Phase shift.—The approach outlined above can lead to a phenomenological understanding of the origin of the phase shift arising from adsorption pseudocapacitance. Thus if the frequency of the signal is low enough, it may be assumed that equilibrium in the initial ion-discharge step is maintained at all times, and the coverage θ_t at any time t is equal to the coverage which could be observed in the steady-state condition (no a-c signal) when the electrode is polarized to a potential V_t. In order to maintain this condition, the coverage must change at a rate $d\theta_t/dt$ proportional to the rate of change of potential (dV_t/dt). Since for the system defined here, the a-c component of the current is proportional to $d\theta/dt$ (it is assumed that the d-c rate of production of A_2 is virtually unchanged) it follows that $i = k(dV_t/dt) = K' \cos \omega t$ while the a-c contribution V_t to the potential is $V_t = A \sin(\omega t)$, *i.e.*, a phase shift of $\pi/2$ arises limitingly between current and potential.

It can also be seen immediately that if the frequency is higher, so that θ_t cannot change fast enough with V_t, the current will lag behind compared with the situation at very low frequency (apart from it being on the average smaller) and thus the phase difference between i and V will be smaller than $\pi/2$. This is electrically equivalent to adding a resistance in series with the capacitor in an electric circuit, and corresponds physically to the finite reaction resistance $r = (RT/i_oF)$ and to a deviation from complete equilibrium conditions in the initial ion-discharge step.

Rapid Galvanostatic Charging

Equivalent frequency.—The situation during a charging or discharging process conducted at constant current density will now be considered. It will be assumed that in the interval of potential studied, practically all the current is used to deposit or ionize the adsorbed layer of intermediates (*i.e.*, the current due to the steady-state over-all Faradaic process is negligible). The rate of the net discharge reaction, proportional to the rate of change of coverage with time, is thus kept constant under the above conditions (but see below) during a galvanostatic pulse, but may be changed between experiments.

For the case of a-c impedance measurement, Eq. [8a] can be written as

$$\alpha = K\nu \qquad [8b]$$

where

$$\alpha = \frac{|dV/dt|_{max}}{|d\theta/dt|_{max}} = \frac{|dV/dt|_{ave}}{|d\theta/dt|_{ave}} \qquad [8c]$$

and

$$K = 2\pi kr$$

Correspondingly, on a constant current charging curve we have

$$\alpha' = \frac{|dV/dt|}{|d\theta/dt|} = \frac{|dV/dt|}{i/k} \qquad [9]$$

where α' is now an experimentally determined quantity and the equation

$$\alpha' = K\nu \qquad [9a]$$

will then define an equivalent frequency ν' corresponding to the same degree of departure from equilibrium in the initial ion discharge step as occurs during an a-c measurement taken at a frequency ν. For a given constant current charging curve, i = const. and hence α' and consequently ν' are proportional to dV/dt and change with V and t during the charging process. It is also apparent that the equivalent frequency ν' is not only a function of dV/dt but also of i for charging curves taken at different rates, *i.e.*, at different i values since for a given capacity, dV/dt will be larger for larger charging currents.

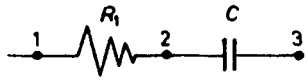

Fig. 1. Equivalent circuit for charging the pseudocapacitance in the nonsteady-state.

The frequency dependence of adsorption pseudocapacitance may be viewed in terms of an electrical model. The fact that a deviation from the equilibrium value of θ and C is observed during an a-c cycle is due to a small change of polarization of the discharge step giving rise to a current which is proportional to potential. Hence the reaction resistance acts as a simple ohmic resistance and a series "R.C." type of circuit (Fig. 1) applies. The same considerations could be applied to d-c charging at constant current. In this case the measured potential is given by

$$V = ir + V_c$$

where R is the reaction resistance and V_c the potential on the plates of the equivalent capacitor. Hence

$$\frac{dV}{dt} = \frac{dV_c}{dt}$$

so that the correct capacities will be observed but at potentials displaced to an extent iR from the reversible value.

However, during galvanostatic charging, i is usually large, and therefore the reaction resistance is potential dependent to an appreciable extent (Tafel behavior). Thus, $\Delta V = ir$ would be a function of V and the C values would depend on i and V in addition to a simple parallel displacement with respect to C (Fig. 2).

The latter explanation provides a basis for correlation of the physical model with the formal calculation.

The fact that the initial ion-discharge step (reaction I) is displaced from its equilibrium condition during galvanostatic charging or discharging, resulting in a distortion of the C-V relationship obtained, was realized already by Dolin and Ershler (9). In later literature (2, 17-19) the surface concentration of adsorbed hydrogen was studied by the "fast charging method," *i.e.*, by applying a constant, high anodic current pulse to the electrode; the effect of current density on the resulting pseudocapacity was not, however, discussed, except

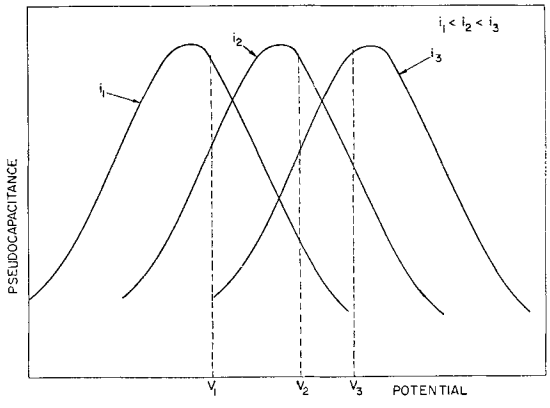

Fig. 2. Effect of irreversibility in the charging reaction on the capacity-potential profiles (schematic); effects shown for low overpotential in the charging step.

with regard to the problem of readsorption of hydrogen (1, 17).

Irreversibility in the discharge step.—We shall consider here, for simplicity, the h.e.r. and assume that a constant anodic current i is applied to the system which is initially on open-circuit at its equilibrium potential. Under these conditions, the only electrochemical reactions which can take place are the formation or ionization of adsorbed hydrogen atoms represented by step I above. It is clear that if i is less than or comparable with the exchange current for step I, the equilibrium in step I will be practially undisturbed during the anodic transient, and the coverage and adsorption pseudocapacitance calculated from the rate of change of potential with time, dV/dt, at each potential V are the true "equilibrium" values. Normally, however, high current densities must be used to ionize the adsorbed hydrogen on the surface [in order to avoid readsorption of hydrogen and other vitiating effects (2, 4)] so that i may become of the same order of magnitude or even larger than i_o.

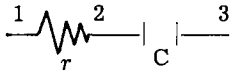
When i is of the order of magnitude of i_o or smaller, the current is linearly related to the overpotential, *i.e.*, a constant reaction resistance r is involved and given by

$$r = \frac{RT}{i_o F} \qquad [10]$$

The quantity r represents physically the degree of reversibility of the reaction considered and the potential drop across this reaction resistance when a current i is passed is simply the overpotential η

$$ir = \frac{i}{i_o}\left(\frac{RT}{F}\right) = \eta \qquad [11]$$

Under the conditions specified above, the electrode acts as a series combination of a capacitor (equal in value to the sum of the d.l. capacitance [assumed relatively negligible] and the adsorption pseudocapacitance) and a resistor, as shown schematically below (Fig. 1)



In theoretical discussions of the potential dependence of adsorption pseudocapacitance, the relevant potential is V_c across the capacitance C as would be measured between the points 2 and 3 above, since it is assumed that equilibrium is not disturbed. Experimentally, however, the potential V_{13} is measured between the points 1 and 3 in Fig. 1a, *i.e.*

$$V_{13} = ir + V_c \qquad [12]$$

Then differentiation with respect to time gives

$$\frac{dV_{13}}{dt} = \frac{dV_c}{dt} \qquad [13]$$

since both i and r are assumed to be constant during the transient. The capacity at the metal-solution interface is obtained from the equation

$$\frac{1}{C} = \frac{1}{i}\left(\frac{dV_{13}}{dt}\right) = \frac{1}{i}\left(\frac{dV_c}{dt}\right) \qquad [14]$$

and would therefore seem to be unaffected by the finite irreversibility of the reaction. From Eq. [12], however, it is clear that the potential V_{13} will differ from that (V_c) which is theoretically significant (1, 5, 6) in determining the potential at which a given value of C is attained, by an amount $\Delta V = ir$ depending on the kinetics of the reaction (its r value) and on the current i. Changing the current density i used in a galvanostatic transient would thus have the effect of shifting the C-V curve without change in shape (but see below) along the potential axis. This is shown schematically in Fig. 2. It is important to realize that while the shape of the C-V relationship is not in the above sense affected by the irreversibility of the reaction, the measured value of C at a particular potential, will depend on the applied current density i. Moreover, for a given V, the value of C may increase or decrease with i depending on the relative positions of the C-V curves for the various i values. Thus, referring to Fig. 2 where three curves are shown corresponding to increasing values of i_1, the value of C measured at a potential V_1 would decrease with increasing i ($i_1 < i_2 < i_3$) while at V_3 it would increase with increasing i. At some intermediate potential V_2 it may first increase and then decrease as i is increased.

It is of interest to consider the case when $i >> i_o$ so that the adsorption equilibrium is highly disturbed. In this case, the reaction resistance may be expressed as

$$r = \frac{RT}{\beta F}\frac{i}{i_o}\exp\left[\frac{\beta\eta F}{RT}\right] \qquad [15]$$

for an anodic process. The reaction resistance is clearly a function of η in the discharge step, but it must be remembered that during the galvanostatic transient, η (with respect to step I) remains practically constant while the change in potential is due mainly to a change in the quasi-reversible potential of the system (step I), associated with the change of coverage (1).[5] Thus the equivalent circuit represented in Fig. 1 is still valid and Eq. [13] and [14] can be applied. The shift of the C-V curve by $V = ir$ will in this case not be proportional to i since r itself is a function of i. When r has the nonlinear form given in [15], the analysis below will apply.

Nonsteady state kinetic theory of charging.—A galvanostatic charging curve corresponds to a steady-current condition but not to a chemical steady-state condition, since a total "charging" current i is made up of components i_C, the capacitative true charging current, and any Faradaic current i_F. The situation also depends on the nature of the consecutive reaction mechanism, *i.e.*, whether or not the desorption step (as in hydrogen evolution) proceeds by a chemical atom recombination step or by an electrochemical atom-ion discharge step. In the former case, all the current passes through the reaction resistance of the discharge step since the desorption is nonelectrochemical; in the latter case, part of the current is involved in electrochemical removal of the intermediate, *e.g.*, adsorbed H, and part in formation of H. The equivalent circuits are hence somewhat different (Fig. 3a, 3b) and a special symbol is required (see Fig. 3b) for the reaction resistance for the electrochemical atom-ion desorption step; electrons and H^+ ions arising from the metal and solution, respectively, are discharged from the ionic double-layer capacitance while charge corresponding

[5] This is only an approximation. As the potential is changed during the galvanostatic charging process, the exchange current density is changed due to (*a*) a change in coverage (19); (*b*) a change in the metal-solution potential difference at the changing reversible potential. Thus, even though i is kept constant, r will change due to the variation in i_o and, hence, η will also change. This would have the effect of changing the shape of the C-V relationship slightly in addition to the lateral shift in the curves. A numerical analysis, however, shows that in most practical cases this effect will be quite small.

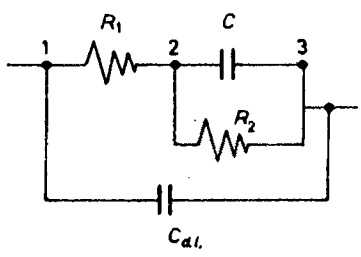


Fig. 3a. Complete equivalent circuit for step I followed by a nonelectrochemical desorption (charging process nonohmic).

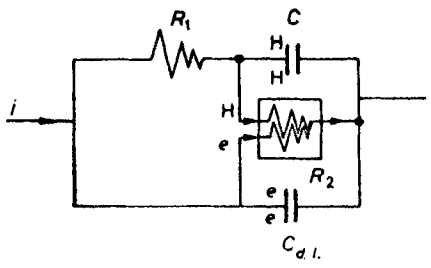

Fig. 3b. Complete equivalent circuit for step I followed by an electrochemical (e.g., atom + ion) desorption step.

to H atoms is withdrawn from the adsorption pseudocapacitance. No representation alternative to the dual channel symbol shown in Fig. 3b is possible for the electrochemical desorption type of process without "short-circuits" being involved.

The general electrochemical reaction sequence[6]

$$M + A^- \rightleftarrows MA + e \qquad (I)$$

$$MA + A^- \rightarrow M + A_2 + e \qquad (III)$$

may be considered. The steady-current condition (see Fig. 3b) is

$$i = i_1 + i_3 \qquad [16]$$

and

$$i_1 = \vec{i}_1 - \overleftarrow{i}_1 = i_C + i_3 \qquad [17]$$

where i_C is the net charging current for the pseudocapacitor.

In the steady state, $i = 2i_3$ ($i_C \rightarrow 0$); i_3 is the leakage current from the pseudocapacity associated with desorption of adsorbed A by step III and is also the electron + ion leakage current across the ionic double-layer capacity $C_{d.l.}$ associated with step III, (in regard to the charge transfer involved).

If θ is the coverage by A at a metal-solution potential difference V, the steady-current condition under Langmuir conditions (cf. 1) gives, in abbreviated form[7]

$$i = k_1 (1-\theta) e^{V/b} - k_{-1}\theta e^{-V/b} + k_3\theta e^{V/b} + C_{d.l.}\left(\frac{dV}{dt}\right) \qquad [18]$$

which gives θ as

$$\theta = \frac{k_1 e^{V/b} - i}{k_1 e^{V/b} + k_{-1} e^{-V/b} - k_3 e^{V/b}} \qquad [19]$$

neglecting the $C_{d.l.}$ term.

In Eq. [18] and [19], the k terms are the indicated "rate constants" which include for brevity of representation also the ion concentration terms allowing for double-layer ion distribution effects. For the purpose of the present calculations, it will not be necessary to specify the k terms nor the potential quantity V in more detail.

Calculating the pseudocapacity (Eq. [1]), we obtain

$$C = kd\theta/dV = \frac{2kk_1k_{-1}/b}{[k_1e^{V/b} + k_{-1}e^{-V/b} - k_3e^{V/b}]^2} - \frac{ki[k_{-1}e^{-V/b} - k_1e^{V/b} + k_3e^{V/b}]/b}{[k_1e^{V/b} + k_{-1}e^{-V/b} - k_3e^{V/b}]^2} \qquad [20]$$

The term in rate constants and V is separated from that involving current i since it is seen [cf. (1), (7), (8)] that the first term becomes the equilibrium pseudocapacitance for A as a function of V when k_1, $k_{-1} >> k_3$ (quasi-equilibrium conditions). For the latter condition then, C differs from its equilibrium value[8] by a kinetic term involving the measured rate i of the galvanostatic pulse (note: this is limiting only the rate of surface charging when the potential range corresponds to negligible net over-all reaction for the mechanism I, II).

[6] An anodic reaction is chosen purely for convenience of representation of the kinetic equations.

[7] Here the symmetry factor for step I and its reverse, and III are, for convenience, assumed equal to 0.5 so that all the b terms are the same. Also, the ionic double-layer charging current $C_{d.l.}(dV/dt)$ has been included in Eq. [18]. This part of i will, however, generally be negligible in potential regions where the adsorption pseudocapacitance is appreciable, which is the condition considered here.

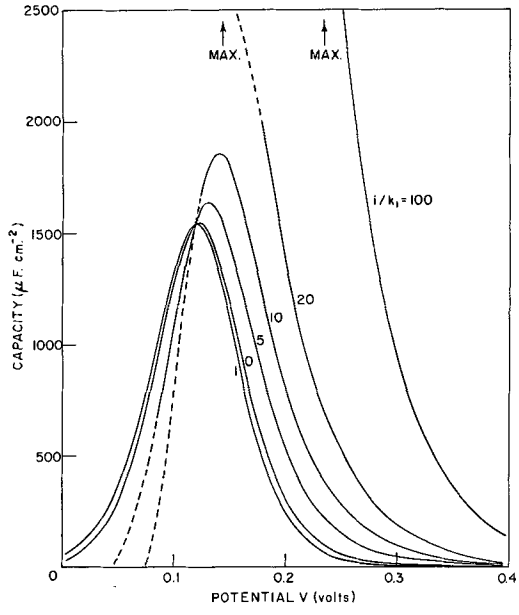

Fig. 4. Capacity-potential profile for galvanostatic charging at various currents expressed as the ratio i/k_1 where k_1 is the kinetic constant in Eq. [20] for the forward direction of step I. (Dotted regions are not experimentally realizable). K_1 the quasi-equilibrium constant in step I is taken as 0.01 [cf ref. (1) and (7)].

The behavior of C with respect to V for a range of i values (expressed as i/k_1) has been computed from Eq. [20] for the "quasi-equilibrium" condition k_1, $k_{-1} >> k_3$ with a value of K_1, the equilibrium constant for step I, equal to 10^{-2} ($= k_1/k_{-1}$) as in previous calculations of C as a $f(V)$ (1, 7, 8). Choice of other values of K_1 simply shifts the scale of potentials over which the variation of C with V occurs (1). The results for C as $f(V)$ are shown in Fig. 4a and 4b, and for θ as $f(V)$ in Fig. 5.

[8] The calculations here differ from those we have given previously (7, 8) which concerned the dependence of C on extent of disturbance of I from equilibrium in the steady current and chemical steady state. Here the analysis applies only to the steady-current condition in transients.

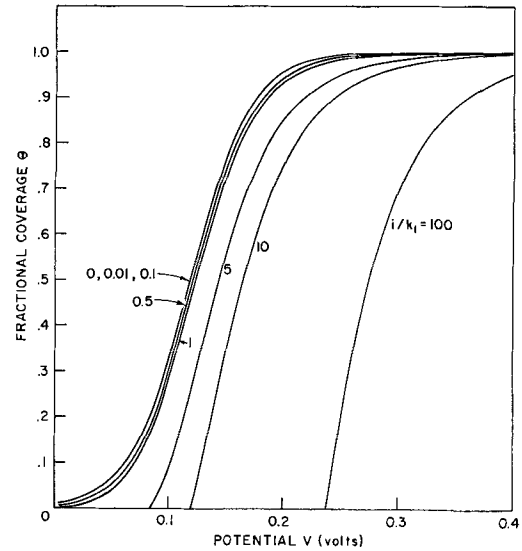

Fig. 5. Coverage θ-potential (V) profiles corresponding to Fig. 4 for various values of the charging rate parameter $1/k_1$.

The calculations indicate that C may either decrease or increase, depending on the potential, with increasing current in the galvanostatic pulse as was concluded qualitatively above and in Fig. 2. The decrease of C occurs over those potentials less than that for which $C = C_{max.}$ in the equilibrium case (k_1, $k_{-1} >> k_3$ and $i \rightarrow 0$) while the increase of C with increasing i occurs at potentials corresponding to $C > C_{max.}$. The change of capacity is linear with i/k_1 as required by Eq. [20], but negative values of θ would appear to be indicated for $i > k_1 e^{-V/b}$. This is, however, a physically impossible condition since the pseudocapacitance can only be charged by the discharge step I which cannot proceed at a rate greater than that defined by its rate constant and respective V and b values, *i.e.*, at the rate $k_1 e^{-V/b}$ when $\theta \rightarrow 0$). The maximum over-all rate in the steady state for the mechanism I, III is $2k_3 e^{V/b}$ which will be less than $k_1 e^{V/b}$ if III is rate-controlling. It is clear therefore that while $k_1 e^{V/b}$ or $k_{-1} e^{-V/b}$ may be greater than i, i cannot be greater than $k_1 e^{V/b}$. Hence the limit for i/k_1 is $i/k_1 = e^{V/b}$ for a potential V.

If the desorption step occurs by a recombination type of process II, the same type of analysis as above will hold provided that the condition k_1, $k_{-1} >> k_2$ is maintained. However, the equivalent circuit will not involve the special element shown in Fig. 3b since no charge transfer is involved in the desorption step. The pseudocapacitance is hence in parallel simply with the leakage resistance corresponding to k_2 and this whole combination provides a parallel leakage admittance across $C_{d.l.}$.

Linear Potential Sweep Method

Here the potential of the system is controlled potentiostatically and is made to change at a predetermined (usually constant) rate. The situation here is thus, in principle, similar to that during galvanostatic charging. Here for α (Eq. [8c]) we would have

$$\alpha = \left| \frac{dv/dt}{d\theta/dt} \right| = f\left(\frac{dV}{dt}, i\right) \qquad [21]$$

where dV/dt rather than i is now the quantity fixed by a device, *e.g.*, a potentiostat controlled by a ramp or triangular wave function, in the external circuit and the observed current is a function of potential and time. A point along the $i - t$ curve obtained experimentally can again be related to an equivalent frequency through Eq. [9a] and the pseudocapacity value, determined by the time-dependent charging current $i_v (= C_v\, dV/dt)$ at potential V, may become a function of the rate of change of potential with time, and of the degree of reversibility of the initial ion discharge step (*e.g.*, step I). Under such conditions $i_V/(dV/dt)$ would not be constant but a function of (dV/dt). This is observed in some cases (27).

The theory of the triangular wave potential sweep method was originally given by Sevcik (28), and the method was examined by Delahay and Perkins (29), for diffusion-controlled reactions; however, the analysis of Sevcik is inapplicable to most of the recent applications to anodic oxidation and electrocatalytic reactions where adsorbed intermediates are involved (4) and the currents are pseudo-Faradaic charging currents or kinetic currents modified by potential-dependent adsorption of intermediates (4). In most of the recent applications, this method has been used somewhat uncritically to obtain qualitative information on possible steps in anodic oxidation reactions. Since neither a steady-state nor a steady-current condition obtains, rigorous kinetic analyses have not previously been made. However, the essential nonsteady-state kinetic theory can be developed as we show below.[9]

We assume that a current i_t is passing at time t in the sweep when the potential is V. For a given sweep $dV/dt = m$, a constant. The current for a charge transfer step involving the production or ionization of an intermediate, *e.g.*, as in reaction I, will be

$$i_t = k_1 (1 - \theta_t)\, e^{V/b} - k_{-1} \theta_t e^{-V/b} \qquad [22]$$

in ranges of V where the rate of the desorption step II is negligible; θ_t is the coverage of the intermediate produced in the discharge step I and prevailing at time t when the potential is V. In the sweep method, this coverage θ_t will not be the same as that in the galvanostatic method at the same potential, since in the latter case the potential adjusts to the coverage with a microscopic extent of charge transfer while here the potential is momentarily set at V, but the coverage must take some time to reach the value it would have in the galvanostatic method at this potential. Generally we shall expect for an ascending (anodic) sweep that $\theta_G > \theta_P$ where G and P represent the galvanostatic and potentiodynamic coverages attained at potential V. The change of coverage during a sweep from potential V_1 to V_2 is obviously

$$\Delta\theta = k \int_{t_1}^{t_2} i_t\, dt \qquad [23]$$

where k is as defined earlier and t_1 and t_2 are times proportional to V_1 and V_2. By analogy with the operations used to obtain Eq. [19], we obtain

$$\theta_t = \frac{k_1 e^{V/b} - i_t}{k_1 e^{V/b} + k_{-1} e^{-V/b}} \qquad [24]$$

where i_t is now dependent on t,V, instead of being constant as in the case of the relation [19]. Separating the term in i_t gives

$$\theta_t = \frac{k_1 e^{V/b}}{f(V)} - \frac{i_t}{f(V)} \qquad [25]$$

where $k_1 e^{V/b} + k_{-1} e^{-V/b}$ has been represented by $f(V)$. Differentiation of [25] enables the capacitance C_V to be expressed in terms of an equilibrium capacitance $C_{V,E}$ [cf. (1, 7, 8)] corresponding to zero net charging rate and a term dependent on dV/dt. Thus

$$\frac{C_V}{k} = \frac{d\theta_t}{dV} = \frac{2k_1 k_{-1}/b}{[f(V)]} + \frac{[f(V)]\left[\frac{i_t}{b} - \frac{di_t}{dV}\right] - \frac{2k_{-1} i_t e^{-V/b}}{b}}{[f(V)]^2} \qquad [26]$$

The first term is recognized (7, 8) as $C_{V,E}$ and i_t can be expressed as

$$i_t = C_V\, dV/dt; \text{ also } \frac{di_t}{dV} = C_V (d^2V/dt^2) + \frac{dV}{dt} \cdot \frac{dC_V}{dV} = \frac{dV}{dt} \cdot \frac{dC_V}{dV}$$

since dV/dt = constant. Hence Eq. [26] gives

$$\frac{C_V}{k} = \frac{C_{E,V}}{k} + \left(\frac{dV}{dt}\right) \frac{\left\{ f(V)\left[\frac{C_V}{b} - \frac{dC_V}{dV}\right] - \frac{2k_{-1} e^{-V/b} C_V}{b} \right\}}{[f(V)]^2} \qquad [27]$$

This has the expected form since $C_V \rightarrow C_{E,V}$ when $dV/dt \rightarrow 0$. C_V is not, however, linear in dV/dt as follows by expressing C_V explicitly as a function of dV/dt. The most explicit form is

$$\frac{C_V}{k} = \frac{\frac{C_{E,V}}{k}[f(V)]^2 - \left(\frac{dV}{dt}\right) f(V) \left(\frac{dC_V}{dV}\right)}{[f(V)]^2 - \frac{k}{b}\left(\frac{dV}{dt}\right)(f(V) - 2k_{-1} e^{-V/b})} \qquad [28]$$

For a given sweep, dV/dt is constant and dC_V/dV could be obtained experimentally [or calculated (1, 7, 8)] by

[9] A brief communication on this matter has been published elsewhere (*J. Electroanal. Chem.*, in press).

means of a differentiating amplifier using a dual beam oscilloscope (cf. 30). The rate constants in $f(V)$ might then be estimated by measurements of dC_V/dV at two or more sweep rates if the processes involved were purely of an adsorption-desorption type. However, this is rarely the case except perhaps for H and O adsorption reactions occurring below their respective reversible potentials.

