value regardless of the initial pressure. Films spread on sub-solutions from which a film from a previous experiment had been removed by sweeping invariably gave higher pressures than the first film spread on 10^{-1} N acetic acid. In order to eliminate this difficulty, octadecylamine acetate was replaced by docosylamine acetate. The solubility effect was not observed in this case.

Experimental Part

Preparation of Materials. Docosylamine Acetate.—Docosylamine acetate was prepared by Dr. F. M. Garland of the Armour and Co. Research Laboratories by a method similar to that described for the preparation of octadecylamine acetate.[2]

Preparation of Sub-solutions.—Sub-solutions were prepared by diluting glacial acetic acid with double distilled water[1] to a concentration of 10^{-1} N.

Apparatus and Procedure.—The film balance was that described in detail by Nutting and Harkins.[7] One degree of the divided circle corresponded to 0.0634 dyne cm.$^{-1}$ pressure on the float; the circle was read to 0.2°.

Docosylamine acetate (*ca.* 23 mg.) was weighed by means of a semi-micro analytical balance into a calibrated 25-ml. volumetric flask, dissolved in ethanol (95%, *ca.* 4 ml.), and diluted with purified benzene to 25 ml. This solution was stored in a 50-ml. ground-glass stoppered volumetric flask. Solutions were spread from a pipet (0.0722 ml. capacity) of the type described by Harkins and Anderson.[8] A period of fifteen minutes after the spreading of the film was permitted before the experiment was started. Pressure readings were made at one-minute intervals on compression to various areas and also, in separate experiments, as rapidly as possible at a much smaller number of areas. Good agreement of results between these two methods was obtained. This indicates that loss due to solubility was negligible.

Experimental Results

Pressure–area isotherms for films of docosylamine acetate on a 10^{-1} N acetic acid sub-solution at 14.8, 19.9 and 24.9° are given in Fig. 2. At

(6) N. K. Adam, *Proc. Roy. Soc.* (London), **A126**, 526 (1930).

(7) G. C. Nutting and W. D. Harkins, THIS JOURNAL, **61**, 1180 (1939).

(8) W. D. Harkins and T. F. Anderson, *ibid.*, **59**, 2189 (1937)

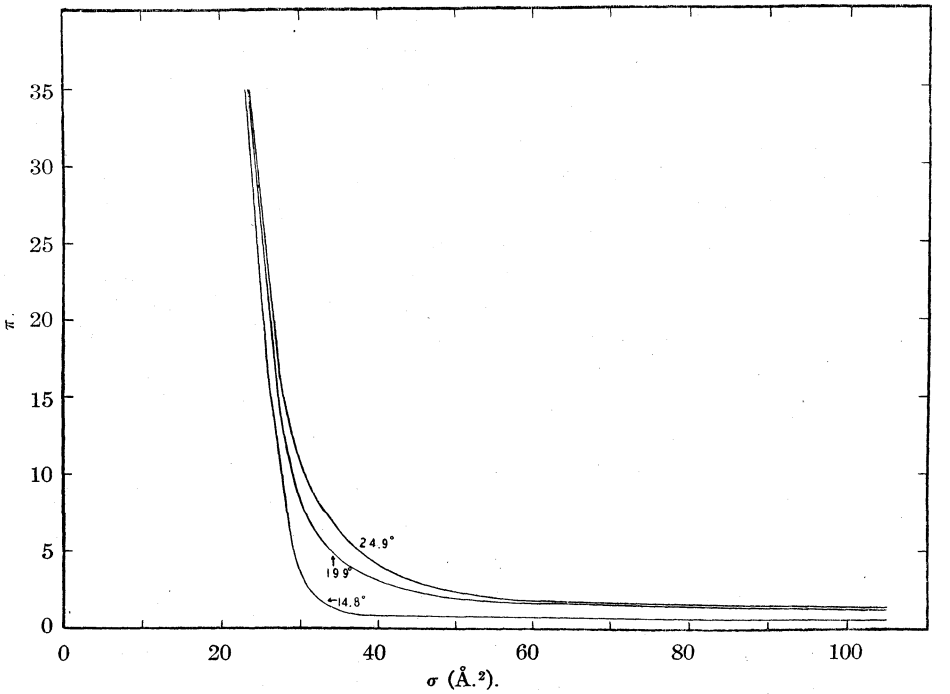

Fig. 2.—Pressure–area isotherms for docosylamine acetate monolayers on 10^{-1} N acetic acid.

large areas per molecule the film is vapor expanded in all three cases, but increased pressure produces condensed films.

The extrapolated area per molecule at zero pressure, at 14.8° is 27.9 sq. Å., at 19.9° it is 29.4 sq. Å. and at 24.9° it is 30.4 sq. Å.

The entropy of spreading is defined by the equation[9]

$$s_s = \frac{q_s}{T} = \left(\frac{\partial S}{\partial \sigma}\right)_T = \left(\frac{\partial \pi}{\partial T}\right)_\sigma$$

A plot of π against T for $\sigma = 35$ sq. Å. gives a value of 0.44 erg cm.$^{-2}$ deg.$^{-1}$ for s_s.

The increase of heat content on spreading may be calculated by use of the equation[9]

$$h_s = \left(\frac{\partial H_s}{\partial \sigma}\right)_T = -\left[\frac{\partial(\pi/T)}{\partial(1/T)}\right]_\sigma$$

At $\sigma = 35$ sq. Å., $h_s = 140$ ergs cm.$^{-2}$. This value is much lower than that obtained for octadecylamine hydrochloride.[1]

Discussion

A comparison of the curves in Fig. 2 shows the effect of temperature on the pressure–area relations of monolayers of docosylamine acetate. They show the normal trend, the film becoming more expanded with increasing temperature. The change between 14.8 and 19.9° is much greater than that in the range 19.9 to 24.9°. The isotherm at 14.8° much more closely approximates that of a true condensed film than does either one of the others.

(9) W. D. Harkins, T. F. Young and G. E. Boyd, *J. Chem. Phys.*, **8**, 954 (1940).

Summary

1. The variation of surface tension of solutions of dodecylamine acetate with concentration has been investigated at a series of temperatures by the ring method.

2. A time effect was observed only at 25° in one solution below the critical concentration for micelle formation. This is in sharp contrast to the behavior of dodecylamine hydrochloride solutions previously reported.

3. It has been pointed out that monolayers of octadecylamine acetate are too soluble to permit investigation by means of the film balance.

4. Insoluble monolayers of docosylamine acetate spread on an acetic acid sub-solution have been investigated by means of the film balance.

5. An increase in temperature causes docosylamine acetate films to become more expanded. The heat of spreading at an area of 35 sq. Å. per molecule was estimated to be 140 ergs cm.$^{-2}$.

The Elimination of Liquid Junction Potentials. IV. The Conditions of Extrapolation[1a]

BY BENTON BROOKS OWEN AND STUART R. BRINKLEY, JR.[1b]

In the preceding communications[2,3,4] of this series it is shown experimentally that accurate thermodynamic information can be derived from cells with heterionic liquid junctions by suitable extrapolations. In each of these investigations the following conditions were fulfilled.

$$\text{Ag, AgCl (s)} \left| \begin{array}{l} \text{AgCl [satd.]} \\ \text{KNO}_3\ [(1-x)m] \\ \text{KCl}\ [xm] \end{array} \right|$$

I. The composition of the liquid systems in contact are so chosen that, in a series of measurements, these systems can be made to approach by extrapolation either absolute identity, or some condition which may be treated by present thermodynamic methods.

II. The ionic strengths of the liquid systems in contact are the same, and the extrapolation is performed at constant ionic strength.

These conditions are the subject of the present communication.

Condition I

The necessity of Condition I scarcely requires comment, but it will be useful to distinguish between and to classify several types of junctions which can fulfill this condition. The classification of junctions will be based upon their characteristics in limiting states attained by extrapolation, because it is ordinarily these characteristics which justify their use in thermodynamic calculations. The concentration of one or more solutes at every junction will be expressed in terms of a variable, x $(1 \geqslant x \geqslant 0)$, which will always be reduced to zero by the extrapolation. Therefore when the properties, or types of any junctions are referred to, it is implied that the condition, $x \rightarrow 0$, has been imposed.

Limiting Liquid Junctions, Type A.—The two liquid systems comprising Type A junctions become absolutely identical in the limit when $x \rightarrow 0$, and their junction potentials are zero. The following cells illustrate this type of junction.

$$\text{H}_2 \left| \begin{array}{l} \text{H}_2\ \text{[satd.]} \\ \text{HCl}\ [m] \end{array} \right| \left| \begin{array}{l} \text{H}_2\ \text{[satd.]} \\ \text{HCl}\ [(1+x)m] \end{array} \right| \text{H}_2 \qquad \text{I}$$

$$\text{Ag, AgCl (s)} \left| \begin{array}{l} \text{AgCl [satd.]} \\ \text{KNO}_3\ [(1-x)m] \\ \text{KCl}\ [xm] \end{array} \right| \left| \begin{array}{l} \text{AgCl [satd.]} \\ \text{KNO}_3\ [m] \end{array} \right| \left| \begin{array}{l} \text{AgCl [satd.]} \\ \text{KNO}_3\ [(1-x)m] \\ \text{AgNO}_3\ [xm] \end{array} \right| \text{AgCl (s), Ag} \qquad \text{II}$$

It is characteristic of such cells that each constituent of the limiting junction solutions, *including soluble components of the electrodes*, is present in both solutions at the same concentration. The electromotive forces of these cells are therefore independent of standard electrode potentials. In other respects such cells may be widely dissimilar. Thus, Cell I is homo-ionic, and its liquid junction potential is thermodynamically defined at *all* values of x. The e. m. f. of this cell is a simple function of transference numbers and activities at all values of x, and is independent of the geometry of the junction. Cell II is heterionic for values of x different from zero, and its junction potential is thermodynamically defined only in the limit.

Limiting Liquid Junctions, Type B. The two liquid systems comprising Type B junctions do not become identical in the limit when $x \rightarrow 0$, but differ only with respect to the soluble components of the two electrodes. The following cells will serve as illustrations.

$$\text{Hg, HgCl (s)} \left| \begin{array}{l} \text{HgCl [satd.]} \\ \text{KCl}\ [m] \end{array} \right| \left| \begin{array}{l} \text{H}_2\ \text{[satd.]} \\ \text{KCl}\ [(1-x)m] \\ \text{HCl}\ [xm] \end{array} \right| \text{H}_2 \qquad \text{III}$$

$$\text{Ag, AgCl(s)} \left| \begin{array}{l} \text{AgCl [satd.]} \\ \text{KCl}\ [xm] \\ \text{KNO}_3\ [(1-x)m] \end{array} \right| \text{KNO}_3\ [m] \left| \begin{array}{l} \text{AgNO}_3\ [xm] \\ \text{KNO}_3\ [(1,x)m] \end{array} \right| \text{Ag} \qquad \text{IV}$$

Although the limiting liquid junction potentials of these cells are not zero, they are of the type which is always present when the so-called "cells without liquid junctions" are used to compare standard electrode potentials. Such junction potentials are neglected in thermodynamic practice, and are therefore integral parts of all measured standard electrode potentials. For example, the replacement of potassium chloride by hydrogen chloride throughout Cell III would lead to the familiar cell

$$\text{Hg, HgCl(s)} \left| \begin{array}{l} \text{HgCl [satd.]} \\ \text{HCl}\ [m] \end{array} \right| \left| \begin{array}{l} \text{H}_2\ \text{[satd.]} \\ \text{HCl}\ [m] \end{array} \right| \text{H}_2 \qquad \text{V}$$

without changing the nature[5] of the liquid junction. Note that the Type A junction of Cell II changed to Type B in Cell IV by elimination of the silver chloride from the right-hand electrode and solution.

Limiting Liquid Junctions, Type C.—The following cells give rise to Type C junctions

$$\text{Ag, AgCl(s)} \left| \begin{matrix}\text{AgCl [satd.]}\\ \text{KCl } [xm]\end{matrix} \right| \left| \begin{matrix}\text{AgCl [satd.]}\\ \text{HCl } [xm]\end{matrix} \right| \text{AgCl (s), Ag} \quad \text{VI}$$

$$\text{Ag, AgCl (s)} \left| \begin{matrix}\text{AgCl [satd.]}\\ \text{KNO}_3\ [xm\,(1-y)]\\ \text{KCl } [xmy]\end{matrix} \right| \left| \begin{matrix}\text{AgCl [satd.]}\\ \text{KNO}_3\ [xm]\end{matrix} \right| \left| \begin{matrix}\text{AgCl [satd.]}\\ \text{KNO}_3\ [xm\,(1-y)]\\ \text{AgNO}_3\ [xmy]\end{matrix} \right| \text{AgCl (s), Ag} \quad \text{VII}$$

The variable y ($1 \geqslant y \geqslant 0$) in the last cell is used to express changes in the ratio of the solute concentrations. In this respect, y plays the same rôle in Cell VII that x plays in Cell II, but the conditions of extrapolation in these otherwise similar cells are quite different. In the operation of Cell II, m is kept constant during a given extrapolation to $x \rightarrow 0$, and the limiting junction becomes two identical solutions of potassium nitrate of concentration, m. In the operation of Cell VII, y and m are kept constant during a given extrapolation to $x \rightarrow 0$, and the junction consists of two solutions which do not become identical in the limit so long as y is different from zero.

Thus, in general, the solutions composing Type C junctions contain constituents which are not shared by both in common, and this asymmetry is not eliminated by extrapolation. The liquid junction potential produced by this asymmetry when $x \rightarrow 0$ is not of the type inherent in "cells without liquid junctions," and cannot logically be neglected. Fortunately there are both experimental and theoretical grounds for believing that it is possible to estimate the magnitudes of such residual junction potentials within reasonable limits. This possibility argues the practical utility of cells which lead to this "calculable" type of junction potential, but does not permit the use of such junctions with the same confidence with which Types A and B are employed in thermodynamic calculations. This category can be made to include cells whose limiting junction potentials are partly calculable and partly neglected. For example, if the silver chloride is eliminated from the right hand solution and electrode of Cell VII, extrapolation to $x \rightarrow 0$ results in a junction with characteristics of both Types C and B. This composite junction might be termed Type CB, but since the asymmetry of the B variety is absorbed in the standard electrode potentials, it will not be necessary to distinguish between Types C and CB in the following discussion.

The estimation of a liquid junction potential, E_j, is based upon the expression[6]

$$-\mathrm{d}\,E_j = \frac{RT}{F} \sum \frac{T_i}{z_i}\,\mathrm{d}\ln m_i\gamma_i \qquad (1)$$

in which T_i, m_i, and γ_i are the transference number, molality and activity coefficient of any ionic constituent, i. The valence, z_i, carries the sign of the charge. The activity coefficients may be disregarded, as the equation will be employed only in the limit, $\mu \rightarrow 0$. The summation extends over all the ion constituents present, except those produced by dissociation of the solvent.[7]

Ordinarily, the exact values of T_i and m_i are not known at all points throughout the region of the junction, and some assumptions are required before equation (1) can be integrated. For this purpose Planck[8] assumed "constrained diffusion" across the junction, and Henderson[9] assumed a "continuous mixture boundary" which leads to linear concentration gradients. Both of these assumptions, as well as those employed in more elaborate treatments[10,11,12] of the problem, yield values of E_j which are in reasonable agreement (plus or minus a few tenths of a millivolt) with each other and with experiment, if the solutions are dilute and differences in ionic mobilities are not extreme. So long as the objectives do not demand more than this reasonable agreement, it is not necessary to decide which, if any, of these assumptions is strictly valid.

With this in mind, and purely as a matter of

(5) The magnitude of the junction potential would vary to some extent depending upon the properties of the electrolyte at the concentration m, but this variation is also neglected. Thus, in determining the activity coefficient of HCl in salt solutions, the same value of E^0 is used regardless of the nature of the salt. Since E^0 contains the junction potential of Cell V at $m = 0$, the calculated activity coefficient contains the variation of this junction potential with the composition of the solutions at finite concentrations.

convenience, the Henderson assumption will be used in the present discussion because it leads to the relatively simple expression

$$-E_j^0 = \text{Lim}\ \frac{RT}{F}\ \frac{\Sigma(\lambda_i^0/z_i)(m_i'' - m_i')}{\Sigma\lambda_i^0(m_i'' - m_i')} \qquad (2)$$

at infinite dilution. This choice does not imply that the authors can dispose of the theoretical objections[11] to the general application of this assumption to heterionic junctions. The primes and double primes in equation (2) refer to concentrations in the immediate neighborhood of the left and right hand electrodes, respectively, and λ_i^0 is the limiting conductance of the i-ions.

In order to evaluate the limit appearing in this equation, the ionic concentrations m_i', m_i'', etc., may be expressed as fractions

$$\rho_i' \equiv m_i'/m', \quad \rho_i'' \equiv m_i''/m'', \text{ etc.} \qquad (3)$$

of the total ionic concentrations, m' and m''. In the limit, as $x \longrightarrow 0$

$$\frac{m'' - m'}{m'' + m'} = 0 \qquad (4)$$

for the Type A and C junctions. The application of this equation to Type B and CB junctions can only be considered permissible in view of the *convention* of disregarding the soluble constituents of the electrodes in cells containing these junctions.

Combination of equations (2), (3) and (4) leads to the following result at infinite dilution.

$$-E_j^0 = \frac{RT}{F}\ \frac{\Sigma(\lambda^0/z_i)(\rho_i'' - \rho_i')}{\Sigma\gamma_i^0(\rho_i'' - \lambda_i')}\ \ln\ \frac{\Sigma\lambda_i^0\rho_i''}{\Sigma\lambda_i^0\rho_i'} \qquad (5)$$

For Type A junctions, $\rho_i' = \rho_i''$, etc., and the logarithmic factor is zero. According to the convention referred to above, this factor is also zero for Types B and CB junctions. For the simplest Type C junctions (Cell VI), equation (2) reduces to the familiar equation of Lewis and Sargent.[13]

MacInnes and Yeh[14] investigated cells of Type VI which contained pairwise combinations of the chlorides of hydrogen, ammonium and the alkali metals. Unfortunately, only two concentrations (0.1 and 0.01) were used, but the values of E_j^0 obtained by linear extrapolation for all combinations (except those involving potassium chloride) are in reasonable agreement with equation (5) the average deviation being 0.11 mv. For the potassium salts the disagreement is of the order of 1.2 mv. Data are available which can be used for a similar "two point" (m = 0.05 and 0.03) extrapolation for the system KCl (m) | KBr (m), and this also is not in accord with equation (5). The disagreement in this case amounts to 0.25 mv.

In order to determine whether the discrepancies obtained with potassium salts represent a failure of the equation or of the "two point" extrapolation, the family of straight lines shown in Fig. 2 of the first paper of this series[2] has been used to obtain interpolated values of $E - 2k \log (xmy) + 2k\alpha\sqrt{\mu}$ which would be applicable to Cell VII. The constants k = 0.05915 and α = 0.506 at 25°. The addition of $k \log K$ (= −0.5768) to these values yields the values of $k \log \gamma_{Cl}\gamma_{Ag} + 2k\alpha\sqrt{\mu} + E_j$ which are plotted as ordinates in Fig. 1.

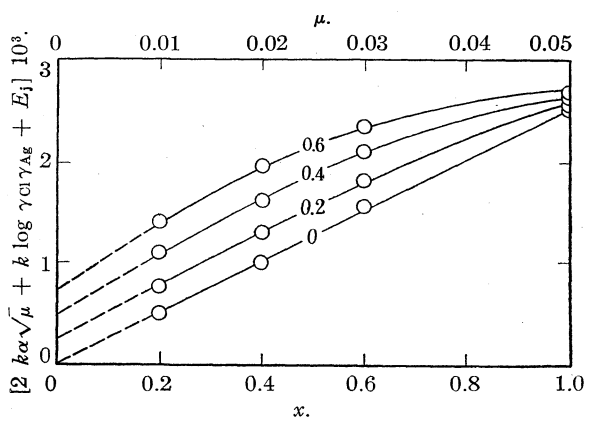

Fig. 1.—Extrapolation of the results for Cell VII. Values of y are indicated on the curves; m is constant and equal to 0.05 mole per kg. of water. The intercepts, E_j^0, were calculated by equation (5).

The abscissa is expressed in terms of x at the bottom, and μ at the top of the figure. Two important conclusions may be drawn from this plot. First, for all values of y greater than zero the plots are not linear, and as the system KCl|$AgNO_3$ is approached (y = 1), a very pronounced curvature appears in the neighborhood of μ = 0.025. Second, the extrapolated portions of the curves have been drawn to intercepts, E_j^0, calculated by equation (5) without producing any apparent discontinuity with the experimental curves. These results supply a reasonable explanation of the discrepancies referred to above, and appear to justify the use of equation (5) in estimating E_j^0 for practical purposes. The rigorous validity of this equation is, of course, a question which cannot be decided by such curved extrapolations from so few data.

(14) D. A. MacInnes and Y. L. Yeh, *ibid.*, **43**, 2563 (1921).

The classification of liquid junctions according to their limiting characteristics ($x \rightarrow 0$) is helpful in determining the propriety of using a given cell for thermodynamic purposes.

The use of Type A junctions assumes the possibility of a suitable extrapolation to $x \rightarrow 0$. If the accuracy of this extrapolation is not inferior to that of the data upon which it is based, the extrapolated quantity is subject to rigorous thermodynamic treatment. The accuracy of such extrapolations appears to fulfil this condition, but only one system with Type A junctions has been investigated.[2]

The extrapolation required for Type B junctions is similar to that for Type A, and appears equally accurate,[3,4] but the extrapolated quantity derived from a Type B junction contains an unknown residual junction potential. Although this unknown potential is disregarded in the use of all of the so-called "cells without liquid junctions," this convention does not always permit a rigorous thermodynamic interpretation of the data. For example, the values of E^0 and the activity coefficients calculated from the electromotive forces of Cell V are somewhat ambiguous for this reason.[5] On the other hand, the modern electrometric determination of ionization constants of weak electrolytes is free from this defect, because the residual junction appears twice in the procedure (in the extrapolations for E^0 and for K) and cancels out.

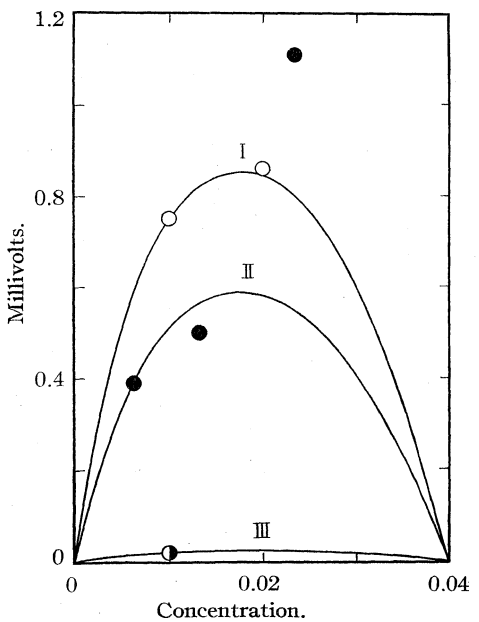

Fig. 2.—Departures of several extrapolations from linearity in dilute solutions. I. Cell VIII: abscissa, chloride (or silver) molality: potassium nitrate concentration constant, 0.01 molal. II. Cell IX: abscissa, total iron wt. normality: hydrochloric acid concentration constant, 0.05 wt. normal. III. Cell III: abscissa, hydrochloric acid normality: ionic strength constant, 0.1 normal.

The extrapolations which result in Types A and B are practically linear when performed at constant ionic strength.[2,3,4] Type C (CB) junctions are produced by extrapolation to zero ionic strength, and may depart widely from linearity, as in Fig. 1. In addition to the uncertainty caused by this curvature, the use of Type C (CB) junctions is under the disadvantage of requiring an estimate of E_j^0. Furthermore, all of the equations proposed for this purpose involve some extra-thermodynamic assumption that is difficult to justify *per se*, and attempts to verify the equations may have to contend with non-linear extrapolations such as those encountered in systems containing potassium salts. These considerations make it undesirable to employ Type C (CB) junctions for any purpose for which Types A and B, or cells "without liquid junctions" can be utilized, and leave room for doubt that condition I is rigorously fulfilled by Type C (CB) junctions.

Condition II

While the extrapolations ($x \rightarrow 0$) are not necessarily performed at constant total ionic strength, it appears that this condition must be fulfilled if a *linear* extrapolation is to be obtained, or even approximated. In the three systems investigated by the authors[2,3] and E. J. King,[4] the deviations of the experimental results from linearity are of the order of the reproducibility of the electromotive forces (0.05 mv.). The liquid junction potentials in these systems were small because of the choice of ions with nearly equal mobilities,[2,4] and the use of buffers[3] when acids were present. In cells containing high liquid junction potentials, there is evidence of only a slight departure from linearity. For example, the available data[15] on Cell III ($m = 0.1$; $x = 0.1$, 0.5, and 1.0) show a maximum deviation of 0.25 mv. from a straight line drawn through the points corresponding to $x = 0$ and $x = 1$. This curvature is illustrated by curve III in Fig. 2, which was constructed as follows: (1) a large-scale plot of the function $E - k \log (mx)$ against mx was made from measurements on Cell III, (2) a smooth curve was drawn through these ex-

(15) A. Unmack and E. A. Guggenheim, *Kgl. Danske Videnskab. Selskab. Math.-fys. Medd.*, X, 8 (1930).

perimental results, and extrapolated to the limit, $mx = 0$, (3) a chord was drawn from $mx = 0$ to $mx = 0.04$, and (4) vertical distances between this chord and the curve were scaled off at several values of mx, and plotted as the ordinates of Curve III, in Fig. 2, against mx as abscissa. Curve III therefore represents the departure of the experimentally determined function, $E - k \log (mx)$, from linearity at acid concentrations (mx) between 0 and 0.04 mole per liter. In this particular case the ionic strength is constant (0.1 mole per liter at 18°), and the departure from linearity is very small.

On the other hand, the upper curves[16] in Fig. 2 illustrate the relatively enormous curvatures encountered when the extrapolation is not performed at constant ionic strength. Curve I shows the departures of the function, $E - 2k \log (xm) + 2k\alpha\sqrt{\mu}$, from linearity for the cell

$$\text{Ag, AgCl (s)} \left| \begin{matrix} \text{AgCl [satd.]} \\ \text{KCl } [xm] \\ \text{KNO}_3\ [m_0] \end{matrix} \right| \begin{matrix} \text{AgCl [satd.]} \\ \text{KNO}_3\ [xm + m_0] \end{matrix} \left| \begin{matrix} \text{AgCl [satd.]} \\ \text{AgNO}_3\ [xm] \\ \text{KNO}_3\ [m_0] \end{matrix} \right| \text{AgCl (s), Ag} \quad \text{VIII}$$

at a constant concentration of potassium nitrate ($m_0 = 0.01$). These results were obtained graphically from the family of straight lines given in Fig. 2 of the first paper in this series.[2] The temperature is 25°, and $m = 0.05$ molal. It is evident that this extrapolation at varying ionic strength is almost useless for practical purposes, although the ionic strength is uniform throughout the cell [equation (4)], and the mobilities of all of the ions are very nearly equal. In this case the departure from linearity is obviously due to variations in activity coefficients, rather than to large changes in E_j.

Curve II in Fig. 2 shows the departures of the function, $E + k \log (c_{Fe^{+++}}/c_{Fe^{++}})$, from linearity for the cell

$$\text{H}_2 \left| \begin{matrix} \text{H}_2\ \text{[satd.]} \\ \text{HCl } [m_0] \end{matrix} \right| \begin{matrix} \text{FeCl}_2 + \text{FeCl}_3\ [m] \\ \text{HCl } [m_0] \end{matrix} \left| \text{Pt} \right. \quad \text{IX}$$

used by Popoff and Kunz.[17] The constant acid concentration, m_0, is 0.05 mole per kilo of solution, and the total iron concentration, m, is here expressed in *equivalents* per kilo of solution to reduce the concentration range covered by the plot.[18] The temperature is 25°. The curvature in this case is probably due to considerable variations in E_j as well as in the activity coefficients.

Summary and Conclusions

In the elimination of liquid junction potentials by extrapolation, it is useful to classify junctions according to their characteristics in the limit obtained by extrapolation. This depends upon the fact that a given pair of junction solutions may lead to quite different limiting cell potentials depending upon the nature of the electrodes employed and the manner in which the limit is approached. Thus, the limiting potential of the liquid–liquid system KNO_3, KCl | KNO_3, $AgNO_3$ can be Type A ($E_j^0 = 0$, as in Cell II), Type B (E_j^0 neglected, as in Cell IV), or Types C and CB (E_j^0 calculable, as in Cell VII as written, or modified by elimination of silver chloride from the right-hand electrode).

New evidence (Fig. 1) is produced to show that the Henderson equation yields values of E_j^0 in reasonable agreement with experiment. An explanation is suggested for the previous failure of this equation in some systems involving the potassium salts.

The practical necessity of performing the extrapolations at constant ionic strength is illustrated by means of graphs (Fig. 2).

NEW HAVEN, CONN. RECEIVED DECEMBER 31, 1941

(16) The construction of Curves I and II is analogous to that just described for Curve III, but differs in the nature of the plotted experimental functions.

(17) S. Popoff and A. H. Kunz, THIS JOURNAL, 51, 382 (1929).

(18) If the *molar* concentration of iron had been used the maximum of Curve II would have been over twice as high. The experimental point at 0.025 normal was disregarded in drawing the curve because it was inconsistent with the data at higher concentrations.

Electric Moments of Inorganic Halides in Dioxane. II. Chlorides of Boron, Aluminum, Iron, Silicon, Germanium and Tin[1]

BY T. J. LANE, P. A. MCCUSKER AND B. COLUMBA CURRAN

In the first paper[2] of this series, the degree of coördination of phosphorus, arsenic and antimony halides with dioxane was estimated from electric moment data. Further similar studies on the chlorides of some other trivalent elements and some of the tetravalent elements of Group IV B have been made. The number of compounds suitable for such study was limited either by low solubility in dioxane or by the occurrence of reactions other than coördination between the halide and dioxane. Whereas the chlorides of boron and aluminum caused no decomposition of dioxane, the corresponding bromides were found to react with this solvent to form decomposition products, the reaction with boron bromide taking place violently. In the case of titanium tetrachloride electric moment data of sufficient accuracy were unobtainable due to the low solubility of the dioxanate in dioxane.

Experimental

Preparation and Purification of Compounds.—Boron chloride was prepared from boron fluoride and aluminum chloride by the method of Gamble, Gilmont and Stiff.[3] The product was purified by several distillations and was finally absorbed in weighed amounts of cold dioxane, the composition of each solution being checked by analysis for chlorine. All manipulations were carried out under conditions which effectively prevented absorption of moisture.

Anhydrous aluminum chloride, a Baker C. P. product, was resublimed three times in a current of carbon dioxide, using an all-glass apparatus. The final product was sublimed directly into weighing bottles and anhydrous dioxane added.

Anhydrous ferric chloride was prepared by passing dry chlorine over heated standard iron wire in an all-glass apparatus. The apparatus was so designed that the product could be sublimed in an atmosphere of chlorine, without removal from the apparatus, through two glass wool plugs in series directly into weighing bottles. The chlorine atmosphere in the receivers was replaced by drawing a slow current of dry air over the sublimate. Analysis for chlorine indicated a purity of 99.8% for the product. Samples were prepared by direct addition of dioxane.

Silicon tetrachloride was prepared and purified by a standard method.[4] The product was fractionally distilled and a middle fraction boiling at 57° was used in sample preparation.

Germanium tetrachloride was obtained by the purification of a sample furnished through the courtesy of the Eagle–Picher Lead Company. Dissolved chlorine was removed by treatment with mercury and the chlorine-free liquid fractionally distilled through a glass-helix packed column. The middle fraction, boiling at 83.6° at 751 mm., was used in sample preparation. Analysis of this fraction for chlorine by the method of Baxter and Cooper[5] indicated a purity above 99%.

Anhydrous stannic chloride, a Baker C. P. product, was fractionally distilled several times in an atmosphere of carbon dioxide and a sample of the distillate sealed off in a glass tube. Absorption of moisture was prevented by opening the glass tube and making up the dioxane solutions in a dry-atmosphere chamber fitted with long-sleeved rubber gloves.

Dioxane for all purposes was purified by refluxing the commercial product over sodium for twenty-four hours and fractionally distilling.

Measurements and Calculations.—Densities and dielectric constants were measured as previously described.[2] The solute polarizations at infinite dilution were calculated by the method of Hedestrand.[6] The $\Delta\epsilon/C_2$ ratio for the dioxane solutions of boron chloride, germanium tetrachloride and stannic chloride showed a slight variation with concentration. The average value of this ratio, rather than an extrapolated value, was used in calculating the total polarization of each compound. The difference in the moments calculated from the average ratio and from that for the most dilute solution is in every case within the limit of accuracy indicated in Table II.

The distortion polarizations listed in Table II were determined in the following manner. The value for germanium tetrachloride is the polarization of the pure liquid.[7] The values for boron chloride and stannic chloride are the total polarizations at infinite dilution in benzene solution.[8] The value for silicon tetrachloride is the molar refraction for the sodium D line in the vapor state,[9] plus ten per cent. The values for aluminum chloride and ferric chloride are the molar refractions for the sodium D line determined in water solution,[10] plus ten per cent.

Attempts to measure the dielectric constants of dioxane solution of boron bromide gave values which changed continuously with time. That decomposition of dioxane results from its interaction with boron bromide was shown by the incomplete precipitation of bromine, as silver bromide, from the hydrolyzed solutions.

Dielectric constants and densities are listed in Table I.

Discussion

The symmetrical planar configuration of boron chloride in inert solvents, as evidenced by its zero moment in benzene,[8] gives way to a tetrahedral complex in donor solvents. The value obtained by Ulich and Nespital[8] for the moment of the etherate of boron chloride, $(C_2H_5)_2O{\cdot}BCl_3$, is 5.98 *D*. Assuming that the ether moment vector, 1.2, makes an angle of 125° with the $^+O\text{-}B^-$ bond, the sum of the $^+O\text{-}B^-$ bond moment and the resultant of the three B–Cl dipoles is 5.2. This value should be equal to the moment of the dioxanate of boron chloride, $C_4H_8O_2{\cdot}BCl_3$. Comparison of the observed moment of boron chloride in dioxane, 4.86, and the moment calculated for the complex, 5.2, indicates that coördination of boron chloride with dioxane is almost complete.

A similar calculation for aluminum chloride from the moment of its etherate,[8] 6.54, yields a value of 5.6 for the moment of $C_4H_8O_2{\cdot}AlCl_3$. The observed moment of aluminum chloride in dioxane is 2.02. This low moment indicates either that the extent of coördination is small, or that in a large number of the complexes two dioxane molecules coördinate with each aluminum atom to form trigonal bipyramids having the three chlorine atoms in the equatorial plane. Such complexes would have zero moments. Since aluminum chloride may be expected to exist as a dimer in completely inert solvents, indications of interaction were sought in cryoscopic measurements on the solutions listed in Table I. These measurements indicated that aluminum chloride is monomolecularly dispersed in dioxane solution. It is difficult to understand how dioxane could break up the aluminum chloride dimers without at the same time forming coördinate bonds with aluminum.

The apparent lack of coördination between ferric chloride and dioxane, as evidenced by the low moment, 1.27, is surprising. The structure of the isolated ferric chloride molecule is not known. The magnetic moment of this compound in the solid state[11] indicates five unpaired electrons. The most probable bond types for a ferric chloride molecule with five unpaired electrons are sp^2 and dsp, the former resulting in a trigonal planar structure having a zero moment, and the latter in an unsymmetrical planar structure having a low moment. Coördination complexes of ferric chloride and dioxane having various configurations are possible, most of which would have large moments. It appears from the observed low moment that only a small percentage of ferric chloride molecules coördinate with dioxane in solution.

The complete lack of coördination between dioxane and silicon tetrachloride, as evidenced by

(11) Pauling, "Nature of the Chemical Bond," Cornell University Press, Ithaca, N. Y., 1939, p. 107.

the zero moment of this compound in dioxane, is of importance in connection with the mechanism of the hydrolysis of silicon tetrachloride. This reaction has been interpreted[12] as resulting from the formation of $^{+}O\text{-}Si^{-}$ bonds with the subsequent splitting off of hydrogen chloride. A mechanism involving the formation of Cl–H bonds would appear more probable unless the smaller size of the water molecule, compared to dioxane, makes the formation of an $^{+}O\text{-}Si^{-}$ bond possible in this special case.

The low moment of germanium tetrachloride in dioxane reveals that only a small amount of interaction takes place between these compounds in solution. Efforts to isolate a solid dioxanate of germanium tetrachloride have been unsuccessful and this confirms the view that very little tendency exists for germanium to expand its valence shell in forming coördinate bonds with dioxane. A comparison of the behavior of germanium and titanium tetrachlorides toward dioxane is of interest. While the solubility of the complex of titanium tetrachloride in dioxane is too small to permit determination of its moment in dioxane, the existence of the crystalline complex indicates that coördination readily occurs, at least in the solid state. The greater size of the titanium atom is probably responsible for the difference in the behavior of titanium and germanium tetrachlorides.

The effect of atomic radius is further shown in the case of stannic chloride. A solid coördination complex having the composition $SnCl_4 \cdot 2C_4H_8O_2$ has previously been reported.[13] That coördination persists in solution is evident from a comparison of the zero moment obtained for stannic chloride in benzene[8] with the value, 3.82, in dioxane. The values[14] reported for $(C_2H_5)_2O \cdot SnCl_4$ and $2(CH_3)_2CO \cdot SnCl_4$ are 3.60 and 7.7, respectively. The possible arrangements of the chlorine atoms and dioxane molecules in the octahedral complexes would permit various configurations having moments ranging from 0 to about 6. For this reason it is not possible to estimate from the data the degree of coördination of stannic chloride with dioxane, but it is evident that dioxane coördinates to a greater extent with stannic chloride than with germanium tetrachloride.

(12) Sidgwick, *J. Chem. Soc.*, **125**, 2672 (1924).

Summary

Electric moments have been determined for boron chloride, aluminum chloride, ferric chloride, silicon tetrachloride, germanium tetrachloride and stannic chloride in dioxane. Coördination between dioxane and boron chloride in solution is almost complete. Ferric chloride appears to interact only slightly with dioxane. The extent of coördination of the group IV B elements increases with increasing size of the central atom, silicon tetrachloride having a zero moment and stannic chloride a moment of 3.8 in dioxane.

The Effect of Temperature on the Surface Tension and Density of Some Halogen Substituted Acetic Acids

BY JOSEPH J. JASPER AND LEWIS ROSENSTEIN

In a recent investigation carried out in this Laboratory, accurate surface tension–temperature data were required for the comparison of certain physico-chemical properties of the halogen substituted acetic acids. Search of the literature revealed the apparent unavailability of such data for most of the compounds involved. To supply this deficiency, the surface tension–temperature data for monobromoacetic acid and monoiodoacetic acid were determined over an appreciable temperature range in their molten states.

Experimental

Materials.—The compounds were Eastman Kodak Company reagent quality. The melting point of the monobromoacetic acid was 49.7° and that of monoiodoacetic acid 81.9°. No decomposition of the latter was observed below 130° during the measurements. The decomposition of this compound below its boiling point is believed to be dependent upon traces of mineral acids and moisture present[1]; therefore, great care was used to prevent traces of those impurities from reaching the molten monoiodoacetic acid.

(1) Eastman Kodak Company, private communication.

Procedure.—Because of the relative simplicity of the process and the necessity of excluding moisture from the molten compounds, the capillary rise method was employed for the surface tension measurements. The apparatus used was a slight modification[2] of that described by Richards and Coombs.[3] To ensure a plane reference liquid surface, the dimensional specifications suggested by Richards and Carver[4] were adopted. The diameter of the reference surface was 45 mm. The capillary tube of the apparatus was calibrated according to the method suggested by Harkins and Brown,[5] in which the focusing method described by Wolff, Shoemaker and Briggs[6] was employed, using a "cold" fluorescent light source. The radius of the capillary was found to be 0.019168 cm.

Density determinations were made with a 20-ml. Pyrex pycnometer, which was provided with an expansion bulb and a ground-glass stopper. This was calibrated with mercury.

The constant-temperature system consisted of a thick-wall Pyrex jar of eighteen liters capacity and an electronic relay controlled by a mercury regulator having a bulb of 250-ml. capacity. The Pyrex jar was insulated with magnesia-asbestos, one inch thick. Two small openings in the insulation, cut diametrically opposite, provided the necessary observation windows. Petroleum oil, the liquid medium of the bath, was found to provide a slower heat transfer than water. Although this effect was largely overcome by increasing the efficiency of stirring, the best temperature precision obtainable was $\pm 0.2°$.

The capillary rise was measured with a short range cathetometer. To ensure thermal equilibrium between the measured liquid and the surrounding oil-bath, at least thirty minutes were allowed. During this time the apparatus was agitated constantly. To equalize the pressure within the system with that of the prevailing atmosphere, the stopcock with which the apparatus was equipped was opened to the air from time to time through a calcium chloride drying tube. Between readings, the capillary was wet by drawing the liquid to the full length of the bore and allowing it to recede spontaneously to its static equilibrium position.

Experimental Results

The equation[7]

$$\gamma = \frac{(h + (r/3))(d_l - d_a)gr}{2}$$

was used to calculate the surface tension γ. In this equation, h is the capillary rise, r the capillary radius, and d_l and d_a, respectively, the densities of the liquid and air during the experiment. Each recorded measurement is the average of ten to fifteen readings. Experimental results are presented in Tables I and II.

TABLE I

DENSITY AND SURFACE TENSION DATA FOR MOLTEN MONOBROMOACETIC ACID

Temp., °C.	Density, g./ml.	$(h + (r/3))$, cm.	$(d_l - d_a)$	Surface tension, dynes/cm.
55	1.9017	2.2561	1.9007	40.30
70	1.8778	2.1870	1.8768	38.57
85	1.8531	2.1230	1.8522	36.96
100	1.8286	2.0454	1.8277	35.13
120	1.7955	1.9648	1.7947	33.14
145	1.7542	1.8446	1.7535	30.40
170	1.7123	1.7237	1.7117	27.72

TABLE II

DENSITY AND SURFACE TENSION DATA FOR MOLTEN MONOIODOACETIC ACID

Temp., °C.	Density, g./ml.	$(h + (r/3))$, cm.	$(d_l - d_a)$	Surface tension, dynes/cm.
85	2.2694	1.8119	2.2685	38.63
90	2.2606	1.7908	2.2597	38.03
95	2.2519	1.7653	2.2510	37.35
100	2.2430	1.7488	2.2421	36.85
110	2.2250	1.7161	2.2242	35.87
120	2.2070	1.6659	2.2062	34.54
130	2.1893	1.6278	2.1886	33.41

These data give straight line relationships. Using the method of least squares, the equations for the best curves were calculated and are given in the following:

For monobromoacetic acid

$$d = 1.93302 - 0.0016482t \quad (1)$$
$$\gamma = 46.20552 - 0.10901t \quad (2)$$

For monoiodoacetic acid

$$d = 2.42118 - 0.0017837t \quad (3)$$
$$\gamma = 48.35779 - 0.11483t \quad (4)$$

The average deviation of the data from these curves is as follows: (1) 0.024%; (2) 0.15%; (3) 0.024%; (4) 0.14%.

Summary

The effect of the temperature on the density and the surface tension of monobromoacetic acid and monoiodoacetic acid in the molten state was determined over an appreciable temperature range. The data obtained gave straight line relationships. The equations were calculated by using the method of least squares.

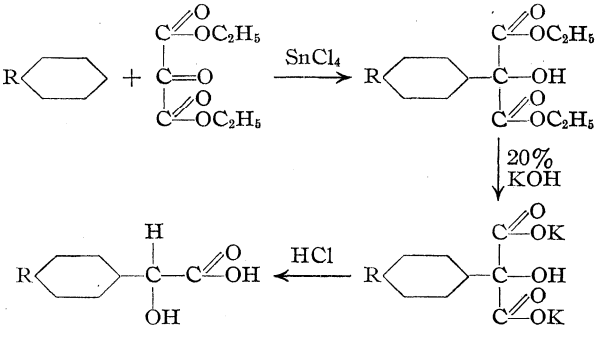
The Preparation of Substituted Mandelic Acids and their Bacteriological Effects. III

BY J. L. RIEBSOMER, DALE STAUFFER, FRANCIS GLICK AND FREDERICK LAMBERT

Up to the present publication in this series,[1,2] we have confined our attention essentially to the preparation of halogen and alkyl substituted mandelic acids in which substitution has been on the benzene ring. This paper not only extends the series of ring substituted compounds but also describes eight compounds in which the hydroxy groups of certain mandelic acids have been changed to acetyl or propionyl. This type of compound was considered of interest because its efficacy as a bacteriocide might give some indication concerning the bacteriological significance of the hydroxyl group in the original molecule.

The Ando synthesis which may be summarized as follows



was used with a number of aromatic compounds such as diphenylmethane, diphenyl, β-methylnaphthalene, α-methylnaphthalene, triphenylmethane, fluorene, acenaphthene and anthracene, hoping to prepare the corresponding hydroxy acetic acids. While the acids prepared from these more complex hydrocarbons may require a stretch of the rules of nomenclature to regard them as derivatives of mandelic acid, yet it seems appropriate to consider them here. Of the eight hydrocarbons listed above, only the first two of the series reacted as expected.

Experimental

The method used for the preparation of the nuclear substituted mandelic acids was the same as previously described.[1,2] The same method was used for β-methylnaphthalene and the other more complex hydrocarbons except that a solvent (usually chloroform) was used either to make a suspension or solution of the solid hydrocarbons.

To prepare the acetyl or propionyl derivatives the appropriate mandelic acid and twice the theoretical amount of acid chloride were refluxed gently for ten to twelve hours. The resulting mixture was cooled and poured into cracked ice. In most cases a solid separated at once. The solid was filtered, dried and crystallized from benzene or benzene–petroleum ether mixtures. Table I summarizes the properties, yields, analyses and bacteriological data for the substituted mandelic acids. The bacteriological activity of each acid is compared with mandelic acid as unity. These tests were made *in vitro* on *B. coli*.

The intermediates for the *p*-benzyl, 2,4-, 3,4- and 2,5-dimethyl mandelic acids boiled under a pressure of 4–5 mm. at 225–230, 150–155, 157–160, and 154–156°, and were obtained in yields of 51, 47, 51, and 47%, respectively. The intermediate from the *p*-phenyl derivative was not distilled, so its yield could not be ascertained.

It will be noticed that no mention is made in Table I of derivatives from α-methylnaphthalene, β-methylnaphthalene, acenaphthene, fluorene, anthracene or triphenylmethane. When α-methylnaphthalene was subjected to the usual reaction conditions, the mixture turned almost black. Upon washing with water and distilling, 7 g. of a viscous oil was produced, b. p. 180–230° at 2 mm. pressure, which apparently was the expected intermediate, but upon saponification and subsequent acidification only a thick oil was formed from which no crystals could be obtained. Essentially the same observations were made with acenaphthene. β-Methylnaphthalene gave a very low yield of an acid, m. p. 146.5–147.5°, neutralization equivalent 217.8, and a carbon–hydrogen analysis which corresponded with a β-methylnaphthylhydroxyacetic acid. We were unable to prove the identity of this product.

In the cases of fluorene and anthracene the mixtures became deep purple in color when stannic chloride was added but none of the expected

Propionyl-*p*-phenyl	0	64	107	284.2	284.0	71.8	5.6	72.3	5.6

products were obtained. The appearance of this purple color is typical of many of these reactions which do proceed as desired.

When triphenylmethane was run through the usual reaction routine, an acidic compound which crystallized from benzene (m. p. 90–95°) was formed but we were unable to get a product with a sharp melting point upon further crystallizations. The neutral equivalent was 335.5; calculated for the expected compound, 318.2, This material discolored upon standing. Its identity was not established.

The structures of the three dimethylmandelic acids described in Table I were determined previously[3] by careful permanganate oxidation to the corresponding dimethylbenzoic acids. The 2,4- and 3,4-dimethylmandelic acids were previously prepared by Ando but not tested bacteriologically.

The mandelic acid prepared from diphenyl was oxidized with dilute permanganate and produced diphenyl-4-carboxylic acid, m. p. 228°, thus indicating this product to be *p*-phenylmandelic acid. The compound prepared from diphenylmethane was shown to be *p*-benzylmandelic acid by permanganate oxidation to *p*-benzylbenzoic acid, m. p. 154–155°.

Discussion

The mixture of isomeric dimethylmandelic acids, which may be obtained using a commercial xylene mixture in the Ando synthesis, shows the same bacteriological activity as the pure isomers (3.5). This mixture would therefore appear to be better than mandelic acid in treating urinary tract infections, especially since its cost of production could be relatively low. Unfortunately, when the mixture of isomers was injected intravenously into rabbits it proved to be somewhat more toxic than mandelic acid. Accordingly its use in medicine is prohibited.

It was hoped that converting the hydroxy group of some of these mandelic acids to the acetyl or propionyl group would throw some light on the significance of the hydroxy group in the bacteriological activity of mandelic acids. It is obvious from the results shown in Table I that the data are conflicting and that no conclusions are justifiable.

The authors wish to express their indebtedness to Dr. R. S. Shelton of the William S. Merrell Co., who kindly carried out the bacteriological and pharmaceutical studies. The funds to support this work were partially provided from the William M. Blanchard Memorial Research Fund.

Summary

1. The synthesis and bacteriological activity of thirteen mandelic acids are reported.

2. Only the dimethyl derivatives show markedly greater activity than mandelic acid, but they proved to be too toxic to be used medicinally.

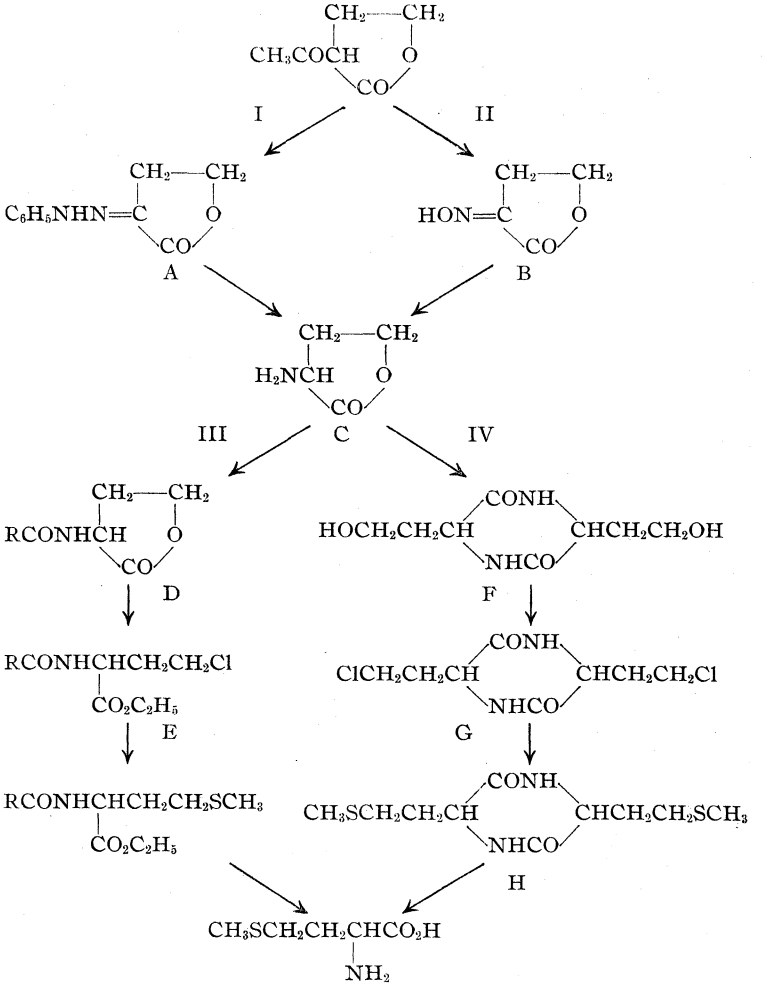
A Convenient Synthesis of *dl*-Methionine

BY H. R. SNYDER, JOHN H. ANDREEN, GEORGE W. CANNON AND CARL F. PETERS

The synthesis of *dl*-methionine from the benzoyl derivative of α-amino-γ-butyrolactone, described by Hill and Robson,[1] does not require the use of the strongly vesicant β-chloroethylmethyl sulfide employed in the syntheses of Windus and Marvel[2] and of Barger and Weichselbaum.[3] However, α-amino-γ-butyrolactone has been difficult to prepare and consequently has not been much used in the preparation of methionine. Recently, certain derivatives of α-amino-γ-butyrolactone have been prepared from the easily available α-aceto-γ-butyrolactone.[4] Feofilaktov and Onishchenko[5] have obtained the hydrochloride of the aminolactone by reduction of α-oximino-γ-butyrolactone with tin and hydrochloric acid. They reduced the phenylhydrazone of α-keto-γ-butyrolactone in the same manner and obtained the hydrochloride of α-amino-γ-hydroxybutyric acid. The oxime and phenylhydrazone[6] were prepared by the action of nitrous acid and ben zenediazonium chloride, respectively, on α-aceto-γ-butyrolactone.

The availability of α-amino-γ-butyrolactone from these reactions suggested a re-examination of the use of its acyl derivatives in the synthesis of *dl*-methionine. However, a possible route to *dl*-methionine involving the conversion of the aminolactone to 3,6-*bis*-(β-hydroxyethyl)-2,5-diketopiperazine was considered more attractive. Fischer and Blumenthal[7] have observed that the aminolactone readily changes to the diketopiperazine. In the accompanying scheme path III (R = C_6H_5) represents the synthesis of Hill and Robson,[1] who employed α-aminobutyrolactone prepared by a more tedious method; path IV represents the projected synthesis by way of the diketopiperazine.



In the present study the phenylhydrazone of α-keto-γ-butyrolactone (A) was prepared by the method of Harradence and Lions[6] and was subjected to catalytic reduction. When the reduction was carried out in ethanol over Raney nickel, temperatures of 100–150° were required and the product was not the aminolactone (C) but the diketopiperazine (F). When the reduction was carried out in ethyl acetate containing acetic an-

hydride, a mixture of acetanilide and α-acetamino-γ-butyrolactone (D, R = CH_3) was produced. It was possible to separate these by water extraction and distillation and thus to obtain α-acetamino-γ-butyrolactone in yields of about 30%. When this substance was treated with hydrogen chloride and ethanol according to the method of Hill and Robson[1] for the corresponding benzamino derivative, the acetyl group was removed and the hydrochloride of α-amino-γ-butyrolactone was produced; none of the desired ethyl α-acetamino-γ-chlorobutyrate (E) was isolated.

α-Oximino-γ-butyrolactone (B) was prepared from ethyl nitrite and α-aceto-γ-butyrolactone in methanol solution. The oxime was hydrogenated over either Raney nickel or palladium-charcoal in methanol or ethanol solution. The resulting solution, after removal of the catalyst, was heated under reflux for twenty-four hours to effect the conversion of α-amino-γ-butyrolactone (C) to the dihydroxydiketopiperazine (F). This substance was obtained from the oxime in yields of 55–60%. It was identical with the diastereoisomeric modification previously obtained by Fischer and Blumenthal.[7] It was converted to 3,6-*bis*-(β-chloroethyl)-2,5-diketopiperazine (G), in yields of 90–95%, by treatment with excess thionyl chloride. 3,6-*bis*-(β-Methylthiolethyl)-2,5-diketopiperazine (H) was obtained in 63% yield from the reaction of the chloro derivative with sodium methylmercaptide. Hydrolysis of this diketopiperazine gave *dl*-methionine in 85–95% yield. These reactions constitute a convenient and economical method for the preparation of the amino acid.

Experimental

1. Hydrogenation of the Phenylhydrazone of α-Keto-γ-butyrolactone in Ethanol.—Acetobutyrolactone was prepared by the method of Knunyantz.[4] It was converted to the phenylhydrazone of α-keto-γ-butyrolactone by the procedure described by Harradence and Lions.[6] The crude phenylhydrazone was washed with water until the washings were free of halide ion, then dried and extracted with boiling ethanol or ethyl acetate to remove colored impurities. In one reduction 70 g. of the phenylhydrazone and 250 cc. of absolute ethanol were placed in a bomb with Raney nickel. Hydrogen under 1700 lb. pressure was admitted and the bomb was heated to 100° for four hours. During this period hydrogen was absorbed slowly, so the temperature was raised to 150° for eight hours. The ethanol was removed from the filtered solution by distillation under diminished pressure. The residue was a mixture of an oil (aniline) and a white solid (the diketopiperazine). The oil was removed by extraction with ether and the residual solid was crystallized from ethanol; it melted at 178–180°. The yield was 20 g. (54%). However, in other runs in which the temperature was kept constant at various temperatures between 100° and 150° the yield did not exceed 20%.

2. Hydrogenation of the Phenylhydrazone of α-Keto-γ-butyrolactone in the Presence of Acetic Anhydride.—A mixture of the phenylhydrazone (115 g.), acetic anhydride (170 cc.), and ethyl acetate (350 cc.) was placed in the bomb with Raney nickel and heated at 125° until hydrogen (initial pressure, 2000 lb.) was no longer absorbed. The solution contained nickel salts which were removed by treatment with hydrogen sulfide. The solvent was removed from the filtered solution by evaporation under 20 mm. pressure from a water-bath maintained at 90°. The residue was added to 500 cc. of cold water and the mixture was stirred rapidly and warmed to 40°. The aqueous solution was separated from the undissolved acetanilide (m. p. 113°) and evaporated to dryness under 20 mm. pressure. The sirupy residue was distilled and the fraction boiling at 175–178° (2 mm.) was collected as a pale yellow sirup which crystallized on standing; m. p. 82–84°. The yield was 29 g. or 30%.

Anal. Calcd. for $C_6H_9O_3N$: C, 50.35; H, 6.30; N, 9.79. Found: C, 50.43; H, 6.40; N, 9.72.

3. Reaction of α-Acetamino-γ-butyrolactone with Ethanol and Hydrogen Chloride.—The procedure of Hill and Robson[1] was used, except that an equivalent weight of α-acetamino-γ-butyrolactone was substituted for the benzamino derivative. The sirup remaining after evaporation of the ethanol was insoluble in ether. After crystallization from acetone it melted at 200–201° (lit.,[5] 201°) and analysis showed it to have the composition of α-amino-γ-butyrolactone hydrochloride; the yield was 40%.

4. Preparation of α-Oximino-γ-butyrolactone.—To a cold (0 to −5°) solution of 256 g. (2 moles) of acetobutyrolactone in 500 cc. of methanol was added 300 g. (4 moles) of ethyl nitrite prepared from hydrochloric acid, sodium nitrite and ethanol.[8] The reaction flask was packed in ice–salt and allowed to stand for fifteen to twenty hours, during which time the ice melted and the temperature of the reaction mixture reached that of the room. The mixture was cooled and the crystalline solid was collected on a filter. The filtrate was concentrated under diminished pressure and the dark-colored residue was heated on the steam-bath with 100 cc. of *n*-butyl alcohol. The mixture was cooled and filtered. The two crops of crystals were combined, washed twice with 100-cc. portions of cold *n*-butyl alcohol and then with ether. The α-oximino-γ-butyrolactone weighed 196–209 g. (85–91%) and melted at 183–185° (lit.,[5] 192°).

5. 3,6-*bis*-(β-Hydroxyethyl)-2,5-diketopiperazine.—Solutions of the oxime in methanol (about 4 cc. per g.) were hydrogenated over a palladium catalyst. The catalyst was prepared by evaporating to dryness a mixture of charcoal, previously washed with nitric acid, and aqueous palladium chloride. Quantities were chosen so that the dry catalyst contained the equivalent of 5% of metallic

(8) Evidently the reaction is catalyzed by a trace of hydrogen chloride, for reactions employing ethyl nitrite made from sulfuric acid have been found to proceed very slowly unless a small amount of an acid is added. For these observations the authors are indebted to Dr. E. E. Howe of Merck and Co., Inc., Rahway, N. J.

palladium. Two grams of the impregnated charcoal was used for each 100 cc. of methanol. The reductions were carried out at low pressure (50 lb. at start). They proceeded very rapidly (thirty minutes for a 25-g. run) and with the evolution of heat. When the hydrogen absorption was complete the catalyst was removed and the solution was heated under reflux for forty-eight hours, then stored in a refrigerator overnight. The crystalline solid was collected and washed with cold alcohol and cold ether; it melted at 186° with decomposition (lit.,[7] 189°). The yields were from 55–60%.

6. 3,6-*bis*-(β-Chloroethyl)-2,5-diketopiperazine.—The following procedure has given the best yields. In a 500-cc. flask fitted with a stirrer and reflux condenser 110 cc. of thionyl chloride was cooled to 0 to −5°, and 15 g. of 3,6-*bis*-(β-hydroxyethyl)-2,5-diketopiperazine was added in one lot. The mixture was stirred and allowed to come to room temperature slowly. The flask was then immersed in a water-bath which was very slowly warmed until the thionyl chloride began to reflux. The mixture was cooled and diluted with 75 cc. of dry ether. The solid was collected on a filter and washed twice with ether, then twice with water. Drying of the product may be facilitated by washing with alcohol and ether. The dry product was a very light yellow or white solid of m. p. 230–231°; the yield was 15.8–17 g. (90–95%). The substance can be recrystallized from ethanol or acetic acid, but the amount of solvent required is large (about 50 cc. per g.) and the melting point is not changed.

Anal. Calcd. for $C_8H_{12}O_2N_2Cl_2$: N, 11.7. Found: N, 11.4.

Larger runs have been made in the same way, but there is danger of uncontrollable boiling of the thionyl chloride when the reaction sets in. Addition of thionyl chloride to the hydroxyl compound suspended in an inert solvent, such as chloroform, gave lower yields and the product was of a dark color. The use of thionyl chloride and pyridine resulted in very poor yields.

7. 3,6-*bis*-(β-Methylthiolethyl)-2,5-diketopiperazine.—The chloro compound was mixed with a solution containing a 10% excess of sodium methylmercaptide (2.2 moles per mole of chloro compound) in absolute ethanol. Absolute ethanol was added until the total volume was about three liters per mole of chloro compound. This mixture, in a flask provided with a reflux condenser, was heated cautiously on the steam-bath. As soon as the reaction began the steam was turned off. Refluxing continued for about ten minutes without external heating; when boiling subsided steam was again applied until the total period of reflux was one hour. The boiling solution was filtered through a heated funnel and the filtrate was cooled in ice-water. The crystals were collected and the mother liquor was used for a second hot extraction of the original residue. The total yield from three such extractions was 63%. The material could be freed of a yellow-colored impurity, which was sometimes present, by washing with water, and the white diketopiperazine so produced melted at 225–226°. It could be recrystallized from ethanol to yield a product melting at 231–232°, but the crude material is satisfactory for the next step.

Anal. Calcd. for $C_{10}H_{18}O_2N_2S_2$: C, 45.9; H, 6.9. Found: C, 46.0; H, 7.0.

8. *dl*-Methionine.—The 3,6-*bis*-(β-methylthiolethyl)-2,5-diketopiperazine was mixed with concentrated hydrochloric acid (15 cc. per g.). The clear solution which resulted when the mixture was warmed was heated under reflux for three hours. The solution was evaporated to dryness under diminished pressure and the residue was dissolved in boiling absolute ethanol (20 cc. per g. of diketopiperazine used). This solution was clarified with charcoal and, while still hot, was treated with pyridine (1–2 cc. per g. of diketopiperazine) until an excess was present. Crystallization of *dl*-methionine began immediately. The mixture was allowed to stand in a refrigerator (0–5°) overnight and the product was collected, washed with cold absolute alcohol and then with absolute ether. The yield of *dl*-methionine was 85–95%.

Summary

A convenient and economical synthesis of *dl*-methionine is described. α-Aceto-γ-butyrolactone is converted to α-oximino-γ-butyrolactone by treatment with ethyl nitrite in the presence of a trace of mineral acid; the α-oximino-γ-butyrolactone is reduced catalytically to α-amino-γ-butyrolactone which changes to 3,6-*bis*-(β-hydroxyethyl)-2,5-diketopiperazine; 3,6-*bis*-(β-chloroethyl)-2,5-diketopiperazine is prepared by the action of thionyl chloride on the corresponding hydroxy compound and is converted to the anhydride of methionine by treatment with sodium methylmercaptide; *dl*-methionine is obtained by acid hydrolysis of the anhydride.

The Behavior of Pyrogallol Trimethyl Ether and 3,4,5-Trimethoxybenzonitrile toward Grignard Reagents

BY CHARLES D. HURD AND H. E. WINBERG

Recently Haller and Schaffer[1] investigated the course of reaction between isobutylmagnesium bromide and 3,4,5-trimethoxybenzonitrile at the refluxing temperature of toluene. In addition to the expected 3,4,5-trimethoxyphenyl isobutyl ketone there was obtained a phenolic ketone and a second neutral ketone. On the basis of the reactions of these compounds, analytical data, and the known reactivity of the methoxyl group in the 4-position of trimethylpyrogallol derivatives, it was suggested that they were 3,5-dimethoxy-4-hydroxyphenyl isobutyl ketone and a 3,5-dimethoxy-4-butylphenyl isobutyl ketone.

At Dr. Haller's suggestion we continued this problem. We confirmed the observations of Haller and Schaffer and have obtained additional evidence for cleavage of the vicinal ether linkage. By increasing the molar ratio of the Grignard reagent from two and one-half to four-fold excess and the reaction time from three to five hours at a temperature of 110°, the yield of hydrolysis products may be greatly increased at the expense of the trimethoxy ketone. However, at 40° and with the longer reaction period cleavage of the ether linkage does not occur, the only product being the trimethoxy ketone.

The cleavage of ethers by Grignard reagents usually requires a reaction temperature of the order of 200°[2] but with more active linkages as in phenyl allyl ether cleavage occurs at 50 to 75°.[3] In trimethylpyrogallol derivatives the methoxyl group in the 4-position can be replaced with hydrogen[4] or hydrolyzed by sulfuric acid[5,6] to the corresponding dimethoxy phenol. It may be anticipated that at 110° Grignard reagents would cause a cleavage of the activated ether linkage.

The structure of the phenolic product resulting from the action of isobutylmagnesium bromide on 3,4,5-trimethoxybenzonitrile was shown to be the suggested 3,5-dimethoxy-4-hydroxyphenyl isobutyl ketone by hydrolysis of 3,4,5-trimethoxyphenyl isobutyl ketone with sulfuric acid to yield the same phenol obtained from the Grignard reaction. Oxidation of the phenol with chromic anhydride in glacial acetic acid produced the known 2,6-dimethoxybenzoquinone, showing the location of the phenolic group. Several attempts were made to oxidize the neutral ketone to 3,5-dimethoxyterephthalic acid,[7] but only intractable tars resulted.

The formation of a phenol is the characteristic reaction in the cleavage of an aryl alkyl ether by a Grignard reagent but in the case of trimethylpyrogallol cleavage may occur at the aryl-oxygen linkage, accounting for the formation of the neutral ketone in which a butyl group has apparently replaced the methoxyl group. When pyrogallol trimethyl ether was heated at 110° with methylmagnesium iodide the only product was 2,6-dimethoxyphenol, obtained in 84% yield. Possibly an activating group in the para position is necessary to sufficiently weaken the aryl-oxygen to cause its cleavage.

Experimental

Trimethoxygallic acid was prepared in 91% yield by methylation of alkaline sodium gallate with methyl sulfate.[8] The acid chloride was prepared readily with phosphorus pentachloride by heating equimolar amounts of the two reagents for fifteen minutes at 100°, whereas attempts to bring about this conversion with thionyl chloride gave far less satisfactory yields. In the former case, phosphorus oxychloride and unused pentachloride were distilled off at 18 mm. and an excess of concentrated ammonium hydroxide was added to the residue. The amide, m. p. 177°, was prepared in 81% yield. It was converted in 93% yield to 3,4,5-trimethoxybenzonitrile, m. p. 86–89°, by heating in benzene solution with phosphorus pentachloride. Neither vacuum distillation nor crystallization from aqueous alcohol was effective in raising the melting point of this material, but isopropyl ether proved to be an efficient solvent. After one crystallization from it, the material melted at 90–92° (literature, 93°).

Reaction of 3,4,5-Trimethoxybenzonitrile with Isobutylmagnesium Bromide

First Experiment.—Haller and Schaffer's[1] conditions were duplicated, starting with 19.3 g. of the nitrile (0.1

(8) "Organic Syntheses," Vol. VI, 1926, p. 96.

mole) and 0.25 mole of isobutylmagnesium bromide. Refluxing in toluene solution, after displacement of the ether as solvent, was for three hours. The yield of 3,4,5-trimethoxyphenyl isobutyl ketone, b. p. 164–166° at 6 mm., was 3.8 g. Haller and Schaffer reported its b. p. as 147–150° (1 mm.) and did not observe its solidification. On standing, our product crystallized spontaneously. These crystals melted at 37–39°. The yield of phenolic product, 3,5-dimethoxy-4-hydroxyphenyl isobutyl ketone, m. p. 93–93.5°, was 4.5 g.

Second Experiment.—The points of difference in procedure were a greater excess of Grignard reagent and a longer period of refluxing. The mixture of 19.3 g. of nitrile and 0.4 mole of Grignard reagent (from 55 g. of isobutyl bromide) was made in ether as before, then the solvent ether was replaced by toluene, and the mixture refluxed for five hours. Only 1.50 g. of 3,4,5-trimethoxyphenyl isobutyl ketone was isolated, but 10.0 g. of 3,5-dimethoxy-4-hydroxyphenyl isobutyl ketone was formed. From the toluene solution there was obtained 6.18 g. of oil boiling at 163–167° (5 mm.) and 1.58 g. boiling at 167–177° (5 mm.). This is presumably 3,5-dimethoxy-4-isobutylphenyl isobutyl ketone. Its semicarbazone melted at 183–184°.[1]

Third Experiment.—By carrying out the reaction at 40° only the trimethoxy ketone was obtained. To the Grignard reagent prepared from 17.1 g. (0.125 mole) of isobutyl bromide in 65 cc. of ether and 3.04 g. (0.125 mole) of magnesium in 100 cc. of ether was added 19.3 g. (0.100 mole) of the nitrile dissolved in 200 cc. of dry toluene. The mixture was maintained at 40° for five hours. It was then poured onto ice containing 30 cc. of concentrated hydrochloric acid. The organic layer was separated, washed with water, and dried over sodium sulfate. Evaporation of the solvents gave 9.26 g. of the unreacted nitrile. The water layer was refluxed for two hours, cooled, and then the resulting oil extracted with ether. The extract was washed with 5% sodium hydroxide, with water, and dried over sodium sulfate. After removal of the solvent the residue boiled at 163–168° (7 mm.) and solidified at room temperature. The yield was 10.7 g. The sodium hydroxide extract contained no alkali-soluble material; hence, hydrolysis to 3,5-dimethoxy-4-hydroxyphenyl isobutyl ketone had not taken place during the reaction.

Oxidation of 3,5-Dimethoxy-4-hydroxyphenyl Isobutyl Ketone to 2,6-Dimethoxybenzoquinone.—To 0.5 g. of the phenol dissolved in 20 cc. of glacial acetic acid was gradually added 1.25 g. of chromic anhydride. After the reaction had subsided, the solution was heated on the water-bath for fifteen minutes, cooled, and 35 cc. of water was added. The resulting solution was extracted three times with chloroform and the extract dried over sodium sulfate. After removal of the solvent, the oil was treated with a small quantity of ether and the insoluble material removed by filtration. The precipitate was recrystallized from glacial acetic acid; m. p. 253–254°. When mixed with an authentic sample of 2,6-dimethoxybenzoquinone[9] there was no depression of the melting point.

3,5-Dimethoxy-4-hydroxyphenyl Isobutyl Ketone from 3,4,5-Trimethoxyphenyl Isobutyl Ketone.—One gram of the trimethoxyphenyl isobutyl ketone was dissolved in 4 cc. of concentrated sulfuric acid. The solution was maintained at 35–40° for twenty hours and then poured onto ice. The resulting mixture was extracted with ether and the extract washed with 5% sodium hydroxide. The alkaline solution was acidified, then extracted with ether and the ether solution dried over sodium sulfate. Evaporation of the ether gave 0.80 g. of the phenol. After one recrystallization from 50% ethanol, it melted at 93°. A mixed melting point with the phenol obtained from the Grignard reaction on the nitrile showed no depression.

Reaction of Pyrogallol Trimethyl Ether with Methylmagnesium Iodide.—To the Grignard reagent prepared from 85.2 g. (0.60 mole) of methyl iodide in 110 cc. of ether and 14.6 g. (0.60 mole) of magnesium in 175 cc. of ether was added 25.2 g. (0.15 mole) of pyrogallol trimethyl ether dissolved in 200 cc. of dry toluene. The reaction mixture was then heated in an oil-bath and the ether removed by distillation, toluene being added gradually to maintain the original volume. After all of the ether had been replaced with toluene, the mixture was refluxed for ten hours with constant stirring. The reaction mixture was then poured on ice containing 80 cc. of concentrated hydrochloric acid. The organic layer was separated, the water saturated with sodium chloride and extracted with ether. The combined organic solution was extracted with 5% sodium hydroxide and dried over sodium sulfate. Evaporation of the solvents left no residue. The alkaline extract was acidified, the water saturated with sodium chloride and extracted with ether. After drying over sodium sulfate, removal of the ether gave 19.4 g. of 2,6-dimethoxyphenol, b. p. 106–108° (4 mm.). When recrystallized from butyl ether the melting point was 55–56°. When treated with benzoyl chloride in pyridine the phenol gave a benzoate[10] melting at 116–117° and with picric acid formed a picrate[11] melting at 61°.

Summary

In the reaction of isobutylmagnesium bromide and 3,4,5-dimethoxybenzonitrile, the yield of abnormal products (3,5-dimethoxy-4-hydroxyphenyl isobutyl ketone and 3,5-dimethoxy-4-isobutylphenyl isobutyl ketone) is favored by a 4:1 excess of Grignard reagent and by a prolonged reaction time at 110°. At 40°, only the normal product (3,4,5-trimethoxyphenyl isobutyl ketone) was obtained.

The structure of 3,5-dimethoxy-4-hydroxyphenyl isobutyl ketone was established by oxidizing it to 2,6-dimethoxybenzoquinone.

Conversion of 3,4,5-dimethoxyphenyl isobutyl ketone into 3,5-dimethoxy-4-hydroxyphenyl isobutyl ketone was effected by the action of sulfuric acid.

Methylmagnesium iodide reacted with pyrogallol trimethyl ether at 110°, to yield 2,6-dimethoxyphenol.

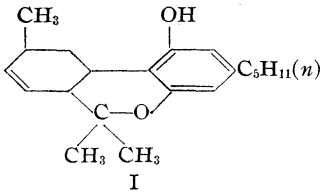
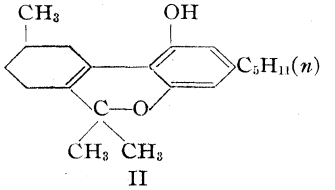
Optically Active Synthetic Tetrahydrocannabinols; *d*- and *l*-1-Hydroxy-3-*n*-amyl-6,9,9-trimethyl-7,8,9,10-tetrahydro-6-dibenzopyrans. XIV[1]

BY ROGER ADAMS, C. M. SMITH AND S. LOEWE

The tetrahydrocannabinol resulting from the isomerization of cannabidiol has been postulated as having structure I and is optically[2] active. A synthetic, racemic tetrahydrocannabinol obtained by the condensation of ethyl 5-methylcyclohexanone-2-carboxylate with olivetol, followed by treatment of the resulting pyrone with excess methylmagnesium iodide has the formula II.[3]



I



II

Compound II has about one-seventh the potency of I, which was derived from a natural source.

This investigation was undertaken to prepare the optically active forms of II and to compare them in physiological activity. Optically active *d*- and *l*-3-methylcyclohexanone were obtained and subjected to the same series of reactions previously used for converting the *dl*-modification to *dl*-tetrahydrocannabinol. Pulegone, upon hydrolysis according to the procedure of Wallach,[4] yielded *d*-3-methylcyclohexanone in what appears to be optical purity. The *l*-form is much less accessible and was finally obtained by the resolution of the *dl*-form through the 1-menthydrazone.[5] The less soluble menthydrazone was the *l,l*-modification, which was readily hydrolyzed to *l*-3-methylcyclohexanone of rotation only slightly lower than that observed for the *d*-form from pulegone. The intermediates in the preparation of the tetrahydrocannabinols derived from the *d*- and *l*-3-methylcyclohexanones showed essentially parallel rotations, but the final products differed considerably. The *l*-pyran happened to be a little more highly colored than usual and was decolorized by refluxing in ethanol with activated charcoal for a longer period than was used in the case of the *d*-form. This apparent racemization was checked using a sample of the *d*-pyran, $[\alpha]^{25}D$ +147° in ethanol. After prolonged refluxing in ethanol with activated charcoal, this substance had $[\alpha]^{28}D$ +123°. It is not improbable that either disproportionation or an actual dehydrogenation may take place. Assuming the *d*-tetrahydrocannabinol to be optically pure, the *l*-modification finally obtained was 87% pure.

Pharmacological tests revealed that the *d*-form is about 40% as active as the racemic and that the *l*-form has between four and five times the physiological potency of the *d*-form. The precise results are shown in Table I.

TABLE I

POTENCY OF OPTICALLY ACTIVE TETRAHYDROCANNABINOLS[a]

	Number of expts.	Potency	Range of variation
dextro-Pyran (II) $[\alpha]^{20}D$ +155	11	0.38	±0.025
levo-Pyran (II) $[\alpha]^{26}D$ −114	9	1.66	± .21

[a] *dl*-Tetrahydrocannabinol was used as standard.

It is pertinent that both the tetrahydrocannabinol (I) from cannabidiol and the purified active fractions from red oil of hemp are[6,7] levorotatory.

Before this investigation was complete, Leaf, Todd and Wilkinson[8] published a description of the *d*-form of the tetrahydrocannabinol (II), made in essentially the same way as herein reported. On the basis of their pharmacological results, using the Gayer test, they estimate the *d*-form to be one-sixth to one-eighth as active as the racemic modification. This discrepancy in their results and ours (about one-third the potency) lies prob-

ably in the method of testing. The Gayer test used by these investigators, in our hands, has been much less quantitative and less reliable an index of potency than the dog-ataxia method used by us for determining the activity of these substances.

In this recent paper of Leaf, Todd and Wilkinson, exception is taken to a previous statement made by us[9] that migration of a double bond from conjugation with a benzene nucleus is without precedent. They consider this statement ill-advised in view of the numerous cases of deconjugation in the literature. They cite as references merely well-known cases of deconjugation in the terpene series which can hardly be considered refutatory to our statement about molecules of the type under consideration, where the double bond is conjugated to a benzene ring and no other group is present in the molecule to which the double bond might conjugate preferably.

Experimental

***d*-3-Methylcyclohexanone.**—The details for the preparation of this product from pulegone are described since Wallach gave none.

From 200 g. of pulegone and 160 cc. of water, heated at 250° for six hours, an organic layer was obtained which was shaken with saturated aqueous sodium bisulfite until solidification occurred. The cake was broken up, about one-third of its volume of ether added, and the whole was shaken, water being added gradually until the bisulfite compound just dissolved. Treatment of the aqueous layer with one-half its volume of saturated sodium carbonate solution yielded 39 g. of *d*-3-methylcyclohexanone or 26.5% of the theoretical. The constants observed were b. p. 164–168°; $n^{20}D$ 1.4445; d^{20}_4 0.9179.

Rotation. $\alpha^{20}D$ +12.21° (pure liquid); *l*, 1; $[\alpha]^{20}D$ +13.3°. Wallach reported $[\alpha]^{15}D$ +13.38°.

The semicarbazone purified from ethanol had a m. p. 181° (cor.); Wallach reported 180°.

Rotation. 0.3625 g. made up to 25 cc. with ethanol at 20° gave αD −0.60°; *l*, 2; $[\alpha]^{20}D$ −20.7°.

***d*-3-Methylcyclohexanone-*l*-menthydrazone.**—A mixture of 1.5 g. of *d*-3-methylcyclohexanone, 3.0 g. of 1-menthydrazide, 0.2 g. of sodium acetate, 0.1 cc. of acetic acid and 20 cc. of ethanol was refluxed for two hours, diluted with water and the product allowed to crystallize. It was purified from 50% ethanol; white needles, softening at 126–130° and melting at 130–136° (cor.).

Anal. Calcd. for $C_{18}H_{32}O_2N_2$: C, 70.06; H, 10.46. Found: C, 70.00; H, 10.39.

Rotation. 0.2700 g. made up to 5 cc. with ethanol at 25° gave αD −3.31°; *l*, 1; $[\alpha]^{25}D$ −61.3°. The product from the mother liquors from the last crystallization gave the same rotation.

***l*-3-Methylcyclohexanone.**—By following the procedure just described, 162 g. of *dl*-3-methylcyclohexanone and 310 g. of *l*-menthydrazide in 400 cc. of ethanol gave a product which after filtering and recrystallizing from 1800 cc. of 65% ethanol, amounted to 195 g. This was recrystallized several times from the same solvent, then repeatedly from petroleum ether (b. p. 60–110°). When much of the more soluble derivative was present, the latter solvent could not be used as the substance tends to separate as a gel. It was found desirable not to heat the compound too much in the solvent and to remove the solvent under diminished pressure. After twenty crystallizations, there was obtained 13 g. of product of very nearly constant rotation, m. p. 146° (cor.).

Anal. Calcd. for $C_{18}H_{32}O_2N_2$: C, 70.06; H, 10.46. Found: C, 70.18; H, 10.94.

Rotation. 0.298 g. made up to 5 cc. with ethanol at 25° gave αD −1.90°; *l*, 1; $[\alpha]^{25}_4$ −31.3°.

Hydrolysis by warming with 10% sulfuric acid followed by steam distillation gave 3.7 g. of ketone; b. p. 164–168°; $n^{20}D$ 1.4449; d^{20}_4 0.9133; d^{25}_4 0.9108.

Anal. Calcd. for $C_7H_{12}O$: C, 74.94; H, 10.79. Found: C, 74.84; H, 10.69.

Rotation. $\alpha^{20}D$ −11.54° (pure liquid); *l*, 1; $[\alpha]^{20}D$ −12.64°.

The semicarbazone, purified from ethanol, melted at 181° (cor.).

Rotation. 0.1154 g. made up to 10 cc. with ethanol at 27° gave αD +0.24°, *l*, 1; $[\alpha]^{27}D$ +20.8°.

***d*- and *l*-Ethyl 5-Methylcyclohexanone-2-carboxylate.**—A solution of 5.95 g. of sodium in 120 cc. of absolute ethanol was cooled to 3° in an ice-bath and with stirring a mixture of 29 g. of *d*- or *l*-3-methylcyclohexanone and 38 g. of pure ethyl oxalate was added gradually. The temperature was maintained at 3–5° during the addition and for an hour thereafter. After standing overnight at room temperature, the reaction mixture was hydrolyzed by pouring onto a mixture of 15 cc. of sulfuric acid and cracked ice. The pale yellow oil was separated and the aqueous solution extracted with chloroform. The combined oil and extracts were washed with water plus a little sodium bicarbonate solution until neutral to congo red, dried and distilled in the presence of powdered soft glass and a trace of iron powder.

The *d*-product boiling at 100–140° (24–28 mm.) was collected and fractionated. The large middle fraction, b. p. 122–124° (15 mm.) was colorless, weighed 29 g. (61%) and had $n^{20}D$ 1.4722; d^{20}_4 1.040.

Anal. Calcd. for $C_{10}H_{16}O_3$: C, 65.18; H, 8.76. Found: C, 64.93; H, 8.68.

Rotation. $\alpha^{20}D$ +94.4° (pure liquid); *l*, 1; $[\alpha]^{20}D$ +90.8°.

After standing two months, this material had $[\alpha]^{28}D$ +73°. This decrease in rotation was probably due to re-establishment of the keto–enol equilibrium, since the value of +90.8° was obtained on freshly distilled material.

Gardner, Perkin and Watson[10] prepared the *d*-modification of this compound from an optically impure sample of *d*-3-methylcyclohexanone by carboxylation of the ketone with sodamide and carbon dioxide followed by esterification; they reported $[\alpha]D$ +84.2 in ethanol. Leaf, Todd and Wilkinson used a sample $[\alpha]^{19}D$ +79.2° (pure liquid).

(9) Adams, Smith and Loewe, THIS JOURNAL, **63**, 1973 (1941).

(10) Gardner, Perkin and Watson, *J. Chem. Soc.*, **97**, 1768 (1910).

Assuming the ester has a maximum rotation of +90.8°, this product corresponds to 93% purity.

The *l*-product was collected at 126–130° (17 mm.); $n^{20}D$ 1.4730; d^{20}_4 1.043.

Anal. Calcd. for $C_{19}H_{16}O_3$: C, 65.18; H, 8.76. Found: C, 65.41; H, 8.69.

Rotation. $\alpha^{20}D$ −88.26° (pure liquid); *l*, 1; $[\alpha]^{20}D$ −84.6°.

d- and l-1-Hydroxy-3-*n*-amyl-9-methyl-7,8,9,10-tetrahydro-6-dibenzopyrone.—These were prepared from the previously described *d*- and *l*-ethyl 5-methylcyclohexanone-2-carboxylates in a synthesis identical with that for the *dl*-modification.[3]

The *d*- and *l*-products were purified from methanol, m. p. 177° (cor.) in each case.

Anal. Calcd. for $C_{19}H_{24}O_3$: C, 75.97; H, 8.03. Found: (dextro form) C, 75.97; H, 7.98; (levo form) C, 76.17; H, 8.13.

Rotation. (*d*-form) 0.3936 g. made up to 25 cc. with ethanol at 28° gave αD +4.20°; *l*, 2; $[\alpha]^{27}D$ +133°. 0.0205 g. made up to 5 cc. with chloroform at 25° gave αD +0.56°; *l*, 1; $[\alpha]^{25}D$ +137°. Leaf, Todd and Wilkinson[8] gave $[\alpha]^{24}D$ +130.3° in chloroform. (*l*-form) 0.1214 g. made up to 25 cc. with ethanol at 27° gave αD −1.23°; *l*, 2; $[\alpha]^{27}D$ −127°.

d- and l-1-Hydroxy-3-*n*-amyl-6,6,9-trimethyl-7,8,9,10-tetrahydro-6-dibenzopyran.—These were prepared from the optically active pyrones with rotations given above by use of excess methylmagnesium iodide as previously described for the *dl*-modification.

The *d*-form had a b. p. of 175–185° (0.1 mm.), bath temp. 205–210°; $n^{20}D$ 1.4550; the *l*-form had identical b. p. and index of refraction.

Anal. Calcd. for $C_{21}H_{30}O_2$: C, 80.20; H, 9.62. Found: (*d*-form) C, 80.01; H, 9.63. (*l*-form) C, 80.07; H, 9.67.

Rotation. (*d*-form) 0.1742 g. made up to 5 cc. with ethanol at 20° gave αD +5.41°; *l*, 1; $[\alpha]^{20}D$ +155°. 0.1456 g. of a sample which had $[\alpha]^{25}D$ +147° in ethanol, made up to 5 cc. with chloroform at 25° gave αD +4.32°; *l*, 1; $[\alpha]^{25}D$ +147.5°. Leaf, Todd and Wilkinson[8] report $[\alpha]^{20}D$ +134.8°. (*l*-form) 0.0873 made up to 5 cc. with ethanol at 26° gave αD −1.99°; *l*, 1; $[\alpha]^{26}D$ −114°.

Pharmacological Tests.—These were performed by the dog-ataxia method as described in previous papers.[7,11,12]

Summary

1. The *d*- and *l*-forms of 3-methylcyclohexanone have been synthesized; the former was prepared by hydrolysis of pulegone; the latter by resolution of the *dl*-methylcyclohexanone through the *l*-menthydrazone.

2. These were converted to the active ethyl 5-methyl-cyclohexanone-2-carboxylates, which were condensed with olivetol to form the *d*- and *l*-pyrones. By the action of excess methylmagnesium iodide, the *d*- and *l*-1-hydroxy-3-*n*-amyl-6,6,9-trimethyl-7,8,9,10-tetrahydro-6-dibenzopyrans resulted.

3. The *l*-modification had four to five times the marihuana activity of the *d*-form.

Sterols. CLI. Rearrangement of 17,21-Dibromo-*allo*-pregnan-3(β)-ol-20-one Acetate[1]

BY RUSSELL E. MARKER, HARRY M. CROOKS, JR., R. B. WAGNER AND EMERSON L. WITTBECKER

Recently,[2] we have shown that an equimolecular quantity of bromine with 20-keto-pregnane compounds introduces a bromine atom at C-17. Further bromination of these compounds substitutes a second bromine atom at C-21. Studies with these compounds have shown them to be particularly susceptible to rearrangement. The monobromo derivative[3] treated with methanolic potassium bicarbonate rearranges to place methyl and carbomethyoxyl groups at C-17. The 17,21-dibromo derivatives[2] under more vigorous alkali treatment yield Δ^{17-20}-pregnen-21-oic acids. The latter rearrangement products are particularly interesting since they can be degraded easily to the etio-cholane series. This fact has given support for their structure. We have now extended some of these reactions to *allo*-pregnan-3(β)-ol-20-one as a further study of the 17,21-dibromo-20-keto-pregnane rearrangement in the *allo* series.

allo-Pregnan-3(β)-ol-20-one or its acetate (I) with an equimolecular quantity of bromine readily forms a 17-monobromide (II) which can be reconverted to the parent compound or converted to 16-*allo*-pregnen-3(β)-ol-20-one by reactions described before.[2] In the same manner 17-bromo-

allo-pregnan-3,20-dione obtained by the cold chromic anhydride oxidation of the unacetylated monobromide can be readily debrominated to give the corresponding saturated or 16,17-unsaturated compounds. In addition the latter can be reduced to the former by zinc and acetic acid.

allo-Pregnan-3(β)-ol-20-one acetate (I) with twice the molecular quantity of bromine forms 17,21-dibromo-pregnan-3(β)-ol-20-one acetate (III). The latter can be formed equally well by the treatment of the monobromide (II) with an equimolecular quantity of bromine.

By the same alkali treatment used for the rearrangement of its C-5 isomer,[2] the dibromide (III) rearranges to give 3(β)-hydroxy-Δ^{17-20}-*allo*-pregnen-21-oic acid (VI). Oppenauer oxidation of the latter followed by a Meerwein reduction of the resulting keto-acid gives the epimeric pregnenoic acid (V). The structures of these acids are now established by ozonolysis. The 3(β)-hydroxy acid (VI) yields isoandrosterone (VII) and the 3(α)-hydroxy acid (V) yields androsterone (IV). As early as 1913 Faworskii[3] showed that 3-methyl-1,3-dibromobutan-2-one reacting with alcoholic potassium hydroxide readily undergoes a rearrangement to give β,β'-dimethylacrylic acid. As a model experiment we have shown that the corresponding dibromide of methyl cyclohexyl ketone in a like manner is converted to cyclohexylidene acetic acid. The pregnenoic acids are analogous to this acid and to that obtained by Faworskii.[4]

The reactions are summarized in the accompanying chart.

We thank Parke, Davis and Company for their generous assistance.

Experimental Part

17-Bromo-*allo*-pregnan-3(β)-ol-20-one Acetate (II).—To a solution of 11 g. of *allo*-pregnan-3(β)-ol-20-one acetate (I) in 500 cc. of acetic acid was added 31 cc. of molar bromine in acetic acid solution, dropwise at room temperature. The solution was allowed to stand for one hour. Ice and cold water were added, and the monobromide was extracted with ether. The ethereal layer was washed successively with water, dilute sodium carbonate solution and water. The solvent was removed and the monobromide acetate was crystallized three times from methanol, m. p. 155°; yield 6.0 g.

Anal. Calcd. for $C_{23}H_{35}O_3Br$: C, 62.9; H, 8.0. Found: C, 62.6; H, 8.0.

17-Bromo-*allo*-pregnan-3(β)-ol-20-one.—To a solution of 17 g. of *allo*-pregnan-3(β)-ol-20-one in 1 l. of acetic acid was added dropwise 54 cc. of molar bromine in acetic acid solu-

tion at room temperature. The solution was allowed to stand ten minutes, and then 1 l. of water was added. The monobromide was extracted with ether. The ether layer was washed well with water and evaporated. The monobromide was crystallized once from dilute methanol and then from ether–pentane, m. p. 93–96°; yield 9 g.

Anal. Calcd. for $C_{21}H_{33}O_2Br$: C, 63.5; H, 8.4. Found: C, 63.6; H, 8.1.

***allo*-Pregnan-3(β)-ol-20-one Acetate from 17-Bromo-*allo*-pregnan-3(β)-ol-20-one.**—A mixture of 2 g. of the bromo compound (II) in 500 cc. of methanol–dioxane mixture and 3 cc. of pyridine was hydrogenated at 40 pounds pressure for two hours using 2 g. of palladium catalyst. The catalyst was filtered off and the filtrate concentrated. An ethereal solution of the residue was washed successively with water, dilute hydrochloric acid solution and water, and then evaporated. The residue was crystallized from methanol, m. p. and mixed m. p. with *allo*-pregnan-3(β)-ol-20-one acetate (I), 142–144°; yield 1 g.

Anal. Calcd. for $C_{23}H_{36}O_3$: C, 76.6; H, 10.1. Found: C, 76.4; H, 10.0.

Reduction of 17-Bromo-*allo*-pregnan-3(β)-ol-20-one with Iron.—A mixture of 0.20 g. of the bromo compound (II), 1 g. of powdered iron and 10 cc. of glacial acetic acid was heated on a steam-bath for two hours. After filtering, water was added and the product extracted with ether. After evaporation of the solvent, the residue was crystallized from methanol, m. p. and mixed m. p. with *allo*-pregnan-3(β)-ol-20-one, 193–194°; yield 0.12 g.

Anal. Calcd. for $C_{21}H_{34}O_2$: C, 79.2; H, 10.8. Found: C, 78.9; H, 10.8.

Catalytic Reduction of 17-Bromo-*allo*-pregnan-3(β)-ol-20-one.—A mixture of 0.50 g. of the bromo compound (II), 5 cc. of pyridine, 50 cc. of dioxane and 1 g. of palladium–barium sulfate catalyst was shaken with hydrogen for three hours at 40 pounds pressure. The catalyst was filtered and the filtrate was vacuum distilled. An ethereal solution of the residue was washed well with water and evaporated. The product was crystallized from methanol, m. p. and mixed m. p. with *allo*-pregnan-3(β)-ol-20-one, 193–194°; yield 0.26 g.

Anal. Calcd. for $C_{21}H_{34}O_2$: C, 79.2; H, 10.8. Found: C, 79.0; H, 10.7.

16-*allo*-Pregnen-3(β)-ol-20-one Acetate from 17-Bromo-*allo*-pregnan-3(β)-ol-20-one Acetate.—A mixture of 1 g. of the bromo compound (II) and 5 cc. of pyridine was refluxed for five hours. Water was added and the mixture was extracted with ether. The ether layer was washed with water, dilute hydrochloric acid and water. The solvent was removed and the residue was treated with Norite in methanol. It was crystallized, m. p. and mixed m. p. with 16-*allo*-pregnen-3(β)-ol-20-one acetate, 163–165°; yield 0.6 g.

Anal. Calcd. for $C_{23}H_{34}O_3$: C, 77.0; H, 9.6. Found: C, 77.0; H, 9.2.

Treatment of 17-Bromo-*allo*-pregnan-3(β)-ol-20-one with Pyridine.—A mixture of 0.50 g. of 17-bromo-*allo*-pregnan-3(β)-ol-20-one and 5 cc. of pyridine was refluxed for six hours. The product was extracted with ether, washed with dilute hydrochloric acid and crystallized from methanol, m. p. and mixed m. p. with 16-*allo*-pregnen-3(β)-ol-20-one, 202–204°; yield 0.25 g.

Anal. Calcd. for $C_{21}H_{32}O_2$: C, 79.7; H, 10.2. Found: C, 79.6; H, 10.1.

***allo*-Pregnan-3(β)-ol-20-one Acetate from 16-*allo*-Pregnen-3(β)-ol-20-one Acetate.**—A mixture of 3 g. of the unsaturated acetate and 6 g. of zinc dust in 150 cc. of acetic acid was heated on the steam-bath for two hours. The zinc was filtered and water was added to the filtrate. This was then extracted with ether. The ethereal solution was washed with water, dilute sodium carbonate solution and again with water. The solvent was removed and the residue was crystallized from methanol and from acetone, m. p. and mixed m. p. with *allo*-pregnan-3(β)-ol-20-one acetate, 143°; yield 2.6 g.

Anal. Calcd. for $C_{23}H_{36}O_3$: C, 76.6; H, 10.1. Found: C, 77.0; H, 9.9.

Oxidation of 17-Bromo-*allo*-pregnan-3(β)-ol-20-one.—To a solution of 3 g. of the bromo compound in 50 cc. of acetic acid was added a solution of 1.5 g. of chromic anhydride in 15 cc. of 80% acetic acid at room temperature. After standing for thirty minutes, water was added and the product was extracted with ether. The acetic acid was washed out. Attempts to crystallize the product gave material with a melting point range.

(a) To a solution of 0.5 g. of the above product was added 10 cc. of dry pyridine and the mixture was refluxed for six hours. Water was added and the product was extracted with ether. The pyridine was removed and the residue was crystallized from ether, m. p. and mixed m. p. with 16-*allo*-pregnen-3,20-dione, 210–212°; yield 0.3 g.

Anal. Calcd. for $C_{21}H_{30}O_2$: C, 80.1; H, 9.6. Found: C, 80.1; H, 9.7.

(b) A solution of 0.50 g. of the crude bromo product in 25 cc. of acetic acid was refluxed for two hours with 1 g. of anhydrous potassium acetate. The solvent was removed and the residue was extracted with ether. Upon concentration, it crystallized, m. p. and mixed m. p. with 16-*allo*-pregnen-3,20-dione, 211–212°; yield 0.30 g.

(c) A solution of 0.50 g. of the crude bromo product was heated on a steam-bath for two hours with 1 g. of iron dust and 20 cc. of acetic acid. It was filtered and the filtrate was extracted with ether. The ethereal solution was washed with water and evaporated. The residue was crystallized from acetone, m. p. and mixed m. p. with *allo*-pregnan-3,20-dione, 200°; yield 0.27 g.

Anal. Calcd. for $C_{21}H_{32}O_2$: C, 79.7; H, 10.2. Found: C, 79.6; H, 10.0.

***allo*-Pregnan-3,20-dione from 16-*allo*-Pregnen-3,20-dione.**—A solution of 0.50 g. of 16-*allo*-pregnen-3,20-dione in 20 cc. of acetic acid was heated with 1 g. of zinc dust on a steam-bath for one hour. The zinc was filtered and water was added to the filtrate. The solid was filtered and crystallized from acetone, m. p. and mixed m. p. with *allo*-pregnan-3,20-dione, 200°; yield 0.35 g.

17,21-Dibromo-*allo*-pregnan-3(β)-ol-20-one Acetate (III).—To a solution of 18 g. of 17-bromo-*allo*-pregnan-3(β)-ol-20-one acetate (II) in 1 l. of acetic acid was added 41.0 cc. of molar bromine in acetic acid at 40°. Water was added and the dibromide was extracted with ether. The ether layer was washed with water, dilute sodium

carbonate solution and water. The solvent was removed and the dibromide acetate was crystallized from methanol, m. p. 174°; yield 12 g.

Anal. Calcd. for $C_{23}H_{34}O_3Br_2$: C, 53.4; H, 6.6. Found: C, 53.0; H, 6.7.

3(β)-Hydroxy-Δ$^{17-20}$-*allo*-pregnen-21-oic Acid (VI).—A solution of 1.5 g. of 17,21-dibromo-*allo*-pregnan-3(β)-ol-20-one acetate (III) in 200 cc. of methanol was heated with 5 g. of potassium hydroxide on the steam-bath for two hours. After adding water, the mixture was extracted with ether. The aqueous layer was acidified and the organic acid (VI) was extracted with ether and crystallized from methanol, m. p. 249°; yield 0.8 g.

Anal. Calcd. for $C_{21}H_{32}O_3$: C, 75.8; H, 9.7. Found: C, 75.7; H, 9.5.

Isoandrosterone (VII) from 3(β)-Hydroxy-Δ$^{17-20}$-*allo*-pregnen-21-oic Acid (VI).—A chloroform solution of 6.7 g. of the acetate of 3(β)-hydroxy-Δ$^{17-20}$-*allo*-pregnen-21-oic acid (VI) was treated with oxygen containing about 6% ozone at the rate of 30 liters of oxygen per hour for three hours. The chloroform solution was poured into 300 cc. of water and stirred for forty-five minutes. The chloroform was distilled on a steam-bath and the water layer extracted with ether. The ether was evaporated and the residue hydrolyzed with 6 g. of potassium hydroxide in 200 cc. of methanol for twenty minutes. Water was added and the mixture extracted with ether. The ether layer was washed with water and then evaporated. The residue was dissolved in 200 cc. of ethanol and refluxed with 4 g. of semicarbazide hydrochloride and 5 g. of sodium acetate in 10 cc. of water for one hour. Water was added and the precipitate was filtered and washed with water and ether. The semicarbazone was crystallized twice from ethyl alcohol–chloroform mixture, m. p. 260–262° dec.; yield 2.1 g.

Anal. Calcd. for $C_{20}H_{33}O_2N_3$: C, 69.1; H, 9.6. Found: C, 69.2; H, 9.6.

A mixture of 0.2 g. of the above semicarbazone in 50 cc. of alcohol was refluxed for an hour with 50 cc. of alcohol containing 5 cc. of concd. sulfuric acid and 10 cc. of water. Water was added and the product was extracted with ether. The ether was evaporated and the residue was crystallized from aqueous methanol, m. p. and mixed m. p. with isoandrosterone (VII), 173–174°; yield 0.1 g.

Anal. Calcd. for $C_{19}H_{30}O_2$: C, 78.6; H, 10.4. Found: C, 78.2; H, 10.3.

3(α)-Hydroxy-Δ$^{17-20}$-*allo*-pregnen-21-oic Acid (V).—A mixture of 3 g. of 3(β)-hydroxy-Δ$^{17-20}$-*allo*-pregnen-21-oic acid (VI), 10 g. of aluminum tertiary-butoxide, 100 cc. of dry toluene and 25 cc. of dry acetone was refluxed for six hours. Ether and hydrochloric acid were added. The ether layer was washed with water and evaporated. The residue was refluxed with 200 cc. of dry isopropyl alcohol and 10 g. of aluminum isopropylate overnight. The solvent was then slowly distilled off over a period of five hours. Ether and hydrochloric acid were added. The ether layer was washed with water and evaporated. The 3(α)-hydroxy acid (V) was dissolved in ether and crystallized. It appears to be much more soluble than the β-form. It was also crystallized from ethyl acetate and finally again from ether, m. p. 232–235°. It gave a depression of 18° when mixed with a sample of 3(β)-hydroxy-Δ$^{17-20}$-*allo*-pregnen-21-oic acid (VI). It did not precipitate with digitonin.

Anal. Calcd. for $C_{21}H_{32}O_3$: C, 75.8; H, 9.7. Found: C, 75.8; H, 9.7.

Androsterone (IV) from 3(α)-Hydroxy-Δ$^{17-20}$-*allo*-pregnen-21-oic Acid (V).—A solution of 1 g. of the above acid in 200 cc. of chloroform was treated with ozone and the product worked up as described for the β-acid. It gave a semicarbazone, m. p. 260–264° dec.; yield 0.4 g.

Anal. Calcd. for $C_{20}H_{33}O_2N_3$: C, 69.1; H, 9.6. Found: C, 69.4; H, 9.5.

A solution of 0.4 g. of the above semicarbazone was refluxed for one hour with 50 cc. of ethanol containing 5 cc. of sulfuric acid and 10 cc. of water. Water was added and the product was extracted with ether. The ether was evaporated and the residue was crystallized from aqueous methanol, m. p. 182–183°. There was no depression in melting point when mixed with an authentic sample of androsterone (XI).

Anal. Calcd. for $C_{19}H_{30}O_2$: C, 78.6; H, 10.4. Found: C, 78.4; H, 10.4.

Cyclohexylidene-acetic Acid from Methyl Cyclohexyl Ketone.—To 31.5 g. of methyl cyclohexyl ketone was added 8.0 g. of bromine at 0°. To this mixture was added a solution of 80 g. of potassium hydroxide in 1 l. of absolute ethanol. This was allowed to stand at room temperature overnight. Water was added and the mixture was then extracted with ether. The water layer was acidified and the acid was extracted with ether. The ether was evaporated and the residue was distilled. The cyclohexylidene acetic acid was solid and was crystallized from dilute methanol, m. p. 89–91°.

Anal. Calcd. for $C_8H_{12}O_2$: C, 68.5; H, 8.6. Found: C, 68.8; H, 8.7.

Summary

The 17-monobromide (II) of *allo*-pregnan-3(β)-ol-20-one and its acetate (I) has been prepared and its dehalogenation reactions studied.

The 17,21-dibromide (III) of *allo*-pregnan-3-(β)-ol-20-one acetate (I) has been shown to undergo a Faworskii rearrangement to give 3(β)-hydroxy-Δ$^{17-20}$-*allo*-pregnen-21-oic acid (VI). The structure has been established by conversions to isoandrosterone (VI) and androsterone (V).

Sterols. CLII. Rearrangement of 16,17-Dibromopregnan-3(β)-ol-20-one[1]

BY RUSSELL E. MARKER, R. B. WAGNER AND EMERSON L. WITTBECKER

During the course of our recent studies of bromopregnan-20-keto compounds, we found that 17,21-dibromopregnan-3(β)-ol-20-one acetate[2] under vigorous alkali treatment yields 3(β)-hydroxy-Δ^{17-20}-pregnen-21-oic acid. We now find that 16,17-dibromopregnan-3(β)-ol-20-one acetate undergoes a rearrangement to give this same product and the corresponding methyl ester.

Bromination of 16-pregnen-3(β)-ol-20-one acetate (I) in acetic acid solution gives a good yield of the 16,17-dibromide (II). That the formation of the latter was not attended by any rearrangement was shown by the simple debromination of the product (II) with methanolic sodium iodide to give the original olefinic compound (I) in almost quantitative yield. The debromination was effected equally well with boiling pyridine. Since the dibromo compound (II) was easily converted to 3(β)-hydroxy-Δ^{17-20}-pregnen-21-oic acid (IV) under exactly the same conditions as those required for the formation of IV from 17,21-dibromopregnan-3(β)-ol-20-one acetate[2] it was necessary to show that these two dibromo compounds were really different. For this purpose, 16,17-dibromopregnan-3(β)-ol-20-one acetate (II) was refluxed with potassium acetate in acetic acid solution. The product isolated was 16-pregnen-3(β)-ol-20-one acetate (I). Similar treatment of 17,21-dibromopregnan-3(β)-ol-20-one acetate has been previously shown[3] to give 21-bromo-16-pregnen-3(β)-ol-20-one acetate. Thus the 16,17-dibromide is readily debrominated to give the olefinic compound, whereas the 17,21-dibromide loses hydrobromic acid under the same conditions to give an unsaturated monobromide. The peculiar reactivity of the 16,17-dibromide is further shown by its action with hydrogen and palladium-barium sulfate catalyst in the presence of dioxane and pyridine to give compound I.

When 16,17-dibromopregnan-3(β)-ol-20-one acetate (II) is treated with a boiling solution of methanolic potassium hydroxide, it gives a mixture of 3(β)-hydroxy-Δ^{17-20}-pregnen-21-oic acid (IV) and the corresponding methyl ester (III). The unsaturated acid agrees in properties and composition with that obtained by similar treatment of 17,21-dibromopregnan-3(β)-ol-20-one acetate. Although the reaction of the latter with alcoholic potash is similar to a reaction reported by Faworskii,[4] who obtained β,β′-dimethylacrylic acid from 3-methyl-1,3-dibromo-2-butanone, we have been unable to find in the literature any analogous rearrangement for α,β-dibromo ketones. Whereas α,β-dibromo ketones are known to hydrolyze to α,β-diketones, it was impossible for our compound to take such a course.

The unsaturated acid (IV) is converted to the unsaturated methyl ester (III) by diazomethane in ether. This methyl ester (III) is identical with the ester isolated in the neutral fraction of this reaction. The ester was not found by us in our previously described rearrangement[2] of the 17,21-dibromo compound, and its isolation here may have an important bearing on any mechanism which might be proposed.

Catalytic hydrogenation of the acid (IV) with Adams catalyst gave a lower melting saturated acid which was identified by composition and physical properties as 3(β)-hydroxypregnan-21-oic acid, previously described by us.[2] Similar hydrogenation of the unsaturated methyl ester (III) followed by alkaline hydrolysis gave the same saturated acid. Both the saturated and the unsaturated (III) methyl esters, acetylated and unacetylated, agree in melting points and properties with the corresponding esters obtained by subsequent treatment of the acid from the rearrangement of the 17,21-dibromide acetate. The saturated methyl ester depresses the melting point of the methyl ester of 3(β)-hydroxy-17-methyl-etiocholanic acid obtained from the reaction of 17-bromopregnan-3(β)-ol-20-one with alcoholic potassium bicarbonate.[5]

In order to furnish additional proof of the identity of this unsaturated acid (IV) it was oxidized by ozonolysis in chloroform to give etio-cholan-3(β)-ol-17-one (V) which was isolated as the semicarbazone. Acid hydrolysis of the latter gives the free hydroxy-ketone (V) which was the same as the compound described before.[2]

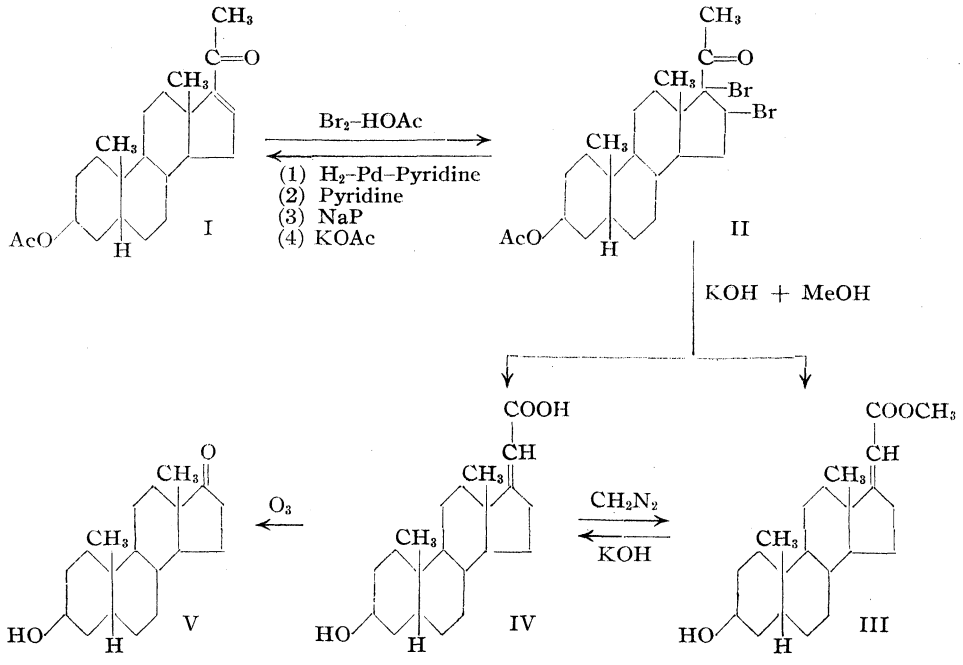
(5) Marker and Wagner, THIS JOURNAL, **64**, 216 (1942).



The reactions discussed are summarized in the chart.

The easy attainment of 3(β)-hydroxy-Δ^{17-20}-pregnen-21-oic acid by the rearrangement of 17,-21-dibromopregnan-3(β)-ol-20-one[5] has encouraged further studies on this acid. Furthermore, it was desirable to prepare several derivatives which would ensure the identity of the rearrangement products from the 16,17-dibromo compound (II).

While we previously[5] reported the degradation of this unsaturated acid (IV) to *etio*-cholan-3(β)-ol-17-one (V) by the method of ozonolysis or chromic anhydride oxidation, we have now found a much better method for this conversion, namely, alkaline potassium permanganate oxidation. The product (V) is isolated directly in the free state and does not have to be purified in the form of the semicarbazone as previously reported. This modification results in a greater over-all yield and furnishes a good source of the hydroxy-ketone.

In order to obtain the hydroxy-ketone having the *epi*-configuration, the methyl ester of the unsaturated acid (III) was successively oxidized and reduced by the Oppenauer and Meerwein procedures. The methyl ester of 3(α)-hydroxy-Δ^{17-20}-pregnen-21-oic acid was not isolated but was ozonized to give *etio*-cholan-(3)α-ol-17-one isolated as the semicarbazone. Hydrolysis of the semicarbazone gave the free hydroxy-ketone which agreed in properties and composition with the reported values for this compound. It was further identified by mixed melting point with an authentic sample of *etio*-cholan-3(α)-ol-17-one.

The fact that α,β-unsaturated acids are easily reduced by sodium and alcohol was used to advantage when the unsaturated acid (IV) was simultaneously reduced at the 17,20-position and epimerized at C-3 by sodium and amyl alcohol to give 3(α)-hydroxy-pregnan-21-oic acid. Oxidation of 3(β)-hydroxy-pregnan-21-oic acid gave the 3-keto acid which by neutral hydrogenation (Adams catalyst) gave 3(α)-hydroxypregnan-21-oic acid. The methyl esters of these acids were prepared to further characterize them and these were reduced by a Bouveault–Blanc reduction to the corresponding pregnan-3,21-diols.

Experimental Part

16,17-Dibromo-pregnan-3(β)-ol-20-one Acetate (II).—To a solution of 5 g. of 16,17-pregnen-3(β)-ol-20-one acetate (I) in 200 cc. of acetic acid was added 14 cc. of molar bromine in acetic acid solution. The mixture was poured into water and filtered. The dibromide was crystallized twice from methanol, m. p. 137–140°; yield 4.8 g.

Anal. Calcd. for $C_{23}H_{34}O_3Br_2$: C, 53.3; H, 6.6. Found: C, 53.5; H, 6.7.

Debromination of 16,17-Dibromopregnan-3(β)-ol-20-one Acetate (II)—(a) With palladium hydrogen and pyridine: a solution of 1 g. of the dibromide (II) in 125 cc. of dioxane and 3 cc. of pyridine was shaken with hydrogen and 2 g. of palladium–barium sulfate catalyst for two hours at room temperature and three atmospheres. The catalyst was filtered, and the solution was evaporated *in vacuo*. An

ethereal solution of the residue was washed with dilute hydrochloric acid and water, and then evaporated. The residue was crystallized three times from methanol, m. p. and mixed m. p. with 16-pregnen-3(β)-ol-20-one acetate (I), 143–144°; yield 0.5 g.

Anal. Calcd. for $C_{23}H_{34}O_3$: C, 77.0; H, 9.6. Found: C, 77.1; H, 9.7.

(b) **With pyridine:** a solution of 1 g. of the dibromide (II) in 5 cc. of pyridine was refluxed for three hours. Water was added, and the mixture was extracted with ether. The ether layer was washed with water, dilute hydrochloric acid and water, and then evaporated. The residue crystallized from methanol, m. p. and mixed m. p. with 16-pregnen-3(β)-ol-20-one acetate (I), 141–144°; yield 0.1 g.

Anal. Calcd. for $C_{23}H_{34}O_3$: C, 77.0; H, 9.6. Found: C, 77.0; H, 9.7.

(c) **With alcoholic sodium iodide:** a solution of 2.1 g. of the dibromide (II) in 100 cc. of methanol was refluxed with 2.2 g. of sodium iodide for one hour. A solution of sodium bisulfite was added and the mixture extracted with ether. The ether layer was washed with water and evaporated. The residue was recrystallized twice from methanol, m. p. and mixed m. p. with 16-pregnen-3(β)-ol-20-one acetate, 141–144°; yield 1.2 g.

Anal. Calcd. for $C_{23}H_{34}O_3$: C, 77.0; H, 9.6. Found: C, 76.7; H, 9.5.

(d) **With potassium acetate:** a solution of 1 g. of 16,17-dibromo-pregnan-3(β)-ol-20-one acetate (II) in 15 cc. of acetic acid was refluxed with 1.5 g. of fused potassium acetate for one hour. The solution was evaporated *in vacuo* and the residue was extracted with ether. The ether layer was washed and evaporated. The residue was crystallized twice from methanol, m. p. and mixed m. p. with 16-pregnen-3(β)-ol-20-one acetate, 140–143°.

Anal. Calcd. for $C_{23}H_{34}O_3$: C, 77.0; H, 9.6. Found: C, 76.9; H, 9.7.

Reaction of Methanolic Potassium Hydroxide with 16,17-Dibromopregnan-3(β)-ol-20-one Acetate (II).—A solution of 5 g. of the dibromide (II) in 1 l. of methanol was refluxed with 25 g. of potassium hydroxide for one hour. Water was added and the mixture was extracted with ether.

Acid Fraction.—The alkaline water layer was acidified with dilute hydrochloric acid and extracted with ether. The ethereal solution was washed with water and evaporated. The crystalline residue was recrystallized from methanol, m. p. and mixed m. p. with 3(β)-hydroxy-Δ^{17-20}-pregnen-21-oic acid, 254–256° dec.; yield 2.0 g.

Anal. Calcd. for $C_{21}H_{32}O_3$: C, 75.8; H, 9.7. Found: C, 76.2; H, 9.7.

(a) **Methyl Ester (III).**—When treated with an ethereal solution of diazomethane, the above unsaturated acid formed a methyl ester, m. p. and mixed m. p. with the methyl ester of 3(β)-hydroxy-$\Delta^{17,20}$-pregnen-21-oic acid, 153–156°.

Anal. Calcd. for $C_{22}H_{34}O_3$: C, 76.2; H, 9.9. Found: C, 76.4; H, 9.8.

(b) **Acetate of (IV).**—The acetate was prepared by the action of pyridine and acetic anhydride on the above unsaturated acid. It was crystallized from dry methanol to give white crystals, m. p. 161–163°.

Anal. Calcd. for $C_{23}H_{34}O_4$: C, 73.7; H, 9.2. Found: C, 73.7; H, 9.2.

(c) **Reduction of Unsaturated Acid (IV).**—A mixture of 200 mg. of the above unsaturated acid was hydrogenated with Adams catalyst at room temperature and three atm. for two hours. The product was crystallized from methanol, m. p. and mixed m. p. with 3(β)-hydroxypregnan-21-oic acid, 219–220°.

Anal. Calcd. for $C_{21}H_{34}O_3$: C, 75.4; H, 10.3. Found: C, 75.5; H, 10.2.

(d) **Acetate of the Saturated Acid.**—When the saturated acid from (c) was treated with pyridine–acetic anhydride mixture it gave an acetate which crystallized from methanol, m. p. and mixed m. p. with 3(β)-acetoxypregnan-21-oic acid, 219–221°.

Anal. Calcd. for $C_{23}H_{36}O_4$: C, 73.3; H, 9.6. Found: C, 73.6; H, 9.7.

(e) **Methyl Ester of Saturated Acid.**—An ethereal solution of 200 mg. of the unacetylated saturated acid from (c) was treated with an ethereal solution of diazomethane to give the methyl ester, m. p. and mixed m. p. with the methyl ester of 3(β)-hydroxypregnan-21-oic acid, 141–143°.

Anal. Calcd. for $C_{22}H_{36}O_3$: C, 75.8; H, 10.4. Found: C, 76.0; H, 10.4.

(f) **Acetate of Saturated Methyl Ester.**—A solution of 100 mg. of the saturated methyl ester from (e) in pyridine–acetic anhydride yielded a product which crystallized from methanol as large white plates, m. p. and mixed m. p. with the methyl ester of 3(β)-acetoxy-pregnan-21-oic acid, 105–106°.

Anal. Calcd. for $C_{24}H_{38}O_4$: C, 73.8; H, 9.8. Found: C, 74.2; H, 9.9.

Neutral Fraction.—The neutral fraction was obtained by evaporating the ether from the alkaline hydrolysis product and crystallizing the residue from methanol, m. p. and mixed m. p. with the methyl ester of the above unacetylated unsaturated acid from (a), 153–156°; yield 0.3 g. This also did not give any depression of melting point when mixed with the methyl ester of 3(β)-hydroxy-Δ^{17-20}-pregnen-21-oic acid.

Anal. Calcd. for $C_{22}H_{34}O_3$: C, 76.2; H, 9.9. Found: C, 76.4; H, 9.8.

(g) **Acetate of the Unsaturated Methyl Ester (III).**—An acetate formed by the pyridine–acetic anhydride procedure crystallized from methanol, m. p. and mixed m. p. with the methyl ester of 3(β)-acetoxy-$\Delta^{17,20}$-pregnen-21-oic acid, 103–105°.

Anal. Calcd. for $C_{24}H_{36}O_4$: C, 74.2; H, 9.3. Found: C, 74.1; H, 9.1.

(h) **Reduction of the Acetylated Unsaturated Methyl Ester (III).**—A solution of 150 mg. of the acetate from (g) in acetic acid was hydrogenated with Adams catalyst at room temperature and three atm. for two hours. The product was crystallized from methanol to give fine white needles, m. p. and mixed m. p. with the methyl ester of 3(β)-acetoxy-pregnan-21-oic acid and with the acetylated saturated methyl ester from (f), 102–105°.

Anal. Calcd. for $C_{24}H_{38}O_4$: C, 73.8; H, 9.8. Found: C, 74.1; H, 9.9.

(i) Hydrolysis of the Saturated Methyl Ester.—A solution of 100 mg. of the saturated methyl ester from (h) in 20% ethanolic potassium hydroxide was refluxed for sixteen hours, the mixture cooled and diluted with water. The solid suspension was washed with ether, acidified, and ether-extracted. The product crystallized from methanol to give white needles, m. p. and mixed m. p. with (3)-hydroxypregnan-21-oic acid and the saturated acid from (c), 218–220°.

Anal. Calcd. for $C_{21}H_{34}O_3$: C, 75.4; H, 10.3. Found: C, 75.3; H, 10.2.

Ozonolysis of 3(β)-Hydroxy-Δ^{17-20}-pregnen-21-oic Acid (IV) Obtained by Rearrangement of the 16,17-Dibromide (II).—Through a solution of 2.1 g. of the unsaturated acid (IV) in chloroform was bubbled oxygen containing 7% ozone at the rate of 30 l. per hour for ninety minutes. The mixture was decomposed with water and the chloroform steam distilled. The product was extracted with ether and the ethereal solution was washed with 10% potassium hydroxide and evaporated. The residue with an ethanolic solution of semicarbazide acetate yielded a semicarbazone which crystallized from methanol, m. p. and mixed m. p. with the semicarbazone of *etio*-cholan-3(β)-ol-17-one (V), 251–253° dec.; yield 0.8 g.

Anal. Calcd. for $C_{20}H_{33}N_3O_3$: C, 69.1; H, 9.6. Found: C, 69.4; H, 9.6.

A solution of the semicarbazone dissolved in 50 cc. of ethanol containing 5 cc. of concd. sulfuric acid and 10 cc. of water was refluxed for one hour. The product was crystallized from ether–pentane to give long needles, m. p. and mixed m. p. with *etio*-cholan-3(β)-ol-17-one, 150–152°.

Anal. Calcd. for $C_{19}H_{30}O_2$: C, 78.6; H, 10.4. Found: C, 78.7; H, 10.3.

In the following experiments only 3(β)-hydroxy-Δ^{17-20}-pregnen-21-oic acid from the rearrangement of 17,21-dibromopregnan-3(β)-ol-20-one acetate[2] was used.

Conversion of 3(β)-Hydroxy-Δ^{17-20}-pregnen-21-oic Acid (IV) to etio-Cholan-3(β)-ol-17-one (V).—To 0.5 g. of 3(β)-hydroxy-$^{17-20}$-pregnen-21-oic acid (IV) suspended in 20 cc. of water was added a solution of 0.5 g. of potassium hydroxide in 20 cc. of water. The mixture was stirred at 0° until all of the acid dissolved. To this solution was added 30 cc. of 2% potassium permanganate, which was the amount necessary to give a permanent pink color. The excess permanganate was destroyed with sodium bisulfite and the mixture extracted with ether. The ethereal solution was washed with water and evaporated. The solid residue was crystallized from ether–pentane to give long needles, m. p. and mixed m. p. with *etio*-cholan-3(β)-ol-17-one (V), 150–152°; yield 0.3 g.

Anal. Calcd. for $C_{19}H_{30}O_2$: C, 78.6; H, 10.4. Found: C, 78.7; H, 10.3.

Methyl Ester of 3(β)-Hydroxy-Δ^{17-20}-pregnen-21-oic Acid.—A solution of 50 mg. of 3(β)-hydroxy-$^{17-20}$ pregnen-21-oic acid (IV) in ether was treated with a cold ethereal solution of diazomethane. The ethereal solution after standing sixteen hours was evaporated and the residue was crystallized from methanol to give white flat plates, m. p. 153–155°.

Anal. Calcd. for $C_{22}H_{34}O_3$: C, 76.2; H, 9.9. Found: C, 76.2; H, 9.9

Conversion of the Methyl Ester of 3(β)-Hydroxy-Δ^{17-20}-pregnen-21-oic Acid to *etio*-Cholan-3(α)-ol-17-one.—To a solution of 4 g. of the methyl ester of 3(α)-hydroxy-$^{17-20}$-pregnen-21-oic acid in 200 cc. of dry toluene was added 25 cc. of dry acetone and 20 g. of aluminum isopropylate. The mixture was refluxed six hours, cooled, and acidified with dilute hydrochloric acid. The product was extracted with ether. After evaporation of the solvent, the residue was again treated with 200 cc. of dry isopropyl alcohol and 20 g. of aluminum isopropylate at reflux temperature for sixteen hours. The solution was slowly distilled over a period of five hours. The residue was acidified with dilute hydrochloric acid and extracted with ether. The product from the removal of the solvent was suspended in water and the volatile oils removed by steam distillation. The water was decanted and the remaining solid was dissolved in methanol and treated with digitonin in the usual manner. The non-digitonin precipitated fraction was dissolved in 200 cc. of chloroform. Through this solution was bubbled oxygen containing 7% ozone for fifteen minutes at the rate of 30 l. per hour. At the end of this time no more ozone was absorbed. The reaction mixture was decomposed with water and the chloroform removed by steam distillation. After cooling, the residue was dissolved in ether and the ethereal solution was washed well with 10% potassium hydroxide. The product from ether was converted to the semicarbazone, which crystallized from ethanol, m. p. 235° dec.; yield 0.5 g.

Anal. Calcd. for $C_{20}H_{33}N_3O_2$: C, 69.1; H, 9.6. Found: C, 68.7; H, 9.6.

The above semicarbazone was dissolved in 25 cc. of ethanol containing 2 cc. of concentrated sulfuric acid and 5 cc. of water. The mixture was refluxed for one hour and then poured into water. The product was crystallized from ether, m. p. and mixed m. p. with *etio*-cholan-3(α)-ol-17-one, 147°.

Anal. Calcd. for $C_{19}H_{30}O_2$: C, 78.6; H, 10.4. Found: C, 78.5; H, 10.3.

Epimerization and Reduction of 3(β)-Hydroxy-Δ^{17-20}-pregnen-21-oic Acid (IV). (a) With Sodium and Amyl Alcohol.—To a solution of 0.5 g. of the unsaturated acid (IV) in 200 cc. of *n*-amyl alcohol was added 10 g. of sodium. The mixture was heated under reflux for nine hours. The cooled reaction mixture was acidified with dilute hydrochloric acid and extracted with ether. The residue from the ether was warmed with 50 cc. of 10% methanolic potassium hydroxide and the alcohol removed. The remaining oily layer was removed with ether. The aqueous layer was acidified and any volatile acids were removed by steam distillation. The cooled mixture was extracted with ether and the product was crystallized from methanol, m. p. 224–226°; yield 0.2 g. This substance is 3(α)-hydroxy-pregnan-21-oic acid. It depressed the melting point of 3(β)-hydroxy-pregnan-21-oic acid and the starting material (IV).

Anal. Calcd. for $C_{21}H_{34}O_3$: C, 75.4; H, 10.3. Found: C, 75.1; H, 10.2.

The methyl ester was prepared in the usual manner with diazomethane and crystallized from 80% methanol as white needles, m. p. 118–119°.

Anal. Calcd. for $C_{22}H_{36}O_3$: C, 75.8; H, 10.4. Found: C, 75.6; H, 10.3.

The acetate of the above methyl ester was prepared by the pyridine–acetic anhydride procedure. It was crystallized from aqueous methanol as white platelets, m. p. 85–87°.

Anal. Calcd. for $C_{24}H_{38}O_4$: C, 73.8; H, 9.8. Found: C, 73.7; H, 10.0.

(b) **By Catalytic Reduction Followed by Epimerization.**—A solution of 0.3 g. of the unsaturated acid in acetic acid was shaken with hydrogen and Adams catalyst for two hours at room temperature and three atm. pressure. This gave 3(β)-hydroxy-pregnan-21-oic acid, previously described.[2] The product was dissolved in 90 cc. of *n*-amyl alcohol and treated with 6 g. of sodium as described in (a). The product was crystallized from methanol, m. p. and mixed m. p. with the material from (a), 224–226°.

3-Keto-pregnan-21-oic Acid.—To a solution of 1 g. of 3(β)-hydroxy-pregnan-21-oic acid in 50 cc. of acetic acid was added a solution of 0.5 g. of chromic anhydride in 50 cc. of 90% acetic acid. After standing one hour at room temperature, the mixture was diluted with water. The precipitated solid was extracted with ether and the ethereal solution was washed thoroughly with water to remove the acetic acid. The solvent was removed and the residue was crystallized from acetone, m. p. 170–172°; yield 0.7 g.

Anal. Calcd. for $C_{21}H_{32}O_3$: C, 75.9; H, 9.7. Found: C, 75.5; H, 9.7.

The methyl ester was prepared as described above and crystallized from aqueous methanol to give white crystals, m. p. 121–123°.

Anal. Calcd. for $C_{22}H_{34}O_3$: C, 76.2; H, 9.9. Found: C, 76.2; H, 10.0.

Reduction of 3-Keto-pregnan-21-oic Acid.—A solution of 200 mg. of the keto acid in dioxane was shaken with hydrogen and Adams catalyst for two hours at room temperature and 3 atm. pressure. The reaction mixture was filtered and the filtrate was evaporated *in vacuo*. The residue was crystallized from methanol, m. p. and mixed m. p. with the above 3(α)-hydroxypregnan-21-oic acid, 223–226°.

Anal. Calcd. for $C_{21}H_{34}O_3$: C, 75.4; H, 10.3. Found: C, 75.6; H, 10.3.

Methyl Ester of 3(β)-Hydroxypregnan-21-oic Acid.—A solution of 200 mg. of 3(β)-hydroxypregnan-21-oic acid in ether was added to a cold ethereal solution of diazomethane. The product was crystallized from methanol as white plates, m. p. 141–143°.

Anal. Calcd. for $C_{22}H_{36}O_3$: C, 75.8; H, 10.4. Found: C, 75.8; H, 10.5.

The above mother liquor was evaporated to dryness and the residue was treated with pyridine and acetic anhydride. The product was crystallized from methanol as white crystals, m. p. 102–104°. This is the acetate of the methyl ester of 3(β)-hydroxypregnan-21-oic acid.

Anal. Calcd. for $C_{24}H_{38}O_4$: C, 73.8; H, 9.8. Found: C, 74.2; H, 9.9.

Pregnan-3(β),21-diol.—To a solution of 0.5 g. of the methyl ester of 3(β)-hydroxypregnan-21-oic acid in 100 cc. of absolute ethanol was added 10 g. of sodium metal. After the vigorous reaction had ceased, the mixture was refluxed for thirty minutes. The excess sodium was dissolved with aqueous ethanol and the reaction mixture was acidified with hydrochloric acid. The product was extracted with ether and the ethereal solution was washed with 10% potassium hydroxide. Acidification of the latter aqueous solution gave a small acid fraction. The neutral fraction from the ether was crystallized from aqueous methanol, m. p. 164–166°; yield 0.1 g.

Anal. Calcd. for $C_{21}H_{36}O_2$: C, 78.7; H, 11.3. Found: C, 7.2; H, 11.5.

The diacetate was prepared by the pyridine–acetic anhydride procedure and crystallized from aqueous methanol, m. p. 76–79°.

Anal. Calcd. for $C_{25}H_{40}O_4$: C, 74.4; H, 10.0. Found: C, 74.3; H, 10.0.

Pregnan-3(α),21-diol.—A solution of 0.5 g. of the methyl ester of 3(α)-hydroxypregnan-21-oic acid in 100 cc. of absolute ethanol was treated as described above. The product crystallized from methanol as white platelets, m. p. 205–206°.

Anal. Calcd. for $C_{21}H_{36}O_2$: C, 78.7; H, 11.3. Found: C, 78.8; H, 11.3.

Summary

Bromination of 16-pregnen-3(β)-ol-20-one acetate (I) yields 16,17-dibromopregnan-3(β)-ol-20-one acetate (II). Alkali treatment of the latter yields a mixture of 3(β)-hydroxy-Δ^{17-20}-pregnen-21-oic acid (IV) and the corresponding methyl ester (III) by a new rearrangement.

3(β)-Hydroxy-Δ^{17-20}-pregnen-21-oic acid (IV) has been converted to *etio*-cholan-3(β)-ol-17-one (V) by a new method and also to *etio*-cholan-3(α)-ol-17-one. Simultaneous reduction and epimerization of (IV) gave 3(α)-hydroxypregnan-21-oic acid. The latter was also prepared by neutral catalytic hydrogenation of 3-keto-pregnan-21-oic acid and by epimerization of 3(β)-hydroxy-pregnan-21-oic acid. Bouveault–Blanc reduction of the methyl esters of the pregnanoic acid (IV) and its epimer gave the corresponding pregnan-3,21-diols.

The Determination of the Bridge Structure of Dipyrrylmethanes. A New Method for the Estimation of Active Hydrogen[1]

BY ALSOPH H. CORWIN AND RUDOLPH C. ELLINGSON[2]

The preceding paper of this series[3] showed that the imide hydrogens of certain dipyrrylmethanes do not react with molten sodium and potassium. Conceivably, these peculiarities could be due to the absence of imide hydrogens as a result of N–C–N bridges instead of C–C–C bridges as usually formulated. A suitable tool for the investigation of this problem would be a method for the determination of active hydrogens which would permit a demonstration that no rearrangement of the carbon–nitrogen skeleton had taken place during the course of the determination. This could be accomplished by regeneration of the original compound if an active hydrogen reagent could be found which would not alter ester or carbonyl groups.

A convenient reagent which has the properties specified above was suggested by the work of Conant and Wheland[4] and that of McEwen.[5] The method involves the titration of a solution of the compound in question with a standardized solution of sodium triphenylmethyl, using the color of the reagent as the end-point indicator. This reagent has the added advantage that it provides a convenient means for the preparation of derivatives, for example, methyl homologs, by reaction with the sodium salt formed during the titration.

To learn whether or not sodium triphenylmethyl is a specific reagent for imide hydrogens, this new method was used on various simple pyrroles. The results of this survey are summarized in Table I.

Perusal of the table establishes the following facts: sodium triphenylmethyl is unreactive toward nuclear methyl groups, carbethoxy groups, bromine or hydrogen on carbon; it is reactive toward imide hydrogens and hydroxyl groups. It is interesting to note that compound V, which is inert to sodium, reacts with this reagent. Compound VII shows more than one active hydrogen and on titration no sharp end-point could be reached. Up to the first mole the color of the reagent disappeared immediately. After that point had been passed, there was a slow fading of the color after each addition of the reagent. McEwen[4] has shown that the pK value of acetophenone is about 19 while that of triphenylmethane is approximately 33. By analogy, the pK value of the eno' form of this acetyl pyrrole should be near to that of acetophenone and the

slowly fading color may be ascribed to slow formation of the enol catalyzed by the strong base used.

The sodium salt of pyrrole II, formed during the titration, can be converted to compound I by reaction with dimethyl sulfate. In the same manner, the mono- and di-N-methyl derivatives of 3,5,-3′,5′-tetracarbethoxy-4,4′-dimethyldipyrrylmethane (X, Table II) may be prepared by successive alkylations after the formation of sodium salts by the sodium triphenylmethyl. This duplicates the reaction series described by Corwin, Bailey and Viohl.[3] In every case the sodium salts were hydrolyzed with water and the starting dipyrrylmethanes were recovered unchanged by the reagent.

The final methane in this methylation series, methane XII, Table II, exhibits peculiarities under the conditions of the reaction. On treatment with sodium triphenylmethyl, the end-point color appears as soon as the amount of reagent equivalent to the solvent blank has been added. When one mole of reagent is added, a flocculent orange precipitate settles out. Treatment of this solution with water regenerates the starting dipyrrylmethane. Attempts to methylate the precipitate with dimethyl sulfate failed and in each case starting material and triphenylmethane were isolated. The isolation of triphenylmethane shows that the orange precipitate is not sodium triphenylmethyl because methylation of this substance gives 1,1,1-triphenylethane.

We interpret the peculiarities noted by the assumption that one of the bridge hydrogens of the di-N-methylmethane is sufficiently acidic to react with sodium triphenylmethyl but that the steric relations of the sodium salt formed make methylation difficult.[6] The color obtained upon addition of sodium triphenylmethyl, according to this explanation, would be that of the substituted dipyrrylmethyl ion. From the broadest point of view, such a reaction as this constitutes a limitation to the method which we use. Actually, however, since the N-sodium salts are colorless, the formation of the colored C-sodium salt does not interfere with the determination of active imide hydrogens.

A variety of dipyrrylmethanes was studied with this reagent. The summary of the titrations is given in Table II.

It should be noted that methane XVII, which was inert to sodium,[3] shows two active hydrogens with sodium triphenylmethyl and that the titration values on compound XX confirm the inertness of a pyrryl CH toward this reagent.

The disodium salt of compound XIII, obtained by this titration, methylates nicely at room temperature to give 1,3,5,1′,3′,5′-hexamethyl-4,4′-dicarbethoxydipyrrylmethane (XXI). The compound prepared by this method shows no melting point depression with that obtained by the condensation of 1,2,4-trimethyl-3-carbethoxypyrrole with formaldehyde.[7]

On treating compound XIII with one mole of sodium triphenylmethyl and subsequently methylating, one obtains a mixture of the mono- and di-N-methyldipyrrylmethanes (XIV and XXI) which can be separated by fractional crystallization since the mono-N-methylmethane is the less soluble in alcohol. Methane XIV, after titration, can be methylated in good yield to give methane XXI. In each case the sodium salts were hydrolyzed to the original compound to make certain that no condensation or cleavage was caused by sodium triphenylmethyl.

The possibility that methane XIII might be N–C–N and show active hydrogens due to an active bridge CH group was eliminated by comparing compound XIV with methane XV obtained by the condensation of 2,4-dimethyl-3-carbethoxypyrrole with acetaldehyde.[8] Although these two substances melt only four degrees apart, mixed melting point shows a marked depression.

Mixed melting points of two of the three possible combinations of methanes XIII, XIV and XXI show depressions; the mixture of XIII and XIV shows no definite depression, however. In spite of this, the evidence is overwhelming that compound XIV is one pure compound. Its analysis agrees well with the calculated values and the possibility of its being an equimolar mixture of XIII and XXI was eliminated by comparison with such a mixture prepared artificially: the artificial mixture melts at 148–150° and its mixed melting point with the methane XIV depresses to 141–142°. Finally, such a mixture can be separated into its components by crystallization while repeated recrystallizations of compound XIV fail to effect any separation.

The several lines of evidence summarized above establish the bridge structure of methane XIII and its methyl derivatives as C–C–C and illus-

TABLE II

	Dipyrrylmethane	Solvent	Active H
X		Benzene	1.72, 1.82[a]
XI		Benzene Dioxane	0.96, 0.96, 1.04 1.06, 1.11, 1.13
XII		Benzene	0.0
XIII		Dioxane	2.12, 2.19
XIV		Dioxane	1.01
XV		Dioxane	1.88
XVI		Dioxane	2.10
XVII		Benzene Dioxane	1.95, 1.97 2.08, 2.00, 2.03
XVIII		Dioxane	1.08, 1.09
XIX		Benzene	2.02, 2.08
XX		Dioxane	1.96, 2.10
XXI		Benzene	0.0

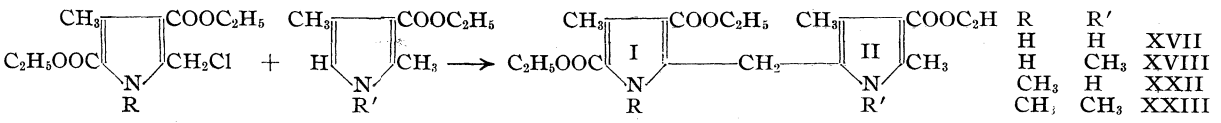
[a] The low values for this compound are undoubtedly due to the use of benzene as a solvent since the mono-sodium salt was later found to precipitate out of the benzene. Our later procedure was to use dioxane as solvent in such cases.

trate the use of the combined titration and methylation technique in a structural investigation.

The study of methane XVII and its methylation products, besides providing proof of its bridge structure, furnishes illustrations of the specificity which may be obtained by the control of reaction conditions and of an unexpected limitation to the method of titration with sodium triphenylmethyl.

Methane XVII was synthesized by application of the following general method

CHART I



in which both R and R′ were H. Its melting point is 158°.

Reaction of this compound with one mole of sodium triphenylmethyl should give a monosodium salt by replacement of the more acidic hydrogen, which, because of the electron-attracting influence of the carbethoxy groups, would be predicted to be that on ring I. Methylation gives a mono-N-methylmethane XXII; m. p. 113°, identical with that prepared by Quattlebaum and Corwin[9] by the method of Chart I in which R is CH_3 and R′ is H. This confirms the prediction as to the relative acidities of rings I and II.

Since the imide hydrogen of ring II is less acidic than that of ring I, its sodium salt will be a stronger base than the sodium salt of ring I, and methylation of the disodium salt should take place most rapidly on ring II as a consequence of the greater availability of electrons at this point. This course of the reaction is that found by experiment. Compound XVIII is formed by monomethylation of the disodium salt. The structure is confirmed by the reaction of Chart I in which R is H and R′ is CH_3. Thus either ring may be selected for specific methylation.

The low solubility of the sodium salt of methane XVIII prevents ready methylation at room temperature. If, however, the disodium salt of XVII is refluxed with two moles of dimethyl sulfate or the monosodium salt of XVIII is refluxed with one mole of dimethyl sulfate, complete N-methylation is accomplished. The structure of the product XXIII melting at 129°, was confirmed by the reaction of Chart I.

When methane XXII was treated in dioxane solution with sodium triphenylmethyl, an intense red-violet color with a blue fluorescence appeared long before one mole of reagent per mole of methane had been added.[8] There was no appreciable precipitate in this solution. Hydrolysis of the solution with water or treatment with dimethyl sulfate gave the same compound in the form of yellow plates melting at 204°. Analysis of the product indicates that a condensation has taken place. The further investigation of the structure of this substance will be the subject of a later communication.

When methane XXII is treated with sodium triphenylmethyl in benzene solution, in which sodium salts are generally much less soluble than in dioxane, a colorless, soap-like precipitate is formed and indications of the condensation reaction appear when nearly one mole of reagent per mole of methane has been added. The violet color and blue fluorescence make it impossible to determine the end-point visually and therefore we cannot titrate accurately for the number of active hydrogens in the molecule. If the solution with its precipitate is immediately treated with water, the sodium salt is hydrolyzed and one obtains an 85% recovery of the starting mono-N-methylmethane XXII. If the solution is treated immediately with dimethyl sulfate, a 60% yield of methane XXIII is obtained.

The anomaly recorded above, while illustrating a limitation of the sodium triphenylmethyl titration, emphasizes one of the advantages of the reagent, namely, that the possibility of regeneration of the starting compound permits a check upon the presence or absence of an undesired side-reaction and thus furnishes a more reliable means for the investigation of structure than the usual active hydrogen determination.

The authors wish to acknowledge their deep indebtedness to Dr. F. Y. Wiselogle for his generous aid and consultation in the manipulation of sodium triphenylmethyl.

Experimental Part

Purification of Nitrogen.—In using standardized solutions of sodium triphenylmethyl, it is necessary to prepare and manipulate the compound under nitrogen that has been freed from carbon dioxide, moisture and oxygen. A convenient purification train is shown in Fig. 1.

Tank nitrogen is passed through a series of six Friedrich's spiral wash bottles. The first two contain 150 cc. each of Fieser's solution.[10] This solution is very effective for removing oxygen. When the first bottle has become exhausted, as evidenced by the change in color, it is refilled with fresh solution and placed in position 2, while bottle 2

(9) Quattlebaum and Corwin, THIS JOURNAL, **64**, 922 (1942).

(10) Fieser, *ibid.*, **46**, 2639 (1924).

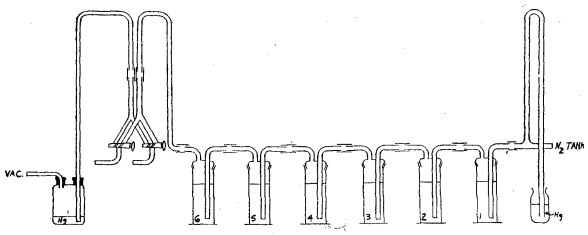


Fig. 1.

is placed in the first position. The third wash bottle contains a saturated lead acetate solution to remove any hydrogen sulfide that may be liberated from the Fieser's solution; in the fourth bottle there is concentrated sulfuric acid to remove water; in the fifth a deep blue toluene solution of the sodium ketyl of benzophenone prepared by dissolving a few grams of benzophenone in dry toluene and adding a small amount of 2% sodium amalgam. This solution removes the last traces of water and oxygen and serves as an indicator for the purity of the nitrogen. The sixth wash bottle contains Nujol in which paraffin has been dissolved to catch the toluene vapors swept from the benzophenone bottle. The train is so constructed that nitrogen can be led to two systems and so arranged that each can be evacuated and filled with nitrogen as many times as necessary, independently of the other. The ground joints of the wash bottles are secured with paraffin during operation.

Preparation of Sodium Triphenylmethyl Solution.—The apparatus in which the sodium triphenylmethyl is prepared consists of a 500-cc. round-bottom flask with a ground joint connection to a filling and sweeping apparatus as shown in Fig. 2. We are indebted to Dr. F. Y. Wiselogle for the design of this apparatus.

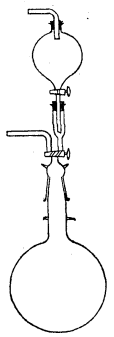

Fig. 2.

The solvents, benzene and ether, are carefully dried over 45% sodium amalgam, distilled and distilled again from 2% sodium amalgam and benzophenone immediately before being used. The blue color of the metal ketyl indicates when the solvents are absolutely dry. The stopcocks and ground joints are lubricated with a lubricant reported by Meloche and Frederick.[11] All parts are baked at 110° for several hours before being used.

In the flask is placed 100 cc. of dry ether and about 20 g. (9–10 cc.) of 45% sodium amalgam is added. In the separatory funnel a solution of 12 g. of pure triphenylmethyl chloride in 100 cc. of dry benzene is placed. The two parts are evacuated and filled with nitrogen three or four times to replace the air. The benzene solution is then run into the flask below. The stopcock is turned so that the lower part is connected to the nitrogen current and the flask shaken for about one-half hour. The flask is left on the nitrogen current to take care of the pressure built up due to vaporization of ether. The stopcock is closed, the separatory funnel removed and the flask placed on a shaking wheel for twelve to fourteen hours.

The sodium triphenylmethyl solution is filtered from sodium chloride and mercury through a 3G4 sintered glass funnel into the storage vessel which is a one liter flask with a delivery tube and inlet neck, each carrying ground glass stopcocks (Fig. 3). On the side arm of the reaction vessel is placed a rubber stopper which fits into the top of the sintered glass funnel and the stem of this has a rubber stopper fitting into the inlet neck of the storage vessel.

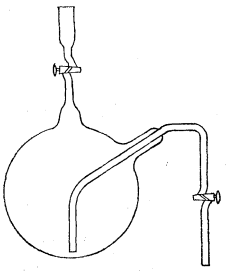

Fig. 3.

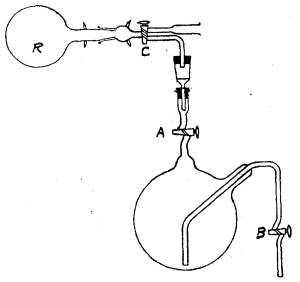

Fig. 4.

The reaction flask and storage vessel are placed in the tilted position (Fig. 4) ready for filtration but are allowed to stand for three or four hours so the finely divided salt, mercury and sodium amalgam have time to settle. This is important or the sintered glass funnel will become stopped up immediately. After the settling, the stopcocks A and B are opened and the vessel evacuated and filled with nitrogen three times; finally stopcock A is closed, the vessel evacuated and the stopcock B is closed. Stopcock C is opened and after the glass funnel has liquid over the bottom, A is opened. The whole apparatus is tilted so liquid always fills the neck of the reaction vessel, R. The filtering proceeds rapidly at first but slows considerably toward the end. After filtering, stopcock A is closed and B opened allowing nitrogen to enter, relieving the vacuum.

The separatory funnel is placed in the neck of the storage vessel and a mixture of 125 cc. of dry ether and 125 cc. of dry benzene is run in. The solution is shaken and is then ready for use. In this way a sodium triphenylmethyl solution of 0.07 to 0.08 molarity is obtained and can be kept for weeks with very little change in strength.

Apparatus for the Titrations.—The apparatus for the titrations is shown in Fig. 5. The storage vessel is mounted high on a ring stand. A tube about four inches long and drawn out at one end is attached to the delivery tube of the vessel by a slip-over rubber seal making the union nearly glass to glass. The narrow end leads into the top of a 10-cc. buret and is also sealed by a slip-over rubber tube. The buret has a side arm about half an inch above the zero mark and is connected to the nitrogen purification train.

The most satisfactory stopcock grease for the buret is graphite and tin amalgam. The two parts of the stopcock are well coated with graphite by rubbing with an extra soft lead pencil and then with a piece of tin that has been dipped in mercury. This lubricant holds the ether–benzene solution very well and will hold a water-pump vacuum quite well. The stopcock does not freeze and may be used several days without relubricating.

The end of the buret carries a rubber stopper that fits into the neck of the reaction flask which is a 50-cc. suction flask to which an "L" side arm has been added. The regular side arm is connected to the purification train while the "L" arm is used for introducing the solvent and the methylating agent.

(11) Meloche and Frederick, THIS JOURNAL, **54**, 3264 (1932).

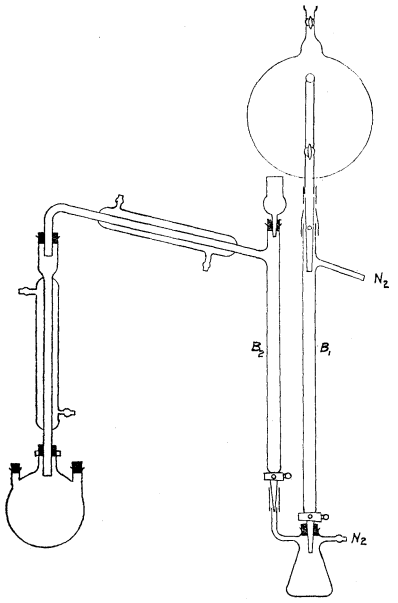

Fig. 5.

The solvent, dioxane or benzene, is refluxed in the flask over 2% sodium amalgam and benzophenone until dry as indicated by the blue color. It is then distilled into the buret, B_2, from which the solvent is measured directly into the reaction vessel. The tip of B_2 fits into the "L" arm of the reaction flask and is sealed with a slip-over rubber tube.

Another reaction vessel was constructed from a 50-cc. suction flask with the "L" side arm and a two-inch glass condenser (Fig. 6). This was used when methylation did not take place at room temperature but required heat. The flask was heated by a small electric furnace.

Directions for Performing a Titration. A. Standardization of Sodium Triphenylmethyl Solution.—The buret is evacuated and filled with nitrogen three times and finally evacuated. Stopcock B of the storage vessel is opened so that a few cc. of solution runs into the buret. B is closed and nitrogen again led into the buret. This amount of reagent is run out and discarded, serving merely to remove any water that may not have been removed on cleaning and drying the buret. The buret is then filled and a definite volume of the solution run into a 50-cc. Erlenmeyer flask containing 20 cc. of distilled water. This flask is heated on a steam-cone to remove the solvents, ether and benzene, cooled and the solution titrated with standard hydrochloric acid using methyl orange as the indicator. Duplicate titrations are run and from these the strength of the reagent solution is calculated.

B. Blanks on the Solvent.—The reaction flasks are dried at 110° to remove all moisture. The empty flask is attached, evacuated and sealed with paraffin at the stopper and rubber slip-over seals while under vacuum. Nitrogen is then allowed to pass in and the evacuation and refilling repeated three times. The flask is evacuated slightly and 5 cc. of solvent measured in from buret B_2 and the stopcock turned to the nitrogen current again. In the meantime the reagent buret has been filled as described earlier. The reagent is then added dropwise, the flask being shaken gently until the permanent orange color appears in the solvent. Duplicates also are performed for this step. For 5 cc. of benzene the blank is 0.22 to 0.26 cc. when the strength of the reagent is 0.07 to 0.08 molar. For 5 cc. of dioxane it is 0.80 to 1.00 cc. for the same strength of reagent. Dioxane that is used as a solvent is purified by storing over calcium chloride for several days, refluxing over sodium for several hours, distilling, and finally distilling from 2% sodium amalgam and benzophenone in the titration apparatus.

C. Titration of the Sample and Methylation.—The pure, dry sample is weighed into the reaction flask and attached to the apparatus. The solvent is introduced as described above for the blank determinations and the reagent buret filled. The reagent is added slowly to the permanent end-point. The number of active hydrogen atoms per molecule of the compound can then be calculated.

If one wishes to hydrolyze the reaction product to see whether or not the starting material will be recovered, the flask is removed, the product treated with water and the material worked up as will be described in the individual experiments.

If one wishes to methylate the reaction product, the solution of dimethyl sulfate is passed into buret B_2, the reaction flask is evacuated slightly and as much of this solution is added as desired. Since the molar quantities used are very small, 1 cc. of dimethyl sulfate is made up to 10 cc. with dry solvent used in the titration to allow a more accurate measurement of the amount of methylating agent. The dimethyl sulfate is also distilled through a small column under vacuum just before being used. For those methylations where heat must be applied the reaction vessel shown in Fig. 6 is used.

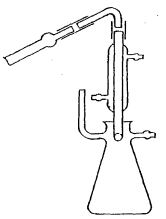

Fig. 6.

Titrations were performed by this method on all the substances listed in Tables I and II with the results shown. In the succeeding section only experiments other than the titrations are described.

1,2,4-Trimethyl-3,5-dicarbethoxypyrrole (I).—2,4-Dimethyl-3,5-dicarbethoxypyrrole (II), (146 mg.) was titrated as described above. The sodium salt formed was methylated by adding 3.5 cc. of dimethyl sulfate. After standing two hours the solution was filtered, the solvent removed and excess dimethyl sulfate destroyed by steam distillation; yield, 110 mg. or 71% of colorless crystals; m. p. 109–111°. The compound gives no melting point depression with a pure sample of the N-methylpyrrole.

Activity of the Reagent toward Nuclear Methyl and Carbethoxy Groups.—To make certain that no reaction had taken place with nuclear methyl and carbethoxy groups, compounds I and III were recovered after the titration by evaporation of the solvent and compound II by hydrolysis of the solution. None showed any depression on mixed melting point with the starting material.

Reactions with 3,5,3′,5′-Tetracarbethoxy-4,4′-dimethyldipyrrylmethane (X). A. Recovery after Titration.—The tetracarbethoxymethane (212 mg.) was titrated in benzene solution. The reaction mixture was shaken with water, the benzene layer separated, dried over sodium sulfate, filtered and evaporated. The residue was extracted with

hexane to remove the triphenylmethane. The crude material (133 mg. or 63%) was crystallized from ethanol; m. p. 134–135°, no depression of m. p. with starting material.

B. Monomethylation.—Two hundred and twenty-eight milligrams of methane X was treated with 11.70 cc. (including 0.40 cc. solvent blank) of 0.0445 molar sodium triphenylmethyl solution. 2.00 cc. of dimethyl sulfate was added and the solution warmed for ninety minutes. The solution was filtered and the solvents removed by steam distillation. The insoluble solid was dried and extracted with 5 cc. of hot hexane to remove the triphenylmethane; yield, 133 mg. or 56%. After recrystallization from alcohol and water the m. p. was 139–140°. There was no depression with compound XI prepared with sodium and dimethyl sulfate but there were marked depressions with methanes X and XII.

C. Dimethylation.—One hundred and ninety-nine milligrams of methane X was treated with 20.19 cc. (including 0.40 cc. solvent blank) of 0.0445 molar sodium triphenylmethyl solution; 3.00 cc. of dimethyl sulfate was added and the solution warmed for ten minutes. The solvents were removed by steam-distillation. The residue was dried and extracted with hexane to remove triphenylmethane; yield, 186 mg. or 91% of the di-N-methylmethane XII.

Reactions with 1,4,4′-Trimethyl-3,5,3′,5′-tetracarbethoxydipyrrylmethane (XI). A. Recovery after Titration.—The procedure was identical with that described for methane X; no depression with starting material.

B. Methylation.—The procedure was identical with that for the monomethylation of compound X with the proper correction for the change in molecular weight; yield, 70–90%. No depression with methane XII.

Reaction with 1,4,1′,4′-Tetramethyl-3,5,3′,5′-tetracarbethoxydipyrrylmethane (XII). A. Treatment with One Mole of Reagent and Hydrolysis.—Three hundred and seven milligrams (0.000635 mole) of the dipyrrylmethane XII in 5 cc. of benzene was treated with enough reagent solution to furnish 0.00064 mole of sodium triphenylmethyl. The permanent end-point appeared as soon as enough solution for the blank had been added. As the addition proceeded a deep red, transient precipitate formed as the drops hit the surface. By the time one mole of reagent had been added there was an orange-yellow substance suspended in the red solution. This solution was treated with water and the product isolated in the usual manner, giving 175 mg. of a colorless solid which after two crystallizations from alcohol melted at 144–145° and did not show a depression with the starting methane.

B. Attempted Methylations.—Two hundred and fifty-six milligrams (0.00053 mole) of methane XII in 5 cc. of benzene was treated with 0.00053 mole of sodium triphenylmethyl; 1 cc. of dimethyl sulfate was added and the solution allowed to stand several hours. It was then shaken with an 8% sodium carbonate solution, washed with water, dried, filtered and evaporated. The residue was extracted with hexane leaving 125 mg. of colorless material which melted at 141–143° and did not depress on mixed m. p. with the starting methane.

The experiment was repeated using 265 mg. of the methane and twice the amount of sodium triphenylmethyl; 85 mg. of material was isolated which proved to be the starting methane.

Two hundred and nineteen milligrams (0.00045 mole) of the dipyrrylmethane in 5 cc. of benzene was treated with 0.00045 mole of sodium triphenylmethyl and 0.0011 mole of dimethyl sulfate and allowed to stand for twelve hours. The solution was filtered and evaporated in vacuum. The residue was boiled with hexane, filtered, and 42 mg. of a pink solid that melted at 92–96° was isolated. The hexane filtrate was evaporated down leaving 200 mg. of residue which was crystallized from alcohol and water; m. p. 87–90°. It showed no depression on mixed melt with triphenylmethane but gave a 30° depression with 1,1,1-triphenylethane. This demonstrated that sodium triphenylmethyl was not present in the solution after treatment with methane XII.

Reactions with 3,5,3′,5′-Tetramethyl-4,4′-dicarbethoxydipyrrylmethane (XIII). A. Recovery after Titration.—The procedure was identical with preceding recoveries; 53 mg. was obtained from 98 mg. and was identical with the starting material.

B. Monomethylation.—Four hundred and thirteen milligrams (0.0012 mole) of methane XIII was dissolved in 10 cc. of dioxane and treated with 0.0012 mole of sodium triphenylmethyl; 1.0 cc. of dimethyl sulfate was added and the sodium salt went into solution rapidly leaving a small amount of sodium methyl sulfate suspended. The solution was washed with water, the benzene–ether layer separated, dried over sodium sulfate, filtered, evaporated and the residue extracted with hexane, leaving 450 mg. of a tan powder. The powder was boiled with 30 cc. of 2:1 alcohol–water and filtered, leaving 290 mg. of undissolved material melting at 150–160°. This was crystallized several times from alcohol and water; m. p. 176° with decomposition. The compound crystallized in colorless plates and depressed with di-N-methylmethane XXI. Mixed m. p. with the starting material (XIII), m. p. 229°, was 178–179° thus showing no definite depression. The filtrate from the first crystallization gave, on cooling, 85 mg. of impure di-N-methylmethane XXI.

Anal. Calcd. for $C_{20}H_{22}N_2O_4$ (methane XIV): C, 66.65; H, 7.83. Found: C, 66.58; H, 7.79.

C. Dimethylation.—Three hundred and fifty milligrams (0.00101 mole) of methane XIII in 10 cc. of dioxane was treated with 0.0020 mole of sodium triphenylmethyl; 1.0 cc. of dimethyl sulfate was added and the solution allowed to stand for several hours. It was then treated in the same manner as for the monomethylation; 255 mg. or 67% of crude di-N-methyl methane XXI was isolated. After five recrystallizations from alcohol and water its melting point rose to 150–152° and showed no depression on mixed melt with a sample prepared by the method of Corwin and Quattlebaum.[7]

Methylation of 1,3,5,3′,5′-Pentamethyl-4,4′-dicarbethoxydipyrrylmethane (XIV).—After titration in 5 cc. of dioxane, the sodium salt from 123 mg. of methane XIV was treated with 0.0007 mole of dimethyl sulfate and warmed gently. After standing for several hours the solution was shaken with water, the benzene–ether layer separated, dried over sodium sulfate, filtered and evaporated in a vacuum. The residue was extracted with 5 cc. of warm hexane; yield, 78 mg. or 61%; m. p. 153°. The melting

point was raised to 157–158° by repeated recrystallizations from alcohol and water. No depression with methane XXI, m. p. 153°, prepared by the method of Corwin and Quattlebaum.[7]

Comparison of Methane XIV with XV.—The bridge methylated methane XV was prepared by the method of Fischer and Bartholomäus.[8] After recrystallization from alcohol and water the melting point was 170°. The melting point of methane XIV was 176°; mixed m. p. 153°.

Reactions of 3,5,4′-Trimethyl-4,3′,5′-tricarbethoxydipyrrylmethane (XVII). A. Recovery after Titration.—The solution obtained by titrating 174 mg. of methane XVII was poured into 50 cc. of water, heated on the steam-cone to remove the ether and benzene, cooled and the solid filtered off. This solid was boiled with hexane, the solution cooled and filtered; recovery, 163 mg. or 94% of crude starting material. After one crystallization from alcohol and water the compound melted at 156–158° and gave no depression with starting material, m. p. 158–159°.

B. Monomethylation of XVII on Ring I.—Two hundred and four milligrams (0.000505 mole) of methane XVII was dissolved in 5 cc. of dioxane and treated with 0.00051 mole of sodium triphenylmethyl. To the clear solution, 0.9 cc. of a 10% solution by volume of dimethyl sulfate and benzene was added and the reaction mixture allowed to stand overnight; 50 cc. of water was added and the mixture heated on the steam-cone to remove the ether and benzene, cooled, the solid removed and dried. The solid was extracted with cold hexane; yield, 153 mg. (72%) of a colorless powder; m. p. 105°. After two crystallizations from water and alcohol, m. p. 110°; mixed m. p. with methane XXII prepared by the method of Quattlebaum and Corwin,[9] no depression.

C. Monomethylation of XVII on Ring II.—Two hundred and two milligrams of methane XVII (0.00050 mole) was dissolved in 5 cc. of dioxane and 0.00104 mole of sodium triphenylmethyl beyond the solvent blank was added. The sodium salt came out as a gelatinous mass; 1.8 cc. of dimethyl sulfate solution (1 cc. in 9 cc. of dioxane) was added. Within two minutes the solution had become apparently clear and within the next few seconds a large amount of a white precipitate separated—much more than the sodium methyl sulfate could account for. The flask was allowed to stand attached to the apparatus overnight; 40 cc. of water was added, the mixture heated on the steam-cone to remove the solvents, cooled and the solid separated and dried. The solid was boiled with 3.0 cc. of hexane, the solution cooled, filtered and the residue washed with cold hexane; yield, 145 mg. or 68%; m. p., after one crystallization from alcohol and water, 96°. Repeated crystallizations raised this to 97°; no depression with methane XVIII prepared by the method given below.

D. Synthesis of 1,3,5,4′-Tetramethyl-4,3′,5′-tricarbethoxydipyrrylmethane (XVIII) by Condensation.—Two and seventy-three hundredths grams of 2-chloromethyl-3,5-dicarbethoxy-4-methylpyrrole was dissolved in 10 cc. of methanol and 1.81 g. of 1,2,4-trimethyl-3-carbethoxypyrrole in 5 cc. of methanol. The solutions were combined and refluxed two hours. The reaction mixture was cooled until crystallization was complete and the solid filtered off; yield, 2.60 g. or 62%; m. p. 92–94°. No attempt was made to recover the product in the mother liquors from the condensation; m. p., after one crystallization from water and alcohol, 96–97°. For analysis, crystallized twice from hexane; m. p. 97°.

Anal. Calcd. for $C_{22}H_{30}N_2O_6$: C, 63.14; H, 7.22. Found: C, 63.08; H, 7.26.

E. Dimethylation of Methane XVII.—One hundred and five milligrams (0.00026 mole) of methane XVII in 5.0 cc. of benzene was treated with 0.000556 mole of sodium triphenylmethyl; 3.0 cc. of dimethyl sulfate solution (1 cc. in 9 cc. benzene) was added and the solution refluxed for forty minutes. The sodium salt dissolved and deposited sodium methyl sulfate; 50 cc. of water was added, the solution heated to remove the benzene and ether, cooled and filtered. The solid was extracted with hexane; yield, 85 mg. or 75%; m. p. 125°; after crystallizing from hexane, m. p. 128–129°; no depression with methane XXIII prepared by the condensation below.

F. Synthesis of 1,3,5,1′,4′-Pentamethyl-4,3′,5′-tricarbethoxydipyrrylmethane (XXIII) by Condensation.—Two and eighty-seven hundredths grams of 1,4-dimethyl-2-chloromethyl-3,5-dicarbethoxypyrrole and 1.81 g. of 1,2,4-trimethyl-3-carbethoxypyrrole were each dissolved in 5 cc. of methanol. The solutions were combined and refluxed for two hours. On cooling the dipyrrylmethane crystallized out; yield 3.85 g. or 89%; m. p. 128–129°. The analytical sample was crystallized twice from alcohol and water and once from hexane; m. p. 129°.

Anal. Calcd. for $C_{23}H_{32}N_2O_6$: C, 63.87; H, 7.46. Found: C, 63.88, 63.80; H, 7.46, 7.38.

Reactions for Methane XVIII. A. Recovery after Titration.—The recovery was performed as for methane XVII; 166 mg. or 79% was recovered from 211 mg. One recrystallization brought the m. p. to 96°; mixed m. p. with XVIII, no depression.

B. Methylation.—The sodium salt obtained by titrating 202 mg. of methane XVIII in benzene was treated with 3.0 cc. of dimethyl sulfate solution and the mixture refluxed for two hours. The product was treated as described under the dimethylation of XVII; yield, 180 mg. or 86%. After two recrystallizations from hexane, m. p. 125–127°; no depression with methane XXIII, m. p. 129°.

Reactions of 3,5,1′,4′-Tetramethyl-4,3′,5′-tricarbethoxydipyrrylmethane (XXII). A. In Benzene; Attempted Titration.—One hundred and ninety-nine milligrams (0.000475 mole) of methane XXII was dissolved in 5 cc. of benzene and treated with 0.00047 mole of sodium triphenylmethyl. As the addition was made, the colorless sodium salt settled out as a soapy mass and as time passed the solution took on a blue fluorescence and violet color indicating that condensation had taken place to some extent.[3] On adding water to the solution, the violet color disappeared. The mixture was warmed to remove the benzene and ether, cooled and filtered. The solid was extracted with a small amount of hexane leaving 170 mg. of a yellow powder melting at 95–105°; after two crystallizations from alcohol and water, m. p. 110°; no depression with starting material.

B. Methylation.—Two hundred and twenty-eight milligrams (0.000545 mole) of methane XXII in 5.0 cc. of benzene was treated with 0.0005 mole of sodium triphenylmethyl and 1.0 cc. of dimethyl sulfate solution was added

immediately. Within a few minutes the sodium salt of the dipyrrylmethane had dissolved. The flask was allowed to stand overnight and the product isolated in the usual manner; yield, 210 mg. of crude material which after two crystallizations from hexane melted at 125°; no depression with methane XXIII, m. p. 129°.

C. Condensation Reaction in Dioxane.[3]—Five hundred and fifteen milligrams (0.00123 mole) of methane XXII was dissolved in 10 cc. of dioxane and treated with 0.00123 mole of sodium triphenylmethyl. After the first drop of reagent had been added, the blue fluorescence noted above appeared. As the addition progressed the solution became cherry-red and finally deep violet. No precipitate was deposited. After ten minutes the flask was removed and the contents poured into water. The violet color disappeared leaving a yellow ether–benzene layer with a blue fluorescence. The mixture was warmed to remove the ether and benzene, cooled, filtered and the yellow solid extracted with hexane, leaving 430 mg. of a yellow powder which melted at 150–192°. After crystallizing twice from ethanol the compound melted at 203–204°; yield, 300–400 mg.

Anal. Calcd. for $C_{20}H_{24}N_2O_5$: C, 64.50; H, 6.49; mol. wt., 372. Found: C, 64.46, 64.44; H, 6.40, 6.43; mol. wt., 388, 369, 379 (b. p. elevation in chloroform).

When the violet solution was treated with dimethyl sulfate, the deep color disappeared immediately but the compound isolated from the reaction was identical with that prepared above. Evidently this material shows a resistance to methylation similar to that of methane XII.

Summary

1. It is shown that a standardized solution of sodium triphenylmethyl may be used to titrate for active hydrogens.

2. This reagent is inert to ester groups, C–Br links and most CH groups.

3. The >CH–CO– linkage is active to sodium triphenylmethyl.

4. The reagent permits a check upon possible condensations by regeneration of the starting material.

5. A dipyrrylmethane with a bridge hydrogen acidic to sodium triphenylmethyl has been discovered.

6. Titration followed by methylation has been used to confirm the structures of a number of dipyrrylmethanes.

7. A method for specific, selective methylation of bifunctional weak acids is presented.

8. A new pyrrole condensation is recorded.

Rearrangements of Pyrrole Rings in the Oxidation of Dipyrrylmethanes[1]

BY ALSOPH H. CORWIN AND KARL J. BRUNINGS[2]

Previous papers of this series[3] have developed the fact that certain pyrrole-carbon single bonds which can cleave to give stable resonating systems are rapidly split by acid at room temperature and below. Brunings and Corwin[4] extended this study with the observation that, under even milder conditions, it is possible to cleave a pyrryl-carbon bond belonging to the resonating system of a pyrrole pigment. This observation provides a starting point for the systematic study of pyrrole pigments which may be of significance with respect to the catabolic processes which these substances undergo in biological systems. The conversion of hemoglobin to bile pigments and the problem of the reactions causing varying sequences of substituents on naturally occurring porphyrins are examples of fundamental biological processes which may be elucidated by studies upon the stability of variously substituted pigments. This paper reports a study of an even readier cleavage of a pyrrole pigment system than that previously discussed.

Our earlier papers show that attempts to prepare mono-N-methyldipyrrylmethenes by the condensation of pyrryl aldehydes with α-free pyrroles yield either symmetrical N-free methenes or products which have not been identified. That this peculiarity is not due to the impossibility of preparing an N-methyl methene was demonstrated by the preparation of 1,3,5,1′,3′,5′-hexamethyl-4,4′-dicarbethoxydipyrrylmethene salts (I).[4] Among the reactions generally used in dipyrrylmethene synthesis, the oxidation of dipyrrylmethanes would appear to be the most reliable for preparing and establishing the structures of

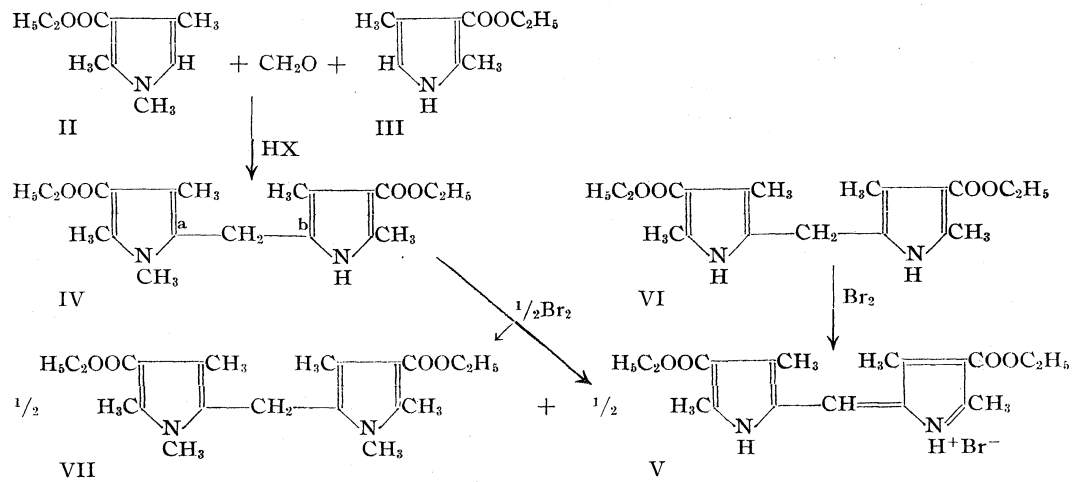

CHART I.

these pigments. This method was successful in the preparation of methene I.

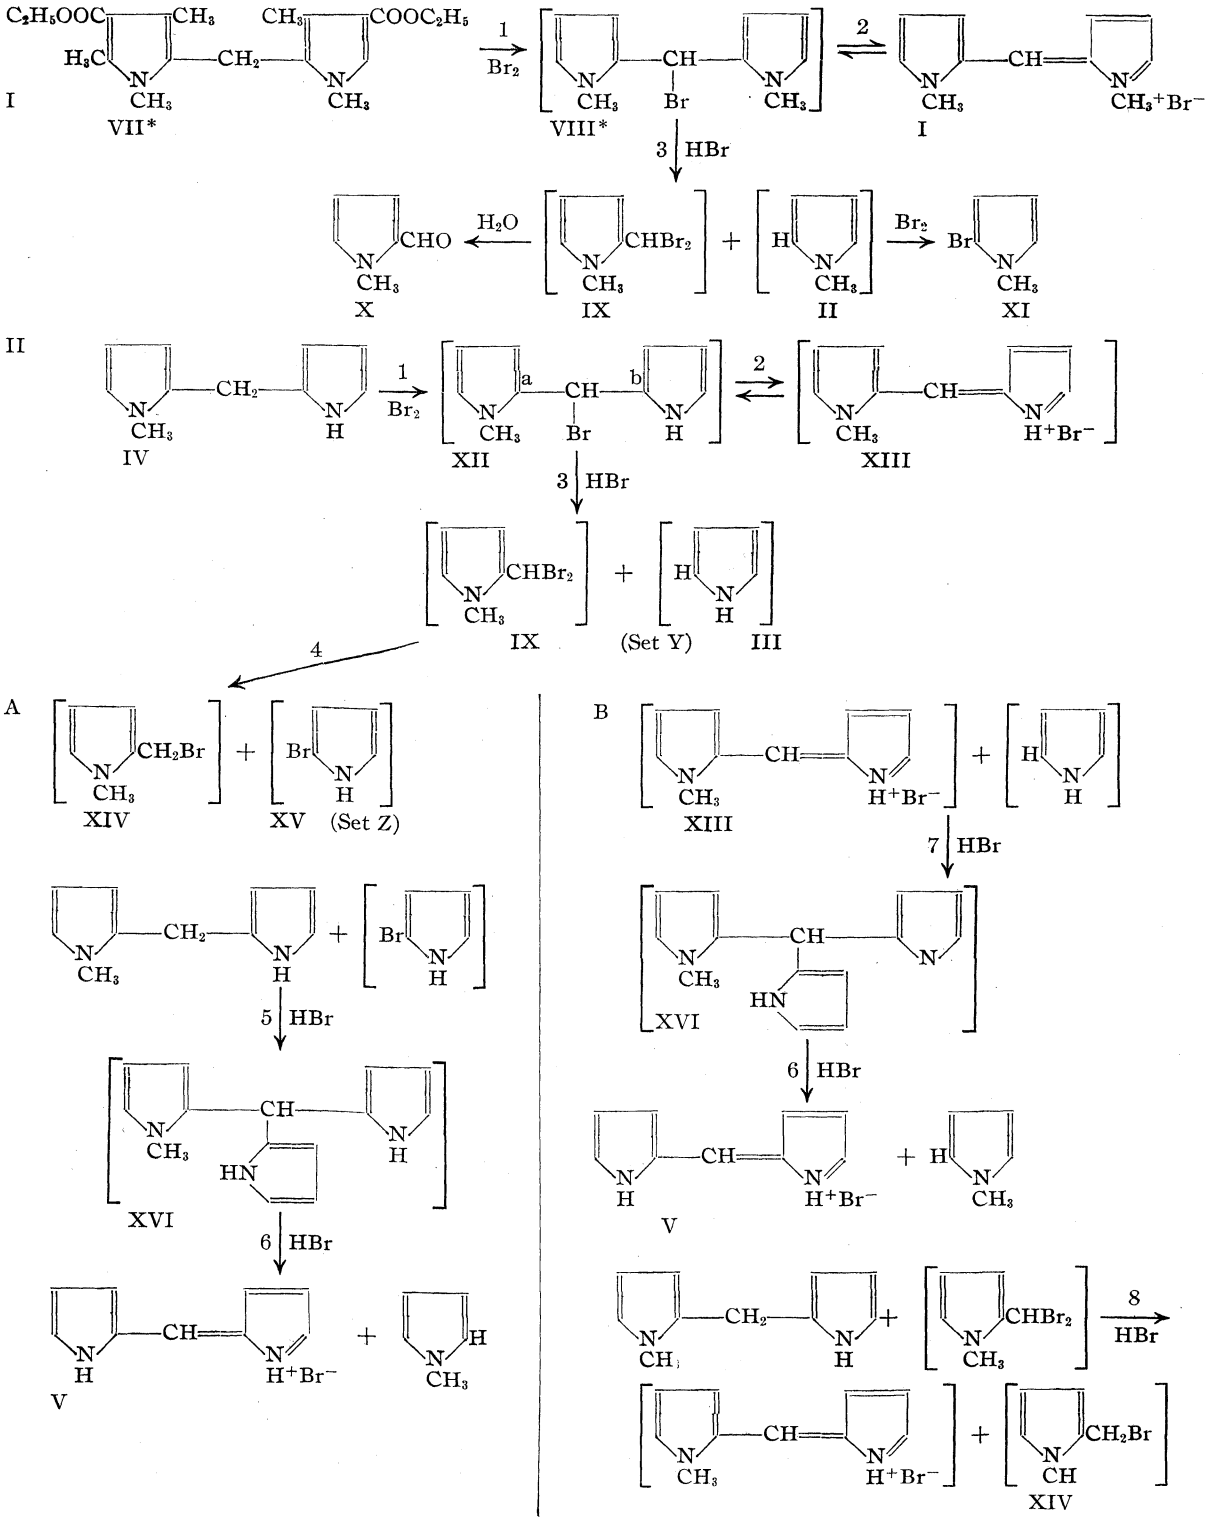
To study mono-N-methylmethane bromination on a comparable system, 1,3,5,3′,5′-pentamethyl-4,4′-dicarbethoxydipyrrylmethane (IV, Chart I) was prepared by the unsymmetrical condensation of the N-methylated and NH α-free pyrroles II and III (Chart I) with formaldehyde. The methane was then brominated under the conditions that had successfully produced the di-N-methyl methene (I). Instead of the expected mono-N-methylmethene (XIII, Chart II) the symmetrical di-NH-methene (V) was obtained in about 60% yield based on the amount of NH-pyrrole ring in the starting methane (IV). Investigation of the mother liquor showed that 1,3,5-trimethyl-2-bromo-4-carbethoxypyrrole (XI, Chart II) was a by-product of the reaction. It was then found that by using only one-half mole of bromine with one mole of methane a practically quantitative yield of pure crystalline di-NH-methene (V) was obtained. Di-N-methyl dipyrrylmethane (VII) was isolated from the mother liquor. The di-NH-methene (V) obtained by this anomalous reaction may be prepared in quantitative yield by the bromination of the corresponding di-NH-methene (VI). These reactions are given in Chart I.

The possibility that the dipyrrylmethane (IV) might be a mixture of the unmethylated and di-N-methylated methanes (VI and VII) was excluded by bromination of actual mixtures of the two symmetrical methanes and by a thorough investigation of the structure of this compound.[1] Any explanation based on the removal of the methyl groups from the nitrogens is excluded by the isolation of the di-N-methyl methane (VII) and N-methyl-α-bromopyrrole (XI) as by-products of the half-molar and molar brominations, respectively, and by the quantitative yield based on the amount of NH-pyrrole in the starting methane.

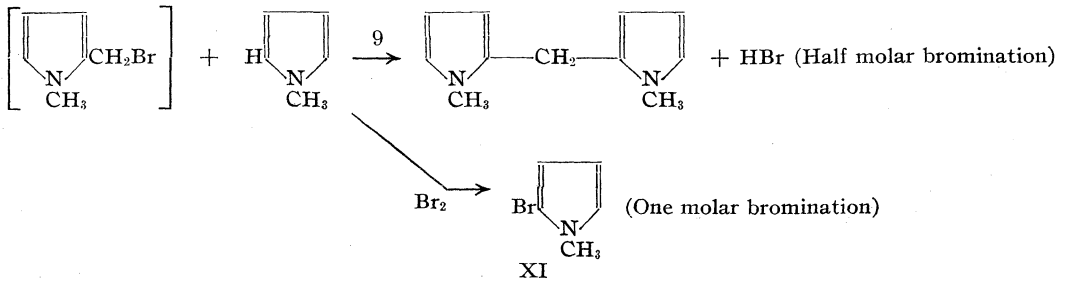
Assured then of the structure of the starting dipyrrylmethane and the stability of the methyl groups on the nitrogens, it is apparent that a cleavage of the C–C bond (IV, a or b) takes place. The motivating force of the reaction is supplied by the hydrobromic acid. Realizing the possibility of acid cleavage, a score of oxidation reactions in neutral and basic medium were tried in an effort to obtain the mono-N-methylmethene. In every case either no reaction occurred or the methane was degraded to products no longer identifiable as pyrrole derivatives. On the other hand, acidic oxidizing agents of low activity, *e. g.*, formic acid or oxygen and mineral acid, are capable of giving the reaction. The rate and completeness of the reaction depend both on the oxidizing agent and the strength of the acid. For example, air in the presence of hydrobromic acid gives a low yield of the methene (V) at a slow rate, while the bromination gives a 75% yield in less than five minutes. The rate of bromine consumption is too fast to measure with accuracy by ordinary techniques. Chlorination results in a rather complete and very rapid reaction but the rate of appearance of the methene is slow.

Cleavage of a dipyrrylmethene system to pyrrole fragments has been shown to take place as a by-reaction in the bromination of the di-N-methylmethane (VII) to the corresponding methene (I) in paper VI of this series. Evidence was presented there to show that the steric interference

of the methyl groups on the nitrogens reduces the stability of the methene system. Although the steric interference between the methyl group and the hydrogen in the mono-N-methylmethene would be considerably less, the lack of symmetry in the Kekulé resonance forms would also lead to a decrease in the stability of the dipyrrylmethene system. Finally, the possibility of the pyrrole



A and B



XI

CHART II.

* The substituents present in the 3, 4 and 5 positions of compound VII are understood to be present on all the remaining pyrrole rings of the chart.

fragments forming insoluble crystalline end-products might be expected to bring about complete cleavage by disturbance of the equilibria.

Fischer and Riedl[5] have demonstrated acid cleavage of two unsymmetrical dipyrrylmethanes under non-oxidizing conditions, and thus the possibility of cleavage of the methane by hydrobromic acid produced in the early stages of the reaction must also be considered in formulating a mechanism for the anomalous bromination of mono-N-methyldipyrrylmethane IV. This alternative may be shown to be untenable by tests on the stability of the methane in the presence of hydrobromic acid under conditions considerably more drastic than those of the bromination. In order to test for cleavage products the methane dissolved in alcohol was boiled with formaldehyde in the presence of both hydrochloric and hydrobromic acids. If the bonds *a* or *b* were broken under this treatment, α-free pyrrole II or III would result. Since both the NH- and N-methylpyrroles condense with formaldehyde to produce dipyrrylmethanes, the mono-N-methylmethane would disproportionate to the di-NH- (VI) and the di-N-methyl- (VII) methanes. Such a disproportionation was not observed.

The di-NH-methene and N-methylpyrrole fragments are also obtained when the mono-N-methylmethane is treated with formic acid in the presence of hydrobromic acid. This reaction might be formulated as resulting from a condensation of formic acid with the α-free pyrrole produced by acid cleavage, a standard methene condensation. However, it can be shown that this explanation is not valid, since formic acid will not condense with the α-free NH-pyrrole under the conditions of the reaction. These experiments show that the cleavage does not occur on the methane and thus oxidation of the methane must be the initial reaction of the bromination.

The extremely fast rate of the reaction and the failure of all methods intended to stop the reaction after the initial bromination make isolation of NH-intermediates in the formation of the di-NH-methene (V) impossible. However, in the case of the bromination of the di-N-methylmethane (VII), previously referred to,[4] the pyrrole fragments resulting from cleavage are actually isolated in addition to the expected di-N-methylmethene from the normal oxidation. Moreover, this reaction lends itself to careful study and evidence has been presented[4] to show that the cleavage does not occur on the methene salt but on an intermediate in the bromination. The chemical and physical properties of the sterically hindered methene suggested that the covalent dipyrrylmethyl bromide (VIII, Chart II) is the intermediate in the reaction. The steps involved in the cleavage of the di-N-methylmethane are given in the first series of reactions in Chart II.

If one assumes that the cleavage of the mono-N-methylmethane proceeds analogously to that of the di-N-methyl system, the problem of setting up a mechanism becomes one of finding established reactions involving the pyrrole derivatives which may be present in the bromination solution and which will produce the di-NH-methene (V) and the N-methylated by-products. Two alternative mechanisms, A and B, are described in the second series of reactions in Chart II. Reactions 1, 2 and 3 of this series are identical with those of the di-N-methyl system in the first series. Cleavage of the dipyrrylmethyl bromide (XII) is postulated to occur at bond b to give the α-dibromomethyl pyrrole (IX) and the α-free pyrrole (III) (Set Y), since cleavage at bond a would yield pyrrole fragments which cannot condense according to known

(5) Fischer and Riedl, *Z. physiol. Chem.*, **207**, 200 (1932).

reactions to produce the products obtained in the bromination.

One mole of bromine cleaves two moles of the methane in the over-all reaction, and, therefore, one of the cleavage products must react with the starting methane (IV). In mechanism A this reaction is preceded by a disproportionation of the primary cleavage products (Reaction 4) to yield α-bromomethylpyrrole (XIV) and the α-bromopyrrole (XV) (Set Z). Reactions of this type have not been studied as yet in the pyrrole series since dihalomethyl derivatives are very difficult to prepare. However, it is reasonable to assume that the intermediate bromopyrrole would be a very good brominating agent and it can be shown that the α-free pyrrole brominates with extreme rapidity. The reaction between the mono-N-methylmethane (IV) and the α-bromopyrrole (XV) (Reaction 5) can be carried out under the conditions of the bromination to give a quantitative yield of the di-NH-methene (V) with a rate which is compatible with that of the bromination. In analogy to similar reactions in the pyrrole series it is reasonable that this reaction should have tripyrrylmethane (XVI) as an intermediate. The cleavage of this tripyrrylmethane with hydrogen bromide (Reaction 6) has also been carried out under comparable conditions[3] to give the expected methene (V) with both the rate and the yield in agreement with those of the bromination. The N-methyl α-free pyrrole (II) has been isolated from both reactions.

The fundamental reaction of the alternative mechanism B is the condensation of the primary cleavage product, the α-free pyrrole (III) and the mono-N-methyldipyrrylmethene (XIII) (Reaction 7) to yield the di-NH-methene (V) through the tripyrrylmethane (XVI). Since the methene (XIII) has not been isolated, this reaction could not be imitated. However, the condensation has well-established analogies in the pyrrole series and its mechanism has been thoroughly worked out.[3] As described above, Reaction 6 may be carried out under conditions of the bromination. The reactions thus far account for only one-half of the yield of the di-NH-methene and, therefore, another oxidation of the starting methane must occur. The dibromomethylpyrrole (IX) is the only oxidizing agent remaining and thus Reaction 8 is postulated to provide an additional mole of mono-N-methylmethene which then reacts according to the preceding scheme, leading to a chain mechanism. This reaction is without analogy in the pyrrole series for the reasons mentioned above. However, the oxidizing action of this type of dihalomethyl derivative can be demonstrated by the reaction between 2-dichloromethyl-3,5-dicarbethoxy-4-methylpyrrole and the mono-N-methylmethane (IV) which again yields the anomalous di-NH-methene. This reaction is very slow and incomplete, a behavior which might be predicted on the basis of the effect of the carbethoxy groups on the pyrrole ring.

Common to both mechanisms (A and B) is the final reaction 9 which accounts for the isolation of the di-N-methylmethane (VII) from the bromination reaction. The isolation of the α-free pyrrole from the formic acid oxidation and the incomplete yield of the di-N-methyl methane from the bromination are in agreement with the generally slow rate of this methane condensation.

Essentially, the question as to which of these two proposed mechanisms is the correct one becomes a problem of determining whether the α-free pyrrole (III) or the starting methane (IV) reacts more rapidly with the dibromomethylpyrrole (IX). Lacking the dibromomethylpyrrole, a selection between the two mechanisms can only be made on indirect evidence. No difference in bromination rate of the pyrrole and methane could be found by the techniques at our disposal, both reactions going to completion in less than five seconds. It is significant, however, that in the cleavage of the di-N-methyl system, α-free pyrrole is never isolated. This is easily interpreted by assuming that the rate of bromination (k_4) of the pyrrole is faster than that of the methane (k_1). It must be pointed out, however, that the comparative rates of bromination may depend upon the type of brominating agent in question and thus might be reversed in going from bromine to α-dibromomethylpyrrole.

Strong positive support is given mechanism A by the low yields obtained when one mole of bromine per mole of methane is employed. In mechanism A the formation of methene depends on the presence of unoxidized starting methane (Reaction 5), while in mechanism B the methene is formed from the oxidation intermediate (XIII) and one of its cleavage products (Reaction 7). Therefore the use of an extra half mole of bromine should either give no methene or at least a greatly diminished yield if mechanism A is valid. According to mechanism B, however, one molar bromina-

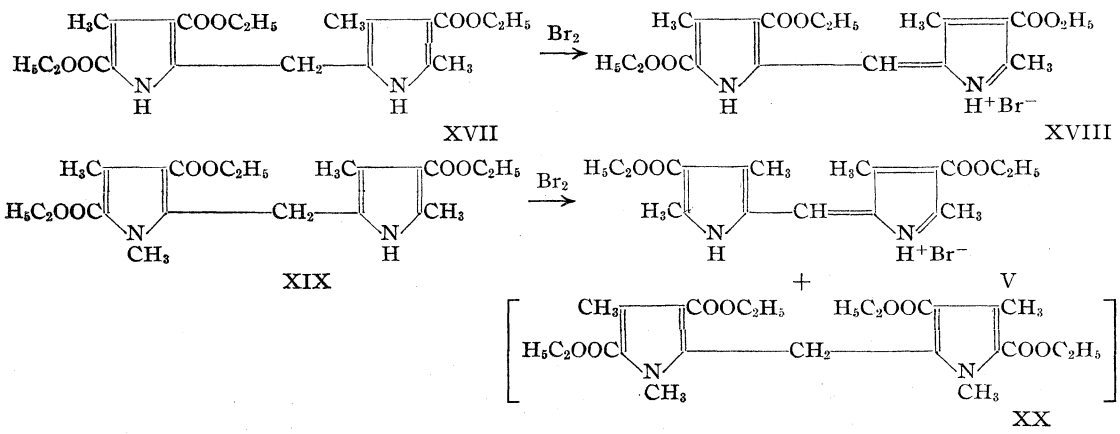


CHART III.

tion should not affect the yield of methene but rather the state of oxidation of the pyrrole fragments. Actually, the yield is depressed almost a half and a considerable amount of unidentifiable by-product is obtained. The fact that a 60% yield of the methene is obtained instead of one mole of α-bromomethylpyrrole (XIV) and one mole of the α-bromopyrrole (XV) may be accounted for by the rapidity with which the bromopyrrole–dipyrrylmethane condensation (Reaction 5) takes place.

Until the mono-N-methylmethene can be prepared and its properties studied, the validity of either one of these mechanisms cannot be uniquely established. It is possible, of course, that both mechanisms operate, the importance of each depending on the conditions under which the bromination is carried out. As indicated above, dibromomethylpyrrole derivatives are unknown and a study of their properties would do much toward elucidating the present unusual reaction.

The anomalous course of the bromination of the mono-N-methylmethane must destroy our confidence in the absolute reliability of this synthetic method as a proof of the structure of dipyrrylmethenes. In order to determine whether this anomalous reaction is in any way general for unsymmetrical methanes, a series of dipyrrylmethanes[6] was subjected to bromination. Of those tried, one other example, the 1,4,3′,5′-tetramethyl-3,5,4′-tricarbethoxydipyrrylmethane (XIX, Chart III) was observed to give the symmetrical methene (V). Bromination of the di-NH-methene (XVII) of the corresponding configuration gave a normal result, while the methane having a methyl group on the other pyrrole ring yielded unidentifiable products. The reactions are given in Chart III.

The oxidation of unsymmetrical dipyrrylmethanes has not been extensively employed as a method of preparing dipyrrylmethenes. However, in a few cases the method has been applied[7,8] successfully to give normal results. On the basis of the studies made on the mono-N-methyl and the di-N-methyl systems,[4] it may be stated that an anomalous course of the methane bromination may be looked for whenever there is reason to believe that the corresponding methene will be unstable. Unfortunately, no reliable criteria exist for predicting the stability of dipyrrylmethenes. The three examples which have been shown to be subject to acid cleavage all contain methyl groups on the nitrogens and it has been shown that the steric interference of these groups gives rise to a reduction in the stability of the dipyrryl systems. Lack of symmetry and the electrical effect of groups on the pyrrole rings are other factors which must be considered in predicting the stability of dipyrrylmethenes but their use must await an orderly correlation of the physical and chemical properties of the many dipyrryl systems now available.

The authors wish to express their appreciation to the Rockefeller Foundation which has supported a portion of this investigation.

The junior author also wishes to acknowledge a grant-in-aid from the Hynson, Westcott and Dunning Fund.

Experimental Section

Preparation of 1,3,5,3′,5′-Pentamethyl-4,4′-dicarbethoxydipyrrylmethane (IV).—A solution of 20 g. of 1,2,4-

(6) Corwin and Quattlebaum, THIS JOURNAL, **64**, 922 (1942).

(8) Fischer and Baumler, *Ann.*, **468**, 74 (1929).

trimethyl-3-carbethoxypyrrole (II) in 100 cc. of alcohol and a solution of 20 g. of 2,4-dimethyl-3-carbethoxypyrrole (III) in 100 cc. of alcohol are mixed in a 500-cc. Erlenmeyer flask and 28 cc. of formalin added. After the temperature has been raised to 45°, 10 cc. of concentrated hydrochloric acid is run in. The temperature is kept below 60° by cooling the flask from time to time in running water. After standing in the cold for several hours, 40 g. of crude product is filtered from the mixture and washed with cold 50% alcohol–water. The material is then refluxed in 50% alcohol–water for one hour and again filtered. Recrystallization of the precipitate from alcohol yields 30 g. of large crystalline plates, melting irreversibly at 178–179°; yield, 75%. Mixed melt with mono-N-methyldipyrrylmethane prepared by Dr. R. C. Ellingson by a different method,[1] 178–179°.

One Molar Bromination of Mono-N-methyldipyrrylmethane (IV).—A solution of 100 mg. of the mono-N-methylmethane (IV) in 10 cc. of dry carbon tetrachloride is placed in a 25-cc. Erlenmeyer flask; 0.05 g. of bromine dissolved in 0.5 cc. of carbon tetrachloride is added quickly while the flask is vigorously twirled. The mixture is allowed to stand several hours in the cold to ensure complete precipitation and then filtered; 35 mg. (58% of the theoretical) of yellow methene-like needles is obtained. This material on treatment with concentrated ammonia and subsequent recrystallization from hexane–benzene yields long red needles, melting with decomposition at 189–190°. Mixed melt with 3,5,3′,5′-tetramethyl-5,5′-dicarbethoxydipyrrylmethene (V), 189–190° with decomposition. Reduction of the original product with palladium–hydrogen gives the dipyrrylmethane corresponding to the configuration of di-NH-methene V.

Isolation of 1,3,5-Trimethyl-2-bromo-4-carbethoxypyrrole (XI) from the One Molar Bromination of Mono-N-methyldipyrrylmethane IV.—The mono-N-methylmethane (1.5 g.) is dissolved in 150 cc. of dry carbon tetrachloride and placed in a 250-cc. Erlenmeyer flask; 200 cc. of water containing 20 g. of potassium carbonate is placed in a separatory funnel and 0.61 g. of bromine dissolved in 6.1 cc. of carbon tetrachloride is then run into the methane solution quickly and the flask shaken for thirty seconds. The mixture is poured immediately into the separatory funnel containing the potassium carbonate solution and shaken vigorously for several minutes. The carbon tetrachloride layer, which is highly colored, is drawn off and dried with anhydrous potassium carbonate. A chromatograph is then prepared using a six-inch column of activated alumina (150–200 mesh) as adsorbent. The solution is passed through the chromatograph developing a bright yellow band of di-NH-methene V on the alumina. In addition to the yellow band of the di-NH-methene another red band develops indicating an additional methene as by-product. After 200 cc. has been collected, a new receiver is used and additional carbon tetrachloride is passed through until a second fraction of 200 cc. is collected. The first fraction is evaporated to dryness and leaves 125 mg. of fine white needles which melt at 54–55°, decompose with gas evolution at 145–150° and give no depression with N-methyl-α-bromopyrrole (XI).[4] The second fraction gives a larger amount of solid with a yellow tinge. On warming to about 60° the whole mass turns blood red. If the mixture is not warmed but recrystallized more α-bromopyrrole may be isolated. This behavior is indicative of the presence of another compound. Since the two pyrroles must be equivalent in state of oxidation to a dipyrrylmethene, the accompanying compound is assumed to be the α-bromomethylpyrrole (XIV, see Chart II). A highly colored third fraction gives a resinous solid which has not been identified.

Half-Molar Bromination of Mono-N-methyldipyrrylmethane IV.—The methane (1.5 g.) is dissolved in 300 cc. of dry carbon tetrachloride and brominated according to the directions given above using 0.37 g. of bromine in 3.7 cc. of carbon tetrachloride; 850 mg. of fine orange-yellow needles is obtained. When submitted to the tests described in the one molar bromination the product is shown to be di-NH-dipyrrylmethene V. The yield is 96% of the theoretical based on the amount of NH-pyrrole in the starting methane.

Isolation of 1,3,5,1′,3′,5′-Hexamethyl-4,4′-dicarbethoxydipyrrylmethane (VII) from the Half Molar Bromination.—The mother liquor of the above reaction is evaporated in a suction flask at room temperature. The resinous residue is taken up in about 25 cc. of dry hexane, decolorized with Norite A and allowed to crystallize. On repeated recrystallization a colorless compound is obtained; m. p. 156–157°. Mixed melt with 1,3,5,1′,3′,5′-hexamethyl-4,4′-dicarbethoxydipyrrylmethane 156–157°.

Oxidation of Mono-N-methyldipyrrylmethane IV with Formic Acid and Hydrobromic Acid.—A solution of 500 mg. of mono-N-methylmethane IV in 100 cc. of carbon tetrachloride is placed in a 250-cc. glass-stoppered Erlenmeyer flask. After the solution has cooled to room temperature 0.2 cc. of formic acid and 5 cc. of aqueous (45%) hydrobromic acid is run in. The flask is then stoppered, wired and placed on a rotary shaker for four hours. At the end of this time the precipitate of red needles is filtered; yield, 200 mg. The precipitate is ground in a mortar with concentrated ammonia. The free base thus formed is recrystallized from hexane–benzene; m. p. (dec.) 190°; mixed melt with di-NH-dipyrrylmethene (V) (free base) 190° (dec.).

Reaction of Formic Acid with 2,4-Dimethyl-3-carbethoxypyrrole (III).—The α-free pyrrole (III) (230 mg.) is dissolved in 100 cc. of carbon tetrachloride and placed in a 250-cc. Erlenmeyer flask; 0.1 cc. of formic acid and 5 cc. of aqueous hydrobromic acid (45%) are run in as above. After four hours of shaking, no crystals are noted and the color of the solution remains light yellow. On heating to 40° and shaking, the reaction mixture does not change color. If the solution is heated to 65° the solution turns deep red, and on cooling a crop of fine red needles is obtained. The product is the expected di-NH-methene (V).

Isolation of 1,2,4-Trimethyl-3-carbethoxypyrrole (II) from Formic Acid Oxidation of Mono-N-methyldipyrrylmethane IV.—The mono-N-methyl methane (500 mg.) is treated with formic acid and hydrobromic acid in the manner described above. After the methene is filtered off, the carbon tetrachloride solution is shaken with saturated sodium bicarbonate solution, separated and filtered. The filtrate is then evaporated to dryness in a filter flask at room temperature. When the residue appears dry, the

filter flask is fitted with a cold finger and the suction continued while the filter flask is warmed to 60–70° on a water-bath. A heavy coating of N-methyl-α-free pyrrole (II) sublimes onto the cold finger; m. p. 61–62°; mixed melt with N-methyl-α-free pyrrole (II), 61–62°.

Chlorination of Mono-N-methyldipyrrylmethane IV.—A solution of chlorine in carbon tetrachloride is prepared by bubbling chlorine slowly through dry carbon tetrachloride. The resulting stock solution is stored over calcium chloride in a glass-stoppered Erlenmeyer flask. Just before using, the solution is standardized using excess potassium iodide and titrating with 0.1 *N* thiosulfate solution. The solution used in the present experiment is 0.56 *N*.

A solution of 100 mg. of dipyrrylmethane IV dissolved in 10 cc. of dry carbon tetrachloride is placed in a 25-cc. Erlenmeyer flask and 1.1 cc. of 0.56 *N* chlorine–carbon tetrachloride (1 mole plus 10%) is added quickly. The solution turns red immediately and then gradually a deep brown. After fifteen minutes fine yellow needles begin to separate; precipitation is complete after standing four hours in the cold. Yield of the di-NH-dipyrrylmethene (V) hydrochloride is 35 mg. or 70% of the theoretical.

Rate of Bromine and Chlorine Consumption in the Bromination and Chlorination of Mono-N-methyldipyrrylmethane IV.—The following standard solutions were prepared: (1) 0.0055 *M* mono-N-methylmethane IV in carbon tetrachloride; (2) 0.0284 *N* bromine in carbon tetrachloride; (3) 0.028 *N* chlorine in carbon tetrachloride; (4) 0.0300 *N* thiosulfate solution.

Approximately 1 g. of potassium iodide was dissolved in 20 cc. of concentrated acetic acid in a 50-cc. glass-stoppered Erlenmeyer flask; 10 cc. of the 0.0055 *M* mono-N-methylmethane solution was pipetted into a 50-cc. glass-stoppered Erlenmeyer flask. To this solution 3.9 cc. of the 0.0284 *N* bromine solution (1 mole) was added quickly, the flask shaken vigorously for five seconds and the potassium iodide solution added immediately. The flask was shaken again and the resulting solution titrated with 0.0300 *N* thiosulfate solution, using starch as an indicator; 3.0% of the bromine remained, indicating 97% consumption in five seconds. A series of experiments gave values ranging from 96–100% consumption of bromine in five seconds.

A similar experiment was run using 11.7 cc. of the standard bromine solution (3 moles). The reaction was terminated after five seconds as described above. Titration with standard thiosulfate solution showed that 92% of 2 moles of bromine had been consumed.

Identical rate measurements were made on the di-N-methyldipyrrylmethane (VII) and the corresponding di-NH-methane (VI). No difference could be observed between the rates of bromine consumption of the di-N-methyl and the mono-N-methyldipyrrylmethanes. A slightly slower rate was observed in the case of the di-NH-methane. An accurate difference could not be ascertained with the methods at our disposal but the difference could be qualitatively reproduced in a series of experiments.

The rate of chlorine consumption by the mono-N-methylmethane was studied in an analogous manner. Titration for chlorine after five seconds reaction time gave a blank in a series of experiments. The rate was thus too fast to measure by this technique.

The rate of bromination of the α-free pyrrole (III) has been measured by other workers[9] in this Laboratory and found to be similar to that of the mono-N-methylmethane.

Behavior of Mono-N-methylmethane IV with Respect to Neutral and Alkaline Oxidation.—As mentioned in the theoretical part of this paper, many attempts were made to carry out the oxidation of the mono-N-methylmethane IV in neutral or basic medium using different reagents under different conditions. In order to test the applicability of the methods to general methene synthesis, every reaction was run on 3,5,3′,5′-tetramethyl-4,4′-dicarbethoxydipyrrylmethane (VI). All results on the mono-N-methylmethane (IV) were negative. The most interesting of the reagents tried was neutral permanganate which, when applied to the di-NH-methane, gives a good yield of very pure dipyrrylmethene in the form of its free base. This method appears to be the best so far developed for preparing the free base of the di-NH-methene V in a high state of purity.

Oxidation of 3,5,3′,5′-Tetramethyl-4,4′-dicarbethoxydipyrrylmethane (VI) by Means of Potassium Permanganate.—The methane (150 mg.) was dissolved in 50 cc. of pure acetone in a 100-cc. Erlenmeyer flask fitted with a reflux condenser. (The acetone used in this reaction was obtained by refluxing commercial acetone for four hours over potassium permanganate.) 100 mg. of C. P. potassium permanganate was dissolved in the smallest amount of distilled water possible. The acetone solution was brought to a boil, the potassium permanganate solution added, and the mixture refluxed for five minutes. The reddish purple solution containing manganese dioxide was then filtered through asbestos; 125 mg. of the di-NH-methene (V) free base was obtained from the highly colored solution by rapid evaporation of the acetone. This material may then be recrystallized by dissolving in very little acetone, adding a small amount of water and allowing to stand overnight. It may also be recrystallized in the usual manner from hexane–benzene; m. p. (dec.) 190°.

The amount of potassium permanganate used in the above experiment was fixed by trial. The use of smaller amounts resulted in an impure product containing starting material; the use of larger amounts lowered the yield considerably. By following the *p*H of the reaction by means of a *p*H meter it was found that the *p*H rose rapidly to 13 and beyond when the methane solution and permanganate were mixed. By passing a stream of carbon dioxide through the reaction mixture, the *p*H could be maintained between 8 and 9. The reaction proceeded in this case much more slowly and considerably less permanganate was necessary. The product was of high purity but the yields were not so satisfactory as in the reaction just described. By using large excesses of permanganate and extending the reflux time, the methane was entirely converted to water soluble, colorless products.

When this technique was applied to the mono-N-methylmethane (IV) a white, crystalline product which was coated by a yellowish oil was obtained. On purification this product was found to consist largely of starting material.

Although many trials were made, no modification could be found whereby the expected methene could be prepared. Starting material was always obtained in decreasing

(9) Corwin and co-workers, unpublished work.

amounts with the use of large excesses of potassium permanganate. On the basis of work by Sackur and Taegener[10] it was hoped that the use of a calculated amount of potassium permanganate in slightly alkaline solution would provide the methene. The results were disappointing since no reaction took place with increasing sodium hydroxide until a point was reached where the solvent itself was oxidized. In such cases the methane was completely destroyed.

Attempted Basic Bromination of Mono-N-methyldipyrrylmethane (IV).—A solution of 2.5 g. of potassium hydroxide dissolved in 100 cc. of methyl alcohol was cooled to −10°; 2 g. of mono-N-methylmethane (IV) was dissolved in 200 cc. of carbon tetrachloride and placed in a 500-cc. three-necked flask equipped with a stirrer and dropping funnel. The methene solution was then cooled in a salt–ice mixture and stirring begun. The potassium hydroxide solution was poured into the flask and 0.9 g. of bromine dissolved in 25 cc. of carbon tetrachloride was added by means of the dropping funnel. After all the bromine solution had been added the stirring was continued for two hours. At the end of this time the solution had a bright yellow tinge. The solvent was evaporated off and water added to dissolve the potassium hydroxide. The yellowish residue after one crystallization proved to be the starting material; 2.25 g. was recovered. Warming the solution had no effect.

Formaldehyde Test on the Cleavage of the Mono-N-methyldipyrrylmethane in the Presence of Hydrobromic Acid.—The methane (500 mg.) was dissolved in 30 cc. of alcohol. To the solution 0.7 cc. of formaldehyde and 2 cc. of 45% hydrobromic acid were added. The solution was refluxed for one hour and the flask set aside to cool. The methane was precipitated by pouring the solution into cold water and filtering. The precipitate was dried and then refluxed with 66% alcohol. The mixture was filtered and the residue recrystallized from alcohol; yield, 425 mg. of beautifully white crystals; m. p. 178–179° (irreversible); mixed melt with starting methane, 178–179°. The filtrate (66%) alcohol was evaporated down and a small precipitate obtained (50 mg.) which melted at 161–162°; mixed melt with starting methane 170–174° (irreversible).

The same treatment was carried out in boiling carbon tetrachloride solution with the same results. It was assumed, therefore, that an appreciable cleavage of the methane under the influence of acid in boiling solvent does not take place.

Bromination of an Equimolar Mixture of the Di-NH-dipyrrylmethane (VI) and Di-N-methyldipyrrylmethane (VII).—The di-NH methane (VI) (250 mg.) is dissolved in 500 cc. of dry carbon tetrachloride by refluxing until the solution becomes clear. 275 mg. (1 mole) of di-N-methylmethane (VII) is then added. After the methane has completely dissolved, the solution is allowed to cool to room temperature and 0.16 g. of bromine dissolved in 1.6 cc. of dry carbon tetrachloride is run from a 10-cc. buret. The flask is then placed in an icebox overnight. The solution on filtering yields 380 mg. of red crystals covered with an appreciable amount of red oil. The crystals are treated with water which dissolves out the red oil (di-N-methylmethene). Weight of the dried crystals is 370 mg. or 85.4% of the theoretical based on one molar bromination of the di-NH-methene. The free base of the methene melts at 190° (dec.).

At the same dilution the yield of the di-NH-methene on half molar bromination of mono-N-methylmethane is 96%. The experiment shows that formation of these two methanes by cleavage of mono-N-methylmethane and recombination of the cleavage products to give a mixture of the two symmetrical methanes cannot account for the anomalous bromination of mono-N-methylmethane.

The apparent contradiction between the results of this experiment and those obtained from the preliminary rate studies, indicating a more rapid bromine consumption by the di-N-methylmethane than by the di-NH-methene may be explained by the greater stability and insolubility of the di-NH-methene. These factors tend to shift the equilibrium of the dipyrrylmethenes and their cleavage products in favor of the di-NH-methene.

Condensation of Mono-N-methyldipyrrylmethane (IV) with 2-Bromo-3,5-dimethyl-4-carbethoxypyrrole (XV) (Reaction 5 Chart II).—The mono-N-methyldipyrrylmethane (360 mg.) is dissolved in 100 cc. of carbon tetrachloride. After cooling the solution to room temperature gaseous hydrogen bromide is passed in for one-half minute. A solution of α-bromopyrrole (XV) in carbon tetrachloride (250 mg. in 25 cc. of carbon tetrachloride) is run into the methane solution. After standing in the cold four hours, the solution on filtering yields 400 mg. of red crystals. The free base melts at 190° (dec.) and gives no depression with di-NH-methene (V); yield, 95%. Evaporation of the mother liquor yields N-methyl-α-free pyrrole.

Comparative Rates of Methene Formation in Mono-N-methyldipyrrylmethane-α-Bromopyrrole Condensation (Reaction 5) and Dipyrrylmethane Bromination.—A solution of 180 mg. of methane (IV) dissolved in 20 cc. of dry carbon tetrachloride (A) and a solution of 100 mg. of the methane (IV) in 15 cc. of dry carbon tetrachloride (B) were prepared in separate 50-cc. Erlenmeyer flasks. Dry, gaseous hydrogen bromide was then passed through each for thirty seconds. To solution A, 45 mg. of bromine dissolved in 0.5 cc. of carbon tetrachloride was added and the flask stoppered; 123 mg. of α-bromopyrrole (XV) in 5 cc. of carbon tetrachloride was then added to solution B. Each solution was allowed to stand for five minutes and then filtered. Solution A gave 70 mg. of the di-NH-methene (V) or 65% of the theoretical. Solution B yielded 165 mg. of methene (V) or 77% of the theoretical. Thus it could be shown that the condensation was a feasible reaction in the bromination.

Cleavage of 1,3,5,3′,5′,3″,5″-Heptamethyl-4,4′,4″-tricarbethoxytripyrrylmethane (XVI) by Hydrogen Bromide under the Conditions of the Bromination of the Mono-N-methyldipyrrylmethane (IV) (Reaction 6).—A solution of 100 mg. of the tripyrrylmethane (XIV) is prepared in a 50-cc. Erlenmeyer flask. Dry, gaseous hydrogen bromide is then passed through the solution for thirty seconds. After five minutes the solution is filtered; 75 mg. or 90% of the theoretical yield is obtained. Evaporation of the mother liquor yields N-methyl-α-free pyrrole (II).

Oxidation of Mono-N-methyldipyrrylmethane (IV) by 2-Dichloromethyl-4-methyl-3,5-dicarbethoxypyrrole.—A solution of 180 mg. of the methane (IV) in 5 cc. of rectified

(10) Sackur and Taegener, *Z. Elektrochem.*, **18**, 718 (1912).

dioxane is prepared in a 25-cc. Erlenmeyer flask. To this solution is added 160 mg. of the dichloromethylpyrrole dissolved in 5 cc. of rectified dioxane. Dry gaseous hydrogen chloride is then passed in until the solution is saturated and the stoppered flask allowed to stand in the cold for several days; 35 mg. of deep red needles is obtained. Tests described above show the product to be the di-NH-methene (V); m. p. (dec.) of the free base 190°.

Bromination of 3,5,4′-Trimethyl-4,3′,5′-tricarbethoxydipyrrylmethane (XVII).—The dipyrrylmethane (XVII) (500 mg.) is dissolved in 500 cc. of dry carbon tetrachloride; 0.2 g. of bromine dissolved in 5 cc. of carbon tetrachloride is added to this solution at room temperature. After standing for several hours 500 mg. of fine red needles is filtered from the mixture. On conversion to the free base, by treatment of the solid methene salt with dilute ammonium hydroxide, this compound is shown to be identical with the unsymmetrical 3,5,4′-trimethyl-4,3′,5′-tricarbethoxydipyrrylmethene (XVIII), synthesized by independent methods; m. p. of free base 125° (dec.); yield 83%.

Bromination of 1,4,3′,5′-Tetramethyl-3,5,4′-tricarbethoxydipyrrylmethane (XIX).—The mono-N-methylmethane (XIX) (0.5 g.) is dissolved in 500 cc. of dry carbon tetrachloride; 0.2 g. of bromine dissolved in 5 cc. of carbon tetrachloride is added quickly to this solution with stirring. The dark red solution is allowed to stand in the cold overnight. On filtration 100 mg. of fine yellow-red needles is obtained. In addition, a large amount of red oil is found on the walls of the flask. No identifiable products have been obtained from this residue. Tests described above showed the red crystals to be the symmetrical di-NH-methene (V).

Summary

1. The oxidation of the leuco base of an unsymmetrical pyrrole pigment to a symmetrical pyrrole pigment having the sequence of substituents which corresponds to one of the pyrrole rings in the base has been observed.

2. This anomalous reaction has been shown to result from a reshuffling of intact pyrrole rings rather than by attack on the pyrrole substituents.

3. The application of this reaction to the study of the regrouping of pyrrole rings in naturally occurring pyrrole pigments is suggested by the mild conditions under which the reaction takes place.

4. The transformation has been shown to involve a cleavage of a carbon–carbon bond in the aromatic system of an intermediate in the reaction.

5. Two similar mechanisms have been proposed and supported by experimental evidence.

6. The oxidation of a number of unsymmetrical dipyrrylmethanes has been studied to test the generality of the anomalous reaction. Another example has been found.

The Preparation and Dehydration of 6-Methoxy-*i*-norcholenyldiphenylcarbinol

BY BYRON RIEGEL, MELVIN F. W. DUNKER[1] AND MCCALIP J. THOMAS[2]

For the systematic degradation of the side chain of methyl 3-hydroxy-5-cholenate (I), an investigation involving the use of the so-called *i*-methyl ether, primarily to protect the hydroxyl group and the double bond, has been made. The dehydration of the carbinol, resulting from the reaction with the Grignard reagent, proved to be a critical reaction provided the *i*-ether structure is retained. Hence, this reaction was studied.

Methyl 3-*p*-toluenesulfonoxy-5-cholenate (II)[3] was converted to methyl 6(α)-methoxy-*i*-cholenate (III) by the usual method, namely, by heating a methanol solution containing anhydrous potassium acetate. The reaction of this *i*-methyl ether methyl ester (III) with phenylmagnesium bromide gave the desired 6(α)-methoxy-*i*-norcholenyldiphenylcarbinol (IV) which melted at 139.0–140.2° and gave a specific rotation of +43.9°. Carbinol (IV) could not be dehydrated in a solution of boiling glacial acetic acid without changing the *i*-methyl ether structure to the normal acetate, thus giving 3-acetoxy-24,24-diphenyl-5,23-choladiene (VII). Even heating a glacial acetic acid solution of carbinol (IV) for a short time caused dehydration with a simultaneous loss of the *i*-ether configuration. Because of the lability of the *i*-steroid structure, particularly toward acidic reagents, many dehydrating agents cannot be used if this structure is to be retained. Although Heilbron, Beynon and Spring[4] had dem-

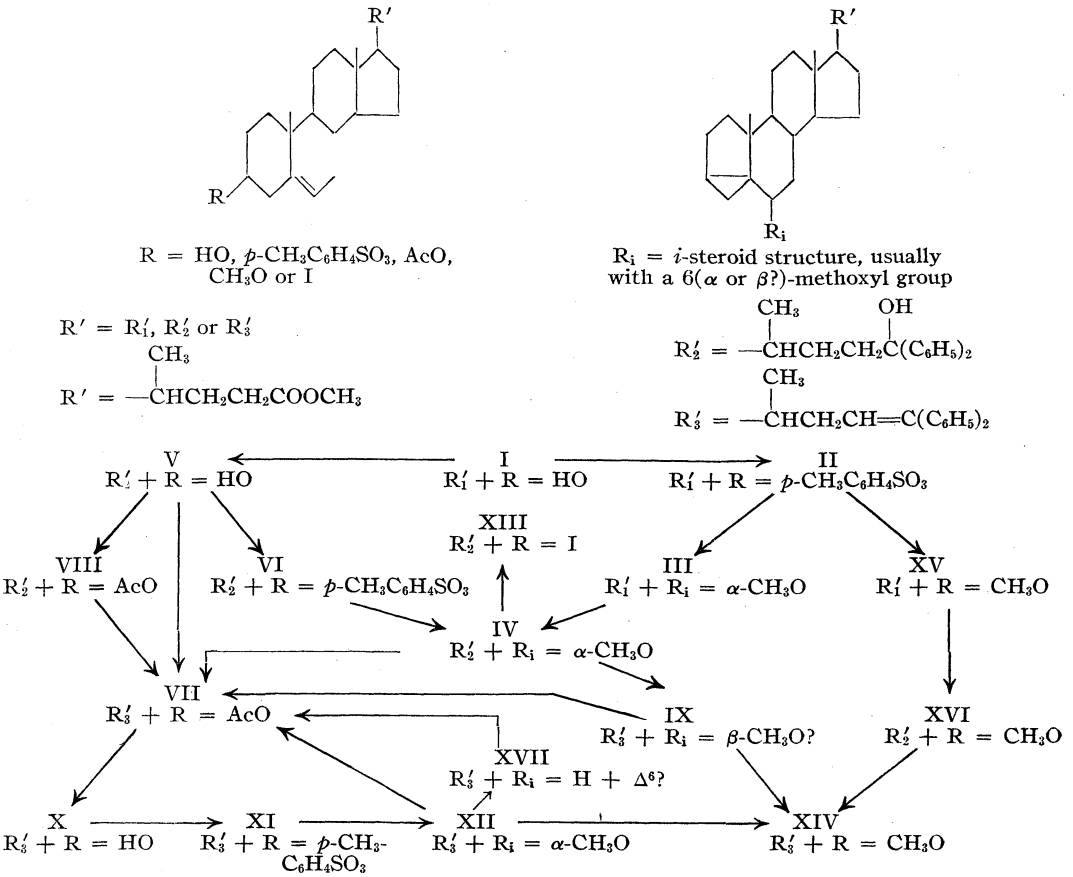
CHART I



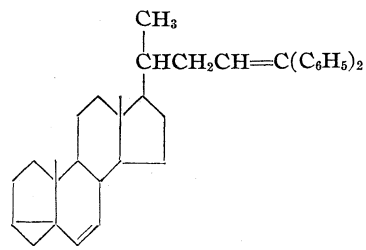
onstrated that bromine destroys the *i*-steroid structure an iodine-catalyzed dehydration of carbinol (IV) in boiling xylene was attempted. Both the analysis of the resulting product and method of preparation suggest that this substance is 3-iodo-5-norcholenyldiphenylcarbinol (XIII). Refluxing a xylene solution of the carbinol containing activated alumina did cause dehydration, but as will be indicated later also produced an isomerization. The product recovered from this treatment melted at 161.8–163° and gave a specific rotation of −39°. Previously all *i*-ether structures have given positive rotations, but as will be pointed out, structure (IX) seems to best explain our experimental data. The carbinol (IV) could not be dehydrated by the following methods and was recovered in each case unchanged; vacuum sublimation, slow distillation of benzene, toluene or xylene solutions and heating to 215° for three hours with anhydrous potassium bisulfate under nitrogen.

To help elucidate the isomerization caused by the aluminum oxide, each important intermediate was synthesized by an independent method as outlined in Chart I, thus substantiating their assigned structures. 3-Hydroxy-5-norcholenyldiphenylcarbinol (V) was produced by treating methyl 3-hydroxy-5-cholenate[3] with phenylmagnesium bromide. Carbinol (V) was converted to 3-*p*-toluenesulfonoxy-5-norcholenyldiphenylcarbinol (VI) which in turn was converted to the *i*-methyl ether carbinol (IV). This substance was identical with that obtained from III as previously described where the *i*-ether configuration was introduced before the Grignard reaction. When carbinol (V) was acetylated at room temperature 3-acetoxy-5-norcholenyldiphenylcarbinol (VIII) was obtained and subsequently converted to the acetoxy-diene (VII) upon refluxing in glacial acetic acid. The latter compound could also be obtained in one step from carbinol (V) merely by refluxing its acetic acid–acetic anhydride solution. The readily available acetoxy-diene (VII) was saponified and the resulting 3-hydroxy-24,24-diphenyl-5,23-choladiene (X) was converted to the *p*-toluenesulfonate (XI).

Heating an anhydrous methanol solution of compound (XI), containing fused potassium acetate, gave 1,1-diphenyl-2[6(α)-methoxy-*i*-bisnorcholenyl]-ethylene (XII). It melted at 109.1–110.1° and gave a specific rotation of +67.8°. The fact that compounds (IX) and (XII) were not identical stimulated further study of their structures.

One characteristic of *i*-methyl ethers is the ease with which they may be rearranged to the normal methyl ethers. Both compounds (IX) and (XII), on refluxing their anhydrous methanol solutions containing a few drops of sulfuric acid, gave 3-methoxy-24,24-diphenyl-5,23-choladiene (XIV), m. p. 114.5–115.3°, rotation −11.55°. The normal methyl ether (XIV) was independently prepared from compound (II) by the following reactions. On heating the *p*-toluenesulfonate (II) in anhydrous methanol, methyl 3-methoxy-5-cholenate (XV) was obtained which on reacting with phenylmagnesium bromide gave 3-methoxy-5-norcholenyldiphenylcarbinol (XVI). This carbinol was dehydrated in the usual manner to give the normal methyl ether (XIV) which was identical with that made by the rearrangement of compounds (IX) and (XII). Another characteristic reaction of *i*-ethers is their smooth conversion to normal acetates by heating their glacial acetic acid solutions. Both compounds (IX) and (XII) were converted by this treatment into the acetoxydiene (VII); however the conversion was effected with greater ease with XII than with IX.

The methods of preparation, analyses and reactions of compounds (IX) and (XII) strongly indicate that they contain the reactive configuration where one carbon atom is common to three rings, one of which is a cyclopropane ring. Steroidal compounds possessing this peculiar structure, first suggested by Wallis, Fernholz and Gephart,[5] are called *i*-steroids. Compound (IX) seems to be an *i*-steroid but contrary to all others possesses a negative rotation. Further study will be necessary to determine the structural changes produced by the alumina. A tentative explanation might be the epimerization of the 6-methoxyl group. We have indicated steroids of this structure with β and the ordinary *i*-steroids (dextrorotatory) with α. Consequently, an attempt was made to isomerize compound (XII) to (IX) by treatment with alumina in xylene; however, a hydrocarbon (XVII) resulted. It melted at 162.0–163.0°, gave a specific rotation of −18.5° and analysis for $C_{36}H_{44}$. We suggest as a provisional structure for this hydrocarbon (XVII)



XVII

The β-form of the *i*-methyl ether appears to be more stable than the α-form, and this may explain why it does not give the hydrocarbon on treatment with alumina. As previously stated, heating glacial acetic acid solutions of *i*-steroids usually destroys the *i*-structure, hence, the hydrocarbon (XVII) was subjected to this treatment and curiously enough gave the well-known 3-acetoxy-24,24-diphenyl-5,23-choladiene (VII). It is interesting and unusual that an acetate should be formed by the uncatalyzed addition of acetic acid to a hydrocarbon. The hydrocarbon (XVII) may represent a type of conjugated system where a carbon–carbon double bond is conjugated with the potentially unsaturated cyclopropane ring. Thus, a possible mechanism for this reaction would be the 1,4 (or 1,5)-addition of acetic acid across this system.

The authors wish to thank the Abbott Laboratories, the Glidden Company, the Rockefeller Foundation, and the Upjohn Company for research grants which made this work possible.

Experimental[6]

Methyl 6(α)-Methoxy-*i*-cholenate (III).—A solution of 3.85 g. of methyl 3-*p*-toluenesulfonoxy-5-cholenate[3] and 3.85 g. of fused potassium acetate in 175 ml. of anhydrous methanol was refluxed for eight hours. After most of the solvent was removed, water and ether were added. The aqueous layer was extracted two more times with ether and the combined ether extracts were washed with water, a solution of sodium bicarbonate and finally with water. On drying the ether solution with anhydrous sodium sulfate and removing the ether, 2.77 g. of light yellow sirup remained. The yield varies from 97–100%. The sirup was dissolved in hexane and shaken with finely powdered activated alumina. This seemed to remove some of the color. After filtering off the alumina and removing the hexane under reduced pressure, an almost colorless sirup remained. All attempts to crystallize it failed, $[\alpha]^{21}D$

+44.1° (79 mg. in 2.42 ml. of chloroform α_D +1.44°; *l*, 1 dm.).

Anal. Calcd. for $C_{26}H_{42}O_3$: C, 77.56; H, 10.52. Found: C, 77.66; H, 10.20.

6(α)-Methoxy-*i*-norcholenyldiphenylcarbinol (IV) from Compound (III).—An ether solution of 2.69 g. of the preceding compound was slowly added to an ether solution of phenylmagnesium bromide prepared from 11 g. of bromobenzene and 1.68 g. of magnesium. The mixture was refluxed for one and one-half hours and then decomposed with ice and a solution of ammonium chloride. The aqueous layer was extracted with ether and the combined ether extracts washed with water, dilute alkali and with water. The ether solution was dried with anhydrous sodium sulfate. Removal of the ether left 4 g. of a yellow sirup. From acetone–petroleum ether 1.972 g. (57%) of crystalline material was obtained. In subsequent runs the yields were above 80%. Crystallization of crude material from acetone–methanol gave white crystals melting at 139.0–140.2°, $[\alpha]^{27}D$ +43.9° (38 mg. in 2.42 ml. of chloroform α_D +0.69°, *l*, 1 dm.).

Anal. Calcd. for $C_{37}H_{50}O_2$: C, 84.36; H, 9.57. Found: C, 84.17; H, 9.55.

3-Hydroxy-5-norcholenyldiphenylcarbinol (V).—On treating 5.5 g. of methyl 3-hydroxy-5-cholenate[3] (I) with an excess of phenylmagnesium bromide as described above, a viscous sirup was obtained. All volatile material was removed by steam distillation; the residue was extracted with ether, dried and the solvent removed. There remained 8.3 g. of sirup from which 3.4 g. of crystalline material was isolated using acetone and methanol as the solvent. Several crystallizations gave white platelets with a peculiar and characteristic m. p. behavior which may be due to the dehydration of the carbinol. The crystals soften at 95°, melt with effervescence, resolidify at 108° and remelt at 169.4–172.2°.

Anal. Calcd. for $C_{36}H_{48}O_2$: C, 84.32; H, 9.44. Found: C, 83.82; H, 9.16.

3-*p*-Toluenesulfonoxy-5-norcholenyldiphenylcarbinol (VI).—A mixture of 1.4 g. of the previously described carbinol (V), 1.08 g. of *p*-toluenesulfonyl chloride and 3 ml. of dry pyridine was warmed slightly to effect solution and allowed to stand at room temperature for twenty-four hours. Water and ether were added to the crystalline mass and the ether layer extracted with water, dilute hydrochloric acid, water, dilute alkali and water. After drying and removing the ether an almost colorless sirup remained. From acetone–petroleum ether 1.47 g. (81%) of crystals, m. p. 143.2–144.0°, were obtained. Several crystallizations again gave material with a peculiar m. p. behavior probably due to the loss of water. It melts at 62°, resolidifies and remelts at 136–137°.

Anal. Calcd. for $C_{43}H_{54}O_4S$: C, 77.44; H, 8.16. Found: C, 77.73; H, 8.33.

6(α)-Methoxy-*i*-norcholenyldiphenylcarbinol (IV) from Compound (VI).—A mixture of 622 mg. of the above *p*-toluenesulfonate (VI), 625 mg. of fused potassium acetate and 100 ml. of anhydrous methanol was refluxed for four hours. The reaction mixture was worked up in the usual manner to give 369 mg. (75%) of white crystals identical with those prepared as described above.

3-Acetoxy-5-norcholenyldiphenylcarbinol (VIII).[7]—A 1.32-g. portion of the crude 3-hydroxy-5-norcholenyldiphenylcarbinol (V) was dissolved in 6 ml. of acetic anhydride and 10 ml. of dry pyridine and allowed to stand at room temperature overnight. The solvent was removed under reduced pressure. The residue was dissolved in acetone and gave 1.17 g. (82%) of crystalline material on standing in the refrigerator. Recrystallization from acetone gave large, clear, flat plates, m. p. 163.2–165.5°. Hattori and Nakamura prepared this compound by a similar method and gave its m. p. as 172–172.5°.

Anal. Calcd. for $C_{38}H_{50}O_3$: C, 82.26; H, 9.08. Found: C, 82.49; H, 9.00.

3-Acetoxy-24,24-diphenyl-5,23-choladiene (VII).—(a) By dehydration of carbinol (VIII): A solution of 1.1 g. of the above carbinol (VIII) in 7 ml. of glacial acetic acid was refluxed for three hours. The acetic acid was removed *in vacuo* and the residue dissolved in acetone from which 1.01 g. (95%) of crystalline material was obtained. Recrystallization from acetone gave brilliantly sparkling, small cubes, m. p. 166.6–167.4°.

Anal. Calcd. for $C_{38}H_{48}O_2$: C, 85.02; H, 9.01. Found: C, 85.18; H, 9.05.

(b) By dehydration and acetylation of carbinol (V): The crude carbinol (V) made from 5.5 g. of methyl 3-hydroxy-5-cholenate,[3] as described above, was dissolved in 40 ml. of glacial acetic acid and 60 ml. of acetic anhydride and refluxed for two hours. The excess acetic anhydride was decomposed by the careful addition of alcohol and heating continued for fifteen minutes, after which the solvent was removed *in vacuo*. The residue crystallized from acetone giving 6.66 g. (88%) of material sufficiently pure, m. p. 165°, for further reactions.

(c) By dehydration, acetolysis and rearrangement of carbinol (IV): When 1.2 g. of carbinol (IV) was dissolved in 15 ml. of glacial acetic acid, refluxed for two hours and worked up in the usual manner, 959 mg. (80%) of the acetoxy-diene was obtained. It gave no melting point depression when mixed with samples prepared by other methods.

3-Hydroxy-24,24-diphenyl-5,23-choladiene (X).—One gram of sodium was dissolved in 150 ml. of 1-propanol to which was added 3.7 g. of the previously described acetoxy-diene (VII). The solution was diluted with water after refluxing two hours. Most of the alcohol was removed under reduced pressure and the product extracted with ether. The ether extract was washed with water, dried and concentrated. On cooling a crystalline mass formed which was separated by filtration and washed with a small quantity of cold acetone. The product weighed 3.01 g. (89%) and melted at 172.2–173°.

Anal. Calcd. for $C_{36}H_{46}O$: C, 87.39; H, 9.37. Found: C, 87.37; H, 9.13.

To 254 mg. of the acetoxy-diene (VII) in 53 ml. of xylene 6 g. of powdered activated alumina was added and the mixture was refluxed for three hours. The alumina was separated by filtration and washed with acetone and ether. The filtrates were combined and the solvents completely removed *in vacuo*. The sirupy residue was dissolved in

(7) J. Hattori and K. Nakamura, *J. Pharm. Soc.* (Japan), **60**, 126 (1940).

acetone–methanol from which several crops of crystals were obtained. The first crop weighed 71 mg. and on recrystallization gave white crystals melting at 173–174°. They gave no melting point depression when mixed with those made by alcoholic saponification.

Anal. Calcd. for $C_{36}H_{46}O$: C, 87.39; H, 9.37. Found: C, 87.20; H, 9.24.

3-*p*-Toluenesulfonoxy-24,24-diphenyl-5,23-choladiene (XI).—A mixture of 3 g. of the well-dried hydroxy-diene (X), 3.01 g. of *p*-toluenesulfonyl chloride and 6 ml. of pyridine was treated as described for the preparation of the *p*-toluenesulfonate (VI) above. The viscous oil, left after the removal of the ether, was dissolved in acetone and cooled, which caused the formation of fine white crystals. They were removed by filtration and washed with petroleum ether; yield 3.35 g. (85%), m. p. 130.6–131.5°.

Anal. Calcd. for $C_{43}H_{52}O_3S$: C, 79.59; H, 8.08. Found: C, 79.31; H, 7.80.

1,1-Diphenyl-2-[6(α)-methoxy-*i*-bisnorcholenyl]-ethylene (XII).—A solution of 1 g. of the *p*-toluenesulfonate (XI), 1 g. of fused potassium acetate in 100 ml. of anhydrous methanol was refluxed for nine hours. The reaction mixture was worked up as described for the preparation of the *i*-methyl ether (III). Removal of the ether gave 878 mg. (100%) of an almost colorless sirup which crystallized from methanol–acetone to give 638 mg. (82%) of large thick needles, m. p. 106–108°. Recrystallization of the needles raised the m. p. to 109.1–110.1°; $[\alpha]^{23}D$ +67.8° (33.2 mg. in 5 ml. of chloroform α_D +0.45°, *l*, 1 dm.).

Anal. Calcd. for $C_{37}H_{48}O$: C, 87.35; H, 9.51. Found: C, 87.65; H, 9.46.

This *i*-methyl ether (XII) was quantitatively converted into the acetoxy-diene (VII) by refluxing in a glacial acetic acid–acetic anhydride solution.

3-Iodo-5-norcholenyldiphenylcarbinol? (XIII).—In an attempt to dehydrate the *i*-methyl ether carbinol (IV) a solution of 100 mg. in 60 ml. of dry xylene containing a few crystals of iodine was refluxed for about two hours. After cooling, the solution was extracted with an aqueous solution of sodium thiosulfate. The xylene solution was dried and the xylene completely removed *in vacuo*. The residue crystallized from acetone giving 60 mg. of shiny prisms, m. p. 168.2–169.4°. Since the compound gave a qualitative test for halogen and the C–H analysis showed only one atom of halogen could be present, we suggest the above structure.

Anal. Calcd. for $C_{36}H_{47}IO$: C, 69.44; H, 7.61. Found: C, 69.28; H, 7.59.

1,1-Diphenyl-2-[6(β)-methoxy-*i*-bisnorcholenyl]-ethylene? (IX).—A solution of 678 mg. of the *i*-methyl ether carbinol (IV) in 125 ml. of dry xylene was concentrated by slowly distilling about 15 ml. of xylene. The solution was then refluxed for three hours after adding 10 g. of powdered activated alumina. A calcium chloride tube was attached to the top of the condenser during the heating. The alumina was separated by filtration and washed with ether. The solvents were removed *in vacuo* and the residue was crystallized from an acetone–methanol mixture. The first crop weighed 304 mg., m. p. 156–158°, but was not homogeneous. Several crystallizations were required before pure material was obtained melting at 161.8–163°, $[\alpha]^{25}D$ −38.6 ± 2° (55.7 mg. in 5 ml. of chloroform, α_D −0.43 ± 0.02°, *l*, 1 dm.).

Anal. Calcd. for $C_{37}H_{48}O$: C, 87.35; H, 9.51. Found: C, 87.72, 87.70; H, 9.06, 9.46.

A solution of 46 mg. of the above compound in 15 ml. of glacial acetic acid and 5 ml. of acetic anhydride was refluxed for two and one-half hours and the reaction mixture worked up in the usual manner. This gave 32 mg. of material melting at 160–165°. Recrystallization from acetone–methanol gave large prisms melting at 165–167° and giving no melting point depression when mixed with an authentic sample of compound (VII). It required more strenuous conditions for this conversion than with compound (XII).

Methyl 3-Methoxy-5-cholenate (XV).—A solution of 5.46 g. of *p*-toluenesulfonate[3] (II) in 150 ml. of anhydrous methanol was refluxed for seven hours. On cooling, crystals formed which weighed 3.79 g. (93.5%) and melted at 108.5–109°. The filtrate was concentrated, diluted with water and extracted with ether. The ether extract was washed with water, dilute alkali and dried. The residue, after removing the ether, gave additional crystalline material from methanol sufficient to make the crude yield practically quantitative. Further crystallization from methanol raised the m. p. to 109.2–109.6°, $[\alpha]^{22}D$ −44.6° (70.5 mg. in 2.42 ml. of chloroform α_D −1.30°, *l*, 1 dm.).

Anal. Calcd. for $C_{26}H_{42}O_3$: C, 77.56; H, 10.52. Found: C, 77.60; H, 10.60.

3-Methoxy-5-norcholenyldiphenylcarbinol (XVI).—Two grams of the above ester (XV) was treated with an excess of phenylmagnesium bromide and the reaction mixture was worked up as described for the preparation of compound (V). The residue left after removing the ether was crystallized from acetone–chloroform giving 2.26 g. (96%) of product melting at 164.8–165.9°.

Anal. Calcd. for $C_{37}H_{50}O_2$: C, 84.36; H, 9.57. Found: C, 84.38; H, 9.58.

3-Methoxy-24,24-diphenyl-5,23-choladiene (XIV).—(a) By dehydration of carbinol (XVI): The previously described carbinol (XVI) was quantitatively dehydrated by refluxing a glacial acetic acid solution for two and one-half hours. The product was crystallized from an acetone–methanol mixture, m. p. 114.5–115.3°, $[\alpha]^{24}D$ −11.55 ± 0.66° (62.8 mg. in 5 ml. of chloroform α_D −0.145°, *l*, 1 dm.).

Anal. Calcd. for $C_{37}H_{48}O$: C, 87.35; H, 9.51. Found: C, 87.14; H, 9.25.

(b) By rearranging the *i*-methyl ether (XII): The *i*-methyl ether ethylene (XII) was smoothly and quantitatively rearranged by refluxing a methanol solution containing a few drops of sulfuric acid. This was confirmed by a melting point and mixed m. p.

(c) By rearranging the *i*-methyl ether (IX): By exactly the same procedure as described in (b) the *i*-methyl ether ethylene (IX) was smoothly and quantitatively rearranged to the normal methyl ether. This was again confirmed by a melting point and a mixed m. p.

Hydrocarbon $C_{36}H_{44}$ (XVII).—In an attempt to rearrange the synthetic *i*-methyl ether ethylene (XII) to

that obtained by the alumina dehydration of carbinol (IV) a hydrocarbon was obtained instead. Ten ml. of solvent was slowly distilled from a solution of 500 mg. of the *i*-methyl ether (XII) in 100 ml. of xylene. To the remaining solution was added 8 g. of powdered activated alumina and the mixture was refluxed for three hours. The alumina was separated by filtration and washed with acetone. The acetone–xylene filtrates were concentrated *in vacuo* and the residue was dissolved in an acetone–methanol mixture from which there was obtained 320 mg. of crystalline material. Several crystallizations gave thick needles melting at 162.0–163.0°, $[\alpha]^{25}D$ −18.5° (51.3 mg. in 5 ml. of chloroform αD −0.19°, *l*, 1 dm.). The needles fluoresced in ultraviolet light.

Anal. Calcd. for $C_{36}H_{44}$: C, 90.70; H, 9.30. Found: C, 90.35; H, 9.33.

A solution of 48 mg. of the above hydrocarbon (XVII) in 15 ml. of glacial acetic acid was refluxed for four hours. The solvent was removed under reduced pressure and the colorless sirup crystallized from acetone–methanol to give 35 mg. of brilliant cubes, m. p. 165–166.5°. From the mother liquors a second crop of 8 mg. was obtained. There was no melting point depression when the substance was mixed with the acetoxy-diene (VII).

Summary

1. 6(α)-Methoxy-*i*-norcholenyldiphenylcarbinol (IV) was prepared by two different methods.

2. The dehydration product of the carbinol (IV) by treatment with activated alumina in boiling xylene was considerably different from compound (XII) where the unsaturated side chain (R_3') was prepared by conventional methods before introducing the *i*-methyl ether configuration. We have tentatively suggested that this may be due to the epimerization of the 6-methoxyl group.

3. In an attempt to epimerize the synthetic product (XII), by alumina in boiling xylene, an interesting hydrocarbon (XVII) was obtained.

4. Heating the hydrocarbon (XVII) in acetic acid caused the addition of acetic acid forming a normal acetate. A mechanism for this reaction has been proposed.

5. Several intermediates and conversion products have been described.

[COMMUNICATION NO. 854 FROM THE KODAK RESEARCH LABORATORIES]

The Action of Alkaline Reagents on the Bimolecular Product Formed by the Action of Acidic Dehydrating Agents on Anhydracetonebenzil

BY C. F. H. ALLEN AND J. W. GATES, JR.

The bimolecular product I that results from the action of acidic dehydrating agents on anhydracetonebenzil is a very reactive substance, having many points of attack for reagents. In this paper are described the results secured by the use of alkaline reagents.

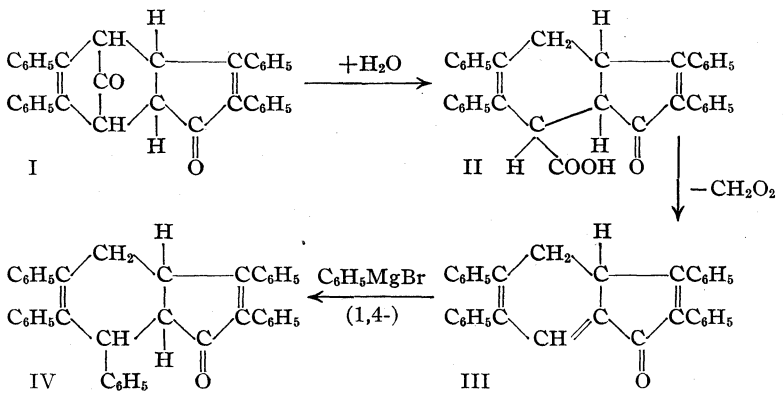
It had previously been observed[1] that Japp's chloride was converted to the bimolecular product by a short (ten-minute) treatment with alcoholic potash, whereas a longer time resulted in a viscous product.[2] It has now been found that this material, also obtainable directly from the bimolecular product itself, will crystallize in time, or at once, if seeded, and that it is mainly a carboxylic acid. The use of sodium methylate or ethylate gives the corresponding methyl and ethyl esters in a few minutes; the ethyl ester has been hydrolyzed to the acid, and the latter reesterified by diazomethane and also converted to an anilide.

(1) Allen and Spanagel, THIS JOURNAL, **55**, 3773 (1933).
(2) Allen and Rudoff, *Can. J. Res.*, **B15**, 327 (1937).

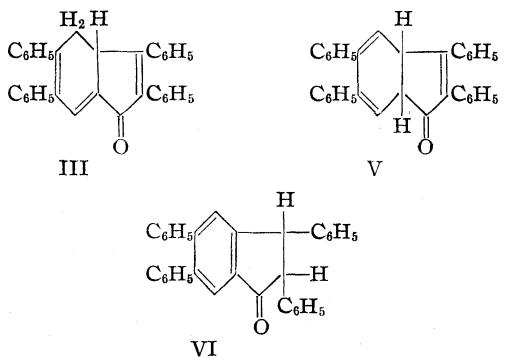
Analyses show that the only change is the addition of one molecule of water (or alcohol, depending upon the reagent); hence the carboxyl group must comprise one of the two carbonyl groups present originally. Since the acid does not lose carbon monoxide when heated, it is the carbonyl bridge that has been cleaved. The bimolecular product and the esters are not attacked by permanganate in acetone, perhaps because of their insolubility, but the sodium salt of the acid is easily oxidized. During the reaction the carboxyl group disappears, and a dienone is formed; this new dienone is an isomer of the one (V) previously obtained by heating the bimolecular product, when the carbonyl bridge is lost as carbon monoxide.[1] Analyses show that the loss, in the case of the acid, is CH_2O_2.

The new dienone is an α,β-unsaturated ketone (III), for it gives both 1,4- and 1,2-addition with the Grignard reagent; this establishes the location of one double bond. Although there is, to be sure, another α,β-unsaturated system involving the

indene ring, the possibility of 1,4-addition of the Grignard reagent to this is excluded by the observation that other indenones containing the same system give only carbinols, formed by 1,2-addition. Taken in conjunction with the disappearance of the carbonyl bridge by alkali, the structure of the acid II follows. The oxidation results are accounted for by a retrograde Michael reaction, in which formic acid (CH_2O_2) is split off, and destroyed by the permanganate.

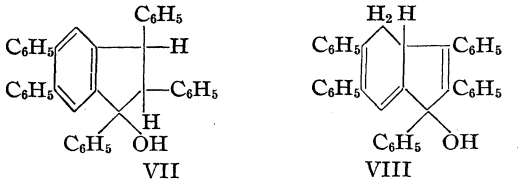


The new dienone III, in contrast to the isomer previously described,[2] does not add maleic anhydride, but, like it, is isomerized by heating to the known indanone VI. The only difference is in the position of the extra hydrogen atoms and double bonds; that is, these are allylic systems, in which rearrangements occur with the greatest of ease; the most stable form is that of the indanone VI, owing to its aromatic structure. The mobility of



the systems makes it almost impossible to state positively which structure goes with which substance, but the available evidence seems to be in best agreement with the structures as assigned.

Even as gentle a reagent as phenylmagnesium bromide is not useful. For example, the carbinol VIII, formed by 1,2-addition and mentioned above, is isomeric with one (VII) easily obtained from the indanone VI, whereas the dienone V



forms a glasslike product with phenylmagnesium bromide.[3] All give the same hydrocarbon on removal of water, that is, there must have been a rearrangement in two of the dehydrations. These reactions will form the subject of a later paper.

When attempts were made to repeat the earlier preparation of the dienone (V), the results were erratic; sometimes it was readily isolated after decarbonylation of the bimolecular product, but at others, under what appeared to be identical conditions, only the rearrangement product, the indanone VI, could be obtained. This difficulty was traced finally to small amounts of sulfuric acid in the bimolecular product (the latter was always formed in the presence of that acid). The mineral acid was thereafter eliminated by adding potassium acetate to the solution from which crystallization took place.

This result influenced us to examine the effect of acid alone upon the dienone V; it was found that mineral acids brought about an isomerization to a different dienone—which proved to be identical with III, described above. Both these, on heating, gave the indanone VI. This is an additional instance of the mobility of the allylic systems present in this series.

The 1,4-addition product IV probably exists largely in the enolic modification IVa, for it evolves 0.7 equivalent of methane when treated with methylmagnesium iodide, and gives an enol acetate IX with acetyl chloride. The latter consumes two equivalents of methylmagnesium iodide, and regenerates the enol; this is the usual behavior of an enol acetate. It is readily brominated, forming a monobromo ketone X, which is unaffected by acetyl chloride. The bromine is in the *alpha* position, since it is removed by methylmagnesium iodide, with regeneration of the starting material.

(3) The absence of mineral acid was ensured by decomposition of the complex with ammonium chloride; otherwise, dehydration occurs and the carbinol cannot be isolated.

X

Experimental

I. The Acid, 3a,4,7,7a-Tetrahydro-2,3,5,6-tetraphenyl-7-carboxyindenone-1 (II) and Related Substances.—The bimolecular product I, 3a,4,7,7a-tetrahydro-2,3,5,6-tetraphenyl-4,7-methanoinden-1,8-dione, was prepared in the usual way,[1] but the benzene solution was refluxed for half an hour, after the addition of anhydrous sodium or potassium acetate, filtered hot and diluted with twice the volume of alcohol or petroleum ether. The average yield of several preparations was 90%.

The acid II was secured as follows. To an alcoholic solution of potassium hydroxide (23 g. in 300 cc.) was added 46.4 g. of the bimolecular product, and the mixture refluxed for four hours; at the end of this time all the solid had dissolved. The solution was poured into 2 l. of water, 70 cc. of concentrated hydrochloric acid added, and the mixture extracted with three 100-cc. portions of chloroform. After drying the extract, distilling two-thirds of the solvent, and diluting with an equal volume of benzene and two volumes of petroleum ether, the acid separates in a yield of 38 g. (79%). After purification from benzene–ligroin, it forms prisms which melt at 275–276°. It is practically insoluble in absolute ethanol.

Anal. Calcd. for $C_{34}H_{26}O_3$: C, 84.7; H, 5.4. Found: C, 84.3; H, 5.3.

The methyl ester, prepared by use of sodium methylate, separated when the solution was chilled after three hours; the yield was 76%, and it forms prisms that melt at 193°. It also resulted when the acid was esterified by diazomethane.

Anal. Calcd. for $C_{35}H_{28}O_3$: C, 84.6; H, 5.4. Found: C, 84.3; H, 5.7.

The ethyl ester was secured in a similar manner but only ten minutes of refluxing was required. Some acid was formed during the manipulation; this was removed by triturating the oil with absolute ethanol. The ethyl ester crystallizes in prisms from alcohol–petroleum ether; m. p. 159–160°.

Anal. Calcd. for $C_{36}H_{30}O_3$: C, 84.7; H, 5.9. Found: C, 84.9; H, 5.9.

The anilide was prepared from the acid chloride in the usual manner; it forms prisms from benzene–petroleum ether; m. p. 269°.

Anal. Calcd. for $C_{40}H_{31}O_2N$: N, 2.5. Found: N, 2.5.

II. The Dienone III, 3a,4-Dihydro-2,3,5,6-tetraphenylinden-1-one.—Twenty-four grams of the acid was dissolved in 2 l. of 3% potassium carbonate, and, while stirring at 85–95°, 350–370 cc. of 6% aqueous potassium permanganate was added dropwise; a yellow precipitate was formed. The cooled suspension was extracted with three 150-cc. portions of chloroform, the solvent removed, and the residue recrystallized from xylene or acetic acid. It forms lemon-yellow prisms that melt at 239–240°. The yield was 12 g. (56%).

Anal. Calcd. for $C_{33}H_{24}O$: C, 90.8; H, 5.5. Found: C, 90.7; H, 5.5.

The isomeric dienone V, reported previously as being obtained by a carefully controlled pyrolysis, resulted in a 70–75% yield by heating the purified bimolecular product for only five to six minutes at 220–225°. When 10 g. of this dienone (m. p. 167°) was suspended in 50 cc. of glacial acetic acid and treated with 5 cc. of 32% hydrogen bromide in acetic acid, the solution became dark red; after warming for half an hour on the steam-bath, the dienone III crystallized quantitatively. A dilute solution of sulfuric acid in acetic acid brought about the isomerization equally well.

The new dienone does not add maleic anhydride. In the Grignard machine it shows one addition without evolution of gas. It isomerized to the indanone VI by heating for half an hour at 300°.

1,2,3,5,6-Pentaphenylindanol-1, VII, was obtained by the action of phenylmagnesium bromide upon the indanone VI in ether in the usual way, decomposing the complex with ammonium chloride. It crystallizes in prisms from benzene–petroleum ether; m. p. 228–229° with dec.

Anal. Calcd. for $C_{39}H_{30}O$: C, 91.0; H, 5.8. Found: C, 90.5; H, 5.7.

This carbinol gave the hydrocarbon, m. p. 222°, described below, when treated with an acetic acid solution of sulfuric acid. The dienone V gave a glasslike carbinol, which formed the same hydrocarbon upon dehydration.

III. The Grignard Reaction.—To a solution of phenylmagnesium bromide (4.8 g. of magnesium, 31.5 g. of bromobenzene, 200 cc. of ether) at room temperature was added a suspension of 25 g. of the dienone III in 50 cc. of ether. After stirring for one hour, the mixture was decomposed by ammonium chloride, and the oily product worked up by an appropriate manipulation; it was found advantageous to inoculate the dried and concentrated solution with some of the carbinol VIII from a previous preparation, and remove it first. The second product was the ketone IV. When the Grignard mixture was decomposed by mineral acid, the hydrocarbon was obtained instead of the carbinol, being isolated after the ketone.

The carbinol, 3a,4-dihydro-1,2,3,5,6-pentaphenylinden-1-ol (VIII) was obtained in a yield of 25%; it separates from benzene–ligroin in needles, m. p. 233°.

Anal. Calcd. for $C_{39}H_{30}O$: C, 91.0; H, 5.8. Found: C, 91.0; H, 6.0.

The hydrocarbon crystallizes in bunches of prisms from benzene–ligroin; m. p. 222°.

Anal. Calcd. for $C_{39}H_{28}$: C, 94.4; H, 5.7. Found: C, 94.1; H, 5.6.

This hydrocarbon does not add maleic anhydride, nor is it affected by hydrogen bromide in acetic acid.

The ketone, 3a,4,7,7a-tetrahydro-2,3,5,6,7-pentaphenyl-

inden-1-one (IV, IVa), forms prisms on crystallization from benzene–petroleum ether. The melting point is usually 178–179°, but occasionally a low-melting form is obtained; this melts at 145–146°, but on admixture with the higher melting form, the observed melting point is 178–179°.[4] The yield was 60%.

Anal. Calcd. for $C_{39}H_{30}O$: C, 91.1; H, 5.9. Found: C, 90.9; H, 6.1.

This ketone does not react with maleic anhydride nor form an oxime. In the Grignard machine it evolves 0.67 mole of methane, indicating that it is enolized to a considerable extent. An acetate is secured in a 70% yield by refluxing an acetyl chloride solution for half an hour; it separates from benzene–ligroin in prisms that melt at 115°.

Anal. Calcd. for $C_{41}H_{32}O_2$: C, 88.5; H, 5.8. Found: C, 88.1; H, 6.0.

When treated quantitatively with methylmagnesium iodide, the acetate consumes two equivalents of reagent without evolution of gas; upon acidification the ketone IV is obtained.

The bromoketone, 3a,4,7,7a-tetrahydro-7a-bromo-2,3,5,-6,7-pentaphenylinden-1-one (X) was secured by bromination in chloroform in the usual manner; it crystallized from chloroform–alcohol solution in pale yellow rods; m. p. 218–219°. It separated from benzene solutions in pointed rods with solvent of crystallization; the solid softened at about 144°, finally melting at 234°.

Anal. Calcd. for (A) $C_{39}H_{29}OBr$: Br, 13.5; for (B) $C_{39}H_{29}OBr \cdot C_6H_6$: C, 80.5; H, 5.2; Br, 11.9. Found: (A) Br, 13.8, 13.2; (B) C, 80.4, 80.2; H, 5.1, 5.1; Br, 11.9, 12.0.

In the Grignard machine both forms consume one mole of reagent without evolution of gas, and regenerate the parent ketone IV.

The bromine is not removed by pyridine or potassium acetate (*e. g.*, there is no adjacent hydrogen atom in the *alpha* position to the carbonyl group) but alcoholic potash gave an intractable black oil. It is unaffected by hydrogen bromide, by acetyl chloride, or by excess bromine.

(4) Drs. Jelley and Titus of these Laboratories report that examination of these substances failed to show any significant differences of readily determinable optical properties.

Summary

The bimolecular product, resulting from the action of acidic dehydrating agents upon anhydracetonebenzil, is transformed into a carboxylic acid by the action of alkaline reagents. The carbonyl bridge disappears in the process, being converted into the carboxyl group.

The acid is decarboxylated and dehydrogenated to give a new dienone, isomeric with one previously known.

The new dienone is also obtained by the action of mineral acids on the one described earlier, and both are isomerized to the same known indanone by acids or heat.

The new dienone gives products with phenylmagnesium bromide formed by both 1,2- and 1,4-addition. The 1,4-addition product is an easily enolizable ketone.

The 1,2-addition product is a carbinol, isomeric with one obtained from the closely related indanone. Both are dehydrated to the same hydrocarbon, which is also formed from the isomeric dienone.

ROCHESTER, NEW YORK RECEIVED MAY 5, 1942

[COMMUNICATION NO. 855 FROM THE KODAK RESEARCH LABORATORIES]

The Structure of the Bimolecular Product Formed by the Action of Acidic Dehydrating Agents on Anhydracetonebenzil

BY C. F. H. ALLEN AND J. W. GATES, JR.

Several years ago[1] from an examination of the substance obtained by degrading the bimolecular product, formed by the action of acidic dehydrating agents upon anhydracetonebenzil I, a structure, III, which seemed in best accord with the available evidence, was suggested for this substance and a mechanism proposed to account for its formation. Others interested in this field[2,3] appear to have accepted these conclusions. The salient features were the dehydration of anhydracetonebenzil to diphenylcyclopentadienone II, which then underwent a diene synthesis with itself, forming the bimolecular product III. The latter lost carbon monoxide on heating, to give an indenone that was rearranged to an isomeric indanone IV, which was then degraded, stepwise, by unambiguous reactions to *o*-terphenyl. Later on[4] several of the intermediate degradation products were synthesized, so that the position of the various groups around the benzene ring was established. Only the pertinent formulas are given below.

The two novel features were the presence of a phenyl group on a carbon atom common to two

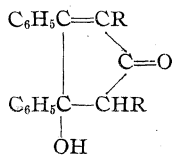
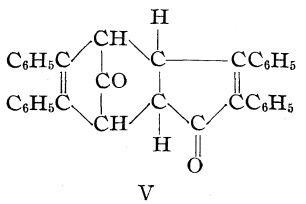
I II III IV

rings in III, and its apparent 1,3-shift to the position in which it is found in the indanone IV. No similar instances have been recorded in the literature. The formation of thiophenol, on sulfur fusion of the dienone formed after the decarbonylation of III, was interpreted in favor of the structure having the phenyl group on the bond common to the two rings, by analogy with the behavior under similar conditions of Ruzicka's alkyl decalins.[5] Further work was accordingly undertaken, with the view of clearing up the uncertainty.

As a result[6] isomeric indenones were discovered and the prevalence of allylic rearrangements in the series was noted. It was found that sulfur dehydrogenation (a high temperature reaction) gave varying amounts of thiophenol in instances where there was no reasonable doubt as to the absence of an angular phenyl group, so this argument lost its force. Furthermore, had the phenyl group been in this position, there should have been more isomers than were found experimentally. Finally, it has been possible[6] to open one ring to form a monocarboxylic acid, which, on oxidation with permanganate, in alkaline solution, gave one of the dienones—all the reactions taking place below 100° under conditions too mild to bring about such a drastic change as a migration of a phenyl group. It has, thus, seemed necessary to abandon



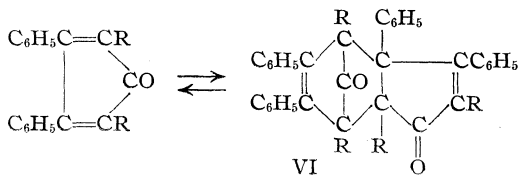


V

both concepts, and to conclude that the phenyl group is in the position where it is found in the indanone, *alpha* to the carbonyl; the new structure is written in formula V.

It differs from the older one first proposed[1] only in an interchange of the angular phenyl group and one hydrogen atom. This was accounted for by assuming a 1,3-shift of a phenyl group. Such a rearrangement was, indeed, proposed in the first paper, but at a different point, namely, following the decarbonylation. The experimental conditions under which the bimolecular products are formed, favor such allylic rearrangements.

The mechanism of the reaction is, as previously outlined, a diene synthesis. Alternative interpretations have had to be excluded, because of the various experimental conditions under which the bimolecular product can be formed, and the fact that substituted anhydracetonebenzils can partake only if there is at least one hydrogen atom left to be removed as water with the hydroxyl group (this is, of course, essential to the production of the intermediate cyclopentadienone).



VI

Now, when in the bimolecular product, R = H, it will exchange (an allylic rearrangement) with the angular phenyl group, giving a substance of type V, but if both R's = CH_3, there will be no further change—in fact, it has been shown that this type, VI, dissociates into its components in most reactions.[7] Any open-chain structure for the bimolecular product is also excluded because such a structure would be impossible with the dimethyl homolog (both R's = CH_3).

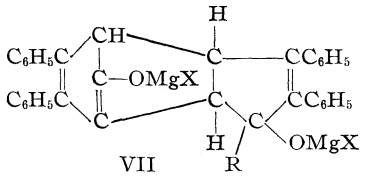
The behavior of the bimolecular product with the Grignard reagent is unusual; in the Grignard machine it shows one active hydrogen and one addition. Previous work[6] has shown that in indenones the carbonyl group always gives carbinols, and that a carbonyl bridge does likewise in the absence of adjacent *alpha* hydrogen atoms.[7] Since the product is always a monocarbinol, that

(5) Ruzicka, *Helv. Chim. Acta*, **5**, 349 (1922).

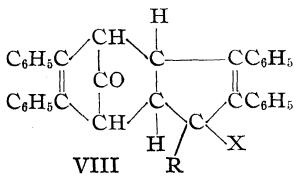
(6) Allen and Gates, THIS JOURNAL, **64**, 2120 (1942).

(7) Allen and VanAllan, *ibid.*, **64**, 1260 (1942).

loses carbon monoxide on heating, it is the keto group on the indene ring that has been attacked, *i. e.*, the one addition has occurred here. But, since no exposed carbonyl group could persist unchanged, the carbonyl bridge must have been protected in some way from the action of the excess reagent. The obvious explanation is that it forms an enolate, VII, thus accounting for the one active hydrogen observed; acidification then regenerates the original carbonyl group.



VII

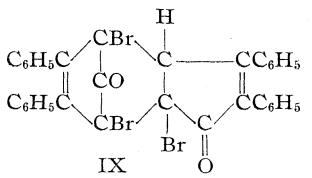


VIII

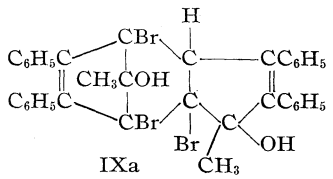
Carbinols, VIII (X = OH), have been prepared in which R = CH_3, C_6H_5, α-$C_{10}H_7$. All carbinols lost carbon monoxide and water, when heated, and gave hydrocarbons. The carbinols were studied in more detail; in the Grignard machine they showed two active hydrogens (one due to enolate and one to carbinol). The hydroxyl was replaced by halogens on treatment with acid halides; they gave isomeric acetates with acetic anhydride and acetyl chloride. The acetates (VIII: R = CH_3, X = $OCOCH_3$) showed one active hydrogen and two additions in the Grignard machine, and regenerated the carbinol, as would be expected.

The bimolecular product was previously reported[1] to give two stereoisomeric dioximes. Both of these have now been hydrolyzed, with production of the bimolecular product; this excludes the possibility that the starting material was a mixture.

The bimolecular product was brominated to form a tribromoketone IX, gave a monochloroketone with phosphorus pentachloride, did not condense with aromatic aldehydes, and was destroyed by concentrated sulfuric acid. The tribromoketone is the result of complete replacement of all the available hydrogen atoms in the *alpha* positions to both carbonyl groups. Its formation excludes any of the open-chained isomeric structures that might be written, confirming the conclusion already mentioned above, concerning the formation of bimolecular products from substituted anhydracetonebenzils. In the Grignard machine it consumes two moles of reagent without evolution of gas. The product is a di-carbinol IXa, for it evolves two equivalents of gas when treated with excess methylmagnesium iodide. These reactions afford confirmation of the assumption previously made in regard to the bimolecular product, that the production of gas is connected with the presence of an enolizable hydrogen; in the tribromoketone there is no *alpha* hydrogen, and the two carbonyl groups behave normally, giving two additions.



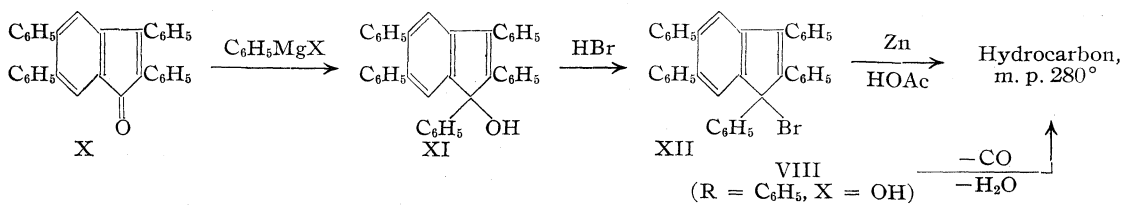
IX



IXa

The monochloroketone is isomeric with one described as a result of chlorination of 3,4-diphenylcyclopenten-3-one-1.[8]

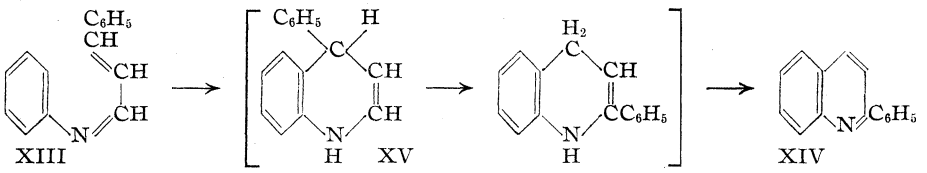
It was mentioned earlier that hydrocarbons were formed by loss of water during decarbonylation. From the phenyl carbinol (VIII: R = C_6H_5, X = OH) the hydrocarbon obtained was identical with one secured from 2,3,5,6-tetraphenylindenone X by the following sequence of reactions



It is obvious from inspection of the formulas that in one instance there has been a rearrangement. The substance in question is also isomeric with a closely related hydrocarbon described previously[6]; a discussion of these and other related compounds will be considered separately.