It is seen that a differential galvanostatic method, *e.g.*, that of Kozlowska and Conway (30), leads to a much simpler and direct analysis of nonequilibrium electrochemical adsorption behavior than is the case for the sweep method which gives a simple result only under equilibrium conditions, *i.e.*, for relatively "reversible" processes.

A rather simpler but only approximate solution which may apply at low sweep rates may be derived by assuming that the capacity C_V differs from $C_{E,V}$ simply by the effect of the finite current i_V given by the galvanostatic current relation [18], *i.e.*, assuming $\theta_t \doteq \theta$ which is equivalent to the condition that θ_t can follow V with a degree of irreversibility which is small. Then

$$C_V = C_{E,V} - k_V i_V \qquad [29]$$

where $C_{E,V}$ is the equilibrium capacity contribution and the second term, proportional to i, has been written as k_V where k_V is a function of V and is defined by comparison of [29] with [20]; it may take a positive or negative sign depending on the partial rate terms in Eq. [20]. The current i_V in Eq. [29] is simply the charging current $C_V dV/dt$ determined by C_V and the potential sweep rate. Then

$$C_{E,V} = C_V + k_V i_V = C_V(1 + k_V\, dV/dt) \qquad [30]$$

At very slow sweep rates it is hence clear that $C_V \rightarrow C_{E,V}$, the experimentally significant equilibrium value, since the charging currents are then limitingly small and the equilibrium in the step of type I is least disturbed.

At somewhat higher sweep rates

$$i_V = (C_{E,V} - k_V i_V)\, dV/dt \qquad [31]$$

or

$$i_V/(dV/dt) = \frac{C_{E,V}}{1 + k_V\left(\frac{dV}{dt}\right)} \qquad [32]$$

The left-hand-side of Eq. [32] is the measured capacity at the given dV/dt, *i.e.*, C_V so that approximately

$$C_V = \frac{C_{E,V}}{1 + k_V\left(\frac{dV}{dt}\right)} \qquad [33]$$

The result will also depend on electrode potential through the potential-dependent terms in k_V (see Eq. [20] and [29]).

From the foregoing discussion, it may be suggested that data derived from the potential sweep method should always be obtained as a function of the sweep rate (cf. 35) and extrapolated to zero frequency. This would apply to calculated capacities, charge corresponding to the area $\int i dt$ under the peak, and the position of the peak currents on the potential axis.

It has been supposed in previous work [*e.g.*, (27)] that a current peak, in the potential-sweep method, which gives an $\int it$ independent of dV/dt is one that is associated with an electrochemical adsorption process. This is a reasonable assumption, but the converse is not necessarily true, *viz.*, that a peak which gives an it product dependent on dV/dt must be associated with steady kinetic or diffusion-controlled process rather than an adsorption. Thus, the charge passed is a pseudo-Faradaic process in which deposition or ionization of an intermediate is involved will depend on the sweep rate. If the sweep is fast enough, in a repetitive sweep experiment, there will be negligible charging of the adsorption pseudocapacitance; the capacity will tend to the double-layer capacity and the charge to that associated with the change of charge held in double layer between the extremes of the signal potential. In a single sweep (ramp signal) experiment, this limitation will, however, not apply since the potential will be steady at the top or bottom of the ramp. It must also be pointed out that the rate of a kinetic process exhibiting an inhibition or passivation, *e.g.*, by coadsorbed oxide intermediates (37), will give a potentiostatic current-voltage relation in the sweep method which can be dependent on the sweep rate since the extent of coverage by the inhibiting species at a given (momentary) potential will be dependent on dV/dt as discussed above in the general case (Eq. [23]).

Applications to Experimental Results

Charging curves.—Charging curves have recently been obtained for the formate oxidation reaction at Pt (cf. 32) by Kozlowska and Conway (31) by the direct and differential galvanostatic method (30) at various cathodic current densities. The results may be used to examine the applicability of Eq. [20]. The capacities associated with the coverage by the electrode of formate radical species (14, 32) are shown in Fig. 6 as a function of the charging current density. It is seen that the capacities increase with increasing cathodic charging current density as indicated by Eq. [20] at high anodic overpotentials when $k_{-1}e^{-V/b} << k_1 e^{V/b}$. The experimental conditions in this work are as indicated in the caption to Fig. 6. Anhydrous formic acid was used as the solvent (cf. 32) in order to minimize complications by reactions involving anodically formed surface oxides of Pt.

Similar conclusions may be obtained from the data of Conway and Vijh (33, cf. 34) for direct and differential galvanostatic charging in the Kolbe reaction at Au in anhydrous trifluoroacetic acid from which residual traces of water were removed by treatment with a

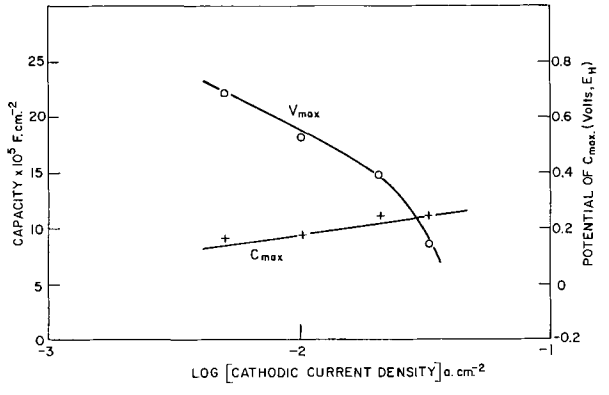

Fig. 7b. Dependence of maximum capacity and potential at which it occurs on cathodic current density (conditions as for Fig. 7a).

small quantity, (<1%) of trifluoroacetic anhydride. Here the adsorbed intermediate responsible for the pseudocapacity is believed (34) to be the CF_3COO radical. The capacity-potential relationships are shown in Fig. 7, for various cathodic discharging rates; again the capacities are dependent on the discharging current density as required theoretically.

Few experimental results exist from which suitable data for a simple irreversible system can be obtained to test the dependence of capacities on sweep rate in the potential sweep method. Will and Knorr (35) have studied the hydrogen ionization reaction in some detail by the sweep method and have experimentally examined the dependence of the potential of the current maximum and of the current itself on dV/dt. This reaction is, however, a relatively reversible one. Gilman and Breiter (35, 36) have studied the anodic oxidation of methanol at various sweep rates. Apart from better resolution of charging detail at the lower sweep rates, the position of the peak current is found to depend on sweep rate and approaches a constant value of potential at the smaller sweep rates. The data derived from their curves are plotted out in Fig. 8 and indicate a variation of the maximum with changing dV/dt, and hence transient current, in the expected manner. However, in these more complex reactions, it is not always pos-

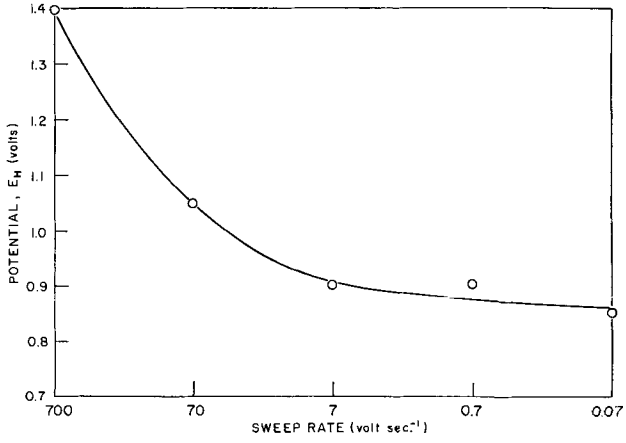

Fig. 8. Potentials of the current maximum in triangular potential sweep curves for methanol oxidation at Pt, as a function of sweep rate [ref. (35)].

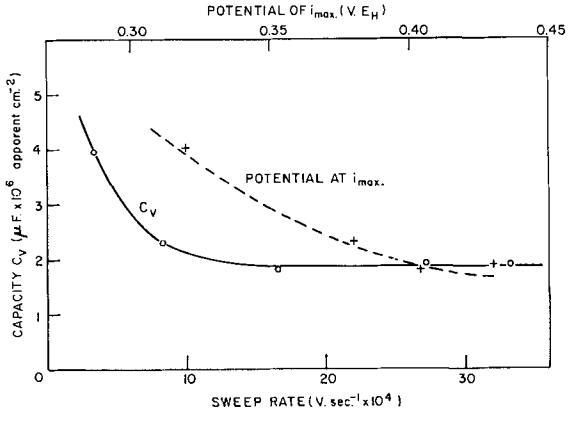

Fig. 9. Maximum capacitance as a function of sweep rate for the adsorption peak in methanol oxidation (27) at platinized platinum. Potentials of current maxima (cf. Fig. 8) also shown.

sible to distinguish between kinetic Faradaic currents and pseudo-Faradaic currents involved in the build up or removal of adsorbed intermediates. In complex reactions, *e.g.*, the oxidation of methanol and of formate in aqueous media both kinetic and pseudo-Faradaic currents, *e.g.*, for surface oxide films function, may pass in the same potential range and influence each other (37). The analysis made above for the capacitance behavior will then not be applicable. In most of the previous work using the potential-sweep method, it is believed that insufficient attention has been paid to these complications.

In another case, the oxidation of methanol at platinized platinum (27), the peak was observed between 0.25 and 0.6v. E_H has been characterized as an adsorption peak on account of the independence of the *it* product (but see above) under the peak on anodic sweep rate. This therefore provides a case of interest in relation to the present discussion. The capacity maxima may be calculated as a function of dV/dt and are shown in Fig. 9 together with the potentials of the capacity maxima. The variation of both quantities with sweep rate is as expected on the foregoing theory. The capacity maxima decrease in this case with increasing charging current (dV/dt) and are displaced to higher anodic potentials (overpotential effect). The actual values of C_V are very large but the electrodes used were platinized so the actual capacities per real cm^2 of electrode area are probably of the order of at least 2000 μF cm^{-2}, a result which could arise under Langmuir conditions (1, 4, 6). However, the above figure for C_V per real cm^2 is on the high side and this apparent large value may in fact indicate some participation of kinetic currents

in the sweep currents observed, a problem we have emphasized above.

Open-Circuit Decay Measurements

Various experimental methods have been proposed (2, 3, 12-16) by which the adsorption pseudocapacitance can be evaluated by studying the rate of decay of potential on open-circuit following steady-state polarization. The situation here is quite different from that in the two cases considered above since the potential of the system is allowed to change by a self-discharge process, without external control of potential or current. Thus the rate of decay of overpotential will be a function of time, but will always be determined by the intrinsic electrochemical time constant RC of the reaction comprised of an equivalent capacitor and a resistor in parallel.[10] The current density flowing internally in the system at any potential will be equal to the steady-state current density measured at the same potential (14). If our initial assumption that the electrode reaction is studied in the potential range where the ion discharge step can effectively be regarded as being at quasi-equilibrium, holds, then the pseudocapacity obtained by any method based on open-circuit decay will represent the true equilibrium value as would be measured at an infinitely low frequency. This is the capacitance quantity required in kinetic interpretations and for relation to isotherms (1, 6-8). The interpretation of results obtained by this method (12) is hence more straightforward than in the other two methods discussed.

Conclusions

It is shown that measurements of the adsorption pseudocapacitance by any method where the current or the potential is controlled by the external circuit may be a function of the externally controlled quantity. While the frequency dependence of the adsorption pseudocapacitance, as measured by an a-c impedance bridge is well known, little regard seems to have been given hitherto to a similar effect which will prevail during galvanostatic or polarographic potential-sweep studies.

The concept of an "equivalent frequency" in d-c transients is introduced and the significance of its variation with time (potential) during a constant d-c charging transient is emphasized, in relation to the theoretical interpretation of the shape of the transient.

The experimentally observed dependence of the adsorption pseudocapacity on the frequency of the applied a-c signal (when measured by the a-c bridge method) over a wide range directly indicates the existence of intrinsic heterogeneities on the electrode surface, coupled with significant hindrance to lateral motion of the adsorbed species on the surface.

Any method depending on the study of the rate of decay of potential on open circuit will yield the "equilibrium" pseudocapacitance value and is therefore to be preferred.

A quantitative kinetic treatment of the dependence of the observed pseudocapacity on the applied current in a galvanostatic charging transient is given and the result is applied to the calculation of analogous effects which arise in the potentiostatic potential-sweep method.

A kinetic treatment is given for the voltage sweep method with regard to the behavior of the pseudocapacitance in adsorption processes. It is concluded that the differential galvanostatic method is preferable.

Applications to experimental results are given.

[10] The capacitor is actually a parallel combination of the ionic double-layer capacity and the adsorption pseudocapacity, but we shall assume here that the former is negligible with respect to the latter. The resistor is the nonohmic differential reaction resistance, defined as $(di/dV)^{-1}$ which is normally a function of exp. [V], or of V at low overpotentials.

The Effect of Pressure on *p*H and Dissociation Constants from Measurements with Buffered and Unbuffered Glass Electrode Cells

Acetic, Formic, Phosphoric, Carbonic Acids Adenosinetriphosphate and Phosphorylcreatine

A. Distèche and S. Distèche

Laboratory of General Biology, Zoology Institute, University of Liege, Liege, Belgium

ABSTRACT

The cell Ag-Ag Cl $\left|\begin{matrix}\text{HCl } (m_1)\\ \text{KCl } (m_2)\end{matrix}\right|$ glass $\left|\begin{matrix}\text{HR or HR + MR}\\ (m_1 + m_2)\ \text{KCl}\end{matrix}\right|$ AgCl-Ag

is used to measure the effect of pressure on the ionization constant K of weak acids (HR) in the presence or not of the corresponding Na or K salt (MR). Double extrapolation, to zero weak electrolyte concentration and zero KCl concentration, yields log K_p/K_1 values at $p = 1000$ kg cm^{-2} and the molal volume change on ionization for the reaction HR $\rightleftharpoons$ R$^-$ + H$^+$ is computed at 1 atm for acetic acid, formic acid, carbonic acid (buffered and unbuffered solutions), phosphoric acid (2^d step), adenosinetriphosphate and phosphorylcreatine.

It has been shown in previous papers (1-3) that the cell

$$\text{Ag-AgCl}\left|\begin{matrix}(m_1)\text{HCl}\\ (m_2)\text{KCl}\end{matrix}\right|\begin{matrix}\text{glass}\\ (\text{Corning}\\ 015)\end{matrix}\left|\begin{matrix}\text{HR or HR + MR}\\ (m_1 + m_2)\text{KCl}\end{matrix}\right|\text{Ag-AgCl}$$

can be used to measure the effect of pressure on the ionization of a weak acid HR in the presence or absence of its Na or K salt (MR). Dissociation constants K can be computed from the emf measurements by extrapolation to zero ionic strength and zero weak electrolyte concentration, and the volume change (ΔV_p^o) induced by pressure p can be calculated at any pressure from the well-known equation

$$\left(\frac{\partial \ln K}{\partial p}\right)_{m,T} = \frac{-\Delta V^o}{RT} \qquad [1]$$

More recently, Hamann (4) used the cell Ag-AgCl | (m_1) HCl | Li — glass | (m_2) KCl + (m_3) KOH | AgCl-Ag to derive ΔV_1^o for water.

In the present paper, we shall investigate in more detail the pressure dependence of the ionization constants of acetic, formic, phosphoric (2nd step), and carbonic acids, either in buffer solutions or in pure acid solutions. Data for organophosphorus compounds such as adenosinetriphosphate and phosphorylcreatine are also described.

Experimental

The equipment described in 1962 (2) is used. It was found that slight hysteresis effects, which sometimes appear when new Ag-AgCl or glass electrodes are tried, are minimized by applying several pressure cycles before making the final experiment.

Methods.—The methods used to derive ionization constants from emf measurements are classic and can be used, in principle, to calculate K and ΔV^o at any pressure with the aid of Eq. [1].

In practice, the choice of a particular method is limited by the fact that the glass electrode cell under pressure exhibits two types of asymmetry potentials: one, normal, which can be taken into account by measuring the emf of the cell with the reference solution on both sides of the glass membrane, and another which arises (2) when the KCl concentration is different in the two compartments. To eliminate this last cause of error, it was found convenient to use the following three cells

1. Ag-AgCl	HCl (0.01M) KCl (0.09M)	HR or HR + MR KCl (0.1M)	Ag-AgCl
2. Ag-AgCl	HCl (0.001M) KCl (0.009M)	HR or HR + MR KCl (0.01M)	Ag-AgCl
3. Ag-AgCl	HCl (0.001M)	HR or HR + MR KCl (0.001M)	Ag-AgCl

The asymmetry due to KCl in cell 3 can be neglected.

The emf (E) of the cells at 1 atm or at pressure p is expressed by the relation

$$E_{1,p}\mathbf{F}/2.3RT = \log (m_H)_{1,p}^{ref.} - \log (m_H)_{1,p}^{x} + 2\log \frac{(\gamma_{HCl})_{1,p}^{ref.}}{(\gamma_{HCl})_{1,p}^{x}} \qquad [2]$$

where m_H is the hydrogen ion concentration (molal scale), γ_{HCl} the mean activity coefficient for HCl, and where *ref.* and x, respectively, refer to the reference half-cell and the cell compartment containing the weak acid HR or its buffer HR + MR (M = Na or K) at concentrations m_{HR} and m_{MR}.

The dissociation constant K of the weak acid is given by the relations

$$\log K = \log \frac{m_H^2}{m_{HR} - m_H} + 2\log \gamma_A = \log k - (A\sqrt{\mu} \pm B\mu) \qquad [3]$$

in the unbuffered half-cell, and

$$\log K = \log \frac{m_H(m_{MR} + m_H)}{m_{MR} - m_H} + 2\log \gamma_A = \log k - (A\sqrt{\mu} \pm B\mu) \qquad [4]$$

in the buffered half-cell

Here $2\log \gamma_A = \log \gamma_H\gamma_R/\gamma_{HR}$ and $(A\sqrt{\mu} \pm B\mu)$ is the usual function of the ionic strength μ used to estimate $2\log \gamma_A$.

The combination of [2], [3], and [4] leads to the expressions

$$2(E_1 - E_p)\mathbf{F}/2.3RT = \log \frac{K_p}{K_1} + \log \frac{(m_{HR} - m_H)_p}{(m_{HR} - m_H)_1} + 2\log \frac{(\gamma_A)_1}{(\gamma_A)_p} + 4\log \frac{(\gamma_{HCl})_1^{ref.}}{(\gamma_{HCl})_p^{ref.}} - 4\log \frac{(\gamma_{HCl})_1^{x}}{(\gamma_{HCl})_p^{x}} \qquad [5]$$

and

$$(E_1 - E_p)\mathbf{F}/2.3RT = \log \frac{K_p}{K_1} + \log \frac{(m_{HR} - m_H)_p}{(m_{HR} - m_H)_1} \cdot \frac{(m_{MR} + m_H)_1}{(m_{MR} + m_H)_p} + 2\log \frac{(\gamma_A)_1}{(\gamma_A)_p}$$

$$+ 2 \log \frac{(\gamma_{HCl})_1^{ref.}}{(\gamma_{HCl})_p^{ref.}} - 2 \log \frac{(\gamma_{HCl})_1^{x}}{(\gamma_{HCl})_p^{x}} \quad [6]$$

for the unbuffered and buffered half-cells, respectively.

When m_H is negligible compared to m_{HR} and m_{MR}, the ionic strength remains constant in the x compartment. The effect of pressure on γ_{HCl} is small

$$\left[\log \frac{(\gamma_{HCl})_{1000}}{(\gamma_{HCl})_1} = 0.003 \text{ in HCl } 0.1\text{M } (5) \right]$$

and as a first approximation one can neglect the terms containing γ_{HCl} which cancel each other at infinite dilution of the weak electrolyte because of the symmetry of the cells.

Equations [5] and [6] then simplify to

$$2(E_1 - E_p)\mathbf{F}/2.3RT = \log \frac{K_p}{K_1} + 2 \log \frac{(\gamma_A)_1}{(\gamma_A)_p} = \log \frac{k_p'}{k_1'} \quad [7]$$

and

$$(E_1 - E_p)\mathbf{F}/2.3RT = \log \frac{K_p}{K_1} + 2 \log \frac{(\gamma_A)_1}{(\gamma_A)_p} = \log \frac{k_p'}{k_1'} \quad [8]$$

for the unbuffered and buffered half-cells, respectively.

The primes indicate that log k' is only known with approximation. The choice of the best suited concentration scales to eliminate log $(\gamma_{A1}/\gamma_{Ap})$ by extrapolation to zero concentration of both weak electrolyte and KCl, is based on the following considerations.

Activity coefficients and pressure are related by the well-known equation

$$\left(\frac{\partial \ln \gamma}{\partial p} \right)_{m,T} = \frac{\overline{V}_2 - \overline{V}_2^\circ}{RT} \quad [9]$$

where $\overline{V}_2$ and $\overline{V}_2^\circ$ are the partial molal volumes of the solute (subscript 2), respectively, at any concentration m, and in the standard state (unit activity, or at infinite dilution in the pure solvent). Integration of [9] yields the simplified relation (5)

$$\log \gamma_p = \log \gamma_1 + C(p-1)\sqrt{m d_o} \quad [10]$$

in which C is a constant and d_o the density of water.