(8) Burton and Shoppee, *J. Chem. Soc.*, 205 (1934).

One other instance, best explained as a 1,3-shift of a phenyl group, has been found in the literature. When cinnamalaniline XIII is heated in acid solution, it forms 2-phenylquinoline XIV.[9] It must be assumed *either* that a 1,3-shift of a phenyl group is involved, *or* that the anil is hydrolyzed in part to its components, the aniline so formed then adding to a molecule of unchanged anil, with subsequent ring closure and dehydrogenation. In considering the first alternative, it should be noted that *before* dehydrogenation the substance XV has an allylic system, in which rearrangements are facile and common.



XIII XV XIV

The explanation involving a 1,3-shift of a phenyl group seems preferable in this case, for Peine showed that cinnamalaniline showed a remarkable stability to acids, there being but a very slight hydrolysis to the components. It is much simpler than the necessary series of consecutive reactions required by the second alternative. We have found that cinnamalaniline is monomolecular, thus excluding interpretations involving polymeric forms.

Experimental

The bimolecular compound V and its two dioximes were prepared as reported previously.[1] Both dioximes (m. p. 176 and 229°) were hydrolyzed by refluxing a suspension of 4 g. of the dioxime in 100 cc. of alcohol containing 25 cc. of concentrated hydrochloric acid for twenty-four hours; after cooling, the precipitate was filtered. The yield was 2.5 g.; the melting point, 202–204°, was not lowered when mixed with the pure bimolecular product.

Bromination: 3a,4,7,7a-Tetrahydro-2,3,5,6-tetraphenyl-4,7,7a-tribromo-4,7-methanoinden-1,8-dione, IX; a mixture of 100 cc. of glacial acetic acid and 5 g. each of bromine and the bimolecular product was heated on the steam-bath for seventy-two hours; after the usual manipulative procedures, 1.5 g. of tribromoketone was obtained. It crystallizes from benzene–ligroin in prisms, m. p. 229–230°.

Anal. Calcd. for $C_{34}H_{21}O_2Br_3$: Br, 34.2. Found: Br, 33.6.

2,3,5,6-Tetraphenyl-1,8-dimethyl-4,7,7a-tribromo-1,8-dihydroxy-3a,4,7,7a-tetrahydro-4,7-methanoindene, IXa, was formed when the diketone IX reacted with methylmagnesium iodide. It crystallizes from benzene–ligroin in rods, m. p. 278°.

Anal. Calcd. for $C_{36}H_{29}O_2Br_3$: C, 58.9; H, 4.0; Br, 32.7. Found: C, 59.2; H, 3.7; Br, 33.0.

It evolved two equivalents of methane in the Grignard machine, consuming 2.7 moles of reagent. Upon acidification, most of the starting material was recovered unchanged.

Chlorination: The monochloroketone was secured by refluxing for one-half hour a benzene solution of 4.6 g. of the bimolecular product and 6.2 g. of phosphorus pentachloride. It separates in prisms from benzene, m. p. 215°.

Anal. Calcd. for $C_{34}H_{23}O_2Cl$: Cl, 7.1. Found: Cl, 6.6.

The Grignard reaction products (carbinols, VIII) were prepared in the usual manner with yields of 75–85%. There was nothing new in the experimental procedures employed when they were treated with acetyl chloride, acetic anhydride and a trace of sulfuric acid, thionyl chloride, hydrogen bromide in glacial acetic acid or phosphorus pentachloride. The properties of the various compounds are given in Table I.

TABLE I

PROPERTIES OF SUBSTANCES RELATED TO THE CARBINOLS

[a] Prisms, from xylene. [b] Prisms, from benzene–petroleum ether. [c] Rods, from benzene–petroleum ether. [d] Needles, from benzene–petroleum ether. [e] Two active hydrogens, no addition in Grignard machine. [f] Action of acetyl chloride. [g] Action of acetic anhydride and one drop of concentrated sulfuric acid. [h] One active hydrogen, two additions in Grignard machine and recover carbinol. [i] Action of phosphorus pentachloride. [j] Action of 32% hydrogen bromide in acetic acid. [k] Action of thionyl chloride.

2,3,5,6-Tetraphenylindenone X was obtained in a 20% yield from the indenone, m. p. 167°,[1] or in a 70% yield from its isomer, m. p. 240°,[6] by heating at 220–280° for fifteen minutes with sulfur; there is a strong odor of thiophenol in each instance.

1,2,3,5,6-Pentaphenylindenol-1, XI, was obtained in a yield of 87% from 2,3,5,6-tetraphenylindenone and phenylmagnesium bromide in the usual manner. It separates from benzene–petroleum ether in prisms, m. p. 220°.

Anal. Calcd. for $C_{39}H_{28}O$: C, 91.4; H, 5.5. Found: C, 91.2; H, 5.5.

(9) Peine, *Ber.*, **17**, 2117 (1884).

1,2,3,5,6-Pentaphenyl-1-bromoindene, XII, resulted on warming an acetic acid solution of hydrogen bromide (30–32%) with one-fourth its weight of the above carbinol for one hour; it was then cooled and diluted with an equal volume of acetic acid; the yield was 89%. It forms prisms, m. p. 203°.

Anal. Calcd. for $C_{39}H_{27}Br$: Br, 13.9. Found: Br, 13.6.

The hydrocarbon, m. p. 280°, was isolated, after refluxing a mixture of 4 g. of the bromoindene, 10 g. of zinc dust, and 50 cc. of acetic acid for three hours, by pouring into 200 cc. of water. The hydrocarbon crystallized on chilling the chloroform extract of the aqueous mixture. It separates in prisms.

The same hydrocarbon was formed by heating the phenyl carbinol (m. p. 226°) of the bimolecular product at 290–310° for one hour; steam and carbon monoxide were evolved. The residue was crystallized from chlorobenzene.

The α-naphthyl homolog was prepared in a similar manner; it forms tiny prisms, m. p. 298°.

Anal. Calcd. for (280°) $C_{39}H_{28}$: C, 94.4; H, 5.7; for (298°) $C_{43}H_{30}$: C, 94.5; H, 5.5. Found: (280°) C, 93.9; H, 5.6; (298°) C, 94.3; H, 5.5.

Cinnamalaniline[10] is monomolecular in boiling alcohol, the calculated value being 187, whereas 194 was found.

Acknowledgment.—We are greatly indebted to Dr. Bell of this Laboratory for the many quantitative examinations, in the Grignard machine, of the substances described in this and related papers.

Summary

A new structure, differing only in the position of a phenyl group and a hydrogen atom, has been proposed for the bimolecular product resulting from the action of acidic dehydrating agents upon anhydracetonebenzil. The new structure is in better accord with the chemical behavior of the substance.

The nature of the Grignard reaction products and related substances is described. A tribromo substitution product has been obtained.

(10) Doebner and Miller, *Ber.*, **16**, 1665 (1883). We are indebted to Mr. VanAllan for the preparation of this substance.

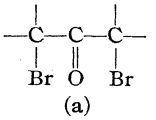
The Structures of Certain Highly Arylated Indenones and their Behavior with Bromine

BY C. F. H. ALLEN AND J. W. GATES, JR.

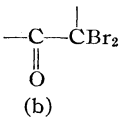
Some time ago[1] it was shown that decarbonylation of the bimolecular product that resulted from the dehydration of anhydracetonebenzil gave a dienone that was rearranged by gentle heating to an isomeric indanone I. On account of the peculiar features of this rearrangement, it was considered desirable to examine the behavior of these substances with other reagents. The action of bromine upon these and closely related substances is described in this paper, and the pertinent structures are discussed. Owing to the reactivity of the system and to the many possible structures, it usually takes a sequence of reactions to enable one to draw significant conclusions.

With one equivalent of bromine, the indanone I gives a monobromoketone, which, with an excess of the reagent, forms a dibromo compound; hydrogen bromide is evolved in both reactions. When the dibromo compound is treated with the Grignard reagent,[2] the monobromoketone is reformed, and a subsequent treatment of this with more Grignard reagent removes the remaining bromine atom and furnishes a fourth, isomeric dienone. The new indenone is very sensitive to heat reverting to its isomer I below its melting point. For this reason, its reactions appear to be those of the indanone, *e. g.*, both give the same dibromo substitution product, and the same phenyl carbinol. Neither of the bromoketones appears to add maleic anhydride.

The replacement of the bromine atoms, stepwise, by the Grignard reagent with the formation of a ketone, shows that they must be in positions *alpha* to the carbonyl group,[3] *i. e.*, either (a) or (b)



(a)



(b)

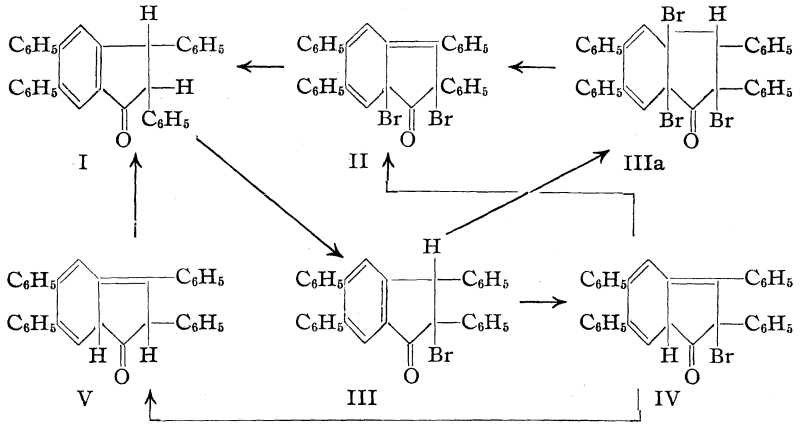
Dibromoketones of type (b), having both bromine atoms on the same carbon atom, however, are very easily hydrolyzed to α-diketones; this property is not exhibited by the dibromoketone

(1) Allen and Spanagel, THIS JOURNAL, **55**, 3773 (1933).

(2) It is of interest to note that in the Grignard machine [Kohler and Richtmyer, *ibid.*, **52**, 3736 (1930)] α-bromoketones show no immediate evolution of gas and use up one mole of reagent (usually interpreted as addition).

(3) Kohler and Tishler, *ibid.*, **54**, 1594 (1932).

in question, consequently, it is best represented by Formula II.



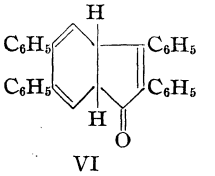
The formation of the dibromoketone II from the indanone I probably takes the following course; the hydrogen atom *alpha* to the carbonyl group is first replaced in the usual manner, giving a monobromoketone III. This can be considered to contain an allylic system, involving the double bond common to both rings, which is isomerized to IV under the influence of the hydrogen bromide present. The resulting ketone now contains a hydrogen atom *alpha* to the carbonyl group and is brominated in the usual way to form II.

An alternative mechanism which avoids the rearrangement suggested is possible for the second step. If the monobromoketone had the structure III, a molecule of bromine could add to the double bond to give IIIa, which would then lose hydrogen bromide. Since this involves an aromatic double bond of the benzene ring, it seems less likely, although the *ortho*-phenyl groups may have a sufficient activating effect to permit of such an addition. Furthermore, the hydrogen atoms, not being *alpha* to a carbonyl group, will be much less active, and have less tendency to be eliminated as hydrogen bromide.

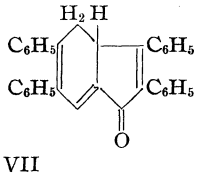
The position of the hydrogen atom in the monobromoketone is less certain. Since this substance was obtained by a reduction of the dibromide by the Grignard reagent, it would seem that it should have the structure IV; in confirmation, the monobromoketone, though secured from the indanone, is unaffected by hydrogen bromide, yet it brominates easily to give the dibromoketone II. Easy bromination is characteristic of only those ketones that have a hydrogen atom in the *alpha* position. Reduction of the dibromide with zinc and acetic acid also replaces the bromine by hydrogen; zinc in acetone or ethyl acetate has no effect—that is, in the dibromide the two bromine atoms are not on adjacent carbon atoms.

The dienone secured by reduction with the Grignard reagent, from its method of preparation and behavior on bromination, most probably is represented correctly by the structure V. In this, it will be noted that the hydrogen atom on the carbon atom common to the two rings is between three double bonds, and would be expected to be unusually likely to isomerize to a more stable system; by virtue of its aromatic structure, the most stable system is the indanone I. This dienone does form the indanone when warmed in solutions below its melting point; the change is very rapid in boiling acetic acid. For this reason, its reaction products, always formed in hot solutions, are identical with those of the indanone.

The dienone VI found earlier[1] was assigned its structure because it added maleic anhydride, gave some thiophenol when heated with sulfur, and was easily rearranged to the indanone I, showing it had the same skeletal structure. In view of the facile migration of hydrogen in this series, the production of thiophenol loses some of its significance—it is noticeable in all the sulfur melts. Its occurrence was interpreted[1] to indicate the presence of an angular phenyl group on the top carbon atom common to the two rings; this phenyl was then assumed to undergo a 1,3-shift in forming the indanone I. Such a shift was at that time without analogy, whereas 1,3-shifts of hydrogen in allylic systems are common. We are now[4] of the opinion that the phenyl group is already in the position where it is found in the indanone and that this dienone has the structure VI; this is in better accord with its chemical behavior.



VI



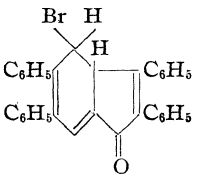
VII

Of these four isomers, the indanone I seems to be the most stable, for the three dienones are con-

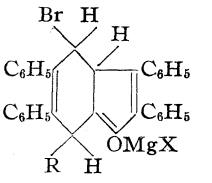
(4) Allen and Gates, THIS JOURNAL, **64**, 2123 (1942).

verted to it by heating.[5] The indanone I is white, whereas the three isomers are various shades of yellow, and it does not add maleic anhydride. On heating with sulfur, hydrogen sulfide is evolved and a red indenone results; this substance has already been degraded stepwise[1] by unambiguous reactions to compounds of known structure.[6] The formula I seems in best accord with these properties. Although the dienone VII gave both 1,2- and 1,4-addition with phenylmagnesium bromide,[7] it was pointed out that this reagent was of no value in determining structures in this series, owing to the prevalance of allylic rearrangements.

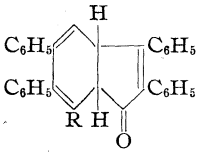
The isomeric dienones VI and VII give the same monobromoketone VIII upon bromination, with evolution of hydrogen bromide. This result would be expected in view of the known ease of the rearrangement of VI to VII.[7] Excess bromine dehydrogenates the monobromoketone. Examination of this ketone VIII in the Grignard machine[2] revealed little.[8] Both methylmagnesium iodide and phenylmagnesium bromide gave mixtures, from which were isolated bromine-free ketones, *different* from the original dienones. The 1,4-addition reaction, resulting in the formation of the ketones, which differ from the original by having an additional phenyl or methyl group, involves the carbonyl group. Thus, this group is not available for other purposes, and the elimination of the bromine must have been a side reaction. The following mechanism seems a plausible interpretation of the facts, and enables one to assign structure VIII to the bromoketone with a considerable degree of assurance. The magnesium enolate formed by the 1,4-addition of the Grignard reagent is shown in IX; upon acidification the enol XI ketonizes, but at some stage, there is a transannular elimination of hydrogen bromide, for the resulting ketone X contains no bromine. This probably occurs in the enol XI, for the requisite hydrogen atom in the 7-position is then activated by its position between the unsaturated linkages.[9,10]



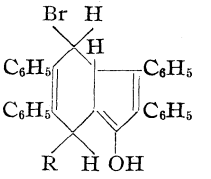
VIII



IX

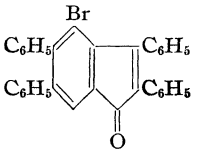


X

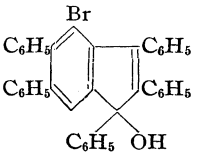


XI

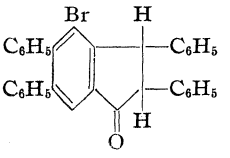
The aromatic ketone that results from the action of excess bromine upon the bromoketone VIII is probably 4-bromo-2,3,5,6-tetraphenylindenone XII. The bromine atom is inactive, phenylmagnesium bromide giving a carbinol XIII. The indenone is reduced to an indanone XIV by zinc and acetic acid, thus paralleling the behavior of the unbrominated indenone.



XII



XIII



XIV

Experimental

2,3,5,6-Tetraphenyl-2,7a-dibromo-2,7a-dihydroindenone-1 II.—This compound was obtained by bromination of the indanone I in the usual manner, using two equivalents of bromine and acetic acid as the solvent. It was also formed by a further bromination of the monobromoketone IV. The latter was secured by a similar procedure, but using one equivalent of bromine and chloroform as a solvent. The properties of these substances are given in Table I.

Both bromoketones were unaffected by hydrogen bromide in acetic acid, and did not add maleic anhydride. The dibromoketone was reduced to the monobromoketone

(5) Examination of the formulas of the isomeric ketones reveals that all the indenones have hydrogen atoms activated by adjacence to two or more double bonds, which are part of an allylic system. They would, therefore, be expected to rearrange to the more stable indanone I system.

(6) Allen, Bell, Bell and VanAllan, THIS JOURNAL, **62,** 656 (1940).

(7) Allen and Gates, *ibid.*, **64,** 2120 (1942).

(8) It should be emphasized that abnormal results from the Grignard machine have little significance, other than to indicate that several reactions are taking place simultaneously. It is always necessary to isolate and determine the nature of the reaction products before drawing useful conclusions. If there is no immediate evolution of gas, it indicates the absence of an active hydrogen atom.

(9) In one fortuitous instance, with methylmagnesium iodide, a bromoketone was isolated; immediate analysis showed 85% of the calculated amount of bromine, all of which was lost on recrystallization.

(10) A direct replacement of bromine in VIII by double decomposition with the Grignard reagent is an admitted possibility, and reaction products of this type may be present in the residual oils which comprise about one-half the reaction product.

[a] Prisms. [b] Needles. [c] Rods. [d] From xylene. [e] From benzene–petroleum ether. [f] From benzene–alcohol. [g] Calcd. mol. wt. 1105; found, mol. wt. (in benzene) 522, 519. The explanation of this discrepancy is unknown.

by reduction with potassium iodide in acetic acid, alcoholic potash, and the Grignard reagent, and to the parent indanone with zinc and acetic acid, by the customary procedures.

2,3,5,6-Tetraphenyl-2,7a-dihydroindenone-1 V.—To a 0.1 mole of phenylmagnesium bromide in 100 cc. of ether was added 6 g. of the monobromoketone III. After it had been stirred for an hour, the mixture was decomposed by ammonium chloride, and the organic material crystallized from benzene–petroleum ether; the yield was 3 g. Heated in the ordinary way, in a capillary tube, it melts at 95°, then solidifies and remelts at 164–166°; if the tube and sample are plunged into a heated bath, the melting point is found to be 125°. By repeated recrystallizations, it isomerizes, most rapidly in acetic acid, to the indanone II, m. p. 176°.

2,3,5,6-Tetraphenyl-3a,4-dihydro-4-bromoindenone-1 VIII resulted when either indenone VI or VII in chloroform solution was brominated in the usual way. It crystallized from benzene–alcohol in lemon-yellow prisms, m. p. 196°d. It does not add maleic anhydride and is unaffected by hydrogen bromide. In the Grignard machine it shows 0.5 active hydrogen and 1.5 addition. Upon treatment with bromine in chloroform, hydrogen bromide is evolved, and an orange indenone (2,3,5,6-tetraphenyl-4-bromoindenone-1 XII, m. p. 234–235°) is isolated from the residue by evaporating to dryness on a water-bath.

This last substance is reduced by zinc and acetic acid (without removal of the bromine) to an indenone XIV in exactly the same way as the unbrominated analog, 2,3,5,6-tetraphenylindenone[1] gave the indanone I, m. p. 176°. It gave a phenyl carbinol XIII with phenylmagnesium bromide.

Reaction Products from the Bromoindenone VIII.—(a) Phenylmagnesium bromide gave a complex mixture, from which the ketone X, (R = C_6H_5) and a bimolecular product were isolated in this order. In the Grignard machine the ketone consumed one equivalent of reagent and evolved a half equivalent of gas (possibly indicating 50% enolization). When treated with phenylmagnesium bromide it gave a new carbinol, 1,2,3,5,6,7-hexaphenyl-3a,7a-dihydroindenol-1 XV, which did not dehydrate with a 2% solution of sulfuric acid in acetic acid.

The ketone behaved in a puzzling manner with hydrogen bromide, the oxygen being lost and a bromine atom introduced. Possibly the acid is added to the carbonyl group and then water is split off. The product XVI is a bromohydrocarbon.

The bimolecular product XVII was assumed to be such because of the bromine analyses; the minimum molecular weight, if one bromine atom is present, is 1100–1200. The substance was secured from two different preparations, and was unchanged on recrystallization from two different solvents. It consumed 2.7 equivalents of reagent (on the basis of this molecular weight), showing two active hydrogens. Upon acidification, about half the starting material was recovered from the black oil. It was not investigated further.

(b) Methylmagnesium iodide likewise gave a complex mixture, from which was isolated the ketone, 2,3,5,6-tetraphenyl-7-methyl-3a,7a-dihydroindenone-1 (X, R = CH_3). In the Grignard machine it consumed one equivalent of reagent and evolved 0.3 equivalent of gas. It was unaffected by hydrogen bromide and did not add maleic anhydride. It readily substituted with bromine; the α-bromoketone, 2,3,5,6-tetraphenyl-7-methyl-3a,7a-dihydro-7a-bromoindenone-1 XVIII, was reduced back to the starting material by methylmagnesium iodide. In one instance a very small amount of an isomeric ketone Xa was obtained.

Summary

The behavior of several closely related isomeric polyphenylated indenones with bromine has been determined. Structures have been assigned the various substances, in accord with the experimental evidence obtained from a series of reactions. The occurrence of allylic rearrangements has again been noted.

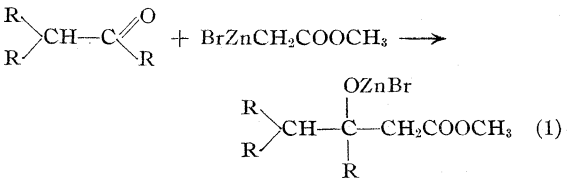
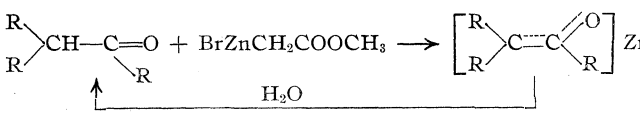
Enolization in the Reformatsky Reaction

BY MELVIN S. NEWMAN

In the Reformatsky reaction it is generally thought that zinc reacts with a bromoester to form an organozinc intermediate which then adds to the ketone or aldehyde to yield a bromozinc derivative of a β-hydroxyester, as follows



The recovery of ketone from the products of such a reaction would seem to indicate incomplete reaction. However, it was found to be a fact that practically all of the theoretical amount of zinc was consumed in experiments where considerable amounts of ketone were recovered. This finding suggested that the ketone reacted in some way with the organozinc intermediate so that on hydrolysis the ketone was regenerated. Bearing in mind the probability that the Reformatsky reaction involves an organozinc intermediate which would be expected to behave like other organometallic compounds, it seemed likely that the recovered ketone was tied up as an enolate during the reaction,[1] as follows



Acetomesitylene was chosen as an excellent test for this hypothesis because it has been shown to react by the enolization mechanism with Grignard reagents[2] and with organolithium[3] and organosodium[3] compounds. It was found that acetomesitylene reacted vigorously with zinc and methyl bromoacetate. After hydrolysis of the reaction mixture 90% of acetomesitylene was recovered and in addition approximately 50% of the theoretical amount of methyl acetate was isolated.

When 23.3 g. of acetomesitylene, 23.0 g. of methyl bromoacetate and 5 g. of freshly sandpapered zinc foil[4] were brought together in 100 cc. of dry sulfur-free benzene, an extremely vigorous reaction ensued. Approximately the theoretical amount of zinc was consumed in a short time. After hydrolysis with dilute hydrochloric acid the benzene layer was distilled. On fractionation of the low boiling fraction, 5.3 g. (50%) of methyl acetate was obtained. This was identified by boiling point, 57–58° uncor., odor and hydrolysis to yield acetic acid, identified as its *p*-bromophenacyl ester[5], m. p. and mixed m. p. 83–84° cor. More methyl acetate was present as judged by the boiling point and odor of intermediate fractions. From the higher boiling fraction there was isolated 20.9 g. (90%) of acetomesitylene, b. p. 124–125° uncor., at 20–21 mm. This was identified further by conversion in 64% yield to 3,5-dinitro-2,4,6-trimethylacetophenone,[6] m. p. and mixed m. p. 139–140° cor.

In a similar experiment it was shown that methyl acetate could be distilled from the reaction mixture before hydrolysis, thereby proving that the methyl acetate formed did not arise from a reaction of any bromozinc intermediate with water. It should be emphasized that the formation of methyl acetate in a Reformatsky reaction is entirely analogous to the formation of methane in a Zerewitinoff determination. In order to rule out the possibility that the methyl acetate might have arisen from some other side reaction, zinc and methyl bromoacetate were refluxed in benzene for a day. Considerable reaction occurred but at no time was a positive organometallic color test with Michler ketone[7] obtained. A small amount of methyl acetate was produced but not nearly enough to account for the methyl acetate resulting when acetomesitylene was present. Therefore, on the basis of the above facts, it is concluded that in the Reformatsky reaction acetomesitylene reacts mainly by the enolization mechanism.

(1) Newman, THIS JOURNAL, **62**, 870 (1940).

(2) Kohler and Baltzly, *ibid.*, **54**, 4015 (1932).

(3) Gilman and Jones, *ibid.*, **63**, 1162 (1941). In this paper it is pointed out that enolization of a ketone prior to reaction with an organometallic compound does not necessarily have to occur. It may be that the initially formed complex between the carbonyl oxygen and the organometallic reagent react so that the products characteristic of an enolization reaction are formed. See also Arnold, Bank and Liggett, *ibid.*, **63**, 3444 (1941).

(4) Natelson and Gottfried, *ibid.*, **61**, 970 (1939). The zinc foil was obtained from the J. T. Baker Co., Phillipsburg, N. J.

(5) Judefind and Reid, *ibid.*, **42**, 1043 (1920).

(6) Fuson and Walker, *ibid.*, **52**, 3269 (1930). Under the same conditions the pure known compound yielded 66% of the derivative.

(7) Gilman and Schulze, *ibid.*, **47**, 2002 (1925). To allow for the possibly lesser reactivity of an organozinc compound, the test solution was heated for one to five hours before hydrolysis, at the suggestion of the Referee. However, the success or failure in obtaining a color test does not affect the argument in favor of enolization, for no appreciable amount of methyl acetate is formed unless acetomesitylene is added.

A solution of 67.5 g. of methyl bromoacetate in 350 cc. of dry sulfur-free benzene and a few crystals of iodine was refluxed over 32 g. of zinc[4] for twenty hours. Shortly after the refluxing commenced the solution turned yellow-green. A test[7] with Michler ketone at this stage was negative. After about thirty minutes of refluxing an orange-yellow viscous complex was seen to adhere to the active spots on the zinc. Some of this complex was removed on a glass rod when it first appeared, but this also gave a negative color test. After twenty hours of refluxing the decanted solution was distilled through a 10–15 plate column. With a reflux ratio of over 80 to 1 about 3 g. of a fraction, b. p. 57–64°, was collected. Methyl acetate was present in this as judged by boiling point, odor, and identification of acetic acid on hydrolysis as the *p*-bromophenacyl ester.[5] On weighing the zinc it was found that 19.5 g. had reacted. This amounts to 68% of that required to react with the bromoester used.

The isolation of ketone from the products of Reformatsky reactions does not necessarily mean that the ketone was tied up as an enolate during the reaction, but, if the theoretical amount of zinc was consumed in a short time during the reaction and if no insoluble complex coated out on the zinc to hinder complete reaction, it seems most likely that enolization offers the best explanation for the recovery of unchanged ketone. In the past few years the author has carried out many such reactions in which, although ample excesses of zinc and bromoesters were present, and approximately the theoretical quantity of zinc was rapidly consumed, considerable amounts of starting ketone were recovered. At the time when most of these reactions were run, the possibility of enolization as a factor in Reformatsky reactions was not under consideration. Accordingly, a thorough study of the factors which influence the enolization of ketones in this reaction cannot be reported. However, it is possible to point out a few observations which seem to be substantiated by the experimental results.

The ketones studied were 1-keto-2-phenyl-1,2,-3,4-tetrahydronaphthalene,[1] I, 1-keto-2-*o*-tolyl-3-methyl-1,2,3,4-tetrahydronaphthalene,[8] II, and 4-keto-1,2,3,4-tetrahydrophenanthrene,[9] III.

Preparation of Keto ne

Ketones I and II were prepared as previously reported. Ketone III was prepared as follows. The acid chloride prepared in benzene solution from 199 g. of γ-2-naphthylbutyric acid and phosphorus pentachloride was dissolved in 500 cc. of sulfur-free dry benzene, and 127 g. of aluminum chloride[10] was added in portions with stirring. Very little hydrogen chloride was evolved and the color of the complex first formed was still a pale yellow-green when 90% of the aluminum chloride had been added. Also there had been considerable evolution of heat. When the last portions of aluminum chloride were added the color deepened rapidly to a red-brown, the temperature started to rise rapidly (cooling required), and much hydrogen chloride was evolved. After regulation of the internal temperature at 35–40° for one hour, the temperature was raised to 60° for an hour and to 65° for one-half hour. The mixture was then cooled and worked up in the usual manner. On rapid vacuum distillation at 2 mm. a pale yellow viscous oil, 170 g. (93%), was obtained. By crystallization from 400 cc. of alcohol, two crops of crystals totalling 157 g. (86%), m. p. 66.0–67.4° cor., were obtained. About 3 to 5% of starting acid was recovered from alkaline extracts of the reaction mixture.

General Description of Procedure

A solution of the pure ketone (usually 0.1 to 0.2 mole) and bromoester (in 15–20% excess) in dry sulfur-free benzene (80–100 cc. per 0.1 mole) was placed in a round-bottom flask fitted to a ground-in condenser which could be changed from refluxing to distilling by turning a stopcock. This solution was distilled for a short while to render completely anhydrous. An excess of freshly sand-papered zinc foil was added while the solution was still hot, and, when desired, a few crystals of iodine were allowed to fall on the foil. In most cases a vigorous exothermic reaction set in as soon as the solution was heated to boiling. Refluxing then continued spontaneously until the reaction was virtually complete. This took about ten to twenty minutes. After further refluxing with added heat for not more than thirty minutes the reaction mixture was cooled and decomposed with dilute hydrochloric acid. The organic material was separated by ether extraction and the unreacted zinc collected and weighed.[11] After thorough washing with dilute acid and water, the solvent was removed from the benzene layer and the residue was heated for a short while in the neighborhood of 200° to effect dehydration. When iodine was used in starting the reaction it was generally unnecessary to add more iodine for dehydration. The residue was vacuum distilled, the distillate refluxed with dilute aqueous-alcoholic potassium hydroxide, and the hydrolyzate separated into acidic and neutral fractions. The original ketone was recovered from the neutral fraction by vacuum distillation, crystallization, or a combination of the two, and the yields of ketone reported represent practically pure ketone. The acid fractions were crystallized from benzene. In some cases all of the acid crystallized. The amounts of non-crystalline acid were determined by evaporating the solvent from the mother liquors to constant weight of residue, and these values were checked by esterification and vacuum distillation of the ester.

Discussion of Results

From a consideration of the experiments cited

(8) Newman, THIS JOURNAL, **62**, 2295 (1940).

(9) Compare Haworth, *J. Chem. Soc.*, 1125 (1932), and Bachmann and Edgerton, THIS JOURNAL, **62**, 2219 (1940).

(10) Calco Chemical Co., Standard grade, anhydrous.

(11) If dilute hydrochloric acid is used, it is possible to separate the zinc rapidly before any appreciable amount of it reacts with the acid. It is surprising how slowly the unreacted zinc is attacked by dilute acids. Washing with acetone hastens the cleaning of the zinc prior to drying and weighing.

below the following conclusions seem justified.[12]

1. The use of a small amount of iodine to initiate the reaction decreases enolization.[13] In two experiments with ketone I and ethyl α-bromopropionate, 38% of acid[14] and 27% of ketone I were obtained when iodine was used. Without iodine the yields were 23% of acid[14] and 42% of ketone. In other experiments with ketone III and ethyl bromoacetate, when iodine was used 87% of acid and 6% of ketone III were isolated. Without iodine the yields were 77% of acid and 17% of ketone.

2. The use of dioxane as a solvent promotes enolization. In experiments with ketone I and ethyl bromoacetate, 68% of acid[14] and a small but undetermined amount of ketone were obtained in benzene as solvent. In pure dioxane the reaction took place more vigorously than in benzene but the yields were 29% of acid[14] and a large but undetermined amount of ketone I. No iodine was used. In other experiments with methyl bromoacetate and ketone II, when iodine was used in benzene, 52% of acid and 41% of ketone II were isolated. In dioxane and with no iodine the reaction was much more vigorous than in benzene but only 10% of acid and 70% of ketone were obtained.

3. The tendency to cause ketones to react by enolization increases in the following esters: ethyl bromoacetate <ethyl α-bromopropionate <ethyl α-bromobutyrate. In experiments with ketone I using no iodine, ethyl bromoacetate yielded 68% of acid[14] and a small amount of ketone, whereas ethyl α-bromopropionate yielded 23% of acid and 42% of ketone. In experiments with ketone I using iodine, ethyl α-bromopropionate yielded 38% of acid[14] and 27% of ketone I, whereas ethyl α-bromobutyrate yielded 28% of acid[14] and 48% of ketone I. In experiments with ketone III using no iodine, ethyl bromoacetate yielded 77% of acid and 17% of ketone III, whereas ethyl α-bromopropionate yielded 55% of acid and 39% of ketone III.

(12) It should be emphasized that the experiments cited were not isolated cases but those in which the results had been duplicated to within a few per cent. In all of these cases the zinc reacted approached the theoretical and in all cases the reactions had proceeded for a maximum of ninety minutes.

(13) The amount of enolization is probably more accurately estimated by the amount of ketone recovered than by the amount of acid isolated. Those cases where the total amount of products accounted for is less than 85% were from earlier work, where the technique was not as good as in later work.

(14) The percentages indicated in these cases represent pure crystalline acid only; additional non-crystalline acid was present but was not accounted for.

Summary

Evidence is presented that the recovery of starting ketone from the products of a Reformatsky reaction may be due to enolization of the ketone during reaction. In the case of acetomesitylene, 90% of the ketone is recovered after reaction. A few factors influencing the enolization of ketones in the Reformatsky reaction are discussed.

COLUMBUS, OHIO RECEIVED APRIL 24, 1942

[COMMUNICATION NO. 863 FROM THE KODAK RESEARCH LABORATORIES]

Investigation of Pyrazole Compounds. I. The Reaction Product of Phenylhydrazine and Ethyl Cyanoacetate

BY A. WEISSBERGER AND H. D. PORTER

Conrad and Zart[1] treated ethyl cyanoacetate with phenylhydrazine, using sodium alcoholate as a condensing agent, and obtained a colorless compound of the composition $C_9H_9N_3O$ and the m. p. 219°. This, they assumed to be 1-phenyl-3-hydroxy-5-pyrazolone-imide, I. However, the reaction between ethyl cyanoacetate and phenylhydrazine could also lead to the isomeric 1-phenyl-3-amino-5-pyrazolone, II. The intermediate in the formation of I might be the β-cyanoacetylphenylhydrazine, III, while the formation of β-imino-β-(β-phenylhydrazino)-propionic ester, IV, as the primary product would lead to II.

The compound synthesized by Conrad and Zart is of importance in color photography,[2] and it appeared desirable to get definite information about its structure. In order to decide between I and II, I was synthesized in an unambiguous way, starting with 1-phenyl-3-carbethoxy-5-pyrazolone, V.[3] This compound can be prepared by ring closure from the well-characterized ethyl

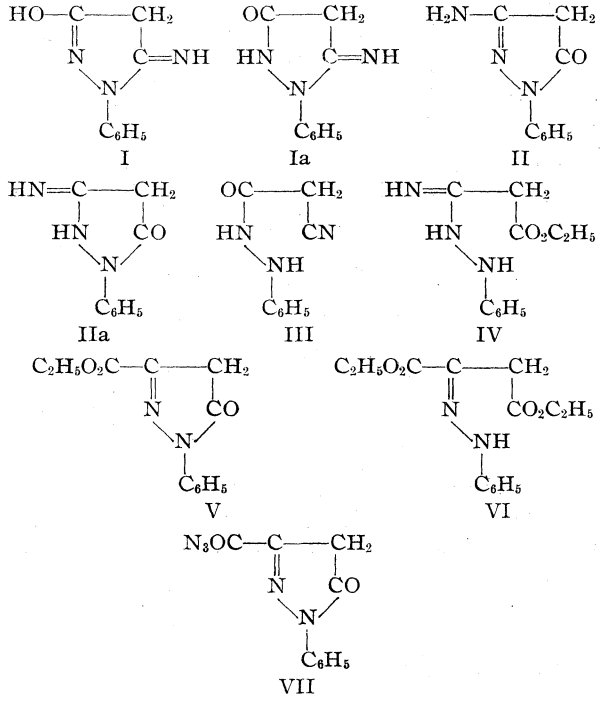
oxalacetate phenylhydrazone,[3] VI. V was transformed to the hydrazide and azide, VII, and the latter subjected to a Curtius degradation. The compound obtained is identical with that prepared according to Conrad and Zart. Hence, *the formulation of this compound as I is erroneous and has to be replaced by II.* The identity of the compound made from V with that prepared according to Conrad and Zart was proved by m. p. and mixed m. p., and by the identical behavior of the two substances in the reactions leading to and the m. p.'s and mixed m. p.'s of the monobenzoyl derivative, the monocarbethoxy derivative and



the reaction product with aniline described below. Both I and II are capable of forming by prototropic shift, equilibria with tautomeric forms, *e. g.*, I with Ia, and II with IIa, and the same applies to the derivatives described below. However, the family of I differs from that of II by the position of the phenyl group, and the two families are not subject to tautomeric interchange. In the following, all compounds which by prototropic shift could form derivatives of pyrazolone will be named as such.

Treatment of II with one mole of benzoyl chloride yields a monobenzoyl derivative which is soluble in aqueous sodium carbonate. A monocarbethoxy derivative of similar behavior is obtained by treatment of II with ethyl chlorocarbonate. The same compound is formed by decomposition of the azide VII in boiling ethanol, which shows that it is 1-phenyl-3-carbethoxyamino-5-pyrazolone. By analogy, the monobenzoyl derivative is 1-phenyl-3-benzoylamino-5-pyrazolone. With phenyl isocyanate II forms a compound of the composition $C_{16}H_{14}N_4O_2$ which is soluble in aqueous sodium carbonate, and, in analogy to the two derivatives just mentioned, is formulated as 1-phenyl-3-phenylcarbamylamino-5-pyrazolone. Treatment of II with one mole of acetyl chloride yields a monoacetyl derivative, behaving like the other monoacyl derivatives. The compound, therefore, is formulated as 1-phenyl-3-acetylamino-5-pyrazolone, IX. Acetylation with excess acetic anhydride gives a diacetyl derivative which is insoluble in carbonate. The second acetyl group is very easily split off by caustic alkali forming IX, and the diacetyl derivative, therefore, is most likely the 1-phenyl-3-acetamino-5-acetoxy-pyrazole. On heating II with aniline, ammonia is split off and C_6H_5NH is introduced. The compound so obtained is soluble in aqueous sodium carbonate. It is, most likely, the 1-phenyl-3-phenylamino-5-pyrazolone.

Experimental

1-Phenyl-3-amino-5-pyrazolone (Method of Conrad and Zart[1]).—To a solution of sodium ethylate prepared from 4.6 g. of sodium and 80 ml. of absolute ethanol, was added 11.3 g. of ethyl cyanoacetate and 10.8 g. of phenylhydrazine. The mixture was heated under reflux in an oil-bath of 120° for sixteen hours. After removal of the alcohol under vacuum, the residue was dissolved in 100 ml. of water and extracted with 50 ml. of ether. The aqueous layer, on acidification with 10 ml. of acetic acid, deposited 8.3 g. of a tan powder, sintering at 208° and melting at 213–215° dec. The product was purified by boiling with 50 ml. of 95% ethanol, cooling, filtering and washing with 10 ml. of ethanol; 7.6 g. (43%), m. p. 216–218° dec. This material is sufficiently pure for the preparation of derivatives. It can be recrystallized from 10 parts of ethanol–dioxane (2:1). After three recrystallizations, including treatment with Norite, small white prisms were obtained, m. p. 218–220°.

At least two equivalents of sodium ethylate are necessary for the reaction, but larger amounts do not improve the yields, which are the highest, if equal moles of phenylhydrazine and ethyl cyanoacetate are employed.[4]

1-Phenyl-3-amino-5-pyrazolone from 1-Phenyl-3-carbethoxy-5-pyrazolone

1-Phenyl-3-carbethoxy-5-pyrazolone was synthesized following, in principle, the method of Wislicenus.[3] A solution of 60 g. of ethyl oxalacetate phenylhydrazone[3] in

(4) These results were obtained in a series of experiments by E. C. Armstrong of these Laboratories. The authors wish to thank Mr. Armstrong for his assistance.

250 ml. of benzene and 10 ml. of glacial acetic acid was heated under reflux for three hours. The product obtained after cooling was washed on the filter with 25 ml. of benzene; 40 g. (80%) of white, feathery needles, m. p. 185–186°.

In the absence of acetic acid no 1-phenyl-3-carbethoxy-5-pyrazolone was formed even though the heating time was doubled, while refluxing in xylene for three hours in the absence of acid gave a yield of 28%. When phenylhydrazine was added gradually to a boiling solution of ethyl oxalacetate in xylene, and water and alcohol were distilled off as they formed, yields of only about 40% were obtained. A yield of 54% was obtained when the phenylhydrazone was heated in about 10 parts of water.

1-Phenyl-5-pyrazolone-3-carboxamide.—Twenty grams of 1-phenyl-3-carbethoxy-5-pyrazolone was stirred in 200 ml. of concentrated ammonium hydroxide (28%) until a clear solution was formed and then left standing for ninety-six hours at room temperature. The solution was acidified with 30% acetic acid to give 15 g. (86%) of almost white crystals which darkened at 215° and melted at 228° dec., recrystallized from 200 ml. of 95% ethanol; 10 g. (57%) of white crystals, m. p. 233–235° dec.

Anal. Calcd. for $C_{10}H_9N_3O_2$: N, 20.7. Found: N, 20.14.

1-Phenyl-5-pyrazolone-3-carboxhydrazide.—A mixture of 34 g. of 1-phenyl-3-carbethoxy-5-pyrazolone and 100 ml. of 42% hydrazine hydrate solution was stirred at room temperature. The solution warmed spontaneously to *ca.* 40° and became clear. After standing for four hours an equal volume of water was added. On acidification with acetic acid, 27.5 g. (86%) of fine, cream colored needles separated, m. p. 235–237° dec. The melting point was not changed by recrystallization from ethanol.

Anal. Calcd. for $C_{10}H_{10}N_4O_2$: N, 25.65. Found: N, 25.19.

1-Phenyl-5-pyrazolone-3-carboxazide.—To a solution of 10 g. of 1-phenyl-5-pyrazolone-3-carboxhydrazide in 200 ml. of 70% ethanol containing 6 ml. of concentrated hydrochloric acid, was added dropwise with stirring 2.3 g. of sodium nitrite in 10 ml. of water, while keeping the temperature below 5°. Stirring was continued at this temperature for one hour. The product was filtered and washed with water; 6.5 g. (62%) of granular orange powder, deflagrating at 140°.

1-Phenyl-3-carbethoxyamino-5-pyrazolone.—A solution of 3 g. of 1-phenyl-5-pyrazolone-3-carboxazide in 30 ml. of absolute ethanol was refluxed for three hours, cooled and filtered; .2 g. (63%) of yellowish crystals, m. p. 197–199°, recrystallized from 70 cc. of 95% ethanol (Norite); white needles, m. p. 198–199°. A mixed m. p. with the 1-phenyl-3-carbethoxyamino-5-pyrazolone described below showed no depression.

1-Phenyl-3-amino-5-pyrazolone.—A solution of 2.5 g. of 1-phenyl-3-carbethoxyamino-5-pyrazolone in 12.5 ml. of 10% sodium hydroxide was heated on the steam-bath for half an hour, then cooled and acidified with acetic acid; 1.4 g. (m. p. 215–216° dec.) of tan crystals, recrystallized from 95% ethanol, small, white prisms; m. p. 218–220° dec. A mixed m. p. with the compound prepared by the method of Conrad and Zart, showed no depression.

Other reactions attempted in the preparation of 1-phenyl-3-amino-5-pyrazolone were given up after the success of the Curtius degradation. The conventional Hofmann degradation of 1-phenyl-5-pyrazolone-3-carboxamide gave uninviting brominated products. When the sodium salt of 1-phenyl-3-chloro-5-pyrazolone[5] was treated with potassium phthalimide in boiling alcohol for twenty hours, or with sodium amide in liquid ammonia at −33° for forty hours, the unchanged starting material was recovered. Treatment with sodium amide in ammonia at 100° under pressure for twenty hours gave no water-insoluble product. The starting material was recovered after treatment of 1-phenyl-5-pyrazolone-3-carboxylic acid with hydrazoic acid in the presence of sulfuric acid following the method of von Braun.[6]

Derivatives of 1-Phenyl-3-amino-5-pyrazolone

1-Phenyl-3-benzoylamino-5-pyrazolone.—A mixture of 5 g. of 1-phenyl-3-amino-5-pyrazolone[7] and 4 g. of benzoyl chloride in 20 ml. of dioxane was stirred and heated on the steam-bath for eighteen hours. The product which crystallized after addition of 5 ml. of water, was purified by slurrying with 15 ml. of methanol; 5 g. (64%) of fine, cream colored needles, m. p. 218–220°, recrystallized from 15 parts of dioxane, m. p. 220–221°.

Anal. Calcd. for $C_{16}H_{13}N_3O_2$: N, 15.06. Found: N, 14.95.

The compound is soluble in 3% sodium carbonate or 2% sodium hydroxide. It is recovered unchanged on acidification with acetic acid.

1-Phenyl-3-carbethoxyamino-5-pyrazolone.—A mixture of 8.75 g. of 1-phenyl-3-amino-5-pyrazolone and 5.4 g. of ethyl chlorocarbonate in 35 ml. of dioxane was stirred and heated on the steam-bath for three and one-half hours. On addition of 5 ml. of water and cooling, 1.5 g. of tan crystals separated, recrystallized from 50 ml. of 95% ethanol; 1 g. of fine white needles, m. p. 198–199°.

Anal. Calcd. for $C_{12}H_{13}N_3O_3$: N, 17.00. Found: N, 16.97.

When the filtrate was diluted with an equal volume of water, 4.6 g. of a tan crystalline product separated which, after recrystallization from 15 ml. of 95% ethanol gave 3 g. of tan crystals, m. p. 106–108°. This product, probably a dicarbethoxy derivative, on heating under reflux in 65 ml. of absolute alcohol with 1 ml. of piperidine for one-half hour yielded 1.2 g. of the 1-phenyl-3-carbethoxy-amino-5-pyrazolone, m. p. 198–199°.

1-Phenyl-3-acetylamino-5-pyrazolone.[4]—To a suspension of 8.75 g. of 1-phenyl-3-amino-5-pyrazolone in 50 ml. of dioxane was added all at once while stirring 5.5 g. of acetyl chloride. The solution formed was warmed in a water-bath at 40° for one hour, cooled, the product collected on the filter and recrystallized from 30 ml. of 95% ethanol; 4.5 g. (43%) of short, white needles, m. p. 218–220°. The m. p. is the same as that of the starting material; however, a mixed m. p. was depressed by about 30–40°.

Anal. Calcd. for $C_{11}H_{11}N_3O_2$: N, 19.35. Found: N, 19.44.

(5) Michaelis and Röhmer, *Ber.*, **31**, 3003 (1898).
(6) von Braun, *Ann.*, **490**, 125 (1931).
(7) Prepared by either method given above.

Toward carbonate and hydroxide solutions the compound behaves like the 1-phenyl-3-benzoylamino-5-pyrazolone.

1-Phenyl-3-acetylamino-5-acetoxypyrazole.[4]—A solution of 8.75 g. of 1-phenyl-3-amino-5-pyrazolone in 50 ml. of acetic anhydride was refluxed for half an hour. After decomposing the mixture in 250 ml. of water, the product was filtered off and recrystallized from 90 ml. of toluene; 8 g. (62%) of fine, cream colored crystals; m. p. 144–145°.

Anal. Calcd. for $C_{13}H_{13}N_3O_2$: N, 16.22. Found: N, 16.12.

The compound is insoluble in 3% sodium carbonate. It dissolves in cold 2% sodium hydroxide with saponification of one acetyl group; on acidification with acetic acid 1-phenyl-3-acetylamino-5-pyrazolone is obtained; m. p. and mixed m. p. 218–220°.

1-Phenyl-3-phenylcarbamylamino-5-pyrazolone.—To a hot solution of 5 g. of 1-phenyl-3-amino-5-pyrazolone in 20 ml. of dioxane was added 3.4 g. of phenyl isocyanate and the mixture heated for two hours on the steam-bath. The product which crystallized on cooling was purified by stirring with 25 ml. of ethanol; 2.3 g. (28%) of pure white microcrystals, m. p. 235–236°.

Anal. Calcd. for $C_{16}H_{14}N_4O_2$: N, 19.0. Found: N, 19.00.

Toward carbonate and hydroxide solutions the compound behaves like the 1-phenyl-3-benzoylamino-5-pyrazolone.

1-Phenyl-3-anilino-5-pyrazolone.—A mixture of 20 g. of 1-phenyl-3-amino-5-pyrazolone[7] and 50 ml. of aniline was refluxed gently over a flame for one and one-half hour, *i. e.*, until the evolution of ammonia slacked off. After some cooling, 100 ml. of chloroform was added and the solution cooled in an ice-bath. The product (14.6 g.) was recrystallized from 300 ml. of 95% ethanol, filtering hot from a small amount of insoluble yellow material; 12 g. (43%) of white, feathery needles, m. p. 219–221°.

Anal. Calcd. for $C_{15}H_{13}N_3O$: N, 16.70. Found: N, 16.77.

The compound is sparingly soluble in cold 3% sodium carbonate, but soluble in cold 2% sodium hydroxide, from which it separates unchanged on acidification.

Summary

1. 1-Phenyl-3-amino-5-pyrazolone was prepared, starting with the ethyl ester of 1-phenyl-3-carboxy-5-pyrazolone, by way of the corresponding hydrazide and azide and Curtius degradation of the latter.

2. The reaction product is identical with the compound prepared by Conrad and Zart[1] from ethyl cyanoacetate and phenylhydrazine and formulated as 1-phenyl-3-hydroxy-5-pyrazolone imide.

3. The compound prepared by Conrad and Zart is, therefore, 1-phenyl-3-amino-5-pyrazolone.

4. A number of derivatives of 1-phenyl-3-amino-5-pyrazolone were prepared.

The Reaction of Methyl Furoate with Benzene and Chlorobenzene

BY CHARLES C. PRICE AND C. F. HUBER

The aluminum chloride-catalyzed reaction of furoic acid with benzene has been found to yield, in addition to α-naphthoic acid,[1] a large amount of an amorphous mixture of acids of higher molecular weight.[2] Although some suggestions as to the nature of certain components of this material were advanced on the basis of degradation products of the crude mixture, the isolation of any pure acids has proved extremely difficult. Since attempts at fractional crystallization or precipitation of the acids or of various derivatives were so generally unsuccessful, the condensation reaction has been investigated employing methyl furoate in place of furoic acid, with the aim of separating by distillation the esters so formed.

McCorkle and Turck[3] were able to isolate a 56% yield of methyl α-naphthoate from the aluminum chloride-catalyzed reaction of methyl furoate with benzene, and Calloway[4] reported that a considerable residue remained after distillation of the naphthoate. We have obtained the same results, isolating methyl α-naphthoate in 32–46% yield accompanied by a residue of higher-boiling products.

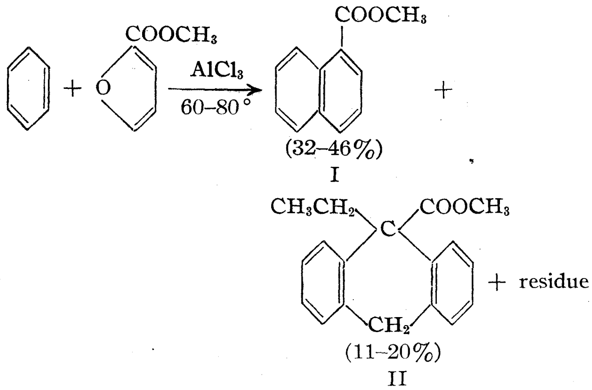
Fractional distillation of this residue under the vacuum of a mercury vapor pump yielded a pale yellow, viscous oil, boiling at 144–145° (0.04 mm.), which crystallized after standing for seven months, m. p. 52–54°. The yield of this substance, which proved to be methyl 9-ethyl-9,10-dihydro-9-anthroate (II), corresponded to 11–20% of the theoretical amount.

(1) Gilman, McCorkle and Calloway, THIS JOURNAL, **56**, 745 (1934).

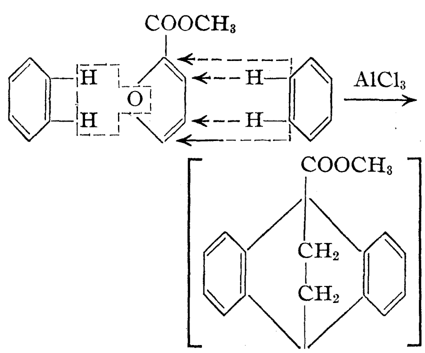
(2) Price, Chapin, Goldman, Krebs and Shafer, *ibid.*, **63**, 1857 (1941).

(3) McCorkle and Turck, *Proc. Iowa Acad. Sci.*, **43**, 205 (1936).

(4) Calloway, *Chem. Rev.*, **17**, 343 (1935).

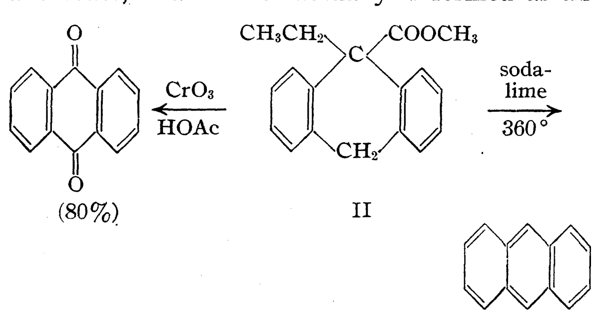


A product of this nature, containing an anthracene nucleus, had been expected on the basis of the previously reported isolation of anthraquinone from the permanganate oxidation of the crude high-molecular-weight acids from the benzene–furoic acid reaction.[2] We had anticipated, however, that its structure would be that of methyl 9,10-*endo*-ethano-9,10-dihydro-9-anthroate (III). Such a compound could be pictured as having been formed by the addition of an *o*-phenylene group across the two double bonds originally present in the furoic acid ring.



III

The crystalline ester (II) actually isolated, however, analyzed consistently for a substance with a molecular formula containing two more hydrogen atoms than the expected *endo*-ethano anthroate, III. If III actually is formed as an intermediate, its anthracene nucleus is not destroyed by the addition of these two hydrogen atoms, however, since II could be converted to anthraquinone in 80% yield by chromic acid oxidation and to anthracene in 61% yield by soda-lime distillation.



(80%) II (61%)

The apparent scission of the *endo*-ethano ring of III to give II is closely analogous to some experiments recorded by Huston and Friedeman.[5] These authors found that treatment of α-phenylethyl or α-phenylpropyl alcohols with benzene and aluminum chloride led principally to the expected product, the 1,1-diphenylalkane.

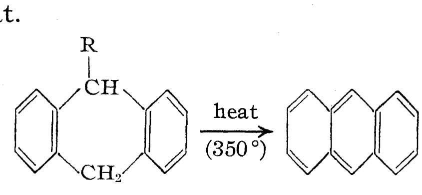
$$C_6H_5CH(OH)R + C_6H_6 \xrightarrow[10°]{AlCl_3} (C_6H_5)_2CHR$$

As the temperature of the reaction mixture was raised to 25°, increasing amounts of diphenylmethane were isolated. The authors expressed the opinion that the source of this material was the catalytic cleavage of the original condensation product.

$$(C_6H_5)_2CHR \xrightarrow{AlCl_3} (C_6H_5)_2CH_2 \text{ and } C_6H_5CH_2R$$

The analogy of this cleavage to that postulated above for conversion of III to II is very close since the two end rings of the anthracene nucleus correspond to the two phenyl groups in the 1,1-diphenylalkanes and the *endo*-ethano group of the former corresponds to the alkyl group of the latter.

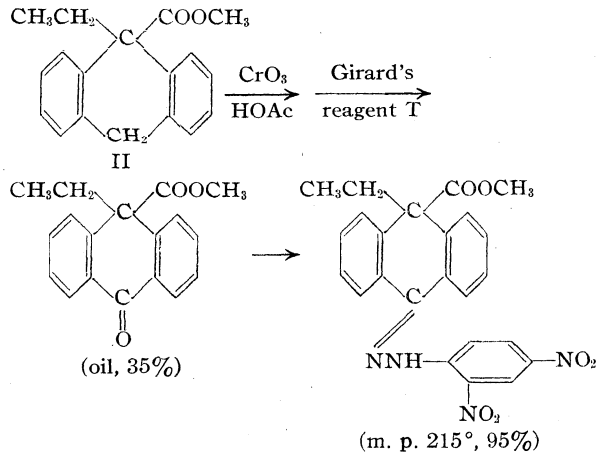
Precedent for the loss of the ethyl as well as the carboxyl group during the soda-lime distillation is to be found in some observations of Liebermann,[6] who found that several 9-alkyl-9,10-dihydroanthracenes were converted to anthracene by heat.



Cleavage of the *endo*-ethano ring to give an ethyl group in the 9-position, rather than an ethyl group in the 10-position or methyl groups in the 9- and 10-positions, follows from the ready oxidation of II to a ketone. Only the 9-ethyl derivative would contain an active methylene group necessary for this conversion.

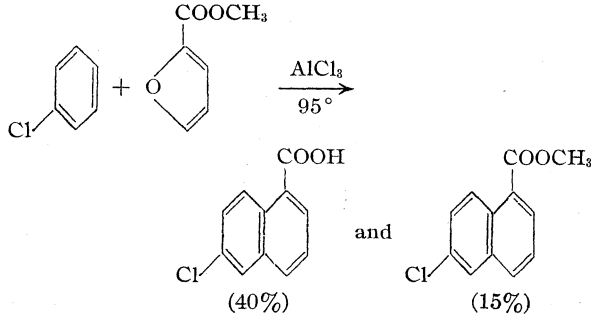
Substantiation for this location of the ethyl group may be derived from the stability of the

(5) Huston and Friedeman, THIS JOURNAL, **40**, 785 (1918).
(6) Liebermann, *Ann.*, **212**, 76 (1882).



ester (II) toward hydrolysis: even saponification in boiling diethylene glycol failed. Of the three possible modes of cleavage of the *endo*-ethano ring, that forming the 9-ethyl derivative would yield the compound with a maximum of steric hindrance to reactions of the ester group.

When the reaction of methyl furoate with chlorobenzene was carried out by exactly the same procedure as that employed for the reaction with benzene, with the exception that the condensation was carried out at 95° rather than 70°, a 40% yield of 6-chloro-1-naphthoic acid was isolated by acidification of the sodium bicarbonate wash liquor. Only a small amount of neutral product remained in the chlorobenzene layer; this consisted principally of methyl 6-chloro-1-naphthoate (15%). The reaction thus differed in two essentials from that with benzene: (1) the ester group was largely cleaved to a carboxyl group and (2) no significant amount of higher molecular weight material was formed. In this latter respect the reaction corresponds to that of furoic acid with chlorobenzene. The yield of chloronaphthoic acid from methyl furoate was nearly three times that from furoic acid.



Thus, for both benzene and chlorobenzene, condensation to form a naphthalene nucleus seems to be far more satisfactory with methyl furoate than with furoic acid.

Experimental

Methyl Furoate plus Benzene.—Methyl furoate (125 g., 1.1 mole) and 625 cc. of dry benzene (thiophene-free and dried over sodium) were cooled in an ice-bath and treated with anhydrous aluminum chloride (267 g., 2.0 moles) at 0°. After the reaction mixture had been stirred at room temperature for two hours, it was heated in an oil-bath at 70° for thirty hours. The dark red-black mixture was poured into ice and hydrochloric acid and stirred for two hours at room temperature to ensure hydrolysis of the aluminum chloride complex. The layers were separated, and the benzene solution was washed once with dilute hydrochloric acid, twice with saturated sodium bicarbonate solution and finally with water. The solution was dried over anhydrous magnesium sulfate, the benzene was removed by distillation, and 250 cc. of a dark oil was obtained. This oil was distilled under reduced pressure and two fractions were obtained: I, methyl α-naphthoate (80 g., 43%) b. p. 100–102° (0.04 mm.), $n^{20}D$ 1.6068, d^{20}_4 1.129; and II, methyl 9-ethyl-9,10-dihydro-9-anthroate, a pale yellow viscous oil (53 g., 20%) b. p. 144–145° (0.04 mm.), $n^{20}D$ 1.5931; after standing for seven months this oil finally crystallized, m. p. 52–54°.

Anal. Calcd. for $C_{18}H_{18}O_2$: C, 81.17; H, 6.80; mol. wt., 266. Found: C, 81.18; H, 6.72; mol. wt., 264, 268.

The residue could not be distilled and when the temperature of the heating bath was raised above 275° it began to decompose, making it impossible to maintain the diminished pressure.

The methyl α-naphthoate was characterized by saponification; 20 g. (0.11 mole) and 150 cc. of 25% potassium hydroxide were placed in a flask and refluxed overnight (twenty hours). The mixture was then cooled, diluted with an equal amount of water and neutralized with dilute hydrochloric acid. Seventeen and one-half grams (95%) of α-naphthoic acid was obtained, which was crystallized from 95% ethanol, m. p. 160–161°. The α-naphthoic acid was further characterized by conversion to the amide by treatment with thionyl chloride followed by ice-cold aqueous ammonia, m. p. 204–205°.

Reaction of II with Soda Lime.—Eight grams (0.03 mole) of II was placed in a distilling flask with 15 g. of soda lime. The flask was heated to slightly above 360° for three-quarters of an hour. It was then set for distillation *in vacuo* and the pressure reduced to 2 mm. An oil distilled which immediately crystallized, yielding 3.3 g. (61%) of anthracene, m. p. 211–212°. Mixed with an authentic sample of anthracene melting at 212–213° it gave a melting point of 211–212°. The hydrocarbon was further characterized by the formation of its picrate, m. p. 136–137°.

Oxidation of II to Anthraquinone.—Five grams (0.019 mole) of II was dissolved in 60 cc. of glacial acetic acid. The solution was stirred while chromic anhydride (12.5 g., 0.125 mole) dissolved in 15 cc. of water and 25 cc. of acetic acid was added slowly from a dropping funnel. It was stirred for three hours longer at room temperature and then poured into 400 cc. of ice-water. A precipitate of anthraquinone (3.2 g., 80%) was obtained. This was crystal-

lized from ethanol, m. p. 268–269°. Mixed with an authentic sample, m. p. 272–273°, it melted at 270–271°. The quinone was further characterized by preparing the derivative with phenylhydrazine, m. p. 180–181°.

Oxidation of II to the Ketone.—Six grams (0.023 mole) of II was dissolved in 75 cc. of glacial acetic acid and cooled to about 10°. The solution was stirred vigorously while 3 g. (0.031 mole) of chromic anhydride, dissolved in 10 cc. of water and 10 cc. of acetic acid, was added slowly. The cooling-bath was then removed and the reaction mixture stirred at room temperature for three-quarters of an hour. It was poured into ice-water (200 cc.) yielding an oil which was extracted with benzene. The benzene solution was washed with sodium bicarbonate solution followed by water. The solvent was evaporated leaving an oil (5.6 g., 90%). This crude ketone was purified by the use of betainehydrazide hydrochloride (Girard's reagent T). The oil was dissolved in 125 cc. of absolute ethanol, to which was added 8.4 g. (0.05 mole) of Girard's reagent T and 12 cc. of glacial acetic acid. The mixture was refluxed for one hour, cooled and poured into 900 cc. of ice-water containing enough sodium hydroxide to neutralize nine-tenths of the acetic acid. The solution was then acid to brom thymol blue indicator. The water solution was extracted three times with 125-cc. portions of benzene, then acidified with enough concentrated hydrochloric acid to make the entire solution 0.5 normal, and allowed to stand overnight. It was again extracted with benzene (250 cc. in three portions). The benzene solution was washed with sodium bicarbonate, followed by water. The benzene was evaporated, yielding 2 g. (35%) of pale, viscous oily ketone. From this material a 2,4-dinitrophenylhydrazone was prepared by refluxing in alcohol solution. Crystals began to separate in a few minutes; yield, 3.1 g. (95%). After crystallization from alcohol and ethyl acetate, the bright red crystals melted sharply at 215°.

Anal. Calcd. for $C_{24}H_{20}O_6N_4$: C, 62.60; H, 4.35; N, 12.18. Found: C, 62.72; H, 4.34; N, 12.32.

Reaction of Methyl Furoate and Chlorobenzene.—Seventy-five grams (0.6 mole) of methyl furoate dissolved in 500 cc. of chlorobenzene was cooled to 0° in an ice-bath. The solution was stirred and 162 g. (1.2 mole) of anhydrous aluminum chloride was added over a period of thirty minutes. The stirring was continued for thirty minutes at 0°, for one and one-half hours at room temperature and finally for twenty-eight hours at 90–100°. The reaction mixture was then poured into a mixture of ice and hydrochloric acid and stirred for three hours at room temperature. The mixture emulsified badly and one liter of ether was added to facilitate the separation. The ether layer was washed with dilute hydrochloric acid, with water, three times with saturated sodium bicarbonate, and finally with water. It was then dried over anhydrous magnesium sulfate and the ether removed by evaporation. The residue was placed in a modified Claisen flask and distilled; 20 g. (15%) of methyl 6-chloro-1-naphthoate was obtained, b. p. 165–170° (2 mm.).

The sodium bicarbonate extract was acidified with hydrochloric acid and 53 g. (44%) of crude 6-chloro-1-naphthoic acid was obtained. This was recrystallized once from 95% ethanol and once from benzene, yielding 46 g. (39%) of 6-chloro-1-naphthoic acid, m. p. 188–189°.

Summary

The aluminum chloride-catalyzed reaction of methyl furoate with benzene has been found to yield methyl α-naphthoate in 32–46% yield while chlorobenzene was converted to 6-chloro-1-naphthoic acid in good yield. Esterification of furoic acid thus appears to favor this condensation to a naphthalene derivative.

In addition to methyl α-naphthoate, the reaction with benzene yielded a higher boiling product in 11–20% yield. Evidence has been presented indicating that this compound is methyl 9-ethyl-9,10-dihydro-9-anthroate.

A Study of the Products Obtained from Starch by the Action of the Amylase of *Bacillus macerans*

BY W. S. MCCLENAHAN, EVELYN B. TILDEN AND C. S. HUDSON

Preliminary experiments on the conversion of potato starch to the crystalline Schardinger dextrins by *Bacillus macerans* showed that the action was produced by a new type of amylase present in bacteria-free filtrates of the cultures.[1] In this paper we wish to report precise data on the nature and extent of the changes in optical rotation,[2] viscosity and reducing action occurring during digestion of various starch samples by purified concentrates[3] of the *macerans* amylase, and to record the yields of alpha and beta dextrins obtainable. Also, the crystalline alpha and beta dextrins have been purified, their constants determined, and their stability toward *macerans* amylase studied.

When *macerans* amylase was allowed to act for one month upon a 2% suspension of potato

(2) In the preliminary publication it was reported that there was no significant change in rotation during digestion, but we now find under more exact test that the change is of considerable magnitude, as shown in Fig. 3.

(3) Tilden, Adams and Hudson, THIS JOURNAL, **64**, 1432 (1942).

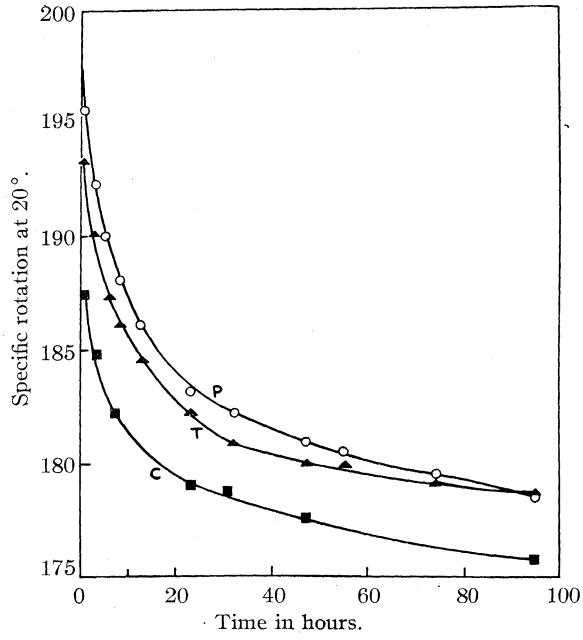

Fig. 1.—Rotatory changes in buffered digests at 20°; *p*H 6.2–6.5; enzyme concentration 10 units per gram of starch in 2% solution: P, potato starch; T, tapioca starch; C, oxidized cornstarch (hypochlorite).

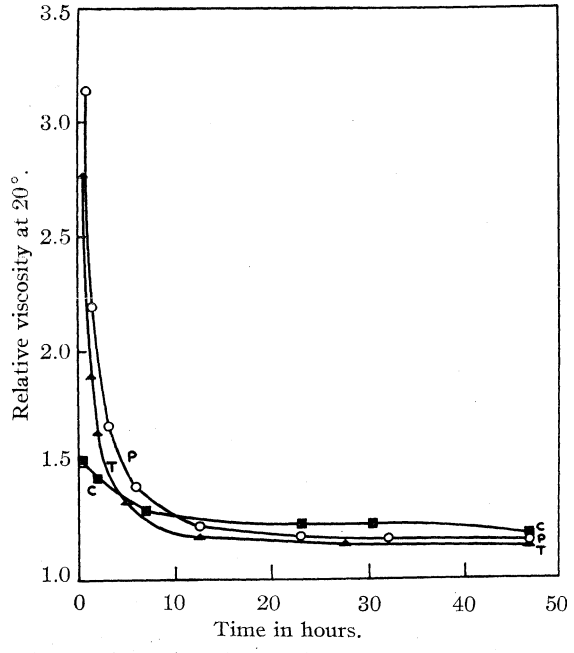

Fig. 2.—Viscosity changes in buffered digests at 20°; *p*H 6.2–6.5; enzyme concentration 10 units per gram of starch in 2% solution: P, potato starch; T, tapioca starch; C, oxidized cornstarch (hypochlorite).

starch, the reducing power[4] was only 1.6%, calculated as the percentage of the total amount of glucose available by complete acid hydrolysis of the starch; this result confirms the earlier work[1a] in showing that the *macerans* enzyme does not produce reducing sugars. Correspondingly low values for reducing power were obtained with digests of tapioca starch and with a commercial thin boiling cornstarch which had been made by the hypochlorite process.

The changes in viscosity and rotation that were observed were very similar for digests of the three starches, as shown in Figs. 1 and 2. Unoxidized defatted cornstarch has been found to give similar results.

The data obtained from digestion of several lots of potato starch, on which the enzyme was allowed to act for periods varying from eight hours to fifty days, are shown in Table I. The presence of the dextrins was demonstrated by the iodine test[1] and confirmed by precipitation of the crystalline products with trichloroethylene. Under the conditions employed the beta dextrin appeared to be formed more gradually than the alpha dextrin, the yield of which appeared to reach a maximum of 20% in the early stages of the conversion. Longer digestion resulted in a higher total yield of dextrins, but there seemed to be a decrease in yield of the crude alpha compound and a definite increase in its rotation, indicating a possible secondary action of the enzyme. This hypothesis was confirmed by experiments in which the enzyme was added to sterile solutions of pure alpha dextrin; the rotation gradually rose from +150.5°[5] to about +169°, while a slight reducing action became evident (Fig. 3 and Table II). No beta dextrin could be detected in the solution at the end of these experiments, and the new dextrin or mixture of dextrins behaved in the iodine test in a manner similar to that of the alpha compound. No effect of the enzyme on sterile solutions of pure β-dextrin was detected.

In an attempt (Digest 4, Table I) to increase the yield of crystalline dextrins, the products were continuously precipitated from solution by adding trichloroethylene soon after the addition of the enzyme, and by allowing the digest to stand for several weeks. Surprisingly, the yield of beta dextrin was thereby increased from 22 to 54%,[6]

(4) Values for reducing power were determined by the Shaffer–Hartmann micro-technique (*J. Biol. Chem.*, **45**, 365 (1921)).

(5) All rotations here reported are specific rotations at 20° for sodium light; *c* is the concentration in grams per 100 ml. of solution, and *l* is the tube length in decimeters. The crystalline dextrins contain water of crystallization, but the rotations are expressed on the anhydrous basis corresponding to their general formula $(C_6H_{10}O_5)_x$.

(6) Beta dextrin has been obtained in a yield of 46% from the action of whole cultures of *Bacillus macerans*.

TABLE I

PREPARATION OF CRYSTALLINE DEXTRINS FROM POTATO STARCH AT 20°[a]

Digest	Time, days	$[\alpha]^{20}D$	Relative viscosity	Reducing power,[b] %	Yield of dextrin, % crude	beta	alpha[c]	$[\alpha]^{20}D$ crude alpha dextrin
1	0.67	+189.8	1.49	0.05	33	9	19	+152
2	3	180.5	1.16	0.25	45	12	20	156

while the yield of alpha dextrin was reduced to 1%.[7] No increase in yield resulted from the addition of fresh enzyme to the mother liquor, hence the limit of the conversion of whole starch appears to be about 55%. No explanation can be advanced as yet for the difference in the relative proportions of the two dextrins obtained under different conditions.

The preparations of beta dextrin, obtained from starch by the action of *macerans* enzyme, were readily purified to constant rotation by recrystallization from water. The specific rotation was always +162.5 ± 0.5° instead of +158°, the value which has previously been accepted.[8] After acetylation and careful purification of the crystalline acetate, deacetylation was found to give rise to beta dextrin of the same high rotation. This was the case irrespective of whether pyridine or zinc chloride was used as the acetylation catalyst. We conclude, therefore, that the higher value is the correct one. In other respects (appearance, solubility, decomposition point, formation of orange-brown needles or prisms with iodine solution, and content of water of hydration) the dextrin was identical with preparations previously described. Alpha dextrin rotated +150.5 ± 0.5°, which is somewhat higher than the value (+148°) recorded by other workers.[9]

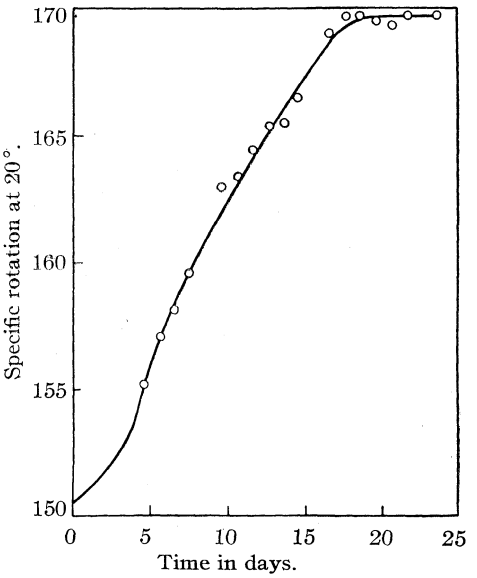

Fig. 3.—Rotatory change in a 2% solution of alpha dextrin at 20°: enzyme concentration 8 units per gram of dextrin (dry basis).

Beta dextrin acetate rotated +125.5° (chloroform); the values given by earlier workers are +121°[8h] and +142°.[9a] Its melting point was 196–196.5° (cor.), and it appears that this constant is a far better criterion of purity than is its rotation, since on several occasions a crystalline

(7) Dr. R. E. Rundle of Iowa State College has reported to us similar results, obtained through the precipitating action of benzene or toluene when used in the digests as preservatives.

product with approximately the correct rotation had a low acetyl content and softened at 140 to 150°. According to Pringsheim and his co-workers,[10] the use of zinc chloride as an acetylation catalyst brings about the depolymerization of both alpha and beta dextrins. This finding has not been confirmed by other investigators,[8e,8h,9b] and we have found no evidence of such behavior in studying beta dextrin and its acetate.[11] Our rotatory data also suggest that many of the conflicting observations with regard to the nature and behavior of these compounds may have been the result of insufficiently purified (though crystalline) materials.[12]

Experimental Part

Purification of the Enzyme.—The enzyme solution which was used had been concentrated and purified by precipitation with acetone, as previously described.[3] It contained one unit of enzyme in 0.05 ml. (1 unit = amount required to convert 30 mg. of starch in thirty minutes at 40°, as indicated by the iodine test).[1b] It had no rotation or reducing power and was free from maltase, as shown by its failure to influence the rotation of a maltose solution.

Comparative Digestions of Potato, Tapioca and Oxidized Cornstarches (Figs. 1 and 2).—The quantity of starch (commercial grade) equivalent to 2.00 g. of dry material was placed in a 100-ml. volumetric flask, and 50 ml. of water and 1 ml. of 0.2 *M* Sørensen phosphate buffer of *p*H 6.2 was added. A smooth paste was produced by swirling the flask in a boiling water-bath; the wall of the flask was then washed down with a little hot water, and the heating continued for thirty minutes. A layer of hot water was allowed to flow over the surface of the starch paste, after which the flask was plugged with cotton and the solution autoclaved for one hour at 125° (the glass stopper was sterilized at the same time). The solution was diluted with hot sterile water, and cooled to 20° overnight. There was then added sufficient enzyme (1 ml. or 20 units) to convert the starch to the brown-violet stage with iodine in about seven hours at 20°, and after dilution to 100 ml. the flask was closed with the sterile stopper and the contents thoroughly mixed. Viscosity measurements were made as described previously.[1b] Part of the digest was centrifuged to remove any traces of material which might clog the viscosity pipet; the centrifuged material was also used for measurements of rotation, while tests for reducing power[4] were made on 5-ml. aliquots. The entire experiment was carried out at 20–21°.

Preparation of Crystalline Dextrins from Potato Starch. (See Table I.)—Substrates containing 20.0 g. (dry basis) of potato starch were prepared in one-liter volumetric flasks in the above manner, except that the buffer solution was omitted. Eighty units (4 ml.) of enzyme was added to Digest 1 and 160 units to each of the others. The changes at 20° in rotation, viscosity, reducing power and appearance with iodine solution were similar to those obtained in the case of the smaller buffered digests. After sixteen hours and three days, respectively, Digests 1 and 2 were boiled for a few minutes to inactivate the enzyme, and the dextrins were precipitated with trichloroethylene. After Digest 3 had stood overnight, half of it was filtered through a Berkefeld *N* filter into a sterile flask and left undisturbed for thirty-two days. The remainder was kept in the stoppered volumetric flask, and after twenty days a portion of the clear solution gave no evidence of contamination when tested on glucose agar. The details of Digest 4 are given in the next section.

About 15 ml. of trichloroethylene was found sufficient to precipitate the crystalline dextrins in these experiments. The mixture was kept for a day at room temperature and was occasionally shaken; the precipitate was filtered on a Büchner funnel, washed with a little water, and suction applied until the precipitate was almost dry.[13] The aqueous layer of the filtrate was then concentrated *in vacuo* to about 100 ml. and treated again with trichloroethylene. A second precipitate was allowed to form at room temperature, and a third was obtained by stirring the mixture in an ice-bath and filtering after it had stood for a day in the refrigerator. Small quantities of dextrin continued to separate over a period of several weeks. The moisture content of the combined products from each experiment was determined by drying at 100° and 12 mm. to constant weight over calcium chloride. The air-dried material was then dissolved in two parts of water and the solution boiled to remove the trichloroethylene. A very small quantity of difficultly soluble material (Schardinger's "Schlamm") was removed by filtering the hot solution through carbon; crystalline beta dextrin separated on cooling the filtrate. A second crop was obtained by concentrating the mother liquor to a thin sirup, seeding, and allowing it to stand several days in the refrigerator.

The filtrate contained the more soluble alpha dextrin, together with a considerable amount of amorphous material. Methanol was added to the concentrated solution at room temperature until turbidity developed. The solution was clarified by filtering with carbon, and crystallization induced by scratching or seeding. By adding more methanol, filtering and allowing to stand, first at room temperature and then in the refrigerator, the yield could be increased; however, in order to obtain the maximum quantity of crude alpha dextrin, it was usually necessary to concentrate the mother liquor to a sirup, add methanol in the manner described, and repeat the process several times. Whenever considerable amorphous material separated, it was removed by filtration with carbon; it was then dissolved in water and the solution tested for the presence of alpha dextrin with iodine. The yields of crude dextrins are given in Table I.

(10) Pringsheim, "Chemistry of the Monosaccharides and of the Polysaccharides," McGraw-Hill Book Co., Inc., New York, N. Y., 1932, p. 280.

(11) The depolymerization theory was based to a great extent upon cryoscopic molecular weight determinations. This method has been shown in a number of instances to lead to erroneous conceptions of the molecular size of polysaccharides and their derivatives [Hanes, *New Phytologist*, **36**, 101 (1937); Klages, *Ann.*, **520**, 71 (1935); Haworth, Hirst and Ant-Wuorinen, *J. Chem. Soc.*, 2368 (1932); Freudenberg and Bruch, *Ber.*, **63**, 535 (1930); Kratky and Mark, *Fortschr. Chem. org. Naturstoffe*, **1**, 255 (1938)].

(12) Samples of alpha and beta dextrin prepared by Dr. Thomas J. Schoch of the Corn Products Refining Company showed the same rotations as our preparations.

(13) When bulky precipitates are obtained in large scale work, it is advantageous to remove the trichloroethylene by washing the filter cake with small portions of methanol.

Precipitation with Trichloroethylene during Digestion (Digest 4, Table I).—After an hour's digestion at 20°, Digest 4 was filtered through filtercel; 50 ml. of trichloroethylene was added to the filtrate, and the digestion was allowed to continue at 20°. The crystalline dextrins were removed by filtration after two, three, five and six weeks, the final crop being obtained after concentrating at low temperature to 100 ml. Three milliliters of enzyme was added to the mother liquor, but no further precipitation occurred after the solution had stood at 20° for several weeks.

Purification of the Dextrins.—The beta dextrin was recrystallized four times from four parts of water. The air-dried product rotated +139.4° (*c*, 1.0; *l*, 4). Its weight became constant after drying at 66° and 12 mm. for ninety minutes over calcium chloride; loss, 14.13%. The specific rotation was therefore +162.4°; other samples showed +163.0° and +162.8°.

Crude alpha dextrin, which contained some amorphous material, was recrystallized by adding methanol to its concentrated aqueous solution, according to the procedure given in the preceding section. Further recrystallizations were made from 70% methanol by dissolving the dextrin in one part of hot water and adding the alcohol to the warm solution. After two such recrystallizations the air-dried material rotated +136.5° (*c*, 1.1; *l*, 4). Its weight became constant after drying five hours at 100° and 12 mm.; loss, which may have been partly methanol, 9.48%. The specific rotation was therefore +150.8°; after two further recrystallizations it rotated +150.4° and +150.3°, respectively, while an entirely different preparation showed +150.8°.

Acetylation of Beta Dextrin.—Five grams of pure, anhydrous, powdered beta dextrin was dissolved in 15 ml. of pyridine, the solution becoming slightly warm. Since cooling the solution caused it to set to a gel, 15 ml. of acetic anhydride was added while it was still warm. The stoppered flask was then shaken and cooled occasionally, its contents becoming homogeneous after half an hour. After standing at room temperature for three days, the solution was poured into 400 ml. of ice water, and the product crystallized immediately in nearly theoretical yield. The acetate was recrystallized four times from seven parts of methanol, from which it separated in the form of elongated, hexagonal plates. It could not be recrystallized satisfactorily from absolute ethyl alcohol, possibly because a partial deacetylation occurred. It melted at 196–196.5° (cor.). The rotation and analytical data were obtained from a portion which had been dried *in vacuo* to remove the methanol and then allowed to stand overnight in the air. This sample rotated +122.3° (*c*, 1.0, chloroform; *l*, 4); its loss in weight after forty-five minutes at 66° and 12 mm. was 2.20%, and hence the specific rotation was +125.0°. A second preparation rotated +125.4°. The dry acetate was extremely hygroscopic, and in order to determine its moisture content accurately it was necessary to employ a modified Abderhalden drying apparatus.[14]

Anal. Calcd. for $(C_{12}H_{16}O_8)_x$: C, 49.99; H, 5.60; CH_3CO, 44.79. Found: C, 50.04; H, 5.86; CH_3CO, 45.85.

(14) Milner and Sherman, *Ind. Eng. Chem., Anal. Ed.*, **8**, 427 (1936).

Four grams of the acetate in 50 ml. of methanol was deacetylated in the cold with 4 g. of potassium hydroxide dissolved in 25 ml. of methanol. The resulting precipitate was dissolved in water, and, after neutralization of the solution with dilute acetic acid, the beta dextrin began to crystallize. The recovery was 92% of the theoretical amount. After two recrystallizations from water, the dextrin rotated +162.9°.

Four grams of dry powdered beta dextrin and 0.5 g. of pulverized zinc chloride were added to 20 ml. of acetic anhydride, and the mixture was heated on the steam-bath for one hour. The hot, faintly yellow solution was poured into a liter of ice-water, and the acetate began to solidify after a few minutes of stirring. The acid was neutralized with sodium bicarbonate, and the product obtained in nearly theoretical yield. After recrystallization the acetate melted at 196–196.5° (cor.). The air-dried sample contained 2.06% moisture and rotated +123.8° (*c*, 1.0; *l*, 4), or +126.3° calculated to the dry basis.

Anal. Calcd. for $(C_{12}H_{16}O_8)_x$: C, 49.99; H, 5.60; CH_3CO, 44.79. Found: C, 50.10; H, 5.96; CH_3CO, 45.62.

A three-gram portion of the acetate was deacetylated. The dextrin was recovered quantitatively, and after two recrystallizations from water it rotated +163.0°.

Action of *macerans* Enzyme on the Crystalline Dextrins.—One-gram samples of the pure, air-dried dextrins were dissolved in hot water in 50 or 100 ml. volumetric flasks. Alpha dextrin solutions were heated fifteen minutes on the steam-bath to remove possible traces of methanol before autoclaving for thirty minutes at 124°; beta dextrin solutions were autoclaved directly. After the flasks had been cooled to 20°, the enzyme was added, and the solutions were diluted to 50 ml. with sterile water. The small amount of beta dextrin which separated after a few days was redissolved by warming to 40° before the flasks were opened. Sterility tests were made on glucose agar at the conclusion of each experiment. The data obtained in several experiments with both dextrins are presented in Table II, while the changes in rotation observed in one non-sterile experiment are shown in Fig. 3.

During the conversion of alpha dextrin the solutions gave iodine tests similar to that of the original substance. The product could be precipitated with trichloroethylene, but no beta dextrin was obtained when the solution was concentrated *in vacuo* to a sirup. Addition of methanol to the solution caused it to cloud, and a mixture of amorphous and crystalline material gradually separated. Methods for fractionating the mixture are being investigated.

The authors wish to express their appreciation to Dr. Thomas J. Schoch of the Corn Products Refining Company for samples of oxidized starch and Schardinger dextrins, and to Dr. E. Justin Wilson, Jr., of this Laboratory for helpful assistance.

Summary

The action of the purified enzyme of *Bacillus macerans* on starch substrates proceeds with a

rapid decrease in viscosity and a gradual decrease in optical rotation. Unlike other amylases, the *macerans* amylase does not increase the reducing power of whole starch to any noteworthy extent.

The Schardinger dextrins have been prepared from potato starch by means of the *macerans* amylase in a maximum yield of 55%. The relative proportions of alpha and beta dextrins in the product have been shown to vary greatly with different digestion conditions; the factors involved in this behavior are receiving further study. Beta dextrin is stable toward *macerans* amylase at 20°, whereas the alpha dextrin is converted, at least in part, to higher rotating material which exhibits slight reducing properties and contains no beta dextrin.

The rotations of carefully purified alpha and beta dextrins have been found to be +150.5 ± 0.5° and +162.5 ± 0.5°, respectively, instead of +148° and +158°, as previously reported. The new value for beta dextrin was confirmed by preparing its acetate (rotation +125.5° in chloroform; m. p. 196–196.5° (cor.)), from which the original high rotating beta dextrin was regenerated. The same beta dextrin acetate was produced when either pyridine or zinc chloride was used as the acetylation catalyst.

The Nature of the Fatty Acids Associated with Starch. The Adsorption of Palmitic Acid by Potato and Defatted Corn and Rice Starches

BY LEO LEHRMAN

It is well known that starches, with the exception of potato, have associated with them small amounts of fatty material which is not extracted by the usual fat solvents, such as ether or carbon tetrachloride.[1] Acid hydrolysis is usually employed to liberate this fatty material, which is therefore termed "fat by hydrolysis" to distinguish it from the fatty material which can be extracted by ether or carbon tetrachloride. The fatty material that can be extracted from raw starches by ether or carbon tetrachloride is usually referred to as extraneous extractable fatty matter. Recently Schoch reported that fat solvents having hydrophilic groups, particularly methanol, the cellosolves and 80% dioxane, extract practically all the fatty acids in three cereal starches.[2] He further reported that the defatted starches retain a number of the usual properties of the original starches. In addition, fatty acid can be introduced into the defatted starches and cannot be removed by extraction with the usual fat solvents, such as ether or carbon tetrachloride. On the basis of these results, Schoch concluded that free fatty acid is present in starch as an extraneous impurity.

This author submitted a comment which stated his reasons for disagreeing with this conclusion and suggested the possibility of the fatty acids being adsorbed by starch.[3] Lately, it has been shown that the amount of fatty material extracted by methanol from corn starch ground in a rod mill is the same as that extracted from the unground corn starch. From this observation the conclusion has been drawn that the fatty acids are not present extraneously.[4] Adsorption has been mentioned in connection with the occurrence of fatty acids in starch but the evidence is meager.[5]

Potato starch has been shown not to contain any "fat by hydrolysis"[6] and, therefore, could be used like a defatted starch. Oleic acid was introduced into potato starch, though only in a small percentage, by refluxing with a methanol solution of the fatty acid.[7] In order to determine how a fatty acid combines with starch, varying concentrations of palmitic acid in a hydrophilic solvent (methanol) were refluxed with potato starch. Palmitic acid was chosen because it occurs in the "fat by hydrolysis" of all starches; it is saturated and, therefore, no special precautions are neces-

sary to prevent oxidation; and finally, it is taken up by corn starch in preference to unsaturated fatty acids.[8] After removing the excess palmitic acid by extraction with carbon tetrachloride, the "fat by hydrolysis" was determined.

A graph of the results of these experiments is a typical Freundlich isotherm indicating that the palmitic acid was probably adsorbed by the potato starch. The experimental work was carried out with defatted corn and rice starches to determine whether a similar Freundlich isotherm would be obtained.

Experimental

Preparation of Defatted Corn and Rice Starch.—Corn and rice starch[9] having negligible extraneous fatty material and 0.65 and 0.69% "fat by hydrolysis," respectively, were extracted in a Soxhlet extractor with methanol for two weeks. Though the "fat by hydrolysis" in each starch had decreased to 0.03%, further extraction had no effect. This result agrees with that found by others.[10] That the methanol extraction of the fat from the starches cannot be due to hydrolysis has already been shown.[11]

Introduction of Palmitic Acid into the Fat-Free Starches.—Ten-gram samples of potato (negligible extraneous fat) and defatted corn and rice starches separately, were refluxed while stirring with 1–20 g. of pure palmitic acid dissolved in 50 ml. of pure methanol for five hours. It was found that longer heating did not increase the amount of palmitic acid taken up by the starches. The mixtures were filtered, the residues washed with carbon tetrachloride and allowed to dry. The residues then were extracted for three hours with hot carbon tetrachloride in a rubber extractor and allowed to dry. The dry starch products were hydrolyzed with dilute hydrochloric acid, cooled, filtered through petroleum ether extracted filter papers, the papers and fatty acids washed several times with distilled water and allowed to dry. The filter papers and fatty acids then were extracted with petroleum ether, the extracts allowed to evaporate in weighed beakers and the residues weighed. Figure 1 is the graph obtained by plotting these values.

Discussion

The fact that the palmitic acid taken up by the starches follows a typical Freundlich isotherm indicates either adsorption or solid solution. While X-ray diffraction patterns would be necessary to decide which phenomenon took place, from the generally accepted amorphous state of starch, adsorption is the more probable. It has already been noted that defatted starches have a number

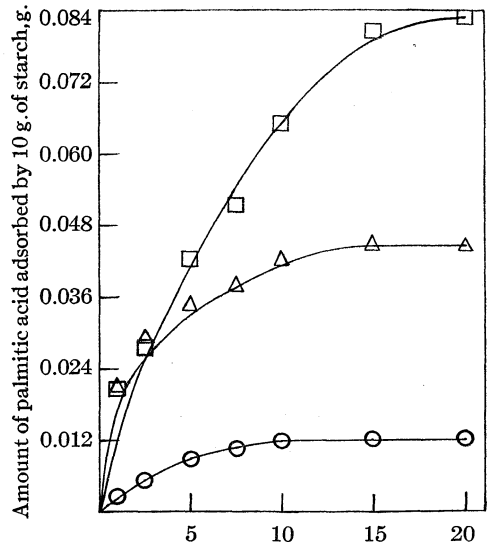

Fig. 1.—Adsorption isotherms of palmitic acid with potato and defatted corn and rice starches; O , potato starch; △, defatted corn starch; □, defatted rice starch.

of the usual physical properties of the original starches. This is to be expected if the fatty acids are adsorbed on the starch. The fact that a starch component is electrically charged only when it contains fatty acid (fat by hydrolysis)[12] can be accounted for on the basis of an adsorption of the fatty acid. There would be no electrical charge if the fatty acid were chemically combined with carbohydrate (such as by esterification or etherification). It is interesting to note that potato starch, which has no fatty acid associated with it, has practically no charged component.[13]

The amount of fatty acid taken up by each starch gives additional weight to the case for adsorption. Thus, potato starch, known to have no fatty acid, adsorbs only a very small amount of palmitic acid compared with defatted corn and rice starches. Furthermore, defatted rice starch, which in its original condition has a higher percentage of "fat by hydrolysis" than corn starch, adsorbs more palmitic acid than defatted corn starch.

It has already been shown that corn starch takes up (adsorbs) saturated fatty acid in preference to unsaturated fatty acid.[8] It is difficult to explain on this basis, however, why defatted corn starch adsorbs less than its original fatty acid content, while defatted rice starch adsorbs more, or that potato even adsorbs any. It does show that these

three starches are different in their surface effects.

All these data are consistent with the conclusion that the fatty acids associated with starch are adsorbed.

Summary

1. Potato and defatted corn and rice starches take up palmitic acid from a methanol solution probably by adsorption.

2. A discussion of known facts leads to the conclusion that fatty acids associated with starch are probably adsorbed.

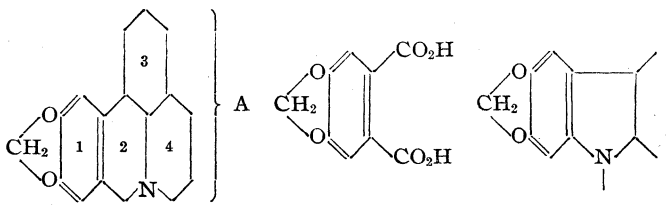
Erythrina Alkaloids. XIII. Studies on the Constitution of Erythraline, Erythramine, and Erythratine

BY KARL FOLKERS, FRANK KONIUSZY AND JOHN SHAVEL, JR.

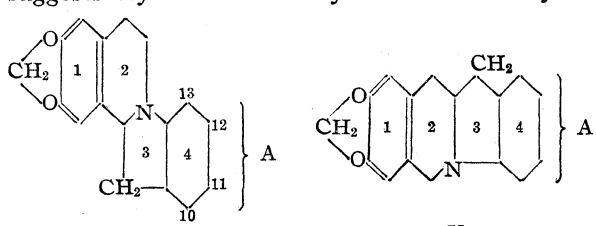
Studies[1] on the constitution of erythramine and erythraline led to the formulation of the partial structure I with the comment that the presence of one five-atom nucleus was not excluded. The initial studies[2] showed that erythramine, $C_{18}H_{21}NO_3$, contains a methylenedioxy group, a methoxyl group, a tertiary nitrogen atom probably common to two nuclei, and an ethylenic double bond, besides one aromatic nucleus. It consists apparently of four nuclei (exclusive of the methylenedioxy bridge), three being partially or completely saturated and one aromatic. Erythraline, $C_{18}H_{19}NO_3$, differs only in having one more ethylenic double bond since dihydroerythramine and tetrahydroerythraline were found to be identical when the free bases and hydriodides were compared. Ring 1 of the partial structure was established by the formation of hydrastic acid (II) by oxidation of erythraline methohydroxide; and rings 1 and 2 were strongly indicated by the very close similarity between the ultraviolet absorption spectra of dihydroerythramine and 6,7-methylenedioxy-1,2,3,4-tetrahydroisoquinoline hydrobromides. The hydroindole formulation (III) which might be anticipated because of the accompanying hypaphorine, which is so widely distributed in seeds of species of *Erythrina*, was excluded by the formation of hydrastic acid. Rings 3 and 4 were indicated tentatively because of the tertiary nitrogen atom. It was of interest that these two alkaloids and lycorine and tazettine, of the *Lycoris* alkaloids, possess methoxyl and hydroxyl groups on hydroaromatic nuclei of structures identical for rings 1 and 2.



A = CH_3O— and one double bond for erythramine
A = CH_3O— and two double bonds for erythraline

I II III

Recently,[3] new structural studies were presented including experiments performed on β-erythroidine, which led to the isolation of indole from the products of potassium hydroxide fusion. Although β-erythroidine appears to differ considerably from erythraline and erythratine in functional groups and nuclear formulation, it was of interest to examine the products from the fusion of erythraline with potassium hydroxide for the presence of indole. By a modified procedure which involved adding erythraline hydriodide in portions to the molten alkali, pure indole picrate, identical with an authentic specimen, was obtained by appropriate technique. Interpretation of the indole formation suggests erythraline and erythramine actually do



IV V

contain one five-atom nucleus, and rings 3 and 4 may be written now as in the C_{16} four-ring structures, IV or V.

Erythratine,[4] $C_{18}H_{21}NO_4$, has now been found to possess one methylenedioxy group, one methoxyl group and one non-phenolic hydroxyl group. It does not contain $CH_3C\equiv$ or $CH_3N\equiv$ groups. The presence of the non-phenolic hydroxyl group was shown by active hydrogen determination, insolubility in sodium hydroxide solution, and formation of benzoyl and acetyl derivatives. Erythratine is a tertiary base, as evidenced by the formation of a methiodide and methohydroxide of expected properties. Erythratine absorbed one mole of hydrogen over a platinum catalyst at atmospheric pressure to give a dihydroerythratine.

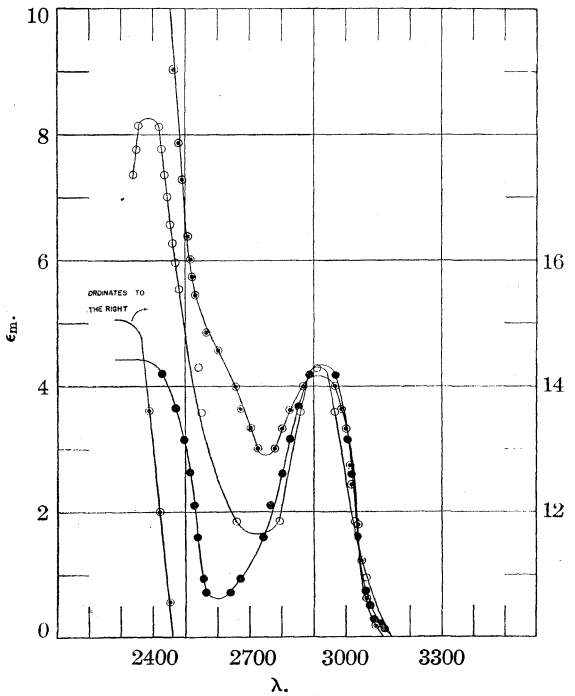

Fig. 1.—Absorption spectra in ethanol for: ●, erythratine; ○, erythramine; ◉, erythraline (note for erythraline that the ordinates are indicated on the right for ϵ_m 10–16). Absorptions are represented in terms of the extinction coefficient computed on the basis of one millimole per liter; wave lengths, in Ångström units.

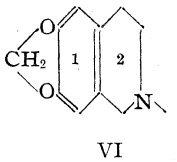
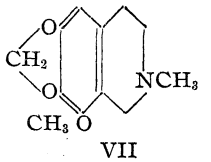
It is seen from the ultraviolet absorption spectra data[5] in Figs. 1 and 2 that erythratine and dihydroerythratine hydrobromide exhibit a maximum at *ca.* 2930 Å. and ϵ_m 4.3 to 4.8, as is also exhibited by erythramine, erythraline, dihydroerythramine hydrobromide and 6,7-methylenedioxy-1,2,3,4-tetrahydroisoquinoline hydrobromide. It has been assumed that this band is characteristic of the partial nucleus VI, and it differs considerably from the corresponding band of the spectrum of hydrocotarnine (VII), shown in Fig. 2, which has



VI



VII

a methoxyl group in addition to the methylenedioxy group on the benzenoid nucleus. The spectra as shown in Fig. 1 for erythratine, erythraline and erythramine differ at wave lengths below *ca.* 2900 Å. probably chiefly in accord with the different double bonds and oxygen groups in rings 3 and 4 for the three alkaloids. The absorption of dihydroerythramine and dihydroerythratine parallels that of the known methylenedioxy-tetrahydroisoquinoline derivative as shown in Fig. 2.

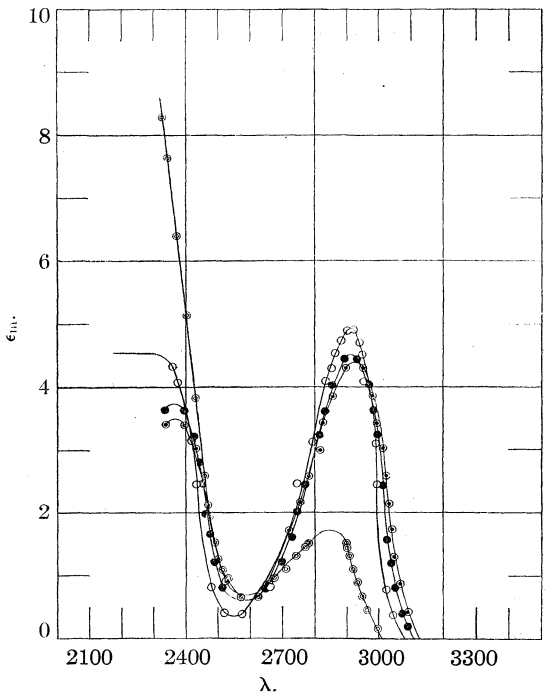


Fig. 2.—Absorption spectra in ethanol for: ○, dihydroerythratine hydrobromide; ●, dihydroerythramine hydrobromide; ◉, 6,7-methylenedioxy-1,2,3,4-tetrahydroisoquinoline hydrobromide; hydrocotarnine represented by curve with concentric circles.

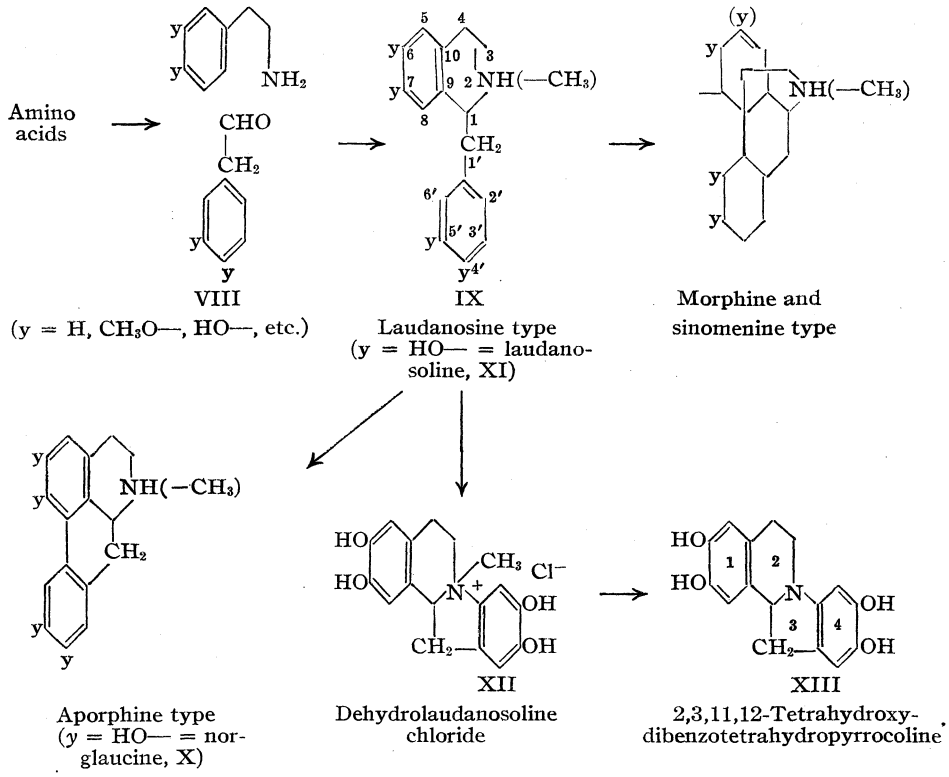
This behavior indicates that the remainder of the alkaloidal structures is not influencing the absorption spectrum of these compounds to any pronounced degree. Thus, erythratine also appears

(4) Folkers and Koniuszy, THIS JOURNAL, **62**, 436 (1940).

(5) Acknowledgment is hereby made to Mr. W. A. Bastedo, Jr., of this Laboratory for the measurements of the absorption spectra.



to contain the methylenedioxy-tetrahydroisoquinoline nucleus (VI) and the methoxyl and hydroxyl groups elsewhere. Taking into account the benzenoid nucleus, one ethylenic double bond, and the functional groups in erythratine, the molecule consists apparently of four fused nuclei (exclusive of the methylenedioxy bridge), three being partially or completely saturated and one being aromatic.

When erythratine was degraded by fusion with potassium hydroxide, and after purification chromatographically of the solvent fraction bases over aluminum oxide, indole was isolated and identified as such and as its picrate. When all these related facts on erythramine, erythraline and erythratine are considered, it appears that erythratine is also represented by structure IV or V when A signifies a methoxyl and hydroxyl group and one carbon–carbon double bond.

Structure IV, rather than V, would be preferred for these alkaloids on the basis of several biogenetical relationships. The nuclei 1, 2 and 4 of IV are inherently a benzyl-tetrahydroisoquinoline derivative dehydrogenated between nuclei 2 and 4 to give the fourth nucleus 3, as may be seen from the following relationships. The generally accepted origin of benzyl-tetrahydroisoquinoline alkaloids (IX) from substituted phenylethyl amines and phenylacetaldehydes (VIII) both *via* amino acids, proposed from the studies of Winterstein and Trier, Barger,[6] and Robinson[7] is shown in the scheme according to VIII → IX. Dehydrogenation with ring closure between atoms 8 and 2′ of IX leads to the aporphine type of alkaloid. Dehydrogenation with ring closure between atoms 10 and 6′ leads to the morphine and simomenine type of alkaloid. Although this formal relationship between the benzylisoquinoline type and the aporphine and morphine types has not been achieved experimentally as yet by oxidative or dehydrogenative reagents, such studies have been made.[8] Of particular interest to these three *Erythrina* alkaloids are the experiments of both Robinson[9] and Schöpf[10] to convert laudanosoline (XI) into norglaucine (X) or to convert directly a benzylisoquinoline type into an aporphine type. The product of several reagents (chloranil, potassium ferricyanide, air, and oxygen over platinum) on XI was dehydrolaudanosoline chloride (XII) which is a quaternary dihydroindole deriva-

(10) Schöpf and Thierfelder, *Ann.*, **497**, 22 (1932).

tive. Instead of effecting ring closure between atoms 8 and 2′, the closure took place between atoms 2 and 2′. Reaction in boiling acetic anhydride converted XII into the tetraacetyl derivative of the pyrrocoline derivative, XIII. Proof of structure XII was established through Hofmann and Emde degradations.

If structure IV represents these three *Erythrina* alkaloids, then Robinson and Schöpf, failing to convert a benzylisoquinoline type directly into an aporphine type, have achieved its conversion into an *Erythrina* type *before* natural alkaloids of this hydropyrrocoline class were recognized!

The methoxyl group of erythramine and erythraline is probably at position 12, on the basis of tyrosine as the precursor.[6] Similarly, the methoxyl and hydroxyl groups of erythratine are probably at positions 11 and 12, as in XIII, although positions 12 and 13 are possible.[6] The ethylenic double bonds in structure IV appear to be in ring 4 and not 3, because the pure alkaloids do not show the Ehrlich color test for indole derivatives. Of course, the pyrrocoline derivative, XIII, and these *Erythrina* alkaloids, if so related, would show some different properties because the natural products are partially saturated in ring 4. Nevertheless, the tetramethyl ether of XIII gave a weak blue color with Ehrlich's reagent, whereas its dehydro (ring 3) derivative gave an intense indole reaction, and an aged specimen of erythratine (better for comparison because it has two oxygen atoms on ring 4 to enhance reactivity) gave a blue color at 25° and a strong royal blue color at 90°. A new specimen of erythratine gave only a slight positive test; presumably, the aged specimen had undergone slight atmospheric oxidation in ring 3. A solution of erythraline with Ehrlich's reagent slowly developed a deep pink color.

Whereas the threshold dose of erythratine hydrobromide for curare-like paralyzation of frogs was 75 mg./kg. injected intralymphatically,[11] the threshold dose of erythratine methiodide was found by Dr. Klaus Unna of the Merck Institute for Therapeutic Research to be 100 mg./kg. frog. As for erythramine and erythraline and their respective methiodides,[1,2] the conversion of the tertiary base, erythratine, into its quaternary methiodide did not enhance its curare-like physiological activity. The threshold dose of dihydroerythratine hydrobromide was 300 mg./kg., but the frogs did not recover.

(11) Folkers and Koniuszy, THIS JOURNAL, **62**, 436 (1940).

Experimental Part

Indole from the Fusion of Erythraline with Potassium Hydroxide.—When 1.07 g. of erythraline hydriodide was ground with 25 g. of potassium hydroxide and fused, only 9 mg. of residue was obtained from the solvent extraction. It gave the color test for indole. It appeared by this procedure[12] that partially decomposed alkaloid floated as a film on the molten alkali during the fusion and the degradation was not satisfactory. After a second similar fusion, on 1.2 g. of erythraline base, only a few mg. of an impure picrate was obtained. Successful characterization of indole was accomplished only after fusion of larger quantities by the following modified procedure.

When 4.28 g. of pure erythraline hydriodide (from *E. glauca* Willd.) was added slowly to 30 g. of well-stirred molten potassium hydroxide, a vigorous reaction ensued with each addition of alkaloid. After all of it had been added, the homogeneous melt was heated for another ten minutes to insure complete reaction. The melt was then carefully poured on 200 g. of ice, and the resulting solution extracted continuously with ether for ten hours.

The ether extract was concentrated carefully to a volume of about 5 ml. by distillation through a Widmer column. The residual ether solution was then concentrated to a moist residue by distillation at 10° at a somewhat reduced pressure. The residue had an indole odor and gave the pink color test with *p*-dimethylaminobenzaldehyde. The picrate (23 mg.) made from this residue showed the m. p. 166.5–168°. After two recrystallizations from benzene in a centrifuge cone, 12 mg. of red indole picrate, m. p. 172–172.5°, was obtained. A mixed melting point with freshly prepared authentic indole picrate, m. p. 172–172.5°, showed no depression of the melting point.

Extraction of the acidified aqueous solution by ether and chloroform yielded residues too small for the isolation of other degradation products.

Indole from the Fusion of Erythratine with Potassium Hydroxide.—A quantity of 8.27 g. of erythratine (newly isolated from *E. glauca* Willd.) was slowly added to 50 g. of well-stirred molten potassium hydroxide. The reaction was quite vigorous, and the melt was heated for another ten minutes, in which time it started to froth considerably. The melt was then carefully poured on 300 g. of ice, and the resulting alkaline solution was extracted continuously with ether for ten hours.

The ether extract was concentrated to a small volume by careful distillation through a Widmer column to minimize the loss of the volatile indole. The residual ether solution was concentrated to a gummy moist residue at 10° at a somewhat reduced pressure.

The residue was dissolved in 5 ml. of ethyl ether and passed over a 1 × 3 cm. column of aluminum oxide Merck (Brockmann). A 2-mm. band of brown decomposition products appeared at the top, while the solution passing through was colorless. The column was developed further with 25 ml. of ether.

To the eluate was added 5 ml. of petroleum ether and after partial concentration on the steam-bath, 163 mg. of crystals of m. p. 52° was obtained. Besides the identity of the melting point with that of indole, they gave with *p*-

(12) Barger and Scholz, *Helv. Chim. Acta*, **16**, 1352 (1933).

dimethylaminobenzaldehyde the pink color reaction characteristic for indole.

Anal. Calcd. for C_8H_7N: C, 82.04; H, 6.02. Found: C, 81.83, 81.86; H, 6.08, 6.09.

On converting a portion of the crystals to the picrate, red needle-like crystals were obtained, m. p. 172–173°. These crystals were mixed with freshly prepared indole picrate (m. p. 172–172.5°) and there was no melting point depression.

Further extractions with ether and chloroform of the original aqueous solution, after acidification, yielded very small residues, which did not satisfactorily permit the isolation of other degradation products.

The Oxygen Atoms of Erythratine.—A Friedrich determination on the hydriodide showed 6.78% —OCH_3 group and no =NCH_3 group; calcd. for one —OCH_3 group, 6.98%. When compared with erythramine and hydrastine, erythratine gave a positive result when tested for the presence of a methylenedioxy group.[13] Erythratine was insoluble in 10% sodium hydroxide solution at 25°. A 117.2 mg. quantity of the base was dissolved in 4 ml. of ethanol, treated with 10 ml. of 10% sodium hydroxide solution, and the mixture was refluxed four hours. Crystals separated on cooling and, by chloroform extraction, a total of 94% of the erythratine was recovered. An active hydrogen determination gave 1.23 to 1.35 active hydrogen atoms for the erythratine hemihydrate base. It is apparent that the fourth oxygen atom exists as a non-phenolic hydroxyl group.

Erythratine does not contain a $CH_3C\equiv$ group as shown by a Kuhn–Roth determination.

O-Benzoyl-erythratine Dihydrate.—To 10 ml. of dry pyridine was added 90 mg. of erythratine and 4 drops of redistilled benzoyl chloride. The solution was refluxed for five minutes and the straw-colored liquid was then poured into 100 ml. of ice and water. A white precipitate and a few oil globules appeared. The oil globules disappeared on the addition of 250 mg. of sodium bicarbonate, but most of the precipitate remained, even after vigorous shaking. Extraction of the mixture by six 25-ml. portions of chloroform dissolved all of the precipitate and concentration of the extracts to dryness *in vacuo* left 104 mg. of transparent gum. The addition of 3 ml. of water caused a partial transformation into a white amorphous solid. A total of 50 ml. of a mixture of ethyl ether and acetone was required to dissolve the solid and gum. The solvent solution was concentrated to 4 ml. which caused immediate crystallization of brown colored needles. They were filtered and washed once with 2 ml. of absolute ethanol; the brown crystals immediately dissolved, leaving 63 mg. of brilliant white needles of m. p. 247–249° (decomp.). These crystals were recrystallized twice from hot absolute ethanol (not very soluble) but the melting point remained at 248–249° (decomp.). A sample was dried for one hour at 100° *in vacuo*, then analyzed. The melting point did not change. The O-benzoyl-erythratine was a dihydrate.

Anal. Calcd. for $C_{25}H_{25}NO_5$: C, 71.65; H, 6.01; N, 3.33. Calcd. for $C_{25}H_{25}NO_5 \cdot 2H_2O$: C, 65.98; H, 6.42; N, 3.07. Found: C, 65.66; H, 6.30; N, 3.22.

O-Acetyl-erythratine.—A 500-mg. quantity of erythratine base was dissolved in 5 ml. of acetic anhydride. After the solution was refluxed ten minutes, it was poured into 100 ml. of ice and water. The solution was made alkaline with sodium bicarbonate and extracted ten times with chloroform, etc. A yield of 503 mg. of pale yellow gum was obtained which was quite soluble in ether and did not crystallize. It was sublimed at 125° and 10^{-4} mm. The sublimate was a white brittle solid which softened at 43 and melted at 55°. In another experiment, the sublimate was resublimed to give a crystalline product melting at 128°. Since the analyses on these products were not entirely satisfactory, the reaction was repeated on larger scale for better purification of the product.

A solution of 2 g. of erythratine in 25 ml. of acetic anhydride was refluxed for twenty minutes, cooled, and poured into 250 ml. of ice and water. Shaking of this mixture caused disappearance of the excess acetic anhydride, and after making the solution alkaline with sodium bicarbonate, it was extracted with ten 25-ml. portions of chloroform. Distillation of the solvent and pumping *in vacuo* left 2.1 g. of acetylated erythratine as a clear gum. Although this erythratine problem was suspended for two years, the acetylated product remained unchanged in physical appearance. It was then sublimed twice at 10^{-4} mm. and 130°. The sublimate was crystalline, m. p. 128–129°.

Anal. Calcd. for $C_{20}H_{23}NO_5$: C, 65.88; H, 6.35; N, 3.92; CH_3CO—, 11.80. Found: C, 66.04; H, 6.35; N, 3.88; CH_3CO—, 12.08 (alkaline hydrolysis), 11.79 (Kuhn–Roth $CH_3C\equiv$ determination).

The check acetyl determination by the Kuhn–Roth method for $CH_3C\equiv$ groups was done to be sure that the product was not an N-acetyl-O-acetyl-erythratine. An N-acetyl group would be expected to be more resistant to hydrolysis, if the formation of one had resulted from a nitrogen ring cleavage in boiling acetic anhydride, as has been observed for the conversion of chelidonine into N-acetyl-anhydrochelidonine.[14,15]

Hydrolysis of O-Acetyl-erythratine.—The following hydrolysis of the O-acetyl derivative to erythratine confirms the absence of nuclear change in the acetylation reaction. A solution of 25 mg. of O-acetyl-erythratine in 4 ml. of 95% ethanol and 10 ml. of 4% hydrochloric acid was refluxed four hours. After diluting to 50 ml. with water, extracting with six 20-ml. portions of chloroform, and the solvent removal, 9.3 mg. of gum was obtained. Addition of one drop of ether caused crystallization; m. p. 170–171°, $(\alpha)_D$ +145°. Addition of sodium bicarbonate and chloroform extraction eventually yielded 12.8 mg. of gum, which crystallized on adding a drop of ether; m. p. 169–170°, $(\alpha)_D$ +145°. Thus, erythratine was recovered, and its extraction from an acid solution is indicative of its low basicity.

Erythratine Methiodide.—A 50-mg. quantity of erythratine ($(\alpha)^{25}_D$ +146.0) was dissolved in 25 ml. of anhydrous ethyl ether and treated with 0.5 ml. of redistilled methyl iodide. The clear liquid became progressively turbid, but no crystals were immediately apparent. The turbid solution was allowed to stand overnight at 25°. This resulted in tiny white crystals that appeared somewhat amorphous; m. p. 121–125°, $(\alpha)^{25}_D$ +109.7, C, 0.164, water.

Anal. Calcd. for $C_{18}H_{21}NO_4 \cdot CH_3I \cdot {}^1/_2H_2O$: C, 48.96; H, 5.40. Found: C, 48.85; H, 5.36.

After drying for two hours at 100° *in vacuo*, the methiodide was fairly well dehydrated; m. p. 135–136°, $(\alpha)_D$ +110.4.

Anal. Calcd. for $C_{18}H_{21}NO_4 \cdot CH_3I$: C, 49.94; H, 5.29. Found: C, 49.56; H, 5.39.

Further drying with heat initiated slight decomposition.

N-Methyl-erythratine Methine.—A solution of 174 mg. of erythratine methiodide in 20 ml. of water was treated with 500 mg. of silver oxide and the mixture was shaken for three hours at 25°, then filtered. The filtrate gave a negative halogen test, and yielded only 1.8 mg. of chloroform-soluble material when extracted five times. The aqueous erythratine methohydroxide solution was concentrated to dryness at 35° and 20 mm. *in vacuo*, then dried for two hours at 35° and 2 mm. The yield of quaternary base was 135 mg. On heating *in vacuo* in an oil-bath at 150°, rapid effervescence occurred. The bubbling stopped after two minutes, but the heating was continued for another two minutes. The methine was shaken with 25 ml. of water for fifteen minutes, but nothing apparently dissolved. When 5 ml. of chloroform was added, all the methine went into the chloroform layer. Concentration of the chloroform solution to dryness yielded 103.2 mg. of methine that could not be crystallized. Sublimation at 2.5×10^{-4} mm. vacuum and a temperature of 110–125° gave a transparent brittle sublimate.

Anal. Calcd. for $C_{19}H_{23}NO_4$: C, 69.29; H, 7.03. Found: C, 68.96; H, 6.75.

Zn Dust Distillation of N-Methyl-erythraline Methine.—A distillation at 500–560° of 400 mg. N-methyl-erythraline-methine mixed with 40 g. of zinc dust yielded a yellow oil. It was completely soluble in 10% hydrochloric acid solution, and concentration of this solution yielded 91 mg. of gummy hydrochloride which could not be crystallized. From this material, 69 mg. of free base was obtained as a yellow gum which likewise could not be crystallized.

Dihydroerythratine Hydrobromide.—A quantity of 494 mg. of pure erythratine hemihydrate was dissolved in 25 ml. of water containing 1 ml. of 40% hydrobromic acid solution. The hydrogenation was performed over 75 mg. of Adams platinum catalyst and at atmospheric pressure. After two hours, one mole of hydrogen was absorbed. The filtrate was concentrated to dryness at 30° and 18 mm. The residue was dissolved in 5 ml. of absolute ethanol and brought to the crystallization point with 5 ml. of ether. After fifteen hours at 10°, 291.1 mg. of pinkish crystals was obtained. Recrystallization did not alter the melting point of 249°. A sample was dried at 100° and 2 mm. for one hour before analysis.

Anal. Calcd. for $C_{18}H_{23}NO_4 \cdot HBr$: C, 54.31; H, 6.07. Found: C, 54.10; H, 6.06.

After standing at 25° for two to three days, decomposition had taken place.

Acknowledgment.—We wish to express our appreciation to Messrs. Hayman, Reiss, Clark and Boos for the microanalyses.

Summary

Erythraline ($C_{18}H_{19}NO_3$), erythramine ($C_{18}H_{21}NO_3$), and erythratine ($C_{18}H_{21}NO_4$) contain a methylenedioxy group, a methoxyl group, a tertiary nitrogen atom common to two nuclei, and two, one and one ethylenic double bonds, respectively. Erythratine contains an additional nonphenolic hydroxyl group. These alkaloids appear to contain four fused nuclei (exclusive of the methylenedioxy bridge), three being partially or completely saturated and one aromatic. Three of the fused nuclei appear to be identical for each alkaloid, the fourth differing in unsaturation and oxygen groups.

Indole was isolated from the fusion of erythraline and erythratine with potassium hydroxide.

They are structurally formulated as hydropyrrocoline derivatives on the basis of present facts. If this formulation be correct, Robinson and Schöpf, failing to convert directly a benzylisoquinoline type of alkaloid into an aporphine type, have achieved its conversion into an *Erythrina* type, before natural alkaloids of this hydropyrrocoline type were known.

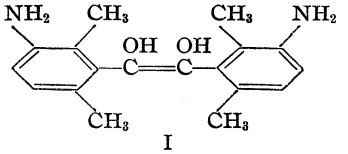
Enediols. X.[1] An Amino Stilbenediol

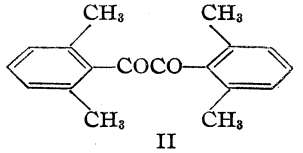
BY REYNOLD C. FUSON AND S. L. SCOTT

The study of the effect of nuclear substituents on the properties of stilbenediols is limited to groups, the presence of which is tolerated by the sensitive enediol group. The most interesting are those that have a profound influence on the character of the benzene ring such as the amino group. The present paper reports the preparation of an enediol which contains this group.

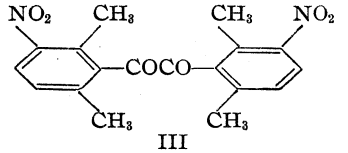
The amino compound selected for study was 1,2-di-(3-amino-2,6-xylyl)-acetylene glycol (I). It was made from 2,6-xylil (II) by nitration followed by catalytic hydrogenation of the dinitro diketone, 3,3′-dinitro-2,6-xylil (III).



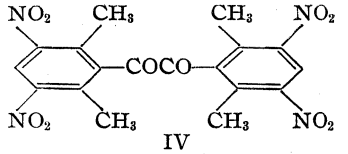
I



II



III



IV

The nitration of 2,6-xylil yielded small amounts of two by-products one of which was identified as the tetranitro derivative, 3,3′,5,5′-tetranitro-2,6-xylil (IV). A procedure was developed, however, which afforded very high yields of the desired dinitro compound (III).

It is extremely interesting that the dinitro diketone failed to form an oxime. That it might do so seemed possible in view of the report that 3-nitromesitonitrile and 3,5-dinitromesitonitrile undergo hydrolysis more readily than does mesitonitrile.[2] Similarly 3,5-dinitromesitaldehyde undergoes the Perkin condensation at a normal rate whereas mesitaldehyde itself reacts very slowly.[3] Thus it would appear that the nitro groups counteract the hindering effect of the *ortho* methyl groups of the mesityl radical. The result of the present work indicates that one nitro group is insufficient to nullify the hindrance afforded by the 2,6-xylyl group.

Although the diaminostilbenediol (I) was actually obtained, it was always contaminated with its oxidation product, the diaminol xylil. The great ease with which it was oxidized to the diketone coupled with the low solubility of both compounds in ordinary solvents made purification extraordinarily difficult. Moreover, the insolubility of the diamino xylil caused the hydrogenation to proceed very slowly and did not afford definite evidence of the existence of the two geometrical isomers that were expected. This was equally true for 3,3′-diacetamino-2,6-xylil.

Tests made on the diaminostilbenediol are reliable, however, since the contaminating diketone offers no interference. The stability of the enediol to air is of the same order as that of 1,2-di-(2,6-xylyl)-acetylene glycol. In other words, the amino groups do not alter greatly this property of the enediol.

Experimental

Nitration of 2,6-Xylil.—Two and three-tenths grams of finely powdered 2,6-xylil was added slowly, with shaking, to 40 cc. of red fuming nitric acid (sp. gr. 1.59–1.60) at 0°. Each portion of the diketone immediately produced a deep red color, which gradually faded to yellow. When the addition was complete the mixture was allowed to stand overnight in a stoppered container. The product was obtained by pouring the mixture on 100 g. of cracked ice. The solid was collected on a filter, washed and dried. The dinitro compound was extracted with acetone from which it crystallized in glistening yellow prisms; m. p. 211–212° (cor.); yield 92%.

Anal. Calcd. for $C_{18}H_{16}O_6N_2$: C, 60.65; H, 4.53; N, 7.86. Found: C, 60.80; H, 4.64; N, 8.11.

A second product, difficultly soluble in acetone, melted at 241–243° (cor.), with decomposition. It was not identified.

The tetranitroxylil (IV) was insoluble in acetone but could be crystallized from glacial acetic acid; m. p. 273–275° (uncor.), with decomposition; yield 1%.

(3) Lock and Bayer, *Ber.*, **72**, 1064 (1939).

Anal. Calcd. for $C_{18}H_{14}O_{10}N_4$: C, 48.42; H, 3.14. Found: C, 48.58; H, 3.16.

In subsequent experiments the nitration mixture was allowed to stand only fifteen minutes after the diketone had been added. At the end of this time the product had crystallized and was removed by filtration. The yield of crude product from 7.5 g. of 2,6-xylil and 121 cc. of fuming nitric acid was 10 g.

The dinitroxylil was treated for long periods with hydroxylamine and also with phenylhydrazine. In each experiment it was recovered unchanged.

Preparation of 3,3′-Diamino-2,6-xylil

(a) **By Catalytic Hydrogenation.**—A mixture of 2.5 g. of the dinitro diketone, 50 cc. of glacial acetic acid and 0.2 g. of platinum oxide was subjected to hydrogenation over a period of eighteen hours. The milky solution was poured into 50 cc. of water, and concentrated hydrochloric acid was added gradually until the solution became clear. The catalyst was removed by filtration and the filtrate made alkaline with ammonium hydroxide. The flocculent white precipitate was collected on a filter, sucked as dry as possible and allowed to stand in a vacuum desiccator over sulfuric acid. The diamino enediol developed a yellow color during the drying process. The yield was 95%. It decolorized a solution of 2,6-dichlorobenzeneoneindophenol. An attempt to recrystallize it from *n*-butyl alcohol converted it to the diamino diketone. The diketone melted at 201–202°.

Anal. Calcd. for $C_{18}H_{20}O_2N_2$: C, 72.93; H, 6.81. Found: C, 73.12; H, 7.06.

When the clear filtrate, obtained from the original hydrogenation mixture, was evaporated nearly to dryness in a nitrogen atmosphere, a mass of white crystals was obtained. These were undoubtedly the hydrochloride of the enediol. They immediately decolorized a basic solution of the indophenol. A silver nitrate test caused the precipitation of metallic silver.

The hydrochloride was very stable when dry but turned yellow when crystallized from alcohol. Washing with dilute sodium hydroxide to free the base produced an orange-colored compound that melted at 229–230° (cor.), with decomposition.

(b) **By Stannous Chloride.**—A mixture of 5 g. of the dinitro diketone, 20 g. of stannous chloride, 25 cc. of concentrated hydrochloric acid and 250 cc. of absolute alcohol was heated under reflux for about eight hours. The diketone had dissolved completely at the end of six hours. By distillation of the solvent the volume was reduced to about 75 cc. The solution was poured into 500 cc. of water and made alkaline to litmus with 10% sodium hydroxide solution. The orange solid that separated was collected on a filter, sucked as dry as possible and recrystallized from *n*-butyl alcohol. The bright red 3,3′-diamino-2,6-xylil melted at 201–202° (cor.); yield 2.45 g.

The diamino compound (1 g.) was converted to 3,3′-diacetamido-2,6-xylil, by heating under reflux for three hours with 20 cc. of acetic anhydride. It separated from methanol or glacial acetic acid in yellow crystals; m. p. 296–297° (uncor.); yield 94%.

Anal. Calcd. for $C_{22}H_{24}O_4N_2$: C, 69.44; H, 6.36. Found: C, 69.51; H, 6.23.

Attempts to hydrogenate the acetylated xylil by the Adams method failed; the diketone was recovered unchanged.

1,2-Di-(3-diacetamido-2,6-xylyl)-acetylene Glycol Diacetate.—A mixture of 0.2 g. of the diamino enediol and 25 cc. of acetic anhydride was heated under reflux for three hours, cooled and poured into water. The hexaacetate separated from methanol in glistening white crystals; m. p. 241–242° (cor.).

Anal. Calcd. for $C_{30}H_{34}O_8N_2$: C, 65.42; H, 6.23; N, 5.09. Found: C, 65.31, 65.57; H, 6.18, 5.97; N, 5.39.

The hexaacetate was also made by treating the enediol hydrochloride with acetic anhydride and pyridine.

Both of the acetylation experiments yielded a yellow by-product, melting at 296–297° (uncor.), which is believed to be 3,3′-diacetamido-2,6-xylil.

Summary

Nitration of 2,6-xylil with fuming nitric acid produces the 3,3′-dinitro derivative in high yields. Reduction of the dinitro compound yields 1,2-di-(3-amino-2,6-xylyl)-acetylene glycol. Its stability to air is comparable with that of the parent enediol, 1,2-di-(2,6-xylyl)-acetylene glycol.

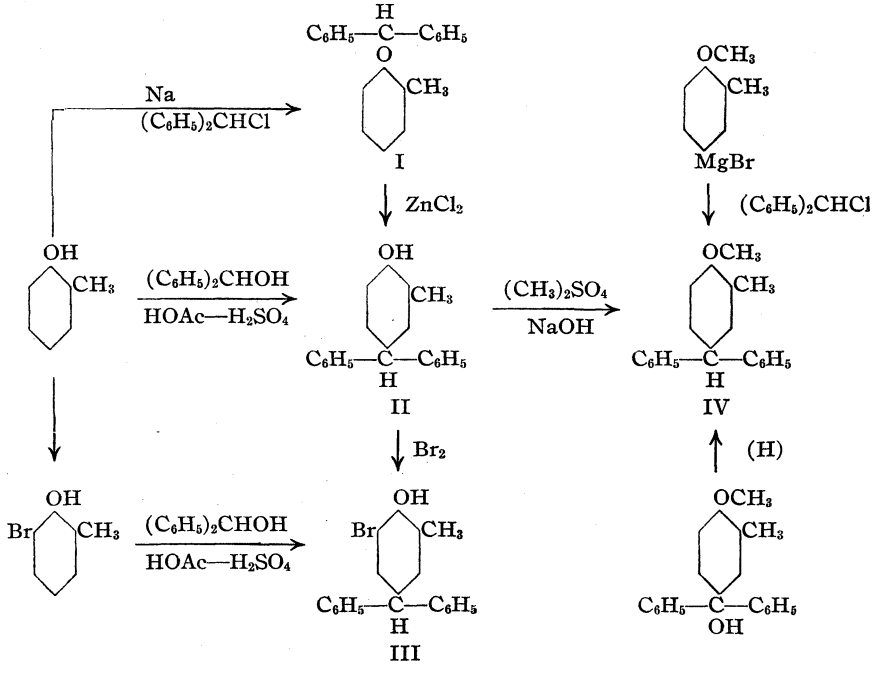
Formation and Rearrangement of the Diphenylmethyl Ether of *o*-Cresol

BY H. A. IDDLES, D. H. CHADWICK, J. W. CLAPP AND R. T. HART

To aid in interpreting the rearrangement of the triphenylmethyl ether of *o*-cresol, or the direct introduction of the triphenylmethyl radical into the *o*-cresol nucleus, the methyl ether of the postulated product, 3-methyl-4-hydroxyphenyltriphenylmethane was synthesized.[1] The complete agreement between rearranged and synthetic products showed that the triphenylmethyl radical had migrated to the para position of the *o*-cresol nucleus.

In similar alkylation studies, earlier investigators[2,3,4,5] have used the less highly substituted diphenylmethyl radical and have recorded the conditions which favor the formation of the diphenylmethyl ether of phenol or lead to the introduction of one, two or three diphenylmethyl radicals into the nucleus. In one experiment, Schorigin[3] treated *o*-cresol with diphenylcarbinol in acid medium and postulated the introduction of one diphenylmethyl radical ortho to the hydroxyl which seemed to be in agreement with his analytical data. Since this interpretation differed from the observed para migration of the triphenylmethyl radical[1] or the isopropyl group,[6] and was not substantiated in any way, a further detailed study of this reaction is presented in this paper.

The direct preparation of the diphenylmethyl ether of *o*-cresol I was accomplished by treating sodium *o*-cresylate in ether solution with diphenylchloromethane. Besides the ether, some free phenolic product II was formed. This could be prepared also by direct rearrangement of the ether with zinc chloride or through the reaction at room temperature of *o*-cresol with diphenylcarbinol in acid medium. The orientation of groups in structure II was established in the first instance by its monobromination and comparison with the diphenylmethyl derivative formed from 6-bromo-*o*-cresol and also by two direct syntheses focusing on structure IV. Thus the rearrangement of I or the direct introduction of one diphenylmethyl radical involves the para position of the *o*-cresol, as was shown in the case of the triphenylmethyl radical.



In addition it was necessary to characterize Schorigin's product, m. p. 139°, which could be prepared by heating *o*-cresol and diphenylcarbinol in an acetic–sulfuric acid medium.[3] As a direct approach, Schorigin's suggested structure V was synthesized by the action of the Grignard reagent on methyl *o*-cresotinate followed by reduction of the resulting carbinol. This synthetic material was further characterized by bromination and comparison with a product formed by condensing 4-bromo-*o*-cresol with diphenylcar-

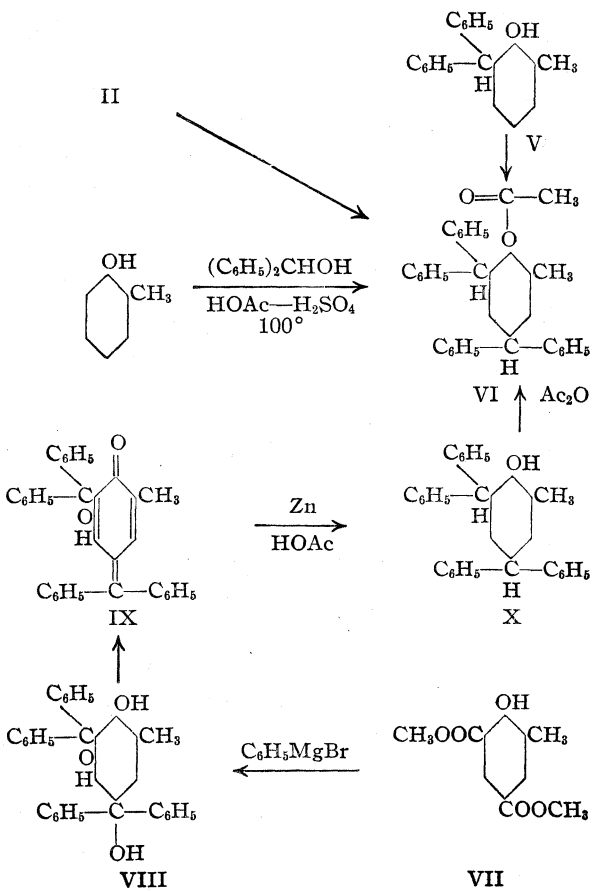
binol. However, the synthetic material of structure V melted at 76–78°, which demonstrated its non-identity with Schorigin's material, m. p. 139°.

When it was determined that Schorigin's material could not be brominated or methylated and that structures II and V would both yield Schorigin's product when heated with diphenylcarbinol in acetic–sulfuric acid medium, then structure VI was suggested in which two diphenylmethyl groups had been introduced and the acetate formed. To establish this postulate, structure VI was synthesized by the action of phenylmagnesium bromide on the dimethyl ester of 6-hydroxyuvitinic acid VII, which passed through a di-carbinol structure VIII to form an orange-colored substance postulated to be IX. In the succeeding steps, this material was reduced by zinc and acetic acid producing a colorless phenol X and treatment with acetic anhydride gave the acetate VI of m. p. 139° which was identical with Schorigin's rearranged product.



Experimental

o-Tolyldiphenylmethyl Ether.—*o*-Cresol (120 g.) in absolute ether (500 ml.) was treated with metallic sodium (10 g.) and, after complete reaction, diphenylchloromethane (66 g.) was introduced slowly. The mixture was refluxed for sixteen hours and for three hours after evaporation of the ether. The reaction mixture was poured into water, extracted with ether and the ether layer was washed with 10% sodium hydroxide and then dried. Upon evaporating the ether, the resulting oil was taken up in ligroin (90–110°) and extracted with Claisen's solution. From the ligroin layer, 10 g. of the desired ether distilled between 175–178° at 4 mm. It was a viscous, yellowish-green oil. The Claisen's extract, upon acidification, produced a rearranged product (25 g.) which was first purified by distillation at 3 mm. pressure and 205–215°, followed by crystallization from ligroin, m. p. 99–100°.

Preparation of Rearranged Compound.—To carry out a direct rearrangement, 5 g. of the *o*-tolyldiphenylmethyl ether was heated with 3 g. of zinc chloride for five hours at 150°. The material was then dissolved in ligroin, washed with water and extracted several times with Claisen's solution. Upon acidification, 3 g. of oil was obtained which was distilled at 213–220° and 3–5 mm. and recrystallized from ligroin yielding a colorless product, m. p. 99°.

The same product was obtained when 20 g. of diphenylcarbinol[7] and 24 g. of *o*-cresol were dissolved in 300 ml. of glacial acetic acid, and 60 g. of concd. sulfuric acid was added over a period of one hour. After standing for 7–8 days, the product was obtained by pouring the reaction mixture into water, extracting with ether, washing with 10% sodium hydroxide, water, and drying the ether extract. Upon evaporation of the ether, the residue was vacuum distilled at 180–185° and 2 mm. and twice recrystallized from ligroin yielding 15 g. of final product, m. p. 101°.

Anal. Calcd. for $C_{20}H_{18}O$: C, 87.5; H, 6.62. Found: C, 87.4; H, 6.62.

Bromination of 3-Methyl-4-hydroxyphenyldiphenylmethane.—Five grams of the rearranged compound, m. p. 101°, was dissolved in 200 ml. of carbon tetrachloride, and to the cooled solution 3 g. of bromine in 20 ml. of carbon tetrachloride was added. After an hour, excess bromine was removed with bisulfite solution and the product recovered. Recrystallization from alcohol gave 4 g. or a yield of 62% of light yellow product, m. p. 117–118°.

Direct Condensation of 6-Bromo-*o*-cresol and Diphenylcarbinol.—Five grams of diphenylcarbinol and 15 g. of 6-bromo-*o*-cresol[8] were dissolved in 100 ml. of glacial acetic acid, and 20 ml. of concd. sulfuric acid was added slowly while cooling. During the addition an oil began to separate and soon solidified. After standing two days, the solid product was filtered off, washed with glacial acetic acid and recrystallized from alcohol with a yield of 7 g. or 70%, m. p. 117–117.5°. A mixed melting point with the above brominated product was 117°.

Anal. Calcd. for $C_{20}H_{17}OBr$: Br, 22.6. Found: Br, 22.4.

Methylation of Compound II.—Three grams of the rearranged compound II, suspended in 200 ml. of 2 *N* sodium hydroxide, was warmed to 40°, and 15 g. of dimethyl sulfate was added over a period of two hours. After destroying excess dimethyl sulfate, the solution was

(7) "Organic Syntheses," Collective Vol. I, 1941, p. 90.
(8) Huston and Neeley, THIS JOURNAL, 57, 2176 (1935).

neutralized with hydrochloric acid and the insoluble organic material separated. The product was taken up in a mixture of 1 part diethyl ether and 9 parts petroleum ether, washed with Claisen's solution and water, and finally recrystallized from alcohol with a yield of 2.11 g. or 67%, m. p. 74–76°.

Anal. Calcd. for $C_{21}H_{20}O$: C, 87.5; H, 6.98. Found: C, 87.5, 87.8; H, 7.05, 7.63.

Direct Synthesis of Compound IV. Procedure I.—A Grignard solution, prepared from 7 g. of 3-bromo-6-methoxytoluene[1] and 3 g. of magnesium turnings in 100 ml. of dry ether, was coupled by adding 7 g. of diphenylchloromethane dissolved in 100 ml. of dry ether during a period of forty minutes. After refluxing for two hours, the ethereal solution was successively washed with dilute hydrochloric acid, 10% sodium carbonate, and water and then dried. Subsequent evaporation of the ether left an oil which was recrystallized from ligroin, yielding 4.3 g. or 43%, m. p. 74–75°.

Procedure II.—Seven grams of 3-methyl-4-methoxytriphenylcarbinol[1] was dissolved in 200 ml. of glacial acetic acid and reduced by adding zinc dust[9] and refluxing for an hour. The zinc dust was allowed to settle and the clear solution decanted into 500 ml. of water. The precipitate was dissolved in hot alcohol, treated with Norite, and yielded 5 g. or 75%, m. p. 75.5°. A mixed melting point using each of the synthetic products with the methylated rearranged product gave no depression.

Reaction of *o*-Cresol and Diphenylcarbinol at 100°.—According to Schorigin's procedure[3] a solution of *o*-cresol (13.5 g.) and diphenylcarbinol (39 g.) in glacial acetic acid (300 ml.) was treated with concd. sulfuric acid (20 ml.) while refluxing on the steam-bath. Purification of the product from alcohol gave 8 g. of colorless material, m. p. 139–140°.

Anal. Calcd. for $C_{35}H_{30}O_2$: C, 87.1; H, 6.27. Found: C, 86.7; H, 6.42.

Preparation of Compound V.—Ten grams of 2-methyl-6-diphenylhydroxymethylphenol, prepared by the reaction of phenylmagnesium bromide on methyl-*o*-cresotinate,[10,11] was reduced with zinc and glacial acetic acid as previously described.[9] Recrystallization from alcohol produced colorless crystals in a yield of 6.5 g. or 70%, m. p. 76–78°.

Anal. Calcd. for $C_{20}H_{18}O$: C, 87.5; H, 6.61. Found: C, 87.1; H, 6.59.

Preparation of 2-Methyl-4-bromo-6-diphenylmethylphenol.—To characterize compound V, 2 g. was treated with 2.2 g. of bromine in carbon tetrachloride and the product recovered and crystallized from dilute alcohol, yielding 1.3 g. or 45%, m. p. 97–100°.

Further, 60 g. of 4-bromo-*o*-cresol[12] and 30 g. of diphenylcarbinol, dissolved in 400 ml. of glacial acetic acid, were heated on the steam-bath while 5 ml. of sulfuric acid was added gradually. Recovery of the condensation product in the usual way gave 17 g. of product, m. p. 100–103°. A mixed melting point of the two bromo derivatives gave no depression and either bromo derivative could be acetylated to give an acetyl derivative, m. p. 157–158°.

Anal. Calcd. for $C_{20}H_{17}OBr$: Br, 22.6. Found: Br, 22.4.

Preparation of the Dimethyl Ester of 6-Hydroxyuvitinic Acid.—The dried potassium salt from 154 ml. of *o*-cresol was placed in the glass liner of a pressure bomb and carbon dioxide forced into the bomb under ninety pounds pressure.[13] The bomb was heated in an electric furnace to 210°, and the pressure of carbon dioxide was increased to two hundred pounds. These conditions were maintained for fifty hours or until absorption of carbon dioxide was complete, as evidenced by no pressure drop. For purification, the solid reaction product was suspended in 700 ml. of hot water, and sodium bicarbonate added until the solution was complete, then treated with Norite, filtered and reprecipitated with dilute hydrochloric acid. After three such treatments, a yield of 105 g. or 36% of a faintly pink product was obtained, m. p. 290–295°.

The methyl ester was then prepared by refluxing 15 g. of the above acid in 200 ml. of absolute methanol and 22 ml. of concd. sulfuric acid.[14] Upon cooling, the ester crystallized from the methanol in a yield of 10 g. or 60%, m. p. 129–130°.

Preparation of Compound IX.—A Grignard solution prepared from 125 g. of bromobenzene and 19.4 g. of magnesium turnings in one liter of dry ether was refluxed while adding 18 g. of compound VII dissolved in 800 ml. of ether. After refluxing for six hours, the reaction product was poured into water containing enough hydrochloric acid for complete solution. The ether layer was separated, washed with water, 10% sodium carbonate and again with water. The ether was evaporated and the residue steam distilled to remove biphenyl. On cooling, an orange solid formed and this was recrystallized from acetic acid in a yield of 27 g. or 75%, m. p. 206–208°. The color and analysis agreed with the aurin structure assigned.

Anal. Calcd. for $C_{33}H_{26}O_2$: C, 87.2; H, 5.76. Found: C, 87.3, 87.1; H, 5.80, 5.92.

Preparation of Compound X.—Ten grams of the aurin-type compound IX was dissolved in 250 ml. of hot glacial acetic acid in a three-necked flask fitted with a stirrer and reflux condenser. Zinc dust (35 g.) was added slowly and refluxing continued for eight hours. After filtering off excess of zinc dust, the reaction mixture was poured into 1000 ml. of ice water yielding a crude product of 9.6 g. No suitable solvent for recrystallization was found, but a vacuum sublimation produced an amorphous product, m. p. 50–60°, which changed to a dark gum upon standing.

Anal. Calcd. for $C_{33}H_{28}O$: C, 89.9; H, 6.41. Found: C, 89.1; H, 6.52.

Since the product could not be crystallized, it was characterized as the 3,5-dinitrobenzoate which was obtained as a colorless crystalline material from dilute acetone, m. p. 206–207°.

Anal. Calcd. for $C_{40}H_{30}O_6N_2$: N, 4.42. Found: N, 4.48.

Preparation of 2-Methyl-4,6-di-(diphenylmethyl) Phenylacetate VI.—Two grams of the phenol X was treated with 7–8 ml. of acetic anhydride and 1 ml. of concd. sulfuric acid. When the reaction mixture had cooled,

water was added and the gummy product recrystallized from alcohol yielding 1.3 g. (60%), m. p. 139–141°. A mixed melting point of this synthetic material with Schorigin's compound showed no depression.

Anal. Calcd. for $C_{35}H_{30}O_2$: C, 87.1; H, 6.27. Found: C, 86.8; H, 6.30.

Summary

1. The rearrangement of the diphenylmethyl ether of *o*-cresol or the direct introduction of the diphenylmethyl group under mild conditions involves the para position of the *o*-cresol.

2. 2-Methyl-4,6-di-(diphenylmethyl) phenylacetate has been synthesized and found to be identical with Schorigin's product obtained by heating diphenylcarbinol and *o*-cresol in an acetic–sulfuric acid medium.

Allylic Rearrangements. XIII. Kinetics and Mechanisms of the Conversion of Crotyl and Methylvinylcarbinyl Chlorides to Acetates and Ethyl Ethers[1]

BY JOHN D. ROBERTS, WM. G. YOUNG AND S. WINSTEIN[2]

Many investigators, notably Hughes, Ingold and collaborators,[3] have demonstrated that the mechanisms of nucleophilic replacement reactions at a saturated carbon atom may be classified into three general types. One mechanism, designated as S_N2 is the familiar[4] bimolecular, usually second-order, substitution of an electron-donor such as hydroxide ion, alkoxide ion or acetate ion for the halide or a similar group as in equation (1), the replacement resulting in a complete Walden inversion.

$$Y^- + RX \longrightarrow YR + X^- \qquad (1)$$

Another mechanism, designated as S_Ni, involves the internal rearrangement of an intermediate compound to give the final product with retention of configuration. An illustration of this mechanism is furnished in equation (2) by the rearrangement of the intermediate from an alcohol and thionyl chloride to produce a chloride and sulfur dioxide.

$$ROSOCl \longrightarrow RCl + SO_2 \qquad (2)$$

The third mechanism, designated as S_N1, is comprised of an electrophilic attack of solvent on halogen or similar groups to yield an unfree[3,5] carbonium ion which subsequently reacts rapidly with an electron donor to yield the final product. Equation (3) represents the sequence of these reactions.

$$\begin{gathered} RX \longrightarrow R^+X^- \longrightarrow R^+ + X^- \\ R^+ + YH \longrightarrow RY + H^+ \text{ or} \\ R^+ + Y^- \longrightarrow RY \end{gathered} \qquad (3)$$

A variation of the S_N1 type of reaction involves the electrophilic attack of such a reagent as silver ion on a halogen group to produce the unfree carbonium ion intermediate.[3,6]

The application of the foregoing types of mechanisms to the replacement reactions of allylic systems[7] has been of great value in explaining the phenomenon of the allylic rearrangement.[7d] The recognition of the possibility of the simultaneous operation of both S_N1 and S_N2 processes, according to equations (4) and (5), has been used to correlate various results with the assumption that the

$$Y^- + -\overset{|}{C}=\overset{|}{C}-\overset{|}{\underset{|}{C}}-X \longrightarrow -\overset{|}{C}=\overset{|}{C}-\overset{|}{\underset{|}{C}}-Y + X^- \qquad (4)$$

S_N2 reaction is normal and the S_N1 reaction yields a mixture, the same mixture resulting from either starting allylic isomer.

For example, the formation of similar but not identical bromide mixtures from the action of hydrogen bromide on crotyl alcohol and methylvinylcarbinol has been explained in this way.[7a]

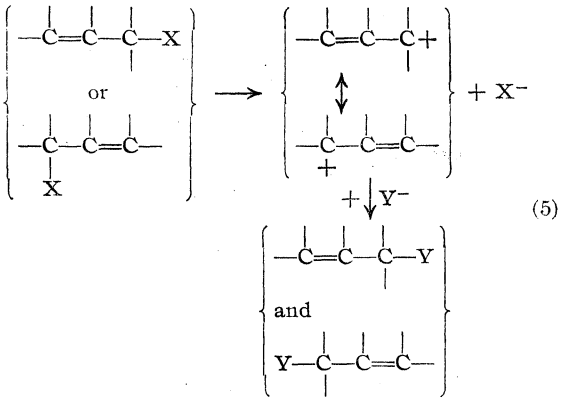
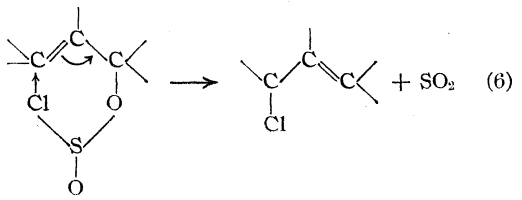
Soc.*, 1912 (1938); (c) Ref. 5, p. 315; (d) After the completion of this manuscript, the paper by Hughes, *Trans. Faraday Soc.*, **37**, 603 (1941), appeared, which reports unpublished work in similar directions to the experiments we report in this article. The conclusions drawn by Hughes are in substantial agreement with our own.



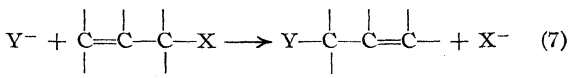
(5)

A special form of the S_Ni mechanism would account for the results obtained by Meisenheimer and Link[8] on the reactions of the α- and γ-ethylallyl alcohols with thionyl chloride. It was reported that the primary isomer gave principally secondary chloride and from the secondary isomer mostly primary chloride was obtained. These reactions may be explained by a rearrangement involving addition of the halogen to the γ-carbon atom, simultaneous shift of the double bond and elimination of sulfur dioxide as shown in equation (6).



(6)

This indicated special form of the S_Ni mechanism suggests a possible abnormal S_N2 reaction,[9] illustrated in equation (7), involving an attack by an electron donor at the γ-carbon atom, a shift of the double bond and elimination of a group, all occurring simultaneously.[10]



(7)

Indeed, the work of Meisenheimer and Beutter[11] on the reactions of cinnamyl chloride with potassium acetate in acetic acid seems to verify that such an abnormal S_N2 reaction does occur.

These investigators found that in solutions of low concentration of potassium acetate, the kinetics of the reaction with cinnamyl chloride in acetic acid were between first- and second-order. At high concentrations of potassium acetate there was obtained a mixture of esters containing a considerable fraction of phenylvinylcarbinyl acetate and, in fact, this fraction of abnormal ester did not decrease with increasing acetate concentration as would be expected if it were produced only by a first-order reaction. Using rate constants which Meisenheimer and Beutter found to fit their data, it is possible to calculate that only 7% of the reaction proceeds by the first-order path at 50° if one starts with an acetic acid solution which is 1 N in cinnamyl chloride and 1.5 N in potassium acetate, whereas 35% of abnormal product was actually isolated. Hence, even if the S_N1 reaction produced only abnormal product, the experimentally found composition seemingly cannot be explained unless an abnormal S_N2 reaction is assumed. However, in the work of Meisenheimer and Beutter,[11] there was no consideration of ionic strength and specific salt effects, so that the large bimolecular contribution to the kinetics may have been only apparent. It is possible that a reinvestigation of this situation would disclose that the conversion of cinnamyl chloride to ester in acetic acid is almost exclusively solvolytic in character. Evidence in favor of this possibility is that cinnamyl chloride gives only cinnamyl acetate on treatment with potassium acetate in acetic anhydride, a solvent sure to be unfavorable[3] for the operation of an S_N1 mechanism.

We have begun investigations designed to show the relative tendencies for S_N1 and S_N2 mechanisms in typical allylic cases and to formulate generalizations as to the products to be expected from the reactions by these mechanisms. In this paper we present the results so far obtained on the conversion of crotyl and methylvinylcarbinyl chlorides to ethyl ethers and acetates with special attention being given to any possible abnormal S_N2 reaction.

Simultaneous First- and Second-Order Reactions.—If, in a conversion of a halide to ether or acetate, both second-order and first-order reactions are proceeding, an apparent bimolecular constant, K_2, calculated by equation (8) where a is the original concentration of halide, b the original concentration of alkoxide or acetate salt, x the concentration of inorganic halide produced at time, t, will show a drift in a rate run. So

$$K_2 = \frac{1}{t(a-b)} \ln [b(a-x)]/[a(b-x)] \qquad (8)$$

(8) Meisenheimer and Link, *Ann.*, **479**, 211 (1930).

(9) (a) Winstein, Dissertation, California Institute of Technology, 1938; (b) Hughes, *Trans. Faraday Soc.*, **34**, 185 (1938).

(10) A mechanism leading to the same result but requiring preliminary addition of a nucleophilic reagent to one of the ethylenic carbons has been proposed by Ogg, THIS JOURNAL, **61**, 1946 (1939).

(11) Meisenheimer and Beutter, *Ann.*, **508**, 58 (1933).

also will K_1 calculated on the basis of a reaction first-order with respect to organic halide. If only a second-order reaction according to equation (1) is proceeding, then K_2 equals k_2 the specific second-order rate constant. Similarly, if only a first-order reaction is proceeding, K_1 will equal k_1 the specific first-order rate constant. If both first- and second-order contributions are important, equation (9) is useful.

$$\frac{dx}{dt} = k_1(a - x) + k_2(a - x)(b - x) \qquad (9)$$

The fraction of reaction F_1 which has proceeded by a first-order reaction at any fraction conversion can be shown to be given by equation (10).

$$F_1 = k_1/(k_2x) \ln (k_1 + k_2b)/[k_1 + k_2(b - x)] \quad (10)$$

Rate Work on the Conversion of Crotyl Chloride to Crotyl Ethyl Ether.—The reaction of crotyl chloride with sodium ethoxide in absolute ethanol displayed second-order kinetics, the first-order reaction which gives rise to hydrogen chloride in the absence of sodium ethoxide being slow enough to enable very good isolation of the second-order reaction. One main source of crotyl chloride was employed and no large rate trends were noticed.[12] Table I summarizes a typical run. Table II summarizes the rate constants obtained at 25.00°, using various original concentrations without attempt to keep ionic strength constant. There is some trend in K_2 with original concentrations, as is usually found in work of this kind.[13] The change of K_2 with the water content of the alcohol from pure alcohol to 10% water, is not very extensive and has about the magnitude of the change of K_2 with concentrations of sodium ethoxide from 0.6 to 0.06 M.

Crotyl chloride in alcohol at 25.00° slowly produces hydrogen chloride and the rate of this solvolytic process was followed. Also, the effect on the solvolytic reaction of adding water was noted. Table IV summarizes the measurements on the solvolytic reaction while Table III presents a typical run.

The usual increase[3,14] in the rate of solvolysis of a halide with increase in the water content of the alcohol solvent is noticed with crotyl chlorides. What fraction of the first-order reaction observed in the absence of sodium ethoxide is due to an S_N1 process (equation 3) and what fraction is due to an S_N2 process (equation 1), involving

(12) Mr. L. Andrews has found in preliminary work that crotyl chlorides prepared in various ways give somewhat variable rate constants. It seems likely that some preparations contain *cis*-crotyl chloride and that an increase in rate is associated with these.

alcohol or water molecules as the attacking reagents, remains to be seen.[15]

From the constants given in Tables II and IV, it is clear that in the reaction of crotyl chloride with aqueous–alcoholic solutions of sodium ethoxide or sodium hydroxide it is necessary to use low concentrations of base and considerable water in the solvent to attain serious proportions of first-order reaction.

Isolation of Products of Reaction of Crotyl and Methylvinylcarbinyl Chlorides with Sodium Ethoxide in Absolute Ethanol.—Crotyl chloride was converted to ether by treatment with sodium ethoxide in absolute ethanol under conditions where essentially second-order kinetics prevailed. When the original crotyl chloride concentration was approximately 0.7 *M* and the NaOEt was approximately 0.9 *M*, ether which was at least 99% crotyl ethyl ether with a maximum of 1% methylvinylcarbinyl ethyl ether was isolated.

No kinetic investigations on the reaction of methylvinylcarbinyl chloride with sodium ethoxide were carried out, but the product of the reaction under conditions favoring a bimolecular reaction was isolated. As shown in Table V the ether produced was at least 96% methylvinylcarbinyl ethyl ether with a maximum of 4% crotyl ethyl ether under the conditions used.

TABLE V

THE PRODUCTS OF REACTION OF ALLYLIC HALIDES WITH ABSOLUTE ALCOHOLIC NaOEt

Halide	Orig. NaOEt Concn. mole/l.	Orig. halide Concn. mole/l.	% Normal product	% Abnormal product
Crotyl chloride	0.9	0.7	100	0
3-Chloro-1-butene	1.8	1.3	>96	<4

It would certainly seem that the bimolecular reaction of sodium ethoxide with the primary and secondary 4-carbon chlorides proceeds without allylic rearrangement.

Product of Reaction of Silver Acetate with the Butenyl Chlorides.—The study of the kinetics of the reactions of the butenyl chlorides with acetate ion in acetic acid showed that it was impossible to isolate the bimolecular replacement reaction free of the solvolytic one, which in the case of an acetic acid solvent, will be more exclusively S_N1 than in absolute alcohol because of the large difference in basicity between acetic acid and ethyl alcohol molecules. In order to determine whether the products of such reactions could be accounted for quantitatively by a normal bimolecular reaction and a partially abnormal solvolytic one, it was necessary to have an estimate of the composition of the product arising from the S_N1 solvolytic reaction. Since there are many indications that reactions of halides with silver salts proceed similarly to S_N1 reactions in that an unfree carbonium ion is produced as an intermediate, the products of reaction of silver acetate with the butenyl chlorides were isolated and taken as an indication of what might be expected from the solvolytic mechanism.

Table VI contains along with other results the composition of the acetates produced from the two chlorides on treatment with silver acetate in acetic acid at 25°. A mixture of acetates is produced from either chloride as expected from a carbonium ion intermediate, but the mixtures are not quite identical. Thus, the primary chloride gives an acetate mixture which is about 63% primary and the secondary chloride gives a mixture which is only 56% primary. This spread seems to be real and Meisenheimer and Link[8] report a similar but somewhat smaller spread in the results from pentenyl chlorides.

TABLE VI

THE COMPOSITION OF BUTENYL ACETATES FROM THE REACTIONS OF CROTYL AND METHYLVINYLCARBINYL CHLORIDES WITH VARIOUS ACETATES

Experimental method	Chloride used	Time of reaction, hr.	Composition of product % primary acetate	% secondary acetate	Yield,[a] %
1 *M* Potassium acetate in acetic acid at 78.6°	primary	138	84	16	87
	secondary	48	51	49	31
	secondary	72	50	50	52
1 *M* Diphenylguanidinium acetate in acetic acid at 78.6°	primary	50	88	12	68
	secondary	45	51	49	66
Potassium acetate in acetic anhydride at 100°	primary	192	100	0	63
Tetraethylammonium acetate acetone at 58°	secondary	194	0	100	53
Silver acetate in acetic acid at 25°	primary	190	65	35	42
	primary	120	60	40	61
	secondary	120	56	44	59

[a] Yield based on the butenyl chloride, assuming reaction goes to completion.

This difference is an interesting one and will be considered more fully in later work. It may be due either to a second-order process in which acetate ion replaces chloride normally, or a termolecular process in which silver ion removes the chloride ion and acetate ion, or an acetic acid molecule simultaneously forms a bond to the carbon atom

(15) Preliminary work has shown that the solvolytic reaction of crotyl chloride in dry alcohol is considerably faster than the reaction of methylvinylcarbinyl chloride.

losing the chloride ion. The possibility of a normal bimolecular substitution of acetate ion for chloride competing with the predominant process when silver acetate is being used, seems unlikely in view of the very low concentration of acetate ion and the relatively rapid action of silver acetate. Whether a third-order process ever contributes in reactions of silver salts is not yet clear. Still another likely explanation is that the inequality in the compositions of the acetate mixtures from the two halides is another indication of the lack of freedom of the carbonium ion being formed.[16]

Kinetics of Reaction of Butenyl Chlorides with Potassium and Diphenylguanidinium Acetates. —The kinetic data on the reaction of potassium acetate with the butenyl chlorides in acetic acid at 78.6 ± 0.1° are summarized in Table VII. The apparent second-order rate constant drifts upward in all the runs except in the one employing crotyl chloride with a high concentration of potassium acetate. This drift indicates a considerable amount of first-order reaction.

High concentrations of materials were employed in these rate measurements because it was desired to isolate reaction products using comparable conditions. Under these conditions potassium chloride precipitates, changing the ionic strength in the course of the reactions. Ionic strength effects and also specific salt effects are so serious in acetic acid that we were unable to treat the data of Table VII so as to obtain first- and second-order rate constants and to decide how much of the reaction proceeded by each of the two paths.

From the work of Steigman and Hammett[17] on the acetolysis of α-phenylethyl choride it appeared to us that diphenylguanidinium acetate was an ideal salt to use in place of potassium acetate since diphenylguanidinium chloride is soluble in acetic acid. Also, diphenylguanidinium chloride and acetate seem to have about the same salt effect, unlike some other salt pairs. Thus, rate measurements on the reaction of diphenylguanidinium acetate with the butenyl chlorides should be relatively free of trends due to change of ionic strength and change of the nature of the salt making up the ionic strength.

The rate measurements using diphenylguanidinium acetate are summarized in Table VIII. Run V is similar to Run I, K_2 now being higher and drifting upward. The drift is small enough to indicate that crotyl chloride reacts predominantly by a second-order path. Run VI using methylvinylcarbinyl chloride and 0.9 M diphenylguanidinium acetate displays a K_2 which drifts upward and a K_1 which is constant.[18] Run VII using a lower concentration of acetate yields a K_2 which drifts upward badly and a K_1 with only a slight downward drift. Clearly methylvinylcarbinyl chloride undergoes a first-order reaction almost exclusively under conditions where crotyl chloride reacts predominantly by a second-order reaction. Runs VI and VII show the large trend in the first-order constant with ionic strength.

From Run V the rate constants for the first- and second-order reactions of crotyl chloride were estimated. By plotting x against t, dx/dt at any time was obtained. A plot of $dx/dt/(a-x)$ against $(b-x)$ gives a straight line according to equation

(16) One might suppose that shielding by the chloride ion being extracted might favor the abnormal product but apparently this effect is overshadowed by the tendency for the cationic charge to favor the carbon atom losing the chloride ion while the chloride ion is still in the immediate vicinity.

(17) Steigman and Hammett, THIS JOURNAL, **59**, 2536 (1937).

(18) It would appear that no very serious amount of reaction of chloride ion with the unfree carbonium ion intermediate occurs nor is there much rearrangement of the halides. In either case drifts in the first-order constant for the secondary isomer would be found, unless some cancellation of effects accidentally takes place. Actually, from the work of Hughes and Ingold and co-workers,[3b] the intervention of chloride ion is less likely to occur in our system than with more complex ones. The intervention of chloride ion may be quite serious in the cinnamyl chloride work of Meisenheimer and Beutter,[11] however.

TABLE VIII

DATA ON THE RATE OF REACTION OF DIPHENYLGUANIDINIUM ACETATE WITH BUTENYL CHLORIDES IN ACETIC ACID

Run V (CrCl) = 1.020 (D.P.G.OAc) = 0.921					Run VI (M.V.C.Cl) = 0.987 (D.P.G.OAc) = 0.925				Run VII (M.V.C.Cl) = 0.987 (D.P.G.OAc) = 0.222

Products of Reaction of Butenyl Chlorides with Potassium and Diphenylguanidinium Acetates in Acetic Acid.—Using conditions that had been explored kinetically, the products of the reactions in acetic acid were isolated and analyzed. Table VI includes the analyses of the products obtained from the reactions with initial concentrations of approximately 1 M. The two salts give about the same products.

The product of reaction of crotyl chloride with diphenylguanidinium acetate was the result of a reaction, 36% of which was first-order, calculated by the use of equation (10) with $b = 0.92$ and x at the time the reaction was interrupted equal to 0.85 (estimated by analogy with Run V, Table VIII). With the information we have so far, the best approximation to the product to be expected from the first-order reaction of crotyl chloride in acetic acid containing diphenylguanidinium acetate, is the same mixture crotyl chloride gives with silver acetate (38% secondary acetate) in spite of some differences in the two reactions. The reaction employing silver acetate proceeds at a lower temperature and is heterogeneous. The unfree crotyl ion may coördinate for the most part with different reagents (acetic acid or acetate ion) in the two reactions.

If one assumes the second-order reaction gives only normal product, then a reaction which is 36% first-order should give 36(0.38) or 14% secondary ester. Actually 12% is obtained.

With potassium acetate 16% of secondary ester is obtained from crotyl chloride. However, the reaction was allowed to proceed more nearly to completion. This is expected to increase the fraction of the reaction proceeding by a first-order path and thus the per cent. of secondary ester obtained from crotyl chloride. Hence there is no evidence for an abnormal second-order reaction of crotyl chloride with acetate ion, the data being entirely compatible with a normal second-order reaction and a first-order reaction yielding a mixture.[19]

Methylvinylcarbinyl chloride gives with either diphenylguanidinium or potassium acetate a mixture of acetates which is 51% crotyl acetate and only 49% secondary acetate. A completely first-order reaction might be expected as a first approximation to yield 56% crotyl acetate by analogy with the silver acetate reaction. Part of the difference between 51 and 56% may be due to a small contribution of a normal second-order reaction to the total reaction of the secondary chloride.

Products of Reaction of Butenyl Chlorides with Acetates in Other Solvents.—If, as it appears, the second-order reactions of the butenyl chlorides are completely normal and a reaction

(19) The failure to find the abnormal bimolecular mechanism seems to be in line with the usual inability of the isolated ethylenic linkage to be susceptible to attack by nucleophilic reagents. However, suitable variation in the structure of the allylic molecule may produce this mechanism.

After this article was submitted for publication we noticed that, in a general article on configurational changes in reactions at a saturated and unsaturated carbon atom, Bergmann [Bergmann, *Helv. Chim. Acta*, **20**, 590 (1937)] claims that this abnormal bimolecular mechanism operates in the reaction of sodium malonic ester and sodium diphenylmethide with active 2-chloropentene-3. It is still possible, however, that some other reason exists for the racemization observed by Bergmann and further confirmation of the mechanism would be desirable.

proceeds partly abnormally only when part of the reaction is S_N1 in character, the proper choice of solvent should enable one to force certain replacement reactions to proceed entirely normally. Non-hydroxylic solvents are known to be unfavorable[3,17] for the solvolytic first-order reactions so that reactions in these solvents might be expected to be normal and quite useful synthetically.

As was expected, the reaction of methylvinylcarbinyl chloride with tetraethylammonium acetate in acetone gave an acetate with no detectable amount of crotyl acetate. Also, crotyl chloride and potassium acetate in acetic anhydride yielded an acetate with no detectable amount of secondary ester. These results are shown in Table VI.

Experimental Part

Crotyl and Methylvinylcarbinyl Chlorides.—Mixtures of chlorides from Shell Development Corporation or prepared from the alcohols with concentrated hydrochloric acid were dried over calcium chloride or potassium carbonate, distilled once and then fractionated through a six-foot column of glass helices. The secondary chloride could be obtained at atmospheric or reduced pressure. For the primary chloride reduced pressure was employed. The pure chlorides: secondary b. p. 24.2–24.6° (178 mm.), 63.5° (750 mm.), $n^{20}D$ 1.4150; primary b. p. 43.7–44.0° (177 mm.), 45.6–45.7° (191 mm.), $n^{20}D$ 1.4351, were used in this work. One pair of chloride samples were kept in a cold room several months with no appreciable change in refractive index. After a year at room temperature, this pair of chlorides showed an increase of 0.0004 and 0.0013 in the refractive index for the primary and secondary chlorides, respectively. This change was largely due to other factors than isomerization for distillation at reduced pressure nearly restored the refractive indices to the old values.

Rate of Conversion of Crotyl Chloride to Ether.—Proper volumes of stock solutions of crotyl chloride and sodium ethoxide in absolute ethanol (Commercial Solvents Gold Shield), water, and absolute ethanol, all previously brought to temperature, were mixed in glass-stoppered Erlenmeyer flasks and kept at 25.00°. The volumes of the alcohol solutions were considered additive. When water was added, an approximate correction on the final volumes was estimated.[20] Aliquot portions of the reaction mixture were withdrawn from time to time and titrated with alcoholic hydrogen chloride or aqueous sodium hydroxide with phenolphthalein as the indicator.

The sodium ethoxide stock solution was freshly made up by dissolving cleaned sodium rinsed with absolute alcohol in absolute alcohol with protection against moisture and carbon dioxide. The solution was standardized before use.

Preparation of Crotyl Ethyl Ether.—A mixture of 92.5 g. of crotyl chloride in 800 ml. of ethanol and 700 ml. of approximately 2 *N* sodium ethoxide was kept ten days at 25° and then diluted with water to six times the volume. The mixture was then extracted with 1000 ml., then 500 ml., and then 250 ml. of pure ether. The ether extracts were washed with a little water and dried over potassium carbonate. Some of the ether was distilled off at 34.1–34.4° through a Weston[21] type column using a good reflux ratio. The residue was distilled through a four-foot modified Podbielniak column. The fractions other than pure diethyl ether collected at 762 mm. were

Fr. 1	1.0 g.	34.1–65.0°	
Fr. 2	3.0 g.	65.0–77.1°	
Fr. 3	34.5 g.	77.1–77.6°	$n^{21}D$ 1.3751
Fr. 4	3.0 g.	77.6–100.8°	
Fr. 5	68.5 g.	100.8–100.9°	$n^{21}D$ 1.4038
Holdup	3.0 g.		

Fraction 3 was a constant-boiling mixture of alcohol and crotyl ethyl ether,[22] so fractions 1, 2, 3 and 4 were poured into 200 ml. of water and the ether separated with the aid of 100 ml. of pure carbon disulfide. The carbon disulfide layer was dried over potassium carbonate and distilled through the four-foot Podbielniak column. The fractions collected other than pure carbon disulfide were as follows at 765 mm.

Fr. 1	2.3 g.	46.7–100.7°	
Fr. 2	9.5 g.	100.7–100.9°	$n^{23}D$ 1.4030
Holdup	2.0 g.		

There was no indication of methylvinylcarbinyl ethyl ether. A generous estimate of the amount of this ether would be one-third of Fraction 1. This places the proportion of secondary ether as less than 1% of the total. The yield of ether was 82%.

Preparation of Methylvinylcarbinyl Ethyl Ether.—A mixture of 63 g. of methylvinylcarbinyl chloride and 500 ml. of approximately 2 *N* sodium ethoxide in absolute ethanol was left two weeks at 25° and four days at 35°. The mixture was poured into 2.5 liters of water and the ether separated with the aid of 200 ml. of pure carbon disulfide and two 100-ml. portions more. The extracts were dried briefly over potassium carbonate and distilled through the four-foot Podbielniak column. The fractions collected at 760 mm. which contained other than water, alcohol and carbon disulfide were

Fr. 1	5.0 g.	46.9–76.4°	
Fr. 2	32.5 g.	76.4–76.8°	$n^{23}D$ 1.3882
Holdup	3.5 g.		

The holdup was distilled through a short Vigreux column, 2.7 g. distilling 77–96° and having $n^{23}D$ 1.3960. This indicated a maximum of 1.4 g. of crotyl ethyl ether out of a total of approximately 37.2 g. (53% yield) considering 2.0 g. of Fraction I as ether.

Kinetic Experiments in Acetic Acid.—The procedure used for the rate determinations was the same as that of Steigman and Hammett[17] except that the excess acetate ion was titrated with a solution of perchloric acid in acetic acid. The acetic acid solvent was purified by treatment with potassium permanganate and then triacetyl borate,[23] material, m. p. 16.6° being obtained. The potassium acetate was dried at 110–120° for three hours and the diphenylguanidine was Eastman Kodak Co. material.

Analysis of Reaction Products in the Ester Preparations.—In order to determine the composition of the esters produced in various conversions of the butenyl chlorides to acetates, runs were made using in each case, unless otherwise specified, 250 ml. of solution approximately 1 *N* in chloride and acetate. Final analysis of the esters with an accuracy of 2 or 3% was accomplished by distillation through a three-foot Podbielniak type column. The results are summarized in Table VI.

Reaction of Potassium and Diphenylguanidinium Acetates with the Butenyl Chlorides in Acetic Acid.—The reaction mixtures of dry base, dry acetic acid and butenyl chloride were held at 78.6° for the desired interval and then poured into ice-water. The acid was carefully neutralized with concentrated sodium hydroxide and the ester was extracted with ether. After being dried over potassium carbonate, the extracts were distilled. A blank experiment was carried out on methylvinylcarbinyl acetate which showed that the ester remained unchanged under the conditions of the experiment.

Reaction of Crotyl Chloride with Potassium Acetate in Acetic Anhydride.—A mixture of 25 ml. of crotyl chloride and 28 g. of dry potassium acetate and 300 ml. of fractionated acetic anhydride (b. p. 139.0–139.1°) was heated on a water-bath under reflux with efficient stirring. After the heating period, the mixture was quite dark. The volatile material was distilled (25–40°) at reduced pressure, the distillate was poured onto crushed ice and the mixture was allowed to stand for an hour to hydrolyze the anhydride. The resulting solution was neutralized and treated as in the previous case. On distillation of the ester, there was no evidence of secondary acetate.

Reaction of Methylvinylcarbinyl Chloride with Tetraethylammonium Acetate in Acetone.—A mixture of 41 g. of tetraethylammonium acetate prepared from the directions of Steigman and Hammett,[17] 20 ml. of the butenyl chloride and 200 ml. of dried and fractionated Merck C. P. acetone was boiled under reflux. After heating, the volatile material was distilled from salts at reduced pressure, the receiver being cooled with a dry-ice-bath. The distillate was then fractionated. There was no evidence of any crotyl acetate in the product.

Reaction of Silver Acetate with the Butenyl Chlorides in Acetic Acid.—A mixture of 45 g. of silver acetate which had been recrystallized from water and dried over sulfuric acid for three days, 25 ml. of butenyl halide and 250 ml. of dry acetic acid was stirred at room temperature. At the end of the reaction period, excess sodium chloride was added, the mixture was filtered and the filtrate was treated as in the case of the runs with potassium acetate in acetic acid.

Summary

The kinetics of conversion of crotyl and methylvinylcarbinyl chlorides to ethyl ethers and acetates and the compositions of the products of the conversions have been studied. The compositions of the products can be well accounted for on the basis that bimolecular replacement of the chloride group by an ethoxide or acetate ion gives rise only to normal product while solvolytic or S_N1 type reaction gives rise to a mixture of allylic isomers.

By choosing conditions unfavorable for the S_N1 type of reaction, it is possible to convert the butenyl halides to the corresponding pure acetates or ethyl ethers.

The Relation of Dielectric Properties to Structure of Crystalline Polymers. I. Polyesters

BY W. A. YAGER AND W. O. BAKER

The interpretation of dielectric properties in terms of molecular structure[1,2] may be attempted for assembles of macromolecules when knowledge of polymer constitution and structure permits recognition of polar groups and of their relative disposition. The following factors have been considered in the succeeding report of the dielectric behavior of linear polyesters.

The most probable source of orientation polarization in solids containing long chain molecules with polar linkages has been attributed to the rotational–vibrational (liberational) motion of atomic groups rather than to the unified displacement of a given molecule.[3,4] Of course, potentials inhibiting rotation around most single bonds, especially the carbon–carbon bond,[5] prevent complete independence of the motion of polar groups from the size and form of their attached chains.

Also, in polymers, the loss component, ϵ'', of the dielectric constant generally deviates from the value it should have at an absorption maximum on the Debye theory for a single relaxation time.[6,7]

In polymer chains, the dipoles do not exhibit Brownian motion along three axes but rather primarily an intrachain kinking.[8] An internal viscosity related to macroscopic plasticity,[9] brittleness and softening has been postulated to cause the absorption. Specific rate constants from the relaxation times can be employed in an absolute rate analysis of the temperature variation of loss. Such treatment, suggested by Eyring,[10] was developed by Frank,[11] and gave a precise correlation in simple alkyl halides with structure and with viscous flow,[12] from which dipole orientation seems to differ considerably in extent of motion.

The linear supercondensation polyesters[13] and polyamides[14] possess many of the desired qualities of model polymers for dielectric studies. These polymers have simple polar groups (ester or amide linkages) regularly spaced along hydrocarbon chains. This intrachain spacing is readily varied, in forming the polymers, by selecting dibasic acids, glycols and diamines of appropriate chain lengths. Thus the effect of articulation or coupling of the orienting units along a given chain may be detected. This variation likewise alters the number of dipoles per cc. and is thus useful in studying the volume polarization. Further, these polymers are generally highly crystalline, and diffraction studies have revealed the relative arrangement of the polar groups in adjacent chains, and whether the dipoles are surrounded by other dipoles or by hydrocarbon groups.[15] The interchain forces constraining dipole motion may be specifically explored by comparing polyesters and polyamides of the same concentration of polar groups per unit of chain length, since the hydrogen bonding from the amido link causes a twofold increase in attraction as estimated from fusion properties. The average chain lengths of the polymers may be determined accurately.[16] Finally, the polymers are prepared essentially chemically pure and of high stability, and the effect of any technically important contaminant such as water may be ascertained and interpreted.

Experimental

Materials.—The seven polyesters were prepared by Mr. C. J. Frosch and Mr. W. S. Bishop of these Laboratories. Procedures similar to those of Carothers[13] were employed. The products were unfractionated and therefore contained the distribution of molecular weights calculated for a random reaction of end groups,[17] and found experimentally.[16] The molecular weights lay in general in the "superpolyester" range, above $M_w \sim 6000$. The products were free from all oxidation or similar degradation. Their high crystallinity and consequent sharp melting points permitted preparation of test discs of precise and constant geometry. The polyesters were melted in vacuum, thus freed of gas bubbles, and allowed to solidify slowly, between glass plates held apart by shims. The thickness of individual samples was quite uniform, and was determined by numerous micrometer readings. Among the discs, the average thickness varied from 40 to 60 mils. Decamethylene oxalate cracked badly on cooling, so that the dielectric results may be complicated by the presence of voids. All of the samples were annealed to states of maximum crystallinity,[18] and were thoroughly dried.

Dielectric Measurements.—For the frequency range 1 to 100 kc., the dielectric constant and equivalent parallel conductance were measured on a shielded conductance–capacitance bridge.[19] Precise and reproducible contact with the electrodes was obtained in a condenser cell described below in connection with the Q-meter, on which measurements from 100 kc. to 75 megacycles were made.

The type 100A Q-meter,[20] the test cell, measuring technique and corrections described in a previous paper[3] were employed for the measurements on the polyesters. All other measurements were made on the much improved type 160A Q-meter employing a new type test condenser and a special thermostat.

The measuring technique previously described[3] is unsatisfactory for measurements above or below room temperature since it requires removal of the test sample from the test condenser at each frequency. The only alternative is to leave the sample in place, tune the LC circuit with the test condenser connected, disconnect the test condenser and retune the circuit with the internal tuning condenser. This method is less desirable than the former because corrections must be applied at high frequencies for the differences in lead inductance and series resistance of the internal tuning and test condensers in computing the capacity

(20) The construction, theory and operation of the Q-meter are described in a manual furnished by the manufacturer, Boonton Radio Corporation, Boonton, New Jersey. The type 100A Q-meter is now superseded by the type 160A, which is a much improved model and covers the frequency range from 50 kc. to 75 mc.

and loss of the test specimen. The capacity of the sample is given by

$$C_x = \frac{C_1 - C_2}{D + B(C_1 - C_2)} - C_f$$

where $D = (1 - \omega^2 L_1C_1)^2$ and $B = (L_2 + L_1(1 - \omega^2 L_1C_1))\omega^2$. C_2 and C_1 denote the capacity of the internal tuning condenser at resonance with the test condenser connected and disconnected, respectively. C_f is the fixed capacity of the test condenser. L_1 and L_2 represent the series inductance of the internal tuning condenser and test condenser, respectively. For the arrangement employed L_1 is 0.00148 μH and L_2 is 0.03 μH. The dielectric loss factor, ϵ'', is given by the equation

$$\epsilon'' = \frac{IZC_{oe}A^2}{C_a}\left[\frac{E_1 - E_2}{E_1E_2} - F_M\right]$$

IZ, the voltage impressed on the measuring circuit, was determined experimentally at each test frequency, and a calibration employed for subsequent tests. C_{oe}, the effective capacity necessary to resonate a given coil at a given frequency, is obtained from the relation

$$C_{oe} = C_1/1 - \omega^2L_1C_1$$

Furthermore, $A = 1 - \omega^2L_2(C_x + C_f)$. E_2 and E_1 represent the readings of the Q-voltmeter in volts at resonance with the test condenser connected and disconnected, respectively. F_M is a factor to correct for series resistance as noted above. It is negligible at frequencies below 10 mc. but increases rapidly with increasing frequency and magnitude of the test capacity. Calibration curves were prepared for F_M *versus* frequency and C_x at room temperature employing the test condenser as a variable air condenser. Although F_M was found to vary somewhat with temperature, this variation was erratic and of a second order so that the room temperature calibration was employed at all temperatures.

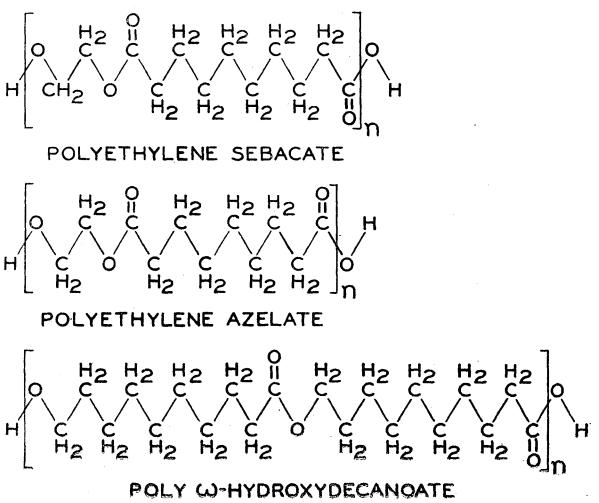

Fig. 1.—Structural formulas of typical polyesters.

A complete description of the new test condenser and thermostat is omitted for brevity. The test condenser of gold-plated brass was designed so that it may be used either as a clamping condenser for a specimen or as a variable air condenser. The electrodes are 2 inches in diameter, with the variable electrode an integral part of the housing which is connected to ground. The high tension electrode is fixed and insulated from the housing by means of clear, fused quartz. Since it is desirable to minimize the lead inductance of the test condenser, the coaxial type of construction was employed. The high tension lead was brought out through a coaxial tube $^3/_8$" in diameter and 4" long. A coaxial jack was mounted directly over the high tension terminal on the Q-meter and was designed so that the test condenser could be connected or disconnected from the measuring circuit simply by screwing it in or out of the coaxial jack.

Thermostating a test condenser in such close proximity to the Q-meter presented some difficulty. The design finally adopted consists essentially of a metal cylindrical jacket fitted at one end with a heating and cooling chamber and constructed so that it will slide over the test condenser. A small ring heater is employed for heating and provision is made for siphoning liquid nitrogen into the cooling chamber. An air thermo-regulator serves for temperature control. This metal thermostat with the test condenser in place fits into a Dewar flask with an opening in the bottom large enough to permit the coaxial tube of the test condenser to pass through. The entire assembly is mounted on top of the Q-meter directly over the coaxial jack and lined up so that the test condenser can be screwed in and out of the jack. The test condenser is screwed out of the jack and kept in a raised position at all times except during a measurement so as to minimize heat exchange between the Q-meter and test condenser.

The d. c. conductivity was negligibly small for all samples.

Results and Discussion

Figure 1 illustrates the planar zigzag chains which comprise most linear polyesters. Only certain types have been shown; for instance, polyethylene azelate represents an odd-membered dibasic acid which results in the two carbonyl dipoles of a chemical repeating unit being parallel, and evidently this same structure could easily be arranged in other polyesters. Chain oscillations continuously distort instantaneously the planarity of the carbon skeleton. Since such motion normal to the chain axis generally requires twisting about valence bonds, the modes contributing the orientational polarization from the models of Fig. 1 will not be uniformly distributed along the chains, for the potentials hindering rotation about bonds

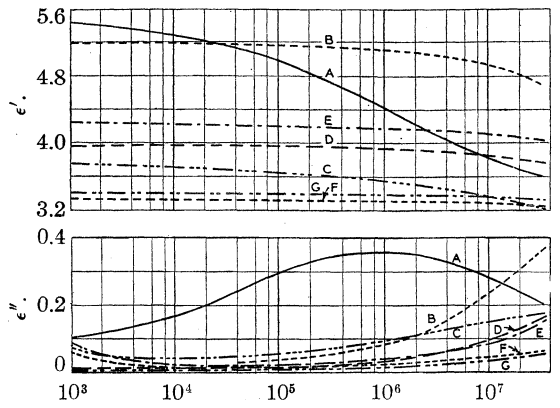

Fig. 2.—Frequency variation of dielectric constant and loss factor of polyesters at 25°: A, polyethylene succinate; B, polyethylene adipate; C, polydecamethylene oxalate; D, polyethylene azelate; E, polyethylene sebacate; F, polydecamethylene sebacate; G, poly-ω-hydroxydecanoate.

at the polar groups probably are lower than for the CH_2–CH_2 bonds.[21] However, the CH_2–O bond may have a high potential.[22] Small segments of the chains may act as relatively stiff units bounded by more flexible linkages. That such chain flexibility does obtain is clearly indicated by the data of Fig. 2, in which the values of ϵ' for such structures as polyethylene sebacate (see Fig. 1) considerably exceed the square of the refractive index, yet successive dipoles along the chain are oppositely directed and should cancel if the whole molecule is rigid. If only the terminal groups on the chains move in the applied field, the static dielectric constant would be virtually independent of the concentration of polar groups in the compound. This is contrary to experimental results, as will appear below. Pelmore and Simons[23] examined this aspect of five linear polyesters containing both opposite and parallel dipoles, as diagrammed in Fig. 1, and likewise concluded from the relaxation times that polar chain segments must be acting.

Although discussion of the effect of polar group concentration would be preferred in terms of specific polarization, there is yet no local field equation adequate for such anisotropic and highly interacting solids.[24] Hence we use simply the static dielectric constant, ϵ_0'. The concentrations are computed as follows.

Let

n_1 = number of —CH_2— groups of molecular weight M_1, per cc.

n_2 = number of polar (ester) linkages of molecular weight M_2, per cc.

ρ = density of the polymer

b = ratio of number of CH_2 to O—C(=O)— groups per chemical repeating unit

$$n_1 = bn_2 \qquad (1)$$

N = Avogadro's number

Then

$$\rho = (n_1M_1 + n_2M_2)/N \qquad (2)$$

The experimental values of these quantities appear in Table I. The densities at 25° were from weighing and displacement of a known volume of inert liquid by the solid polymer. Polyethylene is included to represent the limiting case of all —CH_2— and no polar groups.

TABLE I

Compound	ρ, 25°	$n_1 \times 10^{-22}$	$n_2 \times 10^{-22}$	ϵ_0'
Polyethylene	0.924	4.00	0	2.33
ω-Hydroxypolydecanoate	1.064	3.41	0.38	3.40
Polydecamethylene sebacate	1.086	3.48	.39	3.32
Polydecamethylene oxalate	1.130	3.00	.60	3.70
Polyethylene sebacate	1.148	3.05	.61	4.20
Polyethylene azelate	1.172	2.99	.66	3.96
Polyethylene adipate	1.250	2.64	.88	5.16
Polyethylene succinate	1.358	2.29	1.14	5.60

Relations from Table I appear graphically in Fig. 3. The density of the solids increases linearly with the concentration of polar groups. However,

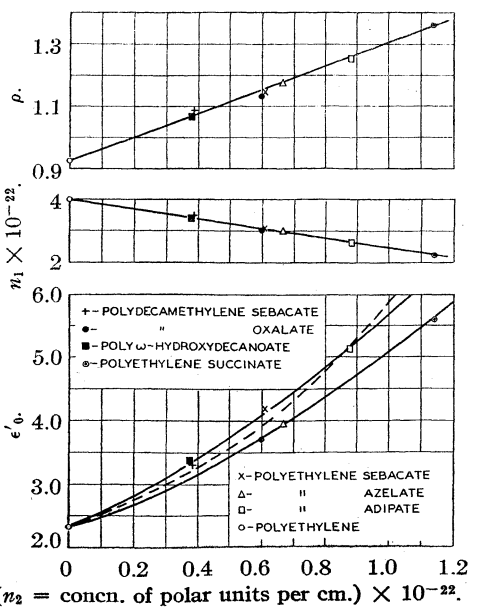

Fig. 3.—Dependence of static dielectric constant and density on concentration of polar groups in polyesters.

this increase in density is actually greater than is caused by the heavier —O—CO— units in the chain. This can be shown by simple calculation, and emphasizes the considerable contribution of the dipole forces to the lattice energy. The proportionality of n_1 to n_2 in agreement with the ratio of the polar to methylene groups *along* the chains agrees with the idea of regular packing in the series. The increase of ϵ_0', the static dielectric constant, with n_2, shown in the lower curves of Fig. 3, emphasizes the comparative independence along the chain of librating polar groups.

The dashed curve on Fig. 3 is the value ϵ_0' would have if the orientation polarization calculated from the equation of Debye for non-interacting dipoles agitated by ordinary Brownian movement, with local fields described by the Lorentz equation, were directly proportional to n_2. However, certainly the above conditions are poor approximations for linear macromolecules in the solid. Hence, we shall not at present discuss the specific polarization, despite the advantages of the Onsager field equation.[25] Also, recent treatments[26] of the internal Brownian motion in randomly-kinked chains[8] require modification for partially crystalline systems, in which considerable sections of the chains are extended in the lattice. In dilute solutions of many chain polymers assignment of effective group moments is less uncertain. There is agreement on highly convolved chains, in which the individual dipoles have almost complete freedom. Further, the molecular dipole moment appears to vary with the square root of the molecular weight.[27–31] The studies of Wyman and Bridgman on the self-polyesters of ω-OH-decanoic acid are especially relevant here, since they concluded that there was nearly complete freedom of group orientation in solutions. Evidence of large interaction (rather than intrachain restraint) reducing the freedom of the dipoles in the solid polymers arises from the two-fold higher specific polarizations (0.8) of polydecanoates found by Bridgman compared to the values (0.4) we estimate for the solid from approximate field equations.

Since the orientation polarization is reduced in the solid compared to the dissolved state, the smooth rise of ϵ_0' with n_2 in Fig. 3 suggests a comparable reduction factor in all of the polyesters. This would agree with the structural evidence[15] of layers of dipole vectors either perpendicular to (odd esters) or inclined at another angle (even esters) with the chain axes. The association of these dipoles may control the solid arrangement. In any case, they occur in layers, and seemingly the interaction is largely in these planes rather than between them, so that the spacing of dipoles *along* the chain is not a predominant factor. However, some interaction along the chain appears in two of the points on the lower solid line on the ϵ_0' curves of Fig. 3. The points on this line for polyethylene succinate and polydecamethylene oxalate show a reduced ϵ_0', expected from the proximity of the dipoles, especially the carbonyl groups, along a given chain. Presumably because of this closeness, the polyethylene succinate chain does not conform to the usual sort of planar zigzag configuration,[15] and polydecamethylene oxalate has an unusual cross-sectional packing.[15] The lower ϵ_0' value for polyethylene azelate is related to another interesting structural change. As noted, the planes containing the polar groups in polyesters having an odd-numbered acid (C_9 for the azelate) are perpendicular to the chain axes. Thus dipoles in adjacent chains come more directly into interaction than when these planes are tilted. Further, the disposition of these resultant dipoles along the chain may actually cause the vertical rather than tilted planes. For in the azelate model of Fig. 1, it is seen that the vector dipoles of the ester groups do not point in the alternately back and forth directions obtaining in the even esters. In the latter, every other dipole along a chain points in the same direction and at the same angle with the chain axis. Thus, the tilted planes containing the carbonyl groups also may be considered to contain rows of "head-to-tail" dipoles. However, in the odd polyesters the vector dipoles all lie on the same side of a given chain. If the chains shifted so that the carbonyl groups in adjacent molecules formed one tilted plane containing "head-to-tail" dipole vectors, the dipoles attached to the other ends of the acid unit (say the azelaic unit) would be uncompensated between chains and would tend to shift the chains back. The vertical form of the odd polyesters with the dipoles shifted neither one way nor the other in adjacent chains probably represents the minimum energy, as indicated by the X-ray

Figure 4 illustrates the frequency dependence of ϵ' and ϵ'' for polyethylene sebacate over a temperature range down to $-98.5°$. Representative data are shown in Table II. As suggested on Fig. 2, absorption maxima occur at the lower temperatures. These are shown as a function of temperature for various frequencies up to 75 mc. in Fig. 5. Wide deviations from the ideal Debye behavior are evident, in agreement with most other polymer systems.[3,7] The ϵ'' *vs.* ln f peaks are much broader, and max. ϵ'' is lower, than expected from the theory for a single relaxation time. However, the concept of group orientation inhibited by interchain potentials is supported by the temperature studies. For it is apparently possible to eliminate absorption and to reduce ϵ' to little more than the square of the refractive index on reducing the kinetic energy of the groups by cooling. The absorption maxima may be readily shifted along the frequency scale by temperature. As the temperature is lowered, the number of groups possessing the energy requisite for surmounting the barriers opposing libration decreases. This means that the absolute reaction rate[32] is reduced, and the polar units are finally unable to follow an alternating field. Thus, at a given temperature, the frequency of maximum ϵ'' indicates about the rate constant at which most of the orienting units are able to oscillate over the barriers. Of course, for gases, on the Debye theory the frequency of maximum absorption equals $1/\tau'$, where τ' is the relaxation time for the dipoles, but in a liquid or solid a given dipole interacts on the surrounding matter to produce an additional polarization so that the relaxation time of the medium, τ, obtains. The familiar expression

$$\tau = \tau' [(\epsilon_0 + 2)/(\epsilon_\infty + 2)] \qquad (3)$$

relates these two relaxation times, where ϵ_0 is the dielectric constant at zero, and ϵ_∞, at infinite frequency. Since the expression above for relating τ to τ' really involves an accurate formula for the local field, which is not yet known for these solids, we shall regard τ for the dielectric as a rough measurement of the rate process for the movement of the atomic groups. It is hoped that subsequently this approximation may be improved. Also, the problem of the distribution of relaxation times about an apparent average value will be omitted from this preliminary discussion.

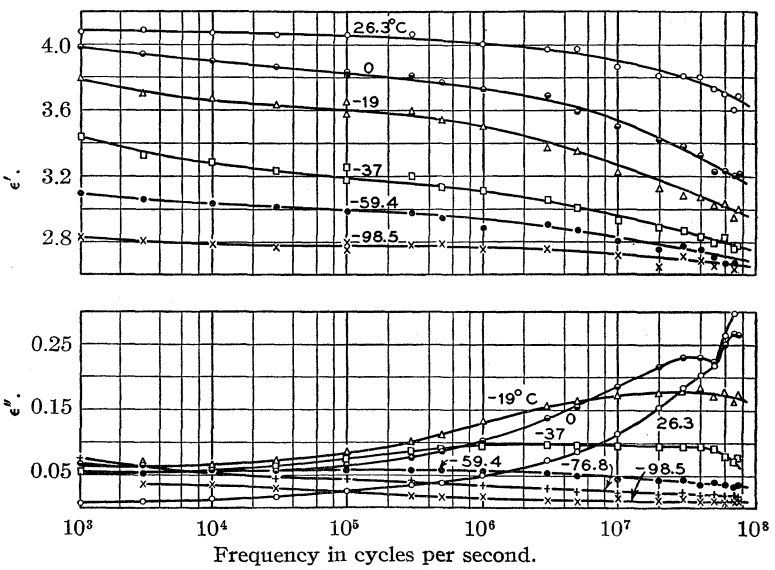

Fig. 4.—Frequency variation of ϵ' and ϵ'' of polyethylene sebacate, $-100°$ to $25°$.

The hindered orientation of groups in polyethylene sebacate may then be regarded as analogous to a unimolecular reaction[10,11] whose

(32) S. Glasstone, K. Laidler and H. Eyring, "The Theory of Rate Processes," McGraw-Hill Book Co., Inc., New York, N. Y., 1941.

absolute rate constant, k', is in general given by

$$1/\tau = k' = Ce^{-E/RT} \qquad (4)$$

where C is the "steric" factor, E the activation energy in cal. per mole, T the absolute temperature and R the gas constant.

We assume that E is virtually temperature independent; actually, since E represents a difference between energy levels which does depend on temperature, the corrections of Rushbrooke[33] should properly be applied.

From the loss maximum of Fig. 4, τ is obtained from the frequency producing ϵ'' max. at a given temperature. Although Fig. 5 shows several maxima, the ϵ'' curves here overlap, and do not provide a reliable estimate of the mean τ for a given temperature. A plot of $1/\tau$ against $1/T$ gives a straight line, the slope of which is E/R, and $E =$ 12,100 cal. per mole of orienting groups, for polyethylene sebacate. This value is most significant

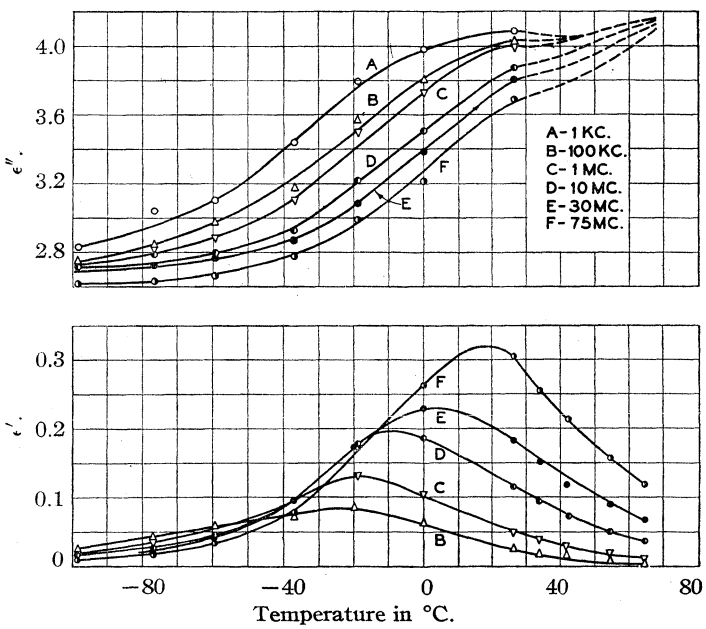

Fig. 5.—Temperature variation of ϵ' and ϵ'' of polyethylene sebacate, 1 kc. to 75 mc.

when compared to the larger value for a polyamide.[34] Further, the entropy term is large; in equation (4), $C = 4.3 \times 10^{18}$. This indicates that the neighbors of an orienting group must cooperate in its motion, such as by momentary displacements to reduce steric hindrance or by concentration of energy in the vicinity, as interpreted previously.[12]

The entropy term in the above expression should be significantly related to the distribution of relaxation times found for a given system. A distribution of relaxation times implies a variety of motions and configurations surrounding the orienting groups and causing different rates of surmounting the restraining barriers. This is just what the entropy of activation, or "activation in many degrees of freedom,"[11] means. Studies connecting explicitly the distribution function with the entropy or "steric" term in the rate equation are in progress.

Reduction in intermolecular coupling appears to give a sharper experimental distribution. Thus, consistent with the above concept, absorption peaks at high temperatures, with high plasticizer contents, or from "soft," weakly interacting polymers at ordinary temperatures are comparatively sharp.

Figure 5 bears interestingly on the phase changes in linear condensation polymers. Their high crystallinity[15,18] precludes a wide softening range, and the rise in ϵ' (accompanied by dispersion) over the broad temperature interval in Figure 5 corresponds to little physical change in the solid. However, the polymer melts (in thermodynamic equilibrium)[35] at ~70°. This is, however, just above the temperature at which the dipoles are able quite freely to follow at least frequencies of 10^8. The ester linkages, or the carbonyl units, are thus undergoing increasingly violent thermal oscillations and are able to surmount the barriers imposed by the lattice array. Figure 5 may thus be regarded as indicating the prelude to fusion. Similar studies on other crystalline polymers including cellulose derivatives give evidence on the role of polar groups in melting. These are also further corroboration of the segment theory of polymer melting.[18]

The occurrence of absorption maxima far below the melting point, as for polyethylene succinate in Fig. 2, simply marks the onset of a particular oscillation—not necessarily that required for breakdown of the lattice.

Summary

The dielectric constant and loss of typical linear polyesters have been determined (over a

(33) G. S. Rushbrooke, *Trans. Faraday Soc.*, **36**, 1055 (1940).

120° temperature range for one) for the frequency interval 1 kc. to 75 mc. These macromolecular chain polymers are of known structure and composition, so that the observed polarization and dispersion were related to the orientation and concentration of polar groups in the chains and to their relative positions in adjacent chains. The dielectric constants, ϵ', of all of the polymers exceed the refraction value even at room temperature. The oscillation of individual dipole groups (ester linkages) contributes the orientation polarization. These dipoles interact somewhat along a given chain, but chiefly between chains, to cause the observed broad dispersion. The polyesters exhibit principally high frequency absorption, with maxima at low temperatures. This supports the concept of small oscillating units in the chains, in agreement with the observed activation energy of orientation.

The packing of the chains is strongly influenced by the dipoles and the formation of dipole layers makes the interaction, which contributes to dielectric absorption, largely independent of polar group concentration.

The dielectric results reveal thermal motion in the polymers. These chain oscillations are supposed to account for mechanical properties such as thermal retraction associated with chain kinking in long chain molecules.

The Relation of Dielectric Properties to Structure of Crystalline Polymers. II. Linear Polyamides

BY W. O. BAKER AND W. A. YAGER

Linear condensation polymers have been selected as appropriate for study of the effects of molecular structure and molecular order on the dielectric properties of solids.[1] They represent an important class of structural and insulating plastics. Polyesters have been treated previously and the general implications of such an investigation have been reviewed. The present report includes preliminary results on the polyamides, in which the —O— of the ester linkage has been replaced by the —NH— group. Conditions for extensive hydrogen bonding have thus been introduced, and the whole structure resembles that of polypeptides and proteins. The dielectric measurements indicate great mobility in the alternating field of some atomic group, possibly a charged hydrogen. The close analogy of the polyamides to the polyesters allows assignment of the observed differences to the NH group. Certain of the results may be examined for direct evidence of isomerism in the amido linkage. Thus, the linear polyamides may assist, as models, in elucidating the structure of proteins.

Experimental

Materials.—The polyamides were obtained commercially (du Pont Company) or from the procedures of Carothers.[2] They were pure, white polymers with weight average molecular weights greater than 10,000. All were carefully protected from degradation during preparation of the test discs.[1] The co-polyamide was of the 50-50 composition noted in the patent describing it.[3] All samples were annealed to states of maximum crystallinity,[4] unless otherwise noted. The sample discs were molded and machined to a two-inch diameter and 50-mil thickness, were thoroughly dried over phosphorus pentoxide, or conditioned as noted, and equipped with electrodes as previously described.[5]

Dielectric Measurements.—The bridge and Q-meter apparatus and technique used for the polyesters were again employed.

The dielectric loss of polyhexamethylene sebacamide at and above 100°, and of polyhexamethylene adipamide at 100% relative humidity was too high for direct measurement on the Q-meter. Consequently, the top electrode of the test cell was raised above the test specimen, thus introducing a series air gap. The effective capacity, C_m and loss, tan δ_m, of this two-layer arrangement were determined on the Q-meter and the true capacity, C_x, and loss, tan δ_x, calculated from the equations

$$\tan \delta_x = \frac{C_a}{C_a - C_m} \tan \delta_m$$

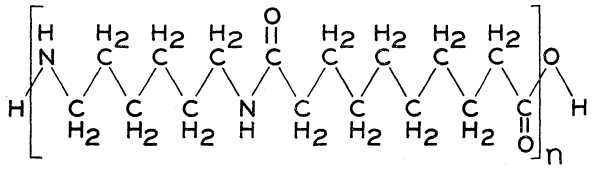
$$C_x = \frac{C_a C_m}{C_a - C_m} \cdot \frac{1}{1 + \tan^2 \delta_x}$$

where C_a represents the series air capacity. C_a was calculated from the above equations by measuring C_m and tan δ_m and then the corresponding C_x and tan δ_x directly on the capacitance and conductance bridge.

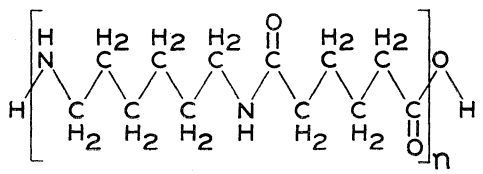
The direct current conductivity of the polyamides was determined after the application of 100 volts for one minute, by use of a Leeds and Northrup H.S. type galvanometer.

Results and Discussion

The structural formulas of two typical polyamides appear in Fig. 1. Evidently, the concentration of polar groups may readily be varied with methylene "spacers," as in the polyesters.[1]



POLYHEXAMETHYLENE SEBACAMIDE



POLYHEXAMETHYLENE ADIPAMIDE

Fig. 1.—Structural formulas of typical linear polyamides.

Likewise, the polar groups in adjacent chains occur in layers,[4] and their interaction includes hydrogen bonding[6] as well as dipole and dispersion forces. The presence of a bonding hydrogen profoundly alters the properties of the polymers. The primary valence chains wander in kinked paths through the crystalline and intercrystalline matter,[4] but in addition a network of secondary forces (hydrogen bonds) obtains. Thus, the interchain forces, and hence the restraints on dipole orientation, should exceed those for the polyesters, as confirmed below. Such predictions of polymer properties from structural formulas have been possible only recently.

Figure 2 shows the dielectric behavior of several polyamides at 25°, with the curves A for polydecamethylene sebacate included for direct comparison. Apparently an appreciable orientation polarization contributed by the motion of the polar groups is present in all of the solids. The polyester has the same concentration of polar links in the chain as the polydecamethylene sebacamide of curve C (9 methylene groups per linkage). The polyamide exhibits significant dispersion at room temperature. The restraint of orientation found in the polyesters[1] appears much increased in the polyamides, in accord with their higher melting points and mole cohesion. The sequence of ϵ' values in Fig. 2 also shows expected increased polarization in the polyamides with increasing concentration of polar groups in the chain. Curve C, for polydecamethylene sebacamide, with 9 CH_2 groups per polar linkage is followed by curve B (polyhexamethylene sebacamide) with 7 and Curve E, for polyhexamethylene adipamide, with 5.

Evidently polyhexamethylene adipamide possesses a broad maximum in ϵ'' at room temperature. This breadth and height of maximum indicate a distribution of relaxation times, generally found in solids. The ϵ'' values for the polyamides have been corrected for d. c. conductivity, which, as noted later, is appreciable for these pure compounds.

The ϵ'' curves in Fig. 2 do not follow the order of the ϵ' for increasing values of the ordinates. This is related to an important aspect of the dielectric behavior of linear polymers. The concentration and resultant moments of the polar groups in the chain determine the essential polarity of the polymer, but it has been emphasized that the interaction with neighboring chains chiefly governs the observed loss. The following discussion indicates some factors causing a variation in interaction and hence in loss. In the melts of these polymers, strong dipole association facilitates the formation of the dipole layers observed in the solid. This layering is distorted, however, in the portions of the polymer which are imperfectly or hardly crystalline, and hence the dipole interaction would be expected to vary with the degree of molecular organization present in the solid studied. This degree of order controls considerably many physical properties of the plastics, such as elastic modulus.[4] Hence, some correlation between physical and mechanical properties and dielectric behavior is a necessary, and observed, consequence of solid structure. The variety of ordered states which may be produced in natural products like

(6) Pauling, "The Nature of the Chemical Bond," Cornell University Press, Ithaca, N. Y., 1939, Chap. IX.

cellulose derivatives[7] should likewise be reflected in their dielectric values; the effect is general. Clearly, the dipoles may be disposed differently in adjacent chains either by shifting along the chain, or rotation about its axis. Both of these conditions are present in the non-crystalline regions of linear polymers, as diffraction studies show.[4,7] If the argument above that the longer relaxation time of the polyamides compared to the polyesters is caused by strong intergroup action, principally hydrogen bonding, is correct, then altered relative positions of the groups should alter the dielectric loss. This is shown by Curves C and D of Fig. 2. Curve C is for annealed polydecamethylene sebacamide, in which the polar groups are as efficiently packed and as extensively hydrogen bonded as the lattice-forming deficiencies of long chains permit.[7] The sample of curve D, however, was the same polyamide rapidly quenched from the melt. It contains relatively few crystallites, and the chain segments are rotated so that the hydrogen bonds are, on the average, less efficiently directed and formed than in the annealed compound. They resemble the hydrogen bonding in a liquid rather than in a well-ordered solid. Still, they are strong enough to stabilize the chains in their disordered configurations of higher free energy (compared to the crystal) for long periods, as shown by the rate of crystallization of polyamides in the solid state.[4] However, the reduced forces in the quenched material permit augmented though still hindered dipole freedom, and hence curve D lies clearly above curve C, for ϵ' and ϵ''. These differences were caused not by a change in the composition of the chains, but only in their *relative positions*.

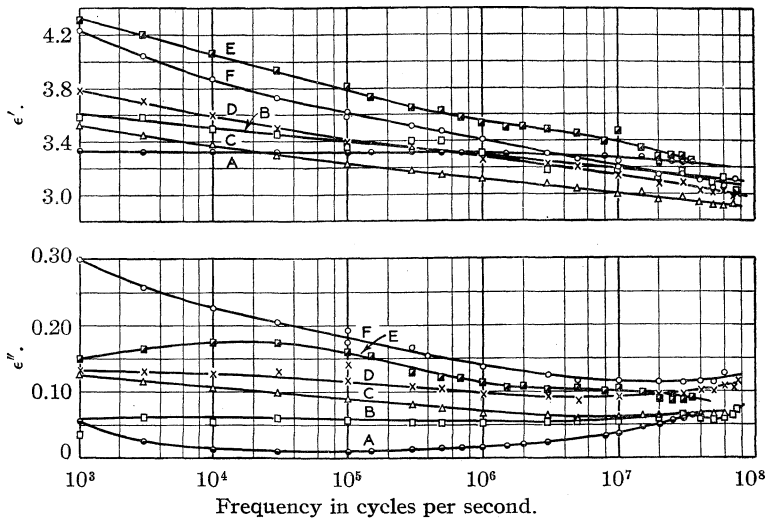


Fig. 2.—Frequency variation of dielectric constant, ϵ', and loss, ϵ'', of polyamides at 25°: A, polydecamethylene sebacate; B, polyhexamethylene sebacamide; C, polydecamethylene sebacamide, annealed; D, polydecamethylene sebacamide, quenched; E, polyhexamethylene adipamide; F, polyhexamethylene–decamethylene adipamide–sebacamide.

The structural variations possible in condensation polymers allow another test of the hypothesis that interaction is modified by relative positions and hydrogen bonding of amido links. If a polyamide is prepared by the intercondensation of two different dibasic acids and two different diamines, say in equimolar ratios, some of the polar groups will associate as usual, but, along a chain, the "repeating units" are quite random in composition, so that many of the dipole groups in adjacent chains will be unable to coincide to form a layer, and will be found surrounded by the hydrocarbon portions of the molecules.[7a] The compound of curve *F* was thus obtained from hexamethylenediamine, decamethylenediamine, adipic acid and sebacic acid.[3] Its average polar group concentration is one per 7 methylene groups, so that it should compare with curve B, yet it shows markedly increased dielectric constant and loss. The average composition of the copolyamide chains is the same as that of polyhexamethylene sebacamide, but the irregular spacing between linkages in the molecule reduces the hydrogen bonding and other interaction in the solid so that ϵ' and ϵ'' are much enhanced. This is further emphatic indication that the chains do not act as units, but that each individual dipole is sensitive to its own environment. Also, the intrachain coupling would be little different in the copolyamides than in the normal polyamides, so seemingly the interchain action alters the dielectric properties. The effect of these changes in interaction in the quenched and co-polyamides on the distribution of relaxation times in the polymer alone forms an extensive study.

The orientation of polar groups is probably not the sole source of high polarization in polyamides, especially at elevated temperatures. A new mechanism which we associate with the isomerism of the amido linkage seems necessary to explain the

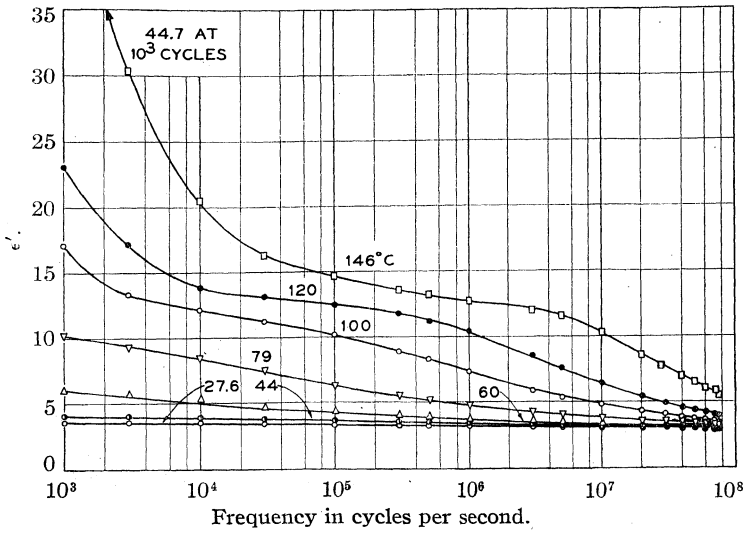

Fig. 3.—Frequency variation of ϵ' of polyhexamethylene sebacamide, 27.6 to 146°.

succeeding results, as in Figs. 3 and 4, for polyhexamethylene sebacamide, which are typical of the series. Some representative values are also given in Table I. At 1 kc. ϵ' has a value at 146° (70° below the melting or softening point of the polymer) of about 48, and ϵ'' is about 27. In addition, as is seen from its temperature variation in Fig. 7, there is a relatively high d. c. conductivity in the compound. The galvanometer behavior indicated that this was not from a space charge. These compounds are likewise free from ionic impurities, as determined by ashing, extraction and quantitative analysis.

The isomerism of the amido linkage has been chiefly considered in the structure of polypeptides and proteins. Hydrogen bonding is important in the molecular configuration of these compounds.[8] A group of the type shown here probably occurs within and between folded polypeptide molecules,[8a] and between the polyamide molecules here treated. Huggins[9] has proposed that the hydrogen in the bridge is virtually ionic. At least one may regard it as in one of two potential minima, one provided by the oxygen and the other by its "own" nitrogen. These two minima are separated by a hump, over which charged hydrogens with requisite energy may oscillate.[10] The dielectric results are consistent with a concept embodying mobile, charged atoms which can contribute an atomic polarization and anomalous dispersion by moving translationally (vibrationally) from one potential minimum to another in the dipole layers. This motion should be strongly temperature-dependent, which is supported by the data of Figs. 3, 4 and 5. The high frequency ϵ'' maxima of Fig. 4 represent a second mechanism and seemingly correspond to the maxima observed at lower temperatures for the polyesters. They occur at elevated temperatures presumably because the oscillations of, say, the carbonyl groups are inhibited by hydrogen bridges of the sort shown in the diagram above. From curve *A* of Fig. 6, obtained as noted before for the polyester[1] (curve B), E =

bridge hydrogen. It may pass over to one or the other of the positions near the O or N but possibly it can also acquire even more freedom and act like a migrant ion over very short distances, thus causing the high d. c. conductance. The temperature coefficient of this conductance appears in Fig. 7,

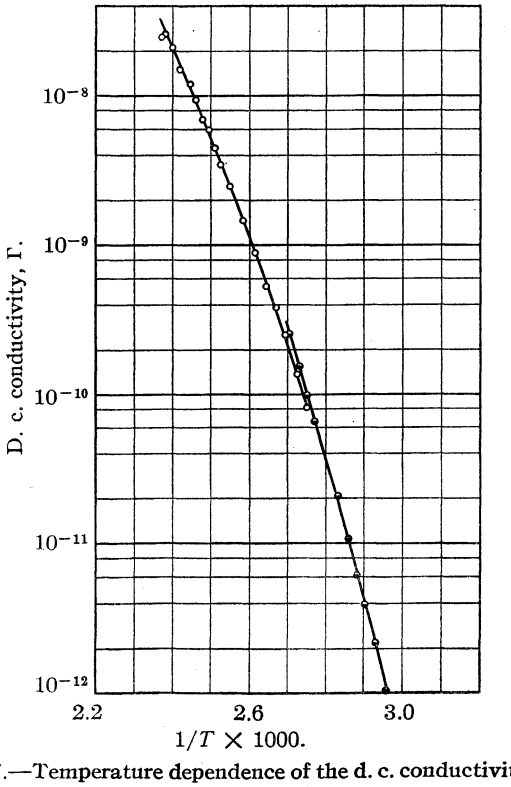

Fig. 7.—Temperature dependence of the d. c. conductivity, Γ, of polyhexamethylene sebacamide.

and corresponds to an activation energy of 29,700 cal. per mole of conducting particle. This value is several fold the dissociation energy for a hydro-

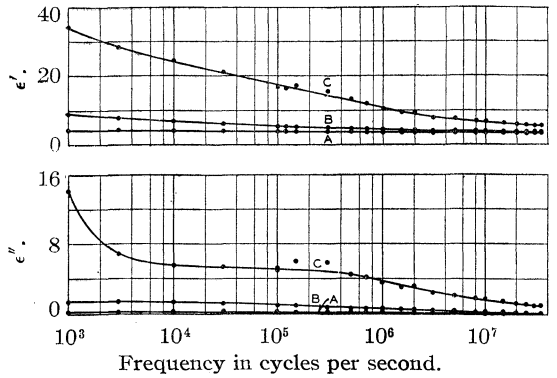

Fig. 8.—Effect of sorbed water on frequency dependence of ϵ' and ϵ'' of polyhexamethylene adipamide at 25°: dry (curves A), 60% R. H. (curves B) and 100% R. H. (curves C).

gen bond,[11] and may well reflect the energy necessary to liberate charged hydrogens from restraining negative force fields around a given N or O atom. It is less than half the energy of the N–H bond, but one would expect this link to be perturbed and weakened by the hydrogen bridges in the solid polyamides and by its adjacent carbonyl. (It should be emphasized that the atomic or nuclei motion cannot contribute, however, to the resonance in the amide linkage.) The d. c. conductance and low frequency loss may thus represent different degrees of the same sort of hydrogen motion. They are not to be regarded as measuring very different phenomena. The low frequency loss may not exhibit a maximum. Molten polyamides and the solids at higher temperatures thus are apparently semi-conducting materials.

It is a striking contrast that the relaxation time of the dielectric is 5×10^{-9} sec. for polyethylene sebacate at $-19°$ and for polyhexamethylene sebacamide at 146°. This large difference may be regarded chiefly as a consequence of the effect of molecular structure on the solid state. The isolated molecules would show no such different kinetic characteristics, nor would they be expected to show diverse intrachain coupling. On the other hand, the polyester melts at 74°, the polyamide at 215°; a 141° interval emphasizes the different forces. The relaxation times reflect thermal motion present in the polymers irrespective of the applied field, and hence are related to the elastic and plastic properties of the solids.

The explanation of hydrogen bridging and charged hydrogen motion in these bridges as the source of the extraordinary dielectric properties of typical linear polyamides suggests that strong hydrogen bonding agents added to the polymers at ordinary temperatures should produce the same effect as elevated temperatures alone. This is confirmed in Fig. 8 for water, whose sorption is of technical importance. Curves A were obtained from polyhexamethylene adipamide dried two weeks over calcium chloride, curves B, for the substance equilibrated (fifty-six days) at 60% relative humidity, and curves C, after immersion in distilled water, all at 25°. Evidently the combination of bound water (about 10% for saturation at room temperature) and the amido groups causes a high dielectric constant and appreciable dispersion. ϵ'' is again corrected for d. c. conductance. Water may be here considered as a loosening (plasticizing) or pseudo-ionizing medium, which substitutes for intermolecular polyamide bonds, and facilitates motion of the whole system.[7] Thus, if the dielectric results are admitted to show enhanced interchain motion directly, the mechanism discussed above could apply to the dependence on *p*H and degree of swelling of the physical properties of polypeptides and proteins. For example, the molecular motion in muscular contraction would be controlled by the degree of interchain force reduction, and hydrogen bonding suppression, as indicated by many other researches. The present results also cause inquiry of how much wandering of hydrogen atoms among peptide linkages, and hence energy exchange, occurs in proteins swollen or thermally agitated. This latter is related to the hypothesis of energy transfer recently proposed by Szent-Györgyi.[12]

We are grateful to Dr. B. S. Biggs and Mr. W. S. Bishop for providing certain of the polyamides studied.

Summary

The dielectric constant and loss have been determined over a 120° temperature interval and over the frequency range 1 kc. to 75 mc. for typical linear polyamides. All of the polymers evidenced dipole orientation accompanied by anomalous dispersion, even at room temperature. The magnitudes of ϵ' and ϵ'' rise with the polar group concentration in the long molecules, but are sharply modified by the interaction between groups in adjacent molecules. The interaction was varied by reducing the crystallinity by quenching, and by forming co-polymers in which the polar groups

(11) See review in J. J. Fox and A. E. Martin, *Trans. Faraday Soc.*, **36**, 897 (1940).

(12) Szent-Györgyi, *Nature*, **148**, 157 (1941); see also London, *J. Phys. Chem.*, **46**, 305 (1942).

were displaced from their usual layer structure. Reduced interaction always caused enhanced polarization.

The dielectric properties of the polyamides show steep temperature coefficients; at 146°, 70° below its melting point, polyhexamethylene sebacamide has $\epsilon' \sim 48$, $\epsilon'' \sim 27$, at 1 kc. This compound also has a high frequency absorption associated with a relaxation process of activation energy 23.3 kcal. per mole, about twice the value for the analogous polyesters. Further, the polyamides show a high d. c. conductivity at elevated temperatures, which may be caused by mobile, charged atoms, such as hydrogen, resulting from isomerism in the amido linkage.

The Dropping Mercury Electrode in Acetic Acid. II. Electrocapillary Curves and the Theory of Maxima[1,2]

BY G. BRYANT BACHMAN AND MELVIN J. ASTLE[3]

In a preceding paper[4] it was shown that ions and molecules with low polarographic reduction potentials give discontinuous current–voltage curves in acetic acid solutions. In the present investigation this phenomenon has been related to the adsorption processes occurring on the drop through a study of electrocapillary curves.

Discontinuities in anhydrous acetic acid are fundamentally the same phenomena as maxima in water systems. They differ in that they seem to be limited to substances of rather low reduction potential. Since the occurrences of maxima in aqueous solutions have been associated with the adsorption of ions and molecules on the mercury drop, it is reasonable to assume that a similar association exists in acetic acid solutions. A convenient method of studying adsorption on charged mercury surfaces is through the medium of electrocapillary curves.

The electrocapillary curve for ammonium acetate in anhydrous acetic acid shows a marked difference from the same curve in water in that the top of the curve is broad and rather flat and two maxima instead of one are present. Double maxima are very uncommon in water although Kemula and Beer[5] observed them in some cases using the dynamic drop weight method. Addition of water causes the two maxima in acetic acid to approach each other and to blend into one well-defined maximum at 50 mole per cent. water (Fig. 1).

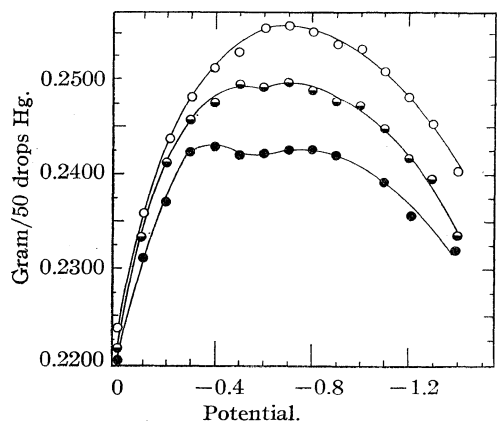

Fig. 1.—The effect of solvent composition on the electrocapillary curve for mercury in ammonium acetate solutions: ●, 0.25 *M* NH_4OAc in acetic acid; ◒, 0.25 *M* NH_4OAc in acetic acid and water (35 mole %); ○, 0.25 *M* NH_4OAc in acetic acid and water (50 mole %).

When salts are added to a solution of ammonium acetate in acetic acid, the effect on the electrocapillary curve depends on the reduction potential of the cation of the salt. If the cation has a half-wave reduction potential more negative than the *first* electrocapillary maximum for solutions of ammonium acetate in acetic acid (about −0.3 volt) then the resulting curves have the same general shape as the electrocapillary curve for ammonium acetate alone. Such cations are designated as Class I cations and include Zn^{++}, Pb^{++}, Cd^{++}, Co^{++}, Sb^{+++}, Ni^{++}, Cr^{+++} and Bi^{+++}. Figure 2 shows typical curves of this sort for Zn^{++} together with the corresponding current–

voltage curves. Solutions of these cations give normal S-shaped curves after degassing and can be determined polarographically in the usual fashion.

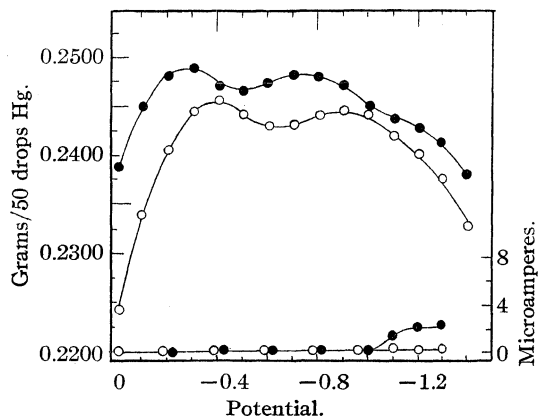

Fig. 2.—Electrocapillary curves (top) and current–potential curves (bottom): O, 0.25 *M* ammonium acetate; ●, 0.25 *M* ammonium acetate, 1.2 × 10^{-3} *M* zinc acetate.

Cations whose half-wave reduction potentials lie at more positive values than the first electrocapillary maximum for solutions of ammonium acetate in acetic acid give irregular and distorted electrocapillary curves. Such cations are designated as Class II cations and include Cu^{++}, Fe^{+++}, Pb^{++++} and Hg^{++}. The behavior of cations of this class is illustrated in Fig. 3 with electrocapillary and current–voltage curves for Cu^{++}. Class II cations cannot be determined polarographically in acetic acid even after their solutions are thoroughly degassed.

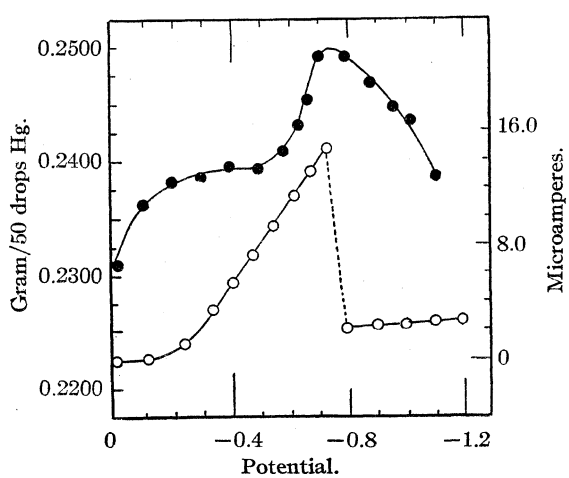

Fig. 3.—Electrocapillary and current–potential curves for the system ammonium acetate–copper acetate–acetic acid, 0.2 *M* ammonium acetate, 1.2 × 10^{-3} *M* copper acetate; ●, electrocapillary curve; O, current–potential curve.

An examination of Fig. 3 reveals that between −0.2 and −0.6 volt the surface tension remains practically constant.[6] In this region then there is no change in the degree of polarization and hence no change in the surface potential of the electrode. This is a result of the fact that the electrons flowing into the mercury drop from the external source are being neutralized by the reduction process. As the discontinuity potential is approached, however, the interfacial tension and the surface potential change very rapidly. Copper ions no longer reach the electrode in sufficient numbers to neutralize the flow of externally impressed electrons. Finally, the electrocapillary maximum is reached and passed, the mechanism of reduction changes radically as evidenced by the abrupt decrease in the current, and the electrocapillary curve becomes normal as the interfacial tension begins to parallel its decline in the absence of Cu^{++} ions.

Two important theories to account for maxima in current–voltage curves have been proposed. The first of these is that of Heyrovsky,[6] who attempted to explain them on the basis of the adsorption of the reducible substance on the growing drop. Ilkovic[7] also considers maxima as being caused by the adsorption of reducible substances on the mercury drop, but differs concerning the force responsible for it. The Heyrovsky and Ilkovic interpretations of maxima meet with much the same difficulties in attempting to explain the electrolysis of salts in acetic acid. In the first place, they do not take into account the change in sign of the drop charge at the maximum of the electrocapillary curve, and hence they do not explain the difference in the behavior of such ions as Cu^{++} and Zn^{++}. In the second place, it is difficult to understand, on the basis of this theory, the abrupt decline in the current which takes place in the reduction of Class II ions. Finally, it is probable that the thickness of the adsorption layer is insufficient to account for the manifold increase in adsorption required to produce the currents observed.[8]

A more recent theory of maxima has been put forward by Antweiler.[9] This theory is based on the observation that there is a vigorous stirring action around the mercury drop at potentials

(6) A similar phenomenon has been observed in aqueous solutions. *Cf.* Heyrovsky, "Actualités scientifiques et industrielles," No. 90, Hermann et Cie., Paris, 1934 .

below that of the electrocapillary maximum, but that the stirring ceases and a well-defined diffusion layer forms at the potential of the maximum.[10] Streaming around the drop destroys the diffusion layer responsible for the concentration polarization and results in the carrying of many more ions to the drop than would otherwise reach it. The stirring action is electro-osmotic in nature and is caused by a tangential potential gradient which arises from a difference in current density between the top and bottom of the drop. The difference in current density is explained by Antweiler as being caused by a preferential adsorption of ions on the under side of the drop. The glass of the electrode partially shields the top of the drop and thus lengthens the path which the ions must travel in diffusing from the solution to the drop surface. Hence, the rate at which the ions are adsorbed is greater at the bottom than at the top of the drop.

The above reasoning accounts for the great increase in the current preceding the maximum but does not explain the sudden fall of the current beyond the maximum. To understand this it is necessary to consider the role of the supporting electrolyte. Taking as an example the electrolysis of Cu^{++} ions in the presence of Na^{+} ions, it is clear that the Na^{+} ions will wander to the cathode along with the Cu^{++} ions but that they will not be discharged, because of their higher reduction potential. The concentration of the Na^{+} ions builds up, especially on the under side of the drop, with the result that the tangential potential is augmented still further and the streaming becomes still more rapid. This is accompanied by a rapid rise in the current. Eventually, however, the concentration of Na^{+} ions becomes so high that the Cu^{++} ions are effectively screened out. When this occurs the current declines, the streaming ceases and normal concentration polarization sets in.

With certain additions and limitations this picture of current–voltage maxima can be carried over quite satisfactorily to reduction phenomena in acetic acid. In the electrolysis of Class II cations a maximum in the current–voltage curve is to be expected as a result of the streaming effect described above. The stirring brings to the drop an ever-increasing number of reducible cations. The current therefore rises more rapidly than would be expected on the basis of normal diffusion. Two different processes now interrupt this rapid increase in the current. (1) The concentration of the supporting cations surrounding the drop may become so high that the ions being reduced are screened out. In this event reduction practically ceases, the current decreases, streaming stops, and a normal diffusion process of reduction is all that remains. (2) The maximum of the electrocapillary curve may be reached. If this occurs the charge on the drop surface becomes nil, and as a result the streaming ceases, the current drops abruptly, and once more a normal diffusion current is all that remains. It is evident that the second process is the one which applies to Class II cations. Our investigations indicate that the electrocapillary maximum always coincides with the potential of the discontinuity, even though the electrocapillary maximum may be shifted to more negative potentials as a result of the reduction process.

The addition of surface active substances would be expected to influence the nature of current–voltage curves to a considerable degree. All such substances are preferentially adsorbed on the mercury drop. They thus interfere with the adsorption of ions from the solution and prevent the establishment of a very high potential gradient. The result is that a more nearly normal diffusion process accompanied by less vigorous stirring is attained. Similar results would be expected with materials which raise the viscosity of the solution sufficiently to make streaming difficult. In Fig. 4 will be seen the effect of gelatin (saturated solution) on the reduction of copper in acetic acid. On the left there is a partially completed copper

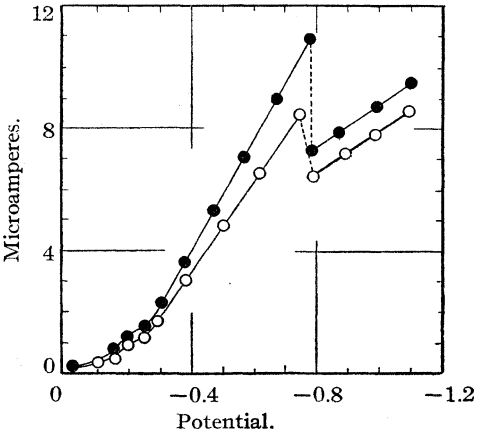

Fig. 4.—Current–potential curves in 0.25 molar sodium acetate solution in acetic acid containing gelatin: O, 10^{-2} molar copper acetate; ●, 2×10^{-2} molar copper acetate.

(10) Antweiler, *Z. Electrochem.*, **44**, 719 (1938).

wave. This wave is almost normal, although the failure to level off at the top indicates that some streaming is occurring. Eventually the curve becomes discontinuous at the potential of the electrocapillary maximum.

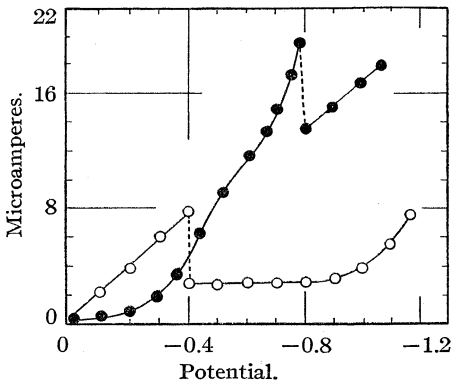

Fig. 5.—The effect of shifting the electrocapillary maximum on the current–potential curves in 0.25 molar ammonium acetate solutions in acetic acid: O, 1.14×10^{-3} *M* benzil in presence of I^-; ●, 2×10^{-4} *M* Bi^{+++} in the presence of NO_3^-.

On the negative side of the electrocapillary maximum the mercury drop is surrounded by adsorbed cations. The concentration of the adsorbed particles will again be greater at the bottom than at the top of the drop. *In water solutions* this results in a potential gradient and a streaming of the electrolyte. As before, a rapid rise in the current takes place as the reduction of the next ion begins. This is interrupted only when the concentration of the supporting ions becomes so great around the mercury drop that the ions being reduced are screened out. From this point on, the process follows the pattern previously discussed (Process 1 for ions of Class I). *In acetic acid* no maxima are observed on the negative side of the electrocapillary maximum. This arises from the fact that the electrocapillary curve in acetic acid is practically flat over the whole voltage range here studied. It was mentioned before that the adsorption of neutral molecules depresses and flattens electrocapillary curves. In this case neutral acetic acid molecules are probably adsorbed on the negative side of the maximum in sufficient concentration to prevent an appreciable adsorption of ions from the solution. Hence the established potential gradient is small, the stirring is negligible and maxima do not occur. The failure of surface active substances, which are often effective in reducing maxima in water solution, to function satisfactorily in acetic acid may be explained in the same way. These substances only tend to cause a broadening of the electrocapillary maximum such as is commonly observed in acetic acid without the addition of other substances. They, therefore, add nothing and detract nothing from the processes already occurring.

The addition of an ion which shifts the position of the electrocapillary maximum to more negative potentials causes the current–voltage curves for certain cations and other substances belonging to Class I to revert to Class II. Thus iodide ion causes the normal curves for bismuth ion and for benzil to become discontinuous (Fig. 5). These substances have half-wave reduction potentials which lie just beyond the electrocapillary maximum on the negative side. In the case of bismuth ions even nitrate ions, which are less powerful than iodide ions in shifting the maximum, can cause a discontinuity to appear.

In aqueous solutions most maxima are rounded in appearance although discontinuous maxima are also observed, especially in solutions of low ionic concentration. Usually discontinuous maxima can be made continuous by the addition of strongly adsorbed substances or by increasing the ionic concentration. Rayman[11] obtained discontinuous maxima for oxygen in 0.001 *N* potassium chloride solution. These became rounded humps when various dyes were added. Similarly, Dillinger[12] added barium chloride to make the discontinuous maxima of dilute mercurous cyanide solutions continuous. The discontinuous maxima in acetic acid are probably a result of the high resistances brought about by the low ionic concentrations possible in a medium of such low dielectric constant. The addition of water permits greater ionization and lower resistance and results in the occurrence of normal rounded maxima. The greater the concentration of the supporting ion, the less water is needed to effect this transformation.

The removal of all traces of oxygen is a *sine qua non* for the obtaining of satisfactory current–voltage curves in acetic acid. Even with relatively concentrated solutions of zinc salts the zinc wave is so small that it is completely obscured by the oxygen normally dissolved in the solution. Since there is ordinarily no discontinuity in the oxygen curve it is evident that it is reduced at potentials more negative than the electrocapillary maximum

(11) B. Rayman, *Coll. Czech. Chem. Commun.*, **3**, 314 (1931).
(12) Dillinger, *ibid.*, **1**, 638 (1929).

and hence belongs to the substances of Class I. However, it is thrown into Class II by the addition of small amounts of iodide ion (Fig. 6). Its reduction potential in acetic acid is therefore not far from that of bismuth ions.

Conclusions

1. The relationship which exists between the electrocapillary maximum of the medium and the half-wave potential of a reducible substance determines to a considerable degree the nature of the current–voltage curves of the substance in acetic acid and probably also in other solvents.

2. Class I substances, which are reduced at potentials more negative than the electrocapillary maximum, exhibit normal electrocapillary curves. They also give normal S-shaped current–voltage curves (after thorough degassing) and can be determined polarographically in the usual fashion. Class II substances, which are reduced at potentials more positive than the electrocapillary maximum, exhibit distorted electrocapillary curves. They also give discontinuous maxima in their current–voltage curves and cannot be determined polarographically.

3. Maxima in acetic acid can be explained satisfactorily on the basis of a streaming of the electrolyte around the mercury drop of the type observed by Antweiler for aqueous solutions. The decline in current following the maximum is caused by a screening out of the reducible ions by the supporting ions, or by the neutralization of charge on the drop occurring at the electrocapillary maximum, whichever occurs first.

4. Ions (like iodide) which shift the position of the electrocapillary maximum to more negative potentials cause certain reducible substances (like oxygen, bismuth ion and benzil) to change from Class I to Class II. Such substances have half-wave reduction potentials close to and on the negative side of the electrocapillary maximum.

5. Things which act to decrease the amount of adsorption of ions on the drop or the amount of streaming around the drop decrease the heights of the maxima. The addition of high molecular weight substances (like gelatin) which increase the viscosity, and the addition of capillary active substances (like methyl red) which decrease the adsorption of small ions by being adsorbed themselves both tend to decrease maxima heights. None of these substances is as effective in acetic acid solutions as in water because acetic acid molecules are themselves adsorbed fairly strongly.

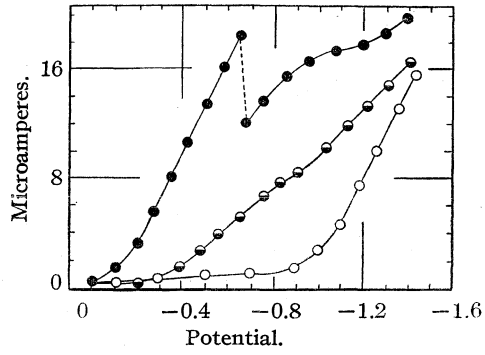

Fig. 6.—Current–potential curves for oxygen in acetic acid solutions: ◒, 0.25 molar ammonium acetate; ●, 0.25 molar ammonium acetate to which a small crystal of KI was added; O, the latter solution after degassing for one hour.

Apparatus and Materials

The electrocapillary curves were determined by the drop weight method.[13] An electrolysis cell constructed in such a way as to make it possible to catch the drops falling from the dropping mercury cathode was attached to a Fisher Elecdropode identical with the one employed in our previous work. The dropping electrode was also identical with the one previously described. The capillary used had a value for $m^{2/3}t^{1/6}$ of 1.1 mg.$^{2/3}$ sec.$^{-1/2}$. After thoroughly degassing the solution to be studied, 50 drops of mercury were collected at each of a number of successively increased potentials. The mercury was then washed, dried and weighed. Since the surface tension is directly proportional to the drop weight, it is only necessary to plot this latter quantity against the potential to obtain curves which are strictly analogous to true electrocapillary curves and which do not differ from them in any detail of form or shape. The potentials plotted were corrected for the *IR* drop of the solutions. This correction is large in the case of acetic acid solutions.

The acetic acid was the "99.5%" acid of the J. T. Baker Chemical Company and was employed without further purification. The salts were all C. P. grade and were carefully dried at 110° before use. The organic materials were Eastman Kodak Co. grade, and were recrystallized once before use. Degassing was accomplished as before with purified natural gas.

Summary

A study of the electrocapillary curves of mercury in acetic acid solutions of various salts reveals some important differences from similar curves in aqueous solutions. With the aid of such curves it has been possible to explain the current–potential curves of various cations and other reducible substances in acetic acid.

Polarographic Investigation of Rhenium Compounds. II. Oxidation of −1 Rhenium at the Dropping Electrode and the Potential of the Re^{+2}–Re^{-1} Couple

BY JAMES J. LINGANE

The reduction of perrhenate ion at the dropping mercury electrode has been discussed in a previous paper from this Laboratory,[1] in which evidence was presented that the −1 oxidation state of rhenium is produced at this electrode under certain conditions. The existence of −1 rhenium was discovered quite recently by Lundell and Knowles,[2] who obtained it by the reduction of perrhenate ion by amalgamated zinc in *cold* dilute sulfuric acid solutions from which air had been carefully excluded. The experiments of Lundell and Knowles were later confirmed by Tomiček and Tomiček.[3] Since the existence of Re^{-1} is of interest from several points of view, and since very little is known about the potentials of the lower oxidation states of rhenium compounds, it seemed worth while to investigate the oxidation of solutions of −1 rhenium at the dropping electrode by the polarographic technique. This study has furnished some interesting information concerning the course of the oxidation of reduced rhenium solutions, and in particular it has supplied data which lead to a fairly accurate estimate of the potential of the Re^{+2}–Re^{-1} couple in dilute sulfuric and perchloric acid solutions.

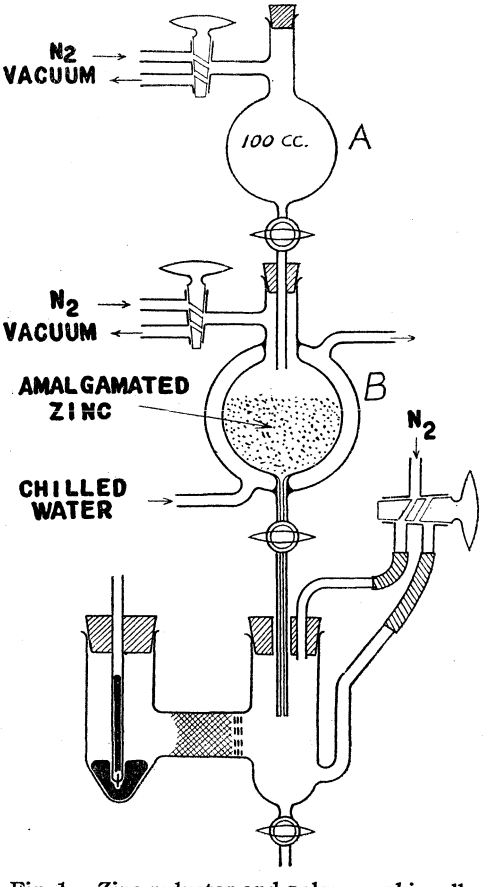

Fig. 1.—Zinc reductor and polarographic cell.

Experimental

Solutions of −1 rhenium were prepared by reducing perrhenate ion with amalgamated zinc in dilute sulfuric acid or perchloric acid. Lundell and Knowles[2] have shown that successful production of Re^{-1} requires the complete absence of oxygen and ice-cold solutions. In the present study it was necessary to work with moderately small volumes of quite dilute solutions since only a small quantity of potassium perrhenate was available, and it was also desired to perform the reductions in an initially dry reductor so that the concentrations of the solutions would remain unchanged. After numerous trials it was finally found that these conditions were fulfilled most satisfactorily by the reductor shown in Fig. 1.

Vacuum technique was employed to free the reductor and solutions from dissolved air, and the reductions were performed in an atmosphere of nitrogen that had been purified by passage over copper gauze at 500°. The reductor proper consisted of the double walled bulb B, the inner bulb of which (125 cc.) was about two-thirds filled with very pure 20-mesh amalgamated zinc. Previous to use the reductor was washed out with dilute sulfuric acid, water, and acetone, and was dried by evacuating to a pressure below 2 mm. for a few minutes. Pure nitrogen was then admitted. The potassium perrhenate solution to be reduced, contained in the 100-cc. reservoir bulb A, was freed from dissolved air by evacuating rapidly until boiling just began and then admitting nitrogen. This was repeated two or three times to ensure complete removal of air. Care was taken to minimize evaporation of water from the solution by evacuating very rapidly and maintaining vacuum for only a few seconds. The solution was then run into the reductor, which had previously been chilled to below 5° by passage of ice-water through the outer jacket. The volume of solution was such (50 cc.) that it covered the amalgamated zinc to a depth of less than a centimeter, and thus intimate contact was obtained between the two phases. Finally the reduced solution was run into the polarographic cell from the capillary delivery tube under an atmosphere of nitrogen, and with the cell

in an ice- and water-bath at 0°. The reductor was then withdrawn and the capillary of the dropping electrode inserted through the same hole in the stopper, which was oversize to act as an exit for the nitrogen. The polarogram of the reduced solution was taken without delay, and, unless otherwise specified, at 0°.

The H-type polarographic cell that was used was similar to that previously described.[4] A medium porosity sintered glass disk (2-cm. diameter) was sealed into the cross tube as close as possible to the right-hand compartment, and this was backed with a plug of 4% agar gel containing 0.2 *M* sodium sulfate. This arrangement provides a good low resistance electrolytic contact between the two halves of the cell and at the same time effectively prevents streaming of one solution into the other. A mercury–mercurous sulfate electrode in the left-hand compartment, with 1 *N* sulfuric acid as electrolyte, was used as the working reference electrode of the cell. The potential of this electrode was measured at frequent intervals against a saturated calomel electrode, and all potential data are referred to the latter electrode as a standard.

The dropping electrode was of the same type described by Lingane and Laitinen,[4] and the rate of flow of mercury (*m*) was determined by means of the volumetric instrument described elsewhere.[5] It was found, as the average of a number of experiments, that the ratio of the rate of mercury flow at 25° to that at 0° was 1.075 in 2 *N* sulfuric acid. This corresponds to an average temperature coefficient for *m* of +0.0030 deg.$^{-1}$ between 0° and 25°. In most experiments the value of *m* was determined at 25° and divided by 1.075 to obtain its value at 0°.

Polarograms were recorded according to the usual technique[6] with a Sargent–Heyrovsky polarograph.

Standard solutions of potassium perrhenate (0.002 to 0.003 *M*) were prepared directly by weight from a pure sample of the salt (obtained from A. D. Mackay Co., New York) which had been dried at 110°.

Results and Discussion

In order to establish the fact that quantitative formation of −1 rhenium was actually obtained under the reduction conditions that were employed, several of the reduced solutions were titrated with a standard ceric sulfate solution. In preliminary experiments samples of the reduced solutions from the reductor were delivered under the surface of an excess of ferric sulfate solution in dilute sulfuric or perchloric acid, and the solution was then titrated with a standard ceric sulfate solution using *o*-phenanthroline ferrous sulfate ("Ferroin") as indicator. This procedure yielded unsatisfactory results because the rate of reaction of ceric ion with the reduced solution was surprisingly slow, even when the solutions were warmed to 40–50° prior to titration. These observations confirm the results of Geilmann and Wrigge,[7] who found that the oxidation of solutions of +3 and +4 rhenium by permanganate, dichromate and ceric ions is quite slow under certain conditions, particularly when substances, such as chloride ion, which form stable complexes with +4 rhenium are present. The following procedure was finally adopted and it led to correct results. The reduced solutions were run directly from the reductor into an excess of standard ceric sulfate solution *under an atmosphere of nitrogen*, and, after standing for at least fifteen minutes under nitrogen, the excess ceric ion was titrated back with a standard ferrous ammonium sulfate solution from a microburet, using Ferroin as indicator. Removal of air from the collecting ceric sulfate solution was found to be essential, and, when it was not done, low and erratic results were obtained, indicating that the rate of reaction of dissolved oxygen with the reduced rhenium compounds is more rapid than that of ceric ion with these compounds.

In order to determine the volume of the reduced solution taken for analysis, the collecting flask (Erlenmeyer flask with drawn out neck) was calibrated for total volume, and at the end of a titration the volume of water required to fill to the mark was measured. This volume was added to the known volumes of ceric solution and ferrous solution used, and the sum was subtracted from the total volume of the flask. The volume of the sample of reduced solution was known with an accuracy of ± 0.1 cc. The results are summarized in Table I.

TABLE I

OXIDATION STATE OF REDUCED RHENIUM SOLUTIONS

Solutions of potassium perrhenate in 2.0 *N* sulfuric acid reduced for 10 min. under nitrogen at a temperature near 5°.

$KReO_4$ Millimolar	Vol. reduced soln., cc.	0.01 *N* $Ce(SO_4)_2$, cc.	Equiv. Ce^{IV} per mole total rhenium
0.105	37.6	3.26	8.3
.209	33.3	5.28	7.6
.418	36.4	12.1	8.0
.836	35.2	23.0	7.8
			Av. 7.9

These results, which confirm the conclusions of Lundell and Knowles[2] and those of Tomiček and Tomiček,[3] show that, within the limits of the experimental error, 8 equivalents of ceric ion were required to oxidize the reduced solutions up to

(4) J. J. Lingane and H. A. Laitinen, *Ind. Eng. Chem., Anal. Ed.*, **11**, 504 (1939).

(5) J. J. Lingane, *ibid.*, **14**, 655 (1942).

(6) I. M. Kolthoff and J. J. Lingane, "Polarography," Interscience Publishers, Inc., New York, N. Y., 1941.

perrhenate ion. Hence there is no doubt that the solutions reduced under the present conditions contain all of the rhenium in the −1 oxidation state. No definite statement can yet be made concerning the actual ionic or molecular state of the −1 rhenium in these solutions, but since the chemistry of rhenium is similar in a number of respects to that of the halogens, it seems reasonable to assume that hydrorhenic acid is a strong acid and that the −1 rhenium is present as rhenide ion, Re^-.

A typical polarogram of a reduced rhenium solution in dilute sulfuric acid at 0° is shown by curve 1 in Fig. 2. In accordance with the usual conventions a negative sign is used to indicate anodic current (electroöxidation), and the sign prefixed to the potential of the dropping electrode, $E_{d.e.}$, signifies the polarity of this electrode with respect to the saturated calomel electrode.

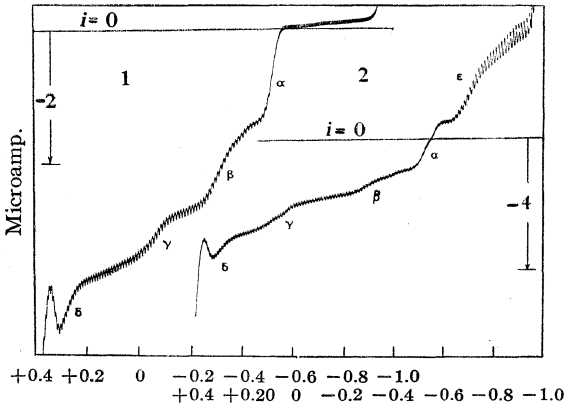

Fig. 2.—Curve 1: Polarogram of a 2.09 × 10^{-4} *M* solution of −1 rhenium in 2.0 *N* sulfuric acid at 0°. Curve 2: Polarogram obtained (at 0°) after partial oxidation by warming to 50° for sixty-five minutes in absence of oxygen.

It is seen that the polarogram (curve 1) consists of three distinct anodic waves, with half-wave potentials of −0.54, −0.3 and −0.05 v. *vs.* the S. C. E., which for the sake of convenient discussion will be referred to as α-, β-, and γ-waves, respectively. These waves correspond to oxidation of rhenide ion to successively higher oxidation states. The abrupt increase in cathodic current at about −0.9 v. results from the discharge of hydrogen ion, and the final increase in anodic current beginning at about +0.35 v. is caused by the oxidation of the mercury of the dropping electrode to mercurous ion. A fourth increase in anodic current, which at first glance appears to be the beginning of a fourth stage in the oxidation of the −1 rhenium, is also observable at +0.25 v. (δ in Fig. 2), and this is followed by an abrupt decrease in current just prior to the final anodic dissolution current of the mercury. Actually, data discussed below disprove the hypothesis that this δ-wave is the beginning of a fourth stage in the oxidation. Since mercurous perrhenate is only slightly soluble, we also considered the possibility that the δ-wave might be caused by the depolarization of the dropping electrode by perrhenate ion (formed in the preceding stage of the oxidation) according to the equation $2Hg + 2ReO_4^- = Hg_2(ReO_4)_2(s) + 2e$. However, this possibility was excluded by polarograms of solutions of potassium perrhenate itself in 1.8 *N* sulfuric acid which showed no indication of such a wave.

The abrupt decrease in current immediately preceding the anodic dissolution current of the mercury has been observed on the anodic waves of other substances, notably hydroquinone,[6,8] and it appears to be a rather general phenomenon in which the inception of the oxidation of the mercury itself inhibits the oxidation of other substances at the dropping electrode.

The significance of curve 2 in Fig. 2 is discussed in a following section.

A polarogram of a reduced rhenium solution in dilute perchloric acid is shown in Fig. 3. It possesses the same general features as the polaro-

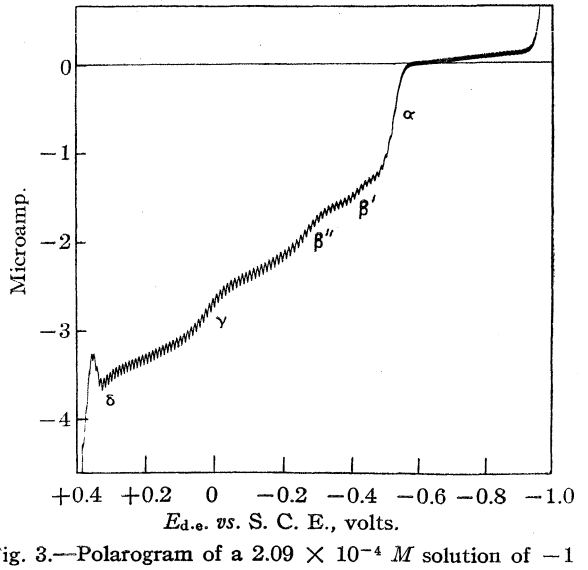

Fig. 3.—Polarogram of a 2.09 × 10^{-4} *M* solution of −1 rhenium in 1.2 *N* perchloric acid at 0°.

gram in dilute sulfuric acid, with the marked exception that instead of a single β-wave the two separate waves indicated in Fig. 3 by β' and β'' are obtained. The sum of these two waves is equal to that of the single β-wave in dilute sulfuric acid. The separate β'-wave is one-half the height of the separate β''-wave, or one-third the height of the α-wave (see Table II), and hence the electron change in the reaction responsible for the β'-wave must be one-third that for the α-wave. This point is important in the interpretation of the oxidation states to which the waves pertain (*vide infra*). There is some indication on the original polarograms that the β-wave in sulfuric acid medium is also composite in nature, but the two parts of the wave are not clearly separated as they are in perchloric acid medium.

A summary of diffusion current data for various concentrations of the reduced rhenium solutions in dilute sulfuric and perchloric acids at 0° is given in Table II.

The diffusion currents have been corrected for the residual current of the acid solution alone in each case. Since the diffusion current depends directly on the sixth root of the drop time,[6,9] and since the latter changes considerably over the potential range involved in the present measurements, a correction for this effect was also made. The requisite data for this correction were obtained by measuring the electrocapillary curve of mercury (drop time *vs.* $E_{d.e.}$) in 1.8 N sulfuric acid at 0°. Values of $(t/t_{max.})^{1/6}$ obtained in this way at +0.2, −0.15 and −0.45 v. were 0.966, 0.992 and 1.00, respectively, and the maximum in the electrocapillary curve was at −0.58 v. The measured diffusion currents were referred to the value of the drop time at the electrocapillary maximum, $t_{max.}$, by dividing by the appropriate value of $(t/t_{max.})^{1/6}$.

From the data in Table II it is evident that the diffusion currents of all the anodic waves are directly proportional to the concentration of −1 rhenium, and hence are diffusion controlled. Since the values of i_d/C are essentially the same in dilute sulfuric and perchloric acids, it is clear that corresponding waves pertain to the same oxidation states in the two media. Although the precision of the data in Table II leaves something to be desired, there is no systematic trend in the values of i_d/C with concentration. It is believed that the variations observable in the values of i_d/C were caused by unequal amounts of evaporation of water from the solutions during the evacuation prior to reduction, in spite of the precautions that were taken to minimize this effect. Similar variations, probably due to the same cause, are noticeable in the data in Table I.

For the present purpose the *ratio* of the diffusion currents of the various waves is of more importance than their absolute values, and it is seen that the values of the ratios in the last columns of Table II are satisfactorily concordant. The rela-

(9) I. M. Kolthoff and E. F. Orlemann, THIS JOURNAL, **63**, 2085 (1941).

tive heights of the anodic waves (*i. e.*, the ratios in Table II) are determined by the oxidation states to which the −1 rhenium is oxidized as each limiting current is attained. When a polarographic limiting current is diffusion controlled the ratio i_d/C is expressible by the Ilkovic equation[6,10]

$$i_d/C = knD^{1/2}m^{2/3}t^{1/6} \quad (1)$$

In this equation, i_d/C is the diffusion current constant (microamperes per millimole per liter), n is the number of electron equivalents per molar unit of the electrode reaction, D is the diffusion coefficient (cm.^{2} sec.$^{-1}$) of the substance that is being reduced or oxidized, m is the rate of mercury flow from the dropping electrode (mg. sec.$^{-1}$), t is the drop time (sec.), and k is a constant whose numerical value is 605 at 25° and 603 at 0°. Unfortunately this equation cannot be applied directly in the present case to determine the n-values of each of the anodic waves, because nothing is known about the diffusion coefficient of rhenide ion under the conditions of the present experiments. However, since the rhenium in these reduced solutions is present entirely in the −1 state, it will be evident that each of the diffusion currents results from the oxidation of the −1 rhenium from the same concentration to successively higher oxidation states, and therefore each is controlled by the rate of diffusion of the rhenide ion. Consequently the ratio of the *total* diffusion currents is the same as the ratio of the n-values of the various waves, and this ratio must be expressible as a ratio of simple integers. Furthermore, the maximum possible value of n is 8, for complete oxidation of rhenide ion to perrhenate ion.

It is immediately evident from the data in Table II, and the polarograms in Figs. 2 and 3, that the n-value for the α-wave is equal to that for the individual β-wave in dilute sulfuric acid, or equal to the combined n-values of the β'- and β''-waves in dilute perchloric acid. Furthermore, since the individual γ-wave is smaller than the individual α- or β-waves, the latter must each correspond to at least a 2-electron oxidation, but the sum of the α- and β-waves cannot correspond to more than a 6-electron change without exceeding the maximum possible n-value of 8 for the total combined diffusion currents. Hence the only patterns of n-values that need be considered are 8/6/3 and 5/4/2. The 8/6/3 pattern requires a ratio of 1.33/1/0.5, and the 5/4/2 pattern a ratio of 1.25/1/0.5, for the cumulative heights of the γ-, β- (or $\beta' + \beta''$), and α-waves. The average observed value of the ratio in dilute sulfuric acid is 1.26/1/0.51, whereas in dilute perchloric acid, with the β-wave resolved into its component β' and β'' parts, the observed ratio is 1.33/1/0.68/0.52. From Figs. 2 and 3 it is seen that the γ-diffusion current increases appreciably with increasing positive potential, even when proper allowance is made for the residual current and the effect of changing drop time with changing potential. Consequently, values for the ratio of the γ- to the β-diffusion current ranging from 1.25 to 1.33 can be obtained depending on the potential at which the γ-diffusion current is measured. The key to the correct pattern of n-values is found in the resolution of the β-wave into its component β' and β'' parts in dilute perchloric acid, and the fact that the individual β'-wave is only half the height of the individual β''-wave, or one-third the height of the α-wave. It seems reasonable to conclude that the correct pattern of n-values is 8/6/4/3. Hence the α-wave corresponds to oxidation of the −1 rhenium to the +2 state, the β'-wave to the +3 state, the β''-wave to the +5 state, and the γ-wave to complete oxidation to the +7 state (ReO_4^-).

In order to test the foregoing conclusion an amperometric titration[11] of a reduced rhenium solution with a standard solution of ammonium hexanitratocerate was carried out, with the result shown in Fig. 4. In this experiment a completely reduced rhenium solution was titrated with an air-free 0.01 N $(NH_4)_2Ce(NO_3)_6$ solution at 0°, and individual polarograms were recorded five to ten minutes after each addition of the ceric solution. Curve 1 in Fig. 4 is a polarogram of 35.0 cc. of the original reduced solution, and the other curves were recorded after successive additions of 3.00-cc. increments of the 0.01 N ceric solution, corresponding to the addition of 0, 2.0, 4.1, 6.2, 8.2, and 10.3 equivalents of oxidant for curves 1 to 6, respectively. It is seen that the anodic current, measured at a potential of +0.2 v. corresponding to the γ-diffusion current, decreased to zero after the addition of somewhat less than 8.2 equivalents of oxidant. The cathodic diffusion current obtained with larger amounts of the oxidant (curve 6) results from the

(11) See Ref. 6 for a discussion of the principles of amperometric titrations.

reduction of the excess ceric ion to the cerous state. This experiment constitutes conclusive proof that the correct pattern of *n*-values is 8/6/4/3, and that the −1 rhenium is completely oxidized to perrhenate ion at potentials at which the γ-diffusion current is attained.

It should be pointed out that the slow reaction of ceric ion with the reduced rhenium compounds should not seriously influence the validity of the conclusions that are drawn from this type of amperometric titration. Consider, for example, an extreme case in which the reaction between the oxidant and reductant is so very slow that it actually only proceeds to a slight extent during the time of a titration. At any point in the titration relatively large amounts of unreacted oxidant and reductant will then be present, and the net current will be the resultant of a cathodic current of the oxidant and an anodic current of the reductant, provided, as in the present case, that the measurements are made at a potential where both diffusion currents are separately attained with pure solutions of the oxidant and reductant. If the diffusion coefficients of the oxidant and reductant are equal, the *net* current will decrease to zero (corrected for the residual current) after an equivalent amount of oxidant has been added, just as if the reaction had been rapid and complete. This unique characteristic of amperometric oxidation–reduction titrations should permit their application to a number of reactions which cannot be followed by other methods that require the establishment of equilibrium conditions throughout the titration.