Infinite dilution in 0.1M KCl (cell 1), 0.01M KCl (cell 2), and 0.001M KCl (cell 3) can be used to define three other reference states and for each medium the partial molal volumes in the standard state will be shifted in first approximation, according to Eq. [11] (6).

$$^{KCl}\overline{V}_2^\circ = \overline{V}_2^\circ + A_V \sqrt{2d_o}\sqrt{\mu} \quad [11]$$

where A_V is a constant.

It follows that extrapolation of $E_1 - E_p$ (Eq. [7] and [8]) on the $\sqrt{m}$ scale will yield values of log K_p/K_1 corresponding to each auxiliary reference state. Equations [1], [9], and [11] show that subsequent extrapolation on the $\sqrt{\mu}$ scale to zero KCl concentration will give log K_p/K_1 in pure water. Further, it is to be expected, if p is not too great, that the two extrapolations will be linear.

When m_H is not negligible, it is practical to calculate m_H' from Eq. [2] using γ_{HCl} values corresponding to the ionic strength at pressure 1 and p. The prime indicates the approximation introduced by the fact that the effect of pressure on the activity coefficient is neglected and that it is assumed that γ_{HCl} in KCl or NaCl is not affected by the weak electrolyte. The values used for γ_{HCl} are taken from Harned and Owen (7). $(m_H')_{1,p}$ is used to calculate $(\log k' - A\sqrt{\mu'})_{1,p}$ from Eq. [3] and [4], again neglecting the effect of pressure on the constant A, which is close to unity.

$(-\log k' + \sqrt{\mu'})_p - (-\log k' + \sqrt{\mu'})_1 = \Delta pK'$, or log k_1'/k_p' is then calculated and can be used for the double extrapolation on the $\sqrt{m}$ and $\sqrt{\mu}$ scales as above.

An alternative consists in twice extrapolating, either $(-\log k' + \sqrt{\mu'})$ or $-\log k' + A\sqrt{\mu'} \pm B\mu'$ or simply, log k', at pressures 1 and p, on the best suited concentrations scale ($\sqrt{\mu}$ or μ) depending on the nature of the electrolyte.

Since the effect of pressure on the activity coefficients is neglected in the calculations, it can be deduced from the difference between the slopes of the extrapolated functions. If needed, the corrected activity coefficients can be used to calculate the ionization functions k (Eq. [3] and [4]) with more accuracy, which in turn will lead to a more precise knowledge of K after a second double extrapolation.

The volumes change on ionization at infinite dilution, (ΔV_1°), is calculated from the slope of a graph of log K_p/K_1 *vs.* pressure at 1 atm (Eq. [1]).

When simplified Eq. [7] and [8] are valid, ΔV_1 values can be read from the slope of $E_1 - E_p = f(p)$ at 1 atm and yield ΔV_1° by double extrapolation.

It is easy to show (2) that $\Delta V_1 = 1.016 \times (E_1 - {}^*E_{1000})$ if V is expressed in cm^3 mole^{-1}, E in millivolts, p in kg cm^{-2}.

*E_{1000} is measured on the tangent of $(E_1 - E_p) = f(p)$ drawn through $p = 1$. In most cases $(E_1 - E_p)$ is a linear function of p up to 1000 kg cm^{-2} and therefore the values for log $K'_{1000}/K_1' = \Delta pK'$ or simply the direct experimental emf shift $(E_1 - E_{1000})$ can be used to extrapolate. In practice, for the media investigated, it was found that whenever $(E_1 - E_p) = f(p)$ graphs displayed some slight curvature, the tangent through $p = 1$ safely could be drawn through E_p at $p = 500$ kg cm^{-2}, with $\Delta V_1 = 2 \times 2.1016 \times (E_1 - E_{500})$ if the effect of dissociation of the weak electrolyte can be neglected.

Corning 015 glass membranes give the correct hydrogen electrode constant, 2.3 $RT/\mathbf{F} \pm 1$ mv or 2%, independently of pressure, the uncertainty being within the limits of the experimental errors.

Results

Acetic acid and acetate buffer.—Figure 1 gives $2\mathbf{F}/2.3RT\ (E_1 - E_p) = \Delta pk' = \log k_p'/k_1'$ $(p = 500$ kg cm$^{-2})$

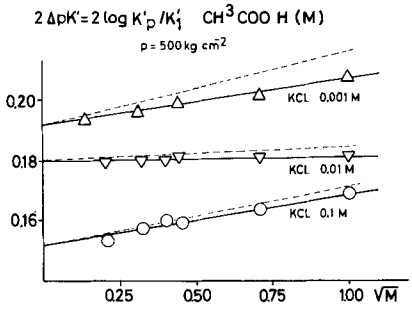

Fig. 1. Acetic acid in KCl 0.1, 0.01 and 0.001M KCl. Extrapolation of log k_p'/k_1' and log K_p'/K_1' to zero acetic acid concentration. Solid lines, log k_p'/k_1' (eq. [7]); dotted lines, $-\log k_p' + \sqrt{\mu_p'} + \log k_1' - \sqrt{\mu_1'} = \Delta pK'$ (eq. [2] and [3]).

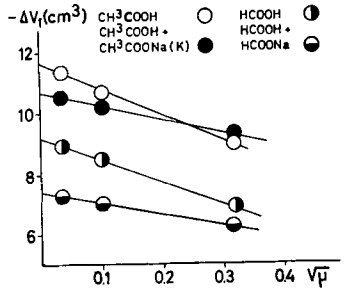

Fig. 2. Extrapolation of $-\Delta V_1$ (cm^3 mole^{-1}) to zero KCl concentration for acetic acid, acetate buffer, formic acid, and formate buffer.

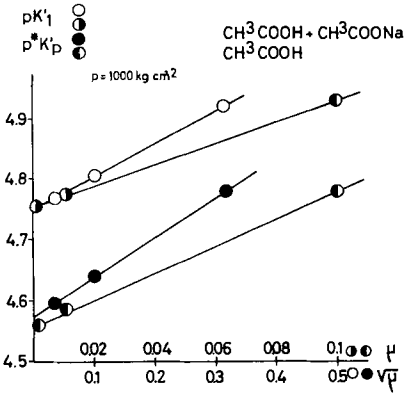

Fig. 3. Extrapolation of pK_1' and pK_p' values obtained at zero acetic acid and acetate buffer concentration, to zero KCl concentration; μ scale, acetic acid; $\sqrt{\mu}$ scale, acetate buffer. p^*K_p' at 1000 kg cm^{-2} is calculated from the slope of $(E_1 - E_p) = f(p)$ at 1 atm for acetic acid; $p^*K_p' = pK'_{1000}$ for acetate buffer where $(E_1 - E_p) = f(p)$ is linear.

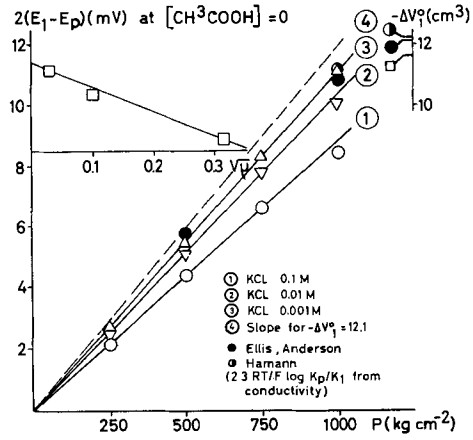

Fig. 4. 2 $(E_1 - E_p) = 2.3\ RT/F \log k_p'/k_1' = f(p)$ at zero acetic acid concentration, in 0.1, 0.01, and 0.001M KCl. Inserts: extrapolation of 2 $(E_1 - E_p)$ to zero KCl concentration and corresponding $-\Delta V_1°$ value (11.6 cm^3 mole^{-1}). 2.3 $RT/F \log K_p/K_1$ and $\Delta V_1°$ from conductivity data [Ellis and Anderson (8); Hamann (9, 10)] are indicated together with the limiting slope of 2 $(E_1 - E_p) = f(p)$ for $-\Delta V_1° = 12.1$.

for acetic acid solutions as a function of $\sqrt{m}$ (Eq. [7]; $2 \times \Delta pK'$ is taken as ordinate to facilitate comparison with Fig. 5 for acetate buffer and for simplicity the symbol K' is used instead of k'). Corresponding values of ΔV_1 at $[CH_3COOH] = 0$ are extrapolated to $[KCl] = 0$ in Fig. 2, which gives $-\Delta V_1° = 11.6$ cm^3.

The slope of the extrapolated function depends both on the ionic strength and the undissociated acid concentration. This explains the difference between the slope for 0.01M KCl and that observed for 0.1M and 0.001M KCl.

A more elaborate treatment (Eq. [2] and [3]) where $pK' = -\log k' + \sqrt{\mu'}$ is first extrapolated on the μ scale to $\mu = 0.1$, 0.01, and 0.001, and then (Fig. 3) to $[KCl] = 0$ on the $\sqrt{\mu}$ scale, yields $-\Delta V_1° = 11.5$ cm^3 mole^{-1}. The * sign of p^*K_p in Fig. 3 denotes that the dissociation constant at $p = 1000$ kg cm^{-2} is calculated from $2 \times 2\ (E_1 - E_{500})$ values (see page 351). The dotted lines in Fig. 1 represent $-\log k_p' + \sqrt{\mu_p'} + \log k_1' - \sqrt{\mu_1'} = \Delta pK'$ derived from these more complicated calculations which give the same result as the simple treatment used to draw the solid lines.

Figure 4 shows $2(E_1 - E_p) = f(p)$ (Eq. [7]) at $[CH_3COOH] = 0$ in KCl 0.1M, 0.01M, and 0.001M, where the $(E_1 - E_p)$ values were obtained from extrapolations of the emf readings on the $\sqrt{m}$ scale at $p = 250$, 500, 750, and 1000 kg cm^{-2}.

The curvature in $2(E_1 - E_p) = f(p)$ is apparent at $p = 1000$ kg cm^{-2} but only in 0.1 and 0.01M KCl. The extrapolation at $[KCl] = 0$ is also given on Fig. 4 and the corresponding $-\Delta V_1°$ value is 11.6 cm^3 mole^{-1}.

This figure is in agreement with our previous preliminary determinations (2) and in reasonable agreement with density and conductivity data (Table I).

The $-\Delta V_1°$ values, published by Ellis and Anderson (8) for $p = 1$, $p = 500$, $p = 1000$ kg cm^{-2} and by Hamann and Strauss (9) for $p = 1$ and $p = 1000$ kg cm^{-2} are indicated on Fig. 4 either in cm^3 mole^{-1} or converted into emf values, together with the limiting slope corresponding to $-\Delta V_1° = 12.1$ cm^3 mole^{-1} (8).

It is clearly seen that the main difference between the conductivity data and our determinations lies in the estimation of the curvature of $2(E_1 - E_p) = f(p) = 2.3RT/\mathbf{F} \log k_p'/k_1'$.

In a buffer containing equal molalities of acetic acid and sodium acetate, $E_1 - E_p$ is a linear function of p up to 1000 kg cm^{-2} at all the KCl concentrations investigated. $(E_1 - E_{1000})$ together with $\Delta pK' = \log K_{1000}'/K_1'$ is given in Fig. 5 as a function of the square root of the total salt and acid concentrations.

The drop of $(E_1 - E_{1000})$ at high dilutions shows that Eq. [7] is no longer valid, and that it is necessary to take the dissociation of acetic acid into account (Eq. [4]) to get the correct values for $\Delta pK' = -\log k_1' + \sqrt{\mu_1'} + \log k_p' - \sqrt{\mu_p'}$.

Extrapolation on the $\sqrt{\mu}$ scale is given in Fig. 2 and shows that $-\Delta V_1° = 10.7$ cm^3 mole^{-1} which agrees with our previous determinations (2) but is 0.9 cm^3 smaller than $-\Delta V_1°$ in acetic acid solutions.

Extrapolation of $-\log k' + \sqrt{\mu'}$ at $p = 1$ and $p = 1000$ kg cm^{-2} first on the μ scale to zero buffer concentration and then to $[KCl] = 0$ on the $\sqrt{\mu}$ scale (Fig. 3), gives identical results. No difference was found with potassium acetate or when the buffer ratio MR/HR is reduced to 1/8.

The value of pK_1 in the unbuffered cell is 4.76, and 4.75 when the buffer is used, in agreement with the results obtained by Hamann (9, 10) (4.77), and by Ellis and Anderson (8) (4.75) from their conductivity determinations. (The extrapolation line for acetate buffer in Fig. 3 has been shifted 0.01 pK unit to coincide with the data for acetic acid, to better show the difference of the effect of pressure).

Formic acid and formate.—Formic acid has been extensively studied in a previous paper (2) from which

[1] Average values taken from Distèche (2) multiplied by the factor 1.016 (see page 35) which was neglected in the 1962 paper.
[2] $\Delta V_1 = -24.1$ cm^3 mole^{-1} is reported from dilatometric experiments by Linderstrom-Lang and Jacobsen (11).

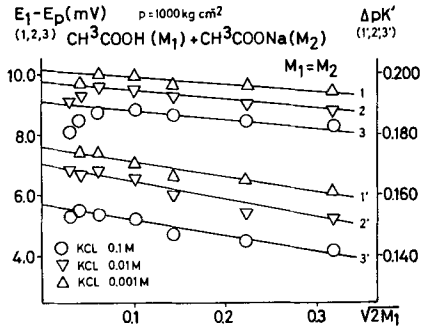

Fig. 5. Acetate buffer in 0.1, 0.01, and 0.001M KCl. 1, 2, 3: $(E_1 - E_p) = 2.3\ RT/F \log k_p'/k_1'$ as a function of the total acetate and acetic acid concentration. 1', 2', 3': extrapolation of $\Delta_pK' = -\log k_1' + \sqrt{\mu_1'} \log k_p' - \sqrt{\mu_p'}$ (Eq. [2] and [4]) to zero buffer concentration.

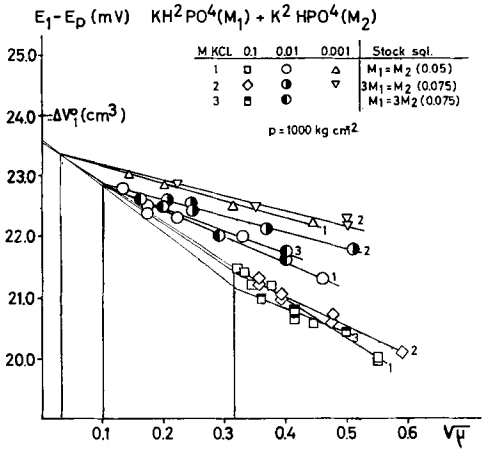

Fig. 6. Phosphate buffer $K_{(2)}$ in 0.1, 0.01, and 0.001M KCl. Extrapolation of $(E_1 - E_p) = 2.3\ RT/F \log k_p'/k_1'$ to zero KCl and buffer concentration at three different buffer ratios; $-\Delta V_1^\circ = 24.0$ cm^3 mole^{-1}.

we take the necessary data to extrapolate $-\Delta V_1$ to [KCl] = 0 on the $\sqrt{\mu}$ scale as shown in Fig. 2. $-\Delta V_1^\circ = 9.2$ cm^3 mole^{-1} in fairly good agreement with the conductivity determinations (Table I) [8.8 cm^3 mole^{-1}, Hamann (10)]. Data for formate buffer, treated in the same way as the acetate buffer, yield $-\Delta V_1 = 7.4$ cm^3 mole^{-1} (Fig. 2).

It is seen on this same figure that the curves for acetic acid and formic acid, for acetate buffer and for formate buffer, run nearly parallel with each other.

Phosphate buffer (2nd step).—In Fig. 6, the results obtained for three different buffer ratios are plotted on the $\sqrt{\mu}$ scale and the double extrapolation leads without any difficulty to $-\Delta V_1^\circ = 24.0$ cm^3 mole^{-1}, which is to be preferred to a preliminary estimate, 23.4 cm^3 mole^{-1}, published in 1962.

Density measurements predict $-\Delta V_1^\circ = 28.1$ cm^3 mole^{-1} (14) but dilatometric experiments by Linderstrom-Lang and Jacobsen [see ref. (11)] give 24.1 cm^3 mole^{-1}.

Adenosine triphosphate and phosphorylcreatine.—Figure 7 indicates that $-\Delta V_1^\circ$ (24.0 cm^3 mole^{-1}) is the same in phosphate buffer and in ATP solutions at pH = 7.0, the double extrapolation being done on the $\sqrt{m}$ and $\sqrt{\mu}$ scales. A slightly smaller value is obtained if both extrapolations are made on the $\sqrt{\mu}$ scale (dotted line).

Figure 8 shows the corresponding results for phosphorylcreatine. $-\Delta V_1^\circ = 21.2$ cm^3 mole^{-1} and is considerably smaller than the volume change observed for phosphate buffer ($K_{(2)}$) and ATP.

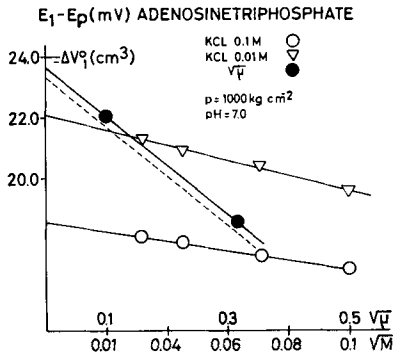

Fig. 7. Adenosinetriphosphate in 0.1 and 0.01M KCl. Extrapolation of $(E_1 - E_p) = 2.3\ RT/F \log k_p'/k_1'$ to zero ATP concentration ($\sqrt{m}$ scale) and to zero KCl concentration ($\sqrt{\mu}$ scale); $-\Delta V_1^\circ = 24.0$ cm^3 mole^{-1}. Dotted lines, both extrapolations are made on the $\sqrt{\mu}$ scale.

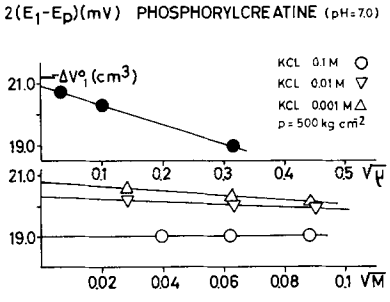

Fig. 8. Phosphorylcreatine in 0.1, 0.01, and 0.001M KCl. Extrapolation of 2 $(E_1 - E_p) = 2 \times 2.3\ RT/F \log k_p'/k_1'$ to zero phosphorylcreatine concentration (lower curves) and to zero KCl concentration (upper curve); $-\Delta V_1^\circ = 21.2$ cm^3 mole^{-1}.

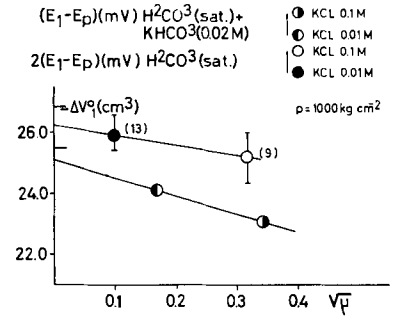

Fig. 9. Extrapolation of 2 $(E_1 - E_p) = 2.3\ RT/F = \log k_p'/k_1'$ for carbonic acid (saturated solution) and $(E_1 - E_p) = 2.3\ RT/F \log k_p'/k_1'$ for bicarbonate buffer (H_2CO_3 sat. + 0.02M $KHCO_3$) to zero ionic strength; $-\Delta V_1^\circ = 26.6$ cm^3 mole^{-1} and 25.5 cm^3 mole^{-1}. The circles on the upper curve represent average values derived from 13 and 9 determinations in 0.01M KCl and 0.1M KCl respectively; the horizontal lines indicate the highest and lowest values.

The ΔV values are calculated from readings at 500 kg cm^{-2} because of the rather marked curvature of the $(E_1 - E_p) = f(p)$ curve.

Control analysis before and after a pressure run failed to indicate any hydrolysis.

It is well known (12) that the $pK_{(2)}$ of phosphoric acid in phosphorylcreatine is strongly affected by the methylguanidinium group, its value being 4.6 instead of 7.2. The difference observed for ΔV_1° is related to this phenomenon insofar as it is related to the ionic solvation energy difference between H_3PO_4 and its ester.

Carbonic acid and bicarbonate buffer.—Our previous determinations of ΔV_1 for carbonic acid in 0.1M KCl (1) gave values as high as 31.0 and 32.3 cm^3 mole^{-1}, but only 22.8-23.9 cm^3 mole^{-1} for the bicarbonate buf-

fer (values corrected for the asymmetry due to KCl when 0.1M HCl is used as reference half-cell). Density data (6) predict 29.0 cm^3 $mole^{-1}$ and conductivity data give 26.5 cm^3 $mole^{-1}$ (13).

Experimental difficulties were encountered especially with carbonic acid solutions, the pH of which shows long-term instability under pressure. The curves giving $(E_1 - E_p) = f(p)$ were constructed from readings taken immediately after quick pressure steps separated by long intervals.

The same problems were met with at the start of the new determinations. Later, however, it was found that stable readings can be obtained provided the silicone oil used in the glass electrode cell is saturated with CO_2 as well as the aqueous solutions and the cell filled from pipettes where the gas phase is pure CO_2. These precautions limit the possibility of CO_2 exchanges between both liquid phases and the escape of CO_2 in the pressure bomb or elsewhere.

The circles on the upper curve of Fig. 9 correspond to the average value of, respectively, 9 and 13 determinations in 0.1M KCl and 0.01M KCl saturated with CO_2.

Extrapolation at $\sqrt{\mu} = 0$ gives $-\Delta V_1^\circ = 26.6$ cm^3 cm^{-3} in agreement with the conductivity experiments.

Bicarbonate buffer containing 0.02M $KHCO_3$ was tested in the same way. The results show very much less dispersion, are in reasonable agreement with our previous determinations, and yield on extrapolation $-\Delta V_1^\circ = 25.5$ cm^3 $mole^{-1}$.

Extrapolation at zero buffer concentration was not tried in this case because of the difficulty of maintaining the buffer ratio constant. The effect of H_2CO_3 on log K_p'/K_1', however, is small (5) compared to the effect of the ionic strength, so that it seems safe to extrapolate.

Discussion

Table I summarizes the ΔV_1° determinations made with a glass electrode cell compared with the data from density and conductivity measurements.

The agreement with conductivity data is fairly good for acetic, formic, and carbonic acid, but the value found for H_3PO_4 from emf measurements is about 2 cm^3 higher. It should be noticed that H_3PO_4 is highly dissociated in diluted solutions which means relatively small pH shifts for large $\Delta pK'$ changes when pressure is applied. This makes ΔV calculations much more sensitive to experimental errors. The ΔV found for phosphate buffer $K_{(1)}$ is in close agreement with the conductivity determinations, but this might be fortuitous since we notice that systematically ΔV values for buffers, from pH measurements, are smaller than the values obtained for pure acid solutions.

The difference is much larger than possible experimental errors: 0.9, 1.8, 2.0, 1.1 cm^3 for acetate, formate, phosphate $K_{(1)}$, and bicarbonate buffer, respectively.

The difference is identical with Na or K salts. This practically eliminates the possibility of an error due to asymmetry in cation composition between the cell compartments since the reference half-cell always contains KCl except for the experiments in 0.001M KCl where the effect of KCl is negligible. However, the cell cannot be made symmetrical with respect to anions. Though it seems rather unlikely, these could be adsorbed on the glass membrane and cause errors in the buffer measurements.

pK values are difficult to determine with precision when dissociation is appreciable and it is known that, for example, the data for phosphoric acid $K_{(1)}$ buffer at different buffer ratios extrapolate to different values of log K depending on the choice of the function to estimate the activity coefficients (17). It can however be shown that a change of the activity coefficients used to calculate m_H shifts both K_p and K_1 and has but little effect on log K_p/K_1 for phosphoric acid, phosphate buffer $K_{(1)}$, and formic acid. For acetic acid, acetate buffer and formate buffer m_H is small except at very high dilutions and can be completely neglected for carbonic acid and bicarbonate buffer.