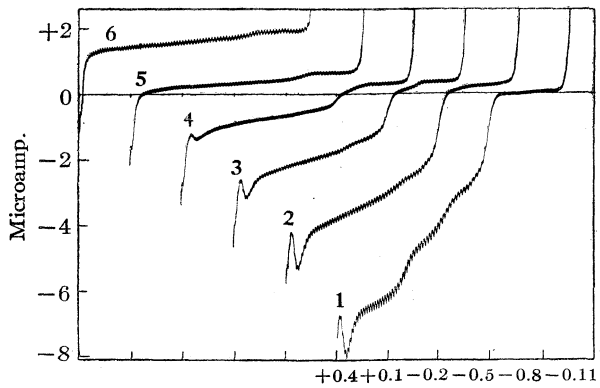

Fig. 4.—Amperometric titration of −1 rhenium with ceric ion: 35.0 cc. of a 4.18×10^{-4} *M* solution of Re^{-1} in 1.2 *N* perchloric acid at 0° plus: (1) none, (2) 3.0 cc. (2.0 equiv.), (3) 6.0 cc. (4.1 equiv.), (4) 9.0 cc. (6.2 equiv.), (5) 12.0 cc. (8.2 equiv.), and (6) 15.0 cc. (10.3 equiv.) of 0.01 *N* $(NH_4)_2Ce(NO_3)_6$.

Data concerning the half-wave potentials of the reduced rhenium solutions are presented in Table III. The values pertaining to the sulfuric acid solutions in the β''-column refer to the single β-wave in these media, and it will be noted that these values are about midway between the half-wave potentials of the separate β'- and β''-waves in the 1.2 *N* perchloric acid solution. It will also be noted that the half-wave potential of the γ-wave is about 0.1 v. more positive in perchloric acid medium than in sulfuric acid solutions. It is evident that the half-wave potentials of all the waves are constant in a given medium and independent of the concentration of rhenium.

From the slopes of the β- and γ-waves it seems clear that the corresponding reactions do not proceed with thermodynamic reversibility at the dropping electrode. However, the slope of the α-wave indicates that the oxidation of Re^{-1} to Re^{+2} does approach reversibility. If this is actually the case, then the equation of the anodic α-wave should be[6]

$$E_{d.e.} = E_{1/2} - \frac{RT}{3F_y} \ln \frac{i_d - i}{i} \qquad (2)$$

where i is the anodic current at any point on the wave and i_d is the anodic diffusion current. The half-wave potential should be given by

$$E_{1/2} = E^0_{+2,-1} - \frac{RT}{3F_y} \ln \left(\frac{D_2}{D_1}\right)^{1/2} \qquad (3)$$

where $E^0_{+2,-1}$ is the reversible standard potential for the reaction written in the direction $Re^{+2} + 3e = Re^{-1}$, and D_2 and D_1 are, respectively, the diffusion coefficients of the Re^{+2} and Re^{-1}. Ac-

tually the second term in Eq. 3 is of very minor importance, and hence $E_{1/2}$ should be practically equal to $E^0_{+2,-1}$. From Eq. 2 the following relation should apply to the difference between the potentials at the one-fourth and three-fourths points on the α-wave at 0°, provided that the reaction proceeds reversibly

$$E_{3/4} - E_{1/4} = \frac{0.0546}{3} \log 9 = 0.017 \text{ v.} \qquad (4)$$

From measurements of several polarograms in both dilute sulfuric and perchloric acids, the averaged observed difference between $E_{3/4}$ and $E_{1/4}$ was found to be 0.030 ± 3 v. It appears, therefore, that the oxidation of Re^{-1} to Re^{+2} does not occur with perfect thermodynamic reversibility. On the other hand, the observed slope of the α-wave is sufficiently close to the theoretical value to indicate that the degree of irreversibility cannot be very great. This is also evident from the character of the composite cathodic–anodic α-wave in partially oxidized solutions (curve 2 in Fig. 2), which displays a smooth transition from anodic to cathodic current without any pronounced inflection at the zero current point. Hence it seems safe to conclude that the reversible potential of the Re^{+2} – Re^{-1} couple must be very nearly equal to the half-wave potential of the α-wave, namely, −0.54 v. *vs.* the S. C. E., or slightly more negative. Rhenide ion is thus a considerably stronger reducing agent than titanous ion, and is about equal to chromous ion in this respect.

In this connection it should be mentioned that Lundell and Knowles[2] performed a potentiometric titration of a solution of −1 rhenium in 1.8 *N* sulfuric acid with a standard permanganate solution, using a *platinum* indicator electrode. The titration curve they obtained showed only two points of inflection, the first after the addition of 2 equivalents of oxidant and the second after the addition of 8 equivalents. However, it is the author's experience from several such titrations with different oxidants that constant potential is established quite slowly, if at all, and since Lundell and Knowles apparently titrated rapidly the significance of the potential break after the addition of two equivalents of oxidant is doubtful and may well be fortuitous. It should be noted that a platinum indicator electrode cannot be expected to indicate the correct potential in a strongly acid solution of −1 rhenium, because the potential of the Re^{+2}–Re^{-1} couple is considerably more negative than the discharge potential of hydrogen ion on a platinum surface. Consequently, Re^{-1} will reduce hydrogen ion at the surface of a platinum electrode, the measured potential will lie between the hydrogen potential and that of the Re^{+2}–Re^{-1} couple, and its actual value will depend on the rate of oxidation of Re^{-1} by hydrogen ion. This effect is evident from the titration curve given by Lundell and Knowles, in which the potential of the platinum indicator electrode was about −0.4 v. *vs.* the saturated calomel electrode at a point midway to the first break, or more than 0.1 v. more positive than the potential observed in the present study. The above conclusion is also borne out by the fact that quantitative deposition of metallic rhenium, with no indication of the formation of Re^{-1}, is obtained when strongly acid solutions of potassium perrhenate are reduced electrolytically at a platinum cathode under such conditions that hydrogen is simultaneously evolved.[2,12,13]

Lundell and Knowles[2] discovered that solutions of −1 rhenium in 1.8 *N* sulfuric acid were slowly oxidized, and acquired a straw-yellow color, when they were warmed to about 50° for thirty to sixty minutes in the absence of oxygen. They found that the partially oxidized solutions required 6 equivalents of permanganate for oxidation to perrhenate ion, and they concluded that the rhenium had been oxidized to the +1 state. These investigators passed pure carbon dioxide through the solutions during the warming process and discovered that the effluent gas contained a volatile sulfur compound which very likely was sulfur dioxide. Tomiček and Tomiček[3] have reported the evolution of hydrogen sulfide, as well as sulfur dioxide, from reduced rhenium solutions in sulfuric acid medium. It thus appears that sulfuric acid, or bisulfate ion, rather than hydrogen ion, is the oxidant responsible for the oxidation of the −1 rhenium under these conditions.

The experiments of Lundell and Knowles led to very concordant results and they leave no doubt that the *average* oxidation state of the rhenium in the warmed solutions was +1. However, a titration technique such as they employed does not prove that all of the rhenium in the partially oxidized solutions is present in a single oxidation state, and their results can be interpreted equally well by assuming that the partially oxidized solu-

(12) C. G. Fink and P. Deren, *Trans. Am. Electrochem. Soc.*, **66**, 471 (1934).

(13) O. Tomiček and F. Tomiček, *ibid.*, **76**, 105 (1939).

tions contained a mixture of two or more oxidation states in proportions that would be equivalent to an average oxidation state of +1. The polarograms obtained in the present study show no indication of a wave corresponding to the +1 state, which would lead one to expect that the +1 rhenium is unstable in respect to disproportionation into higher and lower states. In order to obtain further information on this point the experiment represented by curve 2 in Fig. 2 was performed. After the polarogram of the original reduced solution was recorded (curve 1 in Fig. 2), the solution was heated to 50° under an atmosphere of nitrogen for sixty-five minutes (the conditions employed by Lundell and Knowles) and it was then cooled back to 0° and curve 2 was recorded. The solution acquired the straw-yellow color reported by Lundell and Knowles. One marked effect of the warming process was the production of a new cathodic wave, designated by ϵ in Fig. 2. This wave increased to an abnormally great extent when the polarogram was recorded at 25° instead of 0°, which is fairly good evidence that it is catalytic in nature and similar to the catalytic waves described in a previous paper.[1] It will be noted that the γ-wave in curve 2 has become quite extended, and inspection of the original polarogram shows that it is composite and consists of two parts. The diffusion currents (corrected for the residual current) of the partially oxidized solution are compared with those of the original solution in Table IV.

TABLE IV

COMPARISON OF ORIGINAL DIFFUSION CURRENTS WITH THOSE OF SOLUTION PARTIALLY OXIDIZED BY WARMING

	i_d, microamp.		
	γ	β	α
Curve 1, Fig. 2.	3.55	2.73	1.42
Curve 2, Fig. 2	2.63	1.70	0.93[a]
Decrease, microamp.	0.92	1.03	0.49

[a] Anodic part of the α-wave. The cathodic part is equal to 0.50 microamp.

It is seen that the α-wave became approximately one-third cathodic and two-thirds anodic after warming, which indicates that two-thirds of the rhenium was still present as the Re^{-1} and the remainder in a higher oxidation state or states. The sum of the heights of the cathodic and anodic portions of the α-wave (0.50 + 0.93 = 1.43 microamp.) is the same as the height of the original anodic α-wave.

The *cumulative* γ-diffusion current at +0.2 v. decreased by 0.92 microamp., which is 0.92/3.55 = 0.26, or one-fourth of its original value within the limit of accuracy of the measurements. Assuming for the sake of simplicity that the average diffusion coefficient of the rhenium compounds in the mixed oxidation states in the partially oxidized solution is the same as that of Re^{-1}, we conclude that the one-fourth decrease in the original 8-electron γ-diffusion current corresponds to a 2-electron oxidation. Hence the *average* oxidation state of the rhenium in the partially oxidized solution was +1; a value in agreement with the results that Lundell and Knowles obtained by direct oxidimetric titration.

From the data in Table IV it is seen that the *individual* height of the γ-wave of the partially oxidized solution (2.63 − 1.70 = 0.93 microamp.) is the same, within the limits of the experimental error, with that of the original solution (3.55 − 2.73 = 0.82 microamp.). On the other hand, the individual height of the β-wave decreased by about one-third from 1.31 microamp. (2.73 − 1.42) to 0.77 microamp. (1.70 − 0.93), and this decrease of 0.54 microamp. is equal to the cathodic portion of the α-wave. Since the height of the γ-wave, which corresponds to the oxidation of Re^{+5} to ReO_4^-, remained constant, it appears that none of the rhenium was present in an oxidation state higher than +5. The fact that the individual height of the β-wave, which results from the oxidation of Re^{+2} to Re^{+5}, decreased to about two-thirds of its original value indicates that part of the rhenium was present in an oxidation state greater than +2, because if only Re^{-1} and Re^{+2} had been present the height of the β-wave should not have differed markedly from its original value. It seems reasonable to conclude from these data that the partially oxidized solution still contained about two-thirds Re^{-1}, with the remainder of the rhenium present as Re^{+3}, Re^{+4} or Re^{+5}, or a mixture of these three. A more specific statement of the composition of such solutions must await the acquisition of more extensive data, which we expect from experiments now in progress in this Laboratory.

The existence of −1 rhenium raises an interesting question in regard to its electronic configuration. In the rhenium atom itself the first four quantum levels are completely filled, and the configuration of the outer fifth and sixth levels is $5s^25p^65d^56s^2$. Hence the addition of an electron to produce −1 rhenium could lead to either of the

configurations, (A) $5s^25p^65d^66s^2$, or (B) $5s^25p^66s^26p^6$. It is a significant and generally accepted fact that the negative oxidation states of all other elements involve the formation of stable s^2p^6 octets, and on this basis one is inclined to assign configuration B to Re^{-1}. This configuration, which requires the promotion of all of the original $5d$ electrons to the $6p$ orbital, would be in accord with the marked instability and strong reducing character of Re^{-1}.

Summary

A zinc reductor is described in which reduction can be performed conveniently at a controlled temperature and in the absence of oxygen. The fact that -1 rhenium is produced when ice-cold and air-free solutions of perrhenate ion in dilute sulfuric and perchloric acids are reduced with zinc has been confirmed by oxidimetric titration of the reduced solutions.

Polarograms of solutions of -1 rhenium in 1 to 2 N sulfuric acid at 0° display three anodic waves, whose half-wave potentials are (α) -0.54 v., (β) -0.34 v., and (γ) -0.07 v. *vs.* the saturated calomel electrode. A similar polarogram is obtained in 1 N perchloric acid with the following exceptions: (a) the β-wave is resolved into two separate waves, β' and β'', whose half-wave potentials are -0.42 and -0.26 v., and (b) the half-wave potential of the γ-wave is about 0.1 v. more positive than in sulfuric acid medium. Diffusion current data show that corresponding waves in the two media pertain to the same oxidation states and in both media the diffusion currents are directly proportional to the concentration of -1 rhenium. From the ratio of the heights of the various waves it is concluded that the α-wave results from the oxidation of -1 rhenium to the $+2$ state, the β'-wave to the $+3$ state, the β''-wave to the $+5$ state and the γ-wave to complete oxidation to the $+7$ state (ReO_4^-). This conclusion has been confirmed by amperometric titration of the reduced solutions with ceric ion. Evidence is presented which indicates that the reversible potential of the reaction $Re^{+2} + 3\ e = Re^{-1}$ is equal to, or slightly more negative than, -0.54 v. *vs.* the saturated calomel electrode in dilute sulfuric or perchloric acid medium at 0°.

Partially oxidized solutions, obtained by warming dilute sulfuric acid solutions of -1 rhenium to about 50° for an hour in the absence of oxygen, show an *average* oxidation state of $+1$. However, the polarogram of such a solution indicates that the rhenium is not actually present in the $+1$ state, but as a mixture of Re^{-1} and higher states in proportions that are equivalent to an average oxidation state of $+1$.

The Accommodation Coefficient of Mercury on Platinum and the Heat of Vaporization of Mercury

BY LLOYD B. THOMAS AND FRANCOIS G. OLMER

Introduction

We have been interested in applying the Pirani type pressure gage as a means of determining small total pressures of pure gases and as a means of following quantitatively the progress of gas reactions at low pressure. Such an application to mixtures in which some gaseous compounds are consumed and others produced requires an accurate knowledge of the free molecule heat conductivity of each gas from the surface of the specified filament material. This actual heat conductivity is conveniently expressed in terms of the calculated free molecule heat conductivity and the accommodation coefficient. Since there is available only an admittedly rough estimate of the accommodation coefficient of mercury[1] on platinum and since, in this case, pressures are established in equilibrium with liquid mercury and the measurements apparently lead to a precise method of determining the heat of vaporization which should be generally applicable, we are submitting this work under separate title.

Experimental

A diagram of the tube used is shown in Fig. 1. The filament consists of 31.5 cm. of 0.004 inch C. P. platinum wire (Bishop Company) hung in a loop from tungsten leads in a Pyrex tube 3.0 cm. in diameter. At a distance of 4.5 cm. from the ends of the filament, potential leads of 0.001 inch C. P. platinum wire of 3.0 cm. length are welded on the

(1) W. B. Mann, *Proc. Roy. Soc.* (London), **A146**, 786 (1934).

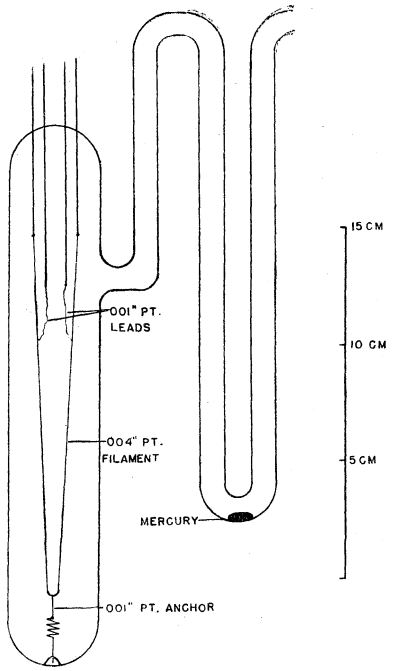

Fig. 1.—Tube I.

main filament and these are led out through two more tungsten seals. At the bottom of the loop a third 0.001 inch platinum wire was attached and this was anchored to the bottom of the tube. This latter was found necessary to eliminate vibration and to prevent the filament being pulled to the glass by electrostatic forces.

A diagram of the electrical circuits is shown in Fig. 2. The temperature coefficient of resistance of the filament was determined with the tube immersed in an oil-bath at temperatures from 0 to 150°. The resistance of the filament at any temperature is given by $R_t = R_0(1 + 0.0039055t)$ where R_0 is the resistance at 0°, t is the centigrade temperature of the filament, and 0.0039055 is the temperature coefficient. To operate the apparatus, the resistance between the potential leads at the desired filament temperature was calculated by the preceding equation and this value was set to the nearest 0.1 ohm on R_2. Current in the filament was then adjusted by means of R_3 (two dial boxes in parallel) until the fall in potential over the filament and R_2 became equal. The current in the circuit and the temperature of the filament were then established accurately by measuring the potential drop across R_1, a N. B. S. type 10 ohm standard resistor with potential contacts. Upon addition of gas the temperature of the filament was again adjusted to the original value by decreasing R_3 and the measurements for determining the new power loss were taken for the new condition.

The experimental tube was connected through a "U" tube and mercury cut-off to a high vacuum system employing the usual condensation pump, mercury cut-offs, McLeod gage, etc. No stopcocks were in the high vacuum line. The mercury vapor pressure was controlled by adjusting the temperature of a droplet of mercury in the "U" tube by means of a Dewar partially filled with water. When necessary this temperature was held constant and the bath stirred by passing air cooled in ice-water into the Dewar at the proper rate to counter the heat leak. The tube itself was immersed in a thermostat containing kerosene held at 30°, about 5° above room temperature.

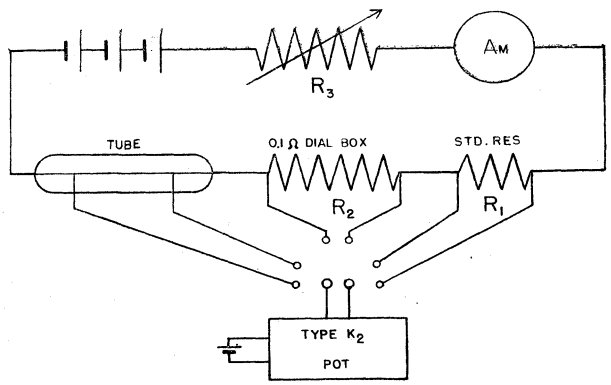

Fig. 2.—Electrical circuit of tube I.

Measurements and Treatment of Data.—The power loss from the filament is measured for a series of mercury vapor pressures from 0 to 15×10^{-4} mm. The filament current is increased with each increase of mercury vapor pressure to bring the temperature of the filament to its original value in order to keep the radiation losses constant. The power losses are plotted against the vapor pressures of mercury at the various control bath temperatures according to the values given in the "International Critical Tables," Vol. III. These vapor pressures are corrected for the thermal transpiration pressure according to the formula $P_t = P_u \sqrt{T_t/T_u}$, in which P_t and P_u are the pressures of mercury in the experimental tube and in the "U" tube, respectively, and T_t and T_u are the corresponding absolute temperatures. To check the applicability of the above formula measurements were made using a 2-mm. capillary as the left arm of the "U" tube of Fig. 1, but no difference could be observed between these measurements and the ones using the uniform 9-mm. "U" tube shown in Fig. 1. The capillary was removed for the data reported here to facilitate thorough evacuation. The mean free path of the mercury atoms at the highest pressures used is at least three times the diameter of the tubes in which the temperature gradients occur, thus giving conditions under which the above transpiration formula holds.

A typical plot of power loss from the filament against corrected mercury vapor pressure (for a filament temperature of 224° in this case) is shown in Fig. 3. The points are seen to fall on a well defined straight line. To obtain such a line

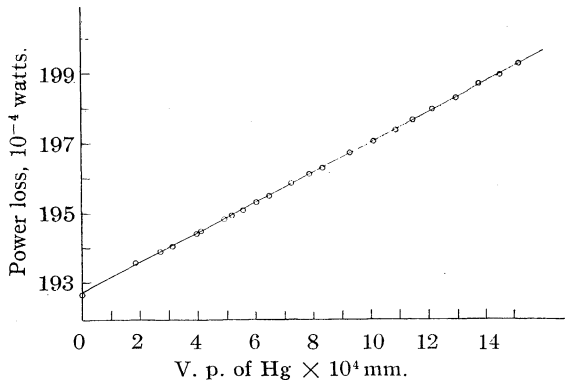

Fig. 3.

it was necessary to make measurements with the mercury cut-off which separates the system of Fig. 1 from the vacuum system closed. Runs made with the system open to the pumps showed a consistent behavior which we have been unable to explain. The observed behavior in such a case may be described with reference to Fig. 3. If the straight line is the best line which can be put through the points, the points lie regularly on an arc below the line from 0 to 6×10^{-4} mm., cross over at 6×10^{-4} and form an arc above the line from 6×10^{-4} to about 10×10^{-4}, and then cross back below the line and appear to lie on a third arc. The deviation of the arcs at the mid-points from the line is of the order of two to three times the radius of the circles of Fig. 3. Each of the four curves taken in this manner has the same form.

The slope of the curves as shown in Fig. 3 is the actual energy lost from the filament surface per second by gas conduction per unit of mercury vapor pressure. This, of course, may be reduced to the power lost per square centimeter of filament surface, per degree temperature difference between the wall and filament per bar of mercury pressure. This quantity will be designated by "$\Lambda_{obs.}$." The theoretical heat conduction, designated as "$\Lambda_{calcd.}$" from a square centimeter of surface per second per degree per bar, assuming complete temperature equilibrium of the rebounding molecules with the surface, has been calculated from kinetic theory to varying degrees of refinement. We have used the expression[2]: $\Lambda_{calcd.} = {}^1/_2(\gamma + 1)C_vP'/(2\pi RT')^{1/2}$ in which γ is the ratio of specific heats, C_v the specific heat at constant volume, P' the pressure, T' the temperature of the gas concerned. In this case with mercury T' is practically the same as the temperature of the wall since the mean path of mercury atoms is of the order of the radius of the tube at the highest pressures used, and the ratio of area of wall to area of filament is of the order of 150. We have used the values $\gamma = 1.67$, $C_v = {}^3/_2 R$, $R = 8.316 \times 10^7/200.6$ ergs/deg. × gram. The accommodation coefficient is the ratio of $\Lambda_{obs.}/\Lambda_{calcd.}$. The values which we have obtained for the accommodation coefficient of mercury are tabulated below. For completeness under the title of this paper and to throw evidence on a point discussed below we have included a set of accommodation coefficients measured with a tube, designated Tube II, in which filament lead losses have been eliminated.[3]

Tube I		Tube II	
ΔT[4]	a	ΔT[4]	a
36.6	0.967	36.3	0.969
114	.910	112	.905
194	.840	199	.844
		202	.828
		275	.757

These values of a are plotted against the corresponding values of ΔT in Fig. 4. The curve has two notable features, namely: the limiting accommodation coefficient as ΔT approaches zero is very close to unity assuming the extrapolation to be valid; and the accommodation coefficient falls off in approximately linear fashion as ΔT increases. This is the only case which we have seen of a simple molecule for which an accommodation coefficient of unity is reported. A high accommodation coefficient is generally associated with a long time of contact of the molecules with the surface or, *i. e.*, strong adsorption tendencies.

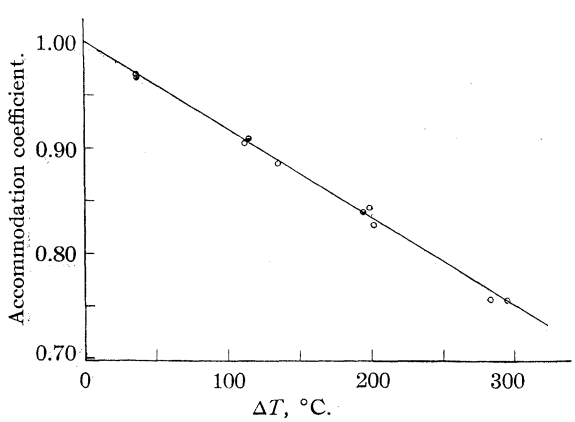

Fig. 4.—O, Values with tube II; ◒, values with tube I.

(3) Description of Tube II to be published currently.

(4) ΔT is the temperature difference between the filament and wall, the latter being 30°.

Keesom and Schmidt[5] have investigated the accommodation coefficients of several gases on glass and have drawn the conclusion that below the critical temperature the heat conduction in a rarified gas becomes independent of the surfaces and the accommodation coefficient becomes unity. From this point of view it is not surprising that the value for mercury is unity since its critical temperature is above 1500°. It is commonly assumed that the accommodation coefficient is independent of the temperature difference, ΔT, of the filament and the impinging gas molecules.[6] This seems to be tacitly assumed at least in defining the accommodation coefficient in which no restriction is made that ΔT approach zero for the determination of its value. In view then of the fact that a value of unity is obtained for the coefficient as $\Delta T \rightarrow 0$ and that, according to Keesom and Schmidt's generalization, it should remain unity to high filament temperature, we are inclined to doubt that the accommodation coefficient is independent of the ΔT at which it is measured. It would be quite improbable that the wall temperature, 30°, chosen in this work happened to be the unique temperature at which the accommodation coefficient of mercury on platinum begins to digress from unity. We suspect that the fall in accommodation coefficient is due primarily to an increasing ΔT rather than an increasing filament temperature. The work of Mann[1] and Mann and Newell[7] on platinum filaments points toward the possibility of another cause of the observed behavior. Their filament surfaces have been freed from contamination, presumably, by heating to high temperature and accommodation coefficient measurements have been taken as soon as possible after lowering the temperature. The initial values obtained in this way are much lower than those obtained before heating the wire, and the values rise with time and approach the original value. This behavior is attributed to the cleaning and subsequent contamination of the surface with adsorbed gas. The behavior observed in the present work could be due to the decreasing extent of adsorption at higher temperature of some gas present in the system—water vapor for example or mercury itself—and hence a changing surface upon which the accommodation coefficient is measured. However, all such effects, if present, must have been rapidly reversible as no inconsistencies or erratic behavior commonly associated with filament surfaces of varying degree of cleanness were evident. In our work the tube was frequently baked out thoroughly at 400°, the tubing of the vacuum system heated with a large brush flame, and the filament temperature raised to 800° during the course of the experiments.

Some points concerning the accuracy of the measurements should be considered. The diameter of the filament was checked by two methods—comparing the observed resistance at 0° and length of the filament with the resistivity of platinum (60.0 ohms per mil. foot), and comparing the mass of a portion of the filament material of known length with the density. Both methods agree with the specified diameter to well within one per cent The filament shows some striation and general roughness under the microscope. No attempt was made to determine the extent of increase in area (above that calculated) due to roughness, but it should be mentioned in this connection that the accommodation coefficients of hydrogen and helium on the same filament material are 0.23 and 0.17, respectively, and the emissivity from this filament material is approximately 20% greater than that given for bright platinum in the "International Critical Tables" over the temperature range 300 to 700°K. The temperature of the filament as measured in this work is a mean value between the potential leads. The resistance of platinum has a very nea ly linear dependence on temperature and the heat conducted to the wall by the gas has a similar dependence on the temperature of the filament. The temperature distribution over the portion of the filament between the potential leads is far from constant in vacuum, and this distribution will be modified with addition of gas giving rise to concealed changes in power loss not due to gas conduction itself but due to changes in the temperature gradients in the filament at the leads and in the potential leads themselves and due to changes in the radiation loss, which is proportional to the temperature to the fourth power, over the new temperature distribution. It is believed that the errors from this source are negligibly small in these measurements on mercury for the following reasons: first, the slope of the power loss *vs.* pressure curves is constant both with mercury and with permanent gases up to pressures corresponding to

(5) Keesom and Schmidt, *Physica*, **3**, 590 and 1085 (1936); **4**, 828 (1937).

(6) See for example J. K. Roberts, *Proc. Roy. Soc.* (London), **A129**, 146, 147 (1930).

(7) Mann and Newell, *ibid.*, **158**, 401 (1937).

many times the gas heat conduction attained in these experiments on mercury vapor; second, values of the accommodation coefficient obtained in a tube constructed to eliminate end losses, and hence having constant filament temperature over the entire length, agree with those obtained with this tube; third, the approximate calculations of the temperature distributions with and without gas show that the above suspected uncertainties would be very small for mercury. Concerning the accuracy of the electrical measurements it should be said that all voltages were read to the limit of the L. and N. Type K-2 potentiometer using a L. & N. galvanometer of 0.005 μ a. sensitivity and 33-ohm resistance. The 10-ohm resistor is guaranteed to a tolerance of 0.01%, and the standard cell was checked against cells recently certified by the Bureau of Standards. The resistance of the filament was adjusted for each measurement in a set to within 0.0005 ohm of the chosen value and the value of R_0 for the filament was checked from time to time. The power loss by gas conduction varied from 11% of the total with the filament at 66° to 3.3% with the filament at 225°.

Measurement of the Heat of Vaporization of Mercury at 10°.—A great many sets of values for the vapor pressure of mercury are in the literature. If we use sets of vapor pressure data differing from that of the "International Critical Tables," different slopes for the curves of the type plotted in Fig. 3, and hence different values for the accommodation coefficient will be obtained. The vapor pressure and accommodation coefficient are mutually indeterminate by the method of this paper, but the measurements allow a determination of the heat of vaporization of mercury which of course has its bearing on any set of vapor pressure data through the equation

$$\frac{\mathrm{d} \ln p}{\mathrm{d}\, T} = \frac{\Delta H_v}{RT^2}$$

By subtracting the power loss in vacuum, W_{vac}, from that at each temperature of the vapor pressure control bath, W_T, one obtains numbers which are proportional to the pressure of mercury vapor P_T in the experimental tube at the temperature of the thermostat bath, 30°. One has then $W_T - W_{\mathrm{vac.}} = \Delta W_T$. The assumption can then be made that $\Delta W_T = kP_T$ which is justified by the experimental fact that it is found to be true with permanent gases for which the pressure can be measured directly with the McLeod gage To determine the heat of vaporization one is interested in the pressure of mercury vapor in contact with the liquid mercury in the "U" tube and this is less than P_T by a thermal transpiration correction factor as mentioned earlier. Designating the equilibrium vapor pressure in the "U" tube by P_T (eq.) one may write

$$\Delta W_T \sqrt{\frac{T}{303}} = kP_T \text{ (eq.)}$$

$$\ln \Delta W_T + {}^1/_2 \ln (T/303) = \ln k + \ln P_T \text{ (eq.)}$$

$$\ln \Delta W_T \text{ (cor.)} = \ln k + \ln P_T \text{ (eq.)}$$

$$\frac{\mathrm{d} \ln P_T \text{ (eq.)}}{\mathrm{d}T} = \frac{\mathrm{d} \ln \Delta W_T \text{ (cor.)}}{\mathrm{d}T} = \frac{\Delta H}{RT^2} \quad \text{or}$$

$$\frac{\mathrm{d} \log_{10} \Delta W_T \text{ (cor.)}}{\mathrm{d}\, 1/T} = -\frac{\Delta H}{R \times 2.303}$$

The values of $\log_{10} \Delta W_T$ (cor.) for five sets of data were plotted against $1/T$ and the slopes of these curves multiplied by $R \log_{10} e$ (4.575 cal./deg.) give $-\Delta H_{\mathrm{vap.}}$ for mercury. The points lie in regular fashion and seem to show a slight curvature in the proper direction to give smaller values of $\Delta H_{\mathrm{vap.}}$ at the higher temperatures. We have taken the slopes of the best lines we could put through the points over the temperature range 0–20°, and our results give the heat of vaporization at approximately 10°. The results of five runs from both Tube I and Tube II are tabulated below.

$T_{\mathrm{fil.}}$, °C.	Tube	$\Delta H_{\mathrm{vap.}}$
66	I	14898
144	I	14897
224	I	14923
232	II	14951
315	II	14930

The mean deviation from the average is 0.12%. We have not made a critical study of the measurements of others on this $\Delta H_{\mathrm{vap.}}$ value, but we can say that our value, 14920 calories, is not outside the probable limits for the correct value.

This method seems to us to offer attractive possibilities as a means of determining heats of vaporization or sublimation of compounds over temperature ranges such that the vapor pressure varies from 10^{-5} up to 10^{-2} mm. If desired, the thermostat could be operated at any temperature and the filament can be operated from a few degrees above this up to as high as desired as long as it does not cause decomposition of the compounds investigated. We hope to test the method on some organic compounds of convenient volatility.

Summary

The accommodation coefficient of mercury on

platinum has been measured at low mercury pressures. It has been found to approach unity as the temperature difference between the filament and wall approaches zero and to fall off about 0.08 for each 100° of this temperature difference. The data obtained in the measurements allow a calculation of the heat of vaporization of mercury. It is suggested that the method might be developed into a precise and convenient one of wide applicability for determining heats of vaporization and sublimation.

Equation of State for Gases at High Pressures Involving Only Critical Constants

BY SAMUEL H. MARON AND DAVID TURNBULL

Several years ago F. G. Keyes,[1] starting with an equation of state involving PV as a linear function of pressure, deduced generalized equations for polar and non-polar gases at low pressures. More recently the authors,[2] using the principle of corresponding states, presented a method for estimating the Beattie–Bridgeman constants of any gas from those of a reference gas. The only supplementary data required were the critical pressures and temperatures of a gas and of the reference, for which nitrogen was taken. The success thus attained suggested that the pressure range over which calculations could be made could be extended appreciably provided an equation of state were available covering a wider range of pressures than that of Beattie–Bridgeman. Consequently an empirical equation of state for nitrogen was deduced, covering the temperature range of −70 to 600°, and for pressures up to 1000 atmospheres.[3] The purpose of this paper is to show how this equation for nitrogen may be extended to other gases, and to present evidence for the validity of such an extension.

Derivation of Equation of State

The nitrogen compressibility data within the temperature and pressure ranges specified are represented with good reproducibility by the equation,[3]

$$PV = RT + \alpha_1' P + \alpha_2' P^2 + \alpha_3' P^3 + \alpha_4' P^4 \quad (1)$$

where the virial coefficients α_1', α_2', α_3', α_4' are functions of the temperature only, and are given by

$$\alpha_1' = a_1 + \frac{a_2}{T} + \frac{a_3}{T^3} \quad (2)$$

$$\alpha_2' = \frac{b_1}{T^2} + \frac{b_2}{T^4} + \frac{b_3}{T^6} \quad (3)$$

$$\alpha_3' = \frac{c_1}{T^2} + \frac{c_2}{T^4} + \frac{c_3}{T^6} \quad (4)$$

$$\alpha_4' = \frac{d_1}{T^2} + \frac{d_2}{T^4} + \frac{d_3}{T^6} \quad (5)$$

a_1, a_2, . . ., b_1, b_2, . . ., etc., are constants independent of temperature and pressure. From (1) the expression for the compressibility coefficient, Z, of nitrogen follows as

$$Z = \frac{PV}{RT} = 1 + \frac{\alpha_1' P}{RT} + \frac{\alpha_2' P^2}{RT} + \frac{\alpha_3' P^3}{RT} + \frac{\alpha_4' P^4}{RT} = 1 + \left[\frac{\alpha_1' P_c'}{RT_c'}\right]\frac{P_r}{T_r} + \left[\frac{\alpha_2'(P_c')^2}{RT_c'}\right]\frac{P_r^2}{T_r} + \left[\frac{\alpha_3'(P_c')^3}{RT_c'}\right]\frac{P_r^3}{T_r} + \left[\frac{\alpha_4'(P_c')^4}{RT_c'}\right]\frac{P_r^4}{T_r} \quad (6)$$

where the substitutions $T = T_c' T_r$ and $P = P_c' P_r$ have been made for T and P. T_c' and P_c' are the critical constants of nitrogen, while T_r and P_r are the reduced temperature and pressure corresponding to T and P.

Now, the indications of various attempts at generalized correlation of compressibilities of gases[4,5] are that Z is, to a fairly close approximation, a function of T_r and P_r only. If this statement be accepted provisionally, then it must follow that at any given values of T_r and P_r Z is the same for different gases, and hence the quantities in brackets in equation (6) must have the same values for all gases obeying the principle of corresponding states. Applying this identity condition to the first quantity in brackets in (6), we obtain for the relation between the primed quantities for nitrogen and the unprimed quantities for any other gas

$$\frac{\alpha_1 P_c}{T_c} = \frac{\alpha_1' P_c'}{T_c'}$$

$$\alpha_1 = \left(\frac{\alpha_1' P_c'}{T_c'}\right)\frac{T_c}{P_c} \quad (7)$$

(1) Keyes, THIS JOURNAL, **60**, 1761 (1938).

(3) Maron and Turnbull, THIS JOURNAL, **64**, 44 (1942).
(4) Dodge, *Ind. Eng. Chem.*, **24**, 1353 (1932).
(5) Lewis, *ibid.*, **28**, 257 (1936).

Substituting now $T = T_c'T_r$ for T in (2), and inserting the result in (7), we find for α_1

$$\alpha_1 = \frac{T_c}{P_c}\left\{\left[\frac{a_1P_c'}{T_c'}\right] + \left[\frac{a_2P_c'}{(T_c')^2}\right]\frac{1}{T_r} + \left[\frac{a_3P_c'}{(T_c')^4}\right]\frac{1}{T_r^3}\right\}$$
$$= \frac{T_c}{P_c}\left[\beta_1 + \frac{\beta_2}{T_r} + \frac{\beta_3}{T_r^3}\right] \quad (8)$$

where β_1, β_2 and β_3 are constants given by the quantities in brackets involving the a's and the critical pressure and temperature for nitrogen.

By extending this procedure to the other α's, it can readily be shown that

$$\alpha_2 = \frac{T_c}{P_c^2}\left\{\left[\frac{b_1(P_c')^2}{(T_c')^3}\right]\frac{1}{T_r^2} + \left[\frac{b_2(P_c')^2}{(T_c')^5}\right]\frac{1}{T_r^4} + \left[\frac{b_3(P_c')^2}{(T_c')^7}\right]\frac{1}{T_r^6}\right\}$$
$$= \frac{T_c}{P_c^2}\left[\frac{\beta_4}{T_r^2} + \frac{\beta_5}{T_r^4} + \frac{\beta_6}{T_r^6}\right] \quad (9)$$

$$\alpha_3 = \frac{T_c}{P_c^3}\left\{\left[\frac{c_1(P_c')^3}{(T_c')^3}\right]\frac{1}{T_r^2} + \left[\frac{c_2(P_c')^3}{(T_c')^5}\right]\frac{1}{T_r^4} + \left[\frac{c_3(P_c')^3}{(T_c')^7}\right]\frac{1}{T_r^6}\right\}$$
$$= \frac{T_c}{P_c^3}\left[\frac{\beta_7}{T_r^2} + \frac{\beta_8}{T_r^4} + \frac{\beta_9}{T_r^6}\right] \quad (10)$$

$$\alpha_4 = \frac{T_c}{P_c^4}\left\{\left[\frac{d_1(P_c')^4}{(T_c')^3}\right]\frac{1}{T_r^2} + \left[\frac{d_2(P_c')^4}{(T_c')^5}\right]\frac{1}{T_r^4} + \left[\frac{d_3(P_c')^4}{(T_c')^7}\right]\frac{1}{T_r^6}\right\}$$
$$= \frac{T_c}{P_c^4}\left[\frac{\beta_{10}}{T_r^2} + \frac{\beta_{11}}{T_r^4} + \frac{\beta_{12}}{T_r^6}\right] \quad (11)$$

If the above considerations are valid, equations (8), (9), (10), and (11) should give the α's for any gas in terms of the constants for nitrogen as they appear in the β's, and the critical pressure and temperature of the gas in question. These α's, then, when substituted in equation (1) for the α's for nitrogen should permit a calculation of the compressibility of various gases from a knowledge of their critical constants and the β's for nitrogen. In other words, the equations for the α's should give the virials of any gas whose PV behavior as a function of P is represented by equation (1).

Results and Discussion

Table I gives the β values calculated from the constants of equations (2) to (5) as published,[3] and from the critical constants of nitrogen, T_c' = 126.0°K. and P_c' = 33.5 atmospheres. From these β's and the appropriate critical constants α's were determined for a number of gases at various reduced temperatures, and these, in turn, were employed with equation (1) to estimate the volumes of these gases at various temperatures and pressures. In line with Newton,[6] the critical temperatures for hydrogen and helium were taken as $T_c + 8$, with the critical pressures as $P_c + 8$, since these definitions for the critical constants were found necessary to generalize the thermodynamic behavior of these gases. The results thus obtained with nine gases are summarized in Table II. Column 1 gives the temperature in °C., column 2 the corresponding reduced temperature, while column 3 the maximum pressure to which the calculations were extended. Finally, columns 4 and 5 give, respectively, the maximum and average percentage deviation of the volumes calculated in this manner from the observed.

TABLE I

β VALUES FOR EQUATIONS (8) TO (12)[a]

$\beta_1 = 1.01961 \times 10^{-2}$	$\beta_7 = -1.2516 \times 10^{-4}$
$\beta_2 = -2.1420 \times 10^{-2}$	$\beta_8 = 4.6408 \times 10^{-4}$
$\beta_3 = -3.2548 \times 10^{-2}$	$\beta_9 = -1.5573 \times 10^{-3}$
$\beta_4 = 3.6991 \times 10^{-3}$	$\beta_{10} = 1.7019 \times 10^{-6}$
$\beta_5 = -4.3022 \times 10^{-3}$	$\beta_{11} = -1.1221 \times 10^{-5}$
$\beta_6 = 1.8289 \times 10^{-2}$	$\beta_{12} = 3.2830 \times 10^{-5}$

[a] These constants are for V in liters, P in atmospheres, and $T = (t°C. + 273.18)°K.$

Before considering these results it should be pointed out that the equation for nitrogen, from which the more general equation presented here is derived, was set up from data which cover the reduced temperature interval 1.61–7 and up to $P_r = 30$. Therefore, in extending this equation through the principle of corresponding states to other gases, it is to be anticipated that the proposed equation will be strictly applicable over the same reduced temperature and pressure interval. Actually it has been found that the equation may be extended to T_r values lower than 1.6 although in such extension the maximum and average deviations which appear are higher than within the specified interval.

The results in Table II indicate that within the range of equations, compressibilities of various gases can be calculated with a maximum deviation no greater than about 4%, and an average deviation less than 2%, up to pressures of 1000 atmospheres in many instances. The reason for not extending all calculations to this pressure is lack of data for comparison. However, in the case of helium, where data are available, the limitation is the high reduced pressure, which is already 58.5 at 600 atmospheres. Any attempts to carry the calculations beyond this large P_r extrapolation result in an appreciable decrease in concordance with observed data.

The results for hydrogen and helium indicate that the equation is suitable for extrapolation to values of T_r much higher than seven. In fact, the agreement for hydrogen at T_r = 18.7 and helium at T_r = 35.6 is not very much worse than at the lower T_r's. On the other hand, the calculations do indicate that extrapolation to values of T_r lower than 1.6 cannot be made as freely. With some sacrifice in accuracy the equation may be applied to T_r values as low as 1.3, although in such cases it is found necessary to decrease the pressure range to be covered. All things considered, it does not seem advisable to recommend the equation for its full pressure range below T_r = 1.55. At T_r = 1.3 the equation should be used only up to pressures of 100 atmospheres, with progressive increase in pressure range up to P_r = 30 as T_r approaches 1.55. Above T_r = 1.55 the equation seems to hold very well even at pressures considerably higher than the reduced pressure range for which the original nitrogen equation was deduced.

To show the superiority of the equation proposed here over a simple equation of state such as van der Waals, Table III gives a comparison of PV's observed and calculated by means of the two equations. Throughout the equation proposed here reproduces the observed compressibility data with a much higher fidelity than does the van der Waals equation. Further, when extended to pressures beyond the upper limits given in the table the van der Waals equation gives deviations which are above 15% and which reach 200–300% as the pressures approach 1000 atmospheres, whereas the equation of this paper still reproduces the data within a few per cent. A further comparison of the present equation with those of van der Waals, Dieterici, and Berthelot with data on hydrogen and oxygen at 0°[7] also shows that up to 1000 atmospheres our equation reproduces much more satisfactorily the data for these gases than do the other equations.

(7) Maron and Turnbull, *Ind. Eng. Chem.*, **34**, 544 (1942).

TABLE III

COMPARISON OF OBSERVED AND CALCULATED PV'S

Gas	Pressure range,[a] atm.	Reduced temp., T_r	PV van der Waals % Max. dev.	PV van der Waals % Av. dev.	PV this paper % Max. dev.	PV this paper % Av. dev.
Methane	30–300	1.694	7.67	3.66	2.14	0.96
Ethane	38.64–311.09	1.631	− 8.43	4.81	−3.10	1.12
Propane	41.23–303.03	1.481	14.05	6.07	−1.90	0.79
Ethylene	50–300	1.667	− 6.44	4.10	−1.57	0.61
Carbon monoxide	25–200	1.663	− 7.16	4.54	−2.57	0.90
Carbon dioxide	75–500	1.548	11.33	6.26	−3.64	2.17

[a] Above the upper limits of pressure indicated the van der Waals equation gives deviations which are 15% or higher, and which reach 200–300% at pressures approaching 1000 atmospheres.

From the equations given in this paper it is readily possible to derive a generalized equation for the compressibility coefficients of gases obeying the principle of corresponding states. If the values of the α's given by equations (8) to (11) be substituted into equation (1), and Z solved for, the result is

$$Z = 1 + \left[\frac{\beta_1}{T_r} + \frac{\beta_2}{T_r^2} + \frac{\beta_3}{T_r^4}\right]\frac{P_r}{R} + \left[\frac{\beta_4}{T_r^3} + \frac{\beta_5}{T_r^5} + \frac{\beta_6}{T_r^7}\right]\frac{P_r^2}{R} + \left[\frac{\beta_7}{T_r^3} + \frac{\beta_8}{T_r^5} + \frac{\beta_9}{T_r^7}\right]\frac{P_r^3}{R} + \left[\frac{\beta_{10}}{T_r^3} + \frac{\beta_{11}}{T_r^5} + \frac{\beta_{12}}{T_r^7}\right]\frac{P_r^4}{R} \quad (12)$$

This equation should reproduce the generalized compressibility coefficient curves deduced empirically by various authors within the ranges specified. That it will do so is evidenced by the comparisons of calculated and observed volumes given in this paper.

Summary

1. Employing the principle of corresponding states, an equation of state for gases is deduced requiring only the critical temperature and pressure of a gas.

2. The equation is shown to be applicable to pressures as high as 1000 atmospheres and reduced temperatures of $T_r = 1.55$ and above.

3. Below $T_r = 1.55$ the equation proposed is applicable down to $T_r = 1.30$ provided the pressure interval covered is reduced to 100 atmospheres at the lower temperature.

4. A comparison of the proposed equation with several other common equations of state shows the present equation to be superior to these.

5. A generalized equation for compressibility coefficients of gases is deduced.

Systems with Boron Trifluoride[1]

BY HAROLD SIMMONS BOOTH AND DONALD RAY MARTIN

The boron atom of boron trifluoride has been found to be an acceptor to form a large number of coördinate compounds. The number of donor atoms has been found so far to be quite small, being confined to the seven elements carbon, nitrogen, oxygen, fluorine, phosphorus, sulfur and argon.

One of the best procedures for the identification of these coördinate compounds is thermal analysis, particularly as applied to liquefied gases. The object of the present investigation was to extend our knowledge of the coördinate compounds of boron trifluoride and various gases by means of therma analysis.

Apparatus and Procedure

The apparatus shown in Fig. 1 is similar in principle and operation to that described in detail by Germann and Booth,[2] save for the following features.

1. Boron trifluoride[3] from the cylinder B was purified by fractional distillation in the fractionating column[4] LH and stored in ampoule T_2 separated by the mercury cut-off MC to prevent contamination from stopcock grease or from leakage.

(4) Booth and Bozarth, *Ind. Eng. Chem.*, **29**, 470 (1937).

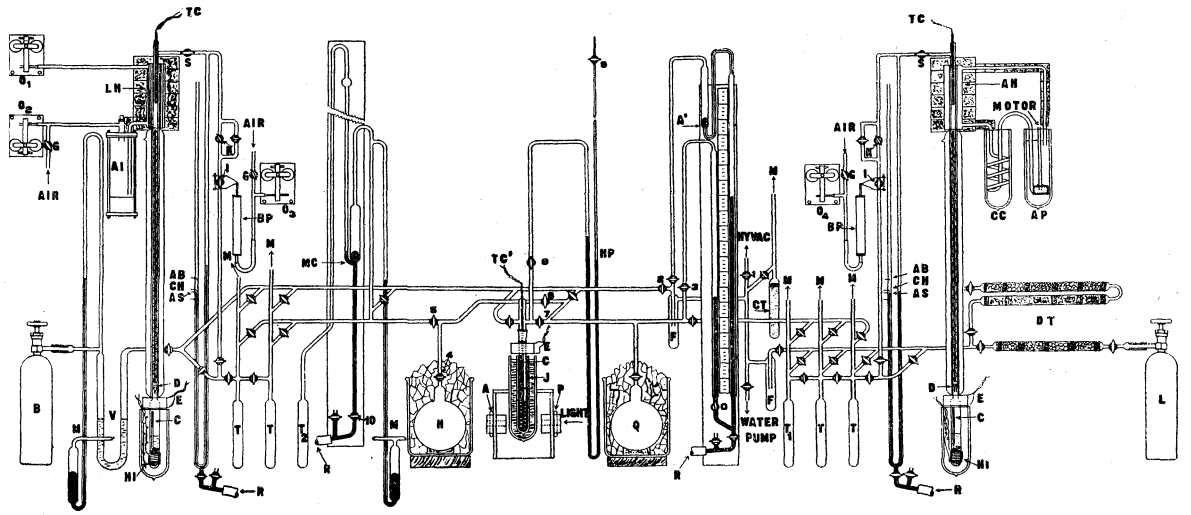

Fig. 1.—Apparatus.

2. In a corresponding fashion the right side of the apparatus contained the fractionating column AH for purifying the gases whose systems with boron trifluoride were to be studied.

3. The freezing points of the liquefied gas mixtures were determined by a triple junction copper–constantan thermocouple TC in a thin-walled glass well (3 mm. in diameter) immersed in the freezing point cell J and recorded on a special Leeds and Northrup Micromax recording potentiometer yielding freezing point determinations accurate to ±0.25 degree (see Fig. 2).

4. The first appearance of crystals on cooling was established in two ways: by the appearance of points of light in the field when the cell was placed between crossed nicols A, P, mounted in a light-proof box, and by the inflection in the cooling curves recorded on the potentiometer.[5]

In the early part of this investigation, on the system methyl chloride–boron trifluoride, we enjoyed the coöperation of Professor W. C. Fernelius of Ohio State University. In applying the procedure as described by Germann and Booth[2] to this system, difficulties in obtaining reproducible results were encountered which led us to undertake a study of the various sources of error in this method.

The following points presented themselves as factors which might in some way affect the accuracy of the determination of freezing points; (1) rate of cooling, (2) chart rate in the recording potentiometer, (3) diameter of freezing point cell, (4) immersion depth of thermocouple, and (5) closeness of the thermocouple to the bottom of the freezing point cell.

(5) Booth and Willson, THIS JOURNAL, 57, 2273 (1935).

Rate of Cooling.—By the use of a partially exhausted Dewar type container for the freezing point cell, it was possible to maintain a cooling rate of three to three and one-half degrees per minute. The moment when crystal formation started was detected by means of polarized light, using polarized disks as shown in Fig. 2.

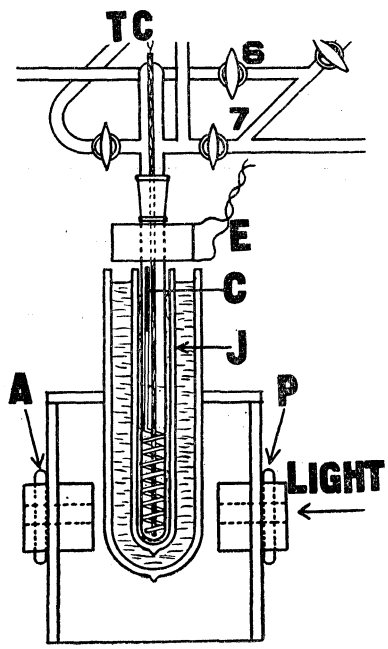

Fig. 2.

Chart Rate in Recording Potentiometer.—The recording potentiometer was found to give

optimum results at a chart rate of eight inches per hour corresponding to 4° min.$^{-1}$.

Diameter of Freezing Point Cell.—In this Laboratory it has been customary to build the freezing point cell of as small a diameter as possible, being just large enough to enable a glass spiral stirrer to operate smoothly between the inner wall of the freezing point cell and the outer wall of the glass thermocouple well. The small diameter freezing point cell was advantageous because it required less gas to give reliable freezing point data.

A study was made with two freezing point cells, one being 14 mm. outside diameter while the other was 19 mm. Provided the thermocouple was sufficiently immersed, reliable freezing point data could be obtained with either freezing point cell.

Immersion Depth of Thermocouple.—It has been reported that a sample depth of 7 cm. above the uppermost thermocouple junction is necessary to obtain reliable freezing point data.[4] With the 14-mm. freezing point cell, an immersion depth of 3.2 cm. above the uppermost thermocouple junction was necessary while the 19-mm. cell required an immersion depth of 3.8 cm. (see Fig. 3). We have found it a safe rule that the uppermost junction of the thermocouple using number thirty-two gage copper and constantan wire, should be immersed at least 4 cm. when the cell is to be used at temperatures around −100°.

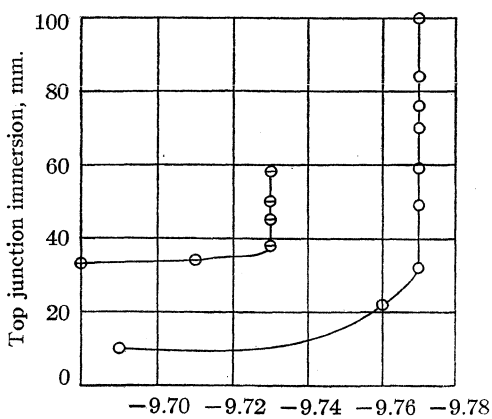

Fig. 3.—Effect of depth of thermocouple immersion on the freezing point: O, 14-mm. cell; ⊖, 19-mm. cell.

Closeness of Thermocouple to the Bottom of the Freezing Point Cell.—It was found that the distance of the thermocouple from the bottom of the freezing point cell had no effect upon the recorded temperature of the freezing point up to a distance of 2 cm. The effect for more than 2 cm. was not studied.

The System Methyl Chloride–Boron Trifluoride

Since fluorine in its compounds is the only member of Group VII of the Periodic Table which has been found capable of donating to the boron atom of boron trifluoride, and since members of the third period of Groups V and VI were found also to donate, it was of interest to determine the behavior of chlorine in methyl chloride.

Second, acetyl chloride has been found to coordinate with boron trifluoride but there is a question as to whether it is the carbonyl oxygen[6] or the chlorine[7] which is donating to the boron atom of boron trifluoride.

Third, earlier work upon this system left some uncertainty as to whether or not a compound was formed. Germann and Cleaveland[8] working in this Laboratory in 1921 studied this system and reported that they obtained a maximum at 15 and 33 mole per cent. of boron trifluoride and an "angular point" at 50 mole per cent. Since they made their own methyl chloride from concentrated sulfuric acid, methyl alcohol and sodium chloride, they postulated that these maxima might be due to methyl ether which might have been present as an impurity. Since methyl ether and methyl chloride boil within 0.3° of each other, they are difficult to separate by distillation.

They continued the work later using some methyl chloride which had been made by chlorinating gas and after five distillations the system was reinvestigated. A simple curve with no maxima and with a eutectic point at 70 mole per cent. boron trifluoride was found.[9] An uncalibrated propane thermometer was used in their study for the determination of the freezing points and as a result all of the values were high.

The methyl chloride used in this investigation was obtained from the Ohio Chemical Company, dried over barium oxide, and fractionally distilled. The freezing points for various mixtures of boron trifluoride and methyl chloride are given in Table I and are plotted in the phase rule diagram, Fig. 4.

The methyl chloride was condensed and stored as a liquid using dry-ice as the refrigerant because when it was solidified, it made a crackling noise

					1.000	126.6	

[a] Mole fractions were established according to the equation used by Germann and Booth.[2] This equation becomes $X_{BF_3} = cP_{BF_3}/(P_h + cP_{BF_3})$ where X_{BF_3} is the mole fraction of BF_3, c is the ratio of the volumes of the calibrated flasks = 1.18910, P_{BF_3} is the pressure exerted by the number of moles of BF_3 introduced into the freezing point cell, and P_h is the pressure exerted by the number of moles of other gaseous component introduced.

and occasionally broke the glass vessel into which it was being condensed.

The freezing point of the pure methyl chloride was found to be −96.65° and that of the pure boron trifluoride to be −126.7 ± 0.25°. A eutectic point was found at 65.5 mole per cent. boron trifluoride and −144.8 ± 0.25°. The curve is of the same type as found by Cleaveland.[9]

The results of the investigation of this system show that the chlorine atom of methyl chloride does not donate to the boron atom of boron trifluoride to form an addition compound at a pressure of one atmosphere.

Since it is the carbonyl oxygen of aldehydes and ketones which donates to the boron atom of boron trifluoride to form addition compounds, and since the chlorine atom has not been found to donate in methyl chloride, it seems logical to expect that it is the carbonyl oxygen of acetyl chloride which is donating to the boron atom of boron trifluoride to form that addition compound.

The System Hydrogen Chloride–Boron Trifluoride

Hydrogen fluoride has been found to form three

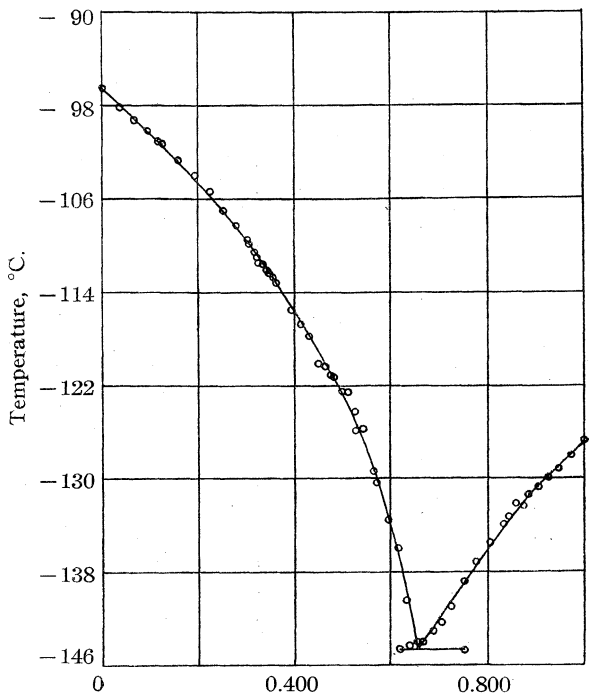

Fig. 4.—The system methyl chloride–boron trifluoride.

addition compounds with boron trifluoride.[10] In each case, however, water was present so that it was the fluoride ion which was donating to the boron atom. It was of interest to see whether anhydrous hydrogen chloride would combine with boron trifluoride. Also, it was of interest to find out if the replacement of the methyl group of methyl chloride by hydrogen in the form of hydrogen chloride would affect the coördinating power of the chlorine atom. For these reasons the system hydrogen chloride–boron trifluoride was investigated.

The hydrogen chloride used in this investigation was prepared from hydrochloric acid and sulfuric acid, dried over phosphorus pentoxide, and fractionally distilled. Care had to be exercised in condensing the hydrogen chloride in the usual manner with liquid air as the condensing agent because when it solidified it broke the glass vessels. It was possible to avoid breakage of the freezing point cell by preventing the temperature of the pure hydrogen chloride from dropping more than 20° below its freezing point. This practice had to be followed until a mole fraction of about two-tenths boron trifluoride was reached.

Pure hydrogen chloride was found to freeze at

−113.1° and pure boron trifluoride at −127.0 ± 0.25°. A phase rule diagram was obtained with a eutectic point at 72.3 mole per cent. boron trifluoride and at a temperature of −134.15 ± 0.25°. The data are given in Table II and shown in Fig. 5.

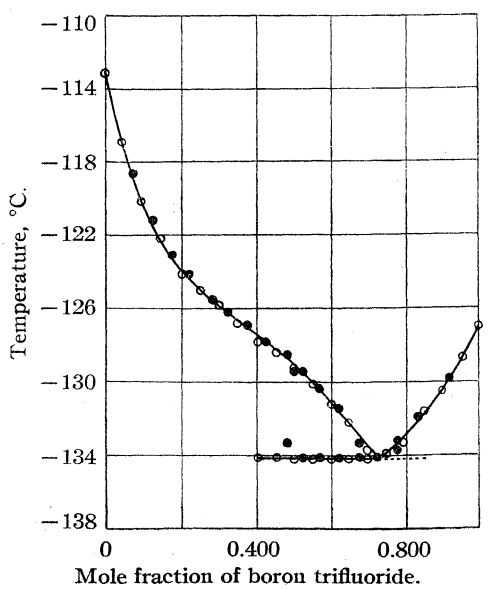

Fig. 5.—The system hydrogen chloride–boron trifluoride: O, first analysis; ●, second analysis.

In most systems where only one eutectic is found, the curve drops slowly with relation to the temperature in the vicinity of the pure components, and then drops rapidly in the vicinity of the eutectic point. The curve obtained with hydrogen chloride and boron trifluoride did just the opposite. This curve dropped rapidly in temperature in the vicinity of the pure components and more slowly in the vicinity of the eutectic point. A similar curve was found by Graff[11] for the system hydrogen chloride–boron trichloride.

As no addition compound was found, it appears that ionization may be the explanation of the difference between the action of hydrogen fluoride with boron trifluoride on the one hand, and of hydrogen chloride and boron trichloride, and of hydrogen chloride and boron trifluoride on the other hand. Also, Wiberg and Sütterlin[12] tried the reaction between hydrogen fluoride and boron trichloride and obtained as reaction products hydrogen chloride on the one hand and boron trifluoride on the other. An additional fraction having a vapor pressure between that of boron trifluoride and that of hydrogen chloride was obtained which had a molecular weight corresponding to the addition compound $BF_3 \cdot 3HCl$ analogous to $BF_3 \cdot 3HF$. They postulated that the reaction between hydrogen fluoride and boron trichloride took place because the fluorine atom of the hydrogen fluoride, through its residual valence, reacted with the boron trichloride, probably forming as a first product in the liquid state $BF_3 \cdot 3HCl$. If such a compound exists in the liquid state, it should have given a maximum in the phase rule diagram at 25 mole per cent. boron trifluoride. No maximum was found and we believe that they were mistaken in their conclusion.

It has been shown that the chlorine atom in both methyl chloride and in hydrogen chloride does not coördinate with the boron atom of boron trifluoride.

The System Nitrous Oxide–Boron Trifluoride

Over one hundred years ago, Kuhlmann[13] noted a reaction between the oxides of nitrogen and their respective acids with boron trifluoride, with the exception of nitrous oxide which he reported did not react. Germann and Booth[2] mention a reaction between nitric oxide and boron trifluoride. One would expect a reaction between nitrous oxide and boron trifluoride in the light of the addition compounds to which each of its constituents

(11) Graff, *Compt. rend.*, **197**, 754 (1933).

(12) Wiberg and Sütterlin, *Z. anorg. allgem. Chem.*, **202**, 37 (1931).

give rise in their respective compounds. The nitrogen atom and the oxygen atom in their respective compounds have been found to donate to the boron atom of boron trifluoride to form addition compounds. Therefore, it was of interest to study the system nitrous oxide–boron trifluoride.

Anhydrous nitrous oxide, of anesthesia quality, from the Ohio Chemical Company, was dried over barium oxide before being fractionally distilled.

In order to fractionate this gas, because of the narrow liquidus range of 2.3°,[14] it was necessary to distil at a pressure of one and one-half atmospheres.

Due to the short liquidus range of nitrous oxide, the freezing point procedure was modified slightly. With pure nitrous oxide or with mixtures on that side of the system, the technique for melting the solid was modified. It was found best to warm gently the wall of the freezing point cell with acetone from the top of the cell to the bottom until it was certain that there was a very small space between the solid and the wall of the freezing point cell. Then the bottom of the cell was warmed rapidly by raising a small bottle of acetone around the bottom. In this manner, the solid at the bottom of the cell was all melted before the liquid on top had acquired too high a vapor pressure. Also, the stirrer was freed more rapidly and could stir the liquid, which prevented an excessive pressure building up due to the liquid on top vaporizing.

The freezing point of the pure nitrous oxide was found to be −91.05° and that of the pure boron trifluoride −126.8 ± 0.25°. The phase rule diagram was a smooth curve with the eutectic occurring at 76.6 mole per cent. boron trifluoride and at a temperature of −138.0 ± 0.25° (see Table III and Fig. 6).

			1.000	126.8	

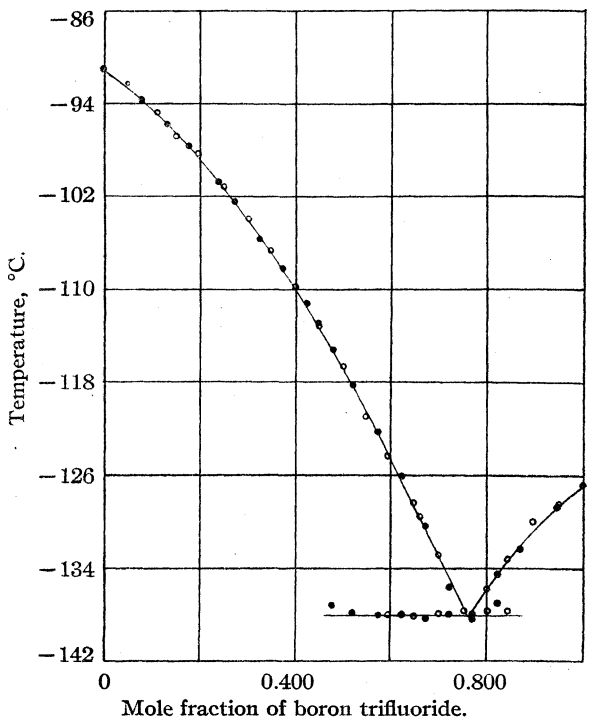

Fig. 6.—The system nitrous oxide–boron trifluoride: O, first analysis; ●, second analysis.

The investigation of this system confirmed the report of Kuhlmann[13] that nitrous oxide and boron trifluoride do not react. The explanation for this is not clear.

The System Sulfur Dioxide–Boron Trifluoride

The sulfur atom and the oxygen atom in their respective compounds have been found to donate to the boron atom of boron trifluoride to form coördination compounds. A compound made up of these two atoms would be expected to coördinate with boron trifluoride. Therefore, the system sulfur dioxide–boron trifluoride was investigated.

The anhydrous sulfur dioxide was obtained from the Ohio Chemical Company, dried over phosphorus pentoxide, and fractionally distilled.

The freezing point of the pure sulfur dioxide was

(14) Blue and Giauque, THIS JOURNAL, 57, 991 (1935).

found to be −73.5° and that of the pure boron trifluoride to be −126.75 ± 0.25°. A maximum was found at 50 mole per cent. of boron trifluoride, indicating a one to one addition compound between sulfur dioxide and boron trifluoride, whose freezing point was found to be −96.0 ± 0.25°. Eutectic points were found on each side of this maximum. One was found to exist at 38.0 mole per cent. boron trifluoride and at a temperature of −97.15 ± 0.25°, while the other eutectic point was found at 95.2 mole per cent. of boron trifluoride and −128.6 ± 0.25° (see Table IV and Fig. 7).

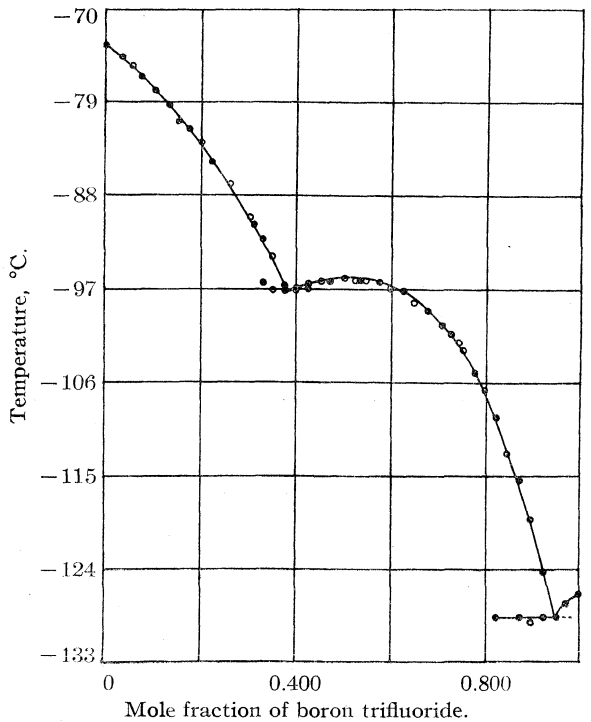

Fig. 7.—The system sulfur dioxide–boron trifluoride: O, first analysis; ●, second analysis.

From the flatness of the maximum obtained it is obvious that the compound is somewhat dissociated above the melting point.

Liquid sulfur dioxide has been found to be a solvent analogous to water and liquid ammonia. Extensive work has been done in this field since 1936 by Jander and his co-workers.[15] Liquid sulfur dioxide is a good solvent for organic and inorganic substances, the solutions being good electrical conductors, while sulfur dioxide itself is a poor conductor. The solutes have been found to be more or less dissociated. The results of their

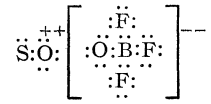
experiments have been explained on the assumption of the following types of dissociation of other solvents

$$2\,H_2O \rightleftharpoons H_3O^+ + OH^-$$
$$2\,NH_3 \rightleftharpoons NH_4^+ + NH_2^-$$
$$2\,SO_2 \rightleftharpoons SO^{++} + SO_3^{--}$$

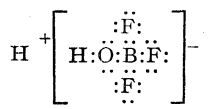
Wickert,[16] who also has been working with liquid sulfur dioxide, suggested that the dissociation of sulfur dioxide might also be written

$$SO_2 \rightleftharpoons SO^{++} + O^{--}$$

The structure of this compound with boron trifluoride might be



analogous to the monohydrate of boron trifluoride

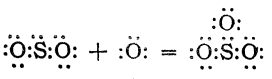


It is this dissociation which would have to take place in order to form the above addition compound with boron trifluoride. This addition compound would fit into the "sulfito" system of acids, bases and salts as developed by Jander.[15] The boron trifluoride addition compound would

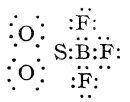
(16) Wickert, *Z. Elektrochem.*, **44**, 410 (1938).

be an acid in the sulfur dioxide system just as it is an acid in the water system.

Hägg[17] has explained the ease of oxidation of sulfur dioxide up to sulfur trioxide as being due to the electron pair on the sulfur. Thus



Thus, we could write the one to one addition compound with boron trifluoride



The fact that hydrogen sulfide formed the compound $H_2S \cdot BF_3$,[2] where only the sulfur can be the donor, would permit this latter mechanism.

Regardless of which structural formula represents sulfur dioxide, it is possible to account for the addition compound between the given structure and boron trifluoride.

(17) Hägg, *Z. physik. Chem.*, **B18**, 199 (1932).

Summary

In the present investigation it has been found that hydrogen chloride and methyl chloride give eutectics and no compounds with boron trifluoride, showing that, at least in these two compounds, chlorine does not act as a donor to boron trifluoride, thus refuting the existence of the reported compound $BF_3 \cdot 3HCl$.

It has been found further that nitrous oxide also will form no compound with boron trifluoride although it has been reported that nitric oxide does. Sulfur dioxide, just as the other parent solvents, water and ammonia, forms a one to one compound with boron trifluoride and two eutectics.

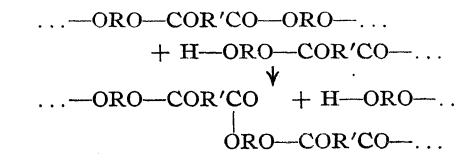
Random Reorganization of Molecular Weight Distribution in Linear Condensation Polymers[1]

BY PAUL J. FLORY

In a recent publication[2] concerned with the viscosities of molten polyesters, it was observed that the viscosity of a mixture of two polyesters decreases when heated. This decrease was attributed tentatively to a change in the distribution of molecular species in the mixture, brought about by the occurrence of ester interchange between terminal hydroxyl groups and ester groups of the polymer chains



where —ORO— and —COR'CO— represent, respectively, the glycol and the dibasic acid residues of a linear polyester formed through polycondensation of a glycol and a dibasic acid. As the result of such an interchange process, an x-mer may react with a y-mer to yield a $(y + z)$-mer and an $(x - z)$-mer. There is no net change in the number of molecules; hence, the number average molecular weight will be unaffected by reorganization processes of this sort. On the other hand, the distribution of species may be altered, and changes in distribution will produce corresponding changes in the weight average molecular weight. Since the viscosity of the molten polyester, composed of a mixture of polymeric species, depends directly on the weight average molecular weight,[2] the viscosity will be sensitive to changes in distribution caused by ester interchange, and these changes can be observed conveniently through viscosity measurements.

Investigations of rates of formation of polyesters and of their degradation[3] by monomeric alcohols have shown that the rate constant for alcoholysis, though somewhat smaller, is similar in magnitude to that for esterification under the same conditions. The two reactions are similarly affected by catalysts and temperature. After polyesterification has proceeded to the point where the average molecular weight is large, the free carboxyls are so overwhelmingly outnumbered by ester groups that the rate of reaction of the free hydroxyls with ester groups will exceed their rate

(1) A portion of this work has been discussed briefly by H. Mark and R. Raff, "High Polymeric Reactions," Interscience Publishers, Inc., New York, 1941, p. 147.

(2) P. J. Flory, THIS JOURNAL, **62**, 1057 (1940).

(3) P. J. Flory, *ibid.*, **62**, 2255, 2261 (1940).

of reaction with acid groups, despite the superiority of the esterification velocity constant. Thus, it is conceivable that ester interchange might exert a profound effect on the distribution of species obtained in the course of a polyesterification process.

It is the purpose of this paper to examine, both theoretically and experimentally, the consequences of interchange processes such as may occur in various linear condensation polymers. It will be shown that ester interchange, or any other analogous process in other polymers, provides a route to the most probable distribution of species. This happens to be the same distribution normally obtained by polycondensation without the occurrence of interchange.

Theoretical

The Equilibrium Distribution.—From a consideration of the kinetics of condensation polymerization, it has been shown that the molecular size distribution in linear condensation polymers containing equal numbers of the two co-reacting functional groups (*e. g.*, OH and COOH) is given by

$$N_x = Np^{x-1}(1-p) \qquad (1)^4$$

where N_x is the number of molecules composed of x monomer units, N is the total number of molecules and p is the extent of reaction, *i. e.*, the fraction of the functional groups which have condensed. Rate of reaction measurements[5] show the reactivity of a terminal functional group to be independent of the size of the molecule. Hence, the probability that any particular functional group has reacted is equal to the extent of reaction p. Equation (1) follows directly from statistical considerations.

In deriving (1) from this point of view it is assumed that once a given pair of functional groups condense, they remain forever united. If an interchange process such as ester interchange occurs, the ultimate distribution will be determined by the equilibria between the various polymer species, not by the rates of their initial formation through condensation. If the free energy of formation of a linkage between an x-mer and a y-mer is independent of x and y, then after equilibrium has been established through interchange, the probability that a particular functional group constitutes a part of an inter-unit linkage remains equal to the degree of conversion p, and the distribution (1) should obtain as before.[6]

The distribution (1) for the "equilibrated" linear polyester can be derived in a manner analogous to the derivation of the Maxwell–Boltzmann energy distribution law. We consider a polymer wherein interchange may occur freely, but in which the net degree of advancement of the inter-unit condensation process is fixed. Here

$$\sum_{x=1}^{\infty} N_x = N \qquad (2)$$

$$\sum_{x=1}^{\infty} xN_x = n_0 \qquad (3)$$

where n_0 is the total number of units and

$$N = n_0(1-p) \qquad (4)$$

Both n_0 and N are constant under the conditions. Equations (2) and (3) are analogous, respectively, to the conditions of conservation of matter and of energy in the Maxwell–Boltzmann derivation.[7] Here we define a micro state as one in which the size x of each molecule is specified. A macro state is defined merely by the numbers of molecules of the various sizes, *i. e.*, by N_1, N_2, N_3, etc. For a given macro state there are

$$W = N!/\Pi N_x! \qquad (5)$$

micro states. Solution of (5) for the maximum value of W consistent with (2) and (3) by the usual variational method yields (1) for the most probable macro state. Thus, under the assumption that the thermodynamic stability of a given inter-unit bond is independent of the size of the molecule and of its position along the chain, the equilibrium distribution ultimately attained by interchange processes is identical with that obtained by random synthesis. The difference in entropy between a mole of a heterogeneous polymer and a mole of the single species of molecular weight equal to the number average molecular weight for the heterogeneous polymer is given by the entropy of mixing expression

$$\Delta S_h = -R\Sigma(N_x/N)\ln(N_x/N) \qquad (6)$$

which may be called the molar entropy of hetero-

(4) P. J. Flory, THIS JOURNAL, **58**, 1877 (1936).

(5) P. J. Flory, *ibid.*, **61**, 3334 (1939).

(6) "Equilibration" of the distribution of species in a polyester containing a small amount of water, which impedes further increase in p, could take place through simultaneous hydrolysis and esterification as well as by ester interchange. In this connection, see G. V. Schulz, *Z. physik. Chem.*, **A182**, 127 (1938).

(7) F. T. Wall, THIS JOURNAL, **62**, 803 (1940), has applied this method to the derivation of the distribution of sequences of like units in random vinyl copolymers. In as much as no interchange subsequent to formation of the polymer chains may occur in this case, it is not immediately obvious that the "most probable" state will be obtained.

geneity. For the most probable distribution, substitution of (1) in (6) gives

$$\Delta S_h = R[\ln(p/1 - p) - (\ln p)/(1 - p)] \quad (7)$$

which also can be obtained directly from the Boltzmann relation $S = k \ln W$, where W is taken to be $W_{max.}$ in (5). For a high molecular weight polymer p is near unity and

$$\Delta S_h \leqq R[1 - \ln (1 - p)] \quad (7.1)$$

or

$$\Delta S_h \leqq R[1 + \ln (\overline{DP}_n)] \quad (7.2)$$

since the number average degree of polymerization is given by

$$\overline{DP}_n = 1/(1 - p) \quad (8)$$

For the entropy of heterogeneity per mole of *structural units*, we have

$$\Delta S_h' = \Delta S_h/\overline{DP}_n \quad (9)$$

These equations express the maximum entropy of heterogeneity, or entropy of mixing, for a given degree of polymerization. Any distribution other than (1) will yield a lower entropy of heterogeneity. The entropy per mole of *polymer* molecules ΔS_h increases without limit as p approaches unity and $\overline{DP}_n$ approaches infinity; the entropy per mole of *structural units* $\Delta S_h'$, after reaching a maximum at a very low degree of polymerization, decreases asymptotically toward zero as $\overline{DP}_n$ increases.

Reorganization in Mixtures.—Since direct synthesis by polycondensation gives at once an equilibrium distribution, in order to observe the effects of interchange it is first of all necessary to obtain some other distribution. A product of greater homogeneity could be obtained by fractional precipitation. When subjected to interchange conditions, its distribution should broaden into the most probable one. An alternative method has been used here. Mixtures of greater heterogeneity have been obtained by mixing two normal products of synthesis, one of low and the other of high average molecular weight. The ensuing homogenization toward the most probable distribution was followed by means of viscosity measurements on the molten mixture.

The viscosity of the melt depends on the weight average chain length $\overline{Z}_w$ according to the relationship[2]

$$\log \eta = A + C\,\overline{Z}_w^{1/2} \quad (10)$$

where A and C are constants, and the weight average chain length is defined by

$$\overline{Z}_w = \Sigma w_x Z_x \quad (11)$$

where w_x is the weight fraction of x-mer. Whereas the number average chain length

$$\overline{Z}_n = \Sigma(N_x/N)Z_x \quad (12)$$

is unaffected by interchange, a transformation in the distribution will produce changes in the weight average chain length $\overline{Z}_w$, which may be calculated from viscosities using (10).

The decamethylene adipate polyesters which have been used are of two types. In the one case, the polymers possessed carboxyl and hydroxyl groups in equivalent quantities; in the other, an excess of glycol was used and the reaction was carried to completion, yielding a product having hydroxyl end-groups exclusively. For polymers of the former type

$$w_x = xp^{x-1}(1 - p)^2 \quad (13)$$

which can be derived from (1),[2,4] and

$$\overline{Z}_n = z/(1 - p) \quad (14)$$

$$\overline{Z}_w = z(1 + p)/(1 - p) \quad (15)[4]$$

$$= 2\,\overline{Z}n - z \quad (16)[2]$$

where z is the mean number of chain atoms per unit. ($z = 9$ for polydecamethylene adipate.) For the mixture composed of weight fractions f_1 and f_2 of polymers characterized by p_1 and p_2, respectively, the averages for the initial mixture are

$$\overline{Z}_n' = \overline{Z}_{n,1}\,\overline{Z}_{n,2}/(f_1\overline{Z}_{n,2} + f_2\overline{Z}_{n,1}) \quad (17)$$

$$= z/(1 - p') \quad (17.1)$$

where $p' = f_1p_1 + f_2p_2$

$$\overline{Z}_w' = f_1\overline{Z}_{w,1} + f_2\overline{Z}_{w,2} \quad (18)$$

After equilibration through ester interchange (in the absence of either further esterification or of hydrolysis) $\overline{Z}_n'$ remains unchanged, but $\overline{Z}_w'$ becomes

$$\overline{Z}_w'' = z(1 + p')/(1 - p') = 2\overline{Z}_n' - z \quad (19)$$

Under the conditions of the experiments reported below, esterification occurs simultaneously with ester interchange, though at a slower rate. Consequently, p' increases slowly during the experiments. Nevertheless, the weight average chain length ultimately should reach a value given by (19), wherein p' is time dependent.

For polyesters prepared from r moles of dibasic acid per mole of glycol, the reaction being carried to completion[3,4]

$$w_x = [(zx + \alpha)r^{(x-1)/2}(1 - r)^2]/[z(1 + r) + \alpha(1 - r)] \quad (20)$$

and

$$\overline{Z}_n = z(1 + r)/(1 - r) + \alpha \quad (21)$$

where α is an "end-group correction" which may be taken equal to three in the present instance.[3]

From statistical considerations analogous to those used in the derivation of (1) and (15)[2,3]

$$\bar{Z}_w = 2z(1 + r)/(1 - r) = 2(\bar{Z}_n - \alpha) \qquad (22)$$

For the mixture of two such polymers, $\bar{Z}_n'$ is given by (17). In this case further esterification is not possible, and equilibration of the mixture through ester interchange yields

$$\bar{Z}_w'' = 2(\bar{Z}_n' - 3) \qquad (23)$$

Experimental Results

The methods used for the preparation of the polyesters and for the measurement of their viscosities in the molten state have been described previously.[2,3] Polymers A and B were prepared by heating excess quantities of decamethylene glycol with adipic acid at 109° in the presence of about 0.1% by weight of *p*-toluenesulfonic acid until the viscosity showed no further change, indicating complete esterification of the adipic acid. In the preparation of Polymer A the mixture was heated sixty hours; for Polymer B twenty-five hours was sufficient for substantially complete esterification.

Data pertaining to these polymers are given in the second and third columns of Table I. The reactants were of high purity,[2] and the quantities used were carefully weighed. At the low temperature of reaction the amounts of glycol removed with effluent water vapor formed in the esterification were negligible. For these reasons the values of r given in the first row of Table I are believed to be accurately representative of the final products. The number average chain lengths given in the second row have been calculated directly from r. Computation of the weight average chain lengths from r (third row of Table I) involves acceptance of the size distribution relationship (20). The constants which have been used in equation (10), *i. e.*

$$\log \eta = -1.435 + 0.1144\, \bar{Z}_w^{1/2} \qquad (10')$$

for the calculation of the viscosities given in the fourth row of the table have been established at 109° for decamethylene adipate polymers having hydroxyl and carboxyl end-groups in equal numbers.[2] The discrepancies between observed and calculated viscosities for the two polymers are doubtless due to minor dependence of the viscosity relationship on the end-groups.[8]

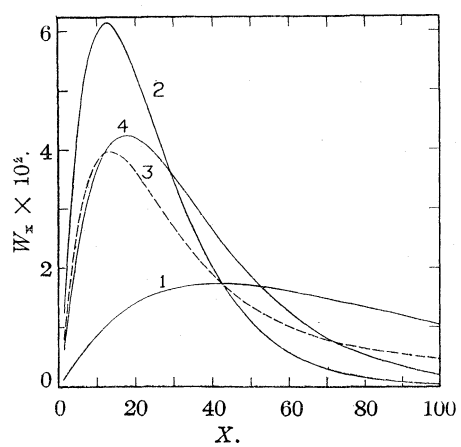


Fig. 1.—Size distribution (weight fraction *vs.* number of units) for the initial polymers A and B (curves 1 and 2, respectively), for the mixture composed of 42.4% of A and 57.6% of B (curve 3), and for the calculated equilibrium distribution for the mixture (curve 4).

[a] The mixture composed of 42.4 weight per cent. of Polymer A and 57.6% of Polymer B. [b] Calculated for the initial mixture prior to interchange using (18).

The distributions of species calculated from (20) for Polymers A and B are shown by curves 1 and 2 in Fig. 1. A mixture consisting of 42.4% by weight of A and 57.6% of Polymer B was employed in the interchange experiment. The distribution curve for the initial mixture, computed by multiplying ordinate values of curve 1 by 0.424 and those of curve 2 by 0.576 and taking the sum, is represented by the broken curve 3. Computed initial values of r, $\bar{Z}_n'$, $\bar{Z}_w'$ and η are given in Table I. Inasmuch as there is no possibility for an increase in the number of inter-unit bonds in the mixture, $\bar{Z}_n'$ must remain fixed during interchange. According to the theory presented above, the distribution of species should be transformed by interchange to the most probable distribution (20), r having the value given in Table I. This distribution is shown by curve 4 in Fig. 1.

(8) See pp. 2256, 2259 of ref. 3.

The weight average chain length for the final distribution 4 is considerably less than that for the initial distribution 3; the calculated viscosities differ correspondingly (see Table I).

The experimental results of this interchange experiment carried out at 109° are given in Table II. As has been observed previously in experiments on polyester mixtures, from fifteen to thirty minutes is required before complete mixing has occurred.[2] Interchange in the present instance is quite rapid due to the presence of an acid catalyst.[3] Hence, a valid extrapolation to the initial viscosity of the mixture prior to interchange is not possible from these data. The final viscosity is somewhat lower than that calculated from (10′) for the most probable distribution (see Table I), but the discrepancy is of the order of that to be expected to result from the inaccuracy of (10′) as applied to hydroxyl terminated polymers.[8]

TABLE II

Time, minutes	Viscosity, poises at 109°
29	6.85
62	5.80
103	5.06
156	4.72
200	4.52

345	4.33
420	4.27
535	4.17
840	4.15

Other interchange experiments have been carried out on decamethylene adipate polyesters having equivalent quantities of hydroxyl and carboxyl end-groups. These were prepared by heating equimolar quantities of the pure glycol and dibasic acid, in the absence of catalyst, until the desired degree of polymerization was reached. Glycol carried out of the reaction mixture with the slow stream of dry nitrogen, used to remove water, was carefully replaced in order to assure sufficiently precise balance between the two end-groups. Polymer C, prepared by heating the reactants at 202° for twenty-nine hours, had a viscosity at 109° of 164 poises. According to (10′) and (16), $\overline{Z}_w = 1017$ and $\overline{Z}_n = 513$. For Polymer D, prepared by heating for two hours at 166°, $\eta_{109°} = 0.532$ poise; accordingly, $\overline{Z}_w = 103.0$ and $\overline{Z}_n = 56.0$. Neutral equivalents of the polymers were in close agreement with those calculated from these values of $\overline{Z}_n$, indicating satisfactory equivalence of the end-groups.

Table III presents a portion of the data for the interchange experiment performed on a mixture consisting of 40% of Polymer C with 60% of Polymer D. The mixture was heated at 109° in a dry nitrogen atmosphere.[9] The weight average chain lengths given in the third column have been computed, using equation (10′), from the measured viscosities given in the second column. Interchange is much slower than in the preceding experiment, due to the absence of an acid catalyst other than is furnished by the unreacted carboxyl end-groups. During the course of the experiment some inter-esterification continued to take place, as is shown by the neutral equivalents given in the fourth column. These were determined by titration of samples removed from the mixture. Values of $\overline{Z}_n$ calculated directly from the neutral equivalents, or number average molecular weights, are given in the fifth column. If interchange equilibrium were fully established, the weight average chain length should equal $2\,\overline{Z}_n' - 9$, according to the theory given above. These "equilibrium" values are presented in the sixth column. The corresponding viscosities calculated using (10′) are given in the last column. The above theory requires that eventually the weight average chain lengths given in the third and sixth columns should coincide; or, the viscosities in the second and last columns should become identical.

The data from this experiment are shown in full

(9) The experiments on mixtures of Polymers C and D are continuations of two of those reported previously[2] in connection with determinations of viscosities of polyester mixtures prior to interchange. It may be noted that the chain lengths of Polymers C and D differ slightly from those employed previously (Ref. 2, Table II, Series II). This discrepancy, which is of no real significance in either investigation, is due to inadvertent use, in the earlier tabulation, of constants in (10) which differ slightly from those used here.

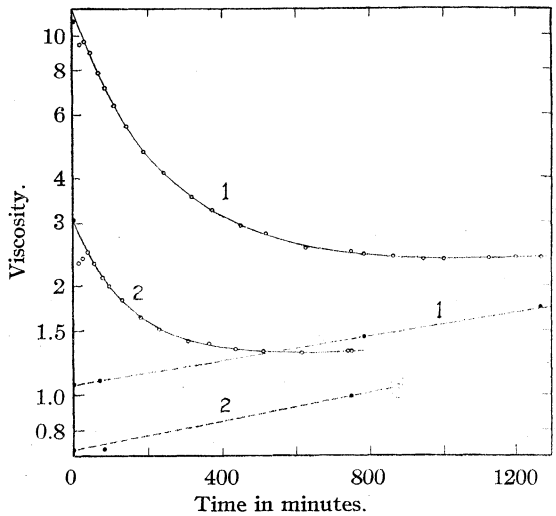

Fig. 2.—Experimental results for mixtures of Polymers C and D.

in Fig. 2. The solid curve 1 represents the observed viscosities (second column of Table III), plotted on a log scale merely for convenience. The dashed curve represents the viscosities (last column of Table III) calculated for interchange equilibrium for the observed neutral equivalent. Similar results obtained at 109° using a mixture composed of 19.7% of Polymer C and 80.3% of Polymer D are represented by the solid and dashed curves 2 in Fig. 2. In each experiment the observed viscosity decreases to a minimum and then increases. During this latter stage the effect on the viscosity of the rate of change in distribution due to interchange is outweighed by the rate of interesterification. When interchange equilibrium has been established, the solid and dashed curves should coincide according to the theory presented herein. To the extent that they are asymptotic, this theory is confirmed.

Discussion

The similarity in rates of ester interchange and esterification assures simultaneous occurrence of interchange during the synthesis of a polyester by interesterification. The distributions of species in normal products of synthesis, such as those from which the mixtures were prepared, are determined to a large extent by interchange equilibria. It could be contended, therefore, that if it is permissible to assume, as has been done above, that the distributions in the initial polymers A, B, C and D are correctly represented by (1) and (13), or (20), these equations necessarily will apply to their mixtures after equilibration through interchange. The above experimental results cannot be regarded as *explicit* experimental proof of adherence to (1), (13) and (20). They demonstrate convincingly, however, that the ultimate transformations of the size distributions in the mixtures are consistent with these equations. To this extent, these results confirm implicitly the correctness of the statistically calculated distributions. Previously they have received indirect substantiation from their applicability to the analysis of viscosities of polymer mixtures,[2] and to the degradation of polyesters by alcohols.[3]

The question may arise as to how one might synthesize a linear polyester having some other distribution. The conversion of cyclic esters to linear polyesters, investigated extensively by Carothers and co-workers,[10,11] is of particular interest in this connection. They have shown[10] that the conversion of the cyclic monomer to linear polymer is conditioned by the presence of small amounts of substances capable of providing functional groups to which the monomers may add successively. For example, in the case of a cyclic ester such as δ-valerolactone, a trace of water may yield the hydroxy acid, with which the lactone may then react as follows

$$\text{HORCOOH} \xrightarrow{+\ \overline{\text{ORCO}}} \text{HORCOORCOOH} \xrightarrow[\text{etc.}]{+\ \overline{\text{ORCO}}} \qquad (24)$$

The addition of the lactone to the linear molecule of increasing length is an ester interchange,[12] which may be very rapid or negligibly slow, depending on the stability of the cyclic monomer, which in turn depends on the size of the ring.[10,11] Bezzi and co-workers[13] have found that lactide is similarly converted to a linear polymer of lactic acid and at a rate which depends directly on the amount (very small) of water added. On the basis of this observation they have discarded the Carothers mechanism (24) in favor of a process consisting of hydrolysis of the lactide followed by polymerization by interesterification. Actually their results do not contradict the much more plausible mechanism (24). Addition of water merely in-

(11) See also, W. H. Carothers, J. A. Arvin and G. L. Dorough, *ibid.*, **52**, 3292 (1930); W. H. Carothers, *Chem. Rev.*, **8**, 353 (1931); J. W. Hill and W. H. Carothers, THIS JOURNAL, **55**, 5031 (1933); F. J. van Natta, J. W. Hill and W. H. Carothers, *ibid.*, **56**, 455 (1934).

(12) Since esters generally interchange with alcohols much more readily than with acids, it is presumed that addition of lactone in (24) occurs predominantly at the hydroxyl end of the chain.

(13) S. Bezzi, L. Ricoboni and C. Sullam, *Mem. accad. Italia, Classe sci. fis., mat. nat.*, **8**, 127 (1937); S. Bezzi and B. Angeli, *Gazz. chim. ital.*, **68**, 215 (1938).

creases the concentration of functional groups to which monomers may add, thereby increasing the over-all rate of conversion of monomer to polymer.

Successive addition of cyclic ester monomers to a fixed number of molecules bearing a suitable functional group (*e. g.*, OH) as in (24) is strictly analogous to the polymerization of ethylene oxide,[14] for which the distribution of species is represented by Poisson's distribution function[15]

$$N_x = Ne^{-\nu}\nu^x - 1/(x-1)! \qquad (25)$$

where

$$\nu = \overline{DP}_n - 1$$

The entropy of heterogeneity for this distribution, obtained by substituting equation (25) in (6) (see Appendix), is given to a close approximation when the degree of polymerization is large by

$$\Delta S_h = \frac{R}{2}[1 + \ln(2\pi\overline{DP}_n)] \qquad (26)$$

The distribution (25) covers a much narrower range than the equilibrium distribution. Correspondingly, its entropy of heterogeneity is less than for the equilibrium distribution as given by equation (7.2). Therefore, if interchange between polymer molecules occurs, the distribution (25) will be broadened toward the equilibrium distribution (1).

The actual distribution of species which will be obtained from the conversion of a cyclic monomer to linear polymer will depend on the extent to which polymer–polymer interchange accompanies the primary addition process (24). If the latter process, an ester interchange between a terminal functional group and a cyclic monomer, is much more rapid than interchange with ester groups of the polymer molecules, the comparatively sharp Poisson distribution (25) will be obtained. In the opposite situation, the more heterogeneous equilibrium distribution (1) should be found. In intermediate cases, distributions of intermediate heterogeneity will be produced.

Other condensation polymers, *e. g.*, the polyamides and polyanhydrides investigated by Carothers and co-workers,[11] are subject to analogous interchange processes. These doubtless can be treated in complete analogy with the polyesters. The concept of a most probable distribution is equally applicable to three-dimensional condensation polymers, although the situation here becomes much more complex. The most probable distributions for equal stability of all possible interunit linkages have been treated by statistical methods in previous publications[16] on three-dimensional polymers.

Appendix

Entropy of Heterogeneity for a Poisson Distribution of Species.—Substituting equation (25) in (6)

$$\Delta S_h = Re^{-\nu} \sum_{x=1}^{\infty} \left\{ \frac{\nu^{x-1}}{(x-1)!} [\nu - (x-1)\ln\nu + \ln(x-1)!] \right\}$$

Shifting the lower limit on the summation to $x = 0$ and replacing x by $x + 1$, and introducing Stirling's approximation for $\ln x!$

$$\Delta S_h = R\left[e^{-\nu} \sum_{x=0}^{\infty} \frac{\nu^x}{x!}\left(\nu - x + \frac{1}{2}\ln 2\pi\right) + e^{-\nu} \sum_{x=0}^{\infty} \frac{\nu^x}{x!} x \ln(x/\nu) + \frac{e^{-\nu}}{2} \sum_{x=0}^{\infty} \frac{\nu^x}{x!} \ln x \right] \qquad (27)$$

Since $\sum_{x=0}^{\infty} \frac{\nu^x}{x!} = e^{\nu}$, the first summation reduces readily to $\frac{R}{2}\ln(2\pi)$. The second and third terms may be evaluated by approximate methods valid when ν is large. Nearly all of the contributions to these sums come in the vicinity of $x = \nu$. Hence, in the case of the second term, we expand $\ln(x/\nu)$ about $(x/\nu) = 1$, giving

$$e^{-\nu} \sum_{x=0}^{\infty} \left\{ \frac{\nu^x}{x!} x \left[\left(\frac{x}{\nu} - 1\right) - \frac{1}{2}\left(\frac{x}{\nu} - 1\right)^2 + \frac{1}{3}\left(\frac{x}{\nu} - 1\right)^3 - \cdots \right] \right\}$$

Summation over five terms of the series yields

$$1 - \frac{1}{2}(1 + 1/\nu) + \frac{1}{3}(4/\nu + 1/\nu^2) - \frac{1}{4}(3/\nu + 11/\nu^2 + 1/\nu^3) + \frac{1}{5}(25/\nu^2 + 26/\nu^3 + 1/\nu^4)$$

To a very close approximation when ν is large, the second term is given therefore by

$$^1/_2(1 + {}^1/_{6\nu}) \cong {}^1/_2$$

The third term may be written

$$\frac{e^{-\nu}}{2} \sum_{x=0}^{\infty} \frac{\nu^x}{x!}[\ln(x/\nu) + \ln\nu]$$

Expanding $\ln(x/\nu)$ in series as above and summing each term, we obtain a power series in $1/\nu$ the first term of which is $-1/2\nu$. Hence, the contribution of the third term is

$$1/2[\ln\nu - 1/2\,\nu + \ldots]$$

(16) P. J. Flory, *ibid.*, **63**, 3083, 3091, 3096 (1941).

Combining the above values for the three terms in (27)

$$\Delta S_h = \frac{R}{2}[\ln(2\pi\nu) + 1 - 1/3\nu - \ldots] \quad (28)$$

Equation (28) reduces to (26) when ν is replaced by $\overline{DP}_n$ and series terms of the order of $1/\nu$ or smaller are neglected.

Summary

The individual molecules of a linear polyester have only a temporary existence when heated to a suitable temperature, due to the occurrence of ester interchange between an ester group of one polymer molecule and the terminal functional group of another. While such processes have no effect on the number average degree of polymerization, they may modify the distribution of species. Such considerations lead to the concept of an entropy of heterogeneity and of an equilibrium size distribution; the latter is identical with that obtained directly by random poly-condensation.

The transformation in the distribution of species in a mixture of polyesters has been observed by viscosity measurements. The results confirm the theoretical predictions.

The conversion of a cyclic ester (lactone) to a linear polyester should yield a much narrower distribution of species than is obtained by poly-condensation, but if ester interchange occurs between the polymer molecules subsequent to their initial formation, the distribution will be broadened.

Dipole Moments in the Vapor State and Resonance Effects in Some Substituted Benzenes

BY EVERETT C. HURDIS AND CHARLES P. SMYTH

The influence of resonance upon the dipole moment of a molecule containing a single polar group has been observed in both aromatic and unsaturated aliphatic molecules and the mutual effects of two polar groups in an aromatic molecule have been noted in a few cases, such as that of *p*-nitroaniline. In the case of two identical groups para to one another on the benzene ring, these mutual effects upon the dipole moments cancel each other and cannot, therefore, be detected, while in the ortho position, the mutual inductive effects of the two groups tend to obscure any effect of the resonance of one upon that of the other. It was hoped that, in spite of the smallness of the differences between the different carbon–halogen moments, accurate determinations in the vapor state of the moments of para-dihalogenated benzenes containing two different halogens might give quantitative evidence of the differences in resonance effects of the halogens. Unfortunately, the possibility of the presence of small quantities of the ortho-disubstituted benzenes as impurities in the samples of the para-compounds, which were too small for extensive purification, reduces the presumed accuracy of the results obtained for these compounds. Measurements upon iodobenzene and confirmation of moment values already in the literature for chloro- and bromobenzene were carried out to check the precision of the measurements and facilitate the interpretation of the results for the dihalogenated benzenes. Measurements were also made upon very pure samples of *o*-xylene and *p*-xylene with the object of observing possible small mutual induction or resonance effects of two adjacent methyl groups and of checking the group moment value to be assigned to a methyl group attached to a benzene ring.

Purification of Materials

Chlorobenzene.—Material from the Eastman Kodak Company was dried over calcium chloride and fractionally distilled; b. p. 130.5° (755 mm.).

Bromobenzene.—Material from the Eastman Kodak Company was dried over calcium chloride and fractionally distilled; b. p. 154.7° (753 mm.).

Iodobenzene, Sample I.—Material from the Paragon Testing Laboratories was fractionally distilled in a column of fourteen theoretical plates; b. p. 188.3° (762 mm.).

Iodobenzene, Sample II.—Iodobenzene was prepared by the method of "Organic Syntheses," Collective Volume I, p. 316, an all glass system being used. Fractionation gave 234 g. of material boiling between 188.2 and 188.5° (760 mm.). This was further distilled under low pressure, the main fraction (b. p. 98° at 37 mm.) being used for the measurements. The freezing point of this sample was measured by means of a platinum resistance thermometer

and found to be −31.8° ("International Critical Tables" gives −31.4°).

p-**Fluorobromobenzene.**—About twelve grams of material from the Eastman Kodak Company (n^{20}D 1.5279, $n^{21.8}$D, 1.5270) was sealed into a trap connected with the gas apparatus. For measurement, a simple fractionation was made by distilling the first 3 g. under vacuum into another trap, and the middle 6 g. into the U-tube from which vapor was introduced into the gas cell.

p-**Fluoroiodobenzene.**—Ten grams of material from the Eastman Kodak Company ($n^{21.8}$D 1.5794) was purified by vacuum distillation in the gas apparatus directly before each measurement, as in the case of the *p*-fluorobromo compound.

p-**Fluoronitrobenzene.**—Material from the Eastman Kodak Company ($n^{23.6}$D 1.5304, n^{25}D 1.5294) was purified by vacuum distillation by the method used for the two dihalogenated benzenes.

o-**Dichlorobenzene.**—A special 99.4% grade of material kindly given us by the Heyden Chemical Corporation was used without further purification; b. p. 180.3° (750 mm.); m. p. −17.1°; n^{25}D 1.5486; n^{20}D 1.5513. "International Critical Tables" gives normal boiling point 179°, melting point −17.6°, n^{20}D 1.549.

o- **and** *p*-**Xylene.**—The hydrocarbons used in this work were supplied as a part of the American Petroleum Institute Pure Hydrocarbon Program. They were prepared and purified at the Pure Hydrocarbon Laboratory, Department of Chemistry, operating as project No. 31 of the Ohio State University Research Foundation. A full description of these products will be published at a later date.

Experimental Results

The dielectric constants of the vapors were measured with the apparatus and, essentially, the same technique that has been previously described.[1] A polarization value, P, was obtained at an absolute temperature, T, by measurements over a wide range of pressure. The value of P given by each such run is shown in Table I, as is also the corresponding value of the dipole moment μ calculated as $\mu = 1.281 \times 10^{-20}[(P - MR_D)T]^{1/2}$. For the dihalogenated benzenes, many of the values represent the averages of two or more runs. The molar refraction for the sodium D line, MR_D, is listed for each compound in Table II together with the average of the moment values in Table I. The moment of fluorobenzene, which is included in Table II for purposes of comparison, has been recalculated from previous measurements,[2] by the use of MR_D instead of the total induced polarization given by temperature dependence without consequent alteration in value. The few measurements on chloro- and bromobenzene were run primarily as a check upon the absolute accuracy of the determinations. The polarization values for chlorobenzene, 72.2 and 72.3 at 436.1°K., are in excellent agreement with

[a] Calculated from data in "International Critical Tables." [b] Landolt–Börnstein (5th ed.). [c] Measured in this Laboratory. [d] Calculated from data furnished by Professor C. E. Boord. [e] Calculated from refractions in Landolt–Börnstein (5th ed.).

the value 72.5 obtained from the data of McAlpine and Smyth[2] by interpolation at this temperature and the values for bromobenzene, 75.8 and 75.7 at 455.8°K. are indistinguishable from the value 75.8 obtained from the data of Groves and Sugden[3] by interpolation. The moment values calculated from these polarizations are slightly higher, 0.02 for chlorobenzene and 0.06 for bromobenzene, than the values obtained in the earlier work by the use of total induced polarization instead of molar refraction. This neglect of the small atomic polarization which may cause the total induced polarization to be slightly higher than MR_D, is evidently unimportant in the case of the monohalogenated benzenes, but is serious in that of the *p*-dihalogenated benzenes. In view of the symmetry of the *p*-xylene molecule, its moment may safely be assumed to be zero. Its polarization was measured only in order to obtain a total induced polarization value, which, as a fair approximation, could be taken equal to that of *o*-xylene and thus used, instead of the MR_D value, to calculate the dependable value for the latter compound in Table II. The difference of 0.2 in the MR_D values for the two compounds indicates that the total polarization of *p*-xylene may differ by a few tenths of a unit from the induced polarization of *o*-xylene. Decomposition of the iodobenzene limits the range of temperature over which the measurements may be made and, probably, causes the unusually large variation in the moment value for it in Table I. The two samples of satisfactory purity give mean moment values differing by 0.07 from each other. The average of these two in Table II is from 0.10 to 0.15 higher than the value to be expected for the vapor on the basis of the values obtained from solution measurements.[4,5] In view of this, the value 1.70 may be high, but it is, probably, less than 0.1 high.

(3) Groves and Sugden, *J. Chem. Soc.*, 971 (1935).

Discussion of Results

It happens that the chloro-, bromo- and iodobenzene moment values in Table II have almost the same differences from one another as the corresponding butyl halides.[6] The fluorobenzene moment is lower than that of chlorobenzene, as the alkyl fluoride moment is lower than that of the alkyl chloride.[7] The slight increases in the values of the bromobenzene and iodobenzene moments lessen the calculated reduction in moment by contributions from structures with double-bonded positive halogens and, hence, show the amounts of double bond character in the C–Cl, C–Br, and C–I bonds to be more nearly equal than previously supposed.[6]

The moment value of *p*-fluorobromobenzene in Table II is 0.3 higher than the difference between the moments of fluoro- and bromobenzene, to which it should be equal in the absence of complicating factors. The presence of a small amount of *o*-fluorobromobenzene as an impurity together with a larger atomic polarization than is assumed in the use of MR_D as the total induced polarization could account for this discrepancy, which is, however, a little large to arise from these causes. The moment value for *p*-fluoroiodobenzene is 0.8 higher than the small difference 0.1 between the moments of fluorobenzene and iodobenzene. It would require about 10% of *o*-fluoroiodobenzene present as an impurity to account for this discrepancy, or, at least, 5% of the ortho compound plus an abnormally high atomic polarization

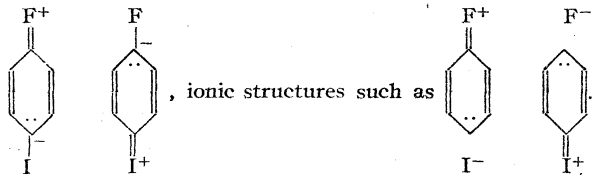
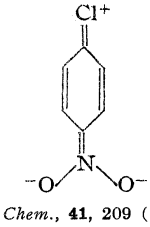
value, both of which possibilities are somewhat remote. The larger moment of the *p*-fluoroiodobenzene seems to correspond to the fact that the electronegativity difference between fluorine and iodine is greater than that between fluorine and bromine, the difference between the two moments coinciding with the I-Br bond moment, 0.4.[8] The moments of the two compounds could be accounted for by writing for their molecules, in addition to their normal covalent structures and their quinoid structures of the type



The much greater electronegativity of the fluorine would make the ionic structure with negative fluorine predominate over that with negative iodine or bromine, giving a moment opposite in direction to that to be expected from the small differences between the moments of the monosubstituted benzenes. These combinations of structures should lead to small moments of the order of magnitude of those observed and differing in value according to the electronegativity differences as observed.

In order to obtain a moment value for nitrobenzene directly comparable with the values in Table II, the previous data[2] were recalculated with MR_D instead of the total induced polarization. The difference between the moment value, 4.25, thus obtained and the moment of fluorobenzene in Table II gives a value 2.68 for *p*-fluoronitrobenzene, 0.19 lower than the observed value in Table II. Although part of this difference could arise from the presence of *o*-fluoronitrobenzene as an impurity in the para compound, it has been previously pointed out[9] that the moment of *p*-chloronitrobenzene, 2.78, measured[10] for the vapor of a carefully purified sample is high, probably because of contributions from highly polar structures such as



The elevation, 0.25, of the moment above the calculated value, 2.53, is slightly larger than that in the case of *p*-fluoronitrobenzene, 0.19, which, because of possible impurity, represents an upper limit for the elevation. It appears that, in the case of these two compounds, the presence of the nitro group effects a greater increase in the amount of double bond character in the C–Cl than in the C–F bond.

The polarization of the *p*-xylene vapor in Table I is 0.6 higher than the value 37.07 found for the same sample in the liquid state at 293.1°K. by Dr. P. F. Oesper, a difference of the magnitude and direction normally found between liquid and vapor values. The absence of error due to impurity and to neglect of atomic polarization should make the moment value of *o*-xylene in Table II extremely accurate. It differs by only 0.01 from the value previously used for the moment of two *o*-methyl groups[9] and the natural assumption of an angle of 60° between the two group moments leads to a calculated value 0.36 for the group moment of methyl on a benzene ring in excellent agreement with the moment of toluene, 0.35,[11] on which the above-mentioned value for the two *o*-methyl groups was based. The excellence of this agreement shows, in harmony with previous conclusions, that any mutual inductive or resonance effects between the two ortho-methyl groups are too small to detect by means of dipole moments. It may be mentioned that the use of MR_D instead of the *p*-xylene polarization in calculating the *o*-xylene moment would give a value 0.73 instead of 0.62 and 0.42, instead of 0.36, for the methyl–benzene group moment. Similar use of MR_D instead of the total induced polarization for toluene would give a moment value 0.45 instead of 0.35. This does not mean, however, that the group moment value 0.42 or 0.45 should be used for consistency in calculating the moments of more polar molecules, for which MR_D values have been used in obtaining the moment from the experimental data, since large moment values are little affected by neglect of atomic polarization. The value 0.36 is, therefore, to be regarded as correct for the group moment produced by the attachment of a methyl group to a benzene ring.

The moment of *o*-dichlorobenzene was measured because of the fact that the value, 2.16, obtained by Groves and Sugden[10] from vapor meas-

(8) Smyth, *J. Phys. Chem.*, **41**, 209 (1937).

urements was 0.1 lower than the value found by several investigators from measurements in solution, although the solvent effect, which, in the case of chlorobenzene, lowers the solution value to such an extent that the gas value is 10% higher than that measured in solution, should lead to a similarly lower value for *o*-dichlorobenzene.[9] Since addition of 10% to the solution value, 2.27, for *o*-dichlorobenzene gives a value, 2.50, practically identical with the newly determined gas value, 2.51, in Table II, it is evident that there is no anomaly in the solvent effect for this compound.

The writers wish to express their thanks to Professor C. E. Boord of Ohio State University and Dr. George Calingaert of the Ethyl Gasoline Corporation for the xylenes and to Dr. P. D. Hammond of the Heyden Chemical Corporation for the *o*-dichlorobenzene used in this investigation.

Summary

The dielectric constants of the vapors of chloro-, bromo-, iodo-, *p*-fluorobromo-, *p*-fluoroiodo-, *p*-fluoronitro- and *o*-dichlorobenzene, and of *p*- and *o*-xylene have been measured and used to calculate the dipole moments of the molecules. The moment values found for chlorobenzene and bromobenzene agree closely with those in the literature, while that for iodobenzene is slightly higher than would be expected on the basis of previous measurements in solution. The moment value of *o*-dichlorobenzene is much higher than the one in the literature and in excellent agreement with that obtained by correcting the solution value for solvent effect. The data for the two xylenes give an accurate value, 0.36, for the group moment produced by the attachment of a methyl group to a benzene ring. The moments found for the *p*-disubstituted benzenes are larger than the differences between the corresponding mono-substituted compounds by amounts which may be accounted for by resonance.

Condensation Products of Ketene with Ketones[1]

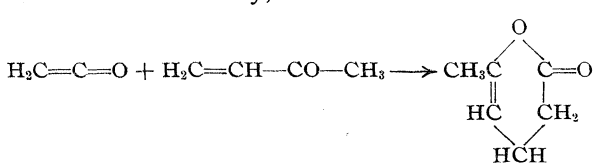
BY B. H. GWYNN WITH ED. F. DEGERING

The reactions of ketene have been studied rather extensively. It has been found to act as the anhydride of acetic acid. Although it is commonly prepared from acetone and therefore contaminated with it to some extent, no one appears to have noted a reaction between the two. Investigations have been reported in which the reactivity of ketene with ketones was studied without a catalyst[2] and in the presence of anhydrous sodium or potassium acetate.[3] No reaction was noted. Acetone has been used as a solvent in the acid catalyzed acetylation of carbohydrates[4] with ketene. A reaction undoubtedly took place in these cases but escaped notice. Similarly, in the acid catalyzed acetylation of butyl alcohol,[5] the ketene was contaminated with acetone, and the two probably reacted to a limited extent.

This investigation has shown that ketene does react with ketones. In the presence of a small amount of sulfuric acid the product is the acetate of the enol form of the ketone, as indicated by the equation

$$H_2C{:}C{:}O + H{\cdot}O{\cdot}C(CH_3){:}CH_2 \left(\rightleftarrows CH_3{\cdot}CO{\cdot}CH_3/H_2SO_4\right) \longrightarrow CH_3{\cdot}CO{\cdot}O{\cdot}C(CH_3){:}CH_2$$

Since the completion of this work, ketene has been reported to react with vinyl ketones to yield cyclic esters of the enol form of *delta* keto acids,[6] an entirely different type of reaction from that observed in this study, as indicated



Experimental Part

Apparatus.—Ketene was generated in a lamp which was constructed in the same manner as one described by Hurd.[7] In order to separate acetone from the ketene, the

pyrolysis gases were passed through two water-cooled spiral condensers, then through two cold traps. The first of these cold traps was kept at 0°, the second at −35 to −40°. The resultant gas was practically acetone-free and was passed into the material with which it was desired to have it react. The inlet tube was placed in such a manner as to direct the entering gas into a rapidly revolving stirrer. The temperature of the reaction tube was maintained at the desired point by means of an oil-bath. An expansion chamber surrounded by an ice-bath was placed so as to return volatile liquids to the reactor. The output of the generator, determined by absorption in caustic,[7] was approximately 0.25 mole (hr). All fractionations were made with a modified Podbielniak column.

Materials Used.—The ketones used in this work were either purchased or prepared by standard methods. In either case they were distilled or fractionated before use except for the acetone, which was Mallinckrodt analytical reagent grade, and the acetophenone, which was Eastman Kodak Company white label grade. The 2,4-dinitrophenylhydrazones were prepared from each of the ketones except 2,6-dimethyl-4-heptanone and 2,4-dimethyl-3-pentanone and found to melt properly. The semicarbazides were prepared from 2,6-dimethyl-4-heptanone and 2,4-dimethyl-3-pentanone and the melting points checked with those in the literature.

Reaction of Ketene with Acetone.—Ketene was passed into a well-stirred solution of one mole of acetone and a trace of sulfuric acid at the rate of 0.25 mole per hour. Forty-one runs were made to determine optimum conditions. The best reaction temperature at atmospheric pressure was found to be about 55°, and the optimum yield of the enol acetate was obtained with 0.007 mole of sulfuric acid and 0.81 mole of ketene per mole of acetone.

In a run which approximated optimum conditions, 0.87 mole of ketene was passed into a solution of 0.007 mole of sulfuric acid in one mole of acetone at 55°. The product was then fractionated to give 39.5 ml. of product boiling in the range 90–96.5°, leaving 8.5 ml. of residue; conversion, 45%. The residue was shown to be principally diketene with some higher polymers and acetic anhydride.

Identification of Product.—Several 90–96.5°-fractions were refractionated and a material obtained which boiled at 96° (750 mm.). This had a sharp, ester-like odor. It reacted quite vigorously with bromine and reduced alkaline permanganate readily. Metallic sodium appeared to induce polymerization. These qualitative observations suggested that the product might be 1-propen-2-ol acetate. This compound was previously prepared by Nieuwland[8] from acetic acid and methylacetylene. He reported a b. p. of 92–94° (736 mm.). The saponification equivalent, as determined, was 106.0, 105.3. Calculated value for 1-propen-2-ol acetate is 100.07. The method is reported to give high values for esters of tertiary alcohols.[9] The 2,4-dinitrophenylhydrazone was prepared by the standard method[10] and a derivative, m. p. 125°, obtained. The derivative prepared from pure acetone melted at 126°, and a mixture of the two melted at 125.5°, thereby indicating the identity of the two. The formation of this derivative occurs in acid solution so that 1-propen-2-ol acetate should revert to acetic acid and acetone.

Anal. Calculated for $C_5H_8O_2$: C, 59.96; H, 8.06. Found: C, 60.03; H, 8.18.

Reaction of Ketene with 2-Butanone.—Several runs were made in which catalyst concentration, temperature and amount of ketene introduced were varied. Optimum conditions, however, were not determined. Best results were obtained by passing ketene, at the rate of 0.25 mole per hour, into a solution of 70 ml. of 2-butanone and 0.007 mole of sulfuric acid for two and one-half hours at 75°. The product was fractionated and 40 ml. of a fraction, b. p. 112–122°, obtained, leaving 5.5 ml. of residue. Refractionation of the 112–122°-fraction gave principally material with a b. p. of 118–120° (751.5 mm.), which could not be further purified by this method. The 2,4-dinitrophenylhydrazone was prepared and found to melt at 110°. A similar derivative prepared from the starting ketone melted at 112°, and a mixture of the two melted at 111.25°. The saponification equivalent was determined.[9] Calculated value for 1-buten-2-ol acetate or 2-buten-2-ol acetate is 114.08. Found: fraction boiling 118–19°, 118.4, 116.4; fraction boiling 119–20°, 113.9, 114.8. The product is, therefore, the acetate of the enol form of 2-butanone but, probably, is a mixture of both possible forms; conversion, 47%.

Phosphoric Acid and *p*-Toluenesulfonic Acid as Catalysts.—Ketene was passed into a solution of 70 ml. of 2-butanone and 3 drops of 85% phosphoric acid for five hours at 55°. The product was fractionated and found to yield only 2 ml. of material, b. p. 112–122°. A similar run using 3 drops of sulfuric acid gave 20 ml. of material boiling in this range. Another run was made in which ketene was passed into 70 ml. of 2-butanone for three and one-half hours at 55° and a small amount of *p*-toluenesulfonic acid. The product was fractionated and it was found to yield no distillate in the range 112–122°.

Reaction of Ketene with Acetophenone.—Ketene was passed through a solution of 3 drops of sulfuric acid in 70 ml. of acetophenone for three and one-half hours at 64°. This product was fractionated and 25 ml. of product obtained, b. p. 85° (2 mm.). The saponification equivalent was determined.[9] Calculated for 1-phenylethenol acetate, 162.08. Found: 160.4. The 2,4-dinitrophenylhydrazone was prepared[10] and found to melt at 243°; derivative from acetophenone, m. p. 244°, mixed m. p. 243.5°, conversion, 19%.

Reaction of Ketene with Mesityl Oxide.—Ketene was passed into a solution of 3 drops of sulfuric acid in 70 ml. of mesityl oxide for three and one-half hours at 75°. The product was fractionated to give 62 ml. of material with a b. p. of 57.5–58° (10 mm.). Calculated saponification equivalent[9] for 4-methyl-1,3-pentadiene-2-ol acetate 140.10. Found: 146.4, 147.0. The 2,4-dinitrophenylhydrazone[10] melted at 200°; derivative from mesityl oxide, m. p. 199°, mixed m. p. 199°. Since this is close to the melting point of the reagent, a mixed melting point was determined for a mixture of reagent and derivative prepared from the ester (m. p. 177–180°). Whereas the derivative formed immediately when the ketone was used, a period of several minutes was necessary when the ester was used. This was the behavior noted with all of these

(8) Nieuwland, THIS JOURNAL, **56**, 1802 (1934).

esters. Conversion, 46.8%. This ester showed some tendency to polymerize to a tar when heated at too high a temperature.

Reaction of Ketene with 2,4-Dimethyl-3-pentanone.—A total of three runs was made with 2,4-dimethyl-3-pentanone at temperatures up to 117°. In one of these runs ketene was passed through a solution of 5 drops of sulfuric acid in 70 ml. of the ketone for four and one-quarter hours at 117°. Upon fractionating only the ketone and a small amount (1.4 ml.) of diketene were obtained. The conditions employed in the other runs were less severe and likewise yielded no ester.

Reaction of Ketene with Pinacolone.—Ketene was passed into a solution of 15 drops (0.007 mole) of sulfuric acid in 70 ml. of pinacolone for two and two-thirds hours (0.66 mole) at 110°. Upon fractionation, 3.5 ml. of a fraction was obtained, b. p. 134–135° (752 mm.). The saponification equivalent[9] of this was only 88.3 as compared with a calculated value of 142 for 3,3-dimethyl-1-buten-2-ol acetate. This probably indicates contamination with diketene, boiling only a few degrees lower. The 2,4-dinitrophenylhydrazone was prepared[10] and separated into two fractions, one of which melted high, the other at 123.5°. The derivative prepared from the ketone melted at 125° and a mixture of the two at 124.5°.

Determination of Physical Properties.—The boiling points, densities and refractive indices for the compounds (or mixtures of isomers) were determined and are shown in Table I.

TABLE I

PHYSICAL PROPERTIES OF ENOL ACETATES

Acetate of	B. p. °C.	Mm.	$n^{20}D$	d^{25}_{25}
Acetone	96	750	1.4001	0.9308
2-Butanone	118–120	751.5	1.4111	.9043
Mesityl oxide	57.5–58	10	1.4611	.9250
Acetophenone	85	2	1.5329	1.0715
4-Methyl-2-pentanone	143–145	741.5	1.4164	0.8695
2-Heptanone	112–114	93	1.4262	.7488
2-Octanone	108	42.5	1.4283	.8692
2,6-Dimethyl-4-heptanone	74	12	1.4281	.8541
Cyclohexanone	99	48	1.4573	.9952

Discussion

In nearly all of the cases investigated, ketene reacted with ketones to form the acetate of the enol form. The exceptions are worthy of mention since they are those which would be expected to react with most difficulty. Diisopropyl ketone, with only two *alpha* (or 4-position) H-atoms to the carbonyl group, did not react at all, whereas pinacolone with three *alpha* (or 4-position) H-atoms, reacted only slightly. In every case where four or more *alpha* (or 4-position) H-atoms were present, reaction occurred to an appreciable extent. Acetophenone, with only three such groupings, reacted quite readily but an additional factor is present in this case—namely, the formation of a conjugated system upon enolization. Although the evidence is not complete, the results strongly indicate that ease of reaction with ketene parallels the ease of enolization of the ketone. This is well illustrated by the much greater ease of reaction of mesityl oxide than of 4-methyl-2-pentanone. Mesityl oxide, in one form at least, is a substituted vinyl ketone and in this investigation it did not show any differences in behavior from the saturated ketones. Although both types of derivative would give the same saponification equivalent, the lactone would not be expected to give a 2,4-dinitrophenylhydrazone identical with that of the starting material.

Summary

Ketene has been found to react with ketones possessing three or more *alpha* (or 4-position) H-atoms to yield the enol acetates. The tendency to react appears to be dependent upon the ease of enolization. The presence of a catalyst is necessary, sulfuric acid being the best of those investigated. Optimum conditions were determined for the reaction with acetone. It was found that higher temperatures favor the acetylation reaction whereas at lower temperatures considerable polymerization of the ketene occurs. The amount of catalyst present is also critical.

The Halogenation of Certain Esters in the Biphenyl Series. I. The Chlorination of 4-Phenylphenyl Acetate[1]

BY CORA MAY SEGURA SAVOY[2] AND JOHN LEO ABERNETHY

A recent review[3] on the relationship of bactericidal activity to structure of substituted phenols suggested the need for a more direct method of preparation of the 4-(4-halophenyl)-phenols. The bactericidal activity of these substances has not been studied. This paper presents a procedure for direct introduction of chlorine into the desired position of the biphenyl nucleus, namely, the 4′-position, when the 4-position contains an acetyloxy group.

It has been shown that bromination of 4-phenylphenylbenzenesulfonate[4] and 4-phenylphenylbenzoate[5] introduces bromine into the 4′-position of the biphenyl nucleus. Hydrolysis of these brominated esters yields 4-(4-bromophenyl)-phenol. On the other hand, bromination of 4-phenylphenyl acetate[6] introduces bromine in an ortho position to the acetyloxy group, and hydrolysis of this ester yields 2-bromo-4-phenylphenol. This difference has been attributed to the difference in sizes of the groups. Thus, the benzenesulfonyloxy and benzoyloxy groups, being much larger than the acetyloxy group, exhibit greater steric hindrance to bromine. Therefore, bromine is shifted to the 4′-position of the biphenyl nucleus in the case of the larger groups, whereas it enters the 3-position in case of the smaller group.

On the basis of these results it was anticipated that chlorination of 4-phenylphenyl acetate would result in an introduction of chlorine in an ortho position to the acetyloxy group. Such was not found to occur. In contrast to bromination, the halogen in this instance entered the 4′-position. This is indeed surprising, if steric hindrance is the predominant factor, in view of the fact that the chlorine atom is considerably smaller than the bromine atom and presumably less steric hindrance should exist to entrance ortho to the acetyloxy group.

4-Phenylphenyl acetate (II) was prepared from 4-phenylphenol (I) by the method of Kaiser.[7] Chlorination of II in the presence of iodine catalyst gave rise to 4-(4-chlorophenyl)-phenylacetate (III). Hydrolysis of this ester took place readily to give a good yield of the desired 4-(4-chlorophenyl)-phenol (IV). That the chlorine had entered the 4′-position was proved by an independent synthesis of IV.

Benzidine (VII) was converted to 4-(4-chlorophenyl)-aniline (VIII), by means of the Sandmeyer reaction, according to the method used by Täubner[8] as modified by van Alphen[9] for the corresponding iodo compound. Diazotization of VIII gave rise to IV. A mixed melting point of the chlorophenylphenol obtained from VII caused no depression. Furthermore, when the chlorophenylphenol obtained from benzidine was acetylated and a mixed melting point was taken with the chlorination product of II, no depression was noted. This is conclusive evidence that chlorination of II resulted in substitution in the 4′-position.

Previous to the independent synthesis of IV from benzidine, it was noted that the melting point (145–146°) of IV was somewhat close to the melting point (133.5–137°) of 4-(4-chlorophenyl)-2,6-dichlorophenol (XI) as obtained by Colbert, Meigs and Mackin.[10] A mixed melting point of these two substances showed them to be different.

During the course of this investigation it was desirable to prepare 2-chloro-4-phenylphenyl acetate (VI) as well as 4-(4-chlorophenyl)-2,6-dichlorophenyl acetate (XII). This was readily accomplished by acetylation of V and XI, respectively, with acetic anhydride and sodium acetate.

Synthesis of 4-(4-chlorophenyl)-phenol leaves only the fluoro compound unsynthesized in this list of 4-(4-halophenyl)-phenols. The corresponding bromo compound has been prepared from 4-phenylphenyl benzenesulfonate[4] and 4-phenylphenylbenzoate[5] as well as from 4-nitro-4′-bromobiphenyl.[11] The iodo compound has been prepared from benzidine.[9]

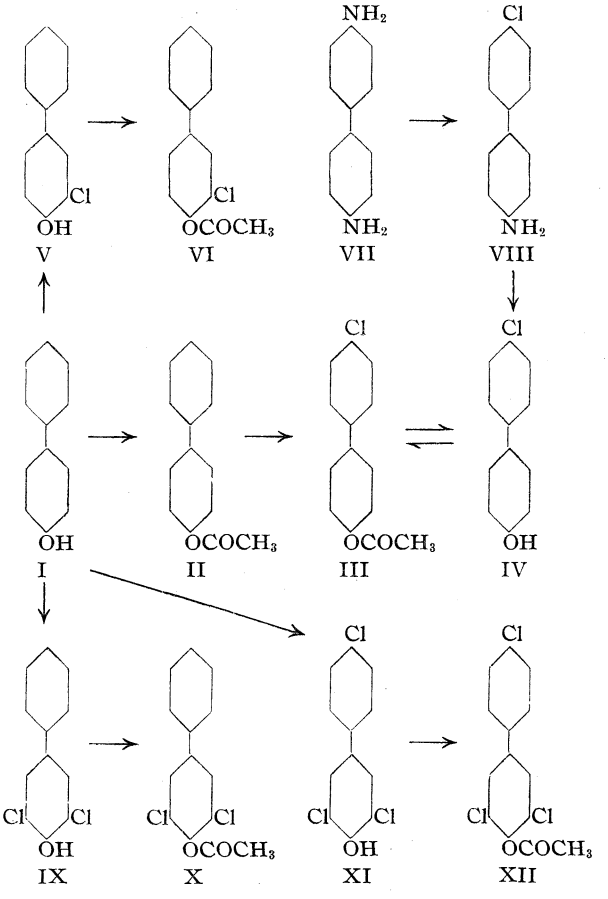
CHART I



Experimental Part

4-(4-Chlorophenyl)-phenyl Acetate (III).—Twenty grams of 4-phenylphenyl acetate, prepared in quantitative yield from 4-phenylphenol,[6] was suspended in 100 cc. of carbon tetrachloride. A trace of iodine was added, and a solution of 7.4 g. (10% excess) of chlorine in 75 cc. of carbon tetrachloride was then added, drop by drop, over a period of two hours. The reaction mixture was stirred during this period and for an additional two hours. When the solvent was removed by distillation under reduced pressure, the crude product crystallized out. After two recrystallizations from methanol, the product, obtained as white plates in 47% yield, melted at 113°. This compound has also been recrystallized from ethanol in approximately the same yield.

An attempt to chlorinate 4-phenylphenyl acetate in sunlight without the use of iodine gave only the original ester.

Anal. Calcd. for $C_{14}H_{11}O_2Cl$: Cl, 14.39. Found: Cl, 14.10, 14.22.

Hydrolysis of 4-(4-Chlorophenyl)-phenyl Acetate.—Five grams of the ester (III) was suspended in a solution of 50 cc. of water, 50 cc. of ethanol, and 5 g. of potassium hydroxide, and refluxed for five minutes; the reaction mixture was allowed to cool and poured into twice its volume of water. The clear solution obtained was acidified, and the white precipitate which formed was filtered and washed with water. The product, which was obtained in nearly quantitative yield, melted at 145–146°. (This was identified as 4-(4-chlorophenyl)-phenol by synthesis from benzidine.) Acetylation of the 4-(4-chlorophenyl)-phenol obtained by hydrolysis of III gave an ester which melted at 113° and which did not depress the melting point of III.

Anal. Calcd. for $C_{12}H_9OCl$: Cl, 17.34. Found: Cl, 17.11, 17.19.

4-(4-Chlorophenyl)-phenol (IV).—Twelve and one-half grams of benzidine was suspended in a dilute solution of hydrochloric acid, cooled, and allowed to react with a solution containing 10 g. of sodium nitrite. An additional 12.5 g. of benzidine was added to the reaction mixture, and the liquid was kept in the ice-box for three days.[8] A cold solution of 10% cuprous chloride in hydrochloric acid was then added. The mixture was allowed to come to room temperature, after which it was heated at 60° for two hours.

The 4-(4-chlorophenyl)-aniline hydrochloride which separated as a brown solid was filtered and washed with water. This product was suspended in a dilute solution of hydrochloric acid, cooled, and allowed to react with a solution containing 10 g. of sodium nitrite. After two hours, the mixture was heated to 60° and kept at this temperature for one hour. A dark brown tarry material separated; the product was extracted from this tar with boiling water. After three recrystallizations from chloroform and petroleum ether, the purified product (IV), obtained in 4% yield on the basis of the benzidine used, melted at 145.5°. A mixture of this compound and the chlorophenylphenol obtained from the hydrolysis of 4-(4-chlorophenyl)-phenyl acetate melted at 146°. Acetylation of 4-(4-chlorophenyl)-phenol obtained from benzidine gave an ester which, after recrystallization from ethanol, melted at 113° and did not depress the melting point of the ester prepared by the chlorination of II.

Anal. Calcd. for $C_{12}H_9OCl$: Cl, 17.34. Found: Cl, 17.21, 17.30.