The fact that the observed differences exist even at infinite dilution eliminates as explanation all the effects which affect the activity coefficients: ionic associations, uncomplete dissociations, salting in and out effects, etc., unless one admits that some of these effects only disappear at extreme dilutions where emf measurements become impossible.

More experiments on, for example, acetate buffer, covering a very wide range of buffer ratios, perhaps will throw more light on this unsolved problem.

Acknowledgment

The authors wish to express their gratitude to Dr. S. D. Hamann, Dr. R. G. Bates, and Professor B. B. Owen, for helpful criticism of the manuscript.

Manuscript received July 27, 1964; revised manuscript received Oct. 27, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

Electrochemical Oxidation of Certain Hydrocarbons and Carbon Monoxide in Dilute Sulfuric Acid

H. Binder, A. Köhling, H. Krupp, K. Richter, and G. Sandstede

Battelle-Institut e.V., Frankfurt(Main), Germany

ABSTRACT

For the hydrocarbons methane through heptane, ethylene, and carbon monoxide anodic potential/current density curves were measured in a galvanostatic half-cell arrangement. Raney platinum proved to be an active catalyst for the conversion of the hydrocarbons. In $3N$ H_2SO_4 at 100°C a stationary current density of 200 ma/cm² was measured for ethane, propane, butane, ethylene, and carbon monoxide, and 100 ma/cm² for methane and pentane. By coulometric analyses the conversion of methane, ethane, and propane to CO_2 was found to be 100%. Complete conversion of butane, pentane, hexane, and heptane apparently requires conditions different from those employed here. In $5N$ H_2SO_4 potential oscillations with time were observed, which were caused by partial poisoning of the electrode on reduction of H_2SO_4 to H_2S and the subsequent self-regeneration of the electrode.

Experiments made at several laboratories (1-8) during the last few years have shown that a variety of hydrocarbons are anodically oxidized in acids and alkalies at temperatures below 100°C and potentials far below the oxygen potential. However, the current densities achieved were very small compared with those obtained on use of hydrogen. For this reason experiments were carried out at working temperatures of up to 200°C (9-12), and a current density of about 200 ma/cm² was obtained in phosphoric acid (11). It is, of course, advantageous to use an electrolyte which does not dissolve the carbon dioxide produced during the reaction. Such an electrolyte is preferably an acid one. At atmospheric pressure and temperatures above 100°C the concentration of, in particular, sulfuric acid is so large that it cannot be used as electrolyte, since it is reduced at such temperatures.

We used Raney platinum metals as fuel cell catalysts (13, 14) at first in the electrochemical combustion of methanol. It was found in further experiments (15, 16) that, in the presence of a Raney platinum catalyst, the derivatives of the saturated hydrocarbons with one to three carbon atoms per molecule, alcohols, aldehydes, and carboxylic acids, are completely converted to CO_2 in $5N$ H_2SO_4 at 80°C. Subsequent investigations were concerned with the conditions at which both hydrocarbons and carbon monoxide can be electrochemically oxidized in sulfuric acid and, for comparison, also in phosphoric acid. In the experiments with the fuels discussed here the anodic potential/current density curves were measured in a galvanostatic half-cell arrangement. Furthermore, coulometric analyses were carried out.

Half-Cell Arrangement

Figure 1 shows the measuring setup for the galvanostatic measurements. The gaseous fuel flows through the porous electrode. Thus the electrodes were tested as bubble electrodes, and only a distinct proportion of the passing fuel was oxidized. The electrodes operated at a gas pressure of about 1.5 atm. The disk-shaped porous test electrode is fixed in a holder of polypropylene providing the gas supply. It is supported at its edge by a Viton gasket, to which it is pressed by means of a cap nut. The electric contact is made by means of two springy insulated wires of platinum-iridium; one of them is designed as a current lead, the other for potential measurements.

The potential of the test electrode was measured by means of a Luggin capillary against a hydrogen electrode kept in the same solution at the same temperature. This reference electrode is an autogenous hydrogen electrode. It consists of a Raney platinum electrode, suspended by a platinum wire, at which hydrogen is evolved electrolytically at a cathodic current density of about 1 ma/cm², another platinum wire forming the anode. At this current density the overvoltage for hydrogen evolution is negligibly small, so that the potential equals the reversible hydrogen potential. For every solution and temperature employed this potential is assumed to be zero.

The counterelectrode, a platinum wire, is contained in a separate vessel joined by a liquid junction. Thus, cathodic reaction products are prevented from reaching the anode.

The anode vessel is closed by means of a ground cover with attached reflux condenser.

The test electrode was subjected to a constant current load, and the potential was recorded. The first reading for every set of conditions was taken after 24 hr of operation; subsequent readings were taken at intervals of about 2 hr each.

Electrodes and Reactants

The electrodes were prepared in the form of porous disks by compacting a mixture of gold powder, forming the electrode skeleton, and powdered Raney platinum aluminum alloy at a pressure of 10^9 dyne/cm². Subsequently, the aluminum of the Raney alloy was dissolved by treating the disk first with dilute KOH solution and then with $7N$ KOH, finally at a temperature of 90°C. These test electrodes were 13 mm in diameter and about 1 mm in thickness. They contained about 180 mg of Raney platinum per square centimeter of geometric surface area.

The Raney platinum alloy was $PtAl_4$. It was prepared by heating an intimate mixture of platinum and aluminum powder in the form of a compacted disk.

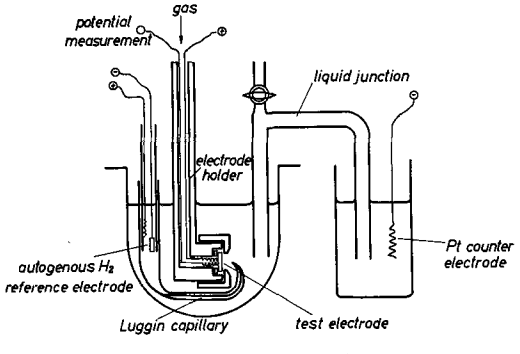

Fig. 1. Half-cell arrangement for galvanostatic measurement with a gas electrode.

The resulting regulus of the alloy was powdered and the 10-25μ size fraction was used for the test electrode in an amount of 60% by volume together with the <60μ size fraction of gold powder which amounted to 40% by volume.

The purity of the gases involved was 99.5 mole %. Technical grade propane was used for reference. The liquid hydrocarbons pentane, hexane, heptane were kept in an evaporator, which was placed on top of the electrode support by means of a short connection tube. The evaporator was heated by a jacket which permitted adjustment of temperatures at which the vapor pressure of the liquid hydrocarbon reached the operating pressure of the electrode (approximately 1.5 atm). In this way the pure hydrocarbon vapor was passed through the electrode.

Experiments in 5N H_2SO_4

The galvanostatic anodic oxidation of propane at the Raney platinum electrode in 5N H_2SO_4 at 100°C failed to yield stationary potentials. At a current density of 50 ma/cm² a potential of 350 mv was measured after a few hours. In the course of several days the potential rose to about 900 mv and then increased more rapidly until the evolution of O_2 started. The electrode could, however, be regenerated by the evolution of O_2 and subsequent cathodic reduction of the oxygen surface layer.

If the current density is reduced to 30 ma/cm², the electrode is capable of self-regeneration. As illustrated in Fig. 2, oscillations of the potential with time are observed. The potential increases within 10-15 hr to about 550 mv, and in the next 30 min rises by some further 150 mv, then remains constant for about 2 hr, and finally drops to about 400 mv within a few minutes. This process recurs periodically. The probable source of these oscillations is seen in a blocking of the electrode surface by a sulfur layer rather than by the oxidation products of propane. In the anodic oxidation of a hydrocarbon water is consumed according to the equation

$$C_nH_{2n+2} + 2n\ H_2O = n\ CO_2 + (6n + 2)\ H^+ + (6n + 2)\ e^-$$

Hence, the sulfuric acid is concentrating in the pores of the electrode and is then reduced by the hydrocarbons. Following the increase in the potential, the sulfur is oxidized and, consequently, the surface of the catalyst is decontaminated.

On use of hydrogen and carbon monoxide in 5N H_2SO_4, gaseous H_2S is formed on the Raney platinum catalyst at 100°C. These reducing agents are so powerful that even 5N H_2SO_4 is reduced. The catalyst is poisoned at open circuit, and the rest potential increases.

Potential Current Density Plots in 3N H_2SO_4

The evolution of H_2S observed in 5N H_2SO_4 at 100°C is avoided if the concentration of the sulfuric acid is reduced. In 3N H_2SO_4 at 100°C H_2S is no longer formed even with carbon monoxide fuel except by selecting a very large flow rate of the gas. The potentials remain constant. At this concentration oscillation of the potentials during the oxidation of the hydrocarbons is no longer encountered.

Table I. Reversible potentials at 100°C and rest potentials of a Raney platinum electrode in 3N H_2SO_4 at 100°C

Fuel	Rev. pot., mv	Rest pot., mv

C_7H_{16}	78	150

Table II. Degree of conversion of some alkanes to CO_2 in 3N H_2SO_4 at 90°C

Reactant	Potential, mv	ψ_{CO_2}, %
CH_4	380	100.2
	620	100.1
C_2H_6	450	99.8
	550	100.5
C_3H_8	320	100.5
	450	99.5
C_4H_{10}	460	101.3
	550	100.8

Table I depicts the rest potentials measured in 3N H_2SO_4 at 100°C, along with the reversible potentials at 100°C calculated from the thermodynamic data. The reversible oxygen potential at 100°C amounts to 1166 mv.

The rest potential of carbon monoxide is larger than the reversible potential. The fact that carbon monoxide yields the hydrogen potential suggests that this compound reacts with water to give carbon dioxide and hydrogen.

The rest potential of ethylene is much larger than the reversible potential, in contrast to saturated hydrocarbons where the variation of the rest potential from the reversible potential is relatively small.

In the case of methane the rest potential closely approximates the reversible potential, but it is unlikely that we should be dealing with a "reversible methane electrode" rather than with a mixed potential.

The stationary potential/current density curves measured with the Raney platinum electrode in 3N H_2SO_4 at 100°C are depicted in Fig. 3 and 4. Carbon monoxide yields a linear characteristic. Its slope is somewhat larger than in the case of hydrogen. Hydrocarbons, too, furnish linear characteristics, except at small current densities where the slope increases towards zero current.

On use of methane the potential is still steady with time at as large a current density as 150 ma/cm². At larger current densities the potential increases with time, since a chemisorbed layer of oxygen starts forming on the platinum surface at potentials above, say, 800 mv. Polarization in the case of methane slightly

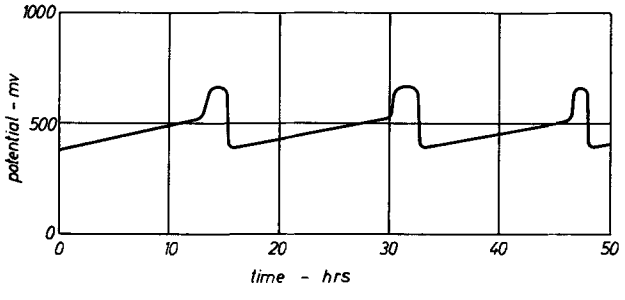

Fig. 2. Potential-time plot of a Raney platinum electrode with propane in 5N H_2SO_4 at 100°C.

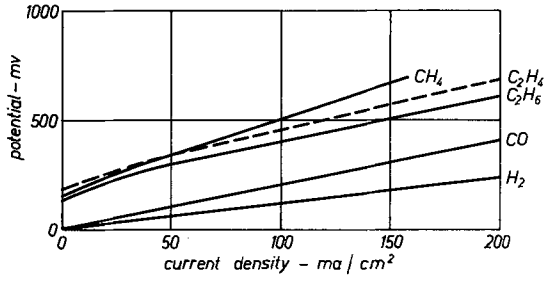

Fig. 3. Potential/current density plots of a Raney platinum electrode with methane, ethane, ethylene, carbon monoxide, and hydrogen in 3N H_2SO_4 at 100°C.

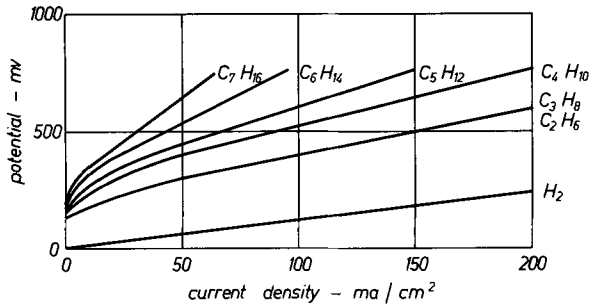

Fig. 4. Potential/current density plots of a Raney platinum electrode with saturated hydrocarbons (and hydrogen for reference) in 3*N* H_2SO_4 at 100°C.

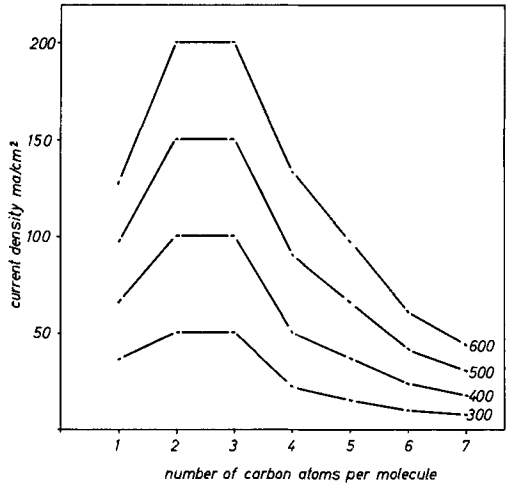

Fig. 5. Current density of a Raney platinum electrode with alkanes in 3*N* H_2SO_4 at 100°C vs. the number of carbon atoms per molecule with the potential as a parameter.

exceeds that with ethane; this is plausible on account of the high thermodynamic stability of the methane molecule. Ethylene likewise leads to a larger polarization than ethane, which, on the basis of the available evidence, may be attributed to rather stable sorbate/catalyst bonds. With ethylene the limiting current density is larger than 300 ma/cm² and the limiting potential larger than 1000 mv.

As is evident from Fig. 4, a stationary current density of at least 200 ma/cm² is obtained with ethane, propane, and butane in the presence of Raney platinum catalyst. If we want to compare the anodic polarization of hydrocarbons with that of hydrogen it should be noted that the reversible potential (cf. Table I) has to be subtracted from the hydrocarbon values, *e.g.*, 85 mv in the case of propane. With increasing chain length of the saturated hydrocarbons the slope ($\Delta\psi/\Delta i$) of the potential/current density

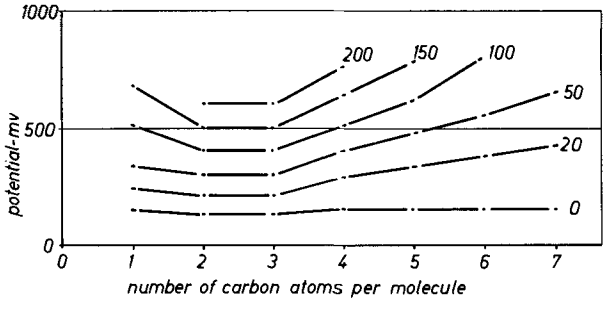

Fig. 6. Potential of a Raney platinum electrode with alkanes in 3*N* H_2SO_4 at 100°C vs. the number of carbon atoms per molecule with the current density (ma/cm²) as a parameter.

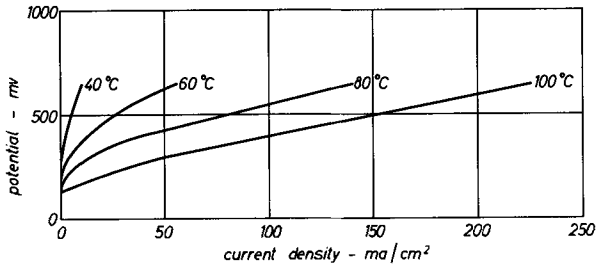

Fig. 7. Potential/current density plots of a Raney platinum electrode with propane in 3*N* H_2SO_4 with the temperature as a parameter.

curve at a given current density increases too. The limiting current density decreases correspondingly. Methane is an exception; with methane the slope is somewhat larger than that with ethane (*cf.* Fig. 3).

The effect of the chain length and hence of the number of carbon atoms per molecule on the oxidation rate is depicted in Fig. 5 and 6. When changing from methane to ethane, the current density increases at a given potential, then remains constant if an additional carbon atom is added and finally drops as the chain length grows.

In Fig. 6 the current density is used as a parameter. It is noted that the potential shows a minimum in the case of ethane and propane. The same applies to the rest potential. The limiting potential is found at about 800 mv. Above this potential a chemisorbed oxygen layer is formed on platinum in sulfuric acid if other substances are absent.

Temperature Dependence of Propane Oxidation

Figure 7 shows potential/current density plots of a Raney platinum electrode with propane in 3*N* H_2SO_4 at various temperatures. There is a marked increase in polarization with falling temperature. At 60°C the potential is 450 mv at a current density of 20 ma/cm², whereas its value drops to 200 mv at 100°C.

A plot of the current density *vs.* the temperature is depicted in Fig. 8, the potential being 500 mv. At 40°C the current density is as small as 5 ma/cm², but strongly rises with increasing temperature to a total of 140 ma/cm² at 100°C.

Replacement of pure propane by technical grade propane at 100°C likewise yields stationary potentials which are only slightly above those of pure propane. Hence, the electrode is not poisoned by possible common contaminations.

Coulometric Analysis

In order to determine the degree of conversion of the hydrocarbons in the anodic oxidation, the carbon dioxide evolved by the reaction was collected and weighed. The quantity of electricity involved was

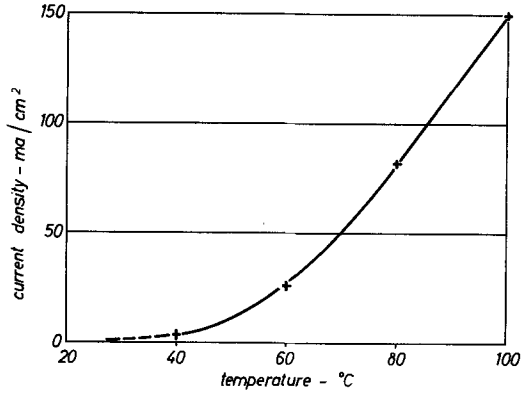

Fig. 8. Current density of a Raney platinum electrode with propane in 3*N* H_2SO_4 vs. the temperature at a potential of 500 mv.

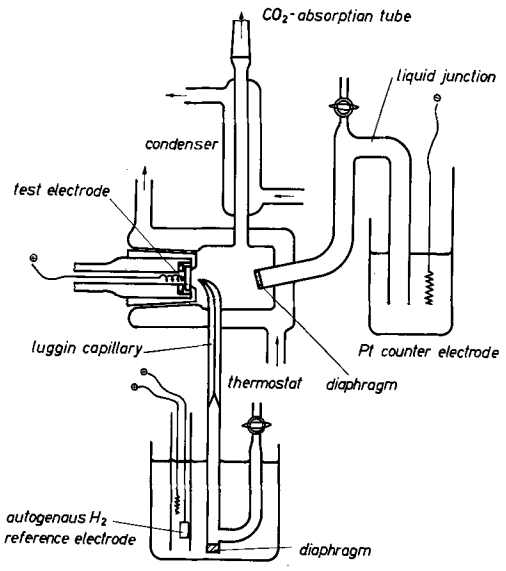

Fig. 9. Apparatus for coulometric analysis with a gas electrode

measured simultaneously. The glass apparatus used in these experiments, again a half-cell arrangement, is shown in Fig. 9. The electrolyte volume in this case is kept as small as possible in order to minimize both the dissolved quantity of gas and the stay period of the gas while passed through the apparatus. This allows the effect of minor variations of flow rate and temperature on the measuring result to be neglected.

The holder for the Raney platinum electrode consists of polypropylene and is provided with a ground section for connecting it to the glass vessel. The vessel is provided with a jacket through which the thermostat liquid flows. The counterelectrode is located in a second vessel which is separated from the anode compartment by a diaphragm in order to avoid undesired reactions. The reference electrode, again an autogenous hydrogen electrode, is contained in a separate tube which is connected to the reaction vessel via a capillary tube.

The escaping gas flows through a small condenser into a tube filled with phosphorus pentoxide and finally reaches a tube packed with NaOH-asbestos for absorption of the carbon dioxide. The flow rate was adjusted such that about 10% of the gas was converted.

The experiments were performed at constant potential. Methane, ethane, propane, butane in $3N$ H_2SO_4 were used at 90°C. The degree of conversion ψ_{CO_2} is derived from the measured quantity m_{exp} of CO_2 and the quantity m_{calc} of CO_2 calculated from the reaction equation and the quantity of electricity involved, as follows

$$\psi_{CO_2} = \frac{m_{exp}}{m_{calc}} 100\%$$

The results are summarized in Table II.

As Table II indicates, the degree of conversion of methane, ethane, and propane is 100%, within the limit of error. Hence, no by-products are formed in the electrochemical oxidation of these hydrocarbons under the conditions applied. This result was obtained at potentials involved in fuel cells.

The complete conversion to CO_2 suggests that all intermediates remain chemisorbed at the catalyst surface. Thus, the hydrocarbon is adsorbed on the electrode surface where it reacts with H_2O molecules that may likewise be adsorbed, and emits electrons to the electrode and protons to the electrolyte until only CO_2 is left on the surface which then is desorbed.

For butane conversion values above 100% were found which are outside the limit of error. This result suggests that the oxidation of butane, at the condition of large flow rates, does not proceed up to the carbon dioxide stage and that partially oxidized products are desorbed. These products are absorbed in the tube packed with NaOH-asbestos so that a larger degree of conversion is erroneously indicated.

At 100°C instead of 90°C, the conversion of propane is no longer complete. As a consequence of the increase in temperature, desorption of partially oxidized hydrocarbons takes place and the desorption products are carried away by the streaming gas.

Since all intermediates can be converted quantitatively (16) to carbon dioxide and water, we believe that propane and butane can also be completely oxidized to carbon dioxide at certain conditions,[1] in particular at flow rates that are compatible with the current intensity, a requirement fulfilled in practical fuel cells anyhow.

Conclusions

The hydrocarbons are oxidized on Raney platinum in dilute sulfuric acid at large current densities; the reaction rate decreases with growing chain length. It is expected from the experimental results that a propane fuel cell can be operated at 100°C which, at a voltage of 0.5v, yields a current density of 100 ma/cm^2. While the exclusive products of the anodic oxidation of methane, ethane, and propane are carbon dioxide and water, complete conversion of butane, pentane, hexane, and heptane apparently requires conditions different from those employed here.

Acknowledgment

Technical Notes

The Distribution of Defects in Aluminum Oxide Films near the Metal-to-Oxide Interface

M. A. Heine and P. R. Sperry

Metals Research Laboratories, Olin Mathieson Chemical Corporation, New Haven, Connecticut

Thin oxide films which form on metal surfaces by thermal or anodic oxidation are known to depart from the bulk stoichiometric composition and to contain impurities and lattice defects. Defects in the oxide structure may contribute to ionic or electronic conduction, depending on their nature and concentration. Hence, they influence the kinetics of formation and the subsequent reactions of the surface films with the environment to which they are exposed. Despite the broad background of experimental data available on bulk semiconductors, little or nothing has been determined about the actual defect structure of that important class of metal oxide films in the order of a few hundred Ångstroms or less in thickness. The great difficulty of obtaining direct experimental data on distribution of defects in such films limits the interpretation of their dry or wet corrosion behavior to some assumed model of homogeneous or inhomogeneous distribution of the defects.