2-Chloro-4-phenylphenyl Acetate (VI).—A mixture of three grams of 2-chloro-4-phenylphenol[10] and one-fourth molecular proportion of anhydrous sodium acetate was gently refluxed for ten minutes in an excess of acetic anhydride. The reaction mixture was allowed to cool and poured into five volumes of water. The ester was collected by filtration and twice recrystallized from ethanol. The white needles obtained in 92% yield melted at 68°.

Anal. Calcd. for $C_{12}H_9OCl$: Cl, 14.39. Found: Cl, 14.17, 14.22.

2,6-Dichloro-4-phenylphenyl Acetate (X).—A mixture of three grams of 2,6-dichloro-4-phenylphenol[10] and one-fourth molecular proportion of anhydrous sodium acetate was refluxed gently for ten minutes in an excess of acetic anhydride. The reaction mixture was allowed to cool and poured into five volumes of water. The ester was collected by filtration in quantities representing a quantitative yield. Two recrystallizations from ethanol reduced the yield of 73%. The white rhombic crystals melted at 64°.

Anal. Calcd. for $C_{14}H_{11}O_2Cl$: Cl, 25.24. Found: Cl, 25.08, 25.16.

4-(4-Chlorophenyl)-2,6-dichlorophenol (XI).—The impure 4-(4-chlorophenyl)-2,6-dichlorophenol was prepared according to the method of Colbert, Meigs and Mackin.[10] This was crystallized several times from carbon tetrachloride, thus yielding the pure compound with a constant melting point of 144°. (A 9% yield was obtained.) When a melting point was taken on a mixture of this compound with the chlorophenylphenol obtained from III it was lowered to 120°.

4-(4-Chlorophenyl)-2,6-dichlorophenyl Acetate (XII).—This product was obtained by acetylating 2,6,4′-trichlorophenylphenol in the same manner used to prepare VI and X. After two recrystallizations from ethanol, the product was obtained as white needles which melted at 79.5°, in a yield of 75%.

Anal. Calcd. for $C_{14}H_9O_2Cl_3$: Cl, 33.72. Found: Cl, 33.50, 33.57.

Acknowledgment.—The writers wish to express their appreciation for the helpful suggestions of Mr. Harry Kornberg during the progress of this investigation and for the assistance of Mr. T. R. Thompson in the analyses of the compounds.

Summary

1. Chlorination of 4-phenylphenyl acetate in the presence of iodine catalyst gave rise to 4-(4-chlorophenyl)-phenyl acetate. Hydrolysis of this ester gave a quantitative yield of 4-(4-chlorophenyl)-phenol. Proof of the structure of 4-(4-chlorophenyl)-phenol was given by an independent synthesis of this compound from benzidine.

2. Purification of 4-(4-chlorophenyl)-2,6-dichlorophenol to a constant melting point (144°) was accomplished by several recrystallizations of the impure substance (m. p. 135.5–137°) previously reported. The acetates of 4-(4-chlorophenyl)-phenol, 2-chloro-4-phenylphenol, 2,6-dichloro-4-phenylphenol and 2,6-dichloro-4-(4-chlorophenyl)-phenol were prepared in good yield.

A Method for the Synthesis of Certain 2-Substituted Phenanthrenes

BY BYRON RIEGEL, MARVIN H. GOLD[1] AND MICHAEL A. KUBICO

A good general method for the preparation of a number of 2-acyl and amino phenanthrenes was required for the synthesis of polynuclear hydrocarbon derivatives. A few such derivatives have been prepared from phenanthrene, but in low yields because the orientation for substitution is chiefly to the 3-position. Not only are the yields low but the separation is quite often difficult.

By the use of the Friedel–Crafts reaction on phenanthrene a 15% yield of the 2-acetylphenanthrene has been obtained. The major product of this reaction[2] was a 65% yield of the 3-acetylphenanthrene. It is possible to separate readily the 2-acetyl derivative because it has the higher melting point and is less soluble. Using the same method, the 2-propionylphenanthrene could be isolated only in an 8% yield,[3] while with succinic anhydride no 2-succinoylated phenanthrene could be isolated.[4] When there is no particular need for the 3-acylphenanthrenes such reactions constitute an unnecessary waste of laboriously purified phenanthrene.

It has been shown that the 2-position is exclusively involved in the substitution reactions[5] of 9,10-dihydrophenanthrene. The reactions with 9,10-dihydrophenanthrene are not accompanied by the usual resinous products encountered with phenanthrene. We have found that 2-acyl-9,10-dihydrophenanthrenes could be easily dehydrogenated by means of sulfur. Although this method requires three steps in contrast to one step by the older method, they are all readily performed in over-all yields as listed in Table I. The amino derivative was made in four steps from phenanthrene, through the 2-amino-9,10-dihydrophe-

nanthrene, previously reported by Krueger and Mosettig.[6]

Experimental[7]

2-Acetylphenanthrene.[2]—The 9,10-dihydrophenanthrene used in this work was prepared by the method described by Fieser and Johnson.[8] The crude 2-acetyl-9,10-dihydrophenanthrene[5] obtained from the reaction of 65 g. of 9,10-dihydrophenanthrene and 31 g. of acetyl chloride was transferred to a 250-ml. Claisen-head sabre flask. After heating the flask to 250°, 12 g. of sulfur was added in 1–2 g. quantities over a period of ten minutes. Heating was continued at 260–280° for about one hour or until no more hydrogen sulfide was evolved. The reaction mixture was allowed to cool somewhat and then distilled at 1–2 mm. By dissolving the crude solid distillate in boiling benzene and adding an equal volume of petroleum ether (b. p. 60–90°), 47 g. of crystalline material (in two crops), m. p. 138–142°, was obtained. This was sufficiently pure for further work and represented an over-all yield of 59% for the two steps or a 53% yield based on phenanthrene. Pure material, m. p. 142–143°, could be obtained by two crystallizations. A high boiling viscous oil remained in the mother liquors.

2-Propionylphenanthrene.—The distillate, from the dehydrogenation of 2-propionyl-9,10-dihydrophenanthrene,[5] gave crystalline material, m. p. 99–102°, from ethanol. An over-all yield of 45%, based on phenanthrene, was obtained. Recrystallization from ethanol raised the m. p. to 103–104°. Bachmann and Struve[3] reported its m. p. as 104–105°.

2-Isobutyryl-9,10-dihydrophenanthrene.—The crude reaction product from 30 g. of 9,10-dihydrophenanthrene and 19.4 g. of isobutyryl chloride was distilled at 2 mm. giving 36.8 g. (88%) of distillate, a sample of which gave crystals, from ethanol, melting at 71.6–72.6°.

Anal. Calcd. for $C_{18}H_{18}O$: C, 86.36; H, 7.24. Found: C, 86.90; H, 7.34.

2-Isobutyrylphenanthrene.—Dehydrogenation of a 10.1-g. sample of the previously described distillate gave a product which crystallized from benzene–ethanol giving 6.06 g. (61%), m. p. 116.8–117.6°. This represents an over-all yield of 48% for the three steps.

Anal. Calcd. for $C_{18}H_{16}O$: C, 87.06; H, 6.50. Found: C, 86.83; H, 6.75.

Methyl β-[2-Phenanthroyl]-propionate.—To a suspension of 8 g. of β-[9,10-dihydro-2-phenanthroyl]-propionic acid[5] in 100 ml. of methanol was added slowly, while swirling, 10 ml. of acetyl chloride. The reaction mixture became hot and the solid acid dissolved. After standing for three hours at room temperature, water and ether were added. The ether extract was washed with a dilute solution of sodium carbonate and treated with Norite and anhydrous sodium sulfate. It was then filtered and the solvent removed under reduced pressure. The residual oil crystallized from methanol giving 7.6 g. (90%) of material sufficiently pure for further reactions. Recrystallization from methanol gave prisms melting at 73.5–74°. Fieser and Johnson[9] reported the m. p. 77–78°. The above esterification is most convenient and is similar to the method described by Freudenberg and Jakob.[10]

Dehydrogenation of a 2.756-g. sample of the methyl β-[9,10-dihydro-2-phenanthroyl]-propionate gave 2.382 g. of crude material which crystallized from acetone–methanol giving 2.185 g. (80%) of product melting 105–107°. Two crystallizations including a treatment with Norite gave glistening white plates, m. p. 112.2–112.6°.

Anal. Calcd. for $C_{19}H_{16}O_3$: C, 78.06; H, 5.53. Found: C, 78.43; H, 5.96.

A small sample was hydrolyzed giving the free acid melting at 203–206° (reported[4] 205–206°).

2-Aminophenanthrene.—2-Amino-9,10-dihydrophenanthrene[6] was smoothly dehydrogenated by means of sulfur. The reaction product was isolated in the form of its hydrochloride in a 68% yield. Liberation of the free amine by the addition of alkali gave a product melting at 85–86°. This amine has been prepared by Bachmann and Boatner[11] through the Beckmann rearrangement of the oxime of 2-acetylphenanthrene.

Summary

1. A convenient and improved method for the preparation of 2-acyl and amino phenanthrenes has been described. This method involves the dehydrogenation of the easily prepared 9,10-dihydrophenanthrene derivatives.

A Convenient Procedure for the Preparation of Deuterium Chloride

BY HERBERT C. BROWN AND CORNELIUS GROOT[1]

In the course of an investigation upon which we have been engaged, the need arose for considerable quantities of deuterium chloride of high purity. Examination of the literature reveals that many methods for the preparation of the substance have been reported. In the main, however, these methods, such as the action of deuterium oxide on anhydrous magnesium chloride at 600°,[2] the reduction of silver chloride with deuterium at 700°,[3] the combination of chlorine with deuterium,[4] or the treatment of sodium chloride with deutero sulfuric acid,[5] either require the prior preparation of intermediates or involve such difficult techniques as to be unsuitable for the preparation of more than small quantities of deuterium chloride.

The procedure based on the reaction of deuterium oxide with thionyl chloride ($SOCl_2 + D_2O \rightarrow SO_2 + 2\ DCl$) has received careful attention as a means of preparing deuterium chloride in appreciable quantities,[6] and the process would be entirely satisfactory but for the difficulty involved in the separation of the product from the accompanying sulfur dioxide. In the recommended procedure, two traps cooled by dry-ice–acetone mixtures are used to remove the greater portion of the sulfur dioxide. However, since this gas possesses an appreciable vapor pressure at −80° (10 mm.), it is evident that the deuterium chloride thus obtained must be contaminated with not inconsiderable quantities of sulfur dioxide. Moreover, the solubility of deuterium chloride in liquid sulfur dioxide at −80° causes losses as high as 15% of the product.

In casting about for a more satisfactory procedure, we examined the possibility of utilizing benzoyl chloride for transforming deuterium oxide into the desired product. Study revealed that at somewhat elevated temperatures deuterium oxide reacts smoothly with the reagent to liberate *two* equivalents of deuterium chloride. The reaction occurs in accordance with the equations

$$C_6H_5COCl + D_2O \longrightarrow C_6H_5COOD + DCl$$
$$C_6H_5COCl + C_6H_5COOD \longrightarrow (C_6H_5CO)_2O + DCl$$

The yield of the gaseous chloride is practically quantitative, the product is analytically pure deuterium chloride, and, finally, the rate at which the gas is generated is readily controlled throughout the preparation.

The apparatus used in the preparation is shown in Fig. 1. The deuterium oxide is contained in the dropping funnel where the long length of capillary tubing serves to maintain the rate of addition of the deuterium oxide constant despite small fluctuations in pressure within the flask.

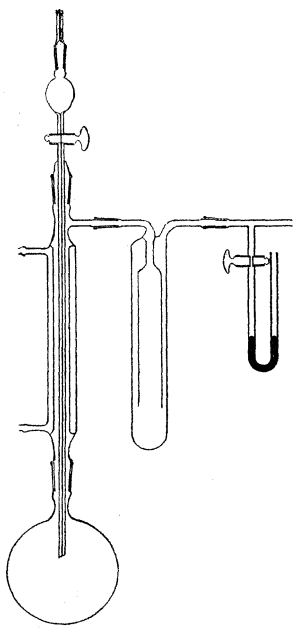

Fig. 1.—Apparatus.

The trap is immersed in an ice-bath to remove traces of benzoyl chloride which are carried past the condenser by the stream of gas. The open manometer is used to indicate the pressure at which the system is operating and to act as a safety valve should the delivery tube become blocked. It also aids in following the course of the reaction. If the delivery tube is closed momentarily (by means of a pinch clamp on a rubber connection), the action of the manometer reveals whether gas is being evolved.

(1) This paper is taken from a dissertation submitted by Cornelius Groot to the Faculty of the Division of the Physical Sciences of the University of Chicago in partial fulfillment of the requirements for the degree of Master of Science.

(2) Lewis, MacDonald and Schutz, THIS JOURNAL, **56**, 494 (1934).

(3) Steiner and Rideal, *Proc. Roy. Soc.* (London), **A173**, 504 (1939).

(4) Bawn and Evans, *Trans. Faraday Soc.*, **31**, 1394 (1935).

(5) Frivold, Hassel and Rustad, *Physik. Z.*, **38**, 193 (1937).

(6) Langseth and Klit, *Kgl. Danske Videnskab. Selskab. Math. fys. Medd.*, **15**, No. 13, 4 (1937).

A few drops of the deuterium oxide is run from the funnel into the flask containing a two to three mole excess of benzoyl chloride (reagent grade). The flask is gently heated until deuterium chloride is evolved at a satisfactory rate, and the temperature is maintained at this level until all of the deuterium oxide has been added and the evolution of gas has noticeably slackened. The temperature is then slowly raised to the boiling point of the benzoyl chloride and maintained there until gas is no longer produced.

At the end of the reaction, a slow stream of dry air is passed into the system through the dropping funnel (the refluxing of the reaction mixture is not interrupted) to force the last traces of deuterium chloride to the outlet. At all times the evolution of deuterium chloride is smooth, easily controlled (the addition of a few chips of porous plate to the reaction flask is advisable), and may be halted simply by removing the source of heat.

The details of one test preparation will be given to illustrate the yields and degree of purity which may be expected.

Five ml. (0.550 equiv.) of deuterium oxide (99.6%) were treated with an excess (*ca.* 1.5 moles) of benzoyl chloride. The deuterium chloride obtained was dissolved in distilled water (contained in a 250-ml. volumetric flask), the solution in the flask diluted to the mark, and samples removed for analysis. Total acidity found was 0.528 equiv. (average of three determinations: 0.526, 0.527, 0.531), representing a yield of 96% of the theoretical. The solution was analyzed volumetrically for chloride ion by the Volhard method; found: 0.529 equiv. (average of three determinations: 0.528, 0.530, 0.530). The deuterium content was determined by the temperature float method on a portion of the solution after the acid had been carefully neutralized with barium oxide and the water distilled; found: 0.528 equiv. of deuterium (average of two determinations: 0.530, 0.526). It is evident that, within the accuracy of the experiment, a nearly quantitative yield[7] of pure deuterium chloride had been obtained

Acknowledgment.—The authors wish to express their thanks to Mr. D. C. Sayles for the chloride ion analyses and to Mr. K. Wilzbach for the deuterium analyses. They also wish to acknowledge gratefully the deuterium oxide generously donated by Professor M. S. Kharasch for this and other investigations.

Summary

Deuterium chloride may be prepared conveniently by the action of benzoyl chloride on deuterium oxide at elevated temperatures. The product is analytically pure and the yields (based on the available deuterium) are practically quantitative.

(7) In three preliminary experiments in which 9 to 18 g. of water (1.0 to 2.0 equiv.) were transformed into hydrogen chloride by this method, the yields obtained were 98.5, 100, 99%.

NOTES

Physical Constants of Methyl Isopropenyl Ketone

BY JOSEPH H. BRANT

The literature dealing with methyl isopropenyl ketone[1-8] shows a considerable variance with respect to the physical constants of this ketone. Two methods of preparation have been described in the recent literature. The liquid phase synthesis from methyl ethyl ketone and formalin has been studied extensively by Morgan and coworkers[2,3] and also by Rutovskii and coworkers.[4,5,6] A vapor phase synthesis has been described by Brant and Hasche[7] in which the ketone is produced in one step starting with methyl ethyl ketone and formalin or paraformaldehyde.

More recently Marvel, Riddle and Corner[8] reported the boiling point of methyl isopropenyl ketone as 45–46° at 40 mm. It would appear that this value is considerably too high.

(5) Rutovskii and Dmitrieva, *ibid.*, **14**, 535 (1941).
(6) Rutovskii and Goncharov, *ibid.*, **14**, 542 (1941).
(7) Brant and Hasche, U. S. Patent 2,245,567.
(8) Marvel, Riddle and Corner, THIS JOURNAL, **64**, 92 (1942).

In order to help clarify this situation regarding the physical constants the following table is presented which shows the effect of time on the physical constants of methyl isopropenyl ketone. The first determinations listed were made within a few minutes after the completion of a careful vacuum distillation. The fraction studied was the middle 75 cc. from an 800-cc. batch and collected in a brine cooled receiver at about −10°. The material used in these tests was stored in a clear glass bottle without an inhibitor present and at room temperature. This sample contained less than 0.01% H_2O.

TABLE I

Age, days	$n^{20}D$	d^{20}_{20}	Age, days	$n^{20}D$	d^{20}_{20}
	1.4163	0.8459	12	1.4242	0.8710
1	1.4162	.8458	13	1.4260	.8758

10	1.4214	.8632	22	Too viscous to examine	
11	1.4230	.8670	30	Glass-like	solid

Other samples have shown comparable behavior except that the change has set in more quickly. One other sample on record was as much polymerized after thirteen hours as the one above was in seven days based on the density and refractive index values. No doubt some catalyzing impurities present in very small amounts account for this variation in rate of polymerization.

It appears necessary that physical constants of pure methyl isopropenyl ketone be determined as soon after distillation as possible even when inhibitors have been added.

The following are constants obtained for pure freshly vacuum distilled methyl isopropenyl ketone made by the vapor phase process.[7]

The Further Nitration of Certain Dinitrobiphenyls

BY FRANCIS H. CASE

2,3′,4,4′-Tetranitrobiphenyl has been obtained by Blakey and Scarborough[1] by the nitration of either 2,3′- or 3,4′-dinitrobiphenyl. These authors were, however, unable to obtain the corresponding trinitro derivatives. In this Laboratory, 2,3′,4-trinitrobiphenyl (m. p. 137–138°, from alcohol) was the sole product isolated after heating 2,3′-dinitrobiphenyl with nitric acid (sp. gr. 1.5) for three minutes.

Anal. Calcd. for $C_{12}H_7N_3O_6$: N, 14.54. Found: N, 14.77.

When 3,4′-dinitrobiphenyl (6 g.) was heated for one hour with nitric acid (50 cc., sp. gr., 1.5), the reaction mixture poured into water, and the precipitate crystallized from benzene, 3,4,4′-trinitrobiphenyl (1.1 g., m. p. 205–206°) was first obtained.

Anal. Calcd. for $C_{12}H_7N_3O_6$: N, 14.54. Found: N, 14.70.

On evaporation of the benzene mother liquors and crystallization from alcohol, 2,3′,4-trinitrobiphenyl (1.5 g., m. p. 136–137°) separated. This product melted unchanged when mixed with the trinitro isomer from 2,3′-dinitrobiphenyl. The structure of the isomer melting at 137–138° follows from its dual method of synthesis; that of the isomer (m. p. 205–206°) depends on the fact that it is different from II, and yet yields the known 2,3′,4,4′-tetranitrobiphenyl on further nitration.

When 3,3′-dinitrobiphenyl (5 g.) was nitrated under the conditions described above for the 3,4′-compound, and the product was crystallized from a mixture of acetone and alcohol, 3,3′,4-trinitrobiphenyl (2.4 g., m. p. 179–180°) was obtained.

Anal. Calcd. for $C_{12}H_7N_3O_6$: N, 14.54. Found: N, 14.53.

The structure of this compound was evident from the fact that on further nitration with mixed acids (1:1) at 100°, 3,3′,4,4′-tetranitrobiphenyl, m. p. 203–204° (from alcohol–acetone), identical (mixed m. p. undepressed) with a sample prepared by Ullmann's method[2] from 3,4-dinitroiodobenzene, was obtained.

Anal. Calcd. for $C_{12}H_6N_4O_8$: N, 16.77. Found: N, 16.90.

Preparation of *p*-Aminobenzenesulfonyl Urea

BY EDWARD H. COX

The procedure for the preparation of the arylsulfonyl ureas[1] has now been applied in making

(1) Cox and Raymond, THIS JOURNAL, **63**, 300 (1941).

p-aminobenzenesulfonyl urea. The therapeutic properties of this compound and some of its salts are under investigation.

***p*-Acetaminobenzenesulfonyl Ethyl-isourea.**—In a five-liter flask provided with a mechanical stirrer was placed 600 g. of anhydrous potassium carbonate, 2 liters of acetone and 100 cc. of water. The suspension of carbonate–acetone–water was stirred and cooled in an ice-bath. To this suspension 272 g. (2.2 moles) of ethyl-isourea hydrochloride was added gradually over a period of one-half hour. With each addition some water was added until the total amount was 400 cc. The ice-bath was removed after the addition and the reaction mixture stirred at room temperature for four hours.

The reaction material was then poured into five liters of water, and the crude product filtered and washed. The weight of the crude dried product was 458 g. (87% yield). It crystallized from 50% acetic acid as white needles and melted at 223–224°.

Anal. Calcd. for $C_{11}H_{15}O_4N_3S$: N, 14.71. Found: N, 14.76, 14.79.

***p*-Aminobenzenesulfonyl Urea.**—One mole (285 g.) of *p*-acetaminobenzenesulfonyl ethyl-isourea (crystallized once from dilute acetic acid) was placed in a two liter flask and covered with 700 cc. of concentrated hydrochloric acid. The isourea first dissolved and then reprecipitated as the hydrochloride. The flask was immersed in a boiling water-bath and the reaction mixture stirred until solution took place (fifteen to twenty minutes). Decolorizing charcoal was added while still hot and the solution was filtered. After the addition of an equal volume of alcohol the filtrate was set aside to crystallize. The dried crystalline product weighed 200 g. (80% yield). White needles were produced when the product was recrystallized from dilute acetic acid. The compound melted with gas formation (ammonia) at 140–146°.[2,3]

Anal. Calcd. for $C_7H_9O_3N_3S$: N, 19.54. Found: N, 19.53, 19.59.

Salts of *p*-Aminobenzenesulfonyl Urea.—The ammonium, potassium and sodium salts were prepared by treating slightly more than one equivalent of the *p*-aminobenzenesulfonyl urea with one equivalent of the metallic carbonate in 50% alcohol. After the addition of the carbonate, ether was added to produce the maximum yield of the salt.

Ammonium Salt. *Anal.* Calcd. for $C_7H_{12}O_3N_4S$: N, 24.12. Found: N, 24.09, 24.19.

Potassium Salt. *Anal.* Calcd. for $C_7H_8O_3N_3SK$: N, 16.59. Found: N, 16.54, 16.56.

Sodium Salt. *Anal.* Calcd. for $C_7H_8O_3N_3SNa$: N, 17.71. Found: N, 17.59, 17.64.

Acknowledgment.—The author thanks the Monsanto Chemical Company for a generous supply of *p*-acetoaminobenzenesulfonyl chloride.

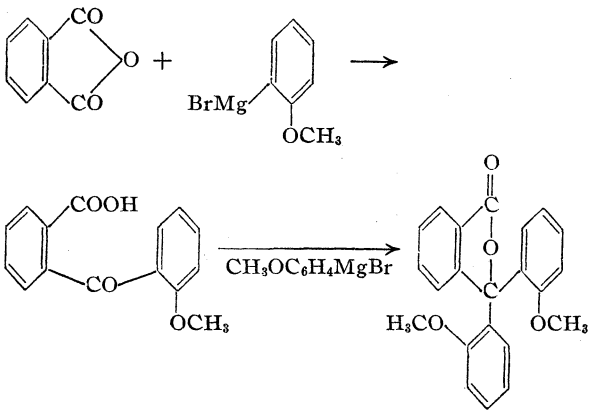
A Synthesis of 2-(2′-Methoxybenzoyl)-benzoic Acid

BY BRADFORD P. GEYER[1]

In the course of a projected synthesis of 1-hydroxyfluorenone it became necessary to prepare a quantity of 2-(2′-methoxybenzoyl)-benzoic acid (I). This keto acid was prepared previously by Sieglitz[2] by methylation of 2-salicylylbenzoic acid. The synthesis of I has now been accomplished, using phthalic anhydride and *o*-bromoanisole as starting materials.



I II

A by-product formed in the Grignard reaction of *o*-anisylmagnesium bromide with phthalic anhydride is 2,2-di-*o*-anisylphthalide (II), reported earlier by Ferrario[3] and by Blicke and Weinkauff.[4]

Experimental

Before preparing the Grignard reagent, *o*-anisylmagnesium bromide, the flask containing 9.6 g. (0.4 mole) of magnesium was heated with a low, free flame to expel traces of moisture. A 20-ml. portion of anhydrous diethyl ether, freshly distilled from an ethereal ethylmagnesium bromide solution and containing 10 drops of ethyl bromide, was placed in the flask with the magnesium. To this mixture, agitated by means of a mercury-seal stirrer, 63 g. (0.34 mole) of *o*-bromoanisole in 100 ml. of diethyl ether, the latter likewise freshly distilled from the same ethylmagnesium bromide solution, was added dropwise. After complete addition of the *o*-bromoanisole, the solution of the arylmagnesium halide was heated under reflux for one-half hour. This Grignard reagent was then introduced slowly, dropwise, to a vigorously stirred, hot solution of 37 g. (0.25 mole) of phthalic anhydride in 600 ml. of thiophene-free benzene, ether being removed simultaneously by distillation. Pale yellowish-white solid formed immediately. After the addition of all of the re-

(4) Blicke and Weinkauff, THIS JOURNAL, **54**, 1452 (1932).

agent, the resulting mixture was stirred for several minutes longer, heated under reflux for two hours and then allowed to cool and stand overnight at room temperature. The reaction flask was cooled in an ice–water-bath and the pale yellow product decomposed with dilute hydrochloric acid. A 300-ml. quantity of diethyl ether was added to dilute the benzene solution of 2-(2′-methoxybenzoyl)-benzoic acid and 2,2-di-*o*-anisylphthalide. The ether–benzene layer was extracted with potassium carbonate solution, and the carbonate extract then run dropwise into vigorously stirred, ice-cold hydrochloric acid. In this way the keto acid first separated as a pasty mass which soon became solid. This pale fawn-colored, granular solid was filtered off and washed with cold diethyl ether. Upon drying, 34.5 g. (54%) of crude acid was obtained. After four recrystallizations from glacial acetic acid, 2-(2′-methoxybenzoyl)-benzoic acid was secured in the form of short, colorless, small prisms; m. p. 143–143.5°; yield 30 g. (47%, based on phthalic anhydride). Sieglitz[2] reported 144–145° as the m. p. of this acid.

Anal. Neutralization equivalent, calcd. for $C_{15}H_{12}O_4$: 256.2. Found: 257.9.

From the above-mentioned benzene–ether layer, after the potassium carbonate extraction and concentration of the solution to a small volume, a colorless powder was obtained. This material, 2,2-di-*o*-anisylphthalide, when recrystallized three times from glacial acetic acid, formed small, colorless crystals, m. p. 148–149°; yield 10.5 g. (18%, based on *o*-bromoanisole). The phthalide was found to be soluble in concentrated sulfuric acid with a very deep violet color which gradually changed to ruby-red and finally to orange.

The Dissociation of Hexaarylethanes. XIV.[1] Ethanes Derived from Mixtures of Triaryl Halides

BY C. S. MARVEL AND CHESTER M. HIMEL

Since symmetry seemed to be important in connection with the influence of substituents on the degree of dissociation of triarylmethyls, it occurred to us that treating an equimolecular mixture of two triarylmethyl halides with silver might produce a truly unsymmetrical ethane rather than a mixture of ethanes. Table I contains a list of some mixtures of chlorides which were thus treated and the degree of dissociation calculated from magnetic susceptibility measurements on the assumption that a mixed ethane was formed. In one case (the first in the table) the mixed ethane was prepared by mixing preformed solutions of the individual ethanes rather than by action of silver on the mixed halides.

(1) For the thirteenth communication see *J. Org. Chem.*, **7**, July (1942).

TABLE I

DISSOCIATION OF SOME MIXED HEXAARYLETHANES

Chlorides used	$-\chi \times 10^6$	α at 0.1 *M*, %	α of corresponding ethane at 0.1 *M*, %	Ref.
o-Chlorophenyldiphenylmethyl *o*-Bromophenyldiphenylmethyl	0.6620	14 ± 2	12 ± 1 17 ± 1	1 1
o-Tolyldiphenylmethyl α-Naphthyldiphenylmethyl	.6320	26 ± 2	25 ± 1 27 ± 2	2 3
o-Tolyldiphenylmethyl Di-*o*-tolylphenylmethyl	.6282	27 ± 2	25 ± 1 82 ± 2	2 4
Tri-*p*-diphenylmethyl Tri-β-naphthylmethyl	.6765	25 ± 3[a]	25 ± 5 25 ± 5	3 3
p-*t*-Amylphenyldiphenylmethyl Phenyl-di-*p*-*t*-amylphenylmethyl	.6985	3.5 ± 1	8.0 ± 1 9.0 ± 1	4 4
Tri-*p*-*t*-butylphenylmethyl *p*-*t*-Butylphenyldiphenylmethyl	.6997	3.5 ± 1	20 ± 4 7.5 ± 1	4 4

[a] The actual measurement was made at 0.025 *M* and the dissociation at this concentration was 43 ± 4%. The value in the table was calculated by means of the mass law.

The method and apparatus have been described in previous papers in this series. It can be seen readily that the observed degrees of dissociation are not the average of the two simple ethanes, but in general are lower than this value. There are several equilibria possible in this complicated system and a complete appraisal of the significance of these experimental results will not be possible until these equilibria are more thoroughly studied. Since it seems unlikely that this can be done soon, these results are recorded.

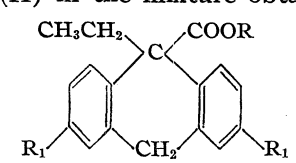
The Reaction of Furoic Acid with Aromatic Compounds. III

BY CHARLES C. PRICE, E. C. CHAPIN AND MARTIN RIEGER

The isolation of methyl 9-ethyl-9,10-dihydro-9-anthroate (I) from the aluminum chloride catalyzed reaction of methyl furoate with benzene[1] suggests the presence of the corresponding acid (II) in the mixture obtained from a similar re-



I (R = CH_3, R_1 = H)
II (R = R_1 = H)
III (R = H, R_1 = CH_3)

(1) Price and Huber, THIS JOURNAL, **64**, 2136 (1942).

action with furoic acid.[2] Oxidation of the crude mixture from the latter reaction to yield anthraquinone has already been presented as evidence for the formation of an acid with an anthracene nucleus.[2] This observation has now been substantiated by degradation of the crude reaction mixture to anthracene by subjecting it to soda-lime distillation. Crystallization from benzene of the oily distillate so obtained yielded anthracene in 10% yield, m. p. 208–210°. Its identity was checked by a mixed melting point determination.

Thus, although the pure acid has yet to be isolated, analogy with the methyl furoate reaction supports the suggestion that the anthroic acid present in the mixture of acids formed from benzene and furoic acid is 9-ethyl-9,10-dihydro-9 anthroic acid (II).

The oily residue left after crystallization of anthracene from the soda-lime distillate was dehydrogenated with sulfur to yield 1,4-diphenylnaphthalene, previously obtained as a degradation product of the acid mixture. It is believed to be derived from 1,4-diphenyl-1,2,3,4-tetrahydro-1-naphthoic acid.[2]

Soda-lime distillation of the crude acid mixture obtained by reaction of toluene and furoic acid yielded 2,7-dimethylanthracene, m. p. 238–239°, which showed no depression in melting point when mixed with an authentic sample. Isolation of this hydrocarbon indicates that this reaction also gives rise to an anthroic acid. Again, the pure acid has yet to be isolated, but analogy with the product from benzene, as well as consideration of the simplest product of the reaction, 6-methyl-1-naphthoic acid, suggests that the anthracenic component of the toluene-furoic acid reaction may be 3,6-dimethyl-9-ethyl-9,10-dihydro-9-anthroic acid (III).

Repeated efforts to isolate a substance from the crude toluene product, corresponding to the 1,4-diphenylnaphthalene obtained from the benzene product, have failed. Attempted decarboxylation of the toluene product by heating with copper chromite in quinoline, successful for the benzene product, yielded a black, intractable tar from the toluene product. Evidently the tar was formed by oxidation, since the black powdery copper chromite catalyst was transformed to a mixture of green chromium oxide powder and small bright balls of metallic copper. Treatment with sulfur or selenium of the pale yellow oil from the mother liquor of the soda-lime distillate led to copious evolution of hydrogen sulfide or selenide, but no crystalline product could be isolated.

A Color Test for Citrinin and a Method for its Preparation

BY HENRY TAUBER, STEPHEN LAUFER AND MILTON GOLL

The following is a color test for citrinin and a method for the preparation of the anti-bacterial substance.

The Color Test.—One mg. of citrinin (prepared as given below) is dissolved in 0.5 cc. of 95% alcohol and 0.3 cc. of 3% hydrogen peroxide is added. The mixture is agitated for one minute. The intense yellow solution becomes first colorless, then light brown. Hereafter, 0.3 cc. of 0.2 *N* sodium hydroxide is added. A deep wine-red color forms at once. On the addition of 0.3 cc. of 0.2 *N* sulfuric acid the wine-red color turns orange-yellow and on the addition of a further 0.3 cc. of 0.2 *N* sodium hydroxide the wine-red color reappears again. In a control tube in which water is substituted for hydrogen peroxide an orange-yellow color develops. This color reaction with sodium hydroxide from intense yellow to orange-yellow was also noted by A. C. Hetherington and H. Raistrick [*Trans. Roy. Soc.*, London, **B220**, 279 (1931)] who stated that "Citrinin is readily soluble in aqueous NaOH giving rise to an orange-yellow solution which on standing changes color to orange-red." This is indeed the case when a fairly concentrated sodium hydroxide solution is added to a citrinin solution. We found, however, that when 0.25 to 0.5 cc. of 0.02 *N* sodium hydroxide is added to 1 mg. of citrinin in 0.5 cc. of ethyl alcohol, a very light pink color forms which does not change in intensity on further addition of the alkali or on standing. H. W. Hirschy and Ruoff [THIS JOURNAL, **64**, 1490 (1942)] have recently observed that above *p*H 9.9 the color of a citrinin solution changed from orange-pink to cherry-red.

Continued exposure of citrinin to dioxane results in a hydrogen peroxide-like reaction. On long exposure to air alcoholic citrinin solutions undergo certain changes which do not appear to be identical with hydrogen peroxide-oxidation.

The hydrogen peroxide–sodium hydroxide color reaction is also given by the original cultures, by the acid precipitated crude citrinin, and after it had been recrystallized from 95% alcohol. Citrinin solutions that have been treated with sodium hydroxide and readjusted to the original *p*H do not give the hydrogen peroxide–sodium hydroxide reaction.

Penicillin obtained from *P. notatum* (A. T. C. C.) gives a lemon-yellow color with this test.

Preparation of Citrinin.—1500 cc. of the filtrate of a fourteen-day old culture of *P. citrinum* prepared according to H. Raistrick and G. Smith [*Chemistry and Industry*, **60**, 828 (1941)] is adjusted to *p*H 3.0 to 2.5 with *N* hydro-

chloric acid. After about five minutes the crystals of crude citrinin are centrifuged off, dissolved in 30 cc. of dioxane at room temperature, and the solution is centrifuged. A small amount of insoluble material is discarded, and to the clear supernatant fluid one volume of distilled water is added. Citrinin crystallizes out immediately in long microscopic needles or plates. If the citrinin concentration is low, it is necessary to add more water in order to effect crystallization. The citrinin is centrifuged off and dried in vacuum at room temperature (yield, 1.5 g.). The melting point is at 163 to 166°. We were able to confirm fully the action of citrinin on *Streptococcus aureus* as reported by Raistrick and associates.

P. citrinum (P25 and ad95) was very kindly sent by Dr. H. Raistrick and forwarded to us through the courtesy of Dr. C. Thom of U. S. Department of Agriculture.

Acidic and Basic Catalysis in Urethan Formation

BY D. S. TARBELL, R. C. MALLATT AND J. W. WILSON

Urethans, because of their favorable characteristics, are frequently used to identify alcohols and phenols. They are usually prepared by heating an alcohol or phenol in the absence of a catalyst.[1] However, scattered statements indicate that this formation of urethans, particularly from phenols, is catalyzed not only by bases[2] but by aluminum chloride[3] and hydrogen chloride.[4] A general survey of the effect of acidic and basic catalysts on urethan formation has therefore been undertaken, but, as this work has been interrupted, the present brief report is now submitted.

Experiments in which equivalent amounts of *o*-cresol and phenyl isocyanate were heated without solvent but with catalyst at 100° and the urethan which had formed after varying times isolated, showed that the following substances have a catalytic effect: sodium carbonate, sodium acetate, pyridine, acetic acid, trichloroacetic acid, zinc chloride and hydrogen chloride. Without a catalyst a yield of less than 50% was obtained after nine hours of heating. The addition of 2% of either zinc chloride or pyridine gave a 100% yield in less than fifteen minutes.

Similar experiments with other phenols varying greatly in acid character, from *p*-nitrophenol to *p*-triphenylmethylphenol, gave in fifteen minutes without a catalyst zero, with the same catalysts, practically 100% yields of urethan. On the other hand, 2,4-dinitrophenol, 2,6-dinitro-4-chlorophenol and picric acid did not form urethans under any conditions tried.

More exact experiments using purified *o*-cresol and α-naphthyl isocyanate were made as follows: solutions of 9.2 mmol. of each reagent and a small amount of a catalyst in 3.00 cc. of purified ligroin (b. p. 60–65°) in stoppered test-tubes, were heated in the vapors of refluxing methanol (65°) and after a definite time cooled in ice and filtered. The resultant crystals were washed twice with 2-cc. portions of cold ligroin in which they are practically insoluble, dried and weighed.

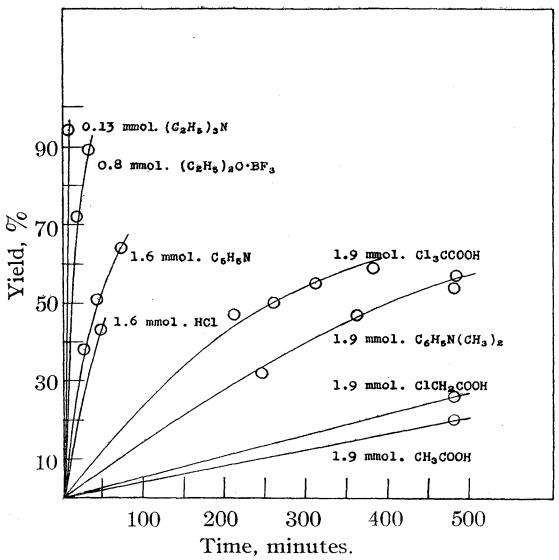

Fig. 1.

The results are shown as curves in Fig. 1, and from them it can be seen that triethylamine is by far the most effective catalyst tried. It is probably significant that it is a much stronger base than the less effective catalysts pyridine and dimethylaniline.[5] Boron fluoride etherate is the most active acid tested, and the catalytic activity of the other acids tested is roughly in the order of their acid strengths in water. When no catalyst was used, only an 11% yield was obtained after nine days, a result which could not be shown on the graph.

An 80% yield of the urethan (m. p. 141–142.5°)[6] was obtained by mixing the above quantities of *o*-cresol and α-naphthyl isocyanate in 30 cc. of ligroin with two drops of triethylamine, and letting the mixture stand for two and one-half hours at room temperature. From this it appears that an excellent and rapid procedure for preparing urethans from phenols in general would be to use the above quantities of materials, reflux the solution a few minutes and cool slowly to allow crystallization.

Phenylurethans of Tertiary Alcohols.—These compounds were prepared by heating a mixture of 2 or 3 g. of the *t*-alcohol with an equivalent quantity of phenyl isocyanate and 0.1 g. of anhydrous sodium acetate for four to five hours on a steam-bath. In each case the reaction product was contaminated with some diphenylurea and unreacted phenyl isocyanate. If the oily product failed to crystal-

Triethylcarbinol	61–61.5	$C_{14}H_{21}NO_2$	71.5	8.9	70.9	8.8
Methylethylbenzylcarbinol	83.5–84	$C_{18}H_{21}NO_2$	76.3	7.5	75.9	7.3
Diethylbenzylcarbinol	96–96.5	$C_{19}H_{23}NO_2$	76.7	7.8	76.7	7.4

[a] Analyses by R. W. King.

Discussion of the mechanism of the catalysis will be deferred, but it seems to be a case of general acid–base catalysis. The tests for determining general acid–base catalysis which are employed in aqueous systems cannot be used readily here, since the isocyanates must be kept in inert solvents.

It is hoped to study this catalysis effect in greater detail and to include the reactions of alcohols and isocyanates.

Optical Properties of 2-Sulfanilamidopyrimidine (Sulfadiazine)

BY ALBERT S. WILKERSON

Thanks to the courtesy of Mr. Leonard Dhein of the American Cyanamid Company, Bound Brook, New Jersey, we have been able to determine the optical and related properties of a sample of sulfadiazine (m. p. 254°)[1] with the following results: monoclinic, colorless, transparent to translucent; luster vitreous. Cleavage pinacoidal at right angles, perfect. $H = 1$–2. Solubility 0.0123 g./100 cc.,[1] H_2O at 37°. Optically biaxial positive; $\alpha = 1.680$, $\beta = 1.695$, $\gamma = 1.788$; all ± 0.002, $2V = 45$–$46°$, $Y//b$, $Z \wedge c = 20°(?)$, elongation$//b$.

(1) R. O. Roblin, *et al.*, THIS JOURNAL, **62**, 2002 (1940), found 255–256° with decomposition; they found the solubility to be 0.0123 g./100 cc.

NEW COMPOUNDS

Certain Naphthylidene Sulfanilamide Derivatives

The procedures employed for the preparation of the following compounds were modifications of methods used in the preparation of the aniline derivatives of the sulfonated α- and β-naphthoquinones.[1,2] To conform with *Chemical Abstracts* the nomenclature of these compounds was suggested by Dr. Austin M. Patterson.

N^4-(3-Hydroxy-4-oxo-1(4)-naphthylidene)-sulfanilamide.—A solution of 8.6 g. of sulfanilamide (Eastman Kodak Co.) in 200 cc. of water at 60–65° was added with stirring to a solution of 13.0 g. of 1,2-naphthoquinone-4-sodium sulfonate (Eastman purified by the method of Folin[3]) in 300 cc. of water at 45–50°. The reaction mixture after standing for fifteen minutes at room temperature was kept in the ice box overnight. The reddish orange precipitate was filtered off, washed with water and dried in a vacuum desiccator over sulfuric acid; yield, 9.9 g. (60%). The compound melted at 271–273° (uncor.). It is insoluble in cold water, very difficultly soluble in hot water, very soluble in alkali, formic acid, slightly soluble in hydrochloric acid, alcohol, dioxane and acetone.

Anal. Calcd. for $C_{16}H_{12}O_4SN_2$: N, 8.53. Found: N, 8.41.

N^4-(3-Hydroxy-4-oxo-7-sulfo-1(4)-naphthylidene)-sulfanilamide, Sodium Salt.—To a solution containing 2.7 g. of 1,2-naphthoquinone-4,6-sodium disulfonate[1] in 75 cc. of water, 1.7 g. of sulfanilamide was added. The mixture was stirred mechanically until all the solid went into solution. This required fifteen minutes. Then 1.5 cc. of superoxol was added and stirring continued for an additional ten minutes. The deep red-brown solution was clarified with a small amount of Merck activated charcoal to remove the brown impurity. Upon addition of 10 g. of powdered sodium chloride the solution became a thick paste in a few minutes. After cooling in the ice box for two hours, the dark red needles were filtered off and dried in a vacuum desiccator over sulfuric acid. The weight of the crude material (contaminated with sodium chloride) was 4.6 g. It was recrystallized by solution in 50 cc. of water at 60° and subsequent chilling. The crystalline compound was filtered off, washed with ice-cold water, ice-cold 95% alcohol, ether and dried in a vacuum desiccator over sulfuric acid; yield, 2.2 g. (41%).

Anal. Calcd. for $C_{16}H_{11}O_7S_2N_2Na$: N, 6.50. Found: N, 6.51.

N^4-[4-Oxo-3-(*p*-sulfamylanilino)-2-sulfo-1(4)-naphthylidene]-sulfanilamide.—A solution of 1.7 g. of sulfanilamide in 100 cc. of water at 80° was added with stirring to a solution of 1.6 g. of 1,4-naphthoquinone-2-potassium sulfonate[4] in 50 cc. of water at 55°. As soon as the temperature of the mixture reached 50°, a small amount of yellow orange crystals (not identified) separated. These were filtered off by suction and discarded. To the filtrate at 30° was added 1 cc. of concentrated hydrochloric acid and the reaction mixture cooled in the ice box for three hours. The bright red needles that separated were filtered off, washed with cold water and dried in a vacuum desiccator over sulfuric acid; yield, 1.4 g. (50%). The material was recrystallized from 40 cc. of boiling water. It is fairly soluble in hot water. Dried in a vacuum desic-

Some Diamino Peptides

Dimethylamine reacted with *p*-nitro-β-bromopropionanilide to form *p*-nitro-β-dimethylaminopropionanilide, m. p. of the hydrochloride, 200–201°. A portion of this was transformed into the methochloride and both substances were reduced catalytically in alcohol containing hydrogen chloride to give, respectively, *p*-amino-β-dimethylaminopropionanilide dihydrochloride (I), colorless felted needles, m. p. 218–219°, and *p*-amino-β-dimethylaminopropionanilide methochloride hydrochloride (II), hygroscopic crystals, m. p. 211–212°.

N,N-Diethylethylenediamine,[1] prepared by the reduction (sodium and alcohol) of diethylglycine nitrile, reacted with *p*-nitrobenzoyl chloride, forming β-[*p*-nitrobenzoylamidoethyl]-diethylamine hydrochloride, colorless needles melting at 164–5°. This substance and its ethochloride were reduced catalytically in alcoholic hydrogen chloride to β-[*p*-aminobenzoylamidoethyl]-diethylamine dihydrochloride (III), m. p. 176.5–178°, and to β-[*p*-aminobenzoylamidoethyl]-triethylammonium chloride, hydrochloride (IV), which forms stubby prisms melting at 228°.

Reduction of β-dimethylaminopropionitrile gave γ-dimethylaminopropylamine, m. p. of the dihydrochloride, 182–184° The base reacted with *p*-nitrobenzoyl chloride to form γ-[*p*-nitrobenzoylamidopropyl]-dimethylamine hydrochloride, m. p. 190–192°. This was reduced catalytically in alcoholic hydrogen chloride solution to γ-[*p*-aminobenzoylamidopropyl]-dimethylamine dihydrochloride (V), m. p. 184–185°.

Reduction of the *p*-nitrophenylurethan of β-hydroxyethyltriethylammonium chloride yielded β-[*p*-aminophenylcarbamatoethyl]-triethylammonium chloride, hydrochloride (VI), which forms irregular prisms melting at 138–139°.

By the reduction of β-[*p*-nitrobenzoyloxyethyl]-triethylammonium chloride, there was obtained β-[*p*-aminobenzoyloxyethyl]-triethylammonium chloride, hydrochloride (VII), m. p. 214–215°. This has been reported[2] previously, but the synthesis used was not free from ambiguity.

The salts described here were crystallized from absolute alcohol or from alcohol–ethyl acetate mixtures. The analytical data are in the table.

Some New Quaternary Salts

Methylaniline and octadecyl iodide reacted to yield methyloctadecylaniline, a yellow oil, b. p. (3 mm.), 234°. This was treated in benzene solution with methyl iodide forming octadecylphenyldimethylammonium iodide which crystallized in leaflets from ethyl acetate.

Cyclohexylethylamine (prepared from cyclohexylacetic acid by the sequence: acid → acid chloride → amide → nitrile → amine) was methylated by the Clarke–Eschweiler method. The resulting tertiary amine reacted with benzyl chloride in ether to give cyclohexylethylbenzyldimethylammonium chloride.

Benzyl-β-bromoethyldimethylammonium bromide was prepared from benzyldimethylamine and ethylene bromide.

Triethylamine and α-menaphthyl chloride (α-naphthylmethyl chloride) yielded α-menaphthyltriethylammonium chloride. Data on these substances are presented in the subjoined table.

Some Mono- and Disubstituted Guanidines

The guanidines here described were all prepared by conventional methods. The S-methyl-isothiourea sulfate method (generally applicable with amines of moderate strength and water solubility) was used to prepare the five following: β-[N-morpholinoethyl]-guanidine sulfate (from aminoethylmorpholine), β,β-diethoxyethylguanidine sulfate (from amino acetal), N,N-dicyclohexylguanidine sulfate (from dicyclohexylamine), N-benzyl-N-methylguanidine sulfate (from benzylmethylamine) and δ-phenoxybutylguanidine sulfate (from δ-phenoxybutylamine prepared by reduction of γ-phenoxybutyronitrile). In all these cases the salt was isolated by evaporation of the reaction mixture

(1) Ristenpart, *Ber.*, **29**, 2526 (1896).
(2) Einhorn and Uhlfelder, *Ann.*, **371**, 138 (1909).

and crystallized from mixtures of polar and non-polar solvents. Diethoxyethylguanidine sulfate crystallized best from *n*-butanol–ethyl acetate. The others were crystallized from alcohol–ether.

N-Benzyl-N-α-naphthylguanidine Hydrochloride.—Benzyl-α-naphthylamine was refluxed in amyl alcohol with 1 mol of cyanamide and 1.2 mols of hydrogen chloride. On cooling, ether was added and the hydrochlorides separated as a purple sirup. Attempts to crystallize having failed, the mixture was dissolved in water and ammonia added. Some unreacted benzylnaphthylamine separated together with most of the color. The aqueous layer was then basified with sodium hydroxide and the precipitated guanidine taken into ether. After drying over potassium carbonate, alcoholic hydrogen chloride was added. The salt was recrystallized from alcohol–ether mixtures.

N,N′-Dihomoanisylguanidine Hydrochloride.—To a solution of 2 mols of homoanisylamine in absolute ether was added, with shaking and ice-cooling, a solution of 1 mol of cyanogen bromide in ether. After standing one-half hour the ether was evaporated by a stream of dry air, a little absolute alcohol added to homogenize the mixture and the whole was heated three hours in an oil-bath at 150°. The material was then dissolved in water, the base liberated with alkali, and extracted with ether. On drying over potassium carbonate a crystalline solid appeared on the surface of the drying agent. The ether was decanted off, the solid dissolved in chloroform and transformed into the hydrochloride by alcoholic hydrogen chloride. It was recrystallized from alcohol–ether, forming lustrous plates.

N-Methyl-N′-α-naphthylguanidine.—Methylamine and α-naphthylisothiocyanate yielded N,N′-methylnaphthylthiourea. Methylation with methyl sulfate gave the S-methyl derivative which was desulfurized in the usual manner with lead oxide and ammonia.

Data on these compounds are presented in the table.

Some Quaternary Salts from β-Dimethylamino-β′-cymoxydiethyl Ether

A concentrated aqueous solution of sodium thymolate or sodium *p*-chlorothymolate was heated under reflux with β,β′-dichlorodiethyl ether. After separation of the aqueous layer, unreacted dichlorodiethyl ether was removed *in vacuo*, and the residue was heated for seven hours at 145° (*p* = *ca.* 150 lb.) in a glass-lined bomb with 33% methanolic dimethylamine. After removal of volatile materials on the steam-bath under diminished pressure, the residual tertiary amines were partially purified by solution in acid and extraction with ether; on liberation with alkali, they were obtained as oils which could not be distilled *in vacuo*, but were converted directly into quaternary salts by warming on the steam-bath with the appropriate halides. The salts crystallized from acetone or alcohol on addition of ether.

N,N-Dimethylethylenediamine and Some Derivatives

The readily available dimethyl glycine nitrile[1] can be reduced by sodium and absolute alcohol to give N,N-dimethylethylenediamine. This is a colorless liquid boiling, when anhydrous, at 107°. As its dehydration is difficult and its dihydrochloride (melting around 160°) is also hygroscopic, it is better characterized through a derivative. The following compounds were prepared as outlined, nitro derivatives being reduced with Adams catalyst in alcoholic solution containing hydrogen chloride. β-[*p*-Nitrobenzoylamidoethyl] dimethylamine hydrochloride (I), formed from *p*-nitrobenzoyl chloride and the diamine, was hydrogenated catalytically yielding β-[*p*-aminobenzoylamidoethyl]-dimethylamine dihydrochloride (II). The methochloride of I was reduced to β-[*p*-amino-

(1) v. Braun, *Ber.*, **40**, 3937 (1907).

benzoylamidoethyl]-trimethylammonium chloride, hydrochloride (III).

The diamine reacted with *p*-nitrophenyl isocyanate to give β-[*p*-nitrophenylureidoethyl]-dimethylamine; m. p. of the hydrochloride, 247–248.5°. From this were obtained β-[*p*-aminophenylureidoethyl]-dimethylamine dihydrochloride (IV) and the corresponding trimethylammonium chloride, hydrochloride (V). The diamine with *p*-nitrophenylacetyl chloride gave the *p*-nitrophenylacetamide, m. p. of the hydrochloride, 190–192.5°, and reduction of this yielded β-[*p*-aminophenylacetamidoethyl]-dimethylamine dihydrochloride (VI). Reduction of the methochloride of the nitro compound gave β-[*p*-aminophenylacetamidoethyl]-trimethylammonium chloride hydrochloride (VII).

With phenyl isothiocyanate the diamine formed N-phenyl-N′-β-dimethylaminoethyl thiourea (VIII) and with *p*-acetamidobenzenesulfonyl chloride it formed the *p*-acetamidobenzenesulfonamide which was hydrolyzed with hydrochloric acid to β-[*p*-aminophenylsulfonamidoethyl]-dimethylamine dihydrochloride (IX). The thiourea was crystallized from benzene–hexane; the hydrochlorides from absolute alcohol.

Some N-Substituted Barbituric Acids

The subjoined table contains data on five new compounds of this type. 1-*p*-Nitrophenyl-5-*i*-butyl-5-ethyl barbituric acid was obtained by nitration[1] of 1-phenyl-5-*i*-butyl-5-ethyl barbituric acid[2] and in turn was reduced catalytically[1] to the *p*-amino derivative. The other three substances were prepared by the conventional method from the corresponding ureas and malonic esters. All crystallized in colorless prisms, the 1-*n*-hexyl derivative from hexane, the others from alcohol.

Some Quaternary Salts Containing Aryloxyethyl and Aryloxypropyl Groups

A number of salts of the two types

$$[p\text{-}ClC_{10}H_{12}O(CH_2)_nN^+Me_2R]Y^- \quad I$$

$$(p\text{-}ClC_{12}H_{16}O)NC_5H_5Br \quad II$$

have been prepared by the following general procedure. Thymol and *p*-chlorothymol, reacting as the sodium salts with ethylene and trimethylene bromohydrins, gave ether alcohols which were transformed into bromides by phosphorus tribromide in the usual manner and the bromides were allowed to react with dimethylamine in methanol at 120–125°. The resulting tertiary amines on treatment with appropriate alkyl halides produced the quaternary salts of type I. As a variant chlorocymoxyethyl bromide was allowed to act on pyridine and 2,4-dimethylthiazole, yielding the members of type II. The quaternary salts were purified by crystallization from absolute alcohol with addition of ether or ethyl acetate.

Basic Indium Salicylates

Insoluble basic indium salicylate analogous to the basic indium salts reported for a number of organic acids[1] results from the interaction of indium salt solutions with those of soluble salicylates.

Basic Indium Salicylate Tri-hydrate.—To 2.0000 g. of anhydrous indium sulfate dissolved in 50 ml. of water was added 25 ml. of a solution containing 4.5553 g. of sodium salicylate (mole ratio of 1 to 3). The resulting finely divided white precipitate was removed by filtration, washed until sulfate and sodium free, and air dried by suction. The product consists of microcrystalline needles which are very slightly soluble in water, ethanol and methanol, insoluble in benzene and toluene, but readily soluble in hot dilute acids. On ignition, the solid chars and is converted quantitatively to indium oxide. Prolonged drying at 110° yields the anhydrous compound.

Anal. Calcd. for $In(C_7H_5O_3)_2OH\cdot 3H_2O$: In, 24.95. Found: In (by ignition), 24.83.

Anhydrous Basic Indium Salicylate.—Two grams of the trihydrate was dehydrated by boiling with absolute methanol. The residue was washed successively with methanol and ether and dried for one hour at 110°. In appearance and behavior it resembles the hydrate.

Anal. Calcd. for $In(C_7H_5O_3)_2OH$: In, 28.27; salicylate, 67.54. Found: In, 28.23; salicylate (bromate titration), 67.64.

COMMUNICATIONS TO THE EDITOR

ON THE CHEMICAL BEHAVIOR OF CAFESTEROL

Sir:

In view of the recent publication of Wettstein, *et al.* [*Helv. Chim. Acta*, **24**, 332E (1941)], which we have just received, it appears desirable to record some of our observations in this field. The existence of a benzenoid ring in cafesterol, as suggested by Slotta and Neisser [*Ber.*, **71**, 2342 (1938)], is highly improbable, since nitric acid oxidation of this compound gives neither benzene tetra- or dicarboxylic acid; from the reaction mixture was obtained only a non-acidic substance, apparently a nitro derivative, m. p. 220–230°. Cafesterol possesses a highly reactive conjugated double bond system in one ring, a fact shown by the formation of the maleic anhydride adduct (m. p. 185–192°), in benzene solution at room temperature or on *gentle* warming. Boiling such a solution promptly causes decomposition. In absolute alcoholic solution cafesterol takes up two moles of hydrogen in presence of palladized charcoal (20% Pd) giving a tetrahydro derivative, m. p. 153–155°, acetate 150–152°. Neither this tetrahydrocafesterol nor its acetate gives any coloration with concentrated hydrochloric acid, while cafesterol in alcoholic solution gives an intense blue to blue-green color reaction with this reagent (Slotta and Neisser). Contrary to the observations of Wettstein, *et al.*, and Slotta and Neisser, on treatment with sodium and alcohol (or amyl alcohol), cafesterol gives a new product, m. p. 153–156°, acetate 162–165°. Despite similar melting points, the difference of this product from cafesterol is shown by the fact that with concentrated hydrochloric acid, its alcoholic solution gives a purple coloration which *does not turn blue even on boiling*. Its acetate on the other hand gives a yellow to orange coloration with the same reagent. Sodium–alcohol treatment does not appear to affect the conjugated double bond system, because the acetate of the product gives a maleic anhydride adduct, m. p. 185°. The adduct gives no coloration with hydrochloric acid at room temperature.

A detailed report will be published at a later date.

DERIVATIVES OF ESTRONE CONTAINING OXYGEN AT POSITION 16

Sir:

The interesting hypothesis, recently advanced by Marrian,[1] that 16-ketoestrone is an estrogen metabolite in the human, leads to the speculation that estriol (theelol) may be formed from estrone by the reduction of 16-ketoestrone. If such a reduction occurs, it is logical to assume that 16-hydroxyestrone may also lie on this metabolic pathway as an intermediate between the dione and glycol forms. In the reduction of 16-ketoestrone, two stereoisomeric 16-hydroxyestrones and four stereoisomeric estriols are theoretically possible. The question also arises whether or not a compound in this series may be regarded as an abnormal estrogen metabolite, which might conceivably play a role in the etiology of carcinoma of the uterus and of the mammary gland.

We have succeeded in preparing (i) the methyl ether of 16-ketoestrone, (ii) a compound believed to be one of the two epimeric 16-hydroxyestrones, and (iii) an estriol which is isomeric with the naturally-occurring theelol.

Estrone was converted to the 16-isonitroso derivative by the method of Litvan and Robinson,[2] and this derivative on reduction with zinc and acetic acid[3] yielded a mixture of α-ketols, from which there was isolated in pure form a compound which is probably a 16-hydroxyestrone (m. p. 234–237°; $[\alpha]^{29.5}D$ −102° in ethanol). This compound was characterized by the following derivatives: oxime (m. p. 222.5–223°), monobenzoate (m. p. 241.5–243.5°), methyl ether (m. p. 174–177°), and oxime of the methyl ether (m. p. 175–177°).

Reduction of a similar α-ketol mixture with hydrogen and Adams catalyst yielded a mixture of estriols, one of the components of which proved to be an isomer of theelol. The isomer of estriol obtained has m. p. of 267–269° and $[\alpha]^{29.5}D$ +88° (in ethanol). A mixed melting point with theelol shows a depression of 10°. It gives a methyl ether melting at 141–142° and a triacetate melting at 152°.

(1) Marrian, *Bul. New York Acad. Med.*, **15**, 27 (1939).
(2) Litvan and Robinson, *J. Chem. Soc.*, 1997 (1938).
(3) Stodola, Kendall and McKenzie, *J. Org. Chem.*, **6**, 841 (1941).

Oxidation with copper acetate of the mixture of α-ketols obtained from estrone methyl ether gave 16-ketoestrone methyl ether, obtained as flat needles, orange in color (m. p. 176–178°). It gives a dioxime (m. p. 230°) identical with that prepared by oximating 16-isonitrosoestrone methyl ether. The dione gives an intense violet color with concentrated sulfuric acid.

The dioxime of 16-ketoestrone (free phenol) was also prepared in the hope that this derivative might be useful in detecting the dione in tissue or fluid, should it be present as predicted by Marrian. 16-Ketoestrone dioxime (m. p. 230–231°) gives no colored complex with nickelous or cobaltous ions, but produces a yellowish-green solution with alcoholic copper acetate. The copper complex may be extracted with chloroform, and the color intensity is such that the eye can detect it at the level of 10 γ per cc.

The melting points listed above are uncorrected.

We are now attempting to prepare the other isomeric 16-hydroxyestrone and the remaining two isomeric estriols.

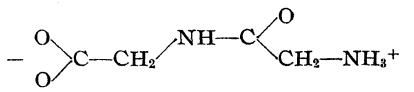
THE CRYSTAL STRUCTURE OF β-GLYCYLGLYCINE

Sir:

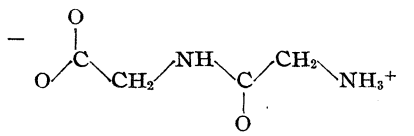
Some time ago the determination of the crystal structure of glycylglycine was undertaken as a continuation of the X-ray diffraction studies[1] which are a part of a program of research upon the constitution and configuration of proteins. This determination, the first concerned with a linear peptide, was stopped last year because of the war, and in view of the uncertainty of completing the work the results at hand are briefly described in this letter.

The crystals were grown from aqueous *n*-propyl alcohol and all three modifications described by Bernal[2] were eventually obtained, although not simultaneously as in his crystallization. Because of the shortness of the *b* axis the needle-like beta form was selected for investigation. Using Cu Kα rays complete sets of oscillation pictures were prepared about *a* and *b* and some oscillations were made about *c* to confirm the length of that axis. Weissenberg pictures of the [010] zone were made for intensity comparisons. The cell has a = 17.89 Å., b = 4.62 Å. and c = 17.06 Å., with β = 125°10′, and contains eight molecules. This *c* is twice that given by Bernal and the space-group instead of $P2_1/a$ as given by him, is either A*a* or A2/*a*. The latter was tentatively assumed and present results indicate it is probably correct.

A Patterson projection parallel to *b* yielded preliminary *x* and *z* parameters. The configurations I, suggested by Bernal, and II were tried, and it was found that only with II could the projection be interpreted. The parameters were



I



II

improved by Fourier projections and least squares,[3] the latter to resolve CO groups not resolved in the projections. The present agreement between calculated and observed intensities in this zone is good, but minor discrepancies indicate that there may be a few errors in signs or that the contributions from hydrogen atoms should be considered. A tentative set of *y* parameters has also been selected so as to yield reasonable interatomic distances both within and between molecules and these give qualitative agreement between calculated and observed intensities in the [100] zone.

Because of the approximate nature of the parameters, particularly the *y*'s, there is no point in listing interatomic distances. The chief results are first, that the configuration is that of II with the molecule coplanar within present errors except for the terminal nitrogen atom, which lies out of the plane by several tenths of an ångström, and, second, that the zwitterion form is correct. The terminal nitrogen is surrounded at the usual N–H $\cdots$O distance by three oxygen atoms of other molecules, two carboxyl and one carbonyl. All the indicated hydrogen bond angles about the nitrogen are tetrahedral to within 10°. The imino nitrogen is also forming a hydrogen bond to a carboxyl oxygen of a neighboring molecule.

NEW BOOKS

Thorpe's Dictionary of Applied Chemistry. By JOCELYN FIELD THORPE and M. A. WHITELEY, Assisted by Eminent Contributors. Fourth Edition (Revised and Enlarged), Vol. V, FEH.-Glass, including an Abridged Index to Volumes I-V of the New Edition. Longmans, Green and Company, Inc., 55 Fifth Avenue, New York, N. Y., 1942. xxiii + 610 pp. With illustrations. 15.5 × 23 cm. Price, $25.00.

The earlier volumes of this Fourth Edition have already been reviewed in THIS JOURNAL (**59,** 2477; **61,** 222; **62,** 237; **63,** 884). This fifth volume of 609 pages covers a part of the alphabet which required 275 pages in the earlier edition. The new edition is almost completely rewritten. There has been a noticeable deterioration in the quality of the paper which is far from uniform in color and texture in the different parts of the book. But there has been no deterioration in the quality of the text. This excellent book has been issued promptly in spite of difficulties modestly described, "When, owing to war conditions, the work of the Dictionary could no longer be carried on in London it was transferred to the University Chemical Laboratory, Cambridge." Another obstacle was the death of the Editor-in-Chief, Sir Jocelyn Thorpe, which occurred on June 10, 1940, the day of publication of Volume IV of the Dictionary. M. A. Whiteley, formerly Associate Editor, has had the editorial responsibility for the completion of this volume, which, however, was well advanced at the time of the death of Sir Jocelyn Thorpe. It is a pleasure to express appreciation and admiration for the typically British determination to carry on successfully in spite of hindrances which would stop many a less resolute people.

GRINNELL JONES

Liebig and after Liebig. A Century of Progress in Agricultural Chemistry. Publication of the American Association for the Advancement of Science, No. 16. Publication Committee: CHARLES A. BROWNE, Chairman, RICHARD BRADFIELD, HUBERT B. VICKERY. Edited by FOREST RAY MOULTON. American Association for the Advancement of Science, Smithsonian Institution Building, Washington, D. C., 1942. 111 pp. 19.5 × 26.5 cm.

The ten papers which make up this volume constitute a well-integrated account of the announced subject of the book, namely, of a century of progress in agricultural chemistry. The Introduction by Charles A. Browne on "Justus von Liebig—Man and Teacher" is followed by Section I, "Organic Chemistry, Enzymes and Nutrition," which contains four papers, "Liebig's Influence in the Promotion of Agricultural Chemical Research" by Henry R. Kraybill, "Liebig and the Chemistry of Proteins" by Hubert B. Vickery, "Liebig and the Chemistry of Enzymes and Fermentation" by Arnold K. Ball, and "Liebig and the Chemistry of Animal Nutrition" by Paul E. Howe, and Section II, "Soils, Fertilizers and the Mineral Requirements of Plants," which contains five papers, "Liebig and the Chemistry of the Soil" by Richard Bradfield, "Liebig—The Humus Theory and the Rôle of Humus in Plant Nutrition" by Selman A. Waksman, "Liebig and the Chemistry of Mineral Fertilizers" by Harry A. Curtis, Liebig and the Law of the Minimum" by Charles A. Browne, and "Liebig and the Mineral Requirements of Plants as Indicated by Means of Solution Cultures" by Burton Livingston. For the chemist who is not familiar with the subject of agricultural chemistry, the book will supply an interesting introduction to it, a general account of the field and of the manner in which it has been cultivated and made to fructify. It is a book which is not by any means to be reserved for the library of the specialist.

The book is clearly printed, two columns to the page, and is fully documented. It is illustrated with five pictures and ten diagrams.

TENNEY L. DAVIS

The Amphoteric Properties of Proteins. Vol. XLI, Art. 4 of the Annals of the New York Academy of Sciences. By R. Keith Cannon, A. Kibrick, John G. Kirkwood, L. G. Longsworth, A. H. Palmer and Jacinto Steinhardt. The New York Academy of Sciences, care of the American Museum of Natural History, New York, N. Y. 87 pp. Price $1.25. This monograph is one of several, which if purchased as a set, may be had at a reduced price.

This contribution to protein literature consists of a series of papers presented at a recent symposium sponsored by the New York Academy of Sciences. It conforms to the usual high standards of other symposia sponsored by this Academy.

The first paper of the series, titled "The Amphoteric Properties of Egg Albumin," by Cannon, Kibrick and Palmer "is devoted to a discussion of the contribution

which electrode titrations may make to the quantitative definition of the amphoteric properties of a protein." A considerable body of data showing the effect of the protein concentration, temperature, ionic strength, and nature of the added ions upon the titration curve of acid or base bound *vs.* *p*H is presented for egg albumin solutions. The discussion of these results correlates the observed titration curves with those estimated on the basis of amino-acid composition studies. In the studies of the effect of added electrolyte, it is found that the slopes of the titration curves vary with ionic strength but are nearly independent of the nature of the ions present, while the isoionic point depends upon both the nature and concentration of the ions present. These empirical results are considered in terms of the Linderstrøm-Lang electrostatic theory, and may be quantitatively reconciled only if certain empirical corrections are applied.

Longsworth's contribution, "The Influence of *p*H on the Mobility and Diffusion of Ovalbumin" attempts a correlation of mobilities with other physical properties. He presents mobility and diffusion constant measurements over a wide *p*H range of from 1.8 to 12.8. All buffers used were monovalent, and of 0.1 ionic strength. Protein concentrations were about one-half per cent. These values are compared with net charges as estimated from the titration data of Cannon, Kibrick and Palmer. A study of the ratio of charge (as estimated from titration measurements) to mobility showed that this quantity "is sufficiently constant to warrant the conclusion that, except for minor secondary effects, the mobility of ovalbumin is proportional to the number of equivalents of acid bound by the protein at constant ionic strength at any *p*H within its stability range." The observed value for this ratio does not agree with that computed from the measured frictional coefficient and molecular weight, however, and this discrepancy is discussed. Dr. Longsworth's paper also contains a rather detailed discussion of certain problems relating to the computation of mobilities from electrophoretic patterns.

The paper of Steinhardt on "Participation of Anions in the Combination of Proteins with Acids" describes an extensive study of "the combination of wool with nineteen different acids," and attempts to "establish a quantitative measure of the relative affinities of the anions of various strong acids for proteins on the basis of a small number of measurements of acid combined and *p*H." Steinhardt points out that certain advantages gained by using a protein such as wool keratin, makes possible the analysis of the specific anion effects. A variation in affinity of several thousand fold in going from hydrochloric acid to picric and flavianic acids is postulated. Data showing a similar variation of affinities computed from measurements upon egg albumin solution are also given, although these data are of considerably less quantitative nature. The nature of these protein–anion combinations and other possible significance is also discussed.

A final paper by Kirkwood, "Acid–Base Equilibrium in Solutions of Ampholytes," outlines methods and presents tables which make possible the calculation of the charge separation, or dipole moment, of dipolar ions from measurements of ΔpK, defined as $\log_{10} K_2^0/K_2$ where K_2^0 and K_2 are the acid ionization equilibrium constants for the ionization of HZ^{0+} and HZ, respectively. Here Z^0 and Z^- differ in structure only by the negative charge. Charge separations are presented for some seven amino acids and peptides, using NH_3^+-$RCOO^-$ for HZ and NH_3^+-$RCOO$-CH_3 for HZ^{0+}. Extensions of these simple relations to models containing arbitrary numbers of acidic and basic groups are presented.

Condensations by Sodium. XXI. *n*-Octyl- and *n*-Decylsodium

BY AVERY A. MORTON, JOHN B. DAVIDSON AND ROBERT J. BEST

Propyl, butyl and amyl chlorides, condensed with sodium in petroleum ether, produce, respectively, some 10, 14 and 57% of total acids, the ratios of malonic to monobasic acids being 1.5, 1.3 and 0.3, and form alkylbenzenes to the extent of 43, 70 and 61%.[1] We have now carried out similar condensations with octyl and decyl chlorides, following the usual procedure.

***n*-Octylsodium (J. D.).**—The conventional[2] apparatus and process were used with 25 ml. (0.15 mole) of *n*-octyl chloride and 15 g. (0.65 g. atom) of fine sodium sand in 635 ml. of petroleum ether at −10°. Carbonation by bubbling carbon dioxide below the surface gave yields of pelargonic acid, *n*-heptylmalonic and *n*-hexadecane of 49% (11.7 g.), 15% (2.3 g.) and 7% (1.2 g.), respectively; while allowing it to drift over the surface of the mixture, following Gilman and Pacevitz,[3] gave corresponding yields of 23, 26 and 6%, respectively. Separation of the mono- and di-carboxylic acids in these experiments could not be effected in the usual manner because the malonic acid was soluble in petroleum ether, particularly in the presence of the mono acid. The fatty acid was, therefore, steam-distilled and identified as pelargonic acid by its boiling point 250° (uncor.) (lit.[4] 254°) and its *b*-bromophenacyl ester melting at 65.0–66.2° (lit.[5] 68.5°). The heptylmalonic acid was identified by its melting point 94.8–95.2° (uncor.) (lit.[6] 96.5–98°) and by its neutralization value.

The pink-colored octylsodium product in suspension in petroleum ether was centrifuged, the clear supernatant liquid separated and carbonated, but no acid was recovered after acidification and extraction with ether.

Nonylbenzene (J. D.).—To 16 g. of sodium, suspended with stirring in 200 ml. of sulfur-free toluene at 72°, 25 ml. of alkyl chloride was added dropwise over a one-hour period. There was obtained 7.7 g. of nonylbenzene (51%); b. p. 280–281°; α^{20} 1.485, which gave a *p*-sulfonamide derivative, m. p. 94.5–95°.[7]

***n*-Decylsodium (R. B.).**—Under the same conditions as above, the yield of undecylic acid was 28.4%; that of nonylmalonic acid was 2.3%. The melting points of the undecylic acid and of its *p*-bromophenacyl derivatives were 29.5° and 68.1°, respectively.[8] The melting point of the nonylmalonic acid was 100.5–102.0° (uncor.); temperature of decarboxylation, 140°. It was only slightly soluble in water, very soluble in ether, neutralization equivalent, 116 (calcd. 115). One hour at 160° converted it to undecylic acid.

Undecylbenzene (R. B.).—To 15 g. of sodium in 500 ml. of sulfur-free toluene 60 g. of decyl chloride was added as above. There was obtained 25.3 g. (74%) of undecyl benzene; b. p. 296 ± 1°; α^{20} 1.4824; mol. wt. by the Rast method 235, calculated 232; and *p*-sulfonamide derivative, m. p. 95.7–96.2.

Anal. Calcd. for $C_{17}H_{29}O_2NS$: N, 4.5. Found: N, 4.6 and 4.7.

Attempted Alkylation of Benzene and Anisole (J.D.).—The quantities and procedure for addition of octyl chloride to toluene, but with replacement of the toluene by benzene or anisole, gave after carbonating only 0.2 g. of liquid boiling within the range for octylbenzene. The products from benzene: 11.7 g. (68%) of octane, 6.2 g. (33%) of benzoic acid and 130 mg. of triphenylcarbinol; from anisole, 6.5 g. of phenol and 1.1 g. of an impure yellow acid.

Discussion.—These results show that *n*-octyl- and *n*-decylsodium are formed in about the same quantities and have about the same properties

as amylsodium.[1] The major differences between these chlorides and the lower members of the series are the greater tendency of the reaction mixtures to gel and the occurrence of a pink to gray-white color in place of a blue during the condensation. No evidence could be found of any true solution of these substances in petroleum ether.

Summary

n-Octylsodium and *n*-decylsodium have been prepared by condensation in petroleum ether. The yields and properties were similar to those observed with amylsodium rather than with propyl- or butylsodium.

Condensations by Sodium. XXII. The General Theory of the Wurtz Reaction. The Initial Step

BY AVERY A. MORTON, JOHN B. DAVIDSON AND HERBERT A. NEWEY

This and the following communication record results of a critical inquiry into the mechanism of the Wurtz reaction, particularly as regards the issue of a free radical *vs.* an organometallic intermediate. The latter is deemed adequate. This first paper will show that there is no need for assuming existence of a free radical prior to formation of this organo-sodium compound; the second will show there is no need afterward. The contention that the organometallic intermediate can be regarded as the sole necessary first product will be based on the facts that (a) there is only one organosodium compound formed, and (b) it is formed in essentially quantitative yield. A view that the sodium metal serves as a trap for the free radical is judged unnecessary.

The Organosodium Compound.—The excellent work of Gilman and Pacevitz,[1] in which the organosodium compound was poured on solid carbon dioxide, has shown that there was one amyl radical for every combined sodium atom rather than a mixture of amylsodium and an "amylidene disodium" as previously assumed.[2] Their results have been confirmed in this Laboratory, not only with amylsodium, but also with butylsodium which has shown[3] a greater tendency to form a malonic acid under ordinary conditions of carbonation, *i. e.*, when passing carbon dioxide into the mixture. The result is important because it brings the mechanism of formation of alkylmalonic acids into line with that previously observed[4] for phenylmalonic acid, in that the dicarboxylic acid is a product of a secondary reaction according to the equation

$$RCH_2Na \xrightarrow{CO_2} RCH_2COONa \xrightarrow{RCH_2Na} RCH(Na)COONa \xrightarrow{CO_2} RCH(COONa)_2$$

It is of particular value to this discussion because it eliminates any necessity for assuming the intermediate free radical which accounted for the supposed disodium compound.

The Quantitative Yield.—The higher the yield of organosodium compound, the more obvious the two phases of the reaction. A good yield depends on (a) presence of excess sodium in a finely divided state, (b) absence of a protective coating on the metal and (c) an unreactive carbon–halogen bond.

The first requirement is met by adding the halide to the sodium which is as finely divided as possible and is being agitated vigorously. In earlier work[1] with amyl chloride and sodium, the conversion to an organosodium compound was 95% when one-fifth equivalent of chloride was added and was 63% when an equivalent had been used. We have now raised the final yield to 72% by improved agitation using a stirrer at 10,000 r. p. m. The trend is unmistakenly toward 100% yield.

The second requirement of no protective coating is best realized with a primary alkyl chloride. As seen under a microscope, a primary alkyl chloride produces an insoluble, colloidal, jelly-like mass that usually appears to be pushed out rapidly as a broad band from the interior of a small but seemingly inexhaustible particle of sodium. Characteristic shapes are drawn in Fig. 1. Occasional

(1) Gilman and Pacevitz, THIS JOURNAL, **62**, 1301 (1940).
(2) Morton and Richardson, *ibid.*, **62**, 123 (1940).

eruptions give evidence of a vigorous reaction and of the ability of the chloride to penetrate the colloidal mass rapidly and sustain the rate. In contrast to this ease of contact between halide and metal, the secondary chloride forms an apparently hard and impenetrable coating. No reaction is visible. This difference in the surface coatings probably explains the observations of Richards[5] who found the reaction of ethyl iodide with sodium first order with respect to ethyl iodide. He assumed the presence of a "high stationary radical concentration" and discarded a view that the rate was controlled by diffusion of the iodide to the sodium surface, because the reaction of isopropyl iodide progressed much more slowly than would have been predicted from changes in the diffusion rates. If the coating on the metal surface has not been exactly the same in each case, as indeed seems doubtful, the necessity for assuming a special concentration of free radicals would be obviated.

The third specification is that the carbon–halogen bond should be sufficiently firm that the alkyl halide will not react too rapidly with the organosodium product. Exact information on this matter is lacking because the subject of reactivity is interwoven with that of penetrability of the surface coatings. Highest yields of monosodium compounds have been obtained with primary alkyl chlorides and with chlorobenzene; moderate to poor results with secondary and tertiary chlorides, with alkyl bromides and iodides.

Our opinion is that high yields are obtained when the carbon–chlorine bond is so unreactive that the alkylsodium can be pushed some distance from the metal before undergoing any appreciable reaction; that poor yields are found when the carbon–chlorine bond is so labile that the initial alkylsodium product reacts in the immediate vicinity of the metal surface and thus forms an adhering layer of sodium chloride. This view does much to explain the long existing anomaly that halides which react most readily with water are least reactive with sodium.

Sodium Metal as a Trap.—The suggestion has been made[5] that the mode of addition and the excess metal used in these preparations serve to trap the free radical as fast as formed. If so, the trap is perfect and there is again no need for assuming a free radical. But it is difficult to believe that these ideal conditions serve merely as a trap for a radical which might otherwise be free. The smallest particles we have yet prepared vary from 0.08 to 0.2 mm. in diameter.[6] One drop of alkyl chloride is more than enough to cover the surface of all such metal one molecule thick. Since addition of drops is regular, it would be no time at all before the coating would be appreciable. Certainly, there is no visual evidence that the metal surface is bright and shiny after the first few drops of alkyl chloride have been added; nor is there evidence under the microscope that any part of the metal is exposed. It seems unreasonable to suppose, therefore, that the metal surface beneath the coating on small particles is any more ideal for trapping than is that beneath the surface of very large particles. In both cases this coating must be traversed before the chloride makes contact with the metal. The rate of this diffusion is, therefore, important. The advantage of the finely divided metal reaches only to the point of affording enough surface of this type that the first phase can compete favorably with the second phase for the alkyl halide; not to the point of offering an unlimited area. This view is supported by two earlier experiments[2]; amyl chloride was added to fine sodium sand in one case, and the same sized sand was added to amyl chloride in the second. The yield of decane was approximately the same in each case.

non whatever that requires or profits by assuming a free radical as a precursor of the organosodium compound. If any such radical exists the present methods of testing have not revealed it.

Experiments

Carbonation of *n*-Butylsodium (by H. N.).—The apparatus was similar to that used in previous work. Sodium sand, 35 g. (1.5 g. atoms), activated by 2 ml. of isoamyl alcohol while stirred in 200 ml. of petroleum ether, was treated with 31.5 ml. (0.3 mole) of *n*-butyl chloride added dropwise with an equal volume of petroleum ether at 18–20° over a period of one hour. After being stirred for an additional hour, the mixture was forced from the flask under pressure of nitrogen onto solid carbon dioxide. The yield of valeric acid was 42.2% (0.126 mole); that of propylmalonic acid was 3.3%.

Microscopic Examination of Coating Formed on Sodium (by J. D.).—A small quantity of fine sodium sand was placed in the cavity of a hanging-drop microscope slide which contained *n*-decane. A cover glass was then placed so as to nearly close the cavity. The tip of a specially built micro-pipet was then inserted in the opening and small quantities of alkyl chloride pushed into the cavity by slowly turning a screw device on the far end of the pipet. Observations were made with *n*-propyl, *n*-butyl, *n*-amyl, *n*-octyl, *n*-decyl, cetyl, and *s*-butyl chlorides.

Improved Conditions for Isolating the First Phase (by J. D.).—The apparatus was an improved model of the high-speed stirring equipment described in an earlier paper.[7] A weighed amount (11.5 g. (0.5 atom)) of sodium metal was put in the flask and 340 ml. of *n*-octane added. The mixture was then heated to 105° at which temperature the stirrer was operated at 10,000 r. p. m. until the metal was finely dispersed, after which the stirrer was stopped and the flask allowed to cool. The powder prepared by this method settled slowly and was the finest which so far has been obtained in this work. It required no activation by amyl alcohol.

n-Amyl chloride (30.2 ml. or 0.25 mole) diluted with 30 ml. of *n*-octane was added over a period of one hour during which time a bath of kerosene and solid carbon dioxide kept the temperature at 0°. After one additional hour of stirring (all at 10,000 r. p. m.) at this temperature, the reaction mixture was forced out of the container onto solid carbon dioxide by a pressure of nitrogen. The yield in two separate experiments was 71 and 72% total acids. The best yield previously obtained, using these proportions of reagents, was 63%. This improvement was realized in spite of adverse solvent conditions shown earlier[8] in this series.

Although these conditions are far better than any so far employed, they are still insufficient to give a high yield of organosodium compound from a secondary halide. Under comparable conditions, 2-chlorobutane and 2-chloropentane yielded 1.5 and 2.2% of acids, respectively.

(7) Morton and Knott, *Ind. Eng. Chem., Anal. Ed.*, **13**, 649 (1941).

Summary

The first phase of the Wurtz reaction is reasonably interpreted as the formation of an organosodium intermediate.

Conditions necessary for preparing this intermediate in quantitative yield are described.

Primary halides form a loose porous coating in the surface of sodium. Secondary halides form a comparatively impenetrable coating.

The difficulties in separating the first from the second phases of the Wurtz reaction are discussed.

The function of finely divided sodium sand does not appear to be that of a trap for a free radical.

Assumption of a free radical is unnecessary.

Condensations by Sodium. XXIII. The General Theory of the Wurtz Reaction. Part II. The Second Phase

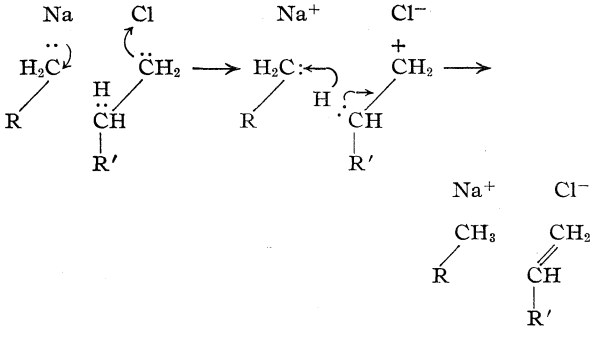
BY AVERY A. MORTON, JOHN B. DAVIDSON AND BARTON L. HAKAN

The previous paper[1] contained evidence that an organosodium compound could represent the first phase of the Wurtz reaction; this paper will show that the reactions of this intermediate with an alkyl or aryl chloride can constitute the concluding phase.

In the main the arguments for this thesis are: (1) disproportionation is a logical consequence of such a reaction; (2) polymerization proceeds according to a regular pattern and products are predictable with an organometallic theory. It is further indicated that the phenomenon of metal–halogen interchange tends to obscure primary processes. Fluctuations in the products of the Wurtz reaction are shown to have no simple explanation on a free radical basis. A critical discussion of certain analogies from which a free radical mechanism for the Wurtz reaction has been inferred is presented.

(1) Morton, Davidson and Newey, THIS JOURNAL, **64**, 2240 (1942).

Disproportionation.—Disproportionation has been so universally accepted as the criterion of a free radical that there has been no attempt to show a derivation from other molecular species.[1a] Nevertheless, a mechanism for this phenomenon by way of an organometallic intermediate appears exceptionally reasonable. If an alkylsodium meets an alkyl halide in such manner that the two alkyl chains are adjacent to each other while sodium halide is being formed, the two alkyl residues will have unlike charges and a proton will be drawn to the alkyl radical having the two unsaturated electrons. The reaction is merely the conventional prototropic change taking place between adjacent portions of two molecules whose inorganic components are effecting, or have just completed, a union.



If this view be accepted, the olefin produced must come from the alkyl halide rather than at random from both participant alkyl radicals. Though conclusions are to some extent obscured by a metal–halogen interchange (see later), all available facts unquestionably point to the correctness of this deduction. In reactions which involved octylsodium and various alkyl halides (Table I), the octane predominated over the octene in every instance.

In parallel studies with amylsodium (Table II) the quantity of pentane in all cases exceeded the amount of pentene.

TABLE I

PRODUCTS OF REACTION OF OCTYLSODIUM WITH ALKYL HALIDES

Halide	Per cent. yield of products: Octane	Octene	Hexadecane	Wurtz product
Ethyl iodide	15.2	8.8	27.9	18.8
Ethyl bromide (V)[a]	14.6	10.3	10.7	31.0
Ethyl bromide	20.1	0.4	11.1	31.4
Ethyl chloride (V)	35.1	0.2	...	10.8
Propyl iodide	16.6	5.5	15.3	13.6
Propyl bromide	20.9	11.0	...	7.8
Propyl chloride	28.6	15.3	...	...

[a] The letter V refers to the fact that the reaction mixture became very viscous.

TABLE II

PRODUCTS[a] OF REACTION OF AMYLSODIUM WITH ALKYL HALIDES

Group	Halide	Pentane, %	Pentene, %	Ratio of pentane to pentene	Decane, %	Wurtz product
1	Methyl iodide	22.3	2.0	11.1	58.4	0
2	*n*-Hexyl iodide	5.4	5.0	1.1	39.8	32.6
	Methyl bromide	7.1	4.9	1.5	44.4	13.1
	Ethyl iodide	8.2	5.7	1.4	30.9	2.1
	n-Butyl iodide	7.8	6.3	1.2	30.4	17.8
3	Ethyl bromide	12.3	8.5	1.4	15.1	24.2
	n-Butyl bromide	13.1	11.4	1.2	10.0	32.0
	n-Hexyl bromide	9.8	8.5	1.2	15.2	45.6
	n-Hexyl chloride	5.1	1.6	3.2	19.8	13.4
	n-Butyl chloride	7.4	2.8	2.7	6.4	8.8
4	Ethyl chloride	11.6	1.1	11.1	9.0	30.2
	Methyl chloride	15.2	1.0	15.2	6.3	43.7

[a] The arrangement is in the approximate order of decreasing decane content in order to illustrate an important point developed later in this discussion.

A third series (Table III) compares (a) reactions between two radicals (amyl and hexyl) in which the inorganic components were interchanged and (b) reactions of hexylsodium with amyl and octyl chlorides which represent radicals smaller and larger than hexyl. The distribution of alkanes and alkenes was again not at random.

TABLE III

PRODUCTS FROM REACTION OF AMYL, HEXYL AND OCTYL RADICALS

Reaction pair: RNa + R′Cl	Hexane, %	Hexene, %	Octane, %	Octene, %	Wurtz product, %
$C_5H_{11}Na + C_6H_{13}Cl$	9.5	11.5			24
$C_6H_{13}Na + C_5H_{11}Cl$	30.	7.7			23
$C_6H_{13}Na + C_8H_{17}Cl$	24.5	7	9.5	22.6	25

In these three series of experiments carried out under different conditions with widely different halides and various alkylsodium compounds, the products of disproportionation were uniformly proportioned according to the principle outlined above.

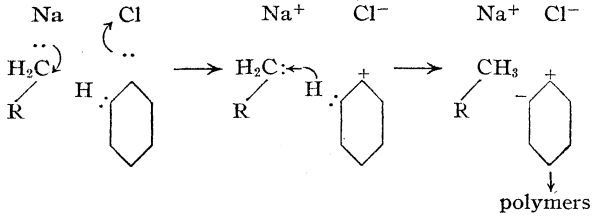
Polymerization.—A previous paper[2] recorded that the reaction of amylsodium with chlorobenzene produced more polymer than any other isolable product; that of phenylsodium with amyl chloride produced less polymer than any other

(1a) This statement was true at the time this article was submitted. Since then a paper by Whitmore and Zook has appeared (THIS JOURNAL, **64**, 1783 (1942)) in which the saturated and unsaturated products of disproportionation are credited as coming from the sodium alkyl and the alkyl chloride, respectively.

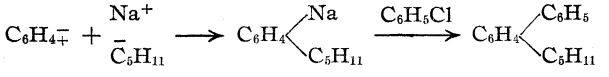
(2) Morton and Fallwell, *ibid.*, **60**, 1429 (1938).

fraction. The total quantity in the last case was about a fifth that obtained from the first pair of reactants.

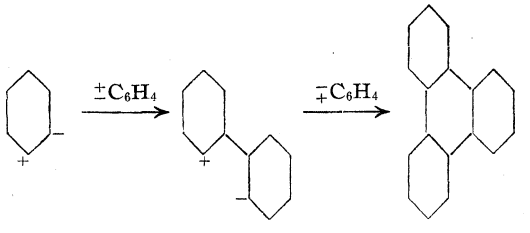
The organometallic mechanism affords an adequate explanation for this polymerization. The disproportionation process between amylsodium and chlorobenzene leads to a dipolar phenylene as shown



This intermediate dipolar compound cannot be stabilized by double bond formation and consequently undergoes further reaction with polar reagents. It may, for example, unite with more amylsodium giving a new organosodium compound which then reacts with more chlorobenzene according to a general scheme outlined



It may also condense with itself. The dimer would be a new dipolar intermediate which could react with more organosodium compound. The trimer could be the stable triphenylene. More complex products are obviously possible



In any event, ortho substituted products should predominate, and the polymer should be composed of more radical from the halide than from the organosodium reagent. These conclusions are supported by facts. In the reaction of chlorobenzene with sodium,[3] the proportion of ortho to para substituted products was more than a thousand to one; in the reaction of amylsodium with chlorobenzene[2] one fraction contained three phenyl to one amyl unit. The triphenylene produced by reaction of chlorobenzene with sodium is thus a consequence of a series of changes by polar reagents rather than an indication that free radicals[4] are at hand.

Metal–Halogen Interchange.—A metal–halogen interchange has been known for some time to occur between lithium alkyls and bromo- and iodo- compounds.[5] Since methyl iodide reacts with octyl- or amylsodium,[6] yielding hexadecane and decane, respectively, this process, too, may be associated with a preliminary formation of amyl iodide according to the equation

$$C_5H_{11}Na + CH_3I \longrightarrow C_5H_{11}I + CN_3Na$$

In agreement with this view, amyl iodide was obtained in 50% yield when amylsodium was added to methyl iodide. The comparative yields of hexadecane (Fig. 1) and of decane (Table II) suggest the extent to which this change occurs in other cases. Iodides in general appear to favor an interchange, and methyl iodide reacts preponderantly in this manner. Chlorides, on the other hand, with the possible exception of the hexyl compound seem to participate only slightly in exchange reactions.

When such an exchange occurs, the new products can then in turn undergo disproportionation or coupling. The results of such secondary reactions complicate seriously the effort to trace primary processes. Since disproportionation is then operating in the reverse order and some alkane is formed from what was originally the alkyl halide, this change is one factor which tends to lower the ratio of alkane to alkene. In any given case, a high yield of symmetrical coupling product would indicate a large amount of metal–halogen interchange and would be associated with a low ratio of alkane to alkene. Qualitatively, the results are in agreement with this view. *n*-Hexyl, *n*-butyl and ethyl iodides and methyl bromide (Table II) each formed decane in over 30% yield and gave a pentane–pentene ratio of from 1.1 to 1.5. On the other hand, the two lowest percentages of decane, *viz.*, those obtained with methyl and ethyl chlorides are associated with the highest ratios. Methyl iodide alone appears anomalous. The majority of the bromides as well as *n*-butyl and hexyl chloride occupy an intermediate position in that the large amount of decane predicted

by a low pentane–pentene ratio appears to have been replaced by relatively higher proportions of Wurtz coupling products. The data in Table II are divided into four groups in order to indicate these relationships.

Variation of the Products.—A radical which is really free might be expected to show a specific chemical behavior toward another reagent irrespective of its source. That is to say, methyl, derived by reaction of the chloride, bromide or iodide with octylsodium, should have one reaction only with octyl, provided, of course, that the environment was constant and the concentration of the methyl radical was always so low that it could not react with itself. Figure 1 shows that such is not the case. Data in Tables II and III do not support this view. This argument may be questioned on the ground that the rate of formation of the methyl radical is different in the three cases. If the method of adding the methyl halide as a vapor in a stream of nitrogen does not keep the concentration sufficiently low, or if other changes are possible during the different periods of formation, then we would conclude that the rate should be fastest with the iodide and slowest with the chloride, and that a rapidly formed methyl radical would promote symmetrical coupling (hexadecane); a slowly formed radical would favor unsymmetrical coupling (nonane). These deductions from the free radical view, however, contribute nothing concrete to the explanation of phenomena in the Wurtz reaction compared with that offered by the organometallic theory.

Apart from considerations of mechanism, the results with the methyl halides are interesting because they show the limits possible in control of the products of the reaction.

Analogies with Other Reactions.—Before the general theory of the Wurtz reaction can be summarized in terms of organometallic compounds, some attention should be given to analogies which have suggested the likelihood of free radicals being the active agent. Polanyi[7] found good reason for postulating the existence of free methyl in reactions of methyl iodide with sodium vapor at extremely low pressures and comparatively high temperatures. The existence of free radicals under conditions highly favorable for their occurrence and above the limit of thermal stability of the alkylsodium compound is, of course, an entirely different matter from the assumption of

(7) Horn, Polanyi and Style, *Trans. Faraday Soc.*, **30**, 189 (1934).

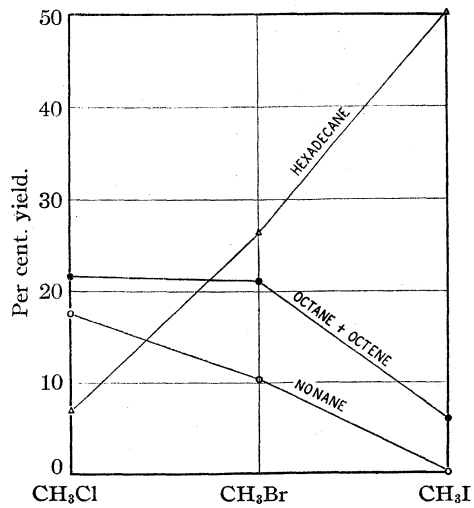

Fig. 1.—Yield of products obtained by reaction of methyl halides with octylsodium.

their existence in a liquid phase at ordinary pressures on a surface of metallic sodium. Where even such ideal conditions as those mentioned have as yet failed to demonstrate the presence of free propyl, butyl and higher members[8] of the series, the conclusion might well be drawn that free radicals, so extremely difficult to obtain in an appropriate environment, would have little chance of being present in such an unfavorable medium as a liquid phase.

Another analogy stems from the vast amount of research on triphenylmethyl and other free radicals of long life. The reasoning in this case is very logical. If there are free radicals of long life, there should be also free radicals of short life. The force of this argument is granted; the opinion that any fact so far submitted definitely indicates their occurrence in the Wurtz reaction is questioned. Assumption of presence of a free radical in a system obviously containing a large proportion of an active polar compound implies that the two-step process involving, first, a change of ion to free radical and then a combination of radicals with themselves is faster than the direct interaction of ions to give the final product. There is no evidence so far available to support the idea that the ion is not itself sufficiently reactive without the interposition of a secondary change to a second intermediate of questionably greater activity. The converse indeed might well be true and the phenomenon of disproportionation which occurs in free radicals of long life, might be itself preceded

(8) Rice and Rice, "The Aliphatic Free Radicals," The Johns Hopkins Press, Baltimore, Md., 1935, pp. 33, 64.

by conversion of the radical to an ion before a proton moves from one radical to the other.

General Summation of Reactions.—All primary and secondary products from the Wurtz reactions can be expressed by the following sets of equations

Reactants		Primary products		Secondary products
First Phase				
$RX + 2Na$	$\longrightarrow$	$RNa + NaX$		
Second Phase				
$RNa + XR''$	$\longrightarrow$	(a) $RR' + NaX$		
		(b) $R_H + R'_{-H} + NaX$	$\longrightarrow$	Polymers
		(c) $RX + R'Na$	$\longrightarrow$	RR, R'R', RR', or $(R'_H + R_{-H})$, $+NaX$

The relative importance of these various reactions differs with the reagents used. As far as the Wurtz coupling product, RR', is concerned, the yields decrease as the radical attached to sodium is benzyl, phenyl or alkyl. This order is the same as the relative affinities for sodium observed in metalation studies. As for the halide half of this reaction, the limited number of observations so far made suggest that bromides as a class are apt to give better results than iodides or chlorides.

The purpose of this work is not, of course, to deny all existence of a free radical in the Wurtz reaction but to point out that in the present state of knowledge on this subject the very phenomena for which the free radical interpretation has been considered essential in reality furnish excellent evidence that an organometallic agent is at work. In spite of very commendable efforts in the past, decisive evidence of any free radical phase which may be present in this common reaction is a goal yet to be reached. On the other hand, the organometallic mechanism is an adequate instrument for interpreting and predicting the reactions known to occur. It is, of course, beyond the scope of this paper to rewrite all equations of disproportionations in the Wurtz reaction which previously have been written as being in agreement with or supporting the free radical concept. It is sufficient to say that all such phenomena can be expressed satisfactorily as the normal behavior of a polar reagent, which has been proved to be present in sizable quantities.

Experiments

Octylsodium and Alkyl Halides (J. D.).—The apparatus consisted of a 500-ml. flask with four creases and an inverted bottom.[9] The usual three-necked addition tube was employed. The stirrer was operated at 1500 r. p. m. *n*-Octylsodium was prepared by adding 0.15 mole of octyl chloride to 15 g. of sodium sand over a one-hour period at −10°, as described before.[1] Methyl, ethyl and propyl halides were then admitted by vaporizing them in a current of nitrogen while the liquid was kept about 10° below its boiling point. The tube between the vaporizer and the reaction vessel was electrically heated in order to prevent condensation of the vapors. The inlet tube terminated just above the surface of the suspension of octylsodium so as to ensure as far as possible a maximum opportunity for reaction of the alkyl halide with excess organosodium compound. One-tenth of a mole of each halide was added except in the case of methyl chloride, which being a gas, was allowed to pass slowly over the surface until reaction was complete. Water was then added to remove excess sodium. The hydrocarbons, RR', were fractionated through a column of the Podbielniak type having about ten theoretical plates, and collected over a 5° range. The octene content of the octane fraction (118–125°) was measured by a bromination method.[10] The hexadecane boiled from 277 to 283°. Percentage yields (Fig. 1 and Table I) are calculated on the basis of the octyl chloride used. For some undetermined reason the reaction mixture occasionally became so viscous that stirring was nearly impossible. The letter (V) in the table indicates when this condition was present.

Amylsodium and Alkyl Halides (J. D.).—The apparatus used in this series was the one mentioned before as operating at 10,000 r. p. m. Amylsodium was prepared by adding 30.2 ml. (0.25 mole) of *n*-amyl chloride to 11.5 g. (0.5 atom) of sodium powder during one hour at 0°. After the reaction mixture had been stirred for an additional hour, 0.177 mole of the alkyl halide was added dropwise at 0° during one-half hour. The mixture was stirred for fifteen minutes longer, then poured on solid carbon dioxide, and later treated with water to remove the very small amount of unreacted sodium metal. The hydrocarbon products were separated as in the foregoing description. Results are tabulated in Table II.

Amyl-, Hexyl- and Octylsodium with Alkyl Halides (B. H.).—The apparatus in this case was, in general, similar to that employed for octylsodium except that the stirrer was operated at 4000 r. p. m. The sodium sand (17.5 g.) was suspended in olefin-free pentane and activated by addition of 1.7 ml. of amyl alcohol. The alkyl halide (1 mole equivalent to 2 g. atoms of sodium metal) dissolved in twice its volume of pentane was added at 0 to −5° over a one-hour period. The second alkyl halide (about 0.7 mole equivalent) was then added at the same rate. After stirring for a brief time longer, carbon dioxide was passed into the mixture to remove any unchanged organosodium compound which was always present in a small amount only, and water was added to remove excess sodium. The hydrocarbon layer was dried over calcium

(10) Uhrig and Levin, *ibid.*, **13**, 90 (1941).

chloride and then fractionated through a packed column having about twenty plates. Yields are given in Table III. Calculation is based on the quantity of alkyl halide added. The percentage yield of the Wurtz coupling product is determined on the basis of the first halide added. All results are the average of two determinations.

Amylsodium and Methyl Iodide (J. D.).—*n*-Amylsodium, prepared as in the previous experiment, was forced, during a fifteen-minute interval, into a flask containing 168 ml. of methyl iodide maintained at a temperature between −30 and 20°. After adding water to remove excess sodium, the organic layer was fractionated in the packed column at reduced pressure. The fraction boiling from 57 to 60° at 30 mm. had a specific gravity of 1.504 (recorded value[11] for amyl iodide 1.517) and weighed 23 g. (47% based on the amyl chloride used). The sodium fusion test for halogen was positive. The 3,5-dinitrobenzoate derivative, prepared from this fraction, melted at 44–45°. The recorded value[12] is 46°.

Summary

Complete explanations for the phenomena of disproportionation and polymerization, hitherto considered as demanding a free radical intermediate, are made on the basis of an organometallic reagent.

The saturated hydrocarbon product of disproportionation comes from the organosodium compound, the unsaturated from the halide.

Amylsodium yields amyl iodide when poured into methyl iodide.

The general basis from which a free radical theory is associated with the Wurtz reaction is critically discussed.

All products in the Wurtz reaction are interpreted on a simple basis by the organometallic mechanism.

Condensations by Sodium. XXIV. The Pyrolysis of Amylsodium

BY AVERY A. MORTON AND HERBERT A. NEWEY

The experiments reported in this paper are directed toward a careful examination of the stability of amylsodium over a wide range of temperature and toward a determination of the type of reaction involved in pyrolysis. The information was of importance to a general understanding of the behavior of amylsodium in various reactions and in particular to the studies on mechanism since an appreciable quantity of pentane or pentene formed by low temperature pyrolysis would nullify some of the conclusions drawn in the previous paper.[1] The products of pyrolysis proved clearly to be the result of metalation and dehydrogenation.

Pyrolysis required thirteen hours at 60° for completion and was fast enough at 120° and above to be observed by rapid evolution of gas. The rate of pyrolysis over a two-hour period was slight at 40°, moderate (22%) at 70°, and approximately complete at 90° (see Fig. 1). The slopes of the curve at 45, 55 and 65° are as 2.4 to 4.9 to 8.7. The logarithms of the reciprocal of these values, plotted against the temperature, give approximately a straight line. Extrapolation of this line to 20 and to 0° shows that the decomposition over a two-hour period was definitely below 1% and probably negligible. Since the time period required for the experiments on the mechanism of the Wurtz reaction was considerably less than that employed in these pyrolysis experiments, there is no danger that the comparative quantities of pentane and pentene were affected by decomposition of the organosodium compound.

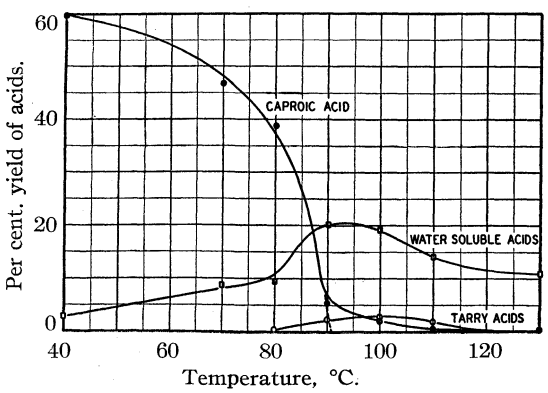

Fig. 1.—Yield of acids obtained after heating amylsodium for two hours at different temperatures.

The curve (Fig. 1) suggests that disappearance of amylsodium is related to appearance of another sodium compound which upon carbonation yields

(1) Morton, Davidson and Hakan, THIS JOURNAL, **64**, 2242 (1942).

very water-soluble carboxylic acids. At 90° the quantity of such acids was 20%. In view of the 60% yield of caproic acid before pyrolysis, it would appear that about one-third of the metal in amylsodium was present in the new compound. The remaining two-thirds had apparently reverted to sodium.

Examination of the acids, which were complex, showed more clearly the direction of the changes. Except for some tarry product, the acids which resulted from carbonation of the pyrolyzed organosodium compound had more than one carboxyl group per original amyl unit (in a preferred fraction nearly two such groups) and showed unsaturation. These changes in their elementary form are pictured by Eqs. 1 and 2.

$$C_5H_{11}Na + C_5H_{11}Na \longrightarrow NaC_5H_{10}Na + C_5H_{12} \quad (1)$$

$$NaC_5H_{10}Na + 2C_5H_{11}Na \longrightarrow NaC_5H_8Na + 2C_5H_{12} \quad (2)$$

The carboxyl groups are not attached to the same carbon atom, since tests on the preferred fraction showed no carbon dioxide evolution below 140°. Neither did the di-acid appear to form an anhydride when heated to 200°. These results suggested remote carbon atoms as points for attachment of sodium. Efforts to simplify identification of the product by hydrogenation failed to produce other than oily products. The possibility of some rearrangements occurring is not excluded, of course. The process of producing unsaturation, if continued a second time, would lead to a diene. Polymerization of such an unsaturated compound would account for the tars and other obviously large polymers produced.

No fragmentation of the carbon chain was evident since gases such as ethylene or propylene were not formed. The only gaseous product evolved was pentane with but a trace of pentene and this hydrocarbon was not evolved rapidly enough to be observed readily under the conditions employed until the temperature was above 120°, far above the point where, after longer periods of heating, the acidic products recovered showed obviously that pyrolysis had been complete.

All of the foregoing results are readily understandable as the behavior of an organosodium reagent without the necessity for assumption of any free radical. However, the mode of decomposition of all organosodium compounds under different conditions is not necessarily the same. For example, Carothers and Coffman,[2] who examined the gaseous products only of the pyrolysis of ethylsodium in absence of any solvent, found that ethylene was the first gas evolved. These investigators assumed also that sodium hydride was formed. The present study showed that this last material was produced at relatively high temperatures and then only in small quantities. Formation of an alkane instead of an alkene as the principal hydrocarbon product of pyrolysis of amylsodium may be due to the longer alkyl chain, the end portion of which can apparently be metalated.

In previous papers,[3] efforts were made to improve the yield of butylmalonic acid by heating amylsodium before carbonation. Little or no increase resulted. These results are confirmed by the present work. The idea of an amylidene disodium is, in view of recent evidence that one amyl radical exists for every combined sodium, no longer tenable.[4] The approximate constancy of the butylmalonic acid noted previously must therefore be ascribed either to a difference in size and reactivity of the solid particles, a common occurrence indeed in these reactions, and to variations in the process of carbonation, which in the light of present knowledge would certainly produce some quantities of the dicarboxylic acid.

Experimental

Amylsodium was made in a creased flask in the usual manner[5] from 19 g. (0.82 g. atom) of sodium sand, 32 g. (0.3 mole) of *n*-amyl chloride, in olefin-free pentane (b. p. 30–40°). The metal was activated as usual with 2 ml. of isoamyl alcohol prior to addition of the chloride. Preparation was carried out at 10–15°, during one hour, and the mixture stirred for one hour longer at the same temperature. The pentane was then removed by distillation and 250 ml. of synthetic *n*-decane added. The mixture was then heated and stirred at the temperature desired for pyrolysis. Carbonation was effected by cooling the mixture to room temperature and forcing it under nitrogen pressure onto lumps of solid carbon dioxide.

After carbonation was complete, water was added to remove excess sodium metal and to dissolve the sodium salts. The aqueous layer was then acidified by hydrochloric acid. Tarry acids which separated were recovered by filtration or lifted out on a stirring rod, washed with water, dried, weighed and titrated. The aqueous layer was extracted with petroleum ether to remove caproic acid, which boiled between 202 and 206° and left little residue. This acid was further identified by conversion to the *p*-bromophenacyl ester melting at 72° (recorded value 72°). The quantity of acid was determined by titration and also by weighing the distillate. The remaining water-soluble

[a] Saponification equivalent. [b] Average molecular weight per amyl unit calculated from the saponification equivalent. [c] Determined by boiling point elevation in acetone in a Swietoslawski apparatus. [d] Each fraction showed unsaturation. One fraction analyzed by catalytic absorption of hydrogen. [e] This fraction probably consists chiefly of methyl butylmalonate. [f] This fraction was considered as a preferred one because it was the lowest boiling of the pyrolyzed products and was the nearest to having two carbomethoxy groups to one amyl chain. [g] Neutralization equivalent of the free acid was 87 as determined by the silver salt.

acids were recovered by saturating the solution with salt and extracting first with ether and then with methyl ethyl ketone. The ether occasionally removed some butylmalonic acid which crystallized, but for the most part the products were extracted only by methyl ethyl ketone and remained as oily liquids after evaporation of that solvent. The results are given in the graph (Fig. 1). All yields are based on the amount of amyl chloride originally added.

A parallel series of experiments was made in which all conditions were the same except that carbonation was effected by bubbling carbon dioxide into the reaction mixture. The results are in general identical save for the formation of larger quantities of butylmalonic acid and the initial occurrence of tar at 68° instead of 80°. The data are therefore not recorded in this paper.

Acidic Products of Pyrolysis.—In general, the water-soluble products were dark brown, viscous materials slightly soluble in ether but readily soluble in methyl ethyl ketone, acetone or alcohol. In the case of the products of pyrolysis at temperatures below 90°, the recovered water-soluble acids could again be redissolved in water readily. Where the pyrolysis had been effected at higher temperatures the dried acid would not redissolve in cold water. A quantity of these acids from pyrolysis at 80 to 100° was esterified with diazomethane. Ten grams of the ester was distilled. The properties of each fraction are recorded in Table I. Although the second fraction was the one most likely to give a single compound, no crystalline ester or derivative could be obtained, even after catalytically hydrogenating, converting to the acid, amide, or *p*-bromophenacyl ester.

The tarry acids recovered from the low temperature pyrolysis were dark brown and sticky materials. As the temperature of pyrolysis increased, they became progressively harder and eventually appeared as a dry fluffy powder. These last products did not dissolve in acetone and formed a methyl ester which was not volatile in a molecular still. Hence their molecular weight was very high. The graph indicates a decrease in the tar formed at higher temperature. Actually the weight of the tar in that range remained fairly constant, the seeming drop being due to a loss in the number of carboxyl groups.

Formic acid, suggesting the presence of sodium hydride, was present in small amounts only and then only among the products of pyrolysis at higher temperatures. Detection was difficult. The method of proving its presence was to evaporate the combined sodium salts of the acids to dryness, add them to glacial acetic acid and fractionate carefully. A sample from the first portion of distillate readily reduced alkaline permanganate. Another sample was diluted with water, the aqueous solution treated with magnesium turnings and the resulting aldehyde[6] treated with dimethyldihydroresorcinol. The dimethone derivative, after being recrystallized, melted at 188–189° and showed no depression when melted with an authentic sample. Although other tests such as steam distillation of the water-soluble acids and treatment of the distillate with potassium permanganate or mercuric chloride showed evidence of its presence, the quantity of formic acid was never more than a trace. In fact, no conclusive evidence could be found that it resulted when the temperature of pyrolysis was kept below 90°.

Hydrocarbon Products from Pyrolysis.—The amylsodium was prepared as before, petroleum ether solvent removed, and *n*-decane added. On heating rapidly, a small amount only of material distilled from the mixture below 120°. No gases were evolved. Between 120 and 130° the mixture in the flask boiled vigorously. The condensate was collected in a trap which was cooled by solid carbon dioxide. All exit gases passed through a second trap containing bromine water. No decoloration occurred. The liquid caught in the first trap boiled between 34 and 40°, most of it at 34 to 36°, suggesting that the product was chiefly *n*-pentane. It decolorized only traces of bromine. On treatment with cold concentrated sulfuric acid less than a fifteenth of the volume was lost. The total volume of liquid collected was 33 ml., which was more than the amount equivalent to the amyl chloride used. The excess might have come from occlusion of some solvent used in preparation or from a complex formation of solvent pentane with amylsodium.

The contents of the reaction vessel, after pyrolysis, were poured on solid carbon dioxide, water was added, and the hydrocarbon layer collected and distilled. This material proved to be *n*-decane which boiled from 172 to 176°, and showed no unsaturation when tested by permanganate. The residue from fractionation contained no high-boiling compounds.

Summary

The rate of decomposition of amylsodium is

(6) Fenton and Sisson, *Chem. Centr.*, **79**, 1379 (1908).

very slight at 40°, fair at 70° and rapid (two hours for completion) at 90°.

Acids, obtained by carbonation of the pyrolyzed organosodium compound, are (a) water soluble, unsaturated compounds with more than one carboxyl group to amyl unit; (b) tarry or insoluble acids which are unsaturated and of relatively high molecular weight.

The sole hydrocarbon product was pentane. The solvent, *n*-decane, was not attacked by the organosodium compound under the conditions employed.

The chemical reactions which occur during pyrolysis involve metalation (dismutation) and dehydrogenation.

CAMBRIDGE, MASS. RECEIVED MARCH 18, 1942

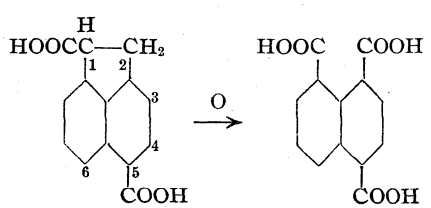
Condensations by Sodium. XXV. Reactions of Amylsodium with Naphthalene, Acenaphthene and Decalin

BY AVERY A. MORTON, JOHN B. DAVIDSON, T. R. P. GIBB, JR., ERNEST L. LITTLE, E. F. CLARKE AND A. G. GREEN

Nearly half of the carbonated product obtained from the reaction of amylsodium with naphthalene is di- and tri-substituted, whereas nearly all of the product in the case of benzene is monosubstituted. Octyl- is more active with naphthalene than is amylsodium and the proportion of higher substituted compounds is slightly increased. The α- and β-monoacids, and the 1,3-, 1,8-, and 2,6-dicarboxylic acids were isolated. The trisubstituted compounds were not examined.

Acenaphthene was expected to behave somewhat similarly to toluene. One sodium atom did, in fact, replace a hydrogen atom in a methylene group but a second one entered the ring, giving a dicarboxylic acid, probably the 1,5-compound, in about 50% yield. Oxidation of this diacid with permanganate gave 1,4,5-naphthalene tricarboxylic acid, showing that one carboxyl must have been attached to a methylene, *i. e.*, in the



1-position, and the second was bound to the 5- or 6-position in the aromatic nucleus. The 5-position is considered more likely because (a) in benzene[1] the directing influence of one sodium atom on a second entering one is largely meta; (b) in naphthalene the influence on substitution of another metal in the same ring is meta; and (c) even in benzylsodium[2] a second metalation, when it does occur, is exclusively in the meta position. The 5-position is also in accord with the general principle[3] that the introduction of substituents into a bicyclic system containing a meta directing group will take place in the unsubstituted ring. Metalation of acenaphthene by an organo alkali compound, butyllithium, has been observed[4a] once before but no product was isolated. Horvitz[4b] also studied the action of amylsodium on acenaphthene but was unable to obtain a product of known purity because of the difficulty in separation.

The action of amylsodium on decalin was most surprising because metalation took place with extreme ease. From a great variety of products a very small amount of a crystalline ester of a tetracarboxylic acid was eventually isolated. It readily formed a dianhydride after being saponified and acidified. The positions of the carbethoxy group are not known but the 1,4,5,8-product is suspected because these positions are reasonably remote from each other, and have the symmetrical arrangement which would increase the tendency of the compound to come out of mixtures in a crystalline form. Moreover, the corresponding acids could easily form a dianhydride of high melting point. The original hope had been that substitution would occur at the tertiary or indented position and that the process would therefore prove to be a new synthetical method in that

series. The crystalline product isolated, however, could not have had a carbomethoxy group in that location because there was no resistance to saponification under ordinary conditions. Furthermore, alkylation[5] of decalin by sodium and amyl chloride after the manner employed successfully for toluene, formed products which, though they boiled in the range expected for amyldecalin, yielded an inappreciable quantity of naphthalene and traces only of amyl mercaptan when fused with sulfur. Both of these products would have been expected had alkylation occurred on the tertiary carbon atom. Metalation of decalin is of more than passing interest because it is the first recorded instance of substitution in a hydrocarbon which does not contain an aromatic nucleus.

Experimental

Amyl- or Octyl-sodium with Naphthalene (J. D.).—*n*-Amyl chloride, 18 ml., was added dropwise to 15 g. of sodium sand suspended in a solution of 50 g. of naphthalene in 240 ml. of ligroin maintained at 72° in an atmosphere of nitrogen in the apparatus used for preparing octylsodium.[6] After carbonating and adding water, the aqueous layer was acidified yielding 4.9 g. of solid product whose neutralization equivalent was 156.2. Ether extraction of the aqueous layer yielded 0.64 g. of acidic material which had a neutralization equivalent equal to 98.5. On the reasonable assumption that the solid precipitate consisted of mono- and di- acids only and that the acids recovered by ether extraction were a mixture of di- and tri-acids, the calculated yields were 14 mono, 10 di, and 2% tri or a total of 26%. From a parallel experiment with *n*-octyl chloride, the yields were 17, 15, and 5%, respectively, or a total of 37%. Separation of pure compounds from the mixture of products was carried out by a series of steps which began with an extraction of the precipitate (4.9 g.) with 4 liters of hot water. The insoluble material was reduced by this treatment to 2.5 g. The aqueous solution, after being cooled, yielded 1.1 g. of precipitate which was fractionally crystallized from a mixture of acetic acid and water. The least soluble portion from the dilute acetic acid was converted to the methyl ester by use of the silver salt and methyl iodide. After being recrystallized from methyl alcohol and then from acetic acid, the methyl ester of the 2,6-di acid (m. p. 189 to 192°) was recovered. The portion moderately soluble (as distinguished from most soluble and least soluble) in dilute acetic acid was sublimed. The sublimate was partially soluble in sodium carbonate. Acidification of the aqueous carbonate fraction gave about 44 mg. of β-naphthoic acid melting 182–184°. The amide melted at 192°. The portion insoluble in sodium carbonate was the anhydride of the 1,8-dicarboxylic acid, melting at 272–275°. The imide melted at 299–300°; the anil at 202–203°. The four liters of aqueous solution from which the above acids had been precipitated was extracted with ether, from which about 1.2 g. of acid was recovered by evaporation of solvent. This material was fractionally crystallized from water and the moderately soluble portion consisting of 212 mg. was sublimed. The volatile product was crystallized from ligroin yielding a very small amount of α-naphthoic acid, melting 159–160°. The non-volatile portion from the sublimation was recrystallized from water, yielding the 1,3- acid which melted at 264–265°. In all cases the yields were very small because of the many steps involved in separation. The properties of the acids were compared with those recorded by Bradbrook and Linstead.[7] Examination of the hydrocarbon layer showed little, if any, evidence of alkylation. An experiment[8] exactly parallel to that between octylsodium and naphthalene but using benzene as the hydrocarbon yielded 33% of benzoic acid with scarcely any phthalic acid. No evidence of alkylation was noted.

Amylsodium and Acenaphthene (T. G.).—*n*-Amyl chloride, 75 ml., was added to 40 g. of fine sodium sand suspended in a solution of 30 g. of acenaphthene in 400 ml. of petroleum ether. The sodium metal was previously activated with 5 ml. of *n*-amyl alcohol. No evidence of any reaction between the metal and acenaphthene was observed. The apparatus was the one used formerly[8] in this series of studies. The temperature was maintained at below 15° during the forty-five minutes required for addition of the chloride. The color changed progressively from gray to blue to dark green. After four hours the temperature was allowed to rise to 30°, where it remained during the next nineteen hours while stirring was continued. The dark green paste was then heated to 40° for one and a half hours, cooled to 9° and treated with a stream of carbon dioxide. After adding water to remove excess sodium, the aqueous layer was filtered, and acidified with hydrochloric acid. The mixture of gummy yellow precipitated acids was filtered and dried, yielding 54 g. of crude material. This product proved extremely difficult to purify by extraction with organic solvents, gradual acidification of the neutralized salts, conversion to methyl ester with dimethyl sulfate and other conventional methods. Contact with air appeared to cause formation of dark brown tars. The residues, after a considerable number of extractions had been made, were finally combined, the mixture suspended in ether, and treated with diazomethane. After one hour the yellow solution was filtered to remove suspended material and allowed to evaporate. Large yellow needle-like crystals of an ester resulted in a yield of approximately 50% calculated on the original amyl chloride used. After being recrystallized from ether, these crystals were colorless and melted at 112°, were lath-shaped with square ends, had an extinction angle of 10° and showed negative elongation.

Anal. Calcd. for $C_{18}H_{14}O_4$: C, 71.2; H, 5.2; sapon. equiv., 135. Found: C, 71.1; H, 5.5; sapn. equiv., 131, 134.

This diester was very soluble in cold methanol, acetone, methyl cellosolve, and carbon tetrachloride, moderately soluble in ether, and sparingly soluble in petroleum ether.

The dicarboxylic acid recovered after saponification was

moderately soluble in carbitol, cellosolve, and *t*-butyl alcohol, sparingly soluble in cold acetone, dioxane, and ether, almost insoluble in chloroform, and water, and insoluble in carbon tetrachloride, benzene and xylene; melting point 292–294°.

Anal. Calcd. for $C_{14}H_{10}O_4$: C, 69.4; H, 4.1. Found: C, 69.4; H, 4.3.

When heated (280°) with an equal weight of lime and copper bronze, the mixture gave acenaphthene as a sublimate; heated in the absence of these agents, it yielded two products which proved to be acenaphthene and an acid melting at 215° (acenaphthene 5-carboxylic acid melts at 217°).

One-tenth gram of the acid was oxidized by excess permanganate solution (2.2%) at 50–60° with stirring. At the end of an hour the solution was decolorized with alcohol, and filtered. A white precipitate was obtained after the filtrate was acidified. This material was redissolved in aqueous alkali, reprecipitated with acid and then crystallized from ether; m. p. 266–268°. The neutralization equivalent was 86, agreeing with the value for a naphthalene tricarboxylic acid. The acid readily changed on drying to the anhydride which melted at 273–275° (cor.).

Anal. Calcd. for $C_{13}H_6O_5$: C, 64.4; H, 2.48. Found: C, 64.3; H, 2.58.

When mixed with an authentic sample[9] of naphthalene-1,4,5-tricarboxylic acid anhydride, no depression of the melting point was obtained.

The mono methyl ester anhydride was also prepared according to the directions of Fieser and Peters[7] and had the properties described by these workers.

Amylsodium and Decalin (E. L., E. C., and A. G.).—Numerous experiments were made in an endeavor to obtain a pure compound readily from the carbonation of the product of amylsodium and decalin. Some of these involved tests with pure *cis* and *trans* decalin but isolation of pure materials was not apparently simplified by such means. The following account is of two experiments employing the method which finally proved successful. Amylsodium was prepared in the usual manner from 100 g. of *n*-amyl chloride and 48 g. of sodium sand in 400 ml. of petroleum ether contained in a 1-liter creased flask. Two hours were required for addition of the chloride at 15 to 20°. Decalin (59.1 g. in one experiment and 119 g. in the other) was then added quickly, and the mixture heated to 49 and 53°, respectively, for two hours. The contents were then cooled to room temperature and treated with a stream of carbon dioxide. Toward the end of the two hour carbonation process the mixture was again heated to a refluxing temperature. Subsequently the excess sodium sand was removed by water and the aqueous layer acidified with hydrochloric acid. The aqueous layer was first extracted with petroleum ether, then saturated with salt and extracted with ethyl ether. The ethyl ether extract was twice esterified with methyl alcohol and hydrochloric acid. This method of esterification was expected to effect a separation of those acids in which the carboxyl group was sterically hindered by being in the indented position. The ester from this step was freed from all acid by washing with aqueous sodium carbonate. The combined esters from both experiments were then fractionated through an 8-plate Podbielniak type column at 2 mm. About 5 ml. of methyl butylmalonate was collected at 64–89°, and 15 cc. of another liquid at 84 to 112°. Crystals then clogged the condenser system. The viscous red oily residue, after standing a week, also formed a mass of crystalline material which had the appearance of a fine mold-like growth over the surface. The crystals from both sources were identical with each other. After being recrystallized from methyl alcohol and water, they melted at 61–62°. The saponification value of 92 was that calculated for the methyl ester of a decalyl tetracarboxylic acid. The molecular weight (Rast) was 374 as compared with a calculated value of 368. The compound proved difficult to burn for analysis.

The product recovered after being saponified and acidified was a white solid which melted near 300° with sublimation. The neutralization equivalent of this material agreed with that calculated for a dianhydride.

Anal. Calcd. for $C_{14}H_{10}O_6$: C, 60.87; H, 4.35. Found: C, 60.8; H, 4.58.

The remaining acids and esters were liquids whose neutralization and saponification equivalents did not agree with any calculated for a mono-, di- or tri-acid, although the scheme of separation by solvent extraction, methylation by both methyl alcohol and acid and by diazomethane (of the difficultly esterified portion) and fractionation was carried to completion. Out of 87.9 g. of total ester (all of the acids were eventually esterified) from both experiments, only 0.15 g. of the methyl decalyltetracarboxylate was obtained. One of the fractions from a methylation by diazomethane had an unusually low saponification equivalent, indicating the presence of even more than four carboxyl groups per decalin unit.

Alkylation of Decalin (E. L.).—*n*-Amyl chloride (200 g.) in 100 ml. of decalin was added gradually to 300 ml. of decalin in which was suspended 96 g. of sodium sand which had been activated by addition of 8.4 ml. of *n*-amyl alcohol. The temperature was maintained at 72 to 80° in expectation that decalin would be converted to amyldecalin in the same manner as toluene was changed to hexylbenzene.[5] The reaction proceeded smoothly at first but after all but 60 ml. of the diluted amyl chloride had been added, the mixture became too solid to stir. The material was allowed to stand overnight under nitrogen, and then treated with a stream of carbon dioxide and reheated for about an hour and a half. The mixture was then allowed to cool. Water was added as usual to remove excess sodium. Much of the metal had agglomerated together in large lumps which were eventually lifted from the mixture with forceps. This agglomeration of sodium particles had been noticed only in the case of some of the experiments with decalin. The hydrocarbon fraction was dried over calcium chloride and fractionated carefully through a packed column of about fourteen plates, in order to remove low-boiling compounds, decane, and decalin. The residue boiling above 194° consisted of about 60 ml. which was then fractionated at 10 mm. through a Podbielniak type column of about eight plates. A portion (2.3 g.) of the fraction (6 cc.) boiling from 124–137° at 10 mm. was mixed with 1.9 g. of sulfur and heated for three hours at 230°. The product was then extracted with small portions

(9) The authors are greatly indebted to Professor L. F. Fieser of Harvard University for his courtesy in furnishing this sample. See Fieser and Peters, THIS JOURNAL, **54**, 4352 (1932).

(200 ml. in all) of ethyl ether. The combined ether extracts were fractionated (final temperature 230°). Since no principal fraction boiling at 126°, the boiling point of *n*-amyl mercaptan, was found, the combined distillate was extracted with sodium hydroxide, the alkali solution then acidified and extracted with ether. The ether was evaporated and the residual foul-smelling liquid treated with 2,4-dinitrochlorobenzene, which produced a few crystals of the *n*-amyl 2,4-dinitrophenyl thioether melting at 80–81° (recorded[10] value 80°). The material left after extraction with alkali was treated with picric acid in hot alcoholic solution. A few yellow crystals melting from 268–273° were obtained. Had the amyl group been substituted in the indented position, the product should have been naphthalene picrate, melting at 149–150°. Several experiments using decalin showed that the above process would give good yields of naphthalene and naphthalene picrate.

Summary

A series of studies on the reaction of amyl-sodium with bicyclic compounds showed that metalation occurred readily in a considerable number of places. The positions of attack were shown by examination of the products of carbonation.

The end-products from naphthalene were both mono-carboxylic acids, at least three dicarboxylic acids, and some tricarboxylic acid.

Acenaphthene was attacked readily; the only product which could be isolated was a dicarboxylic acid, either 1,6- or probably 1,5.

Decalin was attacked very easily and a considerable variety of products was formed. A small amount of the dianhydride of a tetracarboxylic acid was separated. The tertiary hydrogen atom in decalin may be attacked but does not appear to be a favored position.

The Diastereoisomerism of the 9,10,12-Trihydroxystearic Acids and the Geometric Configurations of Ricinoleic and Ricinelaidic Acids

BY J. P. KASS AND S. B. RADLOVE

In the course of an investigation of the dehydration of ricinoleic and ricinelaidic acids to isomeric linoleic acids, it became necessary to identify the parent 12-hydroxy-9,10-octadecenoic acids by means of their partial oxidation to the 9,10,12-trihydroxystearic acids. Theoretical considerations[2,3,4] indicate that each of the geometrically isomeric, dextrorotatory monohydroxy acids should yield two diastereoisomeric trihydroxystearic acids, with the following configurations of the initially dextrorotatory twelfth carbon atom and the newly asymmetric ninth and tenth carbon atoms

$$\begin{array}{lll} \text{I} & a & (12) + (10) + (9) + \\ & b & (12) + (10) - (9) - \\ \text{II} & c & (12) + (10) + (9) - \\ & d & (12) + (10) - (9) + \end{array}$$

Moreover, assuming that no inversion occurs during oxidation, the pairs of the derivatives should be related in such a manner that the products of the *cis*-hydroxylation of one of the unsaturated acids must correspond to the products of the *trans*-addition to its geometric isomer; specifically, the mild alkaline permanganate oxidation of ricinoleic acid should yield two trihydroxystearic acids identical with the pair resulting from the oxidation of ricinelaidic acid with acid hydrogen peroxide, and *vice versa*. This relationship has been shown to obtain uniformly in the monoethenoid[5,6] and linoleic acid[7] series.

The older literature[8] reports the preparation of three of the trihydroxystearic acids under consideration, and intimates the existence of the fourth isomer. The oxidation of ricinoleic acid with cold alkaline permanganate was first shown by Hazura and Grüssner[9] to produce two trihydroxystearic acids, m. p. 110–111° and 140–142°, for which Dieff[10] later reported m. p. of 100–114° and 137–140°. From similarly treated ricinelaidic

acid, Grüssner and Hazura[11] and Dieff[10] succeeded in isolating only one trihydroxystearic acid, m. p. 114–115°, although Mangold[2] claimed that he obtained two substances, m. p. 113–116° and 117–120°, in amounts too small for further identification. The optical activity of only the first isomer, m. p. 110–111°, has been determined by Walden,[3] who found $[\alpha]_D$ −6.25 to −6.0° (c = 10–15 in glacial acetic acid).