There is indirect evidence that thin, room temperature oxide films on aluminum depart from stoichiometry and contain excess metal and/or oxygen vacancies in the vicinity of the oxide metal interface. Grunberg and Wright (1) have demonstrated this particularly well for aluminum, and also for magnesium and zinc which are similarly believed to form thin excess metal oxides. They were able to show a spectrum of electron emission photosensitized within the visible light range on freshly abraded or vacuum deposited aluminum. They gave particular attention to a prominent sharp peak found at a wavelength of 4700Å and concluded that the most likely lattice imperfection contributing to this effect would be a missing oxygen site trapping two electrons and giving rise to an F'-center. The electron emission was attributed to trapped electrons at shallow surface sites. Decay of the emission occurred on further oxidation, with the rate of decay being a function of oxygen partial pressure. Thus, their investigative method could not be extended to stable thicker films.

Work in progress at the authors' laboratory has been aimed toward a more direct study of the nature and distribution of defects in γ-Al_2O_3 films formed on 99.997% pure aluminum. Capacitance and dielectric loss measurements over a wide range of a-c frequency have been used and have been supplemented by electron-optical and other methods, as described in previous publications (2, 3). The experimental method briefly consists of constructing a parallel plate capacitor in which the aluminum substrate forms one electrode, the oxide film is the dielectric, and the other electrode is formed by an aqueous chromate solution connected through a platinum screen. It has been clearly shown in the previous work that contact with this electrolyte introduces no changes into the structure of the film. Corrections for the resistance and capacitance of the solution can be made readily when necessary. From the measured and corrected capacitance and dielectric loss values and from the electrical analog to the film of a capacitance and resistance in parallel, a frequency dependent value of a-c parallel resistance, R_p, can be calculated. Differences of this value between films of equal thickness have been attributed to differences in the ionic or electronic relaxation effects due to gross impurity substitution or departure from stoichiometry (2). At frequencies somewhat greater than 10 kc, it is believed that only the electronic relaxation effects from impurity substitution can be seen, whereas at lower frequencies combined ionic and electronic relaxations contribute to R_p (2).

The a-c resistance determined as above is a total value for the entire film thickness, and it does not give any indication of defect distribution. A valuable extension of the technique was the development of a means of chemically dissolving or thinning the films (3) in a uniform fashion by immersion in a slightly alkaline, passivating chromate solution; the solution again did not affect the structure and composition of the remaining film. Thus, the distribution of the a-c resistance at different frequencies could be determined throughout the thickness of the films, down to a limiting passive film thickness of 20-25Å. All measurements were made at 25°C. Details of the method and some results appear elsewhere (3).

It is of particular interest to examine the high-frequency resistance values (100 kc) in the immediate vicinity of the oxide-metal interface. These high-frequency resistance values have been considered to reflect primarily electronic relaxation effects resulting from departure from stoichiometry or from relatively gross impurity substitution. Previous work (2, 3) was conducted on barrier layer-type films formed anodically in neutral ammonium tartrate solution. Two dissimilar regions of high-frequency a-c resistance were found in these films. First was an inner region, extending to about 90Å from the metal-oxide interface in which the R_p *vs.* total thickness was not linear and in which high-frequency resistivity increased with increasing distance from the oxide-metal interface. Second was a region from 90Å out to the outer oxide surface in which R_p was a linear function of thickness; therefore, this was a region of constant high-frequency resistivity. The latter was attributed to the uniform characteristic γ-Al_2O_3 formed under anodic conditions. It was concluded that the lower resistivity, inner

region was associated with the excess metal defect nature of the film adjacent to the oxide-metal interface.

In the new work reported herein, a similar analysis has been applied to thermal films formed by oxidation of annealed 99.997% pure aluminum sheet, 0.016 in. thick, in dry oxygen and at temperatures from 350° to 500°C. The surface pretreatment, consisting of a 15-min etch in 0.5*N* NaOH followed by a dip in 50% HNO_3, has been found to give a fairly smooth surface free from contamination which would affect subsequent oxidation. The resulting oxide films were composed of γ-Al_2O_3 and had thicknesses ranging between 40 and 85Å. One of the films, formed at 500°C, contained well-developed crystals (Fig. 1a) which gave sharp γ-Al_2O_3 electron diffraction patterns. Those films formed at 450°C and below appeared structureless to the electron microscope (Fig. 1b) and showed rather diffuse rings upon transmission electron diffraction, a characteristic of so-called "amorphous" γ-Al_2O_3. The change from amorphous to mixed crystalline and amorphous film in the range of 450° to 500°C is in agreement with Dignam (4) and others. In spite of these differences in structure, it was found that the R_p *vs.* thickness curves for all of the thermal films coincided almost exactly with that obtained from the inner region of the anodic film; *i.e.*, the entire thermal film within this thickness limit was an excess metal film with varying resistivity. This finding is qualified to the extent that measurements made at 25°C can be considered characteristic of the films as they existed at the elevated temperatures only insofar as these characteristics could be retained during rapid cooling after oxidation.

The curve, R_p *vs.* thickness, for both the anodic and the thermal films in the excess metal region proved to be parabolic, as shown by Fig. 2 in which R_p is plotted against the square of the thickness, giving excellent fit to a straight line. The thickness was calculated from the capacitance measured at 1 kc which is in the frequency range which Lorking (5) considered most suitable for this purpose. The failure of this line to extrapolate to zero resistance at zero thickness may be due to minor residual inaccuracies of obtaining an absolute measure of film thickness and/or to small errors introduced in the high-frequency solution corrections (3). Assuming that the real intercept would be negligibly small in value, the data can be simply described by

$$R_p = kX^2$$

where X is the total thickness at which R_p was measured. Since the incremental resistivity, *i.e.*, the resistivity of any extremely thin element parallel to the metal surface, is directly proportional to the thickness, it follows that the high-frequency conductivity, σ, for a given element of film is inversely proportional to the distance of that element from the metal-oxide interface. An expression for the number of defects, N, contributing to the electronic relaxation is obtained from the general expression for conductivity

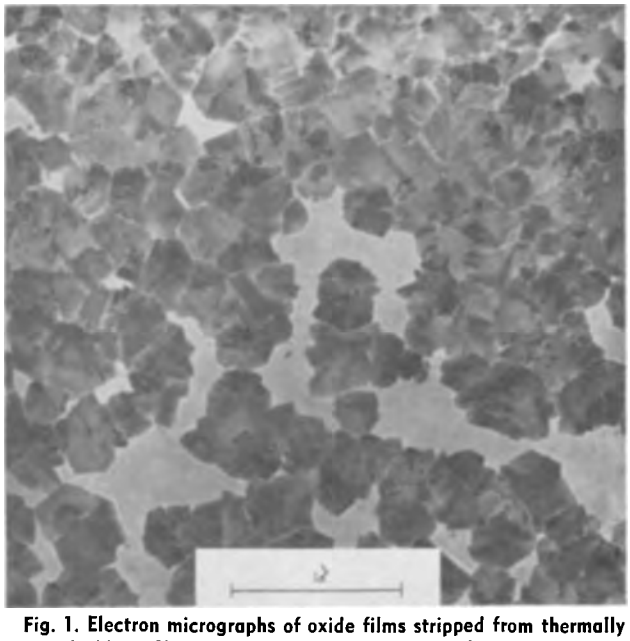

Fig. 1. Electron micrographs of oxide films stripped from thermally oxidized 99.997% pure aluminum: (a) oxidized at 500°C for 20 hr. Magnification approximately 26,500X.

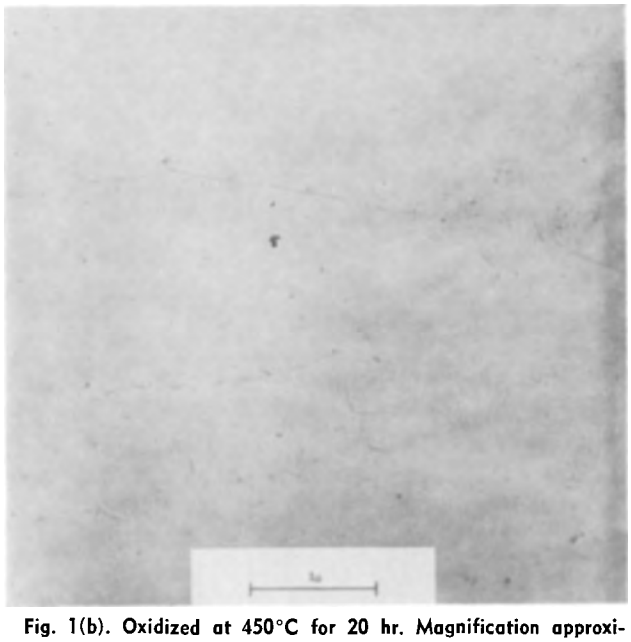

Fig. 1(b). Oxidized at 450°C for 20 hr. Magnification approximately 19,500X.

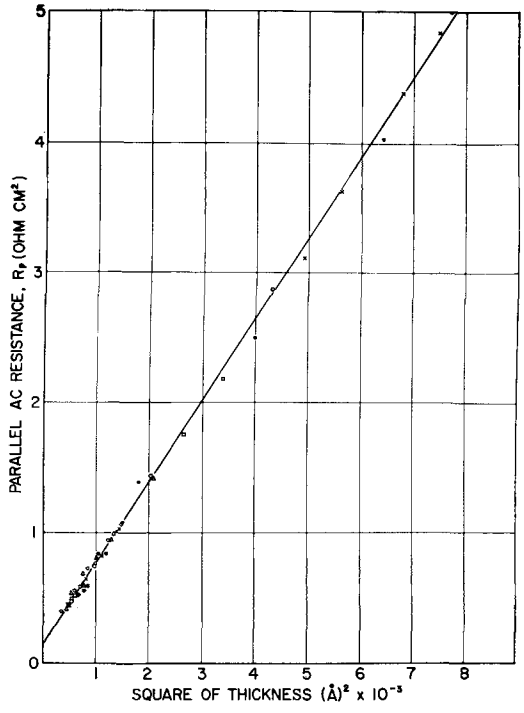

Fig. 2. High-frequency (100 kc) a-c resistance of a variety of γ-Al_2O_3 films plotted against the square of the thickness. The separate points for each individual film are individual measurements made during uniform thinning of the film: X, 500°C; □, 450°C; ○, 400°C; △, 350°C; •, anodic.

where r is the rate in moles sec^{-1} cm^{-2}, c is the concentration of KNO_3 in moles $liter^{-1}$, and P_o and E are constants.

The activation energy, E, is 17.1 kcal $mole^{-1}$ and P_o, which can be regarded as a frequency factor, was found to be 9.2×10^6 cm sec^{-1}.

Discussion

Capacitance studies (1) have revealed that freshly prepared anodic zirconium oxide films are permeable to electrolyte solutions, but microscopic evidence indicates that the surface of the oxide is virtually featureless (3). Several suggestions have been made to account for this permeability, the most reasonable being the existence of invisible cracks perpendicular to the film surface (4). Our experimental observations lead to some tentative conclusions about the nature of the oxide film and the permeation process.

The permeation rate is fairly reproducible. The small deviations in results can be attributed to variations in the ratio of actual film area to apparent film area. This indicates that a reproducible network of interstices, rather than random gross flaws, serve as paths for permeation. Furthermore, the activation energy for the free diffusion of KCl in water is 4.4 kcal $mole^{-1}$ (5) which is nearly four times smaller than the observed activation energy for permeation through the oxide. This also supports the contention that the process is not merely a simple bulk diffusion through large flaws.

The relative concentration independence of the constant, P, is difficult to account for if a pore-free barrier layer similar to that found in porous anodic aluminum oxide (6) exists at the oxide-dilute solution interface. The termination of an interstice by a relatively perfect layer would probably lead to a bottleneck. It is probable, however, that this barrier layer which would most likely be found at the oxide-metal interface during anodization, is removed during the film stripping process. Permeation runs carried out with the oxide surfaces reversed with respect to the KNO_3 solution indicate that the permeation is the same in both directions.

It is likely then, that in the case of these isolated zirconium oxide films we are dealing with a permeation through a network of small interstices where the activation process may be adsorption and desorption of ions upon interstice walls.

Growth and Characterization of Uranium-Doped Germanium Single Crystals

H. R. Killias,[1] S. N. Dermatis, and H. C. Gatos

Department of Metallurgy and Center for Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts

In the course of a study of fission fragment damage in bulk germanium (1), several germanium single crystals doped with uranium were grown successfully. Since such doping experiments have not been reported previously, growth procedure, distribution coefficient, and preliminary results of electrical measurements are presented here.

The crystals were grown from the melt by the Czochralski method using a graphite crucible and prepurified nitrogen as furnace atmosphere. Because of the relatively large atomic size or uranium, a high seed rotation (60 rpm) and a very low pulling rate (0.28 in./hr) were found necessary for successful growth. In a typical charge, a previously prepared master alloy was added containing 0.1 weight per cent (w/o) enriched uranium.[2] The presence of oxygen impurities in the furnace atmosphere was found to be critical because of the rapidly formed uranium oxide particles in the melt which tend to agglomerate at the solid-liquid interface and interfere with the crystal growth leading to the formation of irregularly sized twin bands.

Because the distribution coefficient of uranium in germanium was expected to be low, exceptionally pure uranium had to be used as doping material in order to prevent the preferred incorporation of impurities which have a relatively high solubility in germanium. The following impurity concentrations have been given for the enriched uranium: Al 7 ppm, P < 10 ppm, Zn 3 ppm on an atom basis. These concentrations are small enough not to affect the present results significantly.

An analytical determination of the uranium concentration in the grown single crystals was made by a method recently reported by Price and Walker (2). It is based on the fact that fission fragment tracks in mica crystals can be revealed by etching. Accordingly, a freshly cleaved mica crystal is placed next to the polished surface of the crystal to be analyzed. After an exposure to a thermal neutron flux ϕ the number of fission fragments per unit area (ρ) which have crossed over into the mica is

$$\rho = (1/2) R_o N \eta \sigma \phi \qquad [1]$$

where η is the isotopic abundance of U^{235}, σ the fission cross section of U^{235}, and R_o the effective fission fragment range in germanium. If R_o is taken as 7×10^{-4} cm and the fission track density determined with a microscope, the uranium concentration N can be obtained from Eq. [1]. Such determinations were made on both sides of samples which were later used for electrical measurements. The fission track densities of both sides always agreed within 2% and led to uranium concentrations between 1.5×10^{14} and 2.5×10^{14} at./cm^3 for different samples. Using these values and the uranium concentrations in the melt, the distribution coefficient of uranium in germanium was calculated as $k_o = 4.5 \times 10^{-5}$ with an estimated accuracy of

[1] Present address: General Electric Research Laboratory, Schenectady, New York.

[2] 99.7% U^{235}, obtained from Oak Ridge National Laboratory, Oak Ridge, Tennessee.

Fig. 1. Anomalous x-ray transmission topograph of uranium-doped germanium crystal, $(\bar{2}20)$ reflection, CuK_α radiation; note twin bands and segregated particles. Magnification approximately 7X.

25%. A semiquantitative discussion of this value in terms of a tetrahedral radius or heat of sublimation, as it has been done for other impurities in germanium (3), is not applicable for uranium. As far as the order of magnitude is concerned, however, the present value of k_o seems to be reasonable.

The mica detector method has also been used to study the distribution of uranium in the grown crystals. It was found that the fission track distribution was uniform over the whole sample except for a few small but very dense track clusters which indicated the presence of uranium-containing, segregated particles. This indication was confirmed by anomalous x-ray transmission microscopy (4) (Fig. 1). Embedded in a network of dislocations with Burgers vectors [101] and [011], small circular spots of about 30μ diameter are being observed. Confirmation that these spots are not due to damaged surface areas, such as etch pits, was obtained by the following experiment. A series of topographs was taken of a specimen whose thickness was reduced after each exposure. Individual spots could be followed through the crystal until they disappeared at a certain thickness. No spots were found at any reduced thickness which were not present in the first topograph. By comparing topographs of different (hkl) reflections, it could further be concluded that the observed spots represent particles of spherical shape.

The density of segregated particles varied from 300-400 cm^{-3}. The particle size is probably very close to the observed spot size of 30μ because the strain field of an inclusion falls off very rapidly with distance. Thus, the number of uranium atoms concentrated in these particles is of the order of 10^{17} at./cm^3. The nature of the segregated material could not be determined directly, but it is felt that the particles consist of metallic uranium rather than of uranium oxide or of an intermetallic uranium-germanium compound.

Electrical resistivity and Hall effect for some of the uranium-doped crystals were measured between 80° and 400°K. All crystals investigated are n-type with carrier concentrations between 1×10^{14} and 2×10^{14} cm^{-3}. A comparison of carrier concentration and concentration of dissolved uranium gives an apparent net contribution of 0.80 ± 0.10 electrons per uranium impurity. However, in these preliminary measurements, there were no indications of any donor or acceptor levels over the investigated temperature range. This is somewhat surprising since uranium might be expected to introduce deep multiple impurity levels corresponding to different ionization stages. A close investigation will have to include counter-doping with elements of groups III and V in order to sweep the Fermi level through the energy gap and the extension of electrical measurements to lower temperatures.

Brief Communications

Phase Diagram for the Pseudo-binary System Germanium and Gallium Arsenide

Y. Takeda, T. Hirai, and M. Hirao

Central Research Laboratory, Hitachi Ltd., Kokubunji, Tokyo, Japan

It has been reported by Jenny and Braunstein (1) that the Ge-GaAs alloy system was not a solid solution-type, but its phase diagram has not been established previously. In this communication, we report the phase diagram for the pseudobinary system Ge-GaAs determined by means of thermal analysis, microscopic observation, and x-ray microanalysis. The thermal analysis was made by melting appropriate amounts of Ge and GaAs mixtures in a sealed, evacuated silica ampule with a thermocouple hole at the bottom, holding it above the melting point of GaAs for about an hour and then cooling the melt at 1°C/min.

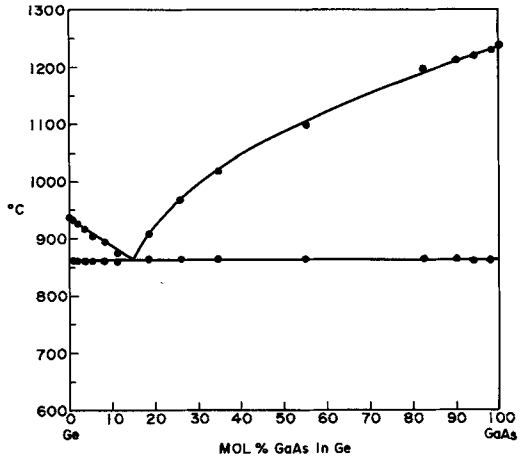

Fig. 1. Phase diagram for the GaAs-Ge system. Estimated solubility of Ge into GaAs and GaAs in Ge is less than 0.5 mole % Ge and 0.25 mole % GaAs, respectively.

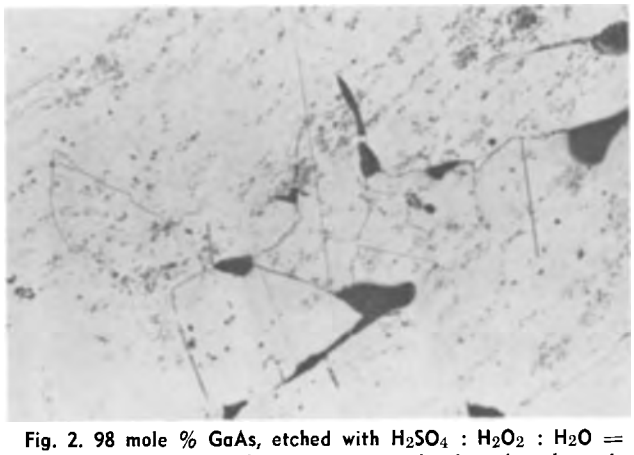

Fig. 2. 98 mole % GaAs, etched with H_2SO_4 : H_2O_2 : H_2O = 1:1:1 solution. The black areas are cracks brought about in solidification. Magnification approximately 145X.

The resultant phase diagram is shown in Fig. 1. This alloy system has a simple eutectic type phase diagram and no intermediate compound was found. The eutectic point lies at 15 mole % GaAs and its temperature is 865°±2°C.

The microstructure of the alloy with the composition of 98 mole % GaAs etched with H_2SO_4:H_2O_2:H_2O = 1:1:1 solution is shown in Fig. 2. This composition showed no sign of the existence of eutectic phase by thermal analysis, but a small amount of a second phase was observed at the grain boundaries of GaAs and this phase was confirmed to be the eutectic composition by x-ray microanalysis.

Figure 3 shows the microstructure of the alloy containing 2 mole % GaAs. The eutectic phase is clearly observed in this alloy, and almost the same pattern is observed for the 0.25 mole % GaAs alloy.

So the estimated solubilities of Ge in GaAs and GaAs in Ge from thermal analysis data are lower than 2 mole % Ge and 0.25 mole % GaAs, respectively.

Kolm *et al.* (2) have reported the solubility of Ge in GaAs to be lower than 0.5 mole % Ge by lattice parameter measurements of Ge-GaAs alloys. We could

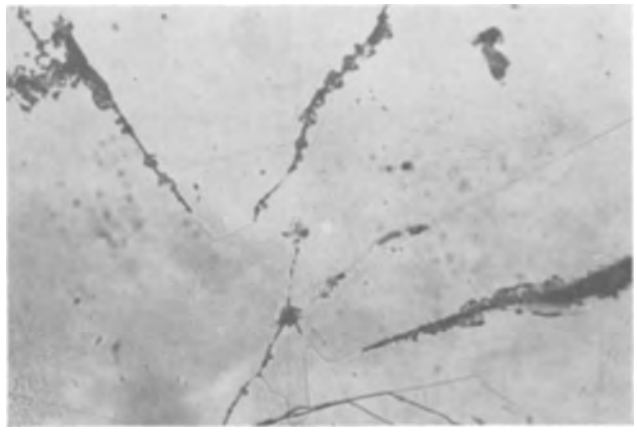

Fig. 3. 98 mole % Ge, etched with H_2SO_4 : H_2O_2 : H_2O = 1:1:1 solution. Magnification approximately 145X.

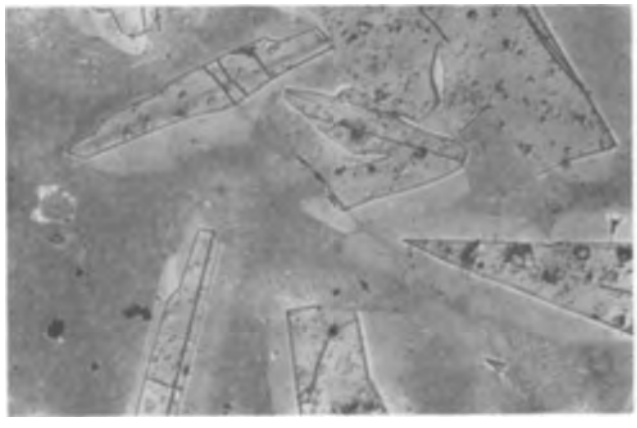

Fig. 4. 50 mole % GaAs, etched with H_2SO_4 : H_2O_2 : H_2O = 1:1:1 solution. Magnification approximately 145X.

not determine the precise solubility limits of Ge in GaAs and GaAs in Ge, but these results indicate that both solubilities are very low, although they do not show true equilibrium solubility limits because of the fast cooling rate.

Figure 4 shows the microstructure of the alloy containing about 50 mole % of GaAs. This appears to show three different phases, GaAs primary crystals, eutectic phase, and the third phase surrounding the GaAs primary crystals. This third phase looks different from the eutectic phase, but it was confirmed to be almost the same eutectic composition by x-ray microanalysis. The reason why the same eutectic phase shows two different patterns is not clear, but this probably results from slight deviation from the eutectic composition due to a difference in diffusion rate of Ga between As, or from a difference in etching condition, near the GaAs primary crystals.

Equilibria of the Mn_2O_3-Mn_3O_4-O_2 Systems

N. G. Schmahl and B. Stemmler

Institut für physikalische Chemie of the University of Saarland, Saarbrücken, West Germany

In the paper of Otto (1) the report of Schmahl and Shenouda (2) could hardly have been referred to. It may be stated that the selected temperatures (2) for Mn_2O_3-Mn_3O_4 to give 1 atm and 0.209 atm (= 1 atm air) are in rather good agreement with the work of Otto.

Since the publication (2) further investigations have been made by us and the results will be published (3). We were able to obtain practically univariance of the Mn_2O_3-Mn_3O_4 system. This could be achieved by treating the samples with oxygen-pressures a little over the univariance pressure within times up to a month. By this procedure lattice defects were removed. We found the temperature dependence of the oxides on the oxygen pressure is different from that usually observed. The values obtained by approaching equilibrium from the higher oxygen pressure side are in agreement with those obtained by approaching from the lower side. (Time required was up to 48 hr.)

It is to be stated, furthermore, that not one but two temperature dependent systems exist. The corresponding straight lines obtained for log pO_2 as a function of $1/T$ meet at 937°C. The line involving the higher pressures is attributed to the α system and that involving the lower to the β system. At temperatures above 937°C only pressures of the α system have been observed. Below 937°C spontaneous transition from β to α occurred several times. The case of a system with higher pressure being stable as compared with a system with lower pressure being metastable was discussed by Schmahl and Shenouda (2).

In light of the above mentioned observations we are compelled to postulate the existence of a third, a metastable modification of Mn_3O_4 in addition to the well-known tetragonal Hausmannite and the well-known spinel, stable above 1172°C. There is a probability that Hausmannite participates in the α system.

Similar results had been reported in a thesis by Eckert (1950) and the results incorporated in ref. (2). (The log pO_2 *vs.* $1/T$ lines meet at 952° instead of 937°C.) These results had been rejected because the possibility of a change in modification in only the Mn_2O_3 had been considered and this does not explain the situation. Data on the β system seem to have been obtained also by Tatievskaya, Chufarov, and Antonov (4). In x-ray investigations of Mn_3O_4 quenched by withdrawing specimens of the α or β system from the furnace the same pattern resulted.

Data for the reaction $6Mn_2O_3 = 4Mn_3O_4 + O_2$

α system: $-4.5758 \log pO_2(\text{atm}) = 45{,}345/T - 35.785$

Values determined at 830°-960°C

β system: $-4.5758 \log pO_2(\text{atm}) = 51{,}526/T - 40.891$

Values determined at 830°-937°C

	α system	β system

Equilibrium Pressures of Oxygen over MnO_2-Mn_2O_3 at Various Temperatures

Earl M. Otto

National Bureau of Standards, Washington, D. C.

ABSTRACT

Oxygen pressures of the pyrolusite form of MnO_2 have been determined in a temperature range of 441°-642°C. The dissociation reaction $4MnO_2(c) \rightleftarrows 2Mn_2O_3(c) + O_2(g)$ has been found to reach a steady state in the forward direction; reaction in the reverse direction was exceedingly slow and did not reach a steady state. $\Delta H°$ and $\Delta S°$ for the reaction at 813°K are 37.87 kcal[1] and 51.28 cal/deg, respectively. With little error these values can be used in the equation

$$-4.5756 \log pO_2(\text{atm}) = 37{,}870/T - 51.28$$

to calculate the pressure for any temperature in the above mentioned range. Conversion to 298.15°K resulted in $\Delta H°_{298} = 38.8$ kcal and $\Delta S°_{298} = 52.8$ cal/deg for the dissociation. The limits of uncertainties are not given here because equilibria were not attained by recombination.

Although many investigations of original experimentation, theoretical calculations and collation of data reported in the chemical literature give information which relate temperature of MnO_2 and oxygen pressure, there is such a lack or omission of critical detail and there is so much disagreement that it was felt desirable to attempt to clear up the discrepancies. There is a lack of measuring and/or reporting precise temperatures and pressures. Frequently there is evidence that no equilibrium was reached. For example, in many instances the temperature of the MnO_2 was raised a few degrees per minute. Preparation of the sample is not always specified, nor is there assurance the sample was dry or desiccant included in the system. Among the investigators there is disagreement not only in the pressure-temperature relationship, but also regarding composition, crystal structure, and nomenclature of the sample and regarding the existence of reversibility of the MnO_2 dissociation. Table I gives in very concise form, pertinent observations made by the various investigations (1-24). When sufficient data were available, pressure-temperature graphs were made and some of these are shown in Fig. 5.

Values for thermodynamic constants of oxides of manganese have been determined experimentally in recent years by Millar (25), Siemonsen (26), Southard (27), Shomate (28), Moore (29), Kelley and Moore (30), Orr (31), and King (32). These values have been collated, adjusted to correlate with newly accepted reference values, and are tabulated by Kelley (33), Rossini (34), Brewer (35), Coughlin (36), Glassner (37), Mah (38), and Dushman (39). Brewer has stated (40) that "further work at higher temperatures and with long heating times is necessary to clarify the equilibrium limits of the solid-solution ranges."

It became evident, therefore, that precise determinations of oxygen pressure-MnO_2 temperature relationships at equilibrium were needed. Furthermore, the question of reversibility needed to be studied.

[1] One thermochemical calorie = 4.1840 joules. $R \ln pO_2 = 2.302585 \times 8.31433$ joules ÷ 4.1840 joules/cal = 4.57563 cal log pO_2.

Experimental

For the lowest two temperatures (441° and 491°C) the apparatus was identical with that previously described by this author (41). A diagrammatic sketch of the apparatus is shown in Fig. 1. For 555°C the sample was contained in a Vycor cup set in a nickel bomb. A nickel delivery tube led outside the furnace to ⅜-in. stainless steel tubing attached by Swagelok fittings to a heavy wall glass manometer containing mercury. Steel capillary tubing then lead to a 250 psi gauge and a high-pressure valve. From mercury to pressure gauge and almost to the valve the system was filled with

Table I. Observations of various investigators

Literature reference	Brief summary of pertinent observations
Moissan (1)	H_2 over heated MnO_2. Reaction began at 230°.
Wright and Luff (2)	H_2 over heated MnO_2. Reaction began at 390°.
Gorgeu (3)	Several varieties MnO_2 heated in air. O_2 evolved at about 400°.
Meyer and Rötgers (4)	MnO_2 prepared from $Mn(NO_3)_2$. Decomposed at 530° in air and at 565° in O_2; 86 hr required; no reversibility.
Askenasy and Klonowski (5)	MnO_2 heated in closed system; 0.26 atm in <5 hr at 478° and >1.37 atm in <5 hr at 536°; reversibility claimed.
Kendall and Fuchs (6)	MnO_2 heated in closed system; 1 atm as 419°; reversibility claimed.
Drucker and Hüttner (7)	MnO_2 heated. Pressure equilibria not constant; reversible below 480°.
Simon and Feher (8)	MnO_2 heated; 0.9 atm at 525°.
Bahr and Sackur (9)	MnO_2 heated in closed system: 1.07 atm at 572° in 68 hr; irreversible.
Von Krüll (10)	MnO_2 heated. Concluded no definite decomposition temperature obtainable.
Blumenthal (11)	Pyrolusite, crystalline, amorphous. See Fig. 5 for pyrolusite.
LeBlanc (12)	X-ray diffraction studies. No solid solutions exist.
Dubois (13)	Various types MnO_2 heated. Decomposed at 300°-600°. Proposes $MnO_{1.90}$.
Herman and Slonim (14)	Several natural MnO_2 ores. No >0.4 atm at no >583°. X-ray diffractions showed no solid solutions.
Kapustinskii and Bayushkina (15)	Heated MnO_2 prepared from $Mn(NO_3)_2$. See Fig. 5.
Sakai, Hukuyama and Okuno (16)	Several kinds MnO_2 heated in air. Decomposed at 500°-580°.
Matsuno (17)	Pyrolusite heated. Decomposed about 650°; temperature depends on crystal size.
Tatievskaya (18)	Decomposition temperature of 627° at 1.24 atm calculated by thermodynamics.
Kulp and Perfetti (19)	In DTA (12.5° rise/hr) break in curve at 580°-670°.
Brenet and Grund (20)	Thermogravimetric analysis. Weight loss at 500°.
McMurdie and Golvato (21)	DTA of pyrolusite. Endothermic break at 670°.
Pascal (22)	More than 150 oxides of manganese exist.
Grasselly and Klivenyi (23)	Product analysis after heating for 3 hr in air. Weight loss at 460°.
Földvari-Vogl and Koblencz (24)	DTA of pyrolusite. Endothermic break at 640°.

All temperatures are in °C. DTA = Differential Thermal Analysis.

trichlorethylene on which the pressure could readily be increased by passing cylinder nitrogen through the high-pressure valve. For 642° the sample was again in a Vycor cup. Now the nickel bomb was very thick walled and was attached to nickel tubing and then stainless steel capillary tubing. A 2500 psi gauge and an oxygen servicing high-pressure valve completed the system. For all temperatures except 642°, pressure readings were taken at constant volume.

In all cases the furnace was located in the thermostatted cabinet (c). Regulated constant current was continuously supplied by means of an automatic voltage regulator connected in series with a lamp bank and the furnace.

The manganese dioxide used was reagent grade pyrolusite assaying 99.5% MnO_2. In a sieve test 9% remained on the 100 mesh sieve, 88% on the 200 mesh, and 3% through the 200 mesh. Further grinding was done sometimes. The sample was dried at 120°C overnight and then weighed into the Vycor capsule. Further drying was done by operating the furnace at 350°C while the system was being evacuated for several hours. The furnace temperature was increased and then held constant for hundreds or several thousand hours while the pressure was approaching an equilibrium or steady value. At each temperature, data on pressure-time relationships were obtained and plotted. Figures 2 and 3 are typical.

By lowering the temperature or by increasing the oxygen pressure attempts were made to reverse the dissociation reaction. The resulting reduction in pressure was so slow in contrast to Mn_2O_3 dissociations (41) that at first it was considered that there was no reduction and the dissociation is irreversible. Figures 2 and 4 show that there is recombination, but that equilibrium was never re-established.

The first sample used in this investigation was mortar ground so fine that it all readily passed through a 100 mesh sieve. After drying the sample at 300°C the system was evacuated to several mm pressure and sealed. The temperature was raised to 513° for a few hours during which time the pressure rose to 1200 mm. The system was cooled to 441°, again evacuated and resealed. It was concluded after 1199 hr that the equilibrium pressure had been reached. That the supply of oxygen was not exhausted was proven by again evacuating and heating to a higher temperature during which time the pressure reached 7.3 atm. The second sample reported was likewise heated to about 500° and the system evacuated before being stabilized at 491° for a total of 524 hr, 336 hr being required to reach a steady pressure. The third sample was preheated to about 580° and the evolved oxygen (18 atm) removed. Then, after 477 hr at 555° by which time the pO_2 was 14 atm and after a partially successful reversal, a second build-up of pressure was allowed to take place, this one reaching 15 atm in 1400 hr and maintaining that pressure for

Table II. Equilibrium data for four temperatures

Temperature, °K	pO_2, atm	Compressibility factor	Fugacity, atm	$-R\ln$ fugacity	"Correction" C	$\Delta Y°/T$, cal/deg
714.15	0.410	1.0001	0.4100	+1.7716	−0.0222	+1.7494
764.15	2.45	1.0007	2.4517	−1.7822	−0.0066	−1.7887
828.15	15.0	1.0046	15.069	−5.3907	−0.0028	−5.3934
915.15	142.7	1.045	149.12	−9.9457	−0.0145	−9.9602
[813]						[−4.6884*]

Compressibility factors were obtained by interpolation and extrapolation of data taken from "Tables of Thermal Properties of Gases" Circular 564 National Bureau of Standards. Fugacity equals the compressibility factor times the pressure.

* This is the predicted value of $\Delta Y°/T$ at 813° as given in the section on Treatment of Data.

1600 additional hr. A noteworthy observation is that 800 hr were needed to reach 14 atm in the second build-up compared to 477 hr in the first. The sample studied at 642° was evacuated at 350° and slowly heated to 642° until the pO_2 was 125 atm. Some oxygen was released; the pressure fell to 110 atm. From 1500 to 1800 hr at 642° the pressure was constant at 142.7 atm. Following this experiment the temperature was raised, and it was noted that, after thermal equilibrium was obtained, the pO_2 again rose indicating some MnO_2 was dissociating. An unsuccessful attempt was made to reach the equilibrium pressure by lowering the temperature from 642° to 475°. Figure 4 shows that the Mn_2O_3 did not undergo recombination in the first 200 hr. Recombinations then became relatively rapid until a total of 870 hr had passed, at which time there was a temporary rise in oxygen pressure and then a decrease, but at a lower rate than the initial. If the recombination taking place between 3000 and 4000 hr were to continue at the same rate, the remaining pressure drop of 115 atm to the equilibrium pressure of 1 atm at 475° would have required a number of years. After the partially successful reversal attempt sufficient MnO_2 remained to obtain essentially the equilibrium pressure at 530° in 3700 hr. The equilibrium data obtained for the four temperatures are given in Table II and Fig. 5. For comparison purposes experimental data from the literature are included in Fig. 5. It is to be noted that the oxygen pressures observed in the present investigation are much greater than any heretofore observed for corresponding temperatures.

Platinum black was blended with pyrolusite in an attempt to catalyze the dissociation of MnO_2 or the reverse action. Figure 3 shows that the platinum actually consumed much of the oxygen and was of no benefit to the study.

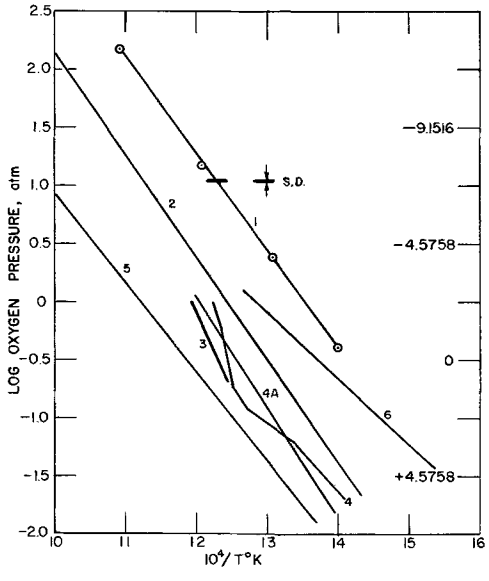

Fig. 5. Oxygen pressure-manganese dioxide temperature. Treatment of Data

In spite of the inability to attain complete reversibility, it is assumed that equilibrium was reached in the forward direction. Since the range in oxygen pressure exceeded 100 atm, it is necessary to use fugacity (fO_2) in calculating values for thermodynamic constants (heat and entropy) of the reaction to give precise correlation of pressure and temperature. In other respects the treatment of the data is similar to that used in the previous paper (41). The method of Prosen (42) was again used to convert the data to yield a theoretical straight line plot of $\Delta Y°/T$ against $1/T$, where this line is the tangent to the $\Delta F°/T$ curve at a selected temperature of 813°K, an approximate midpoint temperature in this study. The pertinent equations involved are

$$\Delta Y°/T = \Delta H°_{813}/T - \Delta S°_{813}$$

and

$$\Delta Y°/T = -4.5756 \log fO_2 + C$$

where C is the correction given by

$$C = -\Delta(H°_t - H°_{813})/T + \Delta(S°_t - S°_{813})$$
$$= -1/T\,\Delta C°_p\,dT + (\Delta C°_p/T)\,dT$$

The $\Delta C°_p$ value for the reaction, obtained from data given by Kelley (33), is

$$\Delta C°_p = -9.78 + 8.00 \times 10^{-3} T + 8.66 \times 10^5/T^2$$

For the 813°K region the correction is

$$C = 3.9311 + 0.004T - 6{,}374.45/T$$
$$+ 4.33 \times 10^5/T^2 - 22.5233 \log T/813$$

Table II gives in successive columns for each equilibrium the temperature, the observed pressures, the compressibility, the fugacity, R ln of fugacity, the Prosen correction, and $\Delta Y°/T$. Also Fig. 5 indicates there is no noticeable difference on this scale between the plot of pO_2 against $1/T$ and the theoretical tangent at 813°K. The constants of this tangent

$$\Delta Y°/T = \Delta H°_{813}/T - \Delta S°_{813}$$

were determined to be

$$\Delta H°_{813} = 37.87 \pm 0.56 \text{ kcal}$$

$$\Delta S°_{813} = 51.28 \pm 0.70 \text{ cal/deg}$$

and the predicted value at 813 was

$$\Delta Y°/813 = -4.688 \pm 0.065 \text{ cal/deg}$$

The indicated uncertainties are the standard deviations of the associated quantities as determined from the least squares fit to the four points of Table II. The uncertainty in the log pO_2 value at 813°K is indicated by the standard deviation shown by the thickness of the line aside curve 1 of Fig. 5. This is evidence that the difference from the other curves cannot be accounted for by errors in measurement. Systematic error due to not actually reaching equilibria could only mean

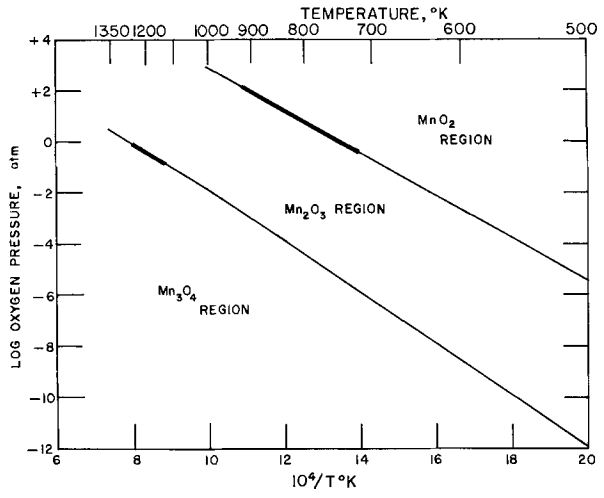

Fig. 6. Regions of stable existence of oxides of manganese

that pressures would have been even higher than those shown here.

If one subtracts from the above constants —0.88 kcal, $(H_{813} - H_{298})$, and —1.50 cal/deg, $(S_{813} - S_{298})$, calculated from the tabulated heat content and entropy data given by Kelley for the substances involved, the resultant constants for the reaction at 298.15°K become

$$\Delta H^\circ_{298.15} = 38.76 \pm 0.6 \text{ kcal}$$

$$\Delta S^\circ_{298.15} = 52.78 \pm 0.7 \text{ cal/deg}$$

Then

$$\Delta F^\circ_{298.15} = 23.0 \text{ kcal}$$

These values may be compared with those given in the literature. Rossini *et al.* (34) selected —124.5 kcal for the ΔHf°_{298} of MnO_2 and —232.1 kcal for that of Mn_2O_3. These yield +33.8 kcal for ΔH°_{298} for the reaction. Mah (38) selected —124.4 kcal for ΔHf°_{298} of MnO_2 and —228.4 kcal for that of Mn_2O_3 giving +40.8 kcal for the reaction. Brewer (35) chose —124.2 kcal and —229.2 kcal for these respective constants which result in 38.4 kcal for the reaction. Using the newly determined value of —228.7 kcal derived by Otto (41) for the ΔHf°_{298} of Mn_2O_3 one obtains for the ΔHf°_{298} of MnO_2 a value of —124.0 kcal. This is in good agreement with those cited above.

The value of ΔS°_{298} may also be compared with that obtained from entropy values given in the literature. Glassner (37) selected entropies at 298°K for MnO_2, Mn_2O_3, and O_2 as 12.7, 26.4, and 49.0 cal/deg, respectively. These yield 51.0 cal/deg for the dissociation of MnO_2 while the value obtained as a result of this investigation is 52.8 cal/deg.

It may be of interest to compare, in tabular form, the present results with those given by Mah.

Temp, °K	298	700	800	900	1000
Present work, atm	4.3×10^{-17}	0.242	7.23	101.5	849
Mah's table, atm	1.71×10^{-19}	0.0238	0.855	14.1	132

Now that equilibrium studies of MnO_2-Mn_2O_3 and Mn_2O_3-Mn_3O_4 have been completed, it is possible to delineate the mutual boundaries of these oxides. By use of tables (38) of entropy and heat-content changes the boundaries (Fig. 6) have been extended above and below the range of temperatures and pressures of the experimentation. At an oxygen pressure of 1.000 atm the equilibrium temperature is 468°C (741°K), while in air at 1.000 atm it is 424°C (697°K).

Acknowledgment

The author wishes to express his gratitude to Dr. W. J. Hamer under whose direction the work was conducted and who maintained keen interest in the study despite the thousands of hours required to obtain equilibria.

Effects of Foreign Ions on Nickel Hydroxide and Cadmium Electrodes

E. J. Casey, A. R. Dubois, P. E. Lake,* and W. J. Moroz

Defence Chemical Biological and Radiation Laboratories, Ottawa, Ontario, Canada

ABSTRACT

The behavior of individual positive and negative electrodes of the sintered-plate nickel-cadmium battery system in the presence of foreign ions in KOH solutions has been examined. Carbonate choke: The variation of electrochemical capacity as a function of carbonate contamination of the electrolyte, temperature, and current density was measured for both positive and negative electrodes. The effect of carbonate on the negative cadmium electrode is much greater than on the positive. The general mechanism and the role of intermediate complexes are discussed. Nitrate shuttle: Self-discharge occurs in cells containing nitrate, as a result of reduction of NO_3^- to NO_2^- at the cadmium electrode with subsequent reoxidation to NO_3^- at the nickel hydroxide electrode. Cations on the positive: Addition of Li^+, Ag^+ Sb^{+3}, Al^{+3}, and As^{+3} to the electrolyte had effects on capacity and on charge-retention of well-formed nickel hydroxide positive electrodes. Lithium promoted the highest average oxidation, particularly at high temperatures (55°C). Arsenic was the best inhibitor of loss of charge. Possible mechanisms are discussed.

Carbonate.—Previous investigations have had as their objective the understanding of the effects on nickel-cadmium batteries of the carbonate which is formed by the reaction of the alkali electrolyte with carbon dioxide absorbed from the air (1). The interest of this Laboratory in these phenomena was awakened several years ago when it was observed that sintered-plate cells with more than 5% carbonate by weight sometimes behaved very peculiarly (2) and always delivered less capacity (3, 4) at low temperatures. However, the unpredictability of when and where it would occur made the verification of a true carbonate effect difficult.

On cadmium metal surfaces the mechanism of the carbonate effect has been studied (4-7) at a more fundamental level, in the absence of the porous sintered nickel matrix. It was concluded (6) that $CO_3^=$ competes with OH^- for adsorption sites on the underlayer which forms as the primary product of the oxidation reaction; and, further, that this competition varies with variation in current, electrolyte composition, and temperature. The important role of an inner double layer, in the underlayer, was stressed.