However, Dean[12] apparently assumed the identity of the two possible pairs of derivatives, while Brady[13] recently repeated the earlier work and stated that the mild alkaline permanganate oxidation of both ricinoleic and ricinelaidic acids produced the same two trihydroxystearic acids, m. p. 110 and 141°, albeit in different proportions. His statement has been accepted by Henshall and Smith.[14] Furthermore, Scanlan and Swern[15] implied that the single trihydroxystearic acid, m. p. 108–109°, which they obtained through the oxidation of the ricinoleic acid of castor oil with hydrogen peroxide in acetic acid, was presumably identical with Hazura and Grüssner's[9] product, m. p. 110–111°, of the alkaline permanganate oxidation of ricinoleic acid, rather than of ricinelaidic acid. Previously, Smit[4] had shown that the oxidation of ricinelaidic acid with perbenzoic acid yielded two trihydroxystearic acids, m. p. 112 and 137°, presumably identical with the compounds formed by the alkaline permanganate oxidation of ricinoleic acid. The latter did not, however, yield any identifiable trihydroxystearic acids with the perbenzoic acid.

In view of the unsatisfactory state of the experimental data and the apparent contradiction between some of the more recent work and the theoretical expectations, it was considered desirable to characterize more fully the trihydroxystearic acids derived from the oxidation of ricinoleic and ricinelaidic acids with both alkaline permanganate and acid hydrogen peroxide. Contrary to the findings of Brady,[13] four distinct diastereoisomers were obtained, the behavior of which was in complete agreement with the theoretical considerations outlined in the introductory section, as shown in the accompanying table. In line with a previous suggestion,[7] each acid has been designated with a Greek letter prefix, the lower-melting isomer in each pair having the lower designation. It is probable that the hitherto unreported γ-trihydroxystearic acid, m. p. 86.8–87.4°, has been overlooked by previous workers because of its relatively pronounced solubility in organic solvents, while the failure of the recent workers[13,15] to recognize the distinction between the α- and δ-trihydroxystearic acids may have been due to the close similarity of the melting points of these substances.

Correlation of the specific rotations of the individual trihydroxystearic acids with their possible stereochemical configurations indicated in the introductory discussion offers corroborative evidence for the *cis*-configuration of ricinoleic acid and the *trans*-configuration of ricinelaidic acid; at least, it presents an analogy between the fatty acids and maleic and fumaric acids, respectively. Where fumaric acid on oxidation with alkaline permanganate yields racemic tartaric acid, ricinelaidic acid similarly produces the strongly dextrorotatory γ-trihydroxystearic and the even more strongly levorotatory δ-trihydroxystearic acid, which are diastereoisomeric because of the presence of the already asymmetric dextrorotatory twelfth carbon atom (structures *a* and *b*, respectively). Conversely, where maleic acid forms *meso*-tartaric acid, ricinoleic acid yields the two weakly levorotatory α- and β-trihydroxystearic acids, the comparatively slight levorotations of these diastereoisomers being due to the partial internal compensation of the strong levorotation of either the ninth or tenth carbon atoms by the other newly asymmetric carbon atom possessing a relatively weaker dextrorotation (either of structures *c* and *d*).

Experimental

Preparation of Ricinoleic and Ricinelaidic Acids.—Castor oil (900 g.) was extracted five times with 500-cc. portions of petroleum ether (b. p. 30–60°). The residue, freed from solvent on the water-bath *in vacuo*, was saponified by boiling for one-half hour with a solution of 360 g. of potassium hydroxide in 243 cc. of water and 1800 cc. of alcohol. The acids were liberated in the usual manner, washed three times with hot water, and dried over sodium sulfate in diethyl ether solution. After filtration and evaporation of the solvent *in vacuo*, the residual acids, which did not solidify completely in the refrigerator at 3°, were extracted four times with large volumes of cold petroleum ether. Evaporation (*in vacuo*) of the solvent from the insoluble acids left 623 g. of an amber oil; I. V. 86.3 (theory for ricinoleic acid, I. V. 85.1). This crystallized completely in the refrigerator.

[a] To avoid confusion arising from the multiplicity of melting points cited and the similarity of the m. p. of the α and δ acids, the previously published m. p. are recorded here with regard to the correct isomeric relationships of the trihydroxystearic acids, rather than their source as reported by the original investigators.

Further purification was effected by treating an alcoholic solution of the potassium salt of the crude ricinoleic acid with an equivalent aqueous solution of barium chloride and recrystallizing the precipitated and washed barium salt three times from 95% alcohol. The barium ricinoleate was then extracted with diethyl ether and the dried, finely powdered salt was suspended in the ether and decomposed by vigorous shaking with successive small portions of dilute hydrochloric acid. Evaporation (*in vacuo*) of the washed and dried ether solution left a colorless oil which solidified in the refrigerator to a crystalline mass, m. p. about 5°. (The crude acid polymerizes very rapidly, for the addition of aqueous barium chloride to the alcoholic solution of the potassium soap of a portion of the acid which was left at room temperature for several weeks produced only a gummy precipitate. However, preliminary saponification of the estolide with an excess of alcoholic alkali and the subsequent isolation of the free acid permitted the recovery of the crystallizable barium salt.)

The ricinelaidic acid was prepared by the action of nitric acid and sodium nitrite on the crude ricinoleic acid which was obtained by the saponification of castor oil previously extracted with petroleum ether as described above. The acids from 1000 g. of castor oil were warmed without preliminary drying to 60° and mixed during vigorous mechanical stirring with 400 cc. of 50% nitric acid at the same temperature. A solution of 30 g. of sodium nitrite in 200 cc. of water was added at once through a delivery tube reaching to the bottom of the reaction flask, and the mixture was vigorously stirred for ten minutes at 60°. The flask was then transferred to an ice-bath and the stirring continued for several hours until the supernatant layer solidified. The product was washed several times with hot water and taken up in five volumes of diethyl ether. The solution was washed with water, dried with sodium sulfate, filtered and chilled. To facilitate the filtration of the voluminous material which separated on chilling, the cooling and filtrations were performed at 10° intervals to −30°. Two recrystallizations of the combined material from diethyl ether yielded 220 g. of white ricinelaidic acid, m. p. 50–51°.

The combined mother liquors from the recrystallizations of the ricinelaidic acid were completely freed from solvent, and the liquid residue was again treated with nitric acid and nitrite exactly as before. An additional 185 g. of ricinelaidic acid was thereby obtained, having a m. p. of 50–51° after a single recrystallization from diethyl ether.

The 405 g. of the crude ricinelaidic acid was taken up in a large volume of boiling petroleum ether, which left undissolved 5 g. of a white crystalline solid, m. p. 134–136°, presumably the natural dihydroxystearic acid.[16] This residue was reserved for future study. Recrystallization of the ricinelaidic acid from petroleum ether raised the m. p. of the main product to 51–52°.[17]

(1) **Oxidation with Alkaline Potassium Permanganate** (a) **Ricinoleic Acid.**—The procedure followed was that of Lapworth and Mottram[18] exactly as employed by Brady.[13] A solution of 5 g. of ricinoleic acid in 2500 cc. of water containing 1.6 g. of potassium hydroxide was stirred for ten minutes at 0° with 5.3 g. of potassium permanganate dissolved in 250 cc. of water. Decolorization was effected with 15 g. of sodium sulfite and an excess of dilute sulfuric acid. The flocculent precipitate was permitted to settle for several hours in the cold, when it was filtered, washed thoroughly with cold water, and finally dried in a vacuum desiccator. After exhaustion with petroleum ether, it was extracted with boiling chloroform. The chloroform-soluble fraction (α-trihydroxystearic acid) was recrystallized from alcohol, then aqueous acetic acid, and again from alcohol; m. p. 109–111.5°; yield, 1.1 g. as a micro-crystalline powder.

The chloroform insoluble fraction (β-trihydroxystearic acid) was similarly recrystallized to yield 1.2 g. of a white powder, m. p. 136–138°.

(16) Ref. 8, p. 226.

(17) Subsequent work in this Laboratory has shown that pure methyl ricinoleate may be very simply prepared by the fractional distillation of the crude mixed methyl esters of castor oil fatty acids through a packed, electrically heated fractionating column. The final purification of ricinelaidic acid is also greatly facilitated by a preliminary fractional distillation of its crude methyl ester. Details of the separations will be described in a forthcoming publication.

(18) Lapworth and Mottram, *J. Chem. Soc.*, **127**, 1628 (1925).

(b) **Ricinelaidic Acid.**—The identical procedure was applied to ricinelaidic acid, 15 g. of which was dissolved with slight warming in a solution of 4.8 g. of potassium hydroxide in 100 cc. of water. (The solid acid is not easily wet and care must be taken to ensure complete solution.) The soap solution was diluted with 2.5 l. of cold water and treated with 16 g. of potassium permanganate in 1 l. of water. After decolorization with 50 g. of sodium sulfite and 250 cc. of 1:4 sulfuric acid, the washed and dried white precipitate was extracted with ligroin. The mixture of crude acids obtained weighed 10.5 g. and melted indefinitely above 70°. The entire product dissolved easily and completely in 100 cc. of warm chloroform. Cooling to approximately 0° precipitated 6 g. of a partially crystalline solid, melting indefinitely above 86° after removal of the stubbornly adhering chloroform with petroleum ether. The chloroform mother liquor was chilled to −40°, at which temperature it deposited about 1 g. of a powder having a m. p. of 83–86° after thorough drying in the vacuum desiccator. The substance remaining in the chloroform was precipitated with ligroin as a waxy solid which melted on rubbing. This was discarded after futile attempts to crystallize it from ether and alcohol.

The main fraction, melting above 86°, was recrystallized twice from chloroform at 0° to yield 3.5 g. of large lustrous plates having a m. p. of 109–110° after washing with ligroin. This compound (δ-trihydroxystearic acid) differed markedly in appearance from the microcrystalline α-trihydroxystearic acid (m. p. 109–111.5°); the m. p. of a mixture of the two was 97–104°.

The solid obtained at −40° was combined with the residue left by the evaporation of the chloroform mother liquors of the δ-trihydroxystearic acid, and the crude product (2.5 g.), m. p. 82–86°, was recrystallized several times from chloroform, aqueous alcohol, and finally from ether, when its m. p. became constant at 86.8–87.4°; the neut. equivalent was 336 (calcd. for trihydroxystearic acid, 332).

Anal.[19] Calcd. for $C_{18}H_{36}O_5$: C, 65.06; H, 10.84. Found: C, 65.20; H, 10.94.

The new acid (γ-trihydroxystearic acid) precipitated on cooling its solutions as a micro-crystalline powder, but slow evaporation left clusters of feathery crystals.

(2) **Oxidation with Hydrogen Peroxide in Acetic Acid.** (a) **Ricinoleic Acid.**—As already pointed out by Scanlan and Swern,[15] whose procedure was used, free ricinoleic acid reacted very sluggishly with the reagent in comparison with its glyceride, despite the purification of the acid immediately before use. Nevertheless, significant amounts of γ- and δ-trihydroxystearic acids were obtained. However, the proportions were different from those obtained with the parent castor oil, which readily produced good yields of the δ-isomer but only small amounts of the γ-acid.

Forty-five grams of pure ricinoleic acid was stirred with a solution of 36 g. of 30% hydrogen peroxide in 50 cc. of glacial acetic acid which had previously been heated for one hour at 80–85° and then cooled to room temperature. The temperature of the mixture rose slowly and spontaneously to 42° in the course of several hours and then dropped without causing the mixture to become homogeneous. The viscous mixture was poured into 400 cc. of hot water. The aqueous layer was siphoned off, and the residue was then refluxed for one hour with 400 cc. of a normal solution of sodium hydroxide. Acidification precipitated the trihydroxystearic acids, which were taken up in chloroform, filtered through decolorizing charcoal and crystallized in the ice-bath to yield 3.35 g. of a crystalline solid having a m. p. of 108.5–110° after one crystallization from alcohol. The m. p. of a mixture of this product with α-trihydroxystearic acid produced by the permanganate oxidation of ricinoleic acid (m. p. 109–111.5°) was 97–100°; that of a mixture with δ-trihydroxystearic acid (m. p. 109–110°) obtained by the permanganate oxidation of ricinelaidic acid was 109–110°.

After evaporation of the mother liquor under vacuum, the residue was extracted with ligroin and finally taken up in diethyl ether. On cooling to below 0°, the ether solution deposited 1.5 g. of a white solid, m. p. 78.5–82.5°. This was dissolved in 50 cc. of ether and cooled to 0°, when a small amount of the δ-acid precipitated. At −40°, the remainder crystallized with a m. p. of 83–87°; this was recrystallized from aqueous alcohol and ether to a m. p. of 86–87°, showing no depression with the γ-trihydroxystearic acid obtained by the permanganate oxidation of ricinelaidic acid.

Equally poor yields of the γ- and δ-trihydroxystearic acids were similarly obtained from ricinoleic acid oxidized with hydrogen peroxide in glacial acetic acid at 0° in the course of one week, according to the method of Hilditch.[5]

The oxidation of about 300 g. of castor oil with 225 g. of 30% hydrogen peroxide in 820 cc. of glacial acetic, previously warmed and cooled as before, duplicated all the observations of Scanlan and Swern,[15] the temperature of the reaction mixture rising quickly to 70°, at which point the mixture became homogeneous. The crude trihydroxystearic acids, obtained after saponification of the reaction product with dilute alkali and subsequent acidification, were recrystallized from alcohol and then toluene to yield about 90 g. of a beautifully crystalline solid, m. p. 109–110°, which was identical with the higher-melting compound produced in the similar oxidation of the free ricinoleic acid and in the permanganate oxidation of ricinelaidic acid. It caused a marked depression in m. p. when mixed with α-trihydroxystearic acid. The mother liquors of the above crystallization were combined and evaporated to a small volume from which about 5 g. of solid material precipitated on cooling. This product was recrystallized from aqueous alcohol, exhaustively extracted with boiling water in which the δ-acid is somewhat soluble, and finally fractionally crystallized from diethyl ether. The first crop, obtained at 0°, melted at 108–110°; the residue melted at 81–85°. Further fractionation of this residue narrowed the m. p. to 85–87°, which was unaffected by admixture with γ-trihydroxystearic acid.

(b) **Ricinelaidic Acid.**—The *trans*-isomeride reacted with the acid hydrogen peroxide as sluggishly as did ricinoleic acid but produced relatively better yields of α- and β-trihydroxystearic acids, which were easily purified. Thirty grams of ricinelaidic acid was stirred into a solution of 22.7 g. of 30% hydrogen peroxide in 32 cc. of glacial acetic which had been warmed for one hour at 80° and

(19) Micro analyses by C. H. Van Etten, Division of Analytical and Physical Chemistry, Northern Regional Research Laboratory.

cooled to room temperature. An additional 18 cc. of the acetic acid was added to facilitate the solution of the solid acid. The temperature of the mixture rose only to 43°. After standing at room temperature for two days, the substantially homogeneous solution was filtered to remove a slight amount of waxy solid and the free acids were recovered from the filtrate by dilution with water, saponification with 100 cc. of 1 *N* sodium hydroxide and acidification as in the procedure followed with ricinoleic acid. The dried crude acids were separated with boiling chloroform, which left undissolved about 4 g. of a white powder, m. p. 137–138.5° without further purification. This proved to be β-trihydroxystearic acid, identical with the corresponding product of the permanganate oxidation of ricinoleic acid.

The chloroform solution readily deposited 4 g. of a white solid, m. p. 110–111°. The mixed m. p. showed no depression with α-trihydroxystearic acid (obtained by the permanganate oxidation of ricinoleic acid) and a wide range in m. p., beginning below 100°, with the δ-trihydroxystearic acid (m. p. 109–110°, derived from the permanganate oxidation of ricinelaidic acid or the peracetic acid oxidation of ricinoleic acid).

Further Purification of the Trihydroxystearic Acids and the Determination of their Specific Rotations.—Prior to the determination of their optical activities, the corresponding lots of trihydroxystearic acids were combined and purified as follows, the m. p. being determined with calibrated Anschütz thermometers: the α-acid was recrystallized from aqueous alcohol and then fractionated from successively smaller volumes of ether, which left undissolved small residues, m. p. 110–124° and 110–114°. The fractionation of the more soluble portion was continued from diminishing volumes of ether until both the insoluble and soluble portions melted at 109.6–112.4°. This substance was readily soluble in chloroform and benzene, which, however, were found to be unsuitable for recrystallization because the substance separated from such solutions carried much solvent and was difficult to filter off. A 95% alcoholic solution containing 5.562 g./100 cc. at 23° showed a rotation in a 2-dm. tube of −0.32°, $[\alpha]^{23}D$ −2.87°; for a glacial acetic acid solution containing 4.497 g./100 cc., the angle of rotation was −0.60°; $[\alpha]^{23}D$ −6.67°. Considering the difference in concentrations, the latter value agrees well with Walden's[3] figure of $[\alpha]D$ −6.25°.

The β-acid was thoroughly extracted with boiling toluene, and then with ether; it was recrystallized from alcohol, 50% acetic acid, again from alcohol, and was finally dried with diethyl and petroleum ethers. The purified acid was a microcrystalline powder which was poorly soluble in acetone, from which it precipitated in a form difficult to filter. The m. p. was 137.6–138.2°. Three additional crystallizations from alcohol followed by another from a large volume of water failed to change its m. p. or appearance. The rotation in a 4-dm. tube of an alcoholic solution containing 1.992 g./100 cc. was −0.31°, $[\alpha]^{23}D$ −3.89°; for the acetic acid solution of 2.152 g./100 cc. it was −1.0°, $[\alpha]^{23}D$ −11.62°.

The combined portions of the γ-acid were treated as before by exhaustion with boiling water and recrystallization from aqueous alcohol and finally from ether. It was the most soluble of the four isomers described; m. p. 86.8–87.4°. The rotation in a 2-dm. tube of an alcoholic solution containing 3.581 g./100 cc. was +0.37°, $[\alpha]^{23}D$ +19.13; for glacial acetic acid (c = 2.039), the rotation was +0.89°, $[\alpha]^{23}D$ +21.82°.

The δ-isomer is readily distinguished from the α-trihydroxystearic acid by its relatively poorer solubility in organic solvents, and by the fact that it is the only one of the four diastereoisomers which readily forms large crystals. It is best recrystallized from toluene. Its m. p. was 109.4–110.4°. The rotation in a 4-dm. tube of a 95% alcoholic solution containing 2.440 g./100 cc. was −2.60°, $[\alpha]^{23}D$ −26.63°; in a 2-dm. tube, for an acetic acid solution containing 4.311 g./100 cc. the angle was −3.34°, $[\alpha]^{23}D$ −38.85°.

Summary

1. The partial oxidation of ricinoleic and ricinelaidic acids with alkaline permanganate and with peracetic acid has been shown to result in four distinct diastereoisomeric 9,10,12-trihydroxystearic acids formed in two inter-related pairs, as expected from theoretical considerations but contrary to statements in the recent literature.

2. The α- and β-trihydroxystearic acids, m. p. 112 and 138°, and $[\alpha]^{23}D$ −6.6 and −11.6° in acetic acid (or −2.9 and −3.9° in ethanol), respectively, were obtained by the oxidation of ricinoleic acid with alkaline permanganate or of ricinelaidic acid with hydrogen peroxide in acetic acid. The γ-trihydroxystearic acid, previously unreported, and the δ-isomer, m. p. 87 and 110°, and $[\alpha]^{23}D$ +21.8 and −38.7° in acetic acid (or +19.1 and −26.6° in ethanol), respectively, were obtained by the oxidation of ricinelaidic acid with alkaline permanganate or of ricinoleic acid with hydrogen peroxide in acetic acid.

3. The optical activities of the four trihydroxystearic acids, previously unreported for three of them, were related to the *cis*- and *trans*-structures of the parent ricinoleic and ricinelaidic acids, respectively.

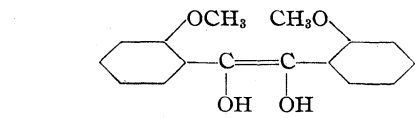
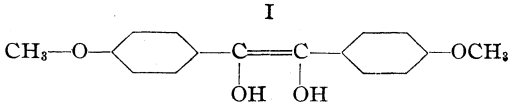
The Effect of Methoxyl toward Stabilizing Ene-diols

BY R. P. BARNES AND WENDELL M. LUCAS[1]

In keeping with a mechanism recently presented in connection with the effect of the *p*-methoxyl group on the rearrangement of anisbenzoin into benzanisoin,[2] the authors set out to investigate the stability of 2,2′-dimethoxydiphenylacetyleneglycol (I) and 4,4′-dimethoxydiphenylacetyleneglycol (II).

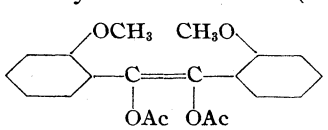


I

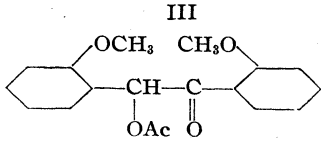


II

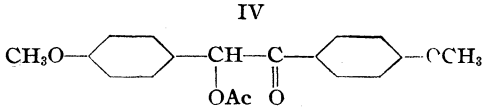
The 2,2′- and 4,4′-dimethoxybenzoins were prepared and acetylated.[3] In cases previously reported,[2,3,4] this method of acetylation has served admirably to convert α-hydroxy ketones into diacetates of ene-diols. In the case of these two substituted benzoins the presence of the methoxyl groups similarly placed in the aromatic nuclei seems to stabilize the benzoins by repressing enolization, with the result that no diacetate is obtained in either case. The monoacetates (IV and V) are obtained in excellent yield in both cases. Further acetylation of the monoacetate (IV) yields a small amount of the diacetate (III); under similar treatment, the monoacetate (V) does not yield any of the diacetate (VIII). Thus



III



IV

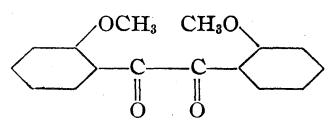


V

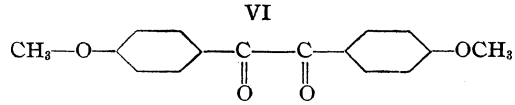
the methoxyl effect is real. The strong electron release tendency of one methoxyl group is offset by the same tendency of the similarly placed methoxyl group from the opposite direction. The para substituents are more powerful than the ortho

The original conception of the effect of similarly placed methoxyl groups was that it would serve to stabilize the ene-diols—or at least prevent ketonization.

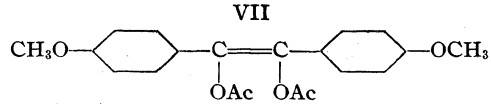
Not being able to obtain the ene-diol diacetates by direct acetylation, we prepared the 2,2′- and 4,4′-dimethoxybenzils, (VI) and (VII), and reduced them catalytically in the presence of acetic anhydride, according to the method of Thompson,[5] producing the diacetates (III) and (VIII),



VI

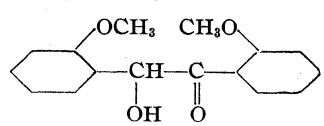


VII



VIII

respectively. These diacetates cannot be hydrolyzed to the monoacetates in acetic acid solution in the presence of potassium acetate.[3] Hydrolysis of the diacetates (III) and (VIII) by means of sulfuric acid resulted in the 2,2′-dimethoxybenzoin (IX) and the 4,4′-dimethoxybenzil (VII), respectively.



IX

Thus the 2,2′-dimethoxydiphenylacetylene glycol (I) shows a tendency toward ketonization, whereas the 4,4′-dimethoxydiphenylacetyleneglycol (II) is autoxidized. These results indicate conclusively that methoxyl groups in the para positions have a greater stabilizing effect on both the

benzoin and the ene-diol, which is the intermediate in the hydrolysis of the diacetate, than do methoxyl groups in the ortho positions.

Experimental

2,2′-Dimethoxylbenzoin Monoacetate (IV).—To a solution of 17 g. of 2,2′-dimethoxybenzoin in 90 cc. of acetic anhydride was added 8.5 g. of freshly fused potassium acetate, and the mixture refluxed on the steam-bath for thirty minutes. After cooling thoroughly, the solution was poured into 500 cc. of cold water and stirred vigorously to decompose the excess acetic anhydride. A yellow oil separated and solidified. It was filtered, washed thoroughly with water and dried. The crude yield was 21 g. This solid was crystallized from ether and melted at 102°.

Anal. Calcd. for $C_{18}H_{18}O_5$: OCH_3, 19.73. Found: OCH_3, 19.66.

4,4′-Dimethoxybenzoin Monoacetate (V).—This monoacetate was prepared from 17 g. of the 4,4′-dimethoxybenzoin under the same conditions as above. The crude yield was 20 g. Recrystallized from ether, it melted at 93.5°.

Anal. Calcd. for $C_{18}H_{18}O_5$: OCH_3, 19.73. Found: OCH_3, 19.76.

Acetylation of the Monoacetates (IV) and (V).—A solution of 5 g. of the 2,2′-dimethoxybenzoin monoacetate in 30 cc. of acetic anhydride was refluxed gently for three and one-half hours with 10 g. of freshly fused potassium acetate. The reaction mixture darkened after one and one-half hours. It was thoroughly chilled and poured with rapid stirring into 500 cc. of cold water. A brown oil separated, which, after several washings with cold water, solidified. The solid was crystallized from 40 cc. of dilute alcohol (3:2), yielding 4 g. of a light brown crystalline solid which melted from 99–101°. This solid was warmed for a few minutes with 75 cc. of ether. A small portion of the solid was insoluble in ether. The ether-soluble portion gave the pure unchanged monoacetate, melting and mix-melting at 102°. Three and one-half grams of unchanged monoacetate was recovered. The ether-insoluble fraction (0.8 g.) was recrystallized from the least amount of alcohol in which it is extremely soluble. The practically colorless crystals melted at 149°.

Anal. Calcd. for $C_{20}H_{20}O_6$: OCH_3, 17.41. Found: OCH_3, 17.34.

A 5-g. sample of the 4,4′-dimethoxybenzoin monoacetate was treated similarly. There resulted 3.5 g. of an oil from which 2.5 g. of the starting material was recovered.

Reduction of 2,2′-Dimethoxybenzil.—To a solution of 5 g. of the benzil in 75 cc. of acetic anhydride was added 1 g. of freshly fused zinc chloride and 0.08 g. of Adams catalyst. The solution was treated for seven and one-half hours in the Burgess–Parr hydrogenation apparatus. At the end of this treatment the product was poured into a liter of ice and water. A solid separated. It was filtered, washed with water, and crystallized from an alcohol–acetone solution. The yield was 2.5 g., melting at 150°, giving no depression in melting point with the 149°-melting substance obtained by way of acetylation of the 2,2′-dimethoxybenzoin monoacetate.

Reduction of 4,4′-Dimethoxybenzil.—A solution of 5 g. of the benzil with 1 g. of freshly fused zinc chloride in 150 cc. of acetic anhydride to which was added 0.1 g. of Adams catalyst, was subjected to hydrogenation for a period of twelve hours. The product was worked up as above. The colorless solid obtained was crystallized from methanol, yielding 3.5 g. of material melting from 118–123°. After repeated recrystallizations, the substance melted from 121–124°.

Anal. Calcd. for $C_{20}H_{20}O_6$: OCH_3, 17.41. Found: OCH_3, 17.49.

A small amount (0.1 g.) of colorless material insoluble in methanol was recrystallized from acetone and melted at 215°. This material failed to give a test for acetic acid.

Treatment of the Diacetates with Acetic Acid and Potassium Acetate.—Both diacetates were subjected to the following treatment: Four-tenths of a gram of the diacetate was dissolved in 10 cc. of acetic acid with 0.7 g. of potassium acetate and refluxed for seven hours. In each case the diacetate was recovered.

Hydrolysis of 2,2′-Dimethoxydiphenylacetyleneglycol Diacetate.—A solution of 0.85 g. of the diacetate in 20 cc. of cold concentrated sulfuric acid is green. This solution was put in an atmosphere of nitrogen and allowed to stand overnight. The green solution was poured onto finely cracked ice. A colorless solid separated. It was filtered, washed and dried and crystallized from alcohol. It melted and mix-melted with the original material at 150°. To a suspension of 0.7 g. of the diacetate in 10 cc. of alcohol was added 30 cc. of 20% sulfuric acid. The mixture was refluxed for one hour. The solid dissolved in about fifteen minutes. The solution was chilled, and a colorless crystalline solid separated. This solid melted from 94–97°. It mix-melted with the monoacetate from 80–85°; it gave no depression when mix-melted with the 2,2′-dimethoxybenzoin.

Hydrolysis of 4,4′-Dimethoxydiphenylacetyleneglycol Diacetate.—One gram of the diacetate was dissolved in 30 cc. of cold concentrated sulfuric acid. The green solution was allowed to stand at room temperature for thirty minutes, and was then poured onto finely cracked ice. A cream colored solid separated. It was filtered, washed and dried, and recrystallized from alcohol. It melted at 133°. The mix-melt with anisil was unchanged.

Summary

1. 2,2′- and 4,4′-dimethoxybenzoins can be effectively acetylated to the corresponding monoacetates, but not to the corresponding acetyleneglycol diacetates.

2. 2,2′- and 4,4′-dimethoxydiphenylacetyleneglycol diacetates can be obtained by catalytic hydrogenation in acetic anhydride solution.

3. The diacetates are not hydrolyzable to the monoacetates in acetic acid solution.

4. When completely hydrolyzed, the intermediate 2,2′-dimethoxydiphenylacetyleneglycol ketonizes to the benzoin, while the intermediate 4,4′-dimethoxydiphenylacetyleneglycol, being more resistant toward ketonization, is autoxidized to the corresponding benzil.

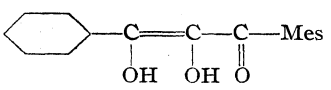
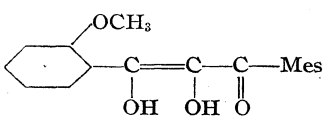
The Preparation and Properties of an Ene-diol. α-o-Methoxyphenyl-β-mesitoylacetylene Glycol

BY R. P. BARNES AND WENDELL M. LUCAS[1]

The effect of 2,2′-dimethoxyl substitution on the stability of benzoin and its ene-diolic modification has already been pointed out.[2] This work was undertaken to determine the effect of introducing the methoxyl group in the ortho position of the phenyl group in α-phenyl-β-mesitoylacetyleneglycol[3] (I). It has been found that the methoxyl-substituted compound (II) is more stable than the unsubstituted compound (I).



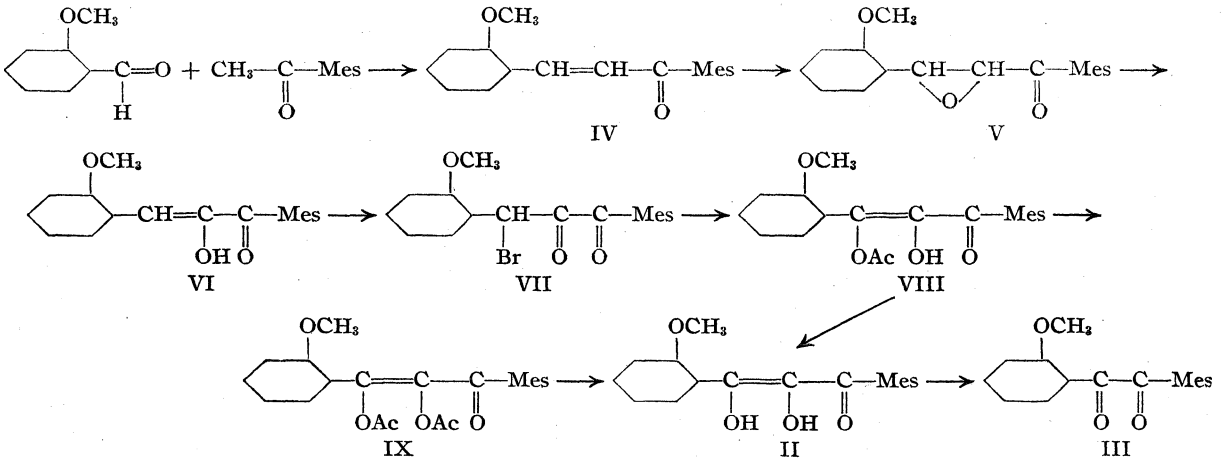
I



II

The ene-diol (II) is a colorless needle-like crystalline solid, extremely soluble in alcohol, very appreciably soluble in water and only sparingly soluble in ether and petroleum ether. It gives a deep greenish-blue color with alcoholic ferric chloride, which color fades gradually to yellow. It bleaches iodine and 2,6-dichlorobenzeneoneindophenol. It is slowly oxidized by atmospheric oxygen. The end-product of these reactions is o-methoxyphenylmesityl diketone (III).

The following schematic representation indicates the manner in which the ene-diol (II) is obtained



Experimental

o-Methoxybenzalacetomesitylene (IV).—A solution of 15 g. of sodium hydroxide in 40 cc. of water was diluted with 100 cc. of alcohol. To this alkaline alcoholic solution was added 23 g. of acetylmesitylene with stirring and chilling. To this cold solution was added slowly and with stirring 28 g. of o-methoxybenzaldehyde. At the end of twenty minutes considerable solid material had separated. Stirring was continued for one hour. The product was filtered, washed, dried and recrystallized from alcohol. The yield was 36 g. of a pale yellow solid, melting at 95°.

Anal. Calcd. for $C_{19}H_{20}O_2$: OCH_3, 11.07. Found: OCH_3, 11.06.

α-o-Methoxyphenyl-β-mesitoylethylene Oxide (V).—To a solution of 31 g. of o-methoxybenzalacetomesitylene in 200 cc. of alcohol was added 14 cc. of 30% hydrogen peroxide. This solution was made alkaline with 25 cc. of 20% sodium hydroxide. It was warmed gently with stirring. As the reaction proceeded considerable heat was evolved. The reaction mixture was maintained at room temperature by cooling. On standing in the cold a cream-colored solid separated. The solution was diluted with water and the product was filtered, washed and dried. Recrystallized from alcohol, the yield was 26 g. of colorless solid, melting at 73–74°.

Anal. Calcd. for $C_{19}H_{20}O_3$: OCH_3, 10.47. Found: OCH_3, 10.29.

The Enolic Modification of Mesityl-o-methoxybenzylglyoxal (VI).—To a solution of 23 g. of the ethylene oxide, dissolved in 125 cc. of alcohol, was added a solution of 15 g. of sodium hydroxide in 30 cc. of water. The mixture was boiled gently for ten minutes. The solution became deep yellow in color. It was cooled and poured into a cold dilute solution of hydrochloric acid. A pale yellow solid

(1) In partial fulfillment of the requirements for the Master's degree.

(2) R. P. Barnes and W. M. Lucas, THIS JOURNAL, **64**, 2258 (1942).

(3) R. P. Barnes and Leila S. Green, *ibid.*, **60**, 1549 (1938).

separated. The solid was filtered, washed, dried and recrystallized from alcohol. The yield was 16 g., melting at 137°.

Anal. Calcd. for $C_{19}H_{20}O_3$: OCH_3, 10.47. Found: OCH_3, 10.60.

An alcoholic solution of this substance gives a cherry-red color with ferric chloride. Kurt Meyer titrations[4] indicate that it is 98% enolic.

α-Bromo-*o*-methoxybenzylmesitylglyoxal (VII).—To a solution of 8 g. of the enol in 75 cc. of carbon tetrachloride was added 8 g. of precipitated calcium carbonate. A solution of 4.4 g. of bromine in 30 cc. of carbon tetrachloride was added dropwise with stirring to the solution containing the calcium carbonate in suspension. Hydrogen bromide was evolved. The enol in solution decolorized the bromine solution instantaneously with the addition of each drop. The resulting orange-colored solution was filtered from the suspended material, and evaporated in a stream of dry air. Final traces of carbon tetrachloride and moisture were removed *in vacuo*. Eleven grams of a deep yellow oil resulted. This oil was crystallized from methanol in golden-yellow needles, melting at 84°.

Anal. Calcd. for $C_{19}H_{19}O_3Br$: OCH_3, 8.2. Found: OCH_3, 8.3.

The bromo compound is non-enolic.

The Acetate of α-Oxy-*o*-methoxybenzylmesityl-α-diketone (VIII).—To a solution of 5.5 g. of the bromo compound in 50 cc. of acetic acid was added 11 g. of freshly fused potassium acetate. The solution was refluxed gently for four hours. It turned cherry-red. The solution was cooled thoroughly and poured into a large volume of cold water and stirred vigorously. A yellow oil separated and solidified. It was filtered, washed and dissolved in alcohol. On chilling a cream colored solid separated, melting from 84–86°. On recrystallization from alcohol, it melted at 94°. The yield was 3 g.

Anal. Calcd. for $C_{21}H_{22}O_5$: OCH_3, 8.75. Found: OCH_3, 8.84.

This compound in alcoholic solution gives a cherry-red color with alcoholic ferric chloride. It is enolic[4] to the extent of 80%.

The Diacetate of α-*o*-Methoxyphenyl-β-mesitoylacetylene Glycol (IX).—One gram of the monoacetate was dissolved in 10 cc. of acetyl chloride and refluxed for one hour. The excess acetyl chloride was pumped off and the oily residue taken up in alcohol, from which solution a colorless solid, melting at 103–104°, was obtained. The yield was 0.8 g.

Seven grams of the bromo compound was dissolved in 66 g. of acetic anhydride, to which solution 10 g. of freshly fused potassium acetate was added. The mixture was refluxed gently for one and one-half hours. It became light yellow and potassium bromide separated. The thoroughly chilled mixture was poured into a large volume of cold water and stirred An orange-red oil separated. It was washed several times with cold water and finally taken up in alcohol, from which solution a colorless solid melting and mix-melting with the above substance at 103–104°, was obtained.

Anal. Calcd. for $C_{23}H_{24}O_6$: OCH_3, 7.83. Found: OCH_3, 7.84.

This substance gives no color with alcoholic ferric chloride.

α-*o*-Methoxyphenyl-β-mesitoylacetylene Glycol (II).—Four grams of the monoacetate was dissolved with stirring in 50 cc. of cold concd. sulfuric acid. The solution was orange colored. It was allowed to stand for thirty minutes at 0°. It was then poured onto finely cracked ice in a g. s. flask. The air in the flask was displaced by nitrogen, the flask was stoppered and shaken vigorously. A fine needle-like colorless solid separated. It was allowed to stand overnight at 0°. It was filtered, washed with a little iced water, then with ether. It was recrystallized from dilute alcohol, yielding 3 g., melting at 105°.

Four grams of the diacetate was treated similarly. The result was about 2 g. of colorless needles, melting and mix-melting with the above substance at 105°.

Anal. Calcd. for $C_{19}H_{20}O_4$: OCH_3, 9.9. Found: OCH_3, 9.8.

This substance is extremely soluble in alcohol and quite soluble in water. It is rather insoluble in ether and insoluble in petroleum ether. It produces a bluish-green color with alcoholic ferric chloride, which color fades gradually to yellow. It decolorizes iodine solution and bleaches 2,6-dichlorobenzeneoneindophenol instantaneously.

The Diketone (III).—Alcoholic test solutions of the ene-diol with ferric chloride, iodine and indophenol blue all resulted in yellow solutions from which a yellow solid, melting at 132°, was obtained. Atmospheric oxidation goes on slowly producing a more highly colored solid, which upon crystallization results in the same light yellow solid, melting at 132°.

Anal. Calcd. for $C_{18}H_{18}O_3$: OCH_3, 10.89. Found: OCH_3, 10.90.

The diketone is cleaved by alkaline hydrogen peroxide, yielding mesitoic and *o*-methoxybenzoic acids, identified by comparison with known samples.

Summary

A new ene-diol, α-*o*-methoxyphenyl-β-mesitoylacetylene glycol, has been synthesized and its properties listed.

The *o*-methoxyl in the phenyl group has rendered the ene-diol more stable than the unsubstituted α-phenyl-β-mesitoylacetylene glycol.

The only product which is obtainable from oxidation reactions is the diketone.

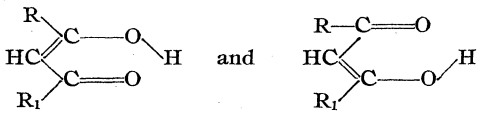
The Properties of *o*-Methoxybenzoylmesitoylmethane

BY R. P. BARNES AND CHAPPELLE C. COCHRANE

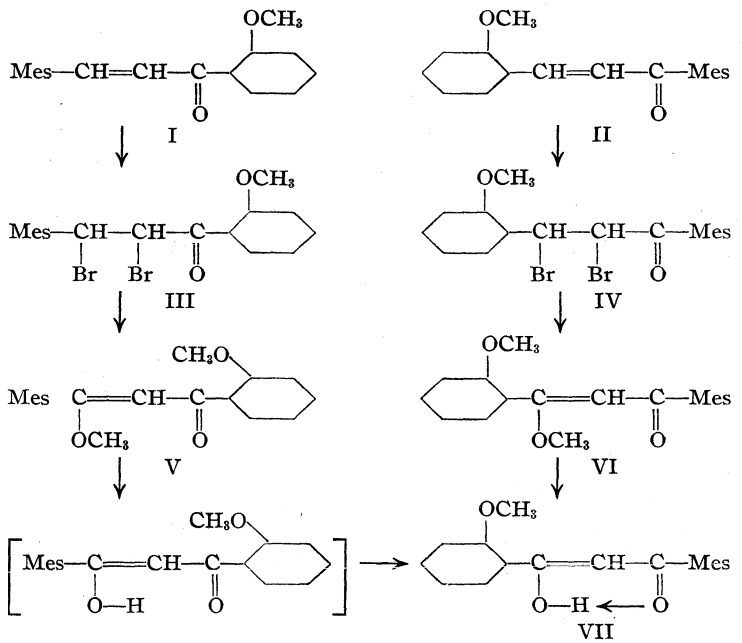
In an earlier paper[1] we reported two series of reactions which gave a single enol, although, according to the mechanism, one would expect two isomeric enols. Sidgwick[2] states that coördination of hydrogen occurs in ordinary chelation in keto-enols



He states further that the strain in the 6-ring with two double links is very small and that the same position of the atoms fits either structure. Thus the fact that two isomeric enols of this type have never been isolated is accounted for.

Steric hindrance is also a very important factor, contributing to the non-existence of two isomeric enols. In this communication we are reporting two parallel series of reactions which give rise to a single enol. The effect of the mesityl nucleus in offering hindrance to 1,2-addition reactions to adjacent carbonyls is well known, and one would predict a single enol on this basis alone in this case. This enol is obviously chelated, being a beta-diketone,[3] and this is evidenced by the fact that it is neither acetylated by the ordinary reactions of acetylation, nor does it yield to O-methylation.

The following series of reactions indicates the manner in which the enol is obtained.



Experimental

The α,β-unsaturated ketone (I) and the dibromides (III) and (IV) were prepared according to standard methods as given in "Organic Syntheses."[4a,b]

The methyl ethers (V) and (VI) were obtained by refluxing 1 g. of each of the respective dibromides for one and one-half hours in methyl alcoholic sodium methylate made by dissolving 0.2 g. of metallic sodium in 20 cc. of the alcohol. Sodium bromide separated. The cooled mixture was poured into a large volume of cold water. The oils which separated in each case were crystallized from methyl alcohol as colorless solids, producing no color with alcoholic ferric chloride.

One gram of each of the methyl ethers (V) and (VI) was dissolved in 50 cc. of methyl alcohol and refluxed for one hour with 10 cc. of concd. hydrochloric acid. On cooling, colorless solids separated, which upon filtering and recrystallizing from methanol melted and mix-melted at 105°. This enol gives a deep red color with alcoholic ferric chloride and is 100% enolic.[5] Repeated treatments with diazomethane always resulted in a recovery of unchanged enol. In like manner treatment with acetic anhydride and sulfuric acid or with acetyl chloride did not effect acetylation of the enol.

TABLE I

Compound	Melting point, °C.	OCH_3 Analyses, % Formula	Calcd.	Found
I	118	$C_{19}H_{20}O_2$	11.07	11.00
III	135	$C_{19}H_{20}O_2Br_2$	7.04	7.01
IV	86	$C_{19}H_{20}O_2Br_2$	7.04	7.00
V	87	$C_{20}H_{22}O_3$	20.00	20.20
VI	85	$C_{20}H_{22}O_3$	20.00	19.93
VII	105	$C_{19}H_{20}O_3$	10.47	10.50

Summary

Herein are reported two parallel series of reactions which give rise to a single enol, for which there is given some chemical evidence of hydrogen bonding.

Esters of Secondary Hydroxyaralkylalkylamines[1]

BY JOHANNES S. BUCK AND RICHARD BALTZLY

The preparation of esters of phenolic secondary amines of the type of 4-hydroxyphenethylmethylamine, wherein the amino group is not also acylated, presents difficulties. No compounds of this type have been found in the literature. The sensitiveness of phenolic esters precludes their use as starting materials for building up the amine, and the reactivity of the amino group of the hydroxyamines prevents preferential acylation of the hydroxy groups.[2] Furthermore, it is not possible to remove only the N-acyl group from the completely acylated hydroxy amine.[3] Protection by the carbobenzoxy group was not found to be feasible as the group did not survive the reactions used.

By extending the method previously described[4] for preparing secondary amines, the authors have succeeded in obtaining the desired O-acyl compounds by a series of smooth reactions of general applicability. In the cases described below, a methoxy- or dimethoxyphenethylbenzylmethylamine was O-demethylated, the phenolic group or groups acylated, and the protecting benzyl group then removed by catalytic hydrogenation. From homoanisylamine were prepared 4-acetoxy-, 4-benzoyloxy- and 4-ethylcarbonatophenethylmethylamines. Similarly N-methylhomoveratrylamine was converted into 3,4-diacetoxy-, 3,4-dibenzoyloxy- and 3,4-diethylcarbonatophenethylmethylamines.

The compounds in question, being stabilized or protected forms of pressors and the like, are of considerable pharmacological interest, and they are being investigated from this point of view.

Experimental

4-Methoxyphenethylbenzylmethylamine Hydrochloride.—4-Methoxyphenethylbenzylamine[5] was methylated by the Eschweiler–Clarke[6] method, using 1.1 mol of formaldehyde and 5 mols of absolute formic acid, and the product was isolated as the hydrochloride. The yield approached the theoretical.

3,4-Dimethoxyphenethylbenzylmethylamine Hydrochloride.—Attempts to prepare this compound from benzylhomoveratrylamine[7] by the foregoing method, gave unsatisfactory results, probably owing to partial cyclization.[8] It was therefore prepared as follows: one mol of 3,4-dimethoxyphenethylmethylamine[9] dissolved in three volumes of ethanol, was treated with one mol of benzyl chloride. After three days the alcohol was evaporated off, water added, and the whole made acid; 0.8 mol of sodium nitrite, in solution, was added, and the whole extracted with ether. The aqueous layer, after making alkaline, was extracted with ether. After evaporation of the ether, the residue was converted into the hydrochloride; the yield was mediocre (30%).

4-Hydroxy- and 3,4-Dihydroxyphenethylbenzylmethylamines.—The corresponding 4-methoxy and 3,4-dimethoxyphenethylbenzylmethylamine hydrochlorides were demethylated with concentrated hydrochloric acid, in a carbon dioxide atmosphere, for two hours at 170°. The colorless solutions were evaporated to dryness *in vacuo*. The yields approached the theoretical.

Acylation of the Phenolic Amines.—Acetylation was accomplished by refluxing the amine hydrochlorides in a mixture of acetic anhydride and acetyl chloride, in which they gradually dissolved. After about two hours, the solvent was removed in an air stream. The residues were ground with acetone and filtered off prior to recrystallization. Use of alcohols in crystallizing the acetoxy derivatives is inadvisable. With the benzoyloxy and ethylcarbonato compounds alcohols are probably permissible but were avoided.[10]

Benzoylation of the phenolic amines was carried out by the Schotten–Baumann method. The oils resulting from the reaction were taken into ether and dried over potassium carbonate before being converted to the hydrochlorides.

The carbethoxylations required a modified Schotten–Baumann technique of which the following is an example. One mol of 4-hydroxyphenethylbenzylmethylamine hydrochloride was dissolved in water and stirred in an atmosphere of nitrogen, with ice-cooling. A solution of sodium hydroxide (3 mols), was run in slowly, 2 mols of ethyl chlorocarbonate being admitted simultaneously, keeping the alkali a little ahead of the chlorocarbonate (any considerable excess of chlorocarbonate could be detected in the stream of escaping nitrogen). The resulting oil was extracted with ether, dried over anhydrous potassium carbonate and the hydrochloride precipitated by gaseous hydrogen chloride.

In the preparation of 3,4-diethylcarbonatophenethylbenzylmethylamine hydrochloride an additional mol of sodium hydroxide and of ethyl chlorocarbonate was used. This compound, however, was not obtained crystalline,

and was debenzylated directly. The yields of both substances are improved somewhat by using greater excesses of alkali and of acylating agent.

Debenzylations.—These were performed by catalytic hydrogenation of the hydrochlorides in 80% acetic acid solution, using a Burgess–Parr apparatus, at room temperature and three atmospheres pressure. Palladized charcoal (from 1.2 g. of palladium chloride and 6 g. of Darco G60) was used as catalyst. The theoretical amount of hydrogen was taken up in two to three hours (from 10 g. of starting material). The solutions were filtered and evaporated to dryness *in vacuo* before recrystallization. The yields were excellent. The secondary amine hydrochlorides are colorless solids, soluble in water and alcohol, moderately soluble in acetone, sparingly soluble in ethyl acetate and insoluble in ether and non-polar solvents.

The authors are indebted to Mr. W. S. Ide for the many microanalyses performed, including some chlorine and nitrogen analyses not recorded here.

Descriptive and analytical data are presented in the table.

Summary

A method has been developed for preparing phenolic esters wherein an unacylated secondary amino group is required on a side chain. The method involves N-debenzylation.

Poly-condensation of α-Amino Acid Esters. I. Poly-condensation of Glycine Esters[1]

BY MAX FRANKEL AND EPHRAIM KATCHALSKI

This paper deals with the poly-condensation of methyl, ethyl and isobutyl esters of glycine and with the further condensation of isolated primary reaction products.

Curtius[2] has shown that under certain conditions glycine ethyl ester yields, besides glycine anhydride, a tetraglycine ethyl ester, the so-called "Biuret Base." This tetrapeptide ester is the highest condensation product which hitherto has been obtained directly from the glycine ethyl ester. No clear results are reported in the literature concerning the formation of the corresponding tetrapeptide ester from glycine methyl ester.[3] In any case it is clear that the tetrapeptide esters were regarded as the highest peptide esters formed by condensation from the glycine ester. Nothing definite seems to be known about the condensation to chains of glycine esters other than those of methanol and ethanol.

(1) Certain minor errors in the manuscript as originally submitted were noted by the Editorial Board. Ordinarily these would have been brought to the attention of the authors prior to publication. International conditions at present are such that it appears impossible to follow this procedure except at the risk of indefinite postponement. The Editor has therefore taken the responsibility to make any corrections which appeared to be unquestionably required.—THE EDITOR.

(2) Curtius, *Ber.*, **37**, 1284 (1904).

(3) Curtius and Goebel, *J. prakt. Chem.*, [2] **37**, 159 (1888).

In a preliminary report[4] we have described some of our results obtained by C-polymerization of glycine ethyl ester. In our experiments we were able to isolate directly polypeptide esters with an average chain length of ten to thirty-five glycine units. These isolated products, when allowed to undergo additional condensation by heating, yield higher linear polymers. In the present paper we describe polymers thus obtained with an average chain length of 48–110 units.

The poly-condensations were carried out (a) with the pure liquid esters and (b) with their solutions in organic, water-free solvents. In a number of experiments in series (a) a stream of gas (nitrogen, hydrogen or oxygen) was passed through the liquid. In the experiments of series (b) solvent and temperature were varied.

The reaction mixtures contained, in addition to the higher condensation products, glycine anhydride and lower peptide esters. The separation was based mainly on the different solubility of the compounds concerned, which permitted the quantitative removal of all lower condensation products by extraction with hot water. A modified sensitive picric acid test, worked out for this purpose, was used in order to follow the complete removal of glycine anhydride. The quantitative removal of the water-soluble lower peptide esters was ascertained by the negative biuret reaction of the washings.

As is usual with products obtained by polymerization, mixtures containing polymer homologs are to be expected. The average chain length of the peptide ester form was ascertained by the determination of the terminal alkoxy group (*cf.* discussion). To avoid circumlocution, the polymerized products discussed in this paper are referred to as, *e. g.*, 20-glycine ethyl ester. It is to be understood that the specific names applied to the preparations merely indicate the average composition which corresponds most closely to the analytical results. They are not to be taken as implying that the preparations are homogeneous specimens of the substance named.

Experimental

I. Poly-condensation of Glycine Ethyl Ester.—The free glycine ethyl ester was liberated from its hydrochloride according to the method of Fischer[5] immediately before carrying out the condensation.

(a) **Poly-condensation of the Free Liquid Ester.**—These experiments were carried out by passing an indifferent gas through the liquid amino acid ester.

1. A stream of dried nitrogen was passed through 4 g. of freshly distilled glycine ethyl ester for twenty-four hours. Access of carbon dioxide and moisture was prevented. The liquid solidifies gradually and after twenty-four hours the passage of gas had to be discontinued. The reaction mixture which was soluble in water and gave a positive biuret reaction and a positive picric acid test was kept for five months in a desiccator over soda-lime. After this time a part of the product was found to be insoluble in hot water. Traces of unchanged ethyl ester were removed by extraction with ether. The fraction insoluble in hot water was separated from the lower condensation products by repeated washing with hot water and centrifuging till the biuret reaction and the picric acid test in the washings became negative. The amount of the vacuum dried fraction insoluble in hot water was about 250 mg.

Properties.—The substance is practically insoluble in the usual organic solvents and even in hot water. In the latter characteristic swelling occurs. In concentrated alkalies and acids the substance dissolves gradually apparently by undergoing hydrolysis. It is horn-like in appearance; no melting point, decomposition at about 280–300°. On heating a suspension with ninhydrin solution the particles gradually become blue-violet in color, the fluid remaining colorless. On allowing a suspension of the substance to stand with a 30% solution of sodium hydroxide and a few drops of a dilute solution of copper sulfate, a positive biuret reaction appears within some hours. This is obviously due to the hydrolysis of the high peptide ester (which owing to its insolubility does not give a positive biuret reaction) to a lower soluble peptide chain showing the biuret reaction. Calcd. for 20-glycine ethyl ester: C_2H_5O, 3.79; N, 23.59. Found: C_2H_5O, 3.87; N, 23.24.

In order to show that during the process of separation, which consists of repeated treatment with hot water, no hydrolysis of the terminal ester group occurs, 50 mg. of the analyzed substance no. 1 was washed repeatedly with hot water and afterward reanalyzed. No change in ethoxy content was found.

Thirty mg. of the 20-glycine ethyl ester was totally hydrolyzed by refluxing with 2 ml. of 10% sulfuric acid for five hours. After quantitative removal of the sulfate by barium hydroxide solution, and boiling with cupric oxide, 54 mg. of the copper salt of glycine was obtained (calcd. amount of $Cu(NH_2CH_2COO)_2 \cdot H_2O$, 56.3 mg.).

Anal. Calcd. for $Cu(NH_2CH_2COO)_2 \cdot H_2O$: Cu, 27.68. Found: Cu, 27.38.

2. Four grams of glycine ethyl ester was treated as in 1 except that hydrogen instead of nitrogen was bubbled through the ester. The experimental details were similar to those of the previous experiment. 200 mg. of a horn-like fraction was obtained. Calcd. for 20-glycine ethyl ester: C_2H_5O, 3.79; N, 23.59. Found: C_2H_5O, 3.99; N, 23.38.

3. On repeating experiment 2 and allowing the reaction mixture to stand in contact with air after the treatment with gas, the water-insoluble fractions which were finally obtained (200 mg.) corresponded in analysis with a 25-glycine ethyl ester. Calcd. for 25-glycine ethyl ester: C_2H_5O, 3.05; N, 23.79. Found: C_2H_5O, 3.09; N, 23.40.

4. When oxygen was used, solidification of the liquid, unlike that in the above experiments, was accompanied

(4) Frankel and Katchalski, *Nature*, **144**, 330 (1939).
(5) Fischer, *Ber.*, **34**, 433 (1901).

by the gradual appearance of a pink color. After keeping the primary reaction mixture in a desiccator for three months, the water-insoluble fraction obtained (160 mg.) corresponded to the 16-glycine ethyl ester. Calcd. for 16-glycine ethyl ester: C_2H_5O, 4.69; N, 23.37. Found: C_2H_5O, 4.66; N, 22.78.

5. Control experiments carried out without passing gas through the esters showed that under otherwise similar conditions no high chain products insoluble in hot water were formed.

(b) **Poly-condensation of the Free Ester in Solution.**— 1. In xylene at room temperature: 3 g. of freshly distilled glycine ethyl ester was dissolved in 12 ml. of pure, water-free xylene and kept for three months at room temperature. The precipitate which developed during this time was filtered, carefully washed with ether and dried *in vacuo* (1.7 g.). It was fractionated as before; 300 mg. of a water insoluble fraction was obtained corresponding to a 12-glycine ethyl ester. This product shows the general behavior of the higher polypeptides mentioned above, including the property of swelling in hot water, except that it is amorphous and not horn-like. Calcd. for 12-glycine ester: C_2H_5O, 6.15; N, 23.00. Found: C_2H_5O, 6.12; N, 22.81.

2. In xylene at boiling temperature: The solution as in (b)1 was refluxed for eight hours and then allowed to stand for two months at room temperature. After the usual treatment, there was obtained 240 mg. of a product similar in properties to that isolated in (b)1. Its analysis indicated an average chain length of 13 units. Calcd. for 13-glycine ethyl ester: C_2H_5O, 5.72; N, 23.11. Found: C_2H_5O, 5.52; N, 23.44.

3. In benzene at room temperature: 4 g. of glycine ethyl ester in 12 ml. of water-free benzene was kept for seventy days at room temperature. The 0.5 g. of precipitate was entirely soluble in hot water and gave both the biuret reaction and the picric acid test. The analytical data correspond to an equimolecular mixture of glycine tetrapeptide ethyl ester and glycine anhydride. *Anal.* Calcd. for this mixture: N, 21.62; C_2H_5O, 11.59; amino N, 3.60. Found: N, 21.47; C_2H_5O, 11.40; amino N, 3.55.

4. In boiling benzene: A solution of the same composition as that of (b)3 was refluxed for seven hours and then kept for seventy days at room temperature. The precipitate was treated as above with hot water and 150 mg. of material corresponding to a 17-glycine ethyl ester was obtained. Calcd. for 17-glycine ethyl ester: C_2H_5O, 4.43; N, 23.44. Found: C_2H_5O, 4.47; N, 23.67.

Total hydrolysis: 30 mg. of 17-glycine ethyl ester was refluxed with 2 ml. of 25% hydrochloric acid for six hours. After approximate neutralization with concentrated alkali, the *p*H of the solution was adjusted to 6.1 with 0.1 *N* sodium hydroxide. The amount of the amino nitrogen after hydrolysis was determined by titration according to Linderstrøm-Lang.[6] *Anal.* Calcd. for total hydrolysis of 17-glycine ester: amino N, 23.43. Found: N, 22.14.

5. No high condensation products have as yet been obtained under our experimental conditions from ether, dioxane and ethanol solutions. From the ethanol solution a precipitate was obtained which, on boiling with absolute alcohol, filtering, and cooling, gave a small number of colorless needle-like crystals. Analysis indicated a mixture of one molecule of glycine anhydride for every two molecules of "biuret base." *Anal.* Calcd. for this mixture: glycine anhydride, 17.2; N, 21.13; C_2H_5O, 13.58; amino N, 4.25. Found: glycine anhydride, 20.6; N, 21.19; C_2H_5O, 13.23; amino N, 4.23. Here, as well as in experiment (b)3, the products isolated may represent molecular compounds between the two components (*cf.* Pfeiffer).[7]

II. Poly-condensation of Glycine Methyl Ester.[8]— Glycine methyl ester hydrochloride was prepared by the method Johnson and Rinehart[9] used for obtaining glycine ethyl ester hydrochloride from methyleneaminoacetonitrile and methanol saturated with gaseous hydrogen chloride. As hot methanol dissolves considerable quantities of ammonium chloride, a recrystallization of the crude glycine methyl ester hydrochloride from ethanol is required to free it from the inorganic salt. The yield from 100 g. of methyleneaminoacetonitrile was 164.5 g. of pure glycine methyl ester hydrochloride.

The liberation of the free ester from its hydrochloride by the methods used for other glycine esters is not satisfactory; poor yields result. A more satisfactory method was worked out in collaboration with Dr. F. Stern using dry ammonia gas in place of sodium hydroxide: 10 g. of glycine methyl ester hydrochloride was suspended in 60 ml. of pure, water-free ether and a stream of carefully dried ammonia was passed with constant shaking at 0° through the suspension. Moisture was excluded. One to two hours later the solution of glycine methyl ester in ether was filtered from the suspended ammonium chloride, the latter washed with ether and the solution carefully dried over anhydrous sodium sulfate. The ether distillation was carried out with an effective column, to avoid loss of the ester. The free ester was then distilled *in vacuo* at 20 mm. and 45°; yield 4.8–5.0 g. of free ester.

(a) **Poly-condensation of the Free Liquid Ester.**— 1. 0.5 g. of freshly prepared glycine methyl ester was kept in a closed vessel for a month at room temperature. The fraction insoluble in hot water corresponded on analysis to 18-glycine methyl ester. Calcd. for 18-glycine methyl ester: CH_3O, 2.93; N, 23.81. Found: CH_3O, 2.96; N, 23.42.

2. Nitrogen was passed through 1.5 g. of glycine methyl ester for twelve hours and the semi-solid reaction mixture allowed to stand at room temperature for one month. After fractionating in the way previously mentioned, about 50 mg. of material averaging 30 units was obtained. Calcd. for 30-glycine methyl ester: CH_3O, 1.78; N, 24.11. Found: CH_3O, 1.77; N, 23.85.

(b) **Poly-condensation of the Free Ester in Solution.**— 1. In ether at room temperature: 1 g. of glycine methyl ester in 3 ml. of water-free ether was allowed to stand for three months; 250 mg. of a 27-glycine methyl ester was isolated by the usual procedure. Calcd. for 27-glycine methyl ester: CH_3O, 1.97; N, 24.06. Found: CH_3O, 1.90; N, 23.89.

2. In boiling xylene: 1.5 g. of glycine methyl ester in 4 ml. of water-free xylene was refluxed for four hours and

(8) The authors are indebted to Miss A. Saperstein for collaboration in this series of experiments.

(9) Johnson and Rinehart, THIS JOURNAL, **46**, 768, 1653 (1924).

then allowed to stand for three months at room temperature. About 200 mg. of 35-glycine methyl ester was obtained. Calcd. for 35-glycine methyl ester: CH_3O, 1.52; N, 24.17. Found: CH_3O, 1.54; N, 24.00.

In general the high glycine peptide methyl esters resemble the analogous ethyl esters but they seem to be slightly more soluble in hot water.[10]

III. Poly-condensation of Glycine Isobutyl Ester.—Glycine isobutyl ester hydrochloride was prepared by the method of Johnson and Rinehart[9]; 20 g. of aminoacetonitrile was refluxed for three hours with a mixture of 183 g. of dry isobutanol saturated with gaseous hydrogen chloride and 380 g. of isobutanol. The alcohol was distilled *in vacuo* from the filtered solution and the residue dried in a desiccator over sulfuric acid. The glycine isobutyl ester hydrochloride crystallizes after long standing as small, hygroscopic crystals; yield 40 g.

The free ester was liberated according to the method of Glenn and Skinner.[11] Dried nitrogen was passed through 5 g. of glycine isobutyl ester for thirty hours. The biuret reaction soon became positive. The cloudy liquid was allowed to stand at room temperature for about one and a half years, during which it became solid. By the usual treatment, 300 mg. of horny, water-insoluble product, free from anhydride, was obtained. It corresponded to a 10-glycine isobutyl ester. *Anal.* Calcd. for 10-glycine isobutyl ester: N, 21.74; C_4H_9O, 11.34. Found: N, 21.83; C_4H_9O, 10.81.

IV. Further Condensation of the Primary Condensation Products of Glycine Esters.—The linear polymers obtained in the above experiments were finely ground and kept at a temperature of about 130° for varying periods of time. They underwent further condensation which was demonstrated by a decrease in the alkoxy percentage. No glycine anhydride was formed during the operation (see Table I).

V. Analytical Methods.—Qualitative tests were made on micro and semi-micro scales. All quantitative determinations were by micro methods. Methoxy and ethoxy determinations were made according to Vieböck[12] using hydrogen iodide of d. 1.96; the determination of isobutoxy groups was carried out as in the preliminary experiments of Furter.[13] It has been found that quantitative results are obtained by extending the heating of the substance in Furter's apparatus for four hours, with hydrogen iodide of d. 1.96, and with a stream of carbon dioxide of five bubbles per second.

Amino nitrogen determinations were made by a micro modification of Linderstrøm-Lang's titration.

The picric acid tests for glycine anhydride were carried out according to a modification of the usual procedure[14] by which the sensitivity was considerably increased. It may be mentioned here that this modification served also as a basis for the quantitative determination of the anhydride in the presence of amino acids, peptides or their esters. This method will be described in detail elsewhere.

Two ml. of a saturated solution of picric acid and 0.2 ml. of 0.1 *N* sodium hydroxide solution were added to 1 ml. of the solution to be tested and the mixture boiled for thirty seconds; a brownish-red color indicates the presence of anhydride. If amino acids, peptides or their esters are present, an equivalent amount of sodium hydroxide has to be added before carrying out the determination. The quantitative determination is carried out colorimetrically.

Discussion

The well-known stability of the free amino acids, which is explicable by their zwitterionic nature, induced us to choose their esters as the starting material.

From the above experiments we conclude that the following factors favor the formation of long-chain peptide esters: elevated temperatures, use of a solvent and the passing of indifferent gases through the esters. In a later paper we shall give an explanation for certain indications (not mentioned here) that carbon dioxide promotes the condensation.

According to the general conception of poly-condensation as formulated by Carothers[15] in particular, a linear chain structure is to be attributed to the products described here. This view is supported by the following experimental indications.

(1) It is possible to prove the presence of alkoxy and amino end-groups in the glycine condensation products, although they are insoluble in water and the usual solvents. The alkoxy group can be detected according to Zeisel,[16] while the presence of the amino group is indicated by the blue coloring of the suspended particles on boiling with ninhydrin.

(2) The results of quantitative hydrolysis as

carried out on substance no. 1 and no. 7, prove that the high poly-condensation products are quantitatively built up of glycine units linked by peptide bonds. The presence of the latter is also indicated by the positive biuret reaction.

(3) The average chain length of the glycine polymers was ascertained by quantitative alkoxy determinations, as in the series of polymer homologs the alkoxy content varies distinctly with growing chain length. NH_2 determinations, although also indicative of the chain length, could not be carried out here owing to the insolubility of the glycine polymers.

(4) The results of alkoxy determinations were throughout in agreement with total nitrogen determinations (Kjeldahl). Moreover, as will be shown in the following paper, in the case of similar alanine poly-condensation products, soluble in water, the results of additional amino group determinations were throughout in very satisfactory agreement with those of alkoxy determinations and fully confirmed the conclusions drawn from the latter as regards the chain length.

Carbon and hydrogen determinations are not suitable means to assess the chain length; the differences in their values for the higher homologs lie within the experimental error.

It appears that high polymers can be obtained more easily and in better yields from the methyl ester than from isobutyl or the ethyl ester of glycine.

Our linear synthetic glycine products resemble in some properties the poly-amides obtained by Carothers[15] by the poly-condensation of di-amines and di-carboxylic acids.

Summary

On condensation under various conditions, glycine ethyl ester yielded a series of water insoluble polymers. The preparations were amorphous and contained ethoxyl in amounts corresponding, respectively, to 12-, 13-, 16-, 17- and 20-glycine peptide ethyl esters. From glycine methyl ester analogous preparations were obtained that contained methoxyl corresponding to 18-, 27- and 30-glycine methyl esters, respectively. Glycine isobutyl ester yielded a product of which the isobutoxy content corresponded to 16-glycine isobutyl ester.

On being heated to 130°, several of these products underwent further polymerization as indicated by decrease in alkoxy content. Preparations that corresponded in composition to 42-glycine ethyl ester and 110-glycine methyl ester were thus secured.

On being subjected to hydrolysis with acid, several of these polymers gave high yields of glycine suggesting that the polymers are in fact polypeptide esters. It appears that high polymers are more easily obtained from glycine methyl ester than from glycine ethyl and isobutyl esters.

The poly-condensation products described are (except the amorphous 12- and 13-glycine ethyl esters) horn-like, practically insoluble in water, in which they show characteristic swelling. They give positive ninhydrin and biuret reactions.

Poly-condensation of α-Amino Acid Esters. II. Poly-condensation of Alanine Ethyl Ester[1]

BY MAX FRANKEL AND EPHRAIM KATCHALSKI

Alanine ethyl ester is a stable compound as compared with glycine ethyl ester. According to Fischer[2] and more recent literature, condensation to a peptide ester giving the biuret reaction has never been observed; moreover, even the formation of alanine anhydride, the so-called lactimide, takes place slowly.

Thus it seemed less probable that alanine ethyl ester would give polymers. We tried therefore to establish experimental conditions specially favorable to intermolecular reaction. Thus, although we obtained clear indications for poly-condensation of alanine ethyl ester on using experimental conditions similar to those described

(1) Certain minor errors in the manuscript as originally submitted were noted by the Editorial Board. Ordinarily these would have been brought to the attention of the authors prior to publication. International conditions at present are such that it appears impossible to follow this procedure except at the risk of indefinite postponement. The Editor has therefore taken the responsibility to make any corrections which appeared to be unquestionably required.—THE EDITOR.

(2) Fischer, *Ber.*, **34**, 433 (1901).

for glycine ester,[3] it was found advantageous to carry out the poly-condensations with the liquid ester under reduced pressure in order to facilitate the splitting off of the ethanol formed during the poly-condensation.

In these experiments various high alanine peptide esters along with alanine anhydride were obtained. The lowest peptide ester hitherto isolated from the condensation mixtures was the alanine tetrapeptide ethyl ester. This hitherto unknown compound represents the alanine analog of the Curtius biuret base—the glycine tetrapeptide ethyl ester. Like the latter it gives a positive biuret reaction with pink-red color. It is soluble in cold water, ether and other organic solvents in which the corresponding glycine peptide ester does not dissolve. As will become clear later, the solubility of alanine peptide esters is in general greater than that of the corresponding glycine polypeptide esters.

The higher alanine peptide esters obtained from alanine ethyl ester corresponded in average chain length with 10, 14 and 16 units, respectively.

These compounds were isolated by molecular distillation from the reaction mixture, from which the ether soluble part, containing unchanged alanine ethyl ester and the alanine tetrapeptide ethyl ester, was previously removed. During the molecular distillation the alanine anhydride was distilled and the remaining fraction consisted only of the high alanine peptide esters. The separation of the latter had to be effected by this technique as the reaction mixtures were entirely soluble in water and could not be fractionated by differences in the solubility of the various condensation products.

The isolated high alanine peptide ethyl esters are insoluble in ether but soluble in water. Their solutions give a positive ninhydrin reaction and an immediate positive biuret reaction with violet color.

As the carrying out of NH_2-determinations was rendered possible by the solubility of the high alanine peptide esters in water, both the alkoxy- and the amino nitrogen groups were determined. The values for chain length calculated in every case from each of these two independent determinations were identical. Total nitrogen content was also in agreement with the formulas derived from the other data.

The determination of the molecular weight of one representative polypeptide ester, the 10-alanine ethyl ester, by the micro method of Barger[4] showed very satisfactory agreement between the molecular weight found (750) and calculated (756).

Another proof for the structure of the poly-condensation products is furnished by hydrolysis and subsequent quantitative determination of the free alanine formed. The results obtained show that the poly-condensates are built up quantitatively from alanine units linked by —CONH— bonds.

It has been found that the primary polymerization products isolated from the reaction mixtures undergo further poly-condensation at 150°. In this way from 14-alanine ethyl ester, polypeptide esters averaging 17, 19 and 23 units were obtained.

Experimental

Alanine ethyl ester was prepared according to Fischer.[2] Freshly distilled ester was used throughout. For reasons explained in the theoretical part the condensations were carried out in closed vessels at reduced pressure. The temperature was varied between room temperature to about 80°.

Poly-condensation at Room Temperature.—Three grams of freshly distilled alanine ethyl ester was kept in a sealed test-tube under reduced pressure (15 mm.) at room temperature for five months. During standing a precipitate formed which finally filled the whole liquid. After opening the test-tube the mixture gave a strong picric acid test and a positive biuret reaction. The mixture dissolved entirely in water. It was repeatedly treated with ether till the latter gave no positive biuret reaction. The ether solution was in each case separated by centrifuging from the insoluble part and finally the ether extracts combined.

1. Separation of Alanine Tetrapeptide Ethyl Ester from Lower Products.—The ether from the combined extracts was evaporated in a desiccator *in vacuo* at room temperature with rigid exclusion of water, the residue dissolved in 1 ml. of dry ethyl acetate and to the clear solution 2 ml. of petroleum ether was added. The oily precipitate formed was separated from the liquid by decantation, washed with petroleum ether and dried in a desiccator *in vacuo* over sulfuric acid and soda-lime.

The dried semisolid oil (150 mg.) shows positive ninhydrin and biuret reactions, the latter with a pink-red color. On analysis it agreed with alanine tetrapeptide ethyl ester. *Anal.* Calcd. for $C_{14}H_{26}O_5N_4$: N, 16.95; amino N, 4.24; C_2H_5O, 13.64. Found: N, 16.62; amino N, 4.20; C_2H_5O, 13.76.

In order to convert the free tetrapeptide ester into its hydrochloride, it was treated with 2 ml. of absolute ethanol previously saturated with gaseous hydrogen chloride. The residue obtained after drying *in vacuo* was treated once more in the same way. Finally a very hygroscopic semisolid product was obtained which by its chlorine content proved to be alanine tetrapeptide ethyl ester hydro-

(3) Frankel and Katchalski, THIS JOURNAL, **64**, 2264 (1942).

(4) Barger, *J. Chem. Soc.*, **85**, 286 (1904); Barger, *Ber.*, **37**, 1754 (1904).

chloride. *Anal.* Calcd. for $C_{14}H_{26}O_5N_4 \cdot HCl$: Cl, 9.68. Found: Cl, 9.53.

From the solution in petroleum ether only alanine ethyl ester could be isolated.

Alanine tetrapeptide ethyl ester hydrochloride prepared from alanine tetrapeptide synthesized in the usual way was found to be identical with the hydrochloride described above. The free alanine tetrapeptide ethyl ester liberated from this ester hydrochloride was identical with the corresponding product obtained by condensation. It dissolves in ether, alcohol and ethyl acetate. From the latter it is precipitated by addition of petroleum ether.

2. Separation of the Higher Alanine Condensation Products from Alanine Anhydride.—The residue remaining after treatment of the primary reaction mixture with ether dissolved in water, showing a slight alkaline reaction. It gave a strong color reaction with picric acid, indicating the presence of anhydride, and blue-violet biuret reaction, indicating the presence of higher peptide esters. Separation between the anhydride and the higher linear poly-condensation products was carried out by molecular distillation. Alanine anhydride distilled over at an external bath temperature of 140° and a pressure of about 10^{-3} mm.; 1.0 g. of alanine anhydride was obtained; melting point 270°. *Anal.* Calcd. for $C_6H_{10}O_2N_2$: N, 19.70; amino N, 0. Found: N, 19.92; amino N, 0.

The amorphous residue from the molecular distillation was free from alanine anhydride; it gave a negative picric acid test and a blue-violet biuret reaction. It was soluble in water and in 80% alcohol; it showed a distinct alkaline reaction. According to analysis it is 10-alanine ethyl ester. *Anal.* Calcd. for 10-alanine ester: N, 18.52; amino N, 1.85; C_2H_5O, 5.95. Found: N, 18.75; amino N, 1.41; C_2H_5O, 5.67.[5]

The molecular weight of this compound was determined by the micro method of Barger[4] using 80% alcohol as solvent and azobenzene as a standard. By this method it has been determined that the molar concentration of a solution containing 10.5 mg. of 10-alanine ethyl ester in 1.5 ml. of solvent is 0.00933; the molecular weight found from these data is 750, the molecular weight calcd. for the 10-alanine ester $C_{32}H_{56}O_{11}N_{10}$, 756; for the 13-alanine ester, 970.

Poly-condensation at 40°.—Three grams of freshly distilled alanine ethyl ester was allowed to undergo condensation as described above except that the temperature was kept at 40°. The separation of the different fractions was carried out as above. 1.1 g. of alanine anhydride, 120 mg. of alanine tetrapeptide ethyl ester and 200 mg. of high poly-condensation product, which proved on analysis to correspond with 16-alanine ethyl ester, were obtained. *Anal.* Calcd. for $C_{50}H_{86}O_{17}N_{16}$: N, 18.95; amino N, 1.18; C_2H_5O, 3.81. Found: N, 18.90; amino N, 1.32; C_2H_5O, 3.84. In its properties the 16-alanine ethyl ester resembled the 10-alanine ethyl ester.

Poly-condensation at 80°.—Three grams of freshly distilled alanine ethyl ester was kept *in vacuo* at a temperature of 80° for one month and then left for about four months at room temperature. The semi-solid substance thus formed was treated as above: 0.8 g. of alanine anhydride; 100 mg. of alanine tetrapeptide ethyl ester and 300 mg. of the higher poly-condensation product were obtained. The latter is according to analysis 14-alanine ethyl ester. *Anal.* Calcd. for $C_{44}H_{76}O_{15}N_{14}$: N, 18.85; amino N, 1.31; C_2H_5O, 4.32. Found: N, 18.47; amino N, 1.29; C_2H_5O, 4.20. The 14-alanine ethyl ester resembles its linear ester homologs mentioned above.

Quantitative Hydrolysis of 14-Alanine Ethyl Ester.—6.450 mg. of the substance, which according to analysis was 14-alanine peptide ethyl ester, was dissolved in 1 ml. of hydrochloric acid (0.2 ml. of concd. HCl in 0.8 ml. of water) and refluxed for eight hours in a flask with ground-in condenser of 2 ml. content. In order to avoid bumping a few platinum tetrahedra were added.

The determination of the free alanine formed by hydrolysis was carried out according to Friedemann and Kendall.[6] The hydrolyzate was diluted in a 50-ml. flask to 17.5 ml. The flask was kept on a boiling water-bath, and within twenty minutes 3 ml. of sodium nitrite (2.5 g. in 100 ml. of water) was added, and within an additional twenty minutes 3 ml. of urea (7.5 g. in 100 ml. of water). The total solution was brought to 50 ml. and the amount of lactic acid determined according to Friedemann and Kendall using 0.005 *N* iodine solution. *Anal.* Calcd. amount of alanine formed after hydrolysis of 6.45 mg. of 14-alanine ethyl ester: 7.72 mg. Found: 7.20 mg. From the results the conclusion may be drawn that the substance which underwent hydrolysis is built up quantitatively of alanine units held together by —CONH— links. The hydrolysis confirms therefore the other analytical results.

Further Poly-condensation of 14-Alanine Ethyl Ester.—14-Alanine ethyl ester was finely ground and kept at a temperature of about 150° for various periods of time. The progress of condensation was demonstrated by the decrease in alkoxy percentage. No anhydride was found during the operation.

TABLE I

POLY-CONDENSATION OF 14-ALANINE ETHYL ESTER ON KEEPING AT 150°

Time, days	0	5	15	30
C_2H_5O, %	4.20	3.67	3.30	2.66
Calcd. chain length	14	17	19	23

Enzymatic Experiment.—The action of pancreatin was tried on the 16-alanine polymer but the results indicated none or very little enzymatic hydrolysis. These peptides are, however, so far removed from the type of structure to be found in naturally occurring proteins that this failure to observe enzyme action has little bearing on the question of the type of linkage present in the polymer.

Summary

Alanine ethyl ester kept in sealed tubes at reduced pressure and at various temperatures polymerized to compounds whose average size corresponded to 10, 14 and 16 alanine ethyl ester units.

(5) Note by the Editor: These analytical data for nitrogen and amino nitrogen agree better with the formula for a 13-alanine ethyl ester ($C_{41}H_{71}N_{13}O_{14}$). This formula would require N, 18.78 and N in NH_2, 1.44. Similarly, the data for the ethoxy group would agree more closely with an 11-alanine ethyl ester ($C_{35}H_{55}N_{11}O_{12}$) which would require C_2H_5O, 5.44.

(6) Friedemann and Kendall, *J. Biol. Chem.*, **82**, 23 (1929); Friedemann, *J. Inf. Diseases*, **47**, 171 (1930).

14-Alanine ethyl ester underwent further polycondensation at 150° to compounds corresponding to 17, 19 and 23 alanine ethyl ester units.

These alanine peptide esters are, unlike their glycine analogs, soluble in water.

Condensations. XVII. The Acylation of the Anions of Certain Alkyl Esters with Phenyl Esters. A New Method for the Preparation of Ethyl Propionylacetate and Certain Related β-Keto Esters[1,2]

BY B. ABRAMOVITCH AND CHARLES R. HAUSER

The difficulty in effecting satisfactorily the Claisen condensation between two different alkyl esters both of which have α-hydrogen is well known. Even when the ester to be acylated is first converted largely into its anion (or sodium enolate) by means of sodium triphenylmethyl and the anion then treated with the acylating ester, a mixture of β-keto esters is generally obtained.[3] Evidently, the ester anion reacts with the α-hydrogen of the second ester more readily than with its carbonyl group, resulting in a hydrogen exchange to yield a mixture of two different ester anions and two different esters from which four β-keto esters might be formed.

Ester anions are acylated by acid chlorides without first undergoing the hydrogen exchange but with the anion of ethyl acetate (or other ester having two α-hydrogens) the β-keto ester first formed is further acylated by the acid chloride yielding mainly the diacylacetate.[4] Although the latter can be satisfactorily ammonolyzed back to the monoacylacetate the over-all yield is generally low. Thus, when the anion of ethyl acetate was treated with propionyl chloride and the resulting dipropionylacetate ammonolyzed, the over-all yield of ethyl propionylacetate was only 16%.

Obviously a suitable reagent for the direct preparation of monoacylacetates, $RCOCH_2CO_2C_2H_5$, should be one which would acylate the anion of ethyl acetate without first undergoing the hydrogen exchange, but one which would not acylate the monoacylacetate. Such an acylating reagent should presumably have a carbonyl group which is more reactive than that of an alkyl ester but one not as reactive as that of an acid chloride. It seemed possible that phenyl esters (or substituted phenyl esters) might serve as suitable acylating reagents, since, as measured by the rates of alkaline hydrolyses, the carbonyl group of phenyl acetate is approximately thirteen times as reactive as that of ethyl acetate,[5] yet phenyl acetate does not appear to be sufficiently reactive to acylate the anion of ethyl acetoacetate.[6] In agreement with these considerations, treatment of the anion of ethyl acetate with phenyl propionate apparently yielded ethyl propionylacetate,[6] but unfortunately the β-keto ester could not be separated from the phenol which was also produced in the reaction. When *p*-diphenyl propionate was used as propionylating reagent, however, the ethyl propionylacetate was readily separated from the relatively high-boiling by-product, *p*-hydroxydiphenyl. The reactions, including the formation of the ester anion by means of the triphenylmethyl ion, and the conversion of the β-keto ester into its anion, may be represented as follows.

$$CH_3CO_2C_2H_5 + {}^-C(C_6H_5)_3 \longrightarrow (CH_2CO_2C_2H_5)^- + HC(C_6H_5)_3$$

$$C_2H_5CO_2C_6H_4C_6H_5 + (CH_2CO_2C_2H_5)^- \longrightarrow C_2H_5COCH_2CO_2C_2H_5 + {}^-OC_6H_4C_6H_5$$

$$C_2H_5COCH_2CO_2C_2H_5 + (CH_2CO_2C_2H_5)^- \longrightarrow (C_2H_5COCHCO_2C_2H_5)^- + CH_3CO_2C_2H_5$$

Using molecular equivalents of ethyl acetate, sodium triphenylmethyl and *p*-diphenyl propionate, the yield of practically pure ethyl propionylacetate was 44% based on the sodium triphenylmethyl. It can be seen from the equations that although the ethyl acetate first reacts with the

(3) Hudson and Hauser, THIS JOURNAL, **63**, 3158 (1941).

(4) It should be pointed out that the acylation of disubstituted acetic acid esters such as ethyl isobutyrate gives good yields of β-keto esters of the type $RCOC(R'R'')CO_2C_2H_5$ (ref. 3, p. 3159).

(6) Unpublished observations by B. E. Hudson in this Laboratory.

equivalent of the base to form the ester anion, one-half of the ester is regenerated when the ethyl propionylacetate is converted into its anion (third step). The equivalent of *p*-diphenyl propionate used is twice the amount theoretically required; however, this excess is desirable, since in an experiment using one-half of an equivalent, the ethyl propionylacetate obtained was contaminated with some ethyl acetoacetate. Although a relatively large amount of sodium triphenylmethyl is required, this method of preparation of ethyl propionylacetate appears to be more satisfactory than either of the two commonly used methods. In one of these, involving the reaction of ethylmagnesium bromide with ethyl cyanoacetate, yields ranging from 12[7] to 60%[8] have been reported, while, in the other, involving the ammonolysis of ethyl propionylacetoacetate,[9] a mixture of ethyl propionylacetate and ethyl acetoacetate is obtained which is difficult to separate. In their book on pyrroles, Fischer and Orth[10] regard the second method as better than the Grignard method even though the yield of ethyl propionylacetate is only 10–12%.

In a similar manner, the anion of *n*-amyl acetate has been propionylated with phenyl propionate giving a 30% yield (based on the sodium triphenylmethyl) of essentially pure *n*-amyl propionylacetate; this β-ketoester boils sufficiently high to be separated by distillation from the phenol which is also formed.

$$C_2H_5CO_2C_6H_5 + (CH_2CO_2C_5H_{11})^- \longrightarrow C_2H_5COCH_2CO_2C_5H_{11} + {}^-OC_6H_5$$

Also, in a similar manner, the anion of ethyl isovalerate has been propionylated with phenyl propionate to give ethyl α-isopropylpropionylacetate.

$$C_2H_5CO_2C_6H_5 + [(CH_3)_2CHCHCO_2C_2H_5]^- \longrightarrow C_2H_5COCHCO_2C_2H_5 + {}^-OC_6H_5$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad |$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad CH(CH_3)_2$$

The by-product, phenol, was readily separated by distillation from the ethyl α-isopropylpropionylacetate, but it was not possible to remove the excess of the phenyl propionate in this manner. The β-keto ester was freed from most of the phenyl propionate by shaking the mixture several times with alkali at room temperature. This treatment hydrolyzed the phenyl propionate to phenol (which was removed as its salt) but did not appreciably affect the β-keto ester, which was obtained somewhat impure in 58% yield. The product on ketonic hydrolysis gave ethyl isobutyl ketone in 50% yield. Ethyl α-isopropylpropionylacetate has been prepared previously by Blaise[11] employing the Reformatsky reaction between ethyl α-bromoisovalerate and propionitrile in which the yield reported is 25–50%.

In connection with the work described above, several unsuccessful attempts have been made to prepare ethyl propionylacetate and related compounds by modifications of certain of the common methods. It is not surprising that the reaction of ethylmagnesium bromide with ethyl cyanoacetate is not very satisfactory for the preparation of ethyl propionylacetate, since the Grignard reagent can attack not only the cyanide group leading to the β-keto ester, but also the ester group or the methylenic hydrogens.[7] In an experiment designed to hinder the attack of the Grignard reagent on the ester group, ethylmagnesium bromide was treated with *t*-butyl-cyanoacetate, but no appreciable amount of *t*-butyl propionylacetate was obtained; apparently the Grignard reacted mainly with the methylenic hydrogen.

The method of Wallingford and co-workers[12] for the preparation of β-keto esters from ketones and ethyl carbonate in the presence of sodium ethoxide is apparently not suitable for the synthesis of ethyl propionylacetate because the ketone, methyl ethyl ketone, undergoes self-condensation too readily. In an attempt to avoid the self-condensation of the ketone, we have converted methyl ethyl ketone into its anion by means of sodium triphenylmethyl and treated the anion immediately with ethyl carbonate; however, the ketone still self-condensed and 50% of the ethyl carbonate was recovered.

Experimental

***p*-Diphenyl Propionate.**—This ester was prepared by a modification of the method used by Chattaway[13] for the preparation of phenyl esters. *p*-Hydroxydiphenyl (Eastman Kodak Co.) (57.5 g., 0.338 mole) was dissolved in a hot solution of 20.3 g. of sodium hydroxide and 2200 cc. of water. The solution was cooled to 15° and 700 g. of crushed ice added, the temperature thus being lowered to approximately 5°. Propionic anhydride (Eastman) (55.2 g., 54.1 cc., 0.425 mole) was then rapidly added to the solution (contained in a large Pyrex bottle), and the

mixture shaken vigorously for thirty seconds. The crude, pasty product was collected on an 8-inch Büchner funnel and sucked dry. The crude product was shaken in a separatory funnel with 1200 cc. of ether, the aqueous layer removed, the ether solution washed with three 200-cc. portions of 8% sodium hydroxide solution, and dried over anhydrous sodium sulfate followed by Drierite. Ether was distilled, final traces being removed by means of a water pump, leaving a fairly pure crystalline mass of *p*-diphenyl propionate, melting at 90–92°. After one recrystallization from absolute methanol (99%) there was obtained 55.5 g. (73% yield) of pure material, m. p. 92–92.5°.

Anal.[14] Calcd. for $C_{15}H_{14}O_2$: C, 79.62; H, 6.24. Found: C, 79.79; H, 6.03.

Ethyl Propionylacetate.—A calibrated 4-liter Pyrex bottle was fitted with a four-hole rubber stopper provided with an inlet tube for dry nitrogen, a mechanical stirrer, a 50-cc. dropping funnel (for ethyl acetate), and a wide glass tube connected to a large dropping funnel (for an ether solution of *p*-diphenyl propionate). The air in the bottle was displaced with nitrogen and 1200 cc. (0.36 mole) of a 0.3 molar sodium triphenylmethyl solution (prepared and analyzed as described previously)[3] transferred to the bottle. To the vigorously stirred solution, chilled in an ice-bath at −5°, was added 31.7 g. (0.36 mole) of ethyl acetate (b. p. 76.9–77.0°), the color of the sodium triphenylmethyl disappearing immediately. After twenty seconds the cold (0°) ether solution (1700 cc.) of *p*-diphenylpropionate (81.4 g., 0.36 mole) was added rapidly (one minute). After the contents in the bottle were stirred in the cold for one hour and forty-five minutes, the bottle was removed from the cold bath, stoppered with a ground glass stopper, vigorously shaken and allowed to warm up to 15° (one-half hour). Glacial acetic acid (40 cc.) was then added, the mixture extracted with water followed by a 10% sodium carbonate solution. The ether solution was dried over Drierite and the solvent distilled. The residue was distilled *in vacuo*, collecting 15.0 g., b. p. up to 160° at 10 mm. Upon refractionation from a modified Claisen flask equipped with a twelve-cm. Vigreux column the distillate gave 0.8 g., b. p. 70–91° at 17 mm., and 11.5 g. (44% yield based on the sodium triphenylmethyl) of ethyl propionylacetate, b. p. 91–92° at 17 mm.[15]; a mid-fraction was taken out for analysis.

Anal.[14] Calcd. for $C_7H_{12}O_3$: C, 58.31; H, 8.39. Found: C, 58.17; H, 8.32.

The product was also characterized by converting it into 1-phenyl-3-ethyl-pyrazolone-5, m. p. 100°,[15] and 3-ethyl-pyrazolone-5-carbamyl-1, m. p. 197°.[15]

On repeating the experiment under similar conditions but using 0.21 mole of *p*-diphenyl propionate to 0.38 mole each of sodium triphenylmethyl and ethyl acetate there was obtained a mixture of ethyl acetoacetate and ethyl propionylacetate.

Ethyl propionylacetate has also been prepared from the anion of ethyl acetate and propionyl chloride through the dipropionylacetate. Directions using a large excess of propionyl chloride have been described previously.[3] In the present investigation 38.7 g. (0.443 mole) of ethyl acetate was treated at 0° with 0.443 mole of sodium triphenylmethyl, and after twenty seconds the ester anion treated with 0.443 mole of propionyl chloride. After fifteen minutes 5 cc. of glacial acetic acid was added and the reaction mixture worked up in the usual manner. There was obtained 13.5 g. (32%) of ethyl dipropionylacetate, b. p. 98–102° at 10 mm., mainly at 100–102°. The dipropionylacetate was ammonolyzed in 50% yield to ethyl propionylacetate, b. p. 91–92° at 17 mm.; yield 50%; over-all yield, 16%; m. p. of phenylpyrazolone, 100°.[15]

n-Amyl Propionylacetate.—A solution (1240 cc., 0.324 mole) of sodium triphenylmethyl was transferred to a calibrated 2-liter Pyrex bottle, fitted with a mechanical stirrer, dropping funnel, and a tube delivering a slow stream of dry nitrogen. To the vigorously stirred solution, cooled in an ice–salt-bath at −10°, was added 42.7 cc. (37.6 g., 0.324 mole) of *n*-amyl acetate (b. p. 147–148°). The color was discharged within thirty seconds and a precipitate was formed. After one minute 48.6 g. (0.324 mole) of phenyl propionate (b. p. 103–104° at 21 mm.) was added. Stirring was continued in the cold for one and one-half hours and the bottle was then stoppered and allowed to warm up to 15° (two hours). Glacial acetic acid (32 cc.) dissolved in 200 cc. of ice-water was then added. The aqueous layer was removed and the ether layer washed with 10% sodium carbonate solution, dried, and the solvent distilled. The residue was distilled *in vacuo* collecting up to 160° at 10 mm. Fractionation of the distillate through a twelve-inch Vigreux column yielded 15 g. (40%) of *n*-amyl acetate (b. p. 60–72° at 25 mm., mainly at 62–64°), 36.0 g. (b. p. 80–93° at 10 mm.) consisting of a mixture of phenol and phenyl propionate, 3.0 g. (b. p. 93–113° at 10 mm., mainly at 98–100°), and 9.0 g. (30% yield based on the sodium triphenylmethyl) of *n*-amyl propionylacetate, b. p. 113–115° at 10 mm.

Anal.[14] Calcd. for $C_{10}H_{18}O_3$: C, 64.5; H, 9.90. Found: C, 65.0; H, 9.89.

The *n*-amylpropionylacetate was converted into 1-phenyl-3-ethylpyrazolone-5, m. p. 100°.[15]

On repeating the experiment using the same proportions of reagents but allowing the reactants to stand at room temperature (28°) for seven hours there was obtained a small yield of *n*-amyl propionylacetate contaminated with some *n*-amyl acetoacetate.

Ethyl α-Isopropylpropionylacetate.—To one liter (0.327 mole) of sodium triphenylmethyl solution at room temperature (27°) was added 49 cc. (42.5 g., 0.327 mole) of ethyl isovalerate (b. p. 134–135°). After shaking the mixture for two minutes the color changed to a dark orange. Forty-nine grams (0.327 mole) of phenyl propionate was then added and the mixture allowed to stand at room temperature for twenty hours. Glacial acetic acid (33 cc.) dissolved in 200 cc. of ice water was added. The aqueous layer was washed with two 75-cc. portions of 10% sodium carbonate solution, dried, and the solvent distilled. The residue was distilled *in vacuo*, collecting 73.5 g. of distillate boiling from 50° at 60 mm. to 180° at 20 mm. The distillate on fractionation through a twelve-inch Vigreux column yielded 15.8 g. (37%) of ethyl isovalerate (b. p. 43–65° at 21 mm., mainly at 43°), 22.6 g. (b. p. 65–102° at 21 mm.) of phenol and phenyl propionate, and

(14) Analysis by S. Gottlieb, Columbia University, New York, N. Y.

(15) Blaise, *Compt. rend.*, **132**, 978 (1901).

27.2 g. (b. p. 102–118° at 21 mm., mainly at 105–110°) consisting of a mixture of phenyl propionate and ethyl α-isopropyl propionylacetate. An ether solution (150 cc.) of this mixture was shaken with ten 50-cc. portions of 10% sodium hydroxide solution, the ether solution dried, and distilled. The residue on fractionation through a twelve-inch Vigreux column yielded 18.3 g. (58% yield based on the sodium triphenylmethyl) of ethyl α-isopropyl propionylacetate, b. p. 107–109° at 21 mm. (b. p. reported in the literature, 107–108° at 21 mm.[11]). An analysis (calcd. for $C_{10}H_{18}O_3$: C, 64.49; H, 9.74. Found: C, 68.24; H, 8.12) indicated that the β-keto ester was still contaminated with phenyl propionate. The product (10.6 g.) was hydrolyzed by refluxing for eight hours with a mixture of 30 cc. of glacial acetic acid, 3 cc. of concentrated sulfuric acid and 3 cc. of water. There was obtained 3.3 g. (50% yield) of ethyl isobutyl ketone, b. p. 133–135°[16] (semicarbazone, m. p. 128–129°[16]).

t-Butyl Cyanoacetate with Ethylmagnesium Bromide.—*t*-Butyl cyanoacetate was prepared[17] in 32% yield from *t*-butyl α-bromoacetate and potassium cyanide in methanol solution.

Anal.[14] Calcd. for $C_7H_{11}O_2N$: N, 9.92. Found: N, 9.67.

t-Butyl α-bromoacetate was obtained in 70% yield by treating *t*-butyl alcohol with α-bromoacetyl bromide in the presence of dimethylaniline.[18]

Sixteen grams (0.11 mole) of *t*-butyl cyanoacetate (b. p. 107–108° at 23 mm.) dissolved in 25 cc. of dry ether was added, with stirring, during one hour to 0.25 mole of cold (0°) ethylmagnesium bromide solution. At first, addition of the nitrile caused the formation of a precipitate and the evolution of gas. The mixture was stirred at room temperature and then allowed to stand for twelve hours. On working up the reaction mixture, the products obtained consisted of a mixture boiling over a very wide range with considerable tarry material.

(16) Douris, *Compt. rend.*, **157**, 57 (1913).

(17) The procedure was similar to that used by Noyes for the preparation of ethyl cyanoacetate, THIS JOURNAL, **26**, 1545 (1904).

(18) For the preparation of *t*-butyl acetate by this method, see Norris and Rigby, THIS JOURNAL, **54**, 2097 (1932).

Methyl Ethyl Ketone with Ethyl Carbonate.—Methyl ethyl ketone (14.4 g., 0.2 mole) (b. p. 80°) was added to 0.2 mole of sodium triphenylmethyl solution cooled in a bath at −5°. The color changed immediately to a light orange. After twenty seconds 23.5 g. (0.2 mole) of ethyl carbonate (b. p. 125.5–126°) was introduced. The bottle containing the mixture was shaken vigorously and allowed to stand in the cold bath, after which it was allowed to warm up (1 hour) to room temperature (30°). The reaction mixture was worked up in the usual manner, and upon fractionation of the products, first at atmospheric pressure and then *in vacuo*, there was obtained 2.4 g. of unreacted ketone (b. p. 75–85°), 11.7 g. (50% recovery) of ethyl carbonate (b. p. 122–127°) and 3.9 g. of 3-methyl heptene-3-one-5, b. p. 60–75° at 20 mm., mainly at 65–70° (reported b. p. 66–68° at 20 mm.).[19] The ketone was converted into the semicarbazone, m. p. 113–114°; reported m. p. 114–115°.[19] The 65–70° fraction on redistillation gave a small fraction which gave a positive ferric chloride test indicating the presence of some β-keto ester.

Summary

1. A study has been made of the use of phenyl esters as reagents for the acylation of the anions of certain alkyl esters.

2. Ethyl propionylacetate has been prepared by the acylation of the anion of ethyl acetate with *p*-diphenylpropionate.

3. *n*-Amyl propionylacetate and ethyl α-isopropyl propionylacetate have been prepared from phenyl propionate and the anions of *n*-amyl acetate and of ethyl isovalerate, respectively.

4. Unsuccessful attempts were made to prepare *t*-butyl propionylacetate from *t*-butyl cyanoacetate and ethylmagnesium bromide, and ethyl propionylacetate from the sodium enolate of methyl ethyl ketone and ethyl carbonate.

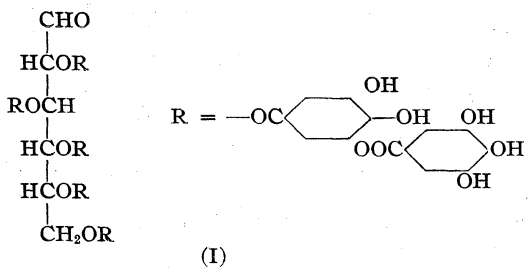
Chemical Constitution and the Tanning Effect. I. Simple Esters and Polyesters of Gallic Acid

BY ALFRED RUSSELL AND W. G. TEBBENS, JR.

Leather is the imputrescible substance that is obtained through treatment of easily putrescible animal protein by various materials. The tanning effect of certain metallic salts (chromium, iron, zirconium, etc.), of aldehydes (chiefly formaldehyde), of various drying oils and, most important of all, natural organic tanning materials, is well established. However, up to the present, no serious attempt has been made to relate the characteristic leather forming properties of any of these with their chemical constitution. It is now proposed to investigate the relation between chemical constitution and the tanning effect of the natural organic tannins through the preparation of relatively simple compounds of known constitution that have tanning properties and produce leather similar to "vegetable" leather in quality. "Vegetable" leather is very distinctive in charac-

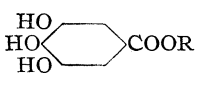
ter and in the present work leather made with pure gallotannin (tannic acid) will be used as a standard for comparison. Emil Fischer[1] proposed that pure gallotannin was penta-*m*-digalloyl glucose (represented in the aldehyde form I).



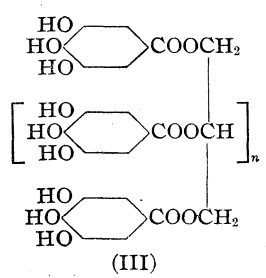
(I)

Incidentally, most natural tannins do not have this structure[2] but are related to the natural plant pigments—chalcones, flavones, anthocyanins, etc.

Using the gallotannin molecule as a model, it is proposed to prepare various phenolic materials of definite constitution and, through actual tanning tests, to measure their tanning properties. The present communication describes the preparation and testing of various simple esters (type formula II) and polyesters (type formula III) of gallic acid.



(II)



(III)

The simple esters of gallic acid were prepared from gallic acid and an excess of the appropriate alcohol using anhydrous hydrogen chloride according to the accepted procedure.[3,4,5]

The polyesters were prepared by condensation of triacetylgalloyl chloride with the appropriate polyhydric alcohol in the presence of quinoline and chloroform, followed by cautious deacetylation with dilute sodium hydroxide.[1] The preparation of such compounds tested as are already known is not included.

The results of tanning tests are as follows: *Very good tannage.* Gallotannin. *No tannage.* Gallic acid, methyl, ethyl, *n*-propyl, isopropyl, *n*-butyl, *n*-amyl, *n*-hexyl gallates, ethylene glycol, glycerol, *d,l*-erythritol, *d*-arabitol sorbitol. *Poor tannage.* Ethylene glycoldigallate, glycerol trigallate. *Fair tannage.* *d,l*-Erythritol tetragallate, *d*-arabitol pentagallate, mannitol hexagallate, sorbitol hexagallate.

(5) Christiansen, THIS JOURNAL, **48**, 1385 (1926).

Experimental

The simple esters of gallic acid were made by passing anhydrous hydrogen chloride into a solution of gallic acid in an excess of the appropriate alcohol until saturated. The mixture was then refluxed for four hours, after which time the excess alcohol was removed under reduced pressure. The residue was then extracted with anhydrous benzene and the product recrystallized from the same solvent.[3-7] An alternative recrystallization procedure for the lower esters was extraction of the residue with hot acetone and addition, with mechanical stirring, of the acetone extract to a large excess of ice-water. The crystalline product so formed contained water of hydration.

***n*-Amyl Gallate.**—Prepared in 58% yield from 100 g. of pure anhydrous gallic acid and 466 g. of redistilled *n*-amyl alcohol. The ester formed fine, white plates after being recrystallized twice from anhydrous benzene, m. p. 127°. It was soluble in benzene, chloroform, acetone, alcohol and ether, and very slightly soluble in water. A blue-black color was given with ferric alum solution. *Anal.* Calcd. for $C_{12}H_{16}O_5$: C, 60.0; H, 6.71. Found: C, 59.9; H, 6.77.

***n*-Hexyl Gallate.**—Prepared in 48% yield from 94 g. of pure anhydrous gallic acid and 511 g. of redistilled *n*-hexyl alcohol. The compound gave white plates from anhydrous benzene after two recrystallizations, m. p. 92°. The ester was soluble in benzene, chloroform, acetone, alcohol and ether and was insoluble in petroleum ether. The ester gave a blue-black coloration with ferric alum solution. *Anal.* Calcd. for $C_{13}H_{18}O_5$: C, 61.4; H, 7.14. Found: C, 60.8; H, 7.21.

The polyesters were prepared by the method developed by Fischer[1] from the appropriate anhydrous, finely powdered polyhydric alcohol and triacetylgalloyl chloride in chloroform and quinoline. The acetyl derivatives paralleled those of Fischer in all cases.

Triacetylgalloyl Chloride.—The method used for the preparation of triacetylgallic acid paralleled that of Fischer.[1] The acid chloride was made in 90% yield by reaction of the anhydrous acid with a 10% excess of freshly distilled thionyl chloride. The product, after removal of the excess thionyl chloride by distillation, was recrystallized twice from carbon tetrachloride, m. p. 104°.

Penta-(triacetylgalloyl)-*d*-arabitol.—6.08 g. of anhydrous, finely powdered *d*-arabitol was taken up in 28.4 g. of freshly distilled anhydrous quinoline and 75 cc. of freshly distilled anhydrous chloroform. 69.0 g. of triacetylgalloyl chloride was added with cooling and the whole shaken for two days at room temperature. The reaction mixture was washed in succession with water, cold 1% sulfuric acid and then with water until neutral to litmus. The chloroform solution was dried over anhydrous sodium

(6) Hamburg, *Monatsh.*, **19**, 594 (1898).
(7) Biddle, THIS JOURNAL, **35**, 96 (1913).

sulfate. After filtering, the solution was taken to dryness on a steam-bath under reduced pressure and the residue was taken up in anhydrous acetone, filtered, and again reduced to dryness. The tan friable solid which weighed 57.4 g. (93%) was finally dried in an Abderhalden pistol at 57° over phosphorus pentoxide and paraffin at 1 mm. pressure for five days, m. p. 72° (sintered). The acetyl compound was tasteless and odorless. It gave no color with ferric alum solution and was insoluble in water. *Anal.* Calcd. for $C_{70}H_{62}O_{40}$: C, 54.5; H, 4.05. Found: C, 54.4; H, 4.08.

***d*-Arabitol Pentagallate.**—30.8 g. of penta-(triacetylgalloyl)-*d*-arabitol was taken up in 60 cc. of acetone and an oxygen-free stream of nitrogen passed into the solution while 330 cc. of 1 *N* sodium hydroxide solution was added with mechanical stirring at such a rate that the reaction temperature was maintained at 0° (ice–salt-bath). The gummy mass which separated was brought into solution by the addition of 100 cc. of acetone. Stirring was continued under a nitrogen atmosphere for two and one-half hours at 0°, 330 cc. of cold 1 *N* sulfuric acid was added, and the acetone was removed from the solution under reduced pressure. The residual solution was extracted with neutral ethyl acetate and the solvent layer dried over sodium sulfate, filtered, and concentrated to dryness under reduced pressure. The golden colored, friable hygroscopic glass produced was suspended in chloroform and then filtered. Repetition of this suspension gave 20 g. of a water soluble product. After drying at 57° over phosphorus pentoxide and paraffin at 1 mm. pressure for five days the color was a very pale tan, m. p. 83° (sintered). This product gave a blue-black color with dilute ferric alum solution. *Anal.* Calcd. for $C_{40}H_{32}O_{25}$: C, 52.6; H, 3.53. Found: C, 52.5; H, 3.52.

Hexa-(triacetylgalloyl)-sorbitol.—The method employed by Fischer[1] for the corresponding mannitol derivative was applied to sorbitol. The white, odorless tasteless product gave no coloration with ferric alum, m. p. 106° (sintered). After drying in an Abderhalden pistol as described for the derivative of *d*-arabitol it was converted to the gallic ester.

Sorbitol Hexagallate.—18.5 g. of hexa-(triacetylgalloyl)-sorbitol was treated by the method employed by Fischer[1] for the production of mannitol hexagallate to give 8.6 g. of gritty, white solid which was dried in a pistol as indicated above (m. p. 76° sint.). It has an astringent taste, was soluble in water and in neutral ethyl acetate, but was insoluble in petroleum ether. It gave a blue color with ferric alum. *Anal.* Calcd. for $C_{48}H_{38}O_{30}$: C, 52.5; H, 3.49. Found: C, 52.6; H, 3.51.

The experimental tannages were carried out on pickled calf-skin using the following standard procedure. A piece of selected pickled calfskin (8″ × 4″, wt. 25–35 g.), covered with three times its weight of 4% aqueous sodium chloride was treated with 25% of its weight of the material to be tested and the whole was rotated slowly in a bottle for from twenty-four to forty-eight hours. The piece of skin was now washed with water to a *p*H of 4.5, dried and compared as to color, feel, texture, flexibility and fullness with a similar piece tanned with gallotannin.

Summary

A number of simple esters and polyesters of gallic acid have been prepared and tested for leather forming properties. None of the simple esters showed any such properties. However, leather forming properties were shown by the polyesters of gallic acid with various polyhydric alcohols. The leather forming properties of the members of the latter series were poor but definite, and seemed to improve on ascending the series.

The Catalytic Properties of Charcoal. IV. Factors Influencing the Indophenol Reaction[1,2]

BY CLAUDE SCHWOB, WITH JOHN E. BIEGNER, KENNETH J. CARSON AND GEORGE V. SCOTT

The indophenol reaction has been used in this Laboratory to investigate the oxidase and peroxidase action of charcoal.[3,4] In this reaction indophenol is formed by the oxidation of a mixture of *p*-phenylenediamine and α-naphthol by oxygen or hydrogen peroxide in the presence of charcoal. It was found that when equimolar amounts of *p*-phenylenediamine and α-naphthol are used, the yield of indophenol diminishes after the first minute. Moreover, in later work, considerable difficulty was encountered in duplicating results.

In an attempt to clear up these points, and in order to gain further knowledge of the mechanism of the reaction, four modes of attack were employed: (a) variation in the concentrations of the individual reagents, (b) study of the *p*H during the course of the reaction, (c) effect of catalyst poisons and (d) study of the factors affecting the recovery of indophenol.

1. Reagent Concentrations.—Previous evidence[4] indicated that excess reagents are responsible for the drop in the yield of indophenol after

(1) Paper III, THIS JOURNAL, **60**, 2483 (1938).

(2) Presented in part at the 102nd meeting of the American Chemical Society, Atlantic City, N. J., September, 1941.

(3) Schwob, THIS JOURNAL, **58**, 1115 (1936).

(4) O'Brien, Tkac and Schwob, *ibid.*, **60**, 2480 (1938).

the first minute. Figure 1 summarizes the results obtained when the amounts of the reagents are varied individually. The concentrations are expressed as multiples of the "normal" amount, the reaction mixture normally containing equimolar amounts of *p*-phenylenediamine and α-naphthol, with a 20-fold excess of hydrogen peroxide, in the presence of sucrose charcoal, the whole being buffered to *p*H 4.5.[4]

Charcoal (curve 1): As expected, the ten-minute yield of indophenol is proportional to the amount of charcoal used, from one-half to twice the normal amount.

α-Naphthol (curve 2): Increasing concentrations of α-naphthol diminish the yield in a very marked manner, indicating that this substance is the chief culprit in the observed destruction of the indophenol. Due to the low over-all yield of indophenol (less than 6% in all cases) only a small amount of α-naphthol is needed for the actual formation of the dye. The excess "destroys" the indophenol in a manner not yet investigated in this Laboratory.

p-Phenylenediamine (curve 3): Excess amine does not affect the yield of indophenol very much. The yield diminishes in the expected manner when the concentration is below "normal."

Hydrogen Peroxide: Experiments involving variation in peroxide concentration were inconclusive. This is very probably due to the fact that charcoal has definite oxidase properties.[4] As the concentration of peroxide is lowered, the oxidase action predominates and obscures the role of the peroxide. However, at high concentrations of peroxide the yield of indophenol is somewhat lower (0.32 mg. of indophenol for 2.5 times normal concentration of hydrogen peroxide). Attempts to investigate the role of the peroxide anaerobically are futile due to the unavoidable decomposition of peroxide by the charcoal, providing an ample supply of oxygen.

2. Hydrogen-ion Concentration.—In addition to the change in the shape of the time–yield curve previously observed with *p*H variation, there is a definite increase in yield as the hydrogen-ion concentration decreases.[4] In the present investigation it was observed that during the course of the indophenol reaction relatively large quantities of an acid substance are formed, leading to a decrease in *p*H in spite of the presence of the buffer. For the "normal" reaction mixture the *p*H drop, measured by means of a glass electrode, was from 4.5 to 2.8 in seven minutes. A large increase in conductivity was observed also as the reaction progressed. It is likely that these effects are due to the liberation of hydrochloric acid as the *p*-phenylenediamine dihydrochloride is consumed, either in the formation of indophenol, or by being independently oxidized to unknown products by the peroxide under the influence of the charcoal.[5]

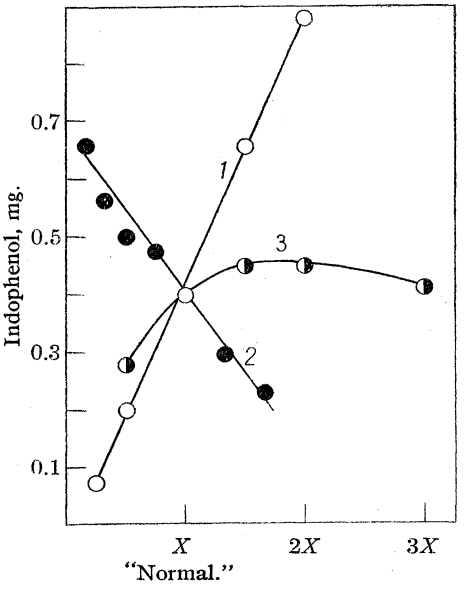

Fig. 1.—Ten-minute yield of indophenol in the presence of varying amounts of: charcoal (curve 1), α-naphthol (curve 2), and *p*-phenylenediamine (curve 3).

3. Catalyst Poisons.—The effects of potassium cyanide and amyl alcohol on the indophenol reaction have already been described.[4] The cyanide inhibits the formation as well as the destruction of the dye, but permits the uncatalyzed formation of indophenol to proceed at the same rate as in the absence of charcoal. The amyl alcohol stops all processes, so that the yield does not change with time after its addition. These different and characteristic effects were reinvestigated by means of conductivity measurements. Using a Fisher Titrimeter, the resistance of the normal reaction mixture, in the absence of poisons, drops with time, reaching a constant value of about one-half the original resistance after thirty minutes. This points to the liberation of hydrochloric acid for thirty minutes. Since indophenol is not being formed throughout

(5) Preliminary observations point to the feasibility of using a conductance method, involving this catalyzed oxidation of *p*-phenylenediamine dihydrochloride, for the rapid estimation of certain enzymes.

this period, the *p*-phenylenediamine must be losing some of its basic character by being oxidized independently.

In the presence of potassium cyanide (0.005 *N*) no drop in resistance can be observed. This indicates that not only does the cyanide poison the charcoal surfaces responsible for the formation and destruction of indophenol, but it also inhibits the independent oxidation of *p*-phenylenediamine.

On the contrary, in the presence of amyl alcohol the usual drop in resistance takes place, showing that the charcoal-catalyzed oxidation of the *p*-phenylenediamine is not affected by the amyl alcohol. Hence it is probable that there are at least two distinct surfaces of charcoal active in the indophenol reaction: (a) the portion of the surface which catalyzes the formation and destruction of indophenol, inhibited by both cyanide and amyl alcohol, and (b) the portion which catalyzes the oxidation of *p*-phenylenediamine, inhibited by cyanide but not by amyl alcohol.

4. Recovery of Indophenol.—It has been observed throughout this investigation that the indophenol-bearing charcoal must not be dried at too elevated a temperature or the indophenol will be destroyed. Another recurring source of annoyance in determining yield has been the varying shades of red which toluene solutions of indophenol exhibit, making colorimetric comparisons difficult and sometimes impossible.

The solid phase destruction of indophenol has been investigated by preparing indophenol-bearing charcoal, analyzing a portion and submitting other portions of the same batch to various treatments before analysis. The charcoal was prepared by using it to catalyze the formation of indophenol, using the "normal" concentrations. After filtering, the charcoal was washed with water and with 70% alcohol in an endeavor to remove most of the reagents and by-products. Alternately pure indophenol was adsorbed on charcoal from alcoholic solution.

The effect of heat was investigated first. Heating the charcoal in the dry state for progressively longer periods at the same temperature, or for the same time at increasing temperatures, causes a gradual destruction of the indophenol. For example, heating at 80° for sixty minutes decreased the indophenol content of a sample from 0.9 mg. per g. of charcoal to 0.5 mg. per g. In an attempt to find the lowest temperature at which indophenol is still destroyed at a significant rate, it was observed that a good deal of destruction takes place at room temperature. A sample of charcoal decreased in indophenol content from 0.6 mg. per g. to 0.3 mg. on exposure to air at room temperature for seventy-two hours.

The effect of excess reagents on this dry destruction of indophenol was studied by allowing the dye-bearing charcoal to adsorb one or another of the reagents from suitable solutions. As expected, the results are generally consistent with the findings described in the first part of this paper. Excess α-naphthol considerably increases the rate of destruction, while excess *p*-phenylenediamine actually increases the indophenol content of the charcoal after heating for one hour at 80°. This seems to be due to α-naphthol on the charcoal carried over from the reaction mixture and reacting with the added diamine. Further support for this view is furnished by the fact that if charcoal is supplied with indophenol by a reaction mixture containing only one-half the usual amount of α-naphthol, the increase in indophenol content on heating in the presence of added *p*-phenylenediamine is much less.

A study of the effect of reagents on indophenol adsorbed on charcoal from solutions of the pure dye in alcohol should be enlightening in these respects, since then none of the reaction mixture would be present to obscure the results. Unfortunately, as soon as charcoal so prepared was dried thoroughly, toluene no longer extracted the indophenol, and these experiments were perforce abandoned.

The second disturbing effect in estimating indophenol yields is the color variation exhibited by different toluene solutions of the dye. It was found that the presence of a trace of ethyl alcohol shifts the color toward the blue. Acid fumes make the solutions more yellow.

5. Conclusions.—A consideration of the present findings in the light of the previous work on the charcoal catalysis of the indophenol reaction enables us to list some of the processes taking place simultaneously or concurrently: A, charcoal catalyzed (1) formation of indophenol, (2) destruction of indophenol when its concentration reaches a definite level dependent on the charcoal, the temperature, and on the *p*H, (3) oxidation of the *p*-phenylenediamine, (4) decomposition of hydrogen peroxide due to the catalase action of the charcoal; B, uncatalyzed (1) slow formation of indophenol.

Summary

The oxidation of α-naphthol and *p*-phenylenediamine in the presence of activated charcoal appears to involve several simultaneous and successive processes. The measurement of the indophenol production is not an adequate test of the charcoal activity.

Cocarboxylase and Related Esters

BY JOHN WEIJLARD

In previous publications concerning synthetic cocarboxylase, a rather indefinite acid mixture prepared by dehydrating orthophosphoric acid has been employed for the phosphorylation.[1,2,3] A different method was employed by H. Weil-Malherbe,[4] who prepared cocarboxylase by interaction of bromo-thiamine with silver pyrophosphate, a reaction that does not fall within the scope of this paper.

The obvious method to prepare cocarboxylase would be the interaction of pure pyrophosphoric acid and thiamine hydrochloride (I). It was found, however, that pyrophosphoric acid itself did not form any thiamine ester whatever, but with anhydrous sodium pyrophosphate as catalyst produced thiamine orthophosphoric acid ester (IV) in fair yields instead of the expected pyrophosphoric acid ester, as shown by the fact that mild hydrolysis produced no phosphoric acid.[2] Similarly, 4-methyl-5-hydroxyethylthiazole (II) formed 4-methyl-5-hydroxyethyl thiazole orthophosphoric acid ester (VI) with pyrophosphoric acid and pyrophosphates. Concentrated sulfuric acid with anhydrous sodium pyrophosphate produced thiamine sulfuric acid ester (III) from thiamine hydrochloride in good yields, but no thiamine pyrophosphoric acid ester could be detected in the reaction mixture.

Phosphorus pentoxide was hydrated to give metaphosphoric acid,[5] and with the acid thus produced it was actually possible to esterify thiamine hydrochloride to thiamine pyrophosphoric acid ester chloride (cocarboxylase) (V). Yields similar to those previously reported[3] of thiamine pyrophosphoric acid ester were obtained when thiamine hydrochloride was esterified with a mixture of phosphorus pentoxide dissolved in pyrophosphoric acid with sodium pyrophosphate as catalyst. Such a solution should be a mixture of meta and pyro acids, with perhaps some unchanged phosphorus pentoxide, similar to the mixture obtained upon dehydrating orthophosphoric acid.[6,7] The mixture from dehydrated orthophosphoric acid gave with 4-methyl-5-hydroxyethylthiazole the compound, 4-methyl-5-hydroxyethylthiazole pyrophosphoric acid ester (VII), isolated as the silver salt,[2,8] which varies in composition according to varying *p*H and salt concentration.

2-Methyl-4-amino-5-bromomethylpyrimidine hydrobromide (VIII) was condensed with 4-methyl-5-hydroxyethylthiazole pyrophosphoric acid ester (VII) on the one hand, and with 5,β-chloroethyl-4-methylthiazole (IX) in the presence of silver pyrophosphate on the other to form cocarboxylase. Cocarboxylase was obtained in these reactions as ascertained by biological tests, but the yields were no higher than those obtained by the more simple direct phosphorylation of thiamine hydrochloride.

Experimental

Thiamine Orthophosphoric Acid Ester.—Five grams of pyrophosphoric acid was heated to faint fuming to remove any excess water, 2 g. of anhydrous sodium pyrophosphate was dissolved in the hot acid, 2 g. of thiamine hydrochloride was added and the mixture held at 150–155° for twenty minutes while stirring continuously. The cooled mass was dissolved in 100 cc. of water, and a slight excess of concentrated barium hydroxide solution was added. The precipitate was removed by centrifugation and discarded, the excess barium removed by adding a slight excess of 10% sulfuric acid and centrifuging. The solution was then concentrated to 60 cc. *in vacuo*. Sufficient one normal silver nitrate solution was added to precipitate the chloride, and the precipitate was removed by centrifuging and was discarded. The solution was neutralized with ammonia and an excess of 1 *N* silver nitrate solution added. The

mixture was centrifuged, the silver salt washed with water and suspended in 100 cc. of water and decomposed with hydrogen sulfide. The sulfide was filtered off and the solution aerated to remove excess hydrogen sulfide. Sufficient hydrochloric acid was added to make the solution eight-tenths normal. An excess of 25% phosphotungstic acid was added, the mixture was centrifuged and the solution discarded. The solid was treated with acetone to cause disintegration of the solid and precipitation of the ester. The mixture was chilled and the supernatant liquid decanted and discarded. The acetone insoluble material was dissolved in 50 cc. of 0.1 *N* hydrochloric acid and 10 volumes of acetone added. The solution was chilled at 0° overnight and filtered. The crude ester was recrystallized twice by dissolving in 0.1 *N* hydrochloric acid to form a 5% aqueous solution, adding three volumes of alcohol and seven volumes of acetone and cooling in ice; yield, 0.40 g. m. p. 200–202°. Hydrolysis with normal acid for one-half hour at 100° produced no phosphoric acid, hence no pyrophosphoric acid ester was present.

Anal. Calcd. for $C_{12}H_{18}O_4N_4ClSP\cdot 2H_2O$: C, 34.50; H, 5.31; N, 13.42; P, 7.44. Found: C, 34.59; H, 5.53; N, 13.22; P, 7.81.

Thiamine Sulfuric Acid Ester.—One gram of anhydrous sodium pyrophosphate was added to 2.5 cc. of concentrated sulfuric acid and heated to 150°. One gram of thiamine hydrochloride was added and the mixture heated at 150° for seven minutes. The mass was dissolved in 40 cc. of water and worked up essentially as above. The ester was finally recrystallized from 12 cc. of 0.1 *N* hydrochloric acid and 60 cc. of alcohol; yield 0.54 g., m. p. 258–259° with decomposition. No phosphorus was present. Its aqueous solution gave no precipitate with barium chloride, but on prolonged boiling with dilute hydrochloric acid the ester hydrolyzed slowly and the sulfate could be precipitated.

Anal. Calcd. for $C_{12}H_{17}O_4N_4ClS_2\cdot H_2O$: C, 36.10; H, 4.80; N, 14.05; S, 16.08. Found: C, 35.73; H, 4.93; N, 14.16; S, 16.26.

4-Methyl-5-hydroxyethylthiazole Orthophosphoric Acid Ester.—Four grams of pyrophosphoric acid was heated to faint fuming. One and seventy-five hundredths grams of 4-methyl-5-hydroxyethylthiazole was added and the mixture stirred and held at 150–160° for one hour. The cooled mass was dissolved in 50 cc. of water and the phosphoric acids removed by adding a slight excess of barium hydroxide solution and centrifuging. The excess barium was removed by adding a slight excess of sulfuric acid and centrifuging. The solution was made neutral with ammonia and an excess of normal silver nitrate solution was added. The precipitate was collected by centrifugation, washed with water several times, then suspended in 50 cc. of water and decomposed with hydrogen sulfide. The

silver sulfide was removed by filtration and the solution concentrated to dryness *in vacuo* at 30°. The residue, a thick oil, was dissolved in absolute alcohol and precipitated with ether. The flocculent white precipitate which resulted was collected on a filter and dried *in vacuo;* yield, 0.45 g., m. p. 162°.

Anal. Calcd. for $C_6H_{10}O_4NSP \cdot H_2O$: C, 29.85; H, 5.01; N, 5.80; P, 12.86. Found: C, 30.00; H, 4.87; N, 5.67; P, 12.98.

4-Methyl-5-hydroxyethylthiazole Pyrophosphoric Acid Ester Isolated as the Silver Salt.[2,3]—Four cc. of 85% orthophosphoric acid was heated until heavy fumes were produced and the hot acid appeared milky (290–310°). Two grams of anhydrous sodium pyrophosphate was dissolved in the hot acid and the mixture cooled down to 150°. One gram of 4-methyl-5-hydroxyethylthiazole was added and the mixture was stirred for one-half hour at 150–155°. The mixture was cooled and dissolved in 40 cc. water and a slight excess of barium hydroxide solution was added. The precipitate was centrifuged off and washed with water. The filtrate and washings were made slightly acid to congo red with 10% nitric acid, then concentrated *in vacuo* at 35° to 30 cc. The solution was made neutral to congo with ammonia, but was still acid to litmus. A few drops of normal silver nitrate solution was added and a small amount of silver chloride filtered off. Fifteen cc. of 50% silver nitrate solution was added and the mixture concentrated at room temperature *in vacuo* to one-half volume. The silver salt crystallized out slowly in the form of needles. The mother liquor was decanted off after three days of standing and the crystals washed first with 50% alcohol, then 90% alcohol, finally 100% alcohol followed by an ether washing; yield 0.40 g.

Anal. Calcd. for $C_6H_8O_7NSP_2Ag_3 \cdot 3/10AgNO_3 \cdot 6/10HNO_3 \cdot 3H_2O$ (mol. wt., 766.6): C, 9.39; H, 1.92; N total, 3.47; N nitrate, 1.64; P, 8.09; Ag, 46.4. Found: C, 9.48; H, 1.89; N total, 3.82; N nitrate, 1.75; P, 8.00; Ag, 48.2. Hydrolysis under mild conditions (normal nitric acid for one-half hour at 100°): found 4.45% P which is 55.6% of the total phosphorus.

Thiamine Pyrophosphoric Acid Ester from Phosphorus Pentoxide Hydrated to Give Metaphosphoric Acid.—To 5 grams of phosphorus pentoxide, 0.65 g. of water was added in a closed vessel, and the mixture held at 150° until the mass was nearly transparent. Two grams of thiamine hydrochloride was added and the mixture held at 150° for one-half hour with stirring. The mass was cooled and dissolved in 100 cc. of water, then worked up as outlined in a previous paper[3]; m. p. 238–240°.

Anal. Calcd. for $C_{12}H_{19}O_7N_4ClSP_2 \cdot H_2O$: C, 30.08; H, 4.42; N, 11.71; P, 12.96. Found: C, 30.01; H, 4.35; N, 11.43; P, 13.43.

Thiamine Pyrophosphoric Acid Ester from Pyrophosphoric Acid with Added Phosphorus Pentoxide.—Five grams of pyrophosphoric acid was mixed with 1.5 g. of phosphorus pentoxide and heated until clear. A mixture of 0.5 g. of anhydrous sodium metaphosphate and 0.5 g. of anhydrous sodium pyrophosphate was added followed by 2 g. of thiamine hydrochloride. The mixture was held at 150–155° for fifteen minutes and worked up according to standard procedure[3]; yield 0.23 g. of cocarboxylase, which is the approximate yield obtained using the indefinite mixture resulting from dehydrating orthophosphoric acid.[2,3]

Anal. Calcd. for $C_{12}H_{19}O_7N_4ClSP_2 \cdot 3/4H_2O$: C, 30.41; H, 4.36; N, 11.80; P, 13.08; H_2O, 2.84. Found: C, 30.45; H, 4.39; N, 11.40; P, 12.80; H_2O, 2.75.

Condensation of 4-Methyl-5-hydroxyethylthiazole Pyrophosphoric Acid Ester and 2-Methyl-4-amino-5-bromomethylpyrimidine Hydrobromide.—A suspension of 0.33 g. of silver salt of 4-methyl-5-hydroxyethylthiazole pyrophosphoric acid ester in water was decomposed with hydrogen sulfide, the sulfide was filtered off, the filtrate concentrated *in vacuo* at room temperature to dryness and the residue dried *in vacuo;* yield, 140 mg. of 4-methyl-5-hydroxyethyl thiazole pyrophosphoric acid ester, a glass that did not readily crystallize. This ester was mixed with 150 mg. of 2-methyl-4-amino-5-bromomethylpyrimidine hydrobromide. Three cc. of liquid petrolatum was added and the mixture held at 110° for five minutes with continuous stirring. The mixture was cooled and the oil washed out with ether. The residue was dissolved in 10 cc. of water and the bromide ion removed by the addition of a slight excess of normal silver nitrate solution and centrifugation. The excess silver was precipitated with hydrochloric acid and the precipitate removed by centrifugation. The clear solution (acid to congo) was mixed with 10 volumes of acetone and the mixture chilled in the ice box overnight. The mother liquor was decanted and the residue crystallized by dissolving in 10 cc. of 0.1 *N* hydrochloric acid, adding 30 cc. of alcohol and 70 cc. of acetone and cooling in ice for two days. After decantation, the crystals were washed with alcohol and ether; yield, 110 mg. The cocarboxylase activity indicated a yield of about 10% cocarboxylase.

Condensation of 5,β-Chloroethyl-4-methylthiazole with 2-Methyl-4-amino-5-bromo-methylpyrimidine Hydrobromide in Presence of Silver Pyrophosphate.—One-half gram of 5,β-chloroethyl-4-methylthiazole (distilling at 82.8–83.8° at 2 mm.), 2 g. of anhydrous silver pyrophosphate and 0.9 g. of 2-methyl-4-amino-5-bromomethylpyrimidine hydrobromide were mixed rapidly with 5 cc. of liquid petrolatum and held at 110° for ten minutes with stirring. The cooled mixture was washed with ether to remove the oil, then disintegrated by shaking with 30 cc. of water and the solution made acid to congo with hydrochloric acid. The solid was centrifuged off and the clear solution mixed with 10 volumes of acetone, then chilled overnight. The crude material was recrystallized as outlined above; yield 0.15 g. The cocarboxylase activity indicated about 10% cocarboxylase.

Acknowledgments.—I wish to express my appreciation to Drs. R. T. Major and J. R. Stevens for advice and interest; to Dr. Alphonse Walti for the cocarboxylase testing; to Mr. Harold Levy for general assistance. The analytical work was carried out by Messrs. D. F. Hayman, W. Reiss, H. Clark and R. N. Boos.

Errata.—The formulas for analyses in the previous article[3] are given as $C_{12}H_{21}O_8N_4ClSP_2 \cdot {}^1/_2\, H_2O$. They should read: $C_{12}H_{19}O_7N_4ClSP_2 \cdot {}^1/_2\, H_2O$.

Summary

It has been shown that pure pyrophosphoric acid produces the orthophosphoric acid esters of thiamine as well as of 4-methyl-5-hydroxyethyl thiazole, and that metaphosphoric acid or phosphorus pentoxide calculated to give metaphosphoric acid is necessary to form the pyrophosphoric acid ester of thiamine (cocarboxylase). Thiamine sulfuric acid ester has been prepared as well as the pyrophosphoric acid ester of 4-methyl-5-hydroxyethyl thiazole. The latter ester was condensed with the pyrimidine portion of cocarboxylase to give a product with cocarboxylase activity. A similar condensation was carried out with the pyrimidine portion and chlorothiazole in the presence of silver pyrophosphate, the isolated reaction product showing cocarboxylase activity.

Absorption of Oxygen by Glutathione in Alkaline Solutions. I. Kinetics of the Reaction at *p*H 9 to 11

BY M. B. YOUNG AND H. A. YOUNG

It has been shown[1] that, in the presence of a copper salt as catalyst and at a *p*H below approximately 8.5, a solution of glutathione is oxidized by oxygen from the mercaptan to the disulfide, that the rate of the reaction increases with increase in *p*H, and that the factor determining the rate is the concentration of the dissociated ion.