Another way of looking at this effect might be through the model of Croft and Tuomi (8-9). In their model the polarizations of the electrode are related to the number and kind of structural defects principally at the electrolyte-oxide interface and in the covering layer itself. The number and kinds of defects are determined by their rate of formation by the anodic current, their rate of combination with each other and with existing defects, and their rate of reaction with the components of the electrolyte.

The fibrous nature and the probable role of the hydroxycarbonate anodic reaction products on cadmium were discussed by Huber (10). Although their chemical composition was reported as early as 1936 (11), and that of the related bicarbonates since 1957 (12), there is still no reliable means of identifying small quantities formed on an anode. To complicate matters, these compounds are unstable. The problem of identification will be discussed in a subsequent report.

The nickel hydroxycarbonates are better known. Gagnon *et al.* (11, 13) showed chemically that nickel hydroxycarbonates can be formed if precipitating conditions are carefully controlled. However, like the cadmium compounds, sufficiently rapid identification of small quantities formed at electrodes is still not possible. There have been some very good recent studies made of the chemical precipitation and properties of nickel hydroxycarbonates (14) which may be used as a starting point in the attempt to understand at least qualitatively the electrochemical behavior. Thus compounds of the general formula $yNiCO_3 \cdot Ni(OH)_2 \cdot H_2O$, where $y = 1$, 3, or 4 have been identified chemically, and they give unique x-ray diffraction patterns (14). They are unstable in strong caustic. Longuet-Escard and Méring (15) have tackled the critical problem of the distortion of the nickel hydroxide lattice by incorporated carbonate ions; and Vasserman and Fomina (16) have followed changes in composition and in x-ray diffraction pattern during ageing, the compound becoming more basic at high *p*H (~12) and less basic at low *p*H (~7). Feitknecht (17) has given a broad and informative perspective of this problem.

Nitrate.—The loss of charge of a nickel-cadmium cell via the "nitrate shuttle" (18) was not recognized until cells with little or no free electrolyte were manufactured. Observations of odd effects of nitrate on voltage have been noticed [*e.g.*, (19)]. It seems to be a unique redox system: both the oxidized (NO_3^-) and reduced (NO_2^-) species are soluble in the electrolyte, are uncomplexed with either the electrolyte or the electrodes, and diffuse at a rate which increases with concentration gradient and temperature. Because nitrate is readily reduced by cadmium metal, and nitrite readily oxidized by charged nickel hydroxide, a mechanism for loss of charge exists by means of electron exchange within the cell.

Positive ions.—Following up a rather ingenious prediction from the solid-state structure of cadmium and its hydroxide, Fleischer (20) was able to demonstrate that the addition of indium metal to the cadmium negative electrode made a sharp decrease in the loss of capacity which usually occurs during cycling. With the above exception, most of the published work within the past few years on cationic additions, including that undertaken by this Laboratory, has dealt with their effect on the behavior of the nickel hydroxide electrode. The addition of lithia to the electrolyte has been standard practice in the pocket-plate battery industry for years. Its effect has been described in the trade as keeping the nickel hydroxide active material "loosened up," with the result that the electrochemical storage capacity does not decrease with prolonged use of the battery. Normally lithia does not need to be added to the sintered-plate battery; this is presumed to be so because the positive active material is spread so thinly over the surface of the sintered matrix that it is substantially all available for electrochemical action at normal temperature. However, to facilitate the formation of plates made by the thermal impregnation

* Present address: 448 Briar Avenue, Ottawa, Ontario, Canada.

process (21) used now by at least two manufacturers, it is sometimes necessary to add lithia to the electrolyte during the forming process. That lithium ions are also beneficial in the sintered plate positive at high temperatures will be demonstrated later.

Although cobalt hydroxide has often been incorporated in pocket-plate batteries since the time of Edison, the introduction of cobalt into the positives of sintered-plate batteries was first made by a European manufacturer during the early 1950's, and most other manufacturers have since followed suit. An additional stimulus for the commercial introduction of cobalt was Winkler's paper (22) in 1955 in which he reported "brilliant improvement" in performance. In general terms, cobalt raises the voltage of the electrode during discharge (*i.e.*, either it raises the reversible emf or it lowers the overvoltage). Further, cobalt has been reported (19) to improve greatly the charge-retention of the positive, and data published recently (23) support this view. After Winkler's paper, the first published systematic study on the effects of cobalt was that of Doran in 1958 (24). With lightly impregnated plates he demonstrated that, in contrast with plates containing pure nickel hydroxides, whose electrochemical storage capacity slowly decreases toward a final steady value (about 60% of the original) during repetitive cycling, the "electrodes containing moderate proportions of cobalt maintain indefinitely a capacity at least as high as that of the pure nickel hydroxide electrode at its transient best." He also found that whereas other ions (Zn^{++}, Mn^{++}, and Cd^{++}) made only minor modifications to the charge (oxidation) and discharge (reduction) curves, Mg^{++} had the very important practical effect of raising the discharge voltage (*i.e.*, lowering the cathodic overvoltage of the positive) by about 50 mv. However, Mg^{++} ions were found to increase the rate of loss of charge from the oxidized nickel hydroxide mass during an idle period.

Further, Doran found (25) that replacement of 5% of the nickel ions by cobalt and 5% by magnesium ions combined the best characteristics of both additions; thus, a stabilized high capacity, as well as discharge at a higher voltage resulted. In his paper, Doran cautioned that one could not extrapolate from his results, obtained with lightly impregnated plates, to battery performance. Subsequent evaluations of complete cells have been inconclusive (26).

In later work (27) it was demonstrated that scandium alone has the combined beneficial effects of the $Mg^{++} - Co^{++}$ addition, and that the discharge voltage is even higher with scandium than with magnesium. Further, "compared with the pure nickel electrode, in addition to the much higher discharge potential, the separation of anodic and cathodic potential is less, and the oxygen overpotential (top-of-charge potential) is higher." Of course, all of these effects are desirable in battery applications.

A basic difficulty arises in a study such as the present one, because the crystal structure of the active nickel hydroxide mass may be different from one experiment to the next on the same material, or from one preparation to another [see ref. (28), *e.g.*]; and, further, the crystal structure may change with "age" and even during "rest" when it is not being oxidized and reduced (8, 29, 30). One preparation (loose, open structure) may be expected to show marginal effects of positive ion additions, while another preparation (more perfectly formed crystallites) may show marked effects. These and other published claims [ref. (31-58)] about electrochemical effects of positive ions have been collected and are recorded in Table I, for comparison later with results of the present work.

Consider what might be the effects of foreign cations on the electrical conductivity of the active nickel hydroxide mass. Two concepts provide the background: (*a*) the mass consists of lamellar hexagonal arrays of positive ions, negative ions and water molecules whose positions are known from x-ray diffraction studies [colorfully described and illustrated by Doran (24), *e.g.*]; and (*b*) the idea (59), that the oxygen atoms of the water and hydroxide ions of the mass remain relatively fixed in the lattice while protons from the electrolyte and electrons from the metallic grid move into the mass during discharge (reduction) and out of the mass during charge (oxidation). Divalent foreign cations should distort the lattice, being of different size, and introduce anion (OH^-) vacancies as the mass becomes oxidized. Into these vacancies water molecules may fit, and facilitate protonic conduction. Doran's results on Mg^{++} and Sc^{++} especially tend to support

this idea. Monovalent cations should do the same, even to the discharged mass [as $Ni(OH)_2$]. Trivalent cations may introduce cation vacancies and so facilitate electronic conduction; or trivalents may be more heavily hydrated, because of smaller size, and facilitate protonic conduction. If electronic conduction through the mass can be made lower relative to protonic conduction, the mass can be anodically oxidized to a higher free energy state at the mass-electrolyte interface before oxygen evolution sets in. An attempt has been made to study these possibilities experimentally.

The rate of self-discharge during an idle period following charging may also be affected by foreign cations. The present work has been designed around the simple premise that the charge, or the oxidation capability of the charged mass, is composed of two parts: (*a*) the "normal capacity," associated with the transformation $Ni(OH)_2 \rightarrow NiOOH$;[1] and (*b*) the "over-capacity"—extra oxygen forced into the NiOOH during charging and trapped there. Thus the charged mass may be represented as

$$\beta\text{-NiOOH[O]}$$

where the extra O is in, as well as on, the crystallites. [See ref. (65) for discussion of $(\beta\text{-NiOOH})_2(O)_{ads.}$] Both the overcapacity and the normal capacity are lost during an idle period, the former faster than the latter. In the present work an attempt has been made to separate the two and then to assess the effects of monovalent and trivalent foreign ions on each decay.

Experimental Methods

The experimental cells consisted of the test electrode suspended between two counter electrodes in a lucite or nylon container. A reference electrode (Hg/HgO), with Luggin capillary tip which was proximal to the test electrode, was added. The stock electrolyte was 30% KOH in distilled water, and protected from rapid CO_2 absorption by a ½-in. layer of mineral oil. The electrolyte was replaced when necessary.

Experiments were of two kinds: (*a*) Charge-discharge cycles were done on a program (Table II) which has been shown [see ref. (3), for example] to reflect quantitatively and reliably the operational electrochemical properties of the electrode. The capacity (charge delivered), 5-sec and mid-point discharge voltages, the shape of the charging curve, and the top-of-charge voltage were recorded at several current densities. (*b*) Charge-retention studies were also carried out: potential decay and capacity loss as a function of time were carefully measured. The decay of open-circuit potential (test electrode to Hg/HgO reference

continuous recording on a potentiometer which was fed only a fraction of the potential of the cell via a high resistance (200,000 ohms) voltage divider; (ii) intermittent measurements of cell potential at appropriate intervals with a L&N slide-wire potentiometer; and (iii) continuous recording of potential by a Type 1230-A General Radio electrometer-amplifier (input impedance minimum 10^9 ohms) coupled with an Esterline Angus recording ammeter. The precision of the measurements was: for the recording potentiometer ±2 mv; L&N ±0.1 mv; 1230-A electrometer ±2 mv.

The cycling and charge-retention programs [(*a*) and (*b*) above] were carried out on duplicate cells to which Li^+, Ag^+, $Sb^{+3} \cdot As^{+3}$ or Al^{+3} had been added. No study of charge retention was done on carbonate-

[1] Note that although the composition NiOOH is manifested in three fairly well-defined physical structures (see X-ray diffraction patterns and cell constants, Fig. 1 and Table I of ref. (60), for example), there is still no unequivocal evidence that the nickel in the compound is trivalent. On the contrary, the x-ray K-edge absorption results of Hanson and Milligan (61) offer no evidence at all for valences other than two in the "higher oxides." Tsutsumi (62) later found similar results with higher oxides, but introduced an uncertainty which has not yet been clarified (63). Perhaps $Ni(OH)_2$ is simply a good container for O and OH, with certain compositions [4 $Ni(OH)_2 \cdot NiOOH$, $Ni_3O_2 \cdot Ni_3O_2(OH)_4$, NiOOH] more stable than others. However, it is believed that trivalent and tetravalent nickel can be stabilized in complexes with certain foreign elements such as phosphorus and arsenic (64).

contaminated electrodes. Duplicate controls, containing no additive, were run simultaneously. All cells containing positive ion additives were thermostated at 55° ± 1°C during most of experiments, with cycling at 27°C done both before and after the high-temperature studies. The electrodes used in the positive ion studies were prepared from commercial (Clevite) sintered nickel plaques made from carbonyl nickel. Impregnation was carried out by the thermal method (21). The plates were then formed, and given 14 electrical cycles on the routine outlined in Table II. This procedure established the "normal" behavior of the electrode. After the characteristics had stabilized, the impurities were introduced into the electrolyte: the Ag^+ first as nitrate, later as oxide, the Li^+ as hydroxide, the As^{+3} as oxide, the Sb^{+3} as oxide and the Al^{+3} as oxide.

For the carbonate studies, electrodes from two commercial sources [prepared by the electrolytic method (66, 67)] as battery plates (by North American and European manufacturers) were used. After electrochemical cycling in 30% KOH (7.2*N* KOH) to constant "normal" capacity, the electrodes were cycled in electrolyte made up of mixtures of various proportions of 7.2*N* KOH and 7.2*N* K_2CO_3 so that the concentration of K^+ remained constant at 7.2*N*. These mixtures correspond roughly to the practical situation after 30% electrolyte has absorbed CO_2 from the air. Experimental data were collected at temperatures of 27°, −18°, −40°, and −54°C. Electrodes were charged at the 1-hr rate for 2 hr, put on open circuit stand for approximately a half-hour, and subsequently discharged at current densities of 3.9, 15.6, or 39 ma/cm² of electrode. Electrolyte compositions[2] of 0, 5, 10, 25, 50, 75 and

only nominal, the actual $CO_3^=$ concentration being closer to a value of 1-1.5%). As a check on reproducibility, at least two electrodes of the same type were used for each experiment. The cycle was repeated from two to five times with each electrode and the results for each particular condition were averaged. In addition, some cadmium electrodes were examined to determine whether the capacity loss during aging is temporary or permanent. The early experiments (3, 4) have been carefully repeated by further experiments on plates from different sources. Selected results which establish the main features of the processes are reported in this paper.

After introduction of the impurity, cycling was continued (Table II) until new stable characteristics had been obtained. In the carbonate studies it was found advantageous to re-cycle in 30% KOH at room temperature before changing the electrolyte composition; but in the positive ion studies this was done only at the very end of the experiment. During the cycling of cells containing added positive ions the experiments were interrupted at convenient times so that measure-

[2] $100\left[\frac{\text{equiv. of } CO_3^=}{\text{equiv. of } CO_3^= + \text{equiv. of } OH^-}\right]$, called "equiv. % $CO_3^=$"

ments of both the decay of voltage and the loss of charge during open circuit stand could be taken. For charge-retention studies the charge was measured as the coulombic output during reduction at the 2-hr rate. The minimum stand time was 30 min, and the longest was six weeks.

Some x-ray diffraction spectra were taken in support of this work by the Physics Section of this Laboratory. In addition, standard qualitative chemical analytical techniques were employed for the identification of impurity ions found at the end of the experiment in both the electrolyte and the electrodes. Corroborative analytical work was done by the Analytical Section. Mines Branch, Ottawa. Basicity and carbonate were determined by double titration, with phenolphthalein and methyl purple indicators. The nickel in the electrodes which was soluble in hot NH_4Cl-NH_4OH was determined quantitatively by the dimethylglyoxime method (68).

Changes in nitrite concentration in the electrolyte were followed by the sensitive sulfanilic acid-alpha naphthylamine hydrochloride color development for NO_2^-, as described by Snell and Snell (69).

Results and Discussion

The Carbonate Choke

The aim of this series of experiments, which was to establish the effects of contamination by carbonate ion on nickel hydroxide and cadmium electrodes and to be able to predict carbonate effects on nickel-cadmium batteries, has not been fully achieved. The results on single electrodes were reproducible to within only about ±10%, even when a fixed parallel geometrical arrangement was used and when the most obvious variables, temperature, concentration and charge and discharge rate, were carefully controlled. The work has pointed up the importance of further variables, some of which cannot be controlled in experiments in which the active material is held within the pores of a sintered plaque. For instance, until more is known of the physical properties of anodically formed hydroxides and hydroxycarbonates of cadmium and nickel, the full explanation of the effects of carbonate contamination, and under what conditions these effects will occur, cannot be predicted. However, the results obtained in the present work permit certain general conclusions to be made and point out suitable directions for further study. The results are discussed in the following two sections.

On cadmium electrodes.—The general trends and measurements on a particular plate for a particular set of conditions were reproducible, but the detailed behavior varied from plate to plate, and also was found to be dependent on the age and electrical history of the plate. In this report the results are summarized in terms of a qualitative model which, in our opinion, includes the principal dependent variables. The general behavior is illustrated with examples selected from experimental results on plates. Essentially the model [summarized in ref. (28)] is as follows: Cd metal oxidizes anodically to a "CdO" underlayer, the primary product,[3] and in all but the very initial stages either metal ions or oxygen-containing species must penetrate the film of CdO if reaction is to continue. Therefore the thickness of CdO is important. It is removed at the CdO-electrolyte interface by a "conversion reaction," in which CdO is complexed into the adjacent electrolyte as $Cd(OH)_4^{-2}$ or $Cd(CO_3)_3^{-4}$ (7), at a rate depending on the composition of the electrolyte at the interface, and settles out on the surface of the CdO layer as $Cd(OH)_2$, $CdCO_3$, or as a hydroxycarbonate. The reaction can continue as long as ions can penetrate the CdO more easily than water can be oxidized to oxygen and the electrons so liberated penetrate the CdO in the opposite direction. Therefore the rate of the conversion reaction is of prime importance: if it is slow, the available capacity will be low. This rate increases with temperature and exposed area. The reaction can go by two routes, via the hydroxy-complex (at rate v_{OH^-}) and via the carbonate-complex ($v_{CO_3^=}$). These complexes are not very soluble and probably also precipitate on the CdO surface. Hence the complicated problem of physical interference by reaction product logically arises, and it cannot be avoided. This introduces the second variable.

The second variable thought to be important is the specific volume of final precipitate. In addition to the complexes $Cd(OH)_4^{-2}$ and $Cd(CO_3)_3^{-4}$, solid, basic cadmium carbonates, $xCdCO_3 \cdot Cd(OH)_2$, can also be formed. Huber stated (10) that these are formed as fibrous (gelatinous) precipitates at the reaction interface where Cd^{++} from the metal meets OH^-, $CO_3^=$, and H_2O from the electrolyte. Several years ago Gagnon *et al.* (11), using a controlled precipitation of weak $Cd(NO_3)_2$ and K_2CO_3 solutions, formed two such compounds, which were chemically distinguishable, corresponding to $x = 10$ and $x = 5$. We have repeated, confirmed, and extended this work and, chemically, have been able to distinguish a third compound corresponding to $x = 4$ (Fig. 1). By the time they were dried and mounted, all gave x-ray spectra basically of $CdCO_3$, but sometimes with additional weak lines due to $Cd(OH)_2$, splitting in two of the three strongest lines and with intensity differences at short spacings. All three are quite unstable, and change composition, to $Cd(OH)_2$ or $CdCO_3$, if washed for a long time or digested in the mother liquor depending on the *p*H. Details of this work will be published elsewhere.

The precipitates found after $Cd(NO_3)_2$ solutions are mixed with 7.2*N* ($KOH + K_2CO_3$) solutions in which the concentration is varied from 0 to 100 equivalent % K_2CO_3 show some striking physical difference (see Fig. 2). In the central, 20-70 equivalent % region, the precipitates are voluminous and gelatinous and when analyzed are found to be composed of $Cd(OH)_2$, K_2CO_3, and $CdCO_3$ with slight variations in x-ray spectra. Those in the end regions of concentration (<20%, >70%) are nearly pure hydroxide or carbonate and

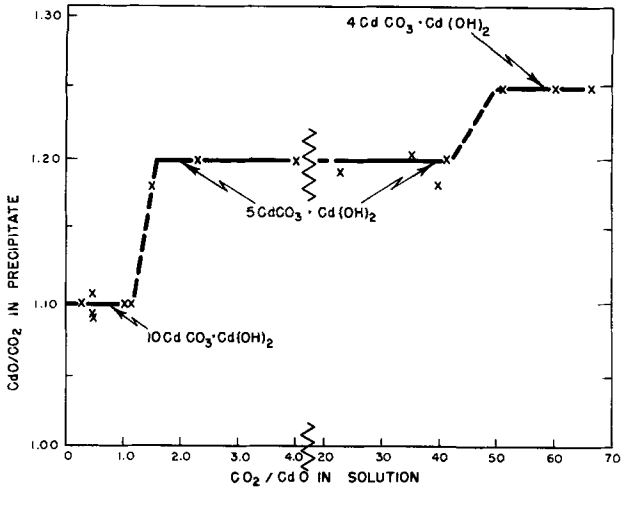

Fig. 1. Analytical results on precipitates and their mother liquors made by controlled mixing of $Cd(NO_3)_2$ with K_2CO_3 of different concentrations.

[3] There has been discussion on this point in the recent literature. We called it "CdO" for reasons discussed in ref. (6) on the basis of interference colors, existence of the conversion reaction, carbonate effects, exponential decay of overpotential, and consideration of likely primary processes. CdO was earlier (70) reported found by electron diffraction techniques, and was found again more recently (71), but others have tried to find it without success (8, 65). This divergence of experience can be rationalized as follows: The rate of the conversion reaction is high, and the underlayer very thin. Thus, during oxidation of cadmium planar electrodes at 0.33 ma cm^{-2} at 27°C in 7.2*N* KOH, the rate of conversion was found (5) to have a value equivalent to 0.26 ma cm^{-2} when the conversion layer was thin, and smaller values as the conversion layer built up. As conversion slows down the thickness of the underlayer increases. Its maximum thickness, at passivation, was estimated (28) to be a few hundred angstroms during current flow. It is rapidly converted to $Cd(OH)_2$ or $CdCO_3$ once the circuit is broken.

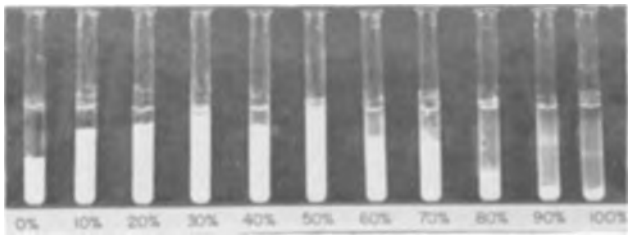

Fig. 2. Precipitates formed by mixing one part of 0.5N $Cd(NO_3)_2$ with one part of 7*N* K^+ in which the K^+ is present from 0 to 100 equiv. % carbonate in hydroxide.

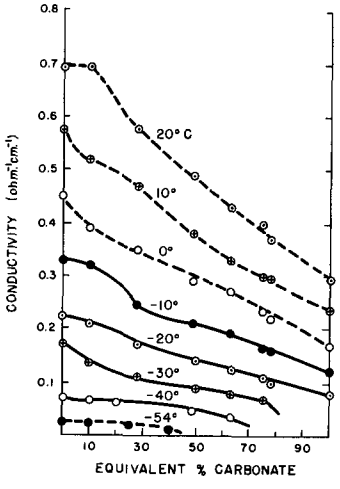

Fig. 3. Conductivity of mixed KOH-K_2CO_3 electrolytes at different temperatures. Total alkalinity: 7.2*N* K^+.

are flaky and/or granular. The specific volume of the final reaction product could be quite important in a porous electrode. For example, a small weight of precipitate could conceivably have a volume large enough to block the "neck" of a pore or displace the electrolyte and cut off all ionic contact between active material and the bulk of the electrolyte. This would make the active material within the pore unavailable for further electrochemical oxidation or reduction.

The third variable is the group of transport properties of the bulk electrolyte: conductance, diffusion, and fluidity. Electrical conductance, for example, falls off nearly linearly with increasing equivalent % carbonate, as is shown in Fig. 3, drawn from our earlier work (4). Presumably, as is usually the case, the corresponding specific rates of diffusion and fluid flow fall off similarly. At high rates and at low temperatures, soon after reduction starts, the ohmic voltage drop almost immediately reduces the cell voltage below the acceptable, useable, cut-off or end value. Decreased diffusion of KOH and K_2CO_3 in the solutions with higher equivalent % carbonate would also be expected to have the same effect, because the concentration gradients set up in the pores of the plate can disperse only slowly. Convective effects within pores and "extrusion" or forced flow of electrolyte into or out of pore due to changes in volume or physical structure of active material are not well understood but, such a transfer of fluid could dramatically affect the electrical output of heavily impregnated plates.