It has also been shown[2] that as the *p*H is increased beyond 8.5, the reaction becomes more complex both with regard to the products formed and to the interpretation of the reaction rates. From approximately *p*H 9 to 11, the volume of oxygen absorbed per mole of glutathione is slightly greater than that calculated to change the mercaptan to the disulfide. The absorption, however, comes to a definite and abrupt end and there is no indication of a further reaction involving the formation of an oxidation product higher than the disulfide. Colorimetric tests with titanium sulfate have shown this excess absorption to be caused by the production of small amounts of hydrogen peroxide, which appears to be quite stable, particularly at *p*H 9, even in the presence of the copper catalyst. As the *p*H increases beyond 11, the reaction involving the disulfide formation

$$2GS^- + {}^1/_2O_2 + H_2O = GSSG + 2OH^- \quad (a)$$

is followed by another reaction involving oxygen and the disulfide produced n (a) and indicated by a continued slow increase in oxygen absorption. This follow reaction increases in rate as hydroxide ion increases while the rate of reaction (a) remains essentially constant until finally all discontinuity in the resulting curve is lost. The volume of oxygen absorbed indicates that the principal product formed is the salt of the sulfinic acid of glutathione and that the follow reaction is

$$GSSG + {}^3/_2O_2 + 2OH^- = 2GSO_2^- + H_2O \quad (b)$$

Again the oxygen absorbed is a few per cent. high, possibly caused by the formation of more hydrogen peroxide or some sulfonic acid.

The reaction has been studied over the *p*H range 9 to 13.3 with glutathione concentration 0.00110 to 0.00880 molar, copper sulfate concentration 0 to 25×10^{-6} molar and oxygen pressure 0.2 to 1.0 atm. The results of three exemplary experiments are shown in Fig. 1 in which approximately equal amounts of glutathione, 5 cc. of 0.00220 molar solution in the presence of copper sulfate of approximately 5×10^{-6} mole per liter, were oxidized by oxygen at 1 atmosphere at hydroxide ion concentrations of 10^{-5}, 0.0431, and 0.171 mole per liter, respectively. The lines A and B indicate the calculated volumes of oxygen to change the mercaptan to the disulfide and to the sulfinic acid, respectively. There is a distinct break in curve 2 near A.

The present publication is concerned with an attempt to explain the kinetics of the simplest of the reactions, *i. e.*, the oxidation of the mercaptan to the disulfide as it occurs at *p*H 9 to 11.

Experimental

The experiments were carried out in the Warburg apparatus at 37°. Four cc. of glutathione

(1) Carl M. Lyman and E. S. G. Barron, *J. Biol. Chem.*, **121**, 275 (1937).

(2) M. B. Young, H. A. Young and Max Kleiber, THIS JOURNAL, **63**, 1488 (1941).

solution was placed in the main compartment of the reaction flask and 1 cc. of a mixture of sodium hydroxide and copper sulfate in the side arm. Oxygen at the desired pressure was used to saturate the solutions and to fill the gas space above (about 10 cc.). After the establishment of temperature equilibrium, the sodium hydroxide–copper sulfate mixture was mixed with the glutathione[3] and the rate of oxygen absorption measured at constant volume. Since the process of mixing necessitated the removal of the apparatus from the thermostat for a few seconds, readings taken during the first minute are considered to be in error.

The apparatus was shaken at a rate of 180 oscillations per minute. Increasing the rate to 320 showed no increase in the rate of oxygen absorption; decreasing it to 100 showed a slight decrease. During several test experiments, the reaction was stopped before completion by adding sufficient sulfuric acid, and the concentration of the unoxidized glutathione determined iodometrically following the procedure of Woodward and Fry.[4] Even in the faster experiments, the total reducing power of the glutathione solution checked the oxygen consumption within 3%. In view of the fact that more than enough oxygen is dissolved in the solution initially to oxidize all of the glutathione, it is assumed that these experiments indicate that equilibrium had been established throughout between the oxygen of the gas phase and that of the solution. Changing the glass surface within the reaction flask by adding glass beads had no effect upon the reaction rate.

C. P. quality chemicals were used throughout without further purification. As was to be expected in a reaction sensitive to traces of catalyst, there was some variation in going from one source of chemical to another, particularly the sodium hydroxide. A bottle of Mallinckrodt heavy metal-free product was finally obtained and used consistently. The water was doubly distilled in Pyrex glass. Various samples of glutathione obtained from different establishments (Eimer and Amend, Paul–Lewis Laboratories) were reasonably reproducible. By using the same supply of reactants, any series of experiments performed within a period of a month or so proved to be reproducible; and when going from one source of glutathione to another, while the absolute rates varied somewhat, the shapes and general form of the absorption curves were always the same.

No buffers were added to the reaction system.

(3) Under the conditions of the experiments the suspension of copper hydroxide dissolved immediately in the glutathione forming a glutathione-copper complex of some kind. For simplification Cu^{++} will refer to Σ Cu in whatever form it may be.

(4) Gladys E. Woodward and Edith G. Fry, *J. Biol. Chem.*, **97**, 465 (1932).

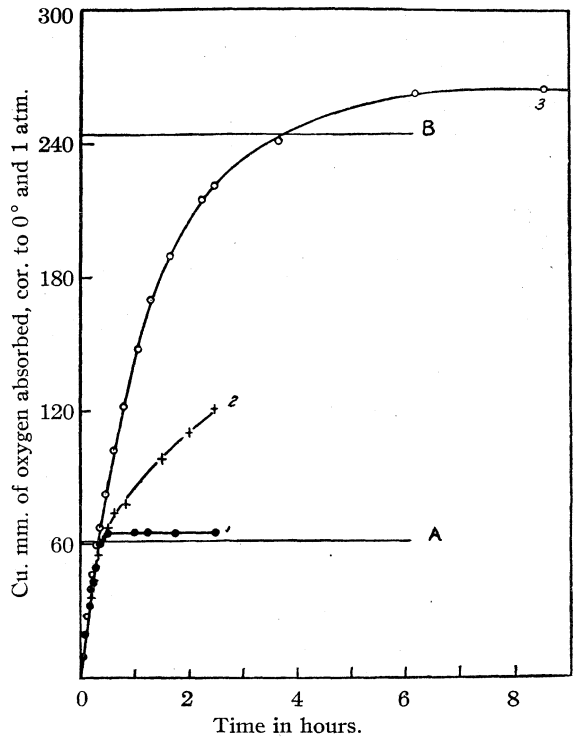

Fig. 1.—Absorption of oxygen at 37° and 1 atm. pressure by glutathione in alkaline solutions.

Experimental Results

Within the chosen *p*H ranges, two types of absorption curves were encountered. In Fig. 2, the curve represents an autocatalytic reaction with its maximum rate occurring at about 75% completion. This type of reaction is always associated with an excess absorption of oxygen. In Fig. 3, the curve represents a reaction which has its maximum rate at zero time. If excess oxygen absorption occurs at all, it is to a much slighter degree. In both figures line A represents the theoretical volume of oxygen required to convert the mercaptan to the disulfide. All kinds of intermediate curves may be obtained, depending upon experimental conditions. Factors tending to produce the first type are high values of the ratio of copper ion to glutathione, high oxygen pressure, and high *p*H. Those tending to produce the latter are conversely low values of the ratio of copper ion to glutathione, low oxygen pressure, and low *p*H.

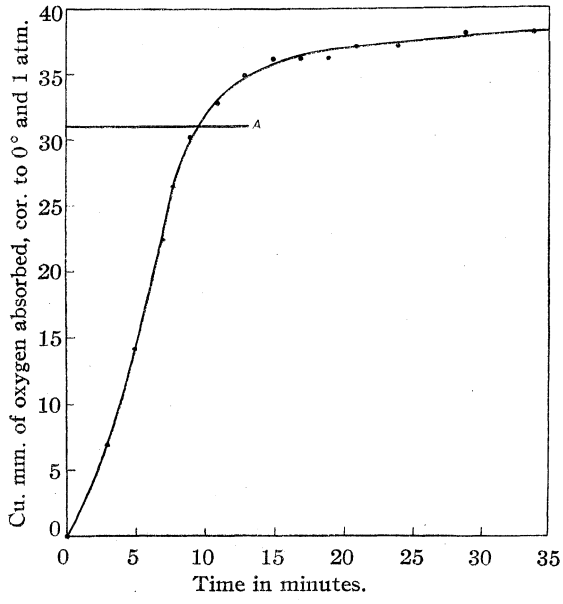

Fig. 2.—Absorption of oxygen by glutathione: GS^- = 0.00111 *M*; Cu^{++} = 4.63 × 10^{-6} *M*; initial *p*H, 10.8 (3.07 equivalents NaOH); O_2, 1 atm.

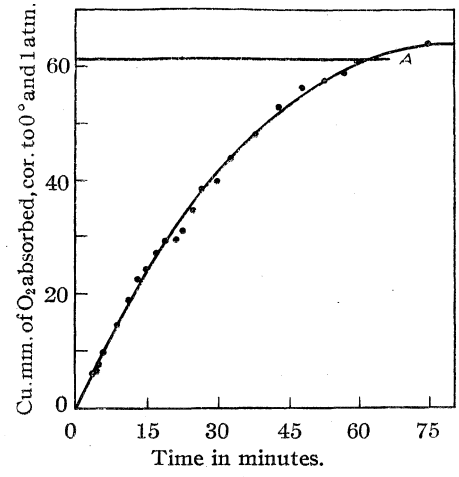

Fig. 3.—Absorption of oxygen by glutathione: GS^- = 0.00220 *M*; Cu^{++} = 4.63 × 10^{-6} *M*; initial *p*H, 9.4 (2.05 equivalents NaOH); O_2, 0.2 atm. (air).

Tests with titanium sulfate indicated that hydrogen peroxide often accumulated during the course of the reaction. In several cases, the amount of hydrogen peroxide formed was determined colorimetrically by comparison with standard hydrogen peroxide solutions to which titanium sulfate had been added. The results are shown in Table I. Although the experimental error in such colorimetric determinations is high, the results indicate that the excess oxygen consumption can be satisfactorily explained by the presence of hydrogen peroxide. They also illustrate the fact that the faster the reaction, the greater the accumulation of hydrogen peroxide.

TABLE I

COMPARISON BETWEEN OBSERVED AND CALCULATED HYDROGEN PEROXIDE CONCENTRATION

GS^-	OH^- equiv.	Cu^{++} × 10^6	O_2	Calcd. $\frac{H_2O_2}{G_2S_2}$	Found $\frac{H_2O_2}{G_2S_2}$	Found H_2O_2	Calcd. H_2O_2

.00397	1.65	10.08	1	.04	.07	1.5 × 10^{-4}	0.8 × 10^{-4}

Effect of Hydroxide Ion.—The variation of reaction rate with hydroxide ion is shown in Fig. 4, where the observed maximum rates are plotted against the equivalents of sodium hydroxide initially added to the reaction mixture. The copper sulfate and glutathione concentrations are 5.0 × 10^{-6} and 0.00220 molar, respectively. As is shown, the rate increases with increase in base until about 3.5 equivalents are present at a *p*H of approximately 11. As more base is added, there is actually a slight decrease, accompanied, however, by the appearance of the follow reaction involving the formation of the sulfinic acid—as referred to earlier.

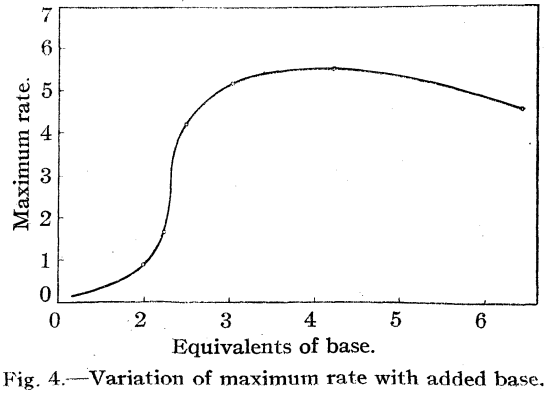

Fig. 4.—Variation of maximum rate with added base.

In 1929 Pirie and Pinhey[5] obtained a titration curve for the then recently discovered glutathione using a product obtained from yeast. For the dissociation of the —SH group, they chose a pK of 9.62. Except for a slight horizontal displacement, we have reproduced quite closely their titration curve using our commercial supply of glutathione at 0.00220 M and including copper sulfate at concentrations comparable to those in the rate experiments (see Fig. 5). The pH values were determined with a Coleman glass electrode, readings being taken immediately after mixing of the glutathione and base. The shaded points represent values obtained with Cu^{++} concentrations of 10×10^{-6} mole per liter; the open circles 5×10^{-6} mole per liter. The three circled points at high pH values have been corrected for errors resulting from glass electrode determinations at the sodium ion concentrations involved. Following the interpretation of Pirie and Pinhey, a value of 10.0 has been chosen as representing the pK of the reaction $GSH = GS^- + H^+$.

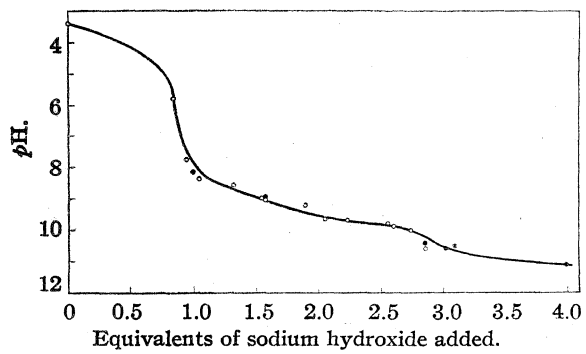

Fig. 5.—Titration curve of glutathione at 25°.

Considering the above results, it is seen that the maximum reaction rate is obtained at the pH where the transformation of GSH to GS^- becomes complete. We have therefore concluded, as did Lyman and Barron,[1] that GS^- is the primary reactant and have looked to the rate results at pH 11 for an explanation of the reaction system. Also, since at this pH, the autocatalytic nature of the absorption curve persists, the effect of the OH^- produced in (a) in transforming any GSH to GS^- as the reaction proceeds cannot be considered a complete explanation for this characteristic.

Effect of GS^- Concentration, pH 11.—Figure 6 shows four experiments in which Cu^{++} was maintained at 5×10^{-6} molar, O_2 at 1 atm., and GS^- varied from 0.00110 to 0.00884 molar. This series of experiments indicates that the effect of GS^- is very slight, since the maximum rates are largely independent of the GS^- concentration. Although not clearly seen on the small plot, the greater the GS^- concentration the nearer the origin to the maximum rates occur.

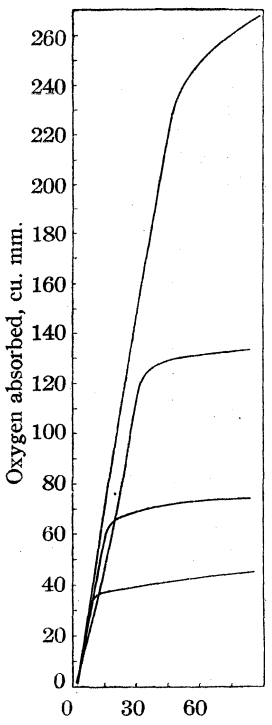

Fig. 6.—Absorption of oxygen by glutathione at various GS^- concentrations: $Cu^{++} = 5 \times 10^{-6}$ M; pH, 10.9 (3.38 equivalents NaOH); O_2, 1 atm. Beginning with lowest curve, GS^- = 0.00111, 0.00220, 0.00440, 0.00884 M, respectively.

Effect of Cu^{++} Concentration and Oxygen Pressure, pH 11.—The effect of varying Cu^{++} concentration is shown in Fig. 7. In all of these experiments GS^- was kept constant at 0.00220 mole per liter and the oxygen pressure at 1 atmosphere. It is observed that small amounts of Cu^{++} ion influence the reaction rate tremendously and that the reaction becomes more autocatalytic as Cu^{++} increases. The residual reaction in 1 is presumably caused by traces of catalyst in the reactants. Again, line A represents the theoretical oxygen consumption. When these autocatalytic curves are plotted on a large scale, it is noticeable that the maximum slope of the curve is nearly proportional to the Cu^{++} concentration. This fact is seen in Fig. 8 where maximum slopes are plotted against Cu^{++} concentration at three different oxygen pressures.

The above observation suggests that as the Cu^{++} increases, a catalyst is formed, the concentration of which controls the rate of oxygen consumption and which is determined by Cu^{++} concentration. Further, in the very rapid runs, the indication is that the steady state concentration of this intermediate is not reached until the reaction is nearly over; but when Cu^{++} is very low, the steady state is reached quite early in the experiment.

(5) Norman W. Pirie and Kathleen Goodwin Pinhey, *J. Biol. Chem.*, **84**, 321 (1929).

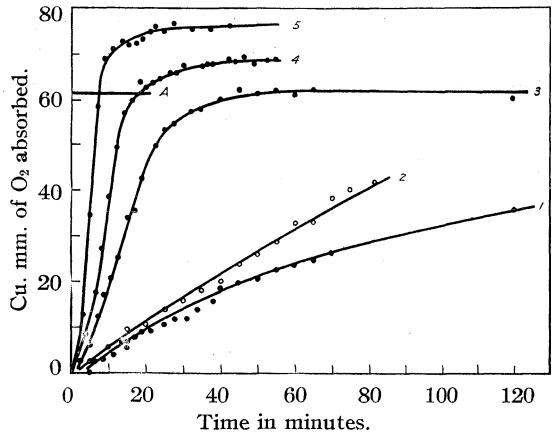

Fig. 7.—Absorption of oxygen by glutathione at various concentrations of Cu^{++}: GS^- = 0.00220 *M*; initial *p*H 10.9 (3.42 equivalents NaOH); O_2, 1 atm.; Cu × 10^6 in 1, 2, 3, 4, 5 is 0, 0.504, 2.52, 5.04, 10.08 *M*, respectively.

The effect of changes in oxygen pressure is also shown in Fig. 8. At very low Cu^{++} concentration, the reaction rate is independent of oxygen pressure but as Cu^{++} increases, this is no longer true. If the maximum rates of Fig. 8 are plotted against the square roots of the oxygen pressures for the three highest Cu^{++} concentrations, a series of lines passing through the origin is obtained. These indicate that, neglecting any effects of absorption or diffusion, the maximum reaction rate at high Cu^{++} concentration varies as the one-half power of the oxygen pressure. During the course of any experiment the oxygen pressure remains essentially constant as less than 1% of the total oxygen available is used.

Rate Law and Mechanism

The foregoing observations that GS^- is the reactive species, that the rate of the autocatalytic reaction is independent of GS^- concentration and dependent upon Cu^{++} concentration together with what is known about the usual role of cupric ion as a catalyst in oxygen reactions suggest the following series of reactions

$$Cu^{++} + GS^- \xrightarrow{(O_2)} X \quad (1)$$

$$X + O_2 \xrightarrow{(GS^-)} G_2S_2 + X \quad (2)$$

$$X + GS^- \xrightarrow{(O_2)} G_2S_2, \text{ with destruction of X} \quad (3)$$

Parentheses indicate that the substances are used in the reaction but do not enter into the rate law. In other words, each of the above incomplete equations indicates the substances entering into the rate-determining step of a series of two or more reactions.

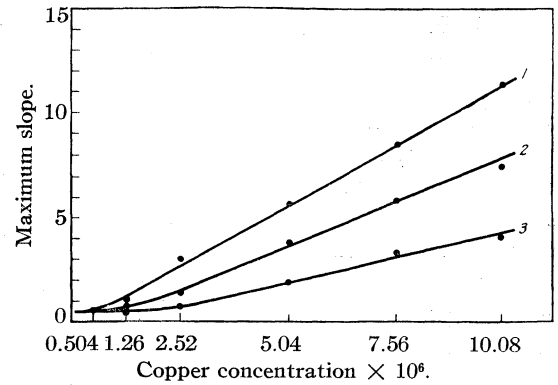

Fig. 8.—Variation of maximum slope with Cu^{++} concentration at *p*H 11.0: O_2 pressures in 1, 2, 3 are 1, 0.5, 0.2 (air) atm., respectively.

Proceeding in the usual manner, and remembering the experimental facts regarding oxygen pressure, the following rate expressions are obtained

$$-\frac{d[GS]}{dt} = k_1(Cu^{++})(GS^-) + k_2(X)(O_2)^{1/2} + k_3(GS^-)(X) \quad (4)$$

$$-\frac{d[X]}{dt} = k_1(Cu^{++})(GS^-) - k_3(X)(GS^-) \quad (5)$$

$$-\frac{d[O_2]}{dt} = -\frac{d(GS^-)}{dt}(2.8 \times 10^4) \quad (6)$$

Equation 6 is obtained assuming that the only reduction product of oxygen is hydroxide ion.

When the catalyst, X, is in a steady state, then

$$X = k_1(Cu^{++})/k_3 \quad (7)$$

When the concentration of Cu^{++}, and consequently X, is relatively high, the maximum rates occur near the end of the experiment, after the concentration of GS^- has been greatly decreased. Under these conditions, the contributions of reactions 1 and 3 to the rate of absorption of oxygen are negligible, and the rate expression may be written

$$-\frac{d[GS^-]}{dt} = k_2(X)(O_2)^{1/2} = k_2\frac{k_1}{k_3}(Cu^{++})(O_2)^{1/2} \quad (8)$$

and

$$-\frac{d[O_2]}{dt} = k_1\frac{k_2}{k_3}(Cu^{++})(O_2)^{1/2}(2.8 \times 10^4) \quad (9)$$

Using the values of maximum rates and Cu^{++} concentration of Fig. 8, a value of 40 is obtained for the function k_1k_2/k_3 at an oxygen pressure of one atmosphere.

The solution to the system of differential equations (4), (5), (6) is elusive. However, by using the method of successive approximations, it is possible to approximate the oxygen consumption as a function of time. By assuming $k_1 = k_3 = 200$ and k_2 between 30 and 40, it was possible to repro-

duce reasonably well the experimental data so far obtained at *p*H 11. The variation of k_2 is considered to be within the range of experimental error. Figure 9 shows the comparison between observed and calculated curves for three cases. Although the agreement is not perfect, it seems sufficiently good to encourage the view that the main features of the autocatalytic reaction are represented by equations (1), (2) and (3). The results of varying the oxygen pressure indicate, however, that the catalytic reaction is probably more complicated than as represented in equation (2). A possible explanation of the one-half power for the oxygen pressure would be the establishment of a rapid reversible equilibrium involving oxygen.

It will be observed from reactions (1), (2) and (3) that, when the concentration of X is low or when oxygen pressure is low, reaction (2) becomes less important, and a departure from the catalytic rate law would be expected. This condition is clearly realized at low oxygen pressures, Fig. 8, where the reaction rate becomes independent of oxygen pressure. Further, if undissociated glutathione can function in the destruction of the catalyst X, but not in its production, the rate law would be expected to fail at hydroxide ion concentration at which the concentration of GS^- was small compared to that of GSH. This assumption is borne out by the experiments at *p*H 9 (Table II) where the reaction rates become dependent upon the concentration of $\Sigma GSH = GSH + GS^-$. Column 6 in Table II represents the approximate per cent. of the reaction completed when the maximum rate occurs.

TABLE II

VARIATION OF MAXIMUM RATE WITH ΣGSH AT *p*H 9

GSH, moles per liter	$Cu^{++}(10^6)$, moles per liter	O_2 pressure, atm.	$H_2O_2(10^4)$ produced, moles per liter	Maximum slope, cu. mm./ minutes	% completion at maximum rate
0.00397	10.08	1	1.5	12.30	5
.00198	10.08	1	1.5	5.22	75
.00100	10.08	1	1.5	5.20	77
.00442	4.63	1		5.64	30
.00220	4.70	1		4.00	75

Hydrogen peroxide has been eliminated as the catalytic agent on the basis of experiments in which hydrogen peroxide, added to the reactants in molar concentrations varying from 1 to 20% of that of the glutathione, did not change the reaction rate. In this respect, the autoöxidation of glutathione differs from that of ascorbic acid in which hydrogen peroxide in the presence of copper ion has been shown to be a definite catalyst.[6]

(6) Dekker and Dickinson, THIS JOURNAL, **62**, 2165 (1940).

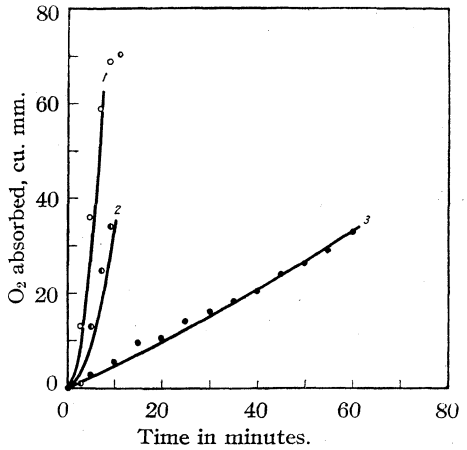

Fig. 9.—Comparison between experimental and calculated curves. The points are experimental; the lines are calculated. Initial *p*H is 10.9 (3.4 equivalents NaOH); O_2, 1 atm. In curves 1, 2, and 3 the concentrations of Cu^{++} (10^6) are 10.1, 5.0, and 0.50 and of GS^- are 0.00220, 0.00110, and 0.00220 *M*, respectively.

Also we have concluded that HO is not the catalyst since, in the *p*H range considered, chloride ion in concentrations varying from 1 to 500% of that of the glutathione does not inhibit the reaction rate.[7]

In view of the widely recognized evidence that peroxy radicals often function as catalysts in the autoöxidation of organic substances, it seems reasonable to identify X as a radical of GS, probably GSO_2, and to write the following reactions as the initiators of the catalysis.

$Cu^{++} + GS^- \rightleftharpoons Cu^{++}GS^-$	rapid, reversible
$Cu^{++}GS^- \longrightarrow Cu^+ + GS$	relatively slow
$GS + O_2 \longrightarrow GSO_2$	rapid

While it is possible to write several series of reactions completing the mechanism, it seems advisable to await the interpretation of results at higher hydroxide ion concentrations before deciding upon the most probable reactions involved.

The authors are indebted to Prof. Max Kleiber for the use of the Warburg apparatus.

Summary

1. The rate of absorption of oxygen by glutathione in the *p*H range 9 to 11 and in the presence of copper sulfate catalyst has been measured. The effect of changes in copper sulfate and glutathione concentrations and oxygen pressure are presented.

2. A rate law and partial mechanism are proposed.

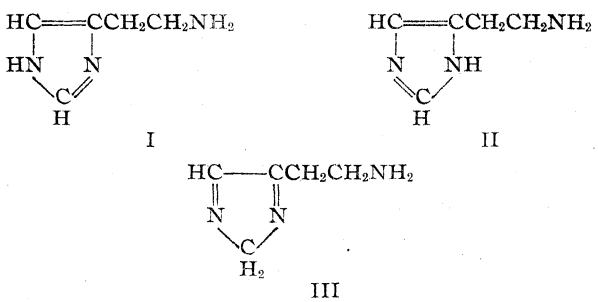
The Relation between Structure and Histamine-Like Activity

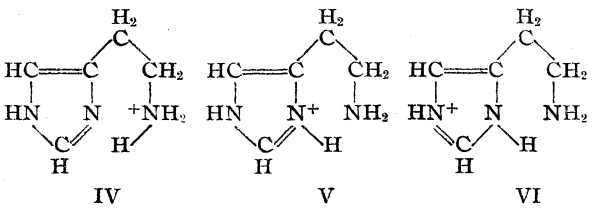
BY CARL NIEMANN AND JOHN T. HAYS

Recently Walter, Hunt and Fosbinder[1] reported that the physiological action of β-(2-pyridyl)-ethylamine is similar to that of histamine and that the action of β-(4-pyridyl)-ethylamine resembles that of epinephrine. This striking difference in the pharmacological behavior of the above two isomeric β-pyridylethylamines led us to inquire as to the physiological properties of the third and remaining isomeric β-pyridylethylamine, *i. e.*, β-(3-pyridyl)-ethylamine in the hope that information about the latter compound would lead to a more general understanding of the relation between structure and histamine-like activity.

dl-β-(3-Pyridyl)-alanine[2] was decarboxylated using the method of Abderhalden and Gebelein[3] to give β-(3-pyridyl)-ethylamine. A comparative study of the physiological properties of the three isomeric β-pyridylethylamines was undertaken by Dr. G. A. Alles of this Institute and it has been found that β-(3-pyridyl)-ethylamine resembles β-(4-pyridyl)-ethylamine in its pharmacological properties and does not show any notable histamine-like activity, which characterizes the pharmacological action of β-(2-pyridyl)-ethylamine.[4] For histamine we may write the three tautomeric structures I, II and III. However, it is clear from



a consideration of the possible resonance forms of each tautomer[5] and from the bond energies[6,7] that at equilibrium we need consider only structures I and II. Under physiological conditions tautomers I and II will add a proton and exist in the form of cations. If we ignore interaction between the side-chain and the nucleus, we must assign equal weight to each cation, but if we assume that side chain–nucleus interaction does take place through the medium of an intramolecular hydrogen bond, it follows that the cation has the structure (IV, V, VI). This ion with respect to



bond distances and chelation is more nearly related to tautomer I than to tautomer II. A similar chelation is to be expected in the cation of β-(2-pyridyl)-ethylamine. Thus it appears that the characteristic pharmacological properties of histamine are associated with structures that have their origin in tautomer I and we may look upon this tautomer as containing the obligatory structural requirements requisite for histamine-like activity.

The similarity of the physiological action of histamine and β-(2-pyridyl)-ethylamine led Walter, Hunt and Fosbinder[1] to conclude that the molecular fragment —CH═N—C($CH_2CH_2NH_2$)—═CH—, which they consider as being present in both histamine (tautomer I) and β-(2-pyridyl)-ethylamine, is primarily responsible for the histamine-like activity of these compounds. Taking advantage of the studies of Hill and Branch[5] and of Schomaker and Pauling,[8] we can give greater precision to the above conclusion of Walter, Hunt and Fosbinder[1] by defining the obligatory structural fragment requisite for histamine-like activity as —CH—*a*—N—*b*—C($CH_2CH_2NH_2$)—*c*—CH— where $a = 1.36 \pm 0.01$ Å., $b = 1.38 \pm 0.02$ Å., and $c = 1.40 \pm 0.01$ Å., and when chelation between the nitrogen atoms occurs in the cation.

A comparison of the structures that can be written for β-(3-pyridyl)-ethylamine and for

tautomer II reveals that each of these substances contains the molecular fragment —CH—*a*—N—*b*—CH—*c*—C($CH_2CH_2NH_2$)—. As β-(3-pyridyl)-ethylamine is devoid of any histamine-like activity, we conclude, on the basis of the preceding argument, that tautomer II is likewise devoid of any histamine-like activity. This conclusion is in accord with and supports the previous contention that tautomer I is the structure responsible for the histamine-like activity of histamine and that the principle obligatory structural requirement for histamine-like activity is the molecular fragment —CH—*a*—N—*b*—C($CH_2CH_2NH_2$)—*c*—CH—.

Experimental[9]

β-(3-Pyridyl)-ethylamine Dihydrochloride.—A mixture of 1 g. of *dl*-β-(3-pyridyl)-alanine[2] and 20 g. of diphenylamine was heated to 245–250° and maintained at that temperature for two hours.[3] The reaction mixture was digested with 40 ml. of 3 *N* hydrochloric acid and the digest allowed to cool to 25° with vigorous stirring. The diphenylamine was removed by extraction with ether, an excess of aqueous sodium hydroxide added to the aqueous phase and the latter extracted with ether. The ethereal solution was dried over sodium sulfate and then acidified with dry hydrogen chloride. The amine dihydrochloride separated as an oil, which was collected and crystallized from 20–25 ml. of hot absolute ethanol. This product (0.4 g.) was recrystallized from a mixture of absolute ethanol and ether to give β-(3-pyridyl)-ethylamine dihydrochloride, m. p. 195–205° with decomposition.

(9) Microanalyses by Dr. G. Oppenheimer and G. A. Swinehart.

Anal. Calcd. for $C_7H_{12}N_2Cl_2$ (195.1): C, 43.1; H, 6.2; N, 14.4; Cl, 36.4. Found: C, 43.3; H, 6.3; N, 14.4; Cl, 36.4.

Preliminary Pharmacological Report.[10]—In the cat both β-(3-pyridyl)-ethylamine and β-(4-pyridyl)-ethylamine are pressor in minimally active and higher doses, being about one-fifth to one-tenth as active as β-phenylethylamine. In the rabbit the pressor responses are not great with minimally active doses and with higher doses an initial depressor effect may be noted that is, however, unlike that of histamine, and is shown in similar degree by both β-(3-pyridyl)-ethylamine and β-(4-pyridyl)-ethylamine. In sufficient concentration both β-(3-pyridyl)-ethylamine and β-(4-pyridyl)-ethylamine decrease movement and tone of isolated rabbit jejunum preparations. This resembles the activity of more than minimally active concentrations of β-phenylethylamine, and is the reverse of the effect of histamine. No stimulant effect in concentrations up to 10^{-3} molar was noted upon isolated guinea-pig ileum preparations though this same concentration of β-phenylethylamine causes some increase in tone and concentrations of but 10^{-6} molar histamine are very active upon such preparations.

Summary

β-(3-Pyridyl)-ethylamine has been prepared and it has been found that this amine, in common with β-(4-pyridyl)-ethylamine and in contrast to β-(2-pyridyl)-ethylamine, has pressor activity. The relation between structure and histamine-like activity is discussed.

(10) The authors are indebted to Dr. G. A. Alles for this report and to Dr. L. A. Walter for samples of β-(2-pyridyl)-ethylamine and β-(4-pyridyl)-ethylamine.

The Addition of Hydrogen Fluoride to the Triple Bond[1]

BY ARISTID V. GROSSE[1a] AND CARL B. LINN

We have recently demonstrated[2] that olefins will add hydrogen fluoride, even in the complete absence of catalysts, to give good yields of alkyl fluorides. Likewise the cyclopropane ring is opened by hydrogen fluoride to give *n*-propyl fluoride. The chemical literature contains no reference to a similar addition of hydrogen fluoride to the triple bond. In view of the ease of addition to the double bond, a similar behavior was expected of the *triple bond*. This proved to be the case and we found that unsaturates of this type readily *add hydrogen fluoride* in the *absence of catalysts*, according to the equations

$$R—C{\equiv}C—R' + HF \longrightarrow R—CF{=}CH—R' \quad (1)$$
$$R—CF{=}CH—R' + HF \longrightarrow R—CF_2—CH_2—R' \quad (2)$$

giving *difluorinated hydrocarbons* of the type

$$R—CF_2—CH_2—R'$$

Previous to our investigation only the two simplest[3] members of this series were known, namely, 1,1-difluoroethane[4] and 2,2-difluoropropane.[5] Subsequently A. L. Henne, in his well known studies of aliphatic fluorine compounds, has extended the reaction of antimony or mercuric

fluorides upon the corresponding dichloro compounds and recently described[6] 2,2-difluorobutane and -pentane. 1,1-Difluoroheptane has also been reported by him.[6]

We have accomplished the *addition* of *hydrogen fluoride* to *ethyne, propyne, butyne-1* and *-2, pentyne-1, hexyne-1* and *-3* and *heptyne-1.*

The formation of an unsaturated monofluoride, according to equation 1 above, was demonstrated only in the case of acetylene where *vinyl fluoride* was isolated. Each of the other alkynes studied yielded a saturated compound analyzing for two atoms of fluorine in the molecule.

The possibility is not excluded that, under appropriate conditions, the method may be developed as a means of preparing monofluorides of the formula RCF=CHR'.

The addition of *both* hydrogen fluoride molecules takes place according to Markownikoff's rule and in line with Kharasch's theory,[7] leading to the attachment of *both* fluorine atoms to the *same* carbon atom.

The structure of our difluoroparaffins was definitely established in the case of the products from ethyne, propyne, butyne-1 and -2 and pentyne-1 by the identity of their physical properties with those prepared by Henne's substitution method from dichlorides of known structure (see Table I; for ethyne see p. 2291).

Further proof of the above-mentioned reaction scheme is the fact that butyne-1 and butyne-2 hydrofluorinate to give an *identical* reaction product, as can also be seen in Table I. Butyne-2 can yield no product with a fluorine attached to a terminal carbon atom and in this case it is shown that the second atom of fluorine entering goes to the already fluorinated carbon, as would be expected.

There is no reason to assume that the entering fluorine atoms take different or abnormal positions in the higher alkynes. A rigid characterization of these compounds, however, is hindered because there is no reaction, as yet, by which a fluorine atom in such a molecule may be converted into another atom or group.[8]

Our difluorides are completely inert and do not lose hydrogen fluoride, in contrast to alphyl fluorides,[2] a point stressed by Henne and Renoll,[5] relative to 2,2-difluoropropane. They have a not unpleasant odor, somewhat like straight chain paraffins. Their indices of refraction are substantially lower than those of paraffins of equal boiling points.

(7) M. S. Kharasch, Engelmann and Mayo, *J. Org. Chem.*, **2**, 298 (1937).

(8) Cyclohexyl fluoride readily can be converted into cyclohexyl chloride by the action of antimony trichloride (unpublished work of the authors).

Experimental

Source of Reagents.—The acetylene was from Prest-O-Lite welding cylinders. The propyne was prepared by us by treating methyl sulfate with sodium acetylide prepared according to the directions of G. F. Hennion.[9] The other alkynes[10] were prepared for us by Dr. Hennion at the University of Notre Dame and fractionated before use. The anhydrous hydrogen fluoride for all these preparations was supplied in cylinders by the Harshaw Chemical Company. It was over 99% pure and contained only 0.1% of water, and less than 0.04% of residue on evaporation at 100°.

The Action of Hydrogen Fluoride on Acetylene.—Preliminary experiments showed that there was *no reaction* when acetylene was passed into hydrogen fluoride at temperatures of −70 and 0°, respectively, although at the latter temperature there was some formation of a solid polymer. In another experiment a mixture of acetylene and hydrogen fluoride in molal ratio 1:3, was passed through a nickel reaction tube packed with nickel shavings, at a temperature of 300°. At a contact time of five seconds, the acetylene went through unreacted except for the formation of a black powder in the heated part of the reaction tube. The exit gas after being freed from hydrogen fluoride had a molecular weight of 26 (acetylene = 24) and contained no constituent of higher boiling point than acetylene. Pressure experiments, however, achieved hydrofluorination of acetylene.

Experiment under Pressure at Room Temperature.—Into a stainless steel autoclave of 1 liter capacity equipped with a mechanical stirrer was charged 128 g. of hydrogen fluoride. To this was connected a line supplying acetylene under pressure from a commercial cylinder. During the course of the reaction the operator was protected by a curtain of steel and remote controls were used. With the reactor at room temperature, the pressure was raised to 13 atmospheres, a temperature rise of 3° being observed. The pressure dropped slowly over a period of hours and was maintained at 8–12 atmospheres for seventy-two hours, during which time the autoclave contents was stirred continuously. The autoclave was then cooled in an ice-bath and the pressure released through a line which scrubbed out the hydrogen fluoride vapors, dried the gas; and then passed through a trap cooled to −78°. 12 g. of water-white liquid condensed in the trap. The non-condensable gas was shown to be pure acetylene. Inside the autoclave was found 30 g. of a polymer, which when washed and dried was a brittle brownish-black solid burning with difficulty.

The condensable gas was distilled on a low temperature Podbielniak column and separated into two constant boil-

(9) Paper presented before the Indiana Academy of Science at Manchester College, November 5, 1937.

(10) A comparison of some physical properties of our butyne-1 and -2 samples will be given in another paper.

ing fractions. Fraction 1, corresponding to 35 mole %, boiled at −72° and had a molecular weight of 45 (Dumas), while fraction 2, equalling 65 mole %, boiled from −26 to −24° and had a molecular weight of 65. Approximately 15% of the acetylene reacting was converted into these two products.

These data check those described by Julius Söll of the I. G. Trust in a German patent[11] for physical constants of *vinyl fluoride* and *2,2-difluoroethane*. Söll prepared them by the *catalytic* hydrofluorination of acetylene in the presence of mercury salts and/or activated charcoal.

Fraction 1 thus corresponds to vinyl fluoride, CF_2=CHF, mol. wt. 46; b. p. −72.2 (760 mm.).[11]

Fraction 2 corresponds to 1,1-difluoroethane, CH_3—CHF_2, mol. wt., 66; b. p. −24.7 (760 mm.).[11]

The refractive index (n_D) of the 1,1-difluoroethane was 1.3011 at −72° or extrapolated to room temperature ≃ 1.255. As far as we know, this is the lowest index of refraction ever recorded for an organic or inorganic liquid compound.

The Action of Hydrogen Fluoride on Propyne and Higher Alkyl Acetylenes

Description of Apparatus and Procedure.—As shown in the attached drawing (Fig. 1) the reaction chamber was a nickel cylinder 5 cm. in diameter, 35 cm. high, and open at the top. Into this was fitted a rubber stopper carrying an oil-sealed nickel stirrer, a dropping funnel, a thermocouple, and a "cold-finger" reflux cooled by dry-ice and acetone. The cylinder was surrounded by a cooling bath of acetone and dry-ice. In the case of propyne the dropping funnel was replaced by a copper tube through which the gaseous alkyne was introduced directly into the liquid hydrogen fluoride.

A distinct temperature effect was noted during the addition of alkyne, the operation requiring around forty minutes. The reaction appeared to be instantaneous. Stirring was continued for an additional thirty minutes and the product worked up immediately. When alkynes above propyne were used, cracked ice was added to the reaction mixture, it was warmed to 0° and poured into a separatory funnel where the water insoluble reaction product was quickly removed from the hydrofluoric acid, washed several times with water, dried with potassium carbonate, and then carefully distilled. With propyne, the above procedure had to be modified so that no product was lost during the dilution of the hydrogen fluoride with water. Water was added slowly from a dropping funnel in a closed system and escaping gas was washed through dilute alkali, dried with soda lime and calcium chloride and condensed in a trap cooled to −78°.

Anal. The liquid difluorides were analyzed for carbon and hydrogen by the technique described by Schiemann and Pillarsky,[12] using, in addition to copper oxide, both lead chromate and silver gauze. The fluorine determination was carried out as previously described.[13]

Results

In our experiments about one-half gram mole of the lower alkynes and one-quarter gram mole of the hexynes and heptynes were charged into the reaction vessel and ten molecular equivalents of anhydrous hydrogen fluoride added. The temperature, initially −70°, was controlled by stirring, etc., so that it did not rise more than 5–15°. The time of addition varied from one to one and one-half hours.

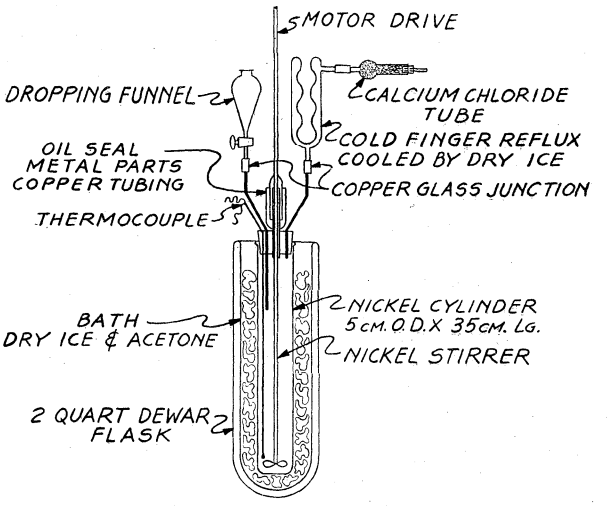

Fig. 1.

A crude liquid product, insoluble in water, was recovered which in every instance weighed 1.24 ± 0.03 times the weight of the alkyne originally charged.

The yield of difluoride based on the alkyne charged averaged 65%, but varied between the extreme limits of 46% in the butyne-1 case and 76% in the case of hexyne-3.[14]

The extreme ease of hydrofluorination of the higher alkynes, which react instantly and completely at temperatures as low as −70°, stands in contrast to the reaction of hydrogen fluoride with acetylene, where hydrofluorination was only achieved by the use of relatively high pressures and a long contact time at room temperature. This enhanced reactivity of higher alkynes contrasted to acetylene is, however, experienced in its other reactions, as recorded in the literature.

Table I gives the properties of our products as determined upon a well-fractionated and sharply boiling cut.

As can be seen from Table I the properties of difluorides formed from ethyne, propyne, butyne-1, butyne-2 and pentyne-1 are in general agreement with the predicted difluorides prepared by the method of Henne and others.

[a] M. p., −104.8°. [b] M. p., −105 to −108°. [c] M. p., −116.9°. [d] M. p., −117.1°. [e] Calcd.: C, 58.97; H, 9.91; F, 31.12. Found: C, 56.4; H, 9.46; F, ≃34.1. [f] Calcd.: C, 58.97; H, 9.91; F, 31.12. Found: C, 58.76; H, 9.81; F, 31.43. [g] Calcd.: C, 61.70; H, 10.37; 29.93. Found: C, 61.51; H, 10.32; F, 28.17. We prepared about 20.8 g. of Henne's difluoride by treatment of antimony trifluoride with acetone dichloride; its mixed melting point with ours −108°.

It is important to note that the difluorides from butyne-1 and -2 were identical among themselves (see Table I; furthermore, the mixed melting point −116.9°, *i. e.*, showed no depression) and also with Henne's compound.

By-Products of the Reaction.—The hydrofluorination of propyne gave a 61% yield of the difluoride, based on the charge. The rest was accounted for in an amorphous, light brown *solid* (7 g. from 19 g. of propyne), similar to the solid encountered in the acetylene reaction. Elementary analysis of this solid showed it to have the composition: C, 79%; H, 9%; F, 12% (by difference) corresponding approximately to the formula $C_6H_{13}F$ or $3C_3H_4$, HF. In the case of alkynes above propyne the crude products on distillation yielded liquids of higher boiling point, higher refractive index and lower density than the main product, indicating alkyne *polymers* rather than fluorides.

Acknowledgment.—The authors wish to thank Mr. Willard Mann for assistance with the laboratory work pertaining to this investigation.

Summary

1. A new reaction, the direct non-catalytic, addition of hydrogen fluoride to alkynes giving a series of difluoroparaffins, of the formula R—CF_2—CH_2—R′, has been described.

2. With the exception of acetylene the alkynes studied, namely, propyne, butyne-1, butyne-2, pentyne-1, hexyne-1, hexyne-3, and heptyne-1, all reacted at temperatures around −70° to give good yields of a difluorinated paraffin.

3. The properties of 2,2-difluoro-propane, -butane, -pentane, -hexane, -heptane and 3,3-difluoro-hexane are described.

4. The hydrofluorination of acetylene was accomplished by contacting it with liquid hydrogen fluoride in an autoclave under pressure. 1,1-Difluoro-ethane and vinyl fluoride were the reaction products isolated.

Tracer Studies with Radioactive Hydrogen. The Synthesis of Labelled Methyl Iodide

BY D. HARMAN, T. D. STEWART AND S. RUBEN

In connection with our work on the Menschutkin reaction[1] it was necessary to prepare methyl iodide with the methyl group labelled by the inclusion of a radioactive carbon or hydrogen atom.

There are two radioactive isotopes of carbon whose half-lives are such that they can be used as isotopic tracers, C^{11} (half-life 20.5 minutes) and C^{14} (half-life 10^3 years). Since the supply of C^{14} is limited we attempted to use the shorter lived isotope. The isotopes have already been employed in a rapid synthesis of other organic compounds.[2,3,4]

The synthesis of $C^{11}H_3I$ used may be summarized by the equations

$$C^{11}O_2 + H_2 \xrightarrow{B.\ coli} HC^{11}O_2H \quad (1)$$

$$HC^{11}O_2H + CH_3OH \longrightarrow HC^{11}O_2CH_3 + H_2O \quad (2)$$

$$HC^{11}O_2CH_3 + 2H_2 \xrightarrow[160°]{CuOCrO_3} C^{11}H_3OH + CH_3OH \quad (3)$$

$$C^{11}H_3OH + HI \longrightarrow C^{11}H_3I + H_2O \quad (4)$$

The reduction of CO_2 to formic acid was accomplished by a fresh suspension of *Bacterium coli*.[5,6]

While the above process is practicable, the time required is about three hours. It was therefore decided to label the methyl groups with radioactive hydrogen.[7] The half life of H^3 is about thirty years[8] and, moreover, samples of high specific radioactivity can be prepared. The chief difficulty in the use of H^3 is in the measurement. It emits very soft beta particles (upper energy limit 10–15 Kev)[7,8,9] and, consequently, it must be counted in gaseous form.

With radioactive hydrogen as a tracer for methyl groups there are several possible modes of preparation in addition to the one above.

$$(CH_3)NO_2 \xrightarrow{HTO} (TCH_2)NO_2 \longrightarrow (TCH_2)NH_2 \longrightarrow (TCH_2)I \quad (1)$$

$$CH_2N_2 \xrightarrow{TI} (TCH_2)I \quad (2)$$

$$CH_2N_2 \xrightarrow{TOH} (TCH_2)OH \xrightarrow{HI} (TCH_2)I \quad (3)$$

The process used here employs the apparatus developed for $C^{11}H_3I$, substituting HT for H_2.

Experimental

Preparation of $C^{11}H_3I$.—About 50 cc. of the aqueous solution of radioactive formic acid was titrated to phenolphthalein and the solution evaporated to dryness *in vacuo* at 100°. The residual sodium formate (about 0.5 g.) was placed in a semi-micro distillation apparatus and to it was added 1 cc. of a solution prepared from 25 g. of sulfuric acid and 50 g. of methanol. The first distillate of about 0.2 cc. was redistilled to give about 0.1 cc. of liquid which contained approximately 60% yield of methyl formate. This yield could be improved. The ester was converted to methanol and methyl iodide by essentially the same process as described below for the tritium derivative.

Preparation of $(TCH_2)I$.—The apparatus used, shown in Fig. 1, was designed to recover unused radioactive hydrogen which was stored in bulb I.

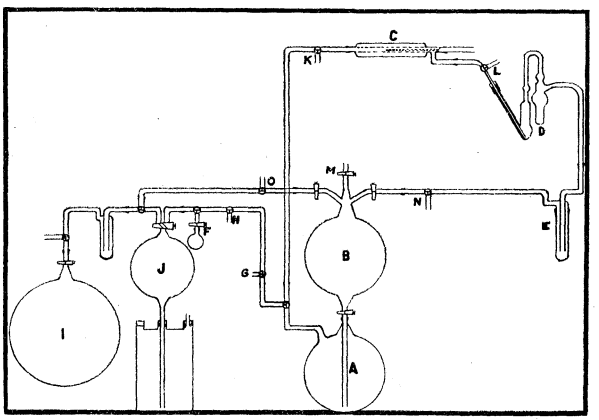

Fig. 1.

A bulb containing the methyl formate was attached at F and cooled in liquid air. The line including J, A and B was filled with hydrogen three times and evacuated. The line from K to N was swept out with a stream of hydrogen. Initially, bulb B is filled with mercury and bulb A has only enough to cover the end of the tube leading from B to A.

The reaction mixture of methyl formate and tritium (HT) was prepared in bulb A by admitting the ester to a pressure of 7.6 cm. of mercury and transferring the tritium with the help of the Toepler pump to give a total pressure of 76 cm. of mercury. This mixture was passed over the catalyst in C and through the Zeisel apparatus[10] at a rate

of about 10 cc. per minute by admitting mercury from B to A. In order to maintain atmospheric pressure mercury is added to B through M. The liquid air trap at E condensed the methyl iodide formed and unused tritium was returned through B eventually to I.

The active methyl iodide containing tritium was made in about 2 g. quantities in better than 75% yield. The crude material of d^{20}_0 1.5268 melted at about −60°. It was redistilled and the vapor passed over phosphorus pentoxide *in vacuo*.

Preparation and Use of Catalyst.—The catalyst was prepared by dissolving 120 g. of cupric nitrate in 100 cm. of water and adding a saturated solution containing 60 g. of potassium carbonate at about 50°. The precipitated basic copper carbonate was filtered off, washed well and dried; 45 g. of the pulverized material was added to 100 cc. of quartz chips (0.5 to 1 mm.) and 50 cc. of chromic acid solution containing 2 g. of CrO_3. The mixture was well stirred and dried on a steam-bath. The catalyst chamber of 3.5-cc. capacity was filled with this material and the catalyst reduced by passing about 20 cc. of hydrogen per minute over it at a temperature of 325° for six hours. Tank hydrogen was passed over the catalyst at 160°, the temperature used for the reduction of the ester, for two hours before each preparation.

Summary

Radioactive methyl iodide has been prepared by two processes, the one leading to a compound containing short-lived C^{11}, the other to a compound containing radioactive hydrogen. Each process is designed for small amounts of material.

A Study of the Menschutkin Reaction Using Radioactive Hydrogen as a Tracer

BY D. HARMAN, T. D. STEWART AND S. RUBEN

The reaction between amines and organic halides

$$R_3N + RX \longrightarrow R_4N^+ + I^- \qquad (1)$$

has been the subject of considerable experimentation and speculation.[1-10]

The kinetics of this reaction are of particular interest because the probability factor in the rate expression

$$\frac{d(I^-)}{dt} = k(R_3N)(RX) = PZe^{-E/RT}(R_3N)(RX) \qquad (2)$$

is unusually low, and, moreover, markedly affected by the solvent. For example, in the reaction between $C_6H_5NH_2$ and $C_6H_5COCH_2Br$ the factor P varies from 4×10^{-11} in benzene to 5×10^{-5} in benzyl alcohol.[10]

The values of log P and E in different solvents for the reaction

$$C_6H_5N(CH_3)_2 + C_6H_5CH_2Br \longrightarrow C_6H_5N^+(CH_3)_2(CH_2C_6H_5) + Br^- \qquad (3)$$

as given by V. A. Gol'tsschmidt and N. K. Vorob'ev[9] are reproduced in Table I.

TABLE I

THE ACTIVATION ENERGY AND PROBABILITY FACTOR FOR THE REACTION OF EQUATION 3

Solvent	$(CH_3)_2CO$	$C_6H_5COCH_3$	$C_6H_5NO_2$	C_2H_5OH
$k \times 10^4$ (30°)	80.5	84.5	118	650
E	9747	9929	11,200	13,800
$-\log P$	4.94	5.08	6.16	8.78

For other types of reaction the value of P is usually close to unity; the very low values in the Menschutkin reaction imply that very few "activated" collisions result in reaction. Many theories have been advanced to account for this abnormality and the present paper presents experimental results which offer a test of some of these explanations.

Moelwyn-Hughes and Sherman[6] have assumed that at least one of the reactants forms an unstable complex with the solvent and that the true reactant is this solvated portion. In such a case the evaluation of the product $(R_3N)(RX)$ of the rate expression is in error and the true value of P could be unity.

Hinshelwood,[5] from a consideration of Eucken's[11] work on the variation of the velocity of sound with frequency in the gas phase, and Norrish,[4] by analogy with a number of photochemical reactions, account for the apparent inefficiency of the activated collisions by assuming an intermediate collision complex which can yield the

final products only if conditions are favorable for stabilization of the products. Otherwise the complex reverts to the reactants. Norrish, in his explanation, invoked the hypothesis of the Franck–Rabinowitch cage effect. While this hypothesis is very helpful to an understanding of what happens before highly activated intermediates (free radicals, etc.) can permanently separate, it seems doubtful if it is important in considering processes where there is very little thermodynamic tendency for recombination of the initial products of dissociation, *i. e.*, where the equilibrium state is far toward dissociation.

Edwards[3] has postulated for benzene solutions, in which the product of the Menschutkin reaction is sparingly soluble, that the reaction is primarily rapid and reversible. He presumes that the rate of the over-all reaction is governed by the rate of formation of the solid product.

$$R_3N + RX \rightleftarrows R_4N^+ + X^- \longrightarrow \text{Solid}$$

The equilibrium in solution favors the original reactants. This hypothesis takes the form of those above, in that a reversibly formed intermediate is involved in the net process.

Experimental Results and Discussion

It is possible to test the theory of a reversibly formed intermediate in the Menschutkin reaction by allowing an amine to react with an alkyl halide which contains a radioactive hydrogen or carbon atom. If the nature of the intermediate is such that the alkyl groups become spatially equivalent with respect to the halide ion before reversion to the initial reactants occurs, radioactivity should be found in the experimentally unreacted amine as well as in the alkyl halide salt. With this in mind, methyl iodide containing radioactive hydrogen or tritium (H^3) was allowed to react with trimethylamine and dimethylaniline, respectively, in both alcohol and benzene solutions.

Two equivalents of trimethylamine stood for three hours in 95% ethanol solution, with one equivalent of methyl iodide containing tritium. The reaction went to completion and the excess amine was examined for tritium content. Less than 1% of the activity to be expected on the basis of random distribution of the methyl groups between the amine and methyl iodide was obtained. An increase of amine concentration to a five-fold excess did not produce detectable interchange. The expected radioactivity appeared in the tetramethylammonium salt formed in the reaction.

Since the reaction between $C_6H_5N(CH_3)_2$ and CH_3I is very slow, the equivalent quantities of the reactants were allowed to stand for three hours at 25°, and then the unchanged $C_6H_5N(CH_3)_2$ was isolated and examined for radioactivity. No activity was found.

Ethanol as a solvent could have promoted ion separation and stabilized the initial reaction product, and, therefore, the reactions were carried out in benzene. The procedures used were the same as those employed when the reactions were carried out in ethanol except that the reaction between $C_6H_5—N(CH_3)_2$ and CH_3I was stopped after thirty minutes, which from previous experience is just prior to separation of crystals. No activity appeared in the unreacted amine in either case.

The sparingly soluble active tetramethylammonium iodide does not exchange methyl groups, at room temperature, with trimethylamine upon standing for eight hours in alcohol or for three days in benzene. The alcohol soluble tetramethylammonium chloride was prepared from the active iodide; it did not exchange with the amine in alcohol solution in eight hours.

It is evident that for the cases studied, no intermediate exists which is rapidly and reversibly formed and in which the iodide ion loses its identity with the methyl group originally present in the active methyl iodide.

Experimental

The following procedure was used for both benzene and alcohol solutions. Five cc. of 0.2 *M* radioactive CH_3I[12] solution was added to 10 cc. of 0.2 *M* trimethylamine solution contained in a 25-cc. flask. After shaking, the mixture was placed in a bath at 25°. When the reaction was carried out in alcohol, crystals began to form in about ten minutes, but with benzene as a solvent an immediate turbidity was observed. At the end of about three hours, by which time the reaction had gone to completion, the excess of amine and the solvent were removed from the salt by first freezing the contents of the flask in liquid air, connecting the latter by a wide bore tube to another flask, evacuating the system, placing the liquid air-bath around the second flask and gently warming the reaction mixture. A quantity of concentrated hydrochloric acid sufficient to convert all of the amine to the hydrochloride was then added to the distillate and the water and solvent removed at 100° under vacuum. When benzene was used as the solvent, 10 cc. of alcohol was added so that upon addition of the hydrochloric acid a homogeneous solution resulted. The flask was then equipped with a dropping funnel, an air inlet and a tube leading to a combustion furnace.

(12) D. Harman, T. D. Stewart and S. Ruben, THIS JOURNAL, **64**, 2293 (1942).

Two cc. of 50% potassium hydroxide was added to the dry salt and the amine generated was swept through a drying tube to the combustion tube by a slow stream of air. Explosions resulted from the use of pure oxygen or of too rich an air mixture. The water formed was collected in a small liquid air trap and converted to hydrogen as follows, by a procedure worked out by Mr. T. H. Norris of this Laboratory. The water was transferred to the bottom of a test-tube (29 × 300 mm.) which was then filled with magnesium turnings and connected, in a vertical position, to a glass coil which in turn was attached to a high vacuum line. After placing the lower end of the tube in liquid air the system was evacuated, the glass coil also immersed in liquid air, and an electric heater placed around the top portion of the tube. When the temperature of the heater was constant, at approximately 625°, the liquid air was removed from the bottom of the test-tube which was then gently heated to vaporize the water. The hydrogen formed was collected in a 3-liter flask on the vacuum line from which it was transferred to a Geiger counter. The counting mixture was composed of about 15 mm. mercury pressure of alcohol and 20.0 cm. mercury pressure of hydrogen. This procedure required about thirty minutes.

The data on a typical experiment are

Original reactants	
Moles methyl iodide	1.02×10^{-3}
Moles trimethylamine	2.00×10^{-3}
Equiv. of methyl group	7.02×10^{-3}
Specific radioactivity of hydrogen (counts/min./g. atom)	
From initial methyl iodide	1.85×10^{7}
From excess trimethylamine	$<1.46 \times 10^{4}$
Calcd. for random distribution	$<1.58 \times 10^{7}$

The last figure in the above calculation gives the activity to be expected in the excess amine if, during the reaction, random distribution ($6.00 \times 1.85 \times 10^{7}/7.02$) were achieved; the activity found corresponds to less than 0.1% of that predicted on the assumption. Two experiments were made in alcohol and one in benzene, as described above. One was made in alcohol in which the concentration of the amine was five times as great as that of the methyl iodide. In all cases there was no exchange within experimental error.

In order to determine whether the excess amine reacts with the quaternary salt

$$(CH_3)_4NI + (CH_3)_3N \longrightarrow (CH_3)_3N + (CH_3)_4NI$$

the amine solution was added to some of the salt formed from active methyl iodide in a previous experiment and whose activity was known. After standing for eight hours in alcohol as a solvent, or for forty-eight hours in benzene, the amine was removed and its activity, determined as above, found to be negligible.

Since tetramethylammonium iodide is not very soluble in alcohol or benzene, the experiment was repeated in alcohol using the corresponding chloride which was prepared from the same sample of iodide. No exchange was evident.

To test the possibility that, in the conversion of the amine to its hydrochloride and regeneration back to the amine, the H of the methyl groups exchanged with those of water, a 50% solution was prepared using very active water which was then used to regenerate amine from inactive trimethylamine hydrochloride. The activity of the amine was determined in the usual manner and no exchange was found.

The procedure for the reaction between dimethylaniline and methyl iodide was the same in both benzene and alcohol. Ten cc. of 0.2 *M* CH_3I was added to 10 cc. of 0.2 *M* $C_6H_5N(CH_3)_2$ and the resulting solution allowed to stand for three hours. A very few small crystals formed in this time, the quantity being greater in alcohol. The solvent and unreacted methyl iodide were separated from the quaternary salt and unreacted amine under vacuum as described above. The amount of methyl iodide in the distillate was determined as a measure of the extent of quaternization; about 1% reaction occurred. The amine was separated from the quaternary salt by treating the mixture with benzene and filtering through a fine sintered glass filter. Most of the benzene in the filtrate was removed by distillation, finally at 100° and 2-mm. pressure, and from a tube which could be placed in the combustion tube to burn the residual amine. The activity in the water was determined as above, and found to be zero within experimental error. While little net reaction had occurred, no exchange of the methyl groups was found.

Summary

Excess trimethylamine was quaternized by methyl iodide in which the hydrogen atoms were in part replaced by radioactive hydrogen or tritium. All the radioactivity was found in the quaternary salt, none in the excess amine. The solvents used were alcohol and benzene. Incomplete quaternization of dimethylaniline in alcohol or benzene produced no radioactivity in the unreacted base. It is concluded that for these cases there is no reaction intermediate which is reversibly formed and in which iodide ion loses its identity with the methyl group to which it was originally attached. Tetramethylammonium iodide or chloride does not methylate trimethylamine in alcohol solution at room temperature in eight hours; suspended in benzene no reaction occurs in three days.

Some Exchange Experiments with Radioactive Tracers

BY S. RUBEN, M. D. KAMEN, M. B. ALLEN AND P. NAHINSKY

In connection with some experiments on photosynthesis in these Laboratories it was found that the centrally bound magnesium of chlorophylls *a* or *b* does not interchange[1] with Mg^{++} at room temperature in 80% acetone–water solution. This rather surprising result induced us to study various other metallo-organic exchange reactions. In this paper we report the results of the following exchange experiments: (1) Fe^{+++} and ferriheme, (2) Fe^{+++} and ferrihemoglobin, (3) Fe^{+++} and ferric pheophytin, (4) Fe^{+++} and ferric tetraphenylporphyrin, (5) Cu^{++} and cupric pheophytin, (6) Fe^{++} and ferrous ortho phenanthroline, (7) Fe^{++} and ferrous α,α'-dipyridyl, (8) Mg^{++} and magnesium 8-hydroxyquinolate.

The first 5 pairs (*i. e.*, the metallo porphyrins) showed no measurable exchange even after long periods. The remaining combinations exchanged at a slow but easily measurable rate. These results seem to indicate that structural factors are more important than covalent-ionic bond character in determining the readiness of a metallic ion (in a metallo-organic compound) to undergo exchange.

Exchange between Magnesium 8-Hydroxyquinolate and Mg^{*++}.—Since the magnesium in chlorophyll did not exchange with Mg^{++}, it was considered of interest to try the exchange with the magnesium salt of 8-hydroxyquinoline. This compound is similar in behavior to the magnesium porphyrins in that they are the only known magnesium compounds which do not form magnesium hydroxide when boiled with concentrated alkali.[2]

Radioactive magnesium, Mg^{27} (10.2 min. half life) was prepared by bombardment[3] of metallic magnesium with 8 m. e. v. deuterons for ten minutes in the 37″ cyclotron. The magnesium was dissolved in concentrated hydrochloric acid, and excess sodium hydroxide added to precipitate magnesium hydroxide. The precipitate was filtered, washed, dissolved and reprecipitated three times in order to remove the last traces of radioactive sodium (Na^{24}) which is also produced by the deuteron bombardment. The final magnesium hydroxide, rid of Na^{24}, was converted into aqueous magnesium chloride and used in this form.

A fresh precipitate of magnesium 8-hydroxyquinolate (carefully freed of excess 8-hydroxyquinoline) was shaken with Mg^{*++} for thirty minutes at room temperature. The quinolate was filtered off, thoroughly washed and found to be strongly radioactive. Indeed, although the exchange took place in a two-phase system, the quinolate contained ~60% of the radio-Mg calculated for complete interchange.

Fe^{+++}–Ferriheme and Fe^{+++}–Ferrihemoglobin.—Because of the above result it seemed pertinent to investigate metalloporphyrins other than chlorophyll. As a result of their investigations of the magnetic properties of hemoglobin and its many derivatives, Pauling and Coryell[4] have concluded that the forces holding Fe^{+++} in ferriprotoporphyrin and ferrihemoglobin are ionic. These compounds readily lend themselves for investigation, particularly since a radioactive isotope of iron, Fe^{59}, of forty-seven days' half-life[5] is known. 1.5×10^{-4} mole of Fe^*Cl_3 in 0.001 molal hydrochloric acid was added to 3×10^{-4} moles of ferriprotoporphyrin dissolved in 95% ethanol. After standing for about two months at room temperature the alcohol was evaporated off. The Fe^*Cl_3 was removed from the solid residue with 0.001 molal hydrochloric acid solution, the insoluble porphyrin being filtered off. The heme was only slightly active, containing ~2% of the Fe*. This small activity could be due to incomplete removal of Fe^*Cl_3.

In a separate experiment, 10^{-5} mole of Fe^*Cl_3 was added to an aqueous solution containing 10^{-5} mole of ferrihemoglobin[6] in a slightly acid solution. After thirty hours at room temperature the hemoglobin was precipitated with excess trichloroacetic acid and filtered off. The bulky precipitate was carefully washed and ignited to yield mainly ferric oxide. This preparation was found to be inactive, containing less than 1% of the radio-iron used. This is in agreement with the findings of Hahn, *et al.*[7]

Iron and Copper Pheophytins.—The magnesium of chlorophyll can be replaced by other metallic ions under suitable conditions without removal of the phytol or methanol. Such compounds are called pheophytins. We have found no exchange between Fe^{*+++} and iron pheophytin or between Cu^{*++} and copper pheophytin, even after two days in 80% acetone solution.

Fe^{+++}–Ferric Tetraphenylporphyrin.—This experiment was carried out in a 0.02 *N* $HClO_4$–water–ethanol–benzene solution in which both ferric and the ferric tetraphenylporphyrin[8] salts are soluble. No exchange of iron (<3%) was found after five days at room temperature.

Fe^{++}–Ferrous Ortho Phenanthroline.—The (presumably) octahedral arrangement of the six nitrogens in the orthophenanthroline complex forms a rather stable configuration around the central iron ion. It was of considerable interest to compare the lability of the metallic ion in this compound with the various organo-metallo com-

pounds reported above. The results are summarized in Table I.

TABLE I

Expt. no.	Molality of $FeSO_4$	Molality of $(C_{12}H_8N_2)_3$-$FeSO_4$	Molality of H^+	Time allowed for exchange	Per cent.[a] of random distribution of Fe^{*++}
1	0.05	0.05	0.2	5 days	100 ± 5
2	.026	.022	.05	4 minutes	7 ± 2
3	.022	.012	.05	60 minutes	35 ± 5

[a] NH_4OH was used to separate ferrous ion and the ferrous phenanthroline.

From Table I it is apparent that in aqueous solution at room temperature iron is exchanged at a slow but easily measurable rate.

Fe^{++}–Ferrous α,α'-Dipyridyl Sulfate.—Ferrous α,α'-dipyridyl is somewhat similar to the phenanthroline complex in regard to structure and stability. It was of interest to study this exchange because ferrous α,α'-dipyridyl sulfate is known to be diamagnetic and Pauling has concluded[9] that the iron–nitrogen bonds are therefore mainly covalent. Thus one might be inclined to predict no exchange of iron atoms. However, this complex does exchange with Fe^{++} in aqueous solution. The results are summarized in Table II.

TABLE II

Molality of $FeSO_4$	Molality of $(C_{10}H_8N_2)_3FeSO_4$	Molality of H^+	Time allowed for exchange	Per cent. of random distribution of Fe^{*+++}
0.016	0.008	0.04	2 hours	23 ± 5

Discussion

It is interesting to note that in ferriprotoporphyrin where the iron is held by electrostatic forces, no exchange was observed even after two months. On the other hand, the α,α'-dipyridyl complex, in which the iron–nitrogen bonds are mainly covalent,[9] undergoes comparatively rapid exchange of iron. Apparently structural relations are more important than bond type.

The compounds discussed above may be separated into two classes: (1) the central metallic ion is surrounded by a fused "ring" and (2) the "ring" consists of two or more separate molecules. The magnesium, copper, and iron compounds of class (1) show extraordinary inertness toward metallic exchange, while the members of class (2) are far more labile in this respect. This difference may be due to the fact that for exchange to occur in the fused ring structures the four[10] metal–nitrogen bonds must be broken *simultaneously*[11] while for compounds of class (2) stepwise dissociation may occur so that in equilibrium with the complex there may be present in varying amounts molecular species in which the metal is held by 4, 2 or fewer bonds.

It would seem that the symmetrical planar electrostatic porphyrin ring is sufficiently strong at room temperature and moderate *p*H to prevent any reversible equilibrium involving the central metal ion. Indeed, we are tempted to generalize and say that at room temperature all metallic-fused "rings" (porphyrins, porphyrazines, phorbins, phthalocyanines, etc.) will not exchange with metallic ions in slightly acid solution. Accordingly, we would predict that disodium phthalocyanine[12] will not exchange with Na^+.

The inertness of metal porphyrins (and similar pyrrole condensed ring structures) toward exchange should be of much help in the study of certain problems in nuclear physics, namely, the search for genetic relations between nuclear isomers,[13,14] where it is imperative to find a compound that will not exchange with the daughter (lower state) isomer.

Acknowledgments.—We are indebted to Professors K. S. Pitzer and G. Mackinney for helpful discussions, and to Dr. S. Aronoff for his cooperation. We wish to thank Professor E. O. Lawrence and the members of the Radiation Laboratory for making these experiments possible.

Summary

1. Magnesium 8-hydroxyquinolate exchanges quite readily with Mg^{++}.

2. Neither ferriheme nor ferrihemoglobin, both of which are paramagnetic, exchanges with Fe^{+++}.

3. Copper and iron pheophytins also do not exchange with Cu^{++} and Fe^{+++}.

4. Ferric tetraphenylporphyrin does not exchange with Fe^{+++} over a period of five days.

5. Ferrous orthophenanthroline exchanges slowly with Fe^{++}.

6. Ferrous α,α'-dipyridyl, which is diamagnetic, also exchanges slowly with Fe^{++}.

7. It appears that the rate of exchange depends more on structure than on bond type (*i. e.*, covalent or ionic).

8. It is suggested that metallo porphyrin compounds may be of help in the search for nuclear isomers among the metallic elements.

Tracer Studies with Radioactive Carbon. The Synthesis and Oxidation of Several Three Carbon Acids

BY P. NAHINSKY, C. N. RICE, S. RUBEN AND M. D. KAMEN

Many three carbon acids, when oxidized with alkaline permanganate, yield one mole each of oxalate and carbonate. Interest in the mechanism of these reactions was aroused when it was discovered[1,2] that with propionate the carbonate is derived mainly from the beta carbon rather than the carboxyl group. In an attempt to learn more about the mechanism, labelled propionate, α- and β-hydroxypropionates have been synthesized and oxidized in the presence of varying concentrations of sodium hydroxide.

Oxidation of Oxalate.—It was found by Wood, *et al.*,[1] that in 0.1 *N* sodium hydroxide the oxalate to carbonate ratio was not one, as found by McNair,[3] but considerably less. This low ratio could be due to further oxidation of the oxalate since it is well-known that permanganate in acid solution oxidizes oxalic acid. Accordingly, the oxidation of oxalate by alkaline permanganate at 100° was investigated. 0.05 *M* sodium oxalate was heated with excess saturated potassium permanganate in varying concentrations of base. After reduction of the excess MnO_4^- by hydrogen peroxide at 0° the manganese dioxide was removed and washed with distilled water. The filtrate and washings were acidified to liberate carbon dioxide, which was swept out with nitrogen and absorbed in 0.3 *N* sodium hydroxide. The $CO_3^=$ was precipitated as calcium carbonate, filtered, dried and weighed. The data are summarized in Table I.

TABLE I

OXIDATION OF OXALATE BY ALKALINE PERMANGANATE

NaOH concn. (moles/l.)	Time for heating, minutes	% Oxalate oxidized
10^{-4}[a]	60	19
0.1	80	3
2	60	0 (<0.4)

[a] Buffered solution.

It is apparent from Table I that only at low hydroxide concentrations is oxalate oxidized at an appreciable rate. Thus, in 2 *N* sodium hydroxide <0.4% of the oxalate was oxidized. This is indeed interesting since it can be estimated[4] that the standard free energy change for the reaction

$$3C_2O_4^= + 2MnO_4^- + 4OH^- = 6CO_3^= + 2MnO_2 + 2H_2O \quad (1)$$

is ~ -250 kilocalories. The oxidation of oxalate cannot be the cause of its low recovery from the propionate oxidation. We have found, because of the low solubility of sodium oxalate in sodium hydroxide solutions, that an appreciable fraction is included or otherwise carried down with the manganese dioxide precipitate. The oxalate is easily extracted from the precipitate by thoroughly washing with distilled water at 100°. If this precaution is observed, and care is taken to exclude carbon dioxide from all external sources, the carbonate to oxalate ratio for propionate, lactate and β-hydroxypropionate is 1.00 ± 0.03 for hydroxide concentrations of 2 *N* and greater.

Synthesis and Oxidation of Propionate.—For the experiments described in this paper the short-lived radioactive isotope of carbon, C^{11} (20.5 minute half life) was used as a tracer. The C^{11} was prepared by bombardment of boron with 8 mev. deuterons. The yield for the nuclear reaction

$$_1D^2 + {}_5B^{10} \longrightarrow {}_6C^{11} + {}_0n^1$$

is appreciable at bombarding energies of ~2 mev. Although elementary boron gives the highest yield of C^{11}, boric oxide or boric acid are more satisfactory targets since the newly formed C* is expelled under bombardment almost completely as volatile oxides of carbon.[5,6] Thus the extraction of the radioactivity was achieved with minimum loss of time. The type of target chamber described by Kurie[7] was used in this work. The active gas, (to which ~10 cc. of tank carbon dioxide was added as carrier) from the target chamber was passed into a heated combustion tube containing cupric oxide and oxidized to carbon dioxide. The carbon dioxide was trapped in a glass spiral immersed in liquid air.

(7) Kurie, *Rev. Sci. Instruments*, **10**, 199 (1939).

The propionate* was prepared by treating CH_3CH_2MgBr (in ether) with C^*O_2 for a few minutes at room temperature. The excess Grignard was hydrolyzed with dilute sulfuric acid and the small amount of unreacted C^*O_2 along with the ether was removed by boiling. Propionic acid was rapidly distilled (at low pressure) from this mixture, excess solid silver sulfate being added to prevent the distillation of hydrobromic acid. Trial experiments showed no hydrobromic or sulfuric acid in the distillate and, moreover, the yield of labelled propionic acid to be ~95%.

After purification of the labelled propionic acid and addition of carrier propionic acid, it was treated with a slight excess of potassium permanganate in varying concentrations of sodium hydroxide at 100° for periods ranging from one-half to two hours. The C^{11} content of weighed aliquots was determined with a thin-wall (0.1 mm. Al) Geiger counter. The weighed precipitates (~0.05 g.) were firmly and evenly distributed on a 5 × 7 cm. rectangle of blotting paper and held in position with a thin film of Duco cement and covered with cellophane. These samples were wrapped around the counter so that the most favorable geometrical conditions for detection of the emitted particles were obtained. The oxalate* was precipitated as $CaC_2O_4 \cdot H_2O$, and counted in the same manner. The results are summarized in Table II.

TABLE II

PERMANGANATE OXIDATION OF LABELLED PROPIONATE

Expt.	Concentration of NaOH, moles/liter	Per cent. of C* in $CO_3^=$		Per cent. of C* in $C_2O_4^=$		$\frac{\alpha C\text{-}\beta C \text{ rupture}}{\alpha C\text{-}COO^- \text{ rupture}}$
1	10^{-4}–10^{-5} (HCO_3^- Buffer)	28.2		71.8		
2	10^{-4}–10^{-5} (HCO_3^- Buffer)	27.6	28.9	72.4	71.1	2.5
3	0.1	30.7		69.3

5	2	30.4		69.6		
6	6	16.5		83.5		5.1
7	11	14.2	13.1	85.8	86.9	6.6
8	11	12.1		87.9		

If the carbonate were derived only from the carboxyl group of the propionic acid, the oxalate, of course, would be devoid of labelled carbon. From the results shown in Table II it is evident that *not only does alpha–beta rupture occur two to six times as often as alpha-carboxyl scission, but that the former process, moreover, is favored significantly by increase of OH^- concentration.*

In addition to the effect of hydroxide ion concentration on the splitting ratio, there is a marked effect upon the rate of the propionate oxidation. The oxidation rate is increased by hydroxyl ion, the rate varying approximately linearly with OH^- concentrations above 2 *N*. This fact should be contrasted with the effect of base upon the oxidation of oxalate by permanganate, where it is found that increasing hydroxyl ion concentration decreases the rate of oxidation so that at 2 *N* concentration there is no observable oxidation. In one hour permanganate in 2 *N* sodium hydroxide at 100° oxidizes ~80% of the propionate in a 0.2 *M* solution. Under the same conditions α- and β-hydroxypropionate are completely oxidized within a few minutes. It was of interest to observe the very large increase in oxidation rate brought about by the presence of a hydroxyl group in either the α or β carbons. If lactate or β-hydroxypropionate are intermediates[8] in the alkaline oxidation of propionate, it follows that the attack upon the ethyl group is the slowest step in the process.

It is desirable to point out that any possible exchange reactions between labelled carbonate ions and any of the possible "active" intermediates, or oxalate, are excluded by the following experiments: (1) Inactive propionate was oxidized in the presence of radioactive carbonate. The oxalate formed during the reaction, as well as the remaining unoxidized propionate, was completely inactive (<0.01% exchanged). (2) Inactive oxalate and radioactive carbonate in 2 *N* sodium hydroxide, and in contact with freshly precipitated manganese dioxide for one hour at 100° did not exchange (<0.01%).

Synthesis and Oxidation of Lactate.—Radioactive lactic acid was synthesized from $C^{11}O_2$ and CH_3CHO by the method described by Cramer and Kistiakowsky.[9] The reactions are

$$C^*O_2 + 4K + NH_3 \xrightarrow{525^\circ} KC^*N + 2KOH + KH \quad (2)$$

$$C^*N^- + CH_3CHO + H_2O \rightleftarrows CH_3CHOHC^*N + OH^- \quad (3)$$

$$CH_3CHOHC^*N + 2H_2O \xrightarrow{H^+} CH_3CHOHC^*OO^- + NH_4^+ \quad (4)$$

After addition of carrier lactic acid the labelled acid was purified by treating the cyanohydrin hydrolysate with decolorizing carbon which contained no acid-soluble impurities. Trial experiments showed that <5% of the lactic acid was

(8) The formation of volatile acids (acetic, etc.) other than carbon dioxide during the propionate oxidation could not be detected.

(9) Cramer and Kistiakowsky, *J. Biol. Chem.*, **137**, 549 (1941).

absorbed. The radioactive acid was separated from the volatile impurities by distillation of the clarified solution *in vacuo*. Cyanide was shown to be absent from the high boiling material (any cyanide present would be oxidized by permanganate to carbonate, and thereby not only raise the carbonate/oxalate ratio but also introduce extraneous C* in the carbonate fraction). Having been made alkaline, the high boiling solution was extracted with several portions of ether, and was freed of dissolved ether by bubbling nitrogen through it for ~ ten minutes. The lactate was oxidized under the conditions described for propionate, only a few minutes being required in this case. A carbonate to oxalate ratio of 1.00 ± 0.03 was obtained when care was taken to exclude carbonate from external sources and the purification described used.

The results are summarized in Table III.

TABLE III

PERMANGANATE OXIDATION OF LABELLED LACTATE

Expt.	NaOH concn. moles/l.	Per cent. of C* in CO_3^-		Per cent. of C* in $C_2O_4^-$		$\frac{\alpha C\text{-}\beta C \text{ rupture}}{\alpha C\text{-}COO^- \text{ rupture}}$
1	2	35.1	31.9	64.9	68.1	2.1
2	2	28.8		71.2		
3	12	34.8	32.2	65.2	67.8	2.1
4	12	37.8		62.2		
5	12	29.0		71.0		
6	12	27.4		72.6		

It seems, within the experimental limits of error, that hydroxide ion has little or no effect on the $\alpha C\text{-}\beta C$ rupture to $\alpha C\text{-}COO^-$ rupture ratio. A comparison of Tables II and III shows that although the ratios for propionate and lactate in 2 *N* sodium hydroxide are about the same, the propionate oxidation alone exhibits a marked response to concentrations of OH^- greater than 2 *N*.

Synthesis and Oxidation of β-Hydroxypropionate.—β-Hydroxypropionate[10] marked with C^{11} in the carboxyl position was prepared from C^*N^- and CH_2ClCH_2OH by the reactions

$$CH_2OHCH_2Cl + C^*N^- \longrightarrow CH_2OHCH_2C^*N + Cl^- \quad (5)$$

$$CH_2OHCH_2C^*N + OH^- + H_2O \longrightarrow CH_2OHCH_2C^*OO^- + NH_3 \quad (6)$$

The alkaline solution of KC*N prepared by Cramer and Kistiakowsky's method[9] (equation 4) was evaporated almost to dryness, and the residue taken up with a small volume of absolute alcohol containing 2-chloroethanol.[11] After being refluxed at 100° for forty minutes, the solution was cooled to 0°, and β-hydroxypropionitrile was added as carrier for the labelled nitrile. The solids separating out on cooling were removed, and alcohol, water and some 2-chloroethanol were distilled from the clear solution *in vacuo*. Next, the remainder of the 2-chloroethanol and the β-hydroxypropionitrile were vacuum distilled off, and a second distillation of this mixture was made to separate the two. Carbonate–bicarbonate buffer solution was added to the alcoholic solution prior to the first distillation in order to prevent distillation of any formate* formed by hydrolysis of cyanide* ion. In the final distillate no HC*N could be detected using the sensitive Prussian blue test. In order to obtain β-hydroxypropionate*, the pure nitrile* was hydrolyzed in concentrated sodium hydroxide solution for ten minutes at 100°. As in the case of the other acid anions, the carbonate to oxalate ratio obtained on oxidation was found to be 1.00 ± 0.03 when precautions were taken to exclude carbon dioxide from external sources. The results are given in Table IV.

TABLE IV

OXIDATION OF LABELLED β-HYDROXYPROPIONATE

Expt.	NaOH concn., moles/l.	Per cent. of C* in CO_3^-		Per cent. of C* in $C_2O_4^-$		$\frac{\alpha C\text{-}\beta C \text{ rupture}}{\beta C\text{-}COO^- \text{ rupture}}$

2	2	29.1		70.9		
3	12	30.0	26.8	70.0	73.2	2.7
4	12	23.6		76.4		

Discussion

Aside from the fact that the α-β carbon bond is broken about two and one-half times as often as the α-carbon–carboxyl bond, it is surprising that at moderate hydroxide ion concentrations all three acid anions yield the same result. This suggests that under these conditions lactate or β-hydroxypropionate are intermediates in the oxidation of propionate. The finding that at concentrations of OH^- above 2 *N*, propionate undergoes even greater preferential α-β rupture while lactate and β-hydroxypropionate exhibit no such effect indicates that *in highly alkaline solution the α-β bond in propionate is broken before either of these positions is hydroxylated.*

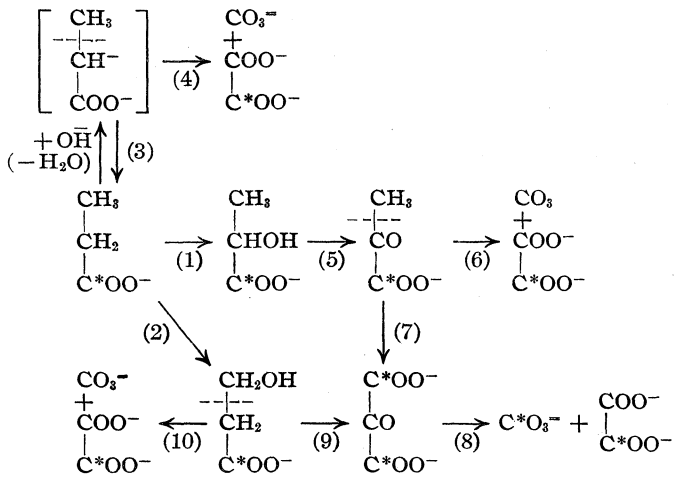
Although the oxidation of propionate, lactate and β-hydroxypropionate is quite complicated, it may be profitable to formulate a sequence of possible intermediates. The outline suggested below correlates the results obtained thus far, and also

(10) Jacobs and Heidelberger, THIS JOURNAL, **39**, 1469 (1917).

(11) Eastman Kodak Co. product redistilled, and having a boiling point of 128–129°.

leads to further predictions and suggests future experiments.

TENTATIVE FORMULATION OF PROPIONATE OXIDATION BY ALKALINE PERMANGANATE



The mesoxalate formed from pyruvate by step (7) is "symmetrical" and therefore the C* content of the carbonate and oxalate formed in (8) will be equal. It is evident from Tables II, III and IV that the rate of (6) is almost equal to the rate of (7), and (10) proceeds at approximately the same rate as (9). In other words *the α-β link is often ruptured before mesoxalate is produced.* While the ratios of (6)/(7) and (9)/(10) are independent of the hydroxide concentration, step (3) is favored over (1) and (2) by increasing alkalinity. The primary step in (3) is the reversible removal of hydrogen ion by OH^- resulting in the formation of $H_3C-\overset{H}{\overset{|}{C}}-COO^-$ which due to the unshared electron pair may be more susceptible to oxidation.

Summary

1. Methods for the rapid synthesis of $CH_3CH_2C^*OOH$, CH_3CHOHC^*OOH, and $CH_2OHCH_2C^*OOH$ using $C^{11}O_2$ are described.

2. Oxidation of these acid anions by alkaline permanganate yields one mole of carbonate and oxalate each.

3. Oxalate is remarkably inert to alkaline permanganate (2 *N* in sodium hydroxide) even at 100°.

4. For propionate in hydroxide solutions of from 10^{-4} to 2 *N* concentration ~71% of the carbonate is derived from the β-carbon. At higher hydroxyl ion concentration the α-β carbon bond is broken even more preferentially.

5. No exchange between $C^*O_3^=$ and $C_2O_4^=$ could be detected.

6. With lactate and β-hydroxypropionate, ~70% of the carbonate originates from the β-carbon, and this value, within the experimental error, is unchanged by altering the hydroxide ion concentration from 2 to 12 *N*.

7. The results indicate that with propionate the α-β carbon bond is broken in strongly basic solutions before either α- or β-hydroxypropionate can be formed as an intermediate in the oxidation.

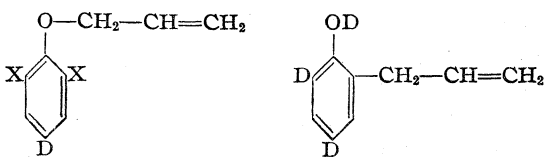
Use of Deuterium as a Tracer in the Claisen Rearrangement

BY G. B. KISTIAKOWSKY AND ROBERT L. TICHENOR

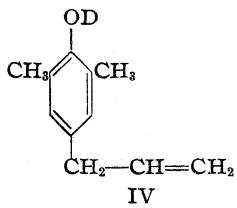
In the mechanisms proposed for the Claisen rearrangement[1] the assumption is made that the hydrogen atom displaced by the migrating allyl group moves to the oxygen atom of the resulting phenol. It was thought that definite evidence of the movement of the displaced hydrogen atom could be obtained by using deuterium as a tracer. We have, therefore, carried out the rearrangement of the allyl ethers of 2,4,6-trideutero-phenol (I) and 4-deutero-2,6-dimethyl-phenol (III). Our results are summarized in Table I.



I(X = D) ⟶ II

III(X = CH_3) ⟶ IV

(1) D. Stanley Tarbell, *Chem. Rev.*, **27**, 495 (1940).



IV

The acetate of IV formed during the analysis for phenolic deuterium showed no detectable deuterium content (analysis by combustion and infrared absorption, estimated << 0.25% deuterium in the resulting water).

TABLE I

Expt. No.	Compound	% D in indicated positions Calcd.[a]	Found[b]	% D on oxygen after rearrangement Calcd.	Found
1	Allyl 2,4,6-tri-deuterophenyl ether	51	51	51	15[e]
2		77	70	70	52
3		77	70	70	52
4	2-Allyl-4,6-di-deuterophenol	50			2.5[c]
5	Allyl 4-deutero-2,6-dimethylphenyl ether	72.3	< 20[d]	< 20	15
6		72	< 20[d]	< 20	13

[a] Assuming equilibrium between the indicated positions, the phenolic hydrogen (the phenol was deuterated before the ether was made) and the heavy water. Losses in alkylation were neglected. [b] Calcd. from total analyses (combustion) and assumption all the deuterium was on the indicated positions. [c] After heating the phenol, not after a rearrangement; see text. [d] These are upper limits assuming all the deuterium in the 4-position. If the methyl groups had been deuterated a far higher value (factor of 21) should have been found. [e] This low value can be attributed to poor technique in this first experiment.

This result together with 5 and 6 of Table I allow us to conclude that in the rearrangement of III all the displaced hydrogen goes to the oxygen; none is to be found elsewhere in the molecule. We may also conclude that the structure of III is correct, *i. e.*, that deuteration of the methyl groups and the meta positions was negligible.

From results 2 and 3 of Table I we see that 74% of the displaced hydrogen of I moves to the oxygen, but some 26% is unaccounted for. The low figure may be due to (1) loss of deuterium by exchange during evolution of hydrogen chloride (see analysis) or (2) to some exchange with other hydrogen of the molecule subsequent to rearrangement. Reason (2) is partly excluded by result 4 of Table I. (1) is reasonable in view of the known exchanges of esters.[2]

(2) Hsü, Ingold and Wilson, *J. Chem. Soc.*, 79 (1938).

Kincaid and Tarbell[3] have found that the rate of ortho rearrangement is first order. It is unlikely that a unimolecular reaction proceeds by two paths of nearly equal free energies of activation. Our results with III indicate that its rearrangement proceeds by a single path. In view of these two facts we are rather inclined to say that the rearrangement of I goes by a single path and that our low results can be attributed to experimental errors.

Result 4 of Table I shows that negligible exchange occurs between the phenolic hydrogen and deuterium in the ortho and para positions of 2-allyl phenol when the phenol is subjected to a heat treatment equal to that employed in the rearrangement of I.

Our picture of the movement of the hydrogen atom in the para rearrangement is not that of a directed jump, but rather that the proton is displaced by the migrating allyl group and subsequently finds its way to some oxygen anion.

Experimental

Deuteration of Phenols.—Ordinary phenol was deuterated by exchange with heavy water in the presence of hydrogen chloride for the time (two hours) and temperature (100°) shown by Koizumi[4] to be necessary for attaining equilibrium. Best and Wilson[5] have shown that only the ortho and para positions of phenol are deuterated under these conditions. 2,6-Dimethylphenol was deuterated by allowing it to exchange with heavy water for thirty hours at 100° in the presence of hydrogen chloride. No previous work has been done on its deuteration and we made no direct determination of the amount of substitution, but subsequent analyses of the ethers showed that the methyl groups and the meta positions did not exchange. We can explain the very low amount of deuterium in the 4 position (< 20% instead of a calculated 72%) by an increased rate of loss during the formation of the ether or by a failure to attain equilibrium in the initial exchange. These analyses of III (Table I) are an upper limit and thus prove that the methyl groups and the meta positions are not deuterated.

Preparation of Ethers.—13.5 g. (0.34 mole) of sodium hydroxide, 25 cc. of water, 15 cc. of freshly distilled allyl bromide, 25 cc. of acetone and 10 g. (0.106 mole) of 2,4,6-deuterophenol (or 13 g. of 2,6-dimethyl-4-deuterophenol)[6] were added quickly in this order to a 3-neck, 250-cc. flask equipped with a wire stirrer, reflux condenser and dropping funnel. The mixture was stirred and refluxed for two hours, cooled, extracted with petroleum ether, and the extract washed with sodium hydroxide, then with water and finally dried over magnesium sulfate (neutral drying

(6) We wish to thank Dr. W. E. Vaughan and the Shell Development Co. for the gift of 2,6-dimethylphenol.

agent to slow exchange). After concentration on the steam-bath the allyl phenyl ether was distilled at a pressure of 10 mm. (2 mm. for allyl 2,6-dimethylphenyl ether) through a small Podbielniak column. A faint yellow color persisted in all our preparations of allyl 2,6-dimethylphenyl ether. All the other compounds were colorless and all of them had boiling points and refractive indices in agreement with those in the literature.

Rearrangement.—The purified ether was placed in a clean Pyrex tube, cooled, evacuated, frozen and melted under vacuum to remove dissolved gases and then sealed off. The tube was heated in a Wood's metal bath until samples of the non-deuterated phenyl ether, rearranging simultaneously, were found to be almost entirely soluble in 20% sodium hydroxide solution. Bath temperatures and times: allyl phenyl ether, 230–240°, five to six hours; allyl 2,6-dimethylphenyl ether, 190–200°, four to five hours.

Analysis of Phenolic Hydrogen.—Three to four grams of the product of rearrangement, 3 cc. of acetyl chloride and a boiling chip were placed in the reaction bulb of a gas train, and the hydrogen chloride which evolved was swept through a dry ice–acetone-cooled trap to remove acetyl chloride, and was collected in a liquid air trap. The liquid air trap was then cut off from the gas train, evacuated and the gas allowed to evaporate into the evacuated infrared absorption cell. A reservoir of ordinary hydrogen chloride was connected to the filling system so that the pressure in the cell could be increased if insufficient gas was obtained from the phenol. When hydrogen chloride was added from the reservoir, the gases were mixed by freezing down in a liquid-air trap.

The infrared absorption of the resulting mixture of hydrogen and deuterium chlorides was measured over the absorption region for both components (3.46 and 4.8 μ).[7] The measurements were made at a total pressure of 368 mm. with a cell 20 cm. long. From the infrared absorption plates a curve of absorption percentage *vs.* wave length was obtained, and by measuring the area of the bands we can estimate the concentration of deuterium by comparing the area with the areas observed when known concentrations of deuterium were present. In determining the area of an absorption band there is considerable uncertainty in determining the base line (the blank). It was found that this base line apparently varied as the cell was used, and, therefore, in all measurements the edges of the absorption curve on either side of the absorption region were used as a base line. This was probably the greatest source of error in the analyses. The accuracy of analysis of a deuterium chloride–hydrogen chloride mixture was not better than ±5% but was sufficient for the present purpose.

Hydrogen Chloride and Deuterium Chloride.—Hydrogen chloride was obtained by dropping hydrochloric acid onto sulfuric acid. Deuterium chloride was made by the method of Langseth and Klit.[8] The resulting gas probably contained traces of sulfur dioxide. The thionyl chloride which we used was purified as recommended by Fieser.[9]

Analysis for Deuterium on Carbon.—Nuclear deuterium was determined by combustion and the density of the resulting water found by the falling drop method or by use of the interferometer.[10]

Acetate of 4-Allyl-2,6-dimethylphenol.—As a check on the course of the reactions used to produce hydrogen chloride, the resulting acetates were purified and identified by their physical constants or by analysis. The acetate of 4-allyl-2,6-dimethylphenol is a new compound, a colorless oil, b. p. (2 mm.) 105–110°, bath temperature 146–160°, $n^{25}D$ 1.5050. *Anal.* Calcd. for $C_{13}H_{16}O_2$: C, 76.42; H, 7.90. Found: C, 76.81; H, 8.33. The phenol from which this acetate was prepared was carefully purified and found to melt at 26–27°, $n^{25}D$ 1.5356. The phenylurethan of this phenol melted at 137–139° (uncor.) after two recrystallizations from ligroin.

Polymerization During Rearrangement.—We were troubled at first by a polymerization of allyl phenyl ether similar to that described by Hurd.[11] Occasionally, some would polymerize during the rearrangement, whereas much of our material gave 95% yields of the expected phenol. It was found that the addition of one drop of allyl bromide to 2 g. of the ether (which was known to rearrange normally) produced polymerization. None of the other reactants or products acted in this manner. Careful removal of allyl bromide during distillation (prevention of diffusion of allyl bromide from first fraction into later fractions in the multiple receiver of the still by removal of first fraction before completing the distillation) gave, in all cases, an ether which rearranged without darkening or polymerization.

Summary

1. The deuterium atom displaced by the migrating allyl group in the Claisen rearrangement of allyl 4-deutero-2,6-dimethylphenyl ether becomes the phenolic deuterium of the product.

2. It has been shown that the bulk of the deuterium displaced by the migrating allyl group in the rearrangement of allyl 2,4,6-trideuterophenyl ether becomes the phenolic deuterium of the product. It is likely that all the displaced deuterium becomes phenolic deuterium.

3. Phenolic tautomerism of 2-allylphenol was not observed to occur to an appreciable extent on heating for the time and temperature necessary to rearrange allyl phenyl ether (six hours at 210–230°).

4. A new method for estimating the deuterium content of hydrogen chloride–deuterium chloride mixtures has been outlined. It has been used in estimating the deuterium content of phenolic hydrogen.

Solubility of Potassium Iodate and Zinc Iodate in Dioxane–Water Mixtures; Effect of Sorting of Solvent Molecules

BY J. E. RICCI AND G. J. NESSE

In the further study of the relationship between the solubility of electrolytes and the dielectric constant of the medium, measurements have been made of the solubilities of potassium iodate and zinc iodate in dioxane–water mixtures at 25° over the complete range of concentrations from 0 to 100% dioxane at intervals of 10% by weight; the measurements thus extend over a dielectric range from 2.10 to 78.55. The results have been used to test the empirical relation between the solubility of slightly soluble electrolytes and the dielectric constant of the solvent, previously reported by Ricci and Davis.[1] An attempt has also been made to estimate the mean ionic radius of these salts by using the Debye expression for the distribution of solvent molecules in a dielectric mixture around ions,[2] in conjunction with the fundamental Born equation relating electrolyte solubility, ionic radius and dielectric constant.[3]

Materials.—A C. P. grade of potassium iodate was used both for the solubility determinations and for the standardization of the silver nitrate solution used in the analyses.

The zinc iodate was prepared by mixing dilute solutions of sodium iodate and zinc nitrate in stoichiometric proportions. The solutions were poured slowly into a large beaker with constant mechanical stirring. The zinc iodate was obtained by evaporating some of the liquid, filtering, washing and drying at 100°. Volumetric analysis by the method described below gave a value of 99.3% $Zn(IO_3)_2$; the additional 0.7% probably represented water not readily driven off by heat without decomposition of the salt.

The dioxane was purified and its purity verified as described in similar investigations.[4]

Solubility Determinations and Analysis.—Mixtures of dioxane and water, prepared in the desired proportions by direct weighing, were stirred with excess of the salt, in 250-ml. glass-stoppered Pyrex bottles. To avoid the introduction of foreign matter into the solutions, vaseline was omitted entirely in stoppering the tubes containing solvents of high dioxane ratio. Sufficient time (two to seven days) was allowed for the attainment of equilibrium, which was verified by determining every solubility from both under- and super-saturation.

For the analysis of the saturated solutions, gravimetric methods were first tried, but discarded. Precipitation and weighing of the iodate as the silver or lead salt from solutions containing zinc ion, gave low results, possibly because of co-precipitation of zinc iodate. Iodometric titration also was discarded because of the difficulty involved in removing the interfering dioxane. Precipitation of barium iodate followed by iodometric titration of the washed precipitate also gave low results. The method finally used involved reduction of iodate to iodide by sodium bisulfite, the excess of reagent being removed by acidification and boiling with dilute sulfuric acid. Except in high dioxane solvents (> 77% for potassium iodate, > 40% for zinc iodate), in which the solubilities are very low, the resulting iodide solution was then analyzed volumetrically, at a *p*H of 9–10, by titration with standard silver nitrate, with eosin as indicator. An appropriate blank was calculated from a series of standardizations against pure potassium iodate similarly treated. For the very low solubilities the iodide was determined gravimetrically as silver iodide; the relative precision of some of these results is very low compared to the volumetric determinations.

Although the literature reports a di-hydrate of zinc iodate,[5] the solid phase in the present experiments was apparently the anhydrous salt. The solid residue from several of the solubility determinations was analyzed after filtration and centrifuging, giving an average of 99.3% $Zn(IO_3)_2$, ranging between 99.0 and 99.5%. KIO_3 is known to form no hydrates, and no analysis was made of this salt as solid phase.

The results of the solubility determinations are given in Table I[6]; each value is the average of at least one determination from each direction of approach to equilibrium. In the iodometric determinations the agreement between such values was about 2/1000 for potassium iodate and 6–7/1000 for zinc iodate. The gravimetric determinations were less precise. The necessary densities required for the calculation of molarities from weight percentages were

determined by weighing appropriate filtered samples of the solutions delivered from calibrated pipets.

On the Rule of Constant Activity Coefficient. —The results have first of all been used in testing further the empirical rule of constant activity coefficient for the calculation of solubilities.[1] It has been noted in many cases that the activity coefficient of a slightly soluble electrolyte in its pure saturated solution is practically constant, independent of the dielectric constant of the medium. Hogge and Garrett[7] have recently reported such behavior for thallous chloride in alcohol–water mixtures up to 60% alcohol, and the same has also been observed for silver acetate in dioxane–water mixtures up to 50% dioxane.[8] This rule of constant activity coefficient for an electrolyte at saturation, which is here being tested again, is still purely empirical. Although an analogy with the behavior of weakly solvated sols has been pointed out by W. Ostwald,[9] a theoretical explanation of this rough constancy has not yet been found. Ostwald had noted, for weakly lyophilic sols such as arsenous sulfide, that the activity coefficient of electrolytes at concentrations causing coagulation is independent of the type of electrolyte and of the dielectric constant of the solvent.[10]

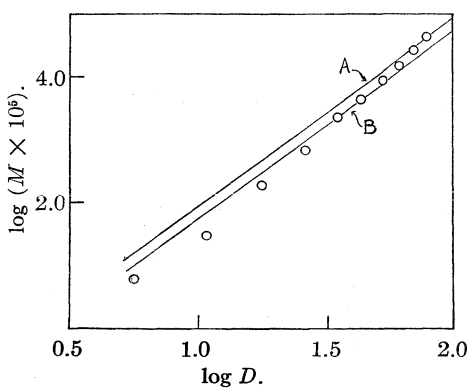

Fig. 1.—Solubility of potassium iodate in dioxane–water mixtures at 25°: A represents eq. 1, with 0% dioxane as reference; B, with 50% dioxane as reference.

As has already been shown,[1] the assumption of such constancy of the activity coefficient offers a simple way of predicting at least approximately the solubility, S_2, in any medium of dielectric constant D_2, from the solubility, S_1, in a reference medium of dielectric constant D_1, inasmuch as by the application of the Debye–Hückel limiting law, it follows that

$$\log S_2 = \log S_1 + 3 (\log D_2 - \log D_1) \qquad (1)$$

According to this equation the solubility in a series of media of varying dielectric will be given, on a plot of log M *vs.* log D, by a straight line with a slope of +3 and passing through whichever point is taken as the reference solubility. Figure 1 represents the observed solubilities for potassium iodate in the dioxane–water mixtures as compared with the straight line expected according to equation (1): A, with the solubility in pure water as reference; B, with that in 50% dioxane as reference. On either basis, solubilities in the various media may be calculated and compared with the observed, the ratios of calculated to observed solubilities being summarized for both salts in Table II. The agreement is satisfactory at least as to the order of magnitude, and is about the same for both the valence types involved and despite a great difference in the actual solubilities of the two salts; the calculation furthermore is independent of any knowledge of ionic diameters necessary for the application of the theoretical equation of Born. The largest deviations in Table II are for zinc iodate in very high dioxane solvents, where, it must be pointed out, the experimental error is probably great. The best straight line drawn through the data for potassium iodate has a slope of about 3.5 as compared to 3 as required by the equation; the zinc iodate points likewise best fit a straight line with a slope of ~ 3.5.

TABLE II

This at least approximate linearity between log M and log D indicates at once that the usual Born equation, requiring a linear relation between log M and $1/D$, must fail. Furthermore, it is interesting to note that because of a substantially

linear relation between log D and mole fraction of water in the solvents, the solubilities as log M are also related roughly linearly to mole fraction of water. These relations are shown simultaneously in Fig. 2, where the linearity is seen quite clearly if the points in almost pure dioxane, in which the determinations are themselves somewhat doubtful, are disregarded. The slopes of these curves (~ -7) are again the same for the two salts.

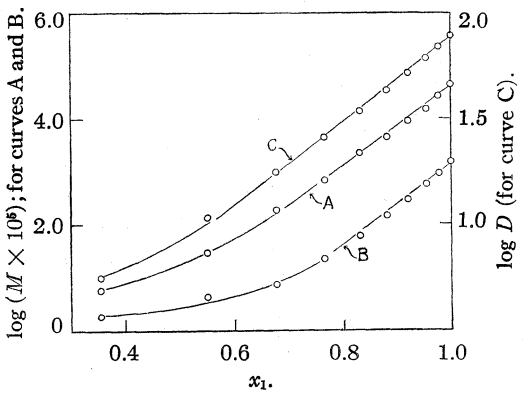

Fig. 2.—Relation between log M, log D, and x_1, mole fraction of water in dioxane–water solvents: A, KIO_3; B, $Zn(IO_3)_2$.

The Born Equation.—In Fig. 3 the results are plotted in accordance with the usual Born equation

$$\log S_1/S_2 = \frac{0.4343\ Ne^2\ z_+ z_-}{aRT}\left(\frac{1}{D_2} - \frac{1}{D_1}\right) \qquad (2)$$

in which the change of solubility depends upon the ionic diameter, a; the symbols N, e, z, R, T have their usual meaning. The theoretical limiting slopes have been calculated with 2.5 Å. as a probable value of a for both salts, by analogy with similar electrolytes such as barium iodate[4] and iodic acid,[11] giving slopes of 97 and 194 for potassium iodate and zinc iodate, respectively. It is again seen that except in very low dioxane solvents, the Born formula predicts solubilities in general far too low. Actually, the limiting slope for the potassium iodate data, as plotted on Fig. 3, corresponds to a value of only ~1.9 Å. for the diameter a.

Correction for Solvent Segregation around Ions.—Since the simple Born equation as just used assumes media of uniform dielectric constant, it should be possible to explain part of the discrepancy between observed and calculated solubilities in these cases by taking into account the non-uniformity of the dielectric constant in the

(11) S. Naidich and J. E. Ricci, THIS JOURNAL, **61**, 3268 (1939).

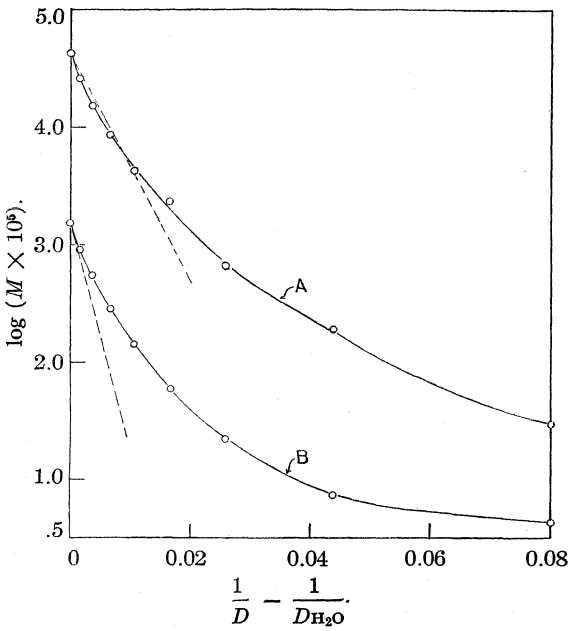

Fig. 3.—Observed solubilities compared with predictions of eq. 2: A, KIO_3; B, $Zn(IO_3)$.

vicinity of charged ions in media consisting of two solvents. We have, therefore, attempted to apply Debye's original treatment[2] for the calculation of this sorting or selective concentration of the more polar solvent by ions in mixed solvents, in order to see to what extent this factor might account for the deviation from the simple Born equation, and in order to derive, if possible, by means of this treatment, following the suggestion of Dunning and Shutt,[12] a value for the mean ionic radius of the electrolytes involved, since Debye's equation requires the sorting of the solvent molecules to be a function of the radial distance from the center of the ion.

According to Debye, this distribution of the two components of a mixed solvent (component 1 having the higher dielectric constant) is given as a function of the ionic charge, the distance from the ion and certain properties of the binary mixture, by the following equation, which we shall call the Debye equation

$$r^4\left(\frac{\bar{v}_2}{\bar{v}_1}\ln\frac{x_1}{x_1^0} - \ln\frac{x_2}{x_2^0}\right) = \frac{e^2 z_i^2}{8\pi RTD^2}\left(\frac{\bar{v}_2}{\bar{v}_1}\frac{dD}{\delta c_1} - \frac{\delta D}{\delta c_2}\right) \qquad (3)$$

The subscripts refer to the two components of the mixed solvent; the quantities x_1, x_2, $\bar{v}_1$, $\bar{v}_2$ and D are values of mole fraction, partial molal volumes and dielectric constant, at the distance r from the center of the ion of valence z_i; x_1^0 and x_2^0 are the

(12) W. J. Dunning and W. J. Shutt, *Trans. Faraday Soc.*, **34**, 1192 (1938).

over-all mole fractions, or x at $r = \infty$; c_1 and c_2, moles of each component per cc. of the mixture.

Since the distribution of dielectric will not be the same in two different mixtures of two solvents, it will be necessary to calculate this distribution and from it to calculate the corresponding value of the free energy change between a solvent of uniform dielectric (H_2O as reference, for example) and a mixed solvent of varying dielectric (or with D as $f(r)$), and if necessary, for each separate ion, inasmuch as this distribution varies with the valence of the ion.

A simplified form of this equation is suggested by Scatchard,[13] for cases in which $d(1/D)/dc_2 = a$ constant, K, when it follows that

$$r^4\left(\frac{\bar{v}_2}{\bar{v}_1}\ln\frac{x_1}{x_1^0} - \ln\frac{x_2}{x_2^0}\right) = \frac{e^2z_i^2\bar{v}_1K}{8\pi RT} \qquad (4)$$

As seen in Fig. 4, this constancy holds only very roughly and for low concentrations of dioxane, in the present system.

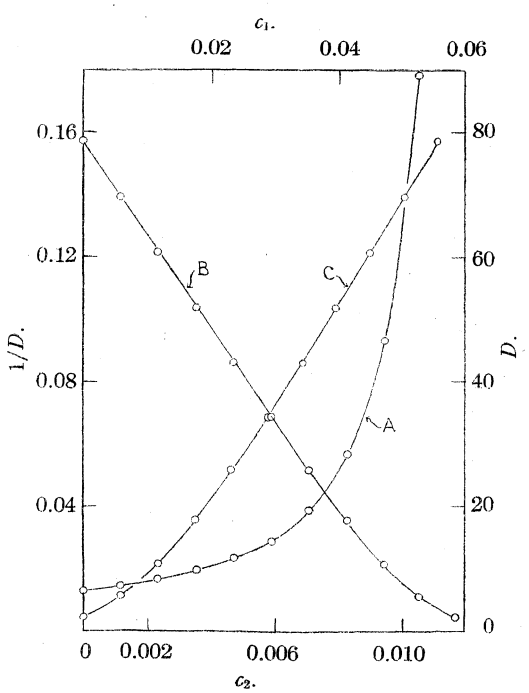

Fig. 4.—Variation of D and of $1/D$ with respect to moles of component per cc., in dioxane–water system: A, $1/D$ with c_2, moles of dioxane per cc.; B, D with c_2; C, D with c_1, moles of water per cc.

It is, therefore, necessary to use the original Debye equation, for which, fortunately, it is found that the derivatives dD/dc_1, and dD/dc_2 are quite constant, up to 60% dioxane, as seen in Fig. 4; they have the values + 1656 and −7550, respectively, for mixtures from 0 to 60% dioxane.

The data for the physical properties of the system water–dioxane required for Fig. 4 and for the use of eq. (3) were taken from the literature.[14] The distribution (r for various values of x_1 and x_2 and hence D as a function of r) was calculated for a univalent ion ($z_i = 1$), in three chosen mixtures of dioxane and water, namely, the 20, 50 and 80% dioxane mixtures (see Table III).

The curve for the distribution around a univalent ion in 50% dioxane is shown in Fig. 5 (curve A), together, for comparison, with the curves, B, for the value of $(1/Dr^2)$ around such an ion in pure water, *i. e.*, a uniform medium with a constant value of $D = 78.55$, and C, for that in a uniform medium with $D = 34.28$, the over-all limiting value of the dielectric constant in the 50% mixture.

Considering separate ions (z_+ and z_-) and separate media (D_1 and D_2), the Born equation may be written as follows

(13) G. Scatchard, *J. Chem. Phys.*, **9**, 34 (1941).

(14) Dielectric constant from ref. 6; densities and partial molal volumes from H. Hovorka, R. A. Schaefer and D. Dreisbach, THIS JOURNAL, **58**, 2264 (1936); **59**, 2753 (1937).

$$\ln\left(\frac{S_1}{S_2}\right) = \frac{Ne^2}{(\nu_+ + \nu_-)2RT}\left(\int_{r_i}^{\infty}\frac{\nu_+z_+^2\mathrm{d}r}{D_2r^2} + \int_{r_i}^{\infty}\frac{\nu_-z_-^2\mathrm{d}r}{D_2r^2} - \int_{r_i}^{\infty}\frac{\nu_+z_+^2\mathrm{d}r}{D_1r^2} - \int_{r_i}^{\infty}\frac{\nu_-z_-^2\mathrm{d}r}{D_1r^2}\right) \quad (5)$$

Here ν_+ and ν_- are the number of positive and negative ions formed from the molecule of the electrolyte and r_i is the effective ionic radius of each ion in each medium.

If $D_2 = f(r)$ from r_i to r_0 and is practically equal to the over-all D_2 at $r = r_0$, and if D_1 is independent of r, as is assumed to be the case with water as the reference medium, we then have, for a 1:1 electrolyte, in which the distribution of D in a mixture is the same for both ions

$$\ln(S_1/S_2) = \frac{Ne^2}{2RT}\left(\int_{r_i}^{r_0}\frac{\mathrm{d}r}{D_2r^2} + \int_{r_0}^{\infty}\frac{dr}{D_2r^2} - \int_{r_i}^{\infty}\frac{\mathrm{d}r}{D_1r^2}\right) \quad (6)$$

and for a 2:1 or 1:2 electrolyte

$$\ln(S_1/S_2) = \frac{Ne^2}{2RT}\left[\frac{4}{3}\left(\int_{r_{i(\pm 2)}}^{r_0}\frac{\mathrm{d}r}{D_2r^2} + \int_{r_{0(\pm 2)}}^{\infty}\frac{\mathrm{d}r}{D_2r^2} - \int_{r_{i(\pm 2)}}^{\infty}\frac{\mathrm{d}r}{D_1r^2}\right) + \frac{2}{3}\left(\int_{r_{i(\pm 1)}}^{r_0}\frac{\mathrm{d}r}{D_2r^2} + \int_{r_{0(\pm 1)}}^{\infty}\frac{\mathrm{d}r}{D_2r^2} - \int_{r_{i(\pm 1)}}^{\infty}\frac{\mathrm{d}r}{D_1r^2}\right)\right] \quad (7)$$

In equations (6) and (7), the integrals $\int_{r_i}^{r_0}\frac{\mathrm{d}r}{Dr^2}$ are to be evaluated graphically in each case from the area below the curve of $1/Dr^2$ against r, as plotted in Fig. 5. The limits, r_i and r_0, are taken in each case as those values of r where $1/Dr^2$ approaches the limit of the corresponding value for H_2O, at the same r, (r_i), and where $1/Dr^2$ approaches the limit of the corresponding value for 20% or 50% dioxane (r_0). The values of these integrals together with the limits used in their graphical evaluation, are shown in Table IV.

TABLE IV

VALUES REQUIRED IN EQS. (6) AND (7)

Mixture, %	z_i	r_i	r_0	$10^4\int_{r_i}^{r_0}\frac{\mathrm{d}r}{Dr^2}$
20	1	2	9	55.7
	2	3	7.5	27.9
50	1	2	8	70.3
	2	2.5	10	52.2
80	1	1.75	14	167.2
	2	2.5	20	119.0

The calculations for the case of $z_i = 2$ are simplified by noting that for fixed values of x_1 and x_2, and hence of D, in a given solvent mixture, the corresponding radial distances, $r_{(2)}$ and $r_{(1)}$, from the centers of divalent and univalent ions, respectively, are related as follows

$$r_{(2)} = 2r_{(1)}; \text{ whence} \quad (8a)$$

$$1/Dr^2_{(2)} = (1/2)\ 1/Dr^2_{(1)}; \text{ and} \quad (8b)$$

$$\int\frac{\mathrm{d}r}{Dr^2_{(2)}} = \frac{1}{2}\int\frac{\mathrm{d}r}{Dr^2_{(1)}} \quad (8c)$$

in which the integration is performed up to the same value of x_2 or of D.

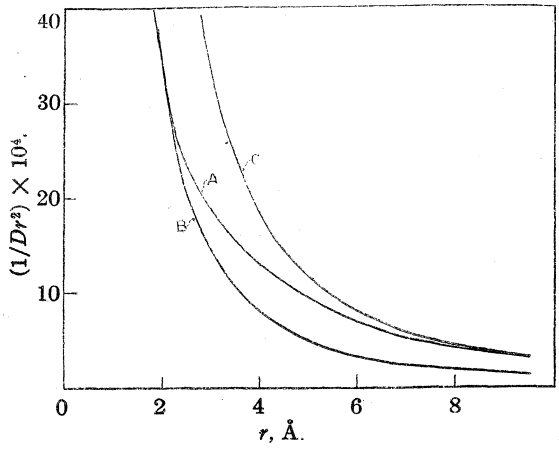

Fig. 5.—Solvent distribution in 50% dioxane–water, around univalent ions: Curve A, calculated from Table III; B, for uniform $D = 78.55$, as in pure water; C, for uniform $D = 34.28$, as in 50% dioxane–water.

The values of log S_1/S_2 then calculated through equations (6) and (7) are shown in Table V. These values refer to 25°, with water as the first medium, ($D_1 = 78.55$ and assumed uniform throughout).

TABLE V

RESULTS CALCULATED BY EQS. (6) AND (7)

Mixture, %	Electrolyte type	Log (S_1/S_2)
20	1/1	0.125
	1/2	.203
50	1/1	.521
	1/2	.839
80	1/1	1.95
	1/2	3.15

Before testing these calculated ratios on the observed solubilities, it must be pointed out that the Born equation refers theoretically to solubilities in zero ionic strength, μ; comparisons of actual solubilities simply neglect inter-ionic effects. The solubilities have therefore all been corrected to $\mu = 0$, by means of the usual Debye–Hückel expression

$$\log S_{\mu=0} = \log S - \frac{(352.6/D^{3/2})\mu^{1/2}}{1 + (2.914\ a/D^{1/2})\mu^{1/2}} \quad (9)$$

and using the values of a cited above in connection with equation (2). The results of these corrections and of the application of the ratios of Table V, are shown in Table VI. The solubilities of the salts silver acetate, silver sulfate and barium

iodate, in dioxane–water mixtures, are taken from ref. 4. The third column in this table, "Obs." $S_{\mu=0}$, lists the actual solubilities as corrected to $\mu = 0$ through eq. (9). Column 4 lists the corresponding solubilities, also at $\mu = 0$, calculated in each case from the limiting aqueous solubility through the ratios of Table V. Column 5 shows that with the exception of the 1:2 electrolytes in very high dioxane solvents, the solubilities thus calculated are distinctly too high, whereas (column 6) solubilities calculated through the uncorrected Born equation (equation 2) are in better agreement with observation in the 20% mixture, but distinctly low in higher dioxane ratios, as may be seen of course from Fig. 3.

The value of log (S_1/S_2) according to the simple Born equation, without taking into consideration the dielectric distribution resulting from solvent segregation, is proportional to the area in Fig. 5 between curves B and C, while according to the modified equation (6 and 7) log S_1/S_2 is measured by the smaller area between the water-curve B and the curve A for the actual mixture. The correction is therefore seen to be in the right direction, increasing the calculated solubilities in low dielectric mixtures. But it was expected that this correction would account for only part of the discrepancy noted in the last column of Table VI and Fig. 3, inasmuch as it seems that still another factor would tend to increase the solubility over that calculated on the ionic basis, namely, the association of ions in low dielectric solvents. The present calculations, however, show a distinct and rather large over-correction. The apparent agreement obtained in the case of the 1:2 electrolytes in very high (80%) dioxane solvents, resulting from the lower and hence "better" calculated solubilities for these cases, must evidently be attributed to the strong influence here of ion association, because of which the observed total or analytical solubilities should always be greater than the ionic concentrations calculated theoretically.

This general over-correction means that the area between curves A and B of Fig. 5 is too small. One purpose of these calculations was to estimate if possible the effective value of r_i required to change this area in order to reproduce the observed value of log S_1/S_2 between 0 and 20% dioxane, and, furthermore, by repeating the process for the ratio between 0 and 50% dioxane, to test the constancy of such a radius in media of varying dielectric. Such an application of the Debye equation, no. 3, was in fact made by Dunning and Shutt[12] to the solubility of silver chloride in water and in 1 M aqueous urea. Although they were able to derive thereby a value for the mean ionic radius of silver chloride in good agreement with crystallographic data, the applicability of the equation to the case of a mixture consisting of two solvents in which the second component (urea) has the higher dielectric constant, has been questioned by Scatchard.[13] In the present case, however, it is obviously impossible to find a value of r_i satisfying the observed ratio of solubilities. At r = 2–2.5 Å. (the limit from which the integration is made), the curve for the mixture (curve A, Fig. 5) is already indistinguishable from that for pure water, both for the 20 and for the 50% solvents, so that the area between the curves cannot be extended by assuming smaller values of r_i; any larger value for r_i of course increases the over-correction by decreasing this area.

We thus meet with two unexpected results: (1) the application of the Debye equation for the distribution of molecules of a mixed solvent around charged particles leads to calculated effects distinctly greater than the observed excess of solubility above the simple Born equation; (2) it is apparently impossible to estimate the "ionic radius" by this method, inasmuch as the actual ion appears to be so intensively selectively solvated by the more polar solvent, that it may be said that the concept of effective ionic radius here loses its meaning.

The first of these results is somewhat surprising inasmuch as it had been believed that the correction would account for only part of the actual discrepancy. The most probable defect in the Debye treatment is the neglect of the discrete structure of the mixed solvent.[13,15] The corpuscular or discontinuous nature of the mixture probably demands a statistical treatment taking into account the actual size, shape and polar properties of the solvent molecules. The other factor explicitly neglected by Debye is the electrostriction or dielectric saturation of the solvent molecules attached to ions. The magnitude of this effect is difficult to estimate[13] but may be appreciable.[16] It would seem, however, that such an effect, like the Debye segregation effect itself, would contribute further to the similarity in the dielectric properties of the medium immediately surrounding the ions, in a series of mixtures of two solvents. It would consequently lead, probably, as does the present calculation of the Debye effect, to the prediction of still smaller changes in solubility between one mixture and another, and thus increase rather than cancel the over-correction.

Concerning the second result, it is of interest to note a similarity between the results of the Born equation when corrected for the non-uniformity of mixed solvents and the empirical relation of Ricci and Davis.[1] In both cases the solubility in other media may be predicted from the solubility in water or in some reference medium without previous knowledge of the always uncertain quantity, ionic diameter. It is obvious that variation of r_i between 1 and 2.5 Å. will hardly change the value of the integrals involved in the examples discussed. While this does not suggest a theoretical reason for the useful empirical equation, it does suggest that there is very possibly a fundamental reason why the effect of the ionic diameter may disappear when the solubilities are compared in different media of mixed solvents.

Summary

1. The solubilities of potassium iodate and zinc iodate have been determined at 25° in mixtures of water and dioxane, up to 100% dioxane.

2. The results are used to test further the empirical rule of the constancy of the activity coefficient of electrolytes at saturation. The agreement between observed and calculated solubilities is satisfactory, at least as to the order of magnitude for both salts.

3. The results are also used to test the applicability of the Born equation when modified for the segregation of solvent molecules by ions in mixed solvents, in an attempt to account at least in part for the generally large negative error in the calculated solubilities in low dielectric media. When this distribution of dielectric is calculated according to the original Debye treatment, the solubilities now predicted for mixtures of low dielectric constant are higher than the observed, indicating an over-correction from the application of the distribution equation.

4. A similarity between the results of the corrected Born equation and the empirical relation of Ricci and Davis is pointed out, in that in both cases the solubilities calculated seem to be independent of the value attributed to the "ionic radius."

Kinetics and Equilibria of the Carbinol Formation of Phenolphthalein

BY MARION D. BARNES AND VICTOR K. LAMER

Introduction

That phenolphthalein fades in concentrated alkali was first observed by A. von Baeyer.[1] The rate of fading and the position of equilibrium were investigated colorimetrically by Kober and Marshall.[2] They attributed the fading process to the reaction of equimolecular proportions of alkali and the red form to yield a tribasic salt of phenolphthalic acid and formulated the process as

$$R^{=} + OH^{-} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} ROH^{\equiv} \qquad (1)$$

$R^{=}$ is the colored form, k_1 is the molar rate constant for the formation of the carbinol $ROH^{\equiv}$, and k_2 is the corresponding constant for the reverse reaction. Biddle and Porter[3] observed that the molar rate constant, k_1, increased with increasing concentration of alkali but did not account for this behavior. Thiel and Jungfer[4] concluded from a spectrophotometric study of the reaction that hydroxyl ion reacts with both the colored phenolphthalein ion and a colorless lactoid phenolphthalein ion to produce the triply charged carbinol.

Lund[5] measured the rate of fading of phenolphthalein at various sodium hydroxide and sodium chloride concentrations, and properly ascribed the increase in molar rate constant with increasing sodium hydroxide to a Brönsted primary salt effect.[6] He employed the Brönsted–Debye Limiting Law (B. D. L. L.) as a means of determining the number of charges on the reactant phenolphthalein ion from the quantitative dependence of the rate of reaction upon the concentration.

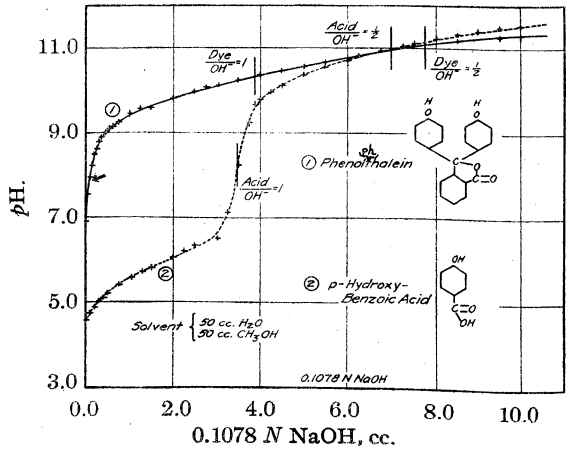

Fig. 1.

However, on plotting his data for log k_1, against the square root of the ionic strength, $\sqrt{\mu}$, he obtained the surprising result that the limiting slope was unity. This slope is one-half that required by the B. D. L. L. for a reaction between an ion of charge -2 and a hydroxyl ion. Since the B. D. L. L. has been abundantly confirmed in all cases where the charge type is definitely known, one would be forced to conclude that the reactant ion of phenolphthalein has a charge of -1 instead of -2.

This behavior became even more anomalous when LaMer and Amis[7] demonstrated that the B. D. L. L. was obeyed precisely for the rate of carbinol formation of Brom Phenol Blue (B. P. B.). The theoretical limiting slope of two (2.02) which was obtained shows that the reactant B. P. B. ion possesses a charge of -2. Phenolphthalein and B. P. B. are structurally similar. Aside from bromine substitution in the phenolic rings and the presence of a sulfonic acid instead of a carboxylic acid radical they possess identical triphenylmethane structures.

The two dyes differ, however, in color and acidic properties. B. P. B. is a relatively strong acid which dissociates hydrogen ions in a dilute or weakly acid solution whereas phenolphthalein is a much weaker acid which dissociates hydrogen ions only in alkaline solution as shown by the titration curve in Fig. 1. The estimated value of $K_1/K_2 \backsimeq 4$ from the titration curve is in accord with the colorimetric determinations of the ratio.[8] We also find that a red color appears on the addition of less than 0.10 mole of hydroxyl ion per mole of phenolphthalein. At first sight this observation might be taken as indicating a charge of less than 2 for the red ion.

Bury's resonance theory,[9] however, requires that the colored form of phenolphthalein should have a charge of -2. This is clearly inconsistent with Lund's data which we have been unable to reconcile with the requirements of the theory by recalculation. The data of Lund are inadequate to establish the mechanism of carbinol formation for phenolphthalein since the equilibrium constant was not measured in order to obtain k_1 from $k_1' + k_2$ by a rigorous mathematical method. The present investigation has been undertaken to determine the charge of the reacting ion from the Brönsted–Debye limiting law and to establish experimentally a mechanism for this carbinol formation which is consistent with well established electrostatic and kinetic principles.

Experimental

A Coleman Double Monochromator Photoelectric Spectrophotometer (Model 10-S) was used to measure the transmittances of the colored solutions. The transmittance measurements are accurate to ±0.1%. The instrument was equipped with specially designed water-jacketed absorption cells (cuvettes) for accurate temperature control. The wave-length scale was calibrated against a didymium glass filter using a slit of 30 mμ width.

Phenolphthalein was twice recrystallized from absolute methanol, m. p. 261–262° (cor.). The absorption maximum was 550 mμ. The stock solution for the fading runs consisted of 0.1721 g. of phenolphthalein in 100 cc. of 50% aqueous ethanol solution. For the regeneration reactions 0.1721 g. of phenolphthalein was dissolved in 100 cc. of 1 M NaOH and used after at least one hour and not more than eight hours. This carbinol solution was pale pink initially, due to traces of unfaded phenolphthalein, but after about twelve hours showed an increasing absorption at 425 mμ, indicating some further reaction. All regeneration experiments were accordingly made on freshly prepared solutions.

Sodium hydroxide solutions were prepared by the method of Sörensen[10] and stored in paraffin-lined bottles protected from carbon dioxide. They were standardized against B. of S. potassium acid phthalate and showed 0.4% residual carbonate by a differential titration.

Neutral sodium chloride solutions were employed.

The temperature was maintained constant to ±0.005° and standardized against a B. of S. platinum resistance thermometer.

Calibrated hypodermic syringes[11] were used to deliver small quantities of reagents accurately.

In a typical fading experiment 1 cc. of phenolphthalein stock solution was added to approximately 499 cc. of sodium hydroxide solution of such a strength that a concentration of 0.006 to 0.02 M sodium hydroxide was obtained on making up to volume. The solution was mixed rapidly and an absorption cell filled therewith. The remaining solution was placed in a paraffin-lined paper milk container in the thermostat. The measurements of the transmittance of the solution which required approximately one and one-half minutes each, were made every fifteen minutes over a period of about three hours. The cuvette with water circulating around it continuously was replaced in the thermostat between observations.

The regeneration runs were made by diluting 1 cc. of stock solution with dilute sodium hydroxide of such strength that concentrations of 0.006 to 0.020 M were obtained on making up to volume.

A Beckmann pH meter was used to measure pH's. No correction for sodium ion was made. The glass electrode yielded stable readings in the alcohol–water solution.[12]

Calculation of Rate and Equilibrium Constants.—The differential expression describing the rate of fading formulated in (1) is

$$-\mathrm{d}[\mathrm{R}^{=}]/\mathrm{d}t = k_1[\mathrm{OH}^-][\mathrm{R}^{=}] - k_2\,[\text{carbinols}] \quad (2)$$

where "carbinols" is written instead of $\mathrm{ROH}^{=}$ to indicate the possibility of a mixture of carbinols in solution. The concentration of hydroxyl ion, $[\mathrm{OH}^-]$, being sensibly constant during the course of a run, the reaction follows a first order course. For convenience in treating the data, k_1' was set equal to $k_1\,[\mathrm{OH}^-]$. The concentration (C) of dye at any moment is related to the transmittance (T) by Beer's law

$$C = k_B \log T \quad (3)$$

For a reversible pseudo-unimolecular reaction, integration of (2) gives

$$k_1' + k_2 = \frac{2.303}{t} \log \left(\frac{c_e}{c_e - c} \right) \quad (4)$$

where c_e is concentration of carbinols at equilibrium and c is concentration of carbinols at time t. Substitution of equation (3) in (4) gives

$$k_1' + k_2 = \frac{2.303}{t} \log \left[\frac{\log T_{t=0} - \log T_e}{\log T_t - \log T_e} \right] \quad (4a)$$