Figure 4a is a schematic illustration of speed of the processes on which the electrical output is thought to depend. A trend downward in the function plotted means there will be a trend downward in the coulombic output obtained. Since the processes are consecutive, the slowest one limits the output. Each of these curves represents a family of similar curves, there being a member for each set of experimental conditions. For example, the curves of Fig. 4b are the results of linear combinations of members of the four families introduced in Fig. 4a. Thus capacity *vs.* composition

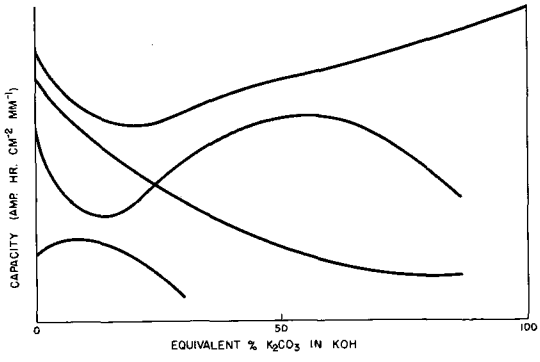

Fig. 4b. Effects of electrolyte composition on charge delivered by negative electrodes under various conditions (schematic).

(*C*/c) curves may take many shapes. Figures 5 to 7 are examples of results chosen from both the earlier report (4) and our more recent confirmatory work.

In addition to the transient effects on the three variables just considered, the results show that plates used in carbonated electrolyte can "age" or develop a permanent decrease in capacity. Although no cadmium has left the plate, some of it becomes passivated in the sense that it cannot be oxidized or reduced. This may be due to a permanent sealing of pores, to a redistribution of the active materials, or to the formation of a nonconducting (salt? oxide?) mass. The three sets of curves in Fig. 5 (25°C) were taken on plates which had a substantial history (at least 100 cycles) in batteries before these tests were done. Not only is the transient carbonate concentration effect very pronounced, but also in two cases, the capacity permanently "lost" was very large. Figure 6 (data at —18°C) illustrates this point even better: the output of a plate (No. 12) early in the tests is contrasted against the output of the same plate near the end of the tests, about 100 cycles later: the capacity *vs.* composition characteristic has changed markedly. Apparently the internal physical character of the plate has changed (*i.e.*, the plate has "aged") so that the capacity *vs.* composition curve has moved to the left and down, as if some solid carbonate had become permanently sealed into the plate, accounting for part of the loss (the permanent loss), while the carbonate in the electrolyte had caused

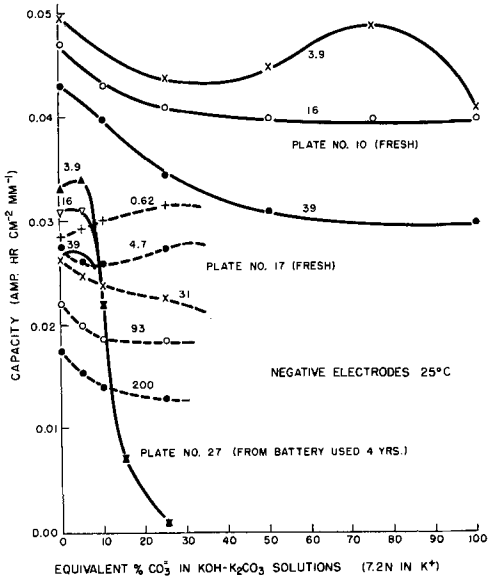

Fig. 5. Electrochemical capacity delivered, at c.d. shown (ma cm^{-2}), by good fair and poor cadmium negative plates at 25°C.

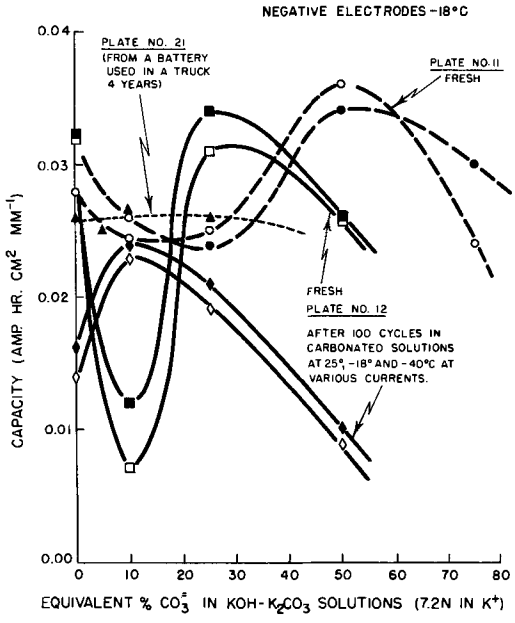

Fig. 6. Electrochemical capacity delivered, at c.d. of 160 ma cm^{-2}, by three different cadmium negative plates at —18°C, in KOH-K_2CO_3 mixtures. Solid symbols, charged at 25°C; open symbols, charged at —18°C.

the rest (the transient loss). The initial characteristics of another plate from the same group (No. 11) and with the same history, are also plotted in Fig. 6. Note the similarity of trend but difference in detailed behavior between supposedly duplicate specimens, plates 11 and 12.

Although somewhat tedious to obtain, these characteristic capacity *vs.* composition (*C*/c) curves clearly display the important, though subtle, differences between supposedly identical porous plates. They are much more sensitive than the Peukert curves (log *C* *vs.* log cd), which have been used to good advantage in assessing the early stages of development of the sintered plate technique [See ref (3) and (21), for example].

Figure 7 shows that differences in detail can be very pronounced at —40°: remarkably good output can be obtained from some plates, very much less from others. These differences are more pronounced the higher the discharge current density. The figure also illustrates the fact that better capacities can usually be obtained at low temperatures (—40°) if charging is also done at low temperatures. Generally at low temperatures the differences are less reproducible than at room temperature. Charge acceptance may be better at low temperature, but it seems to be more likely that the extra charge is due to hydrogen trapped in the pores and in grain boundaries of the nickel sinter, and as nickel hydride.

In summary, there now exists an accumulation of evidence that two kinds of detrimental effects due to carbonate occur on the negative plate: permanent effects related to the history of the plate and due to carbonate locked in the pores, and transient effects related to pore dimensions and the composition of the electrolyte. These effects have been observed on planar cadmium electrodes (5), and now, amplified greatly, on sintered negative plates. Three dependent variables seem to be important: the rate of the conversion reaction, the volume of reaction product (discharge), and the transport properties of the bulk electrolyte. These variables are dependent on electrolyte composition, temperature, and apparent current density, and probably also on pore size, pore size distribution, and interconnections of pores (*i.e.* electrolyte channels) within the plate.

On nickel hydroxide electrodes.—No appreciable effect of carbonate was found on the coulombic capacity of the nickel hydroxide electrode at 25°C. Tran-

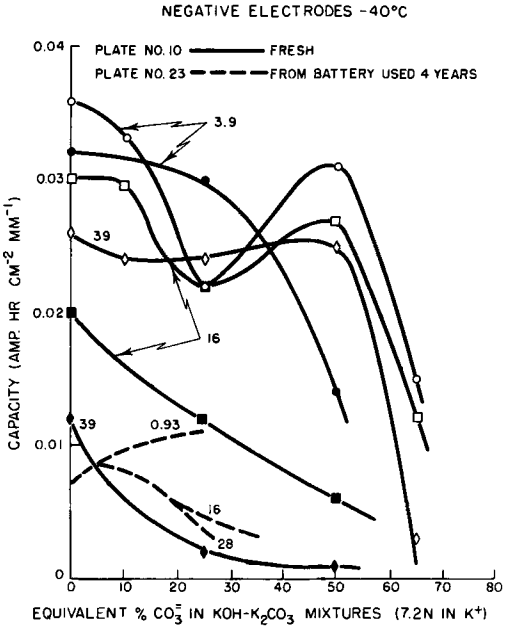

Fig. 7. Electrochemical capacity delivered, at c.d. shown (ma cm^{-2}), by two cadmium negative plates at —40° in KOH-K_2CO_3 mixtures. Solid symbols, charged at 25°C; open symbols, charged at —40°C.

sient effects, but no permanent effects, were found at low temperatures, during studies on 12 plates with upwards of 100 cycles per plate. Since the mechanism of discharge of the positive is still poorly understood, the presentation here is limited substantially to the effects of carbonate found experimentally.

At —18° and —40°C, the loss in capacity due to carbonate was found to be larger for plates which contained a greater amount of active material. In the more heavily loaded plates the capacity was a multivalued function of composition, a behavior similar to that of the negative. Figure 8 shows output at —18°C (following charge at —18°C) for two different plates, one twice as heavily loaded as the other. The general downward trend of the capacity as the electrolyte became more

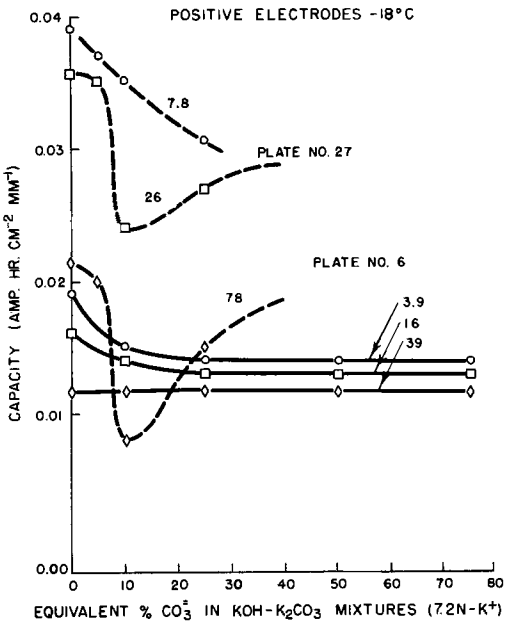

Fig. 8. Electrochemical capacity delivered at —18°C, at c.d. (ma cm^{-2}) shown, by two positive plates, which differ by a factor of two in the amount of nickel hydroxides per unit volume, in KOH-K_2CO_3 mixtures.

heavily carbonated is a behavior similar to that of the negative and is probably related to the decreasing rate of mass transport. The minimum at 10% may be the influence of the formation of bulky nickel hydroxycarbonates as intermediates in the process of electrochemical reduction, for it is evident that the effect was manifested only in the more heavily loaded plates. Unfortunately with nickel, as with cadmium, very little is known about the formation of its hydroxycarbonates as intermediates in the electrode process. Alternatively, possibly the carbonate acts by its ability to penetrate the layer lattice of the nickel hydroxide and distort it (15).

Figure 9 shows capacities delivered at —40°C. It is rather striking that the effect is actually fairly small until the carbonate content becomes so high that the electrolyte becomes glassy (at about 60 equiv. % carbonate), when the rate of transport of water, needed for the discharge reaction

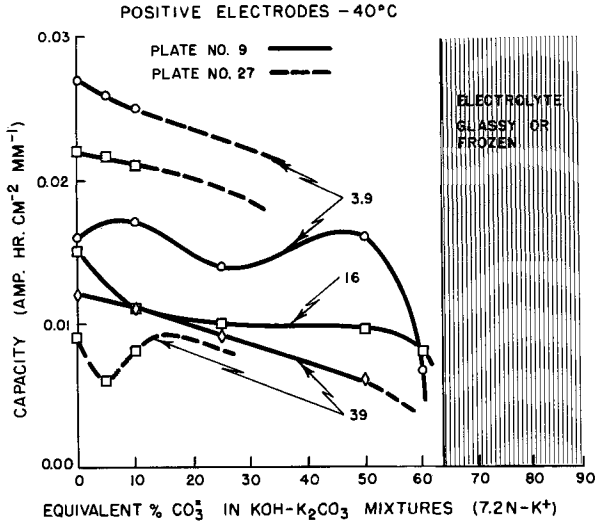

Fig. 9. Electrochemical capacity delivered at —40°C, at c.d. shown (ma cm^{-2}), by two nickel hydroxide plates in KOH-K_2CO_3 mixtures. All charging done at —40°C. (Charging at 25°C gave about the same outputs).

$$H_2O + e^- + NiOOH = Ni(OH)_2 + OH^-$$

falls practically to zero. Perhaps the readily available carbonate ions are literally frozen out of the layer lattice at —40°.

The Nitrate Shuttle

During preliminary work in this study, some positive ions were added to the electrolyte as nitrates. The most notable effect of the additions was the rather impressive loss of capacity during charged stand. Although the loss of charge was first attributed to the cation, a systematic elimination of possibilities by adding oxides instead of nitrates, and finally by adding KNO_3 itself, revealed that the anion was responsible for the effect. The results of experiments with the active materials added directly to the KOH electrolyte showed that Cd metal reduces nitrate rapidly to nitrite and that the oxidized positive plate material (nominally NiOOH) oxidizes nitrite to nitrate. Tests on a three-plate cell confirmed the suspicion that the $NO_3^- — NO_2^-$ couple can conduct a shuttle for electrons from the negative to the positive plate, and thus discharge the cell. Results are shown in Fig. 10. Since negative capacity was well in excess of positive in the test cells, the additive always ended up as nitrite, after the positive had become fully discharged. Subsequently it was shown that charged positive active material can stand alone in nitrate-containing KOH without accelerated self-discharge.

From these results the general mechanism of the nitrate shuttle is clear. Nitrate ion diffuses to the negative and is reduced to nitrite; the nitrite diffuses to the positive and is oxidized to nitrate. The result reported, for the cell containing 7 x 10^{-3} moles/1 KNO_3, in Fig. 10 was the approximate electrical equivalent at 55°C of a 100-ohm resistor connected directly across the terminals. The shuttle probably operates at a rate which is transport-controlled, since the reactions with the solids seemed to be relatively very fast at both the positive and negative electrodes. Since the transport rate (and hence the value of the equivalent resistance) is a function of cell geometry, concentration of nitrate, and temperature, as well as of the permeability constant of the separator, no detailed examination of transport for the experimental cells was worthwhile, and such work was not undertaken.

As a check on current industrial practice, sealed cells (4 AH) from the production line of two manufacturers were opened, and the contents refluxed in a Soxhlet extractor with distilled water for 3 hr. The leachant was then made neutral, and tested for nitrate. Tests for nitrate in both were positive. One had enough nitrate to make the electrolyte of the cell 0.005*N* in nitrate! The nitrate effect and its implications were reported briefly in an earlier paper (18). Reduction of NO_3^-

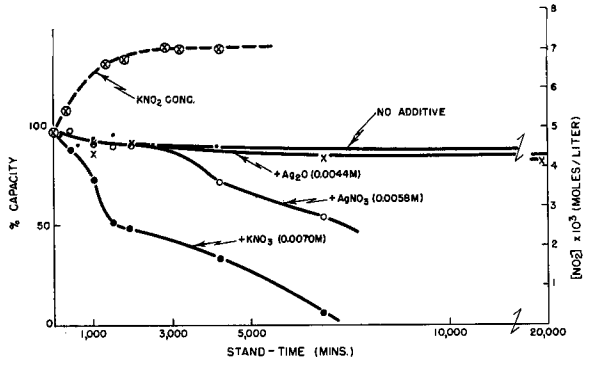

Fig. 10. Effect of nitrate ion on charge retention of positive plates in a 3-plate test cell; 7.2*N* KOH; 55°C; total nitrate added: 7x10^{-3}M. % capacity = 100 $C_t/C_{30\ min}$, where C_t is capacity after charged stand of *t* min, and $C_{30\ min}$ is capacity after charged stand of 30 min.

ultimately to NH_3 and N_2 in sealed cells at high temperatures during prolonged charged stands has been recently reported (72).

A search was made for other possible shuttles, but none was found. The requirements are actually quite stringent: good solubility of both the oxidized and reduced form; rapid oxidation of the reduced form by the charged positive; rapid reduction of the oxidized form by the charged negative; (redox potential E between $Cd/Cd(OH)_2$ and $NiOOH/Ni(OH)_2$ in 7*N* KOH). This search consisted of examination of the redox tables, and then experimentation with likely candidates (*e.g.*, I^-/IO_3^-, Tl^{+1}/Tl^{+3}, quinhydrone, etc.). All these couples lack at least one of the pertinent qualifications. The nitrate shuttle seems to be unique in the alkaline Ni-Cd system. [The iron (Fe^{+2}/Fe^{+3}) shuttle is well known in the $Pb/H_2SO_4/PbO_2$ system.]

There was some indication in this work that the nitrate-nitrite system depressed the voltage of the test cells during overcharge, but more work is required to establish this point.

Foreign Cations in the Nickel Hydroxide Electrode

General observations.—The effect of positive ion additions on (*a*) electrochemical capacity and (*b*) charge-retention and voltage-decay during charged stand were measured and analyzed. The experiments were intended to test the lamellar hydroxide-proton transfer model of nickel hydroxide electrodes.

Duplicate test cells were made up with added Li^+, Ag^+, Al^{+3}, and As^{+3}. These positive ions were added to the electrolyte of the test cells as $Al(OH)_3$, Sb_2O_3, As_2O_3, LiOH, and silver ion as Ag_2O. They were put through a cycling program and a charged-stand program at 55°C, at which temperature the aging effects should be accelerated. Although the information was gained under conditions (full impregnation, high temperature) in which the plate is often found in practice, it may be that introduction of the rapid aging effects has precluded the possibility of isolation of any but the gross effects of the ions added, *i.e.*, all the subtle effects may have been masked by the changes in crystalline form which occur during aging (8, 29, 30). Hence our discussion is limited to those effects which were observed under the specific conditions of this study.

The end-of-charge voltage did not vary appreciably from cycle to cycle. All charging (oxidation) was done for 2 hr at the 1-hr rate based on the theoretical capacity. The shapes of the charging curves varied (slightly), both from cycle to cycle and with different additives, but in no systematic fashion, and are not discussed here. [Lightly impregnated plates show some systematic variations (25).] High end-of-charge voltages with correspondingly high "overcapacities" were obtained with the Li^+-containing cells. This fact will be discussed later.

Other than one isolated inhibition caused by aluminum, no inhibition of the electrochemical oxidation or reduction which could be ascribed to the mono- or trivalent foreign ions was observed on the positive. A fast, sensitive amplifier-oscillograph apparatus was used for several high-rate (5-min) discharges at normal temperatures and at low temperatures (down to —30°C), but no large effects on overpotential were observed which could be ascribed unambiguously to foreign cations. This result may be a significant blow to the proton transfer theory of charge transfer within the active mass, because trivalent cations were expected to trap out anion vacancies into which protons could jump. However, there may be other explanations.

The cations are not as easily lost cathodically from the electrolyte as one might imagine. No silver was found plated out on cadmium; nor was any of the alloy AgCd detected by x-ray diffraction. Aluminum and lithium cannot be plated out in KOH_{aq}. Although AsH_3 and SbH_3 are evolved rapidly, along with H_2, from a cathode in acid solution, the processes are somewhat

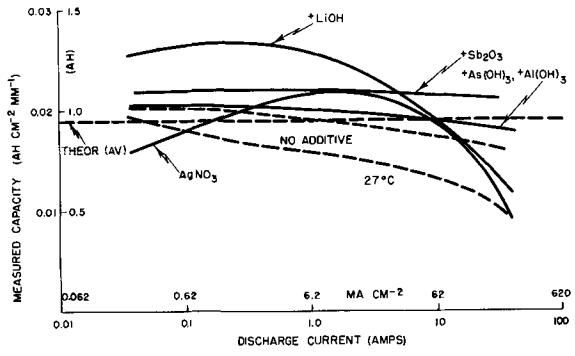

Fig. 11. Charge delivered at 27°C as a function of discharge current density for nickel hydroxide electrodes whose charge retention had been studied for nearly 2 years at 55°C.

different in basic solution. Thus, the silver nitrate-paper test for arsine revealed that when arsenic is added as As_2O_3 to KOH solution it does escape at the cathode as AsH_3, whereas if added as As_2O_5 it does not escape. The As_2O_3 added to a cell behaves as if it were quickly converted to As_2O_5 at the positive and then stayed there. No stibine could be detected either, but the case of antimony is not certain because analysis is difficult.

Charge delivered during reduction.—A progressive increase in the measured capacity with prolonged use was observed for all positive plates. The greatest increase was obtained with those containing foreign cations. This was reflected at all discharge rates, from the 20-hr to the 2-min rate. Better use is made of the active material within the plate when cycled at 55° than at 27°C. Once the "active mass" has become fully active at 55°C, however, the output at 27° approaches that at 55°C, behavior that perhaps could have been predicted from earlier work (73) on the role of water and alkali in the active mass. Figure 11 shows the charge delivered at 27°C by seven plates following protracted studies of charge retention at 55°C, conducted over a two-year period.

The source of increased capacity with life was determined by chemical analysis of the plates. The question posed was: Is the same amount of nickel hydroxide oxidized to a higher average level of oxidation (*i.e.*, to contain more oxygen), or is some of the sintered metal plaque oxidized slowly to give an extra amount of chargeable hydroxides? At the end of the tests the plates were washed in distilled water until neutral; the hydroxides were leached out in warm $NH_4OH = NH_4Cl$, and the leachant analyzed for soluble nickel using the dimethylglyoxime method (68, 69). A substantial increase in soluble nickel occurred during the tests [Table III: row (4) minus row (1)]. The fact that some of the original sinter was converted into active material was confirmed by the loss in weight of the sintered plaques, *i.e.*, 10-15% of their original weight per unit volume. The oxidation probably occurred during the prolonged (weeks) charge-retention tests at 55°C, not during the relatively insignificant charging time (2 hr). The rate of this corrosion reaction is doubtless a function of purity of the nickel powder from which the sinters were made.

The definite effects which could be ascribed unambiguously to the presence of the foreign cations were: (*a*) In all cells containing foreign cations, the sintered nickel matrix oxidized more during the tests than did the control electrodes with no foreign cations. (*b*) One positive in a cell containing $Al(OH)_3$ at one stage (cycle 55) was fully charged, yet could not be electrolytically reduced (discharged). This "passivation" was finally broken by an anodic pulse of high current density. Perhaps it was the physical breakdown of a skin of gamma alumina (an electronic conductor at high field strengths) formed on the exposed active sites of the active mass. This condition was observed only once.

Table III. Theoretical and measured electrochemical capacity of nickel hydroxide electrodes

Condition	100 × capacities, amp-hr cm^{-2} mm^{-1}				
	Normal	+ LiOH	+ $As(OH)_3$	Sb_2O_3	+ $Al(OH_3)$
1. Theoretical, based on weight gain (before tests)	1.80	1.85	1.80	2.05	1.97
2. Last measured (3-hr rate) 27°C	1.6	1.8	1.5	1.4	1.6
3. Last measured (3-hr rate) 55°C	2.3	2.8	2.4	2.1	2.2
4. Theoretical, based on soluble nickel (after tests)	3.0	3.6	2.6	3.0	2.8

Notes on each condition: 1, All weight gained during impregnation was assumed to be due to $Ni(OH)_2$; 2, cycle 56; 3, cycle 80; 4, Leached in a mixture of 1*N* NH_4OH + 1*N* NH_4Cl at 60°C for at least 24 hr.

Although values given for theoretical capacities are averages of 4 determinations, the errors are such that the numbers are reliable to only ±5%. In addition, numbers in row 1 might be systematically low because of excess drying; numbers in row 4 might be systematically low because of incomplete leaching. Reproducibility of measurements of electrochemical capacity during test program (Table II), as determined from the 3-hr rate discharge was ±4%.

(c) Positives in Li^+-containing cells consistently showed high "overcapacities," to be discussed next.

Charge retention.—Figures 12 and 13 show the charge (normalized: $C_r \equiv C/C_{Theor}$) delivered at the 2-hr rate by 12 plates after they had been stored for various lengths of time in the electrolyte at 55°C. This converging decay is linear in log time (t) for upwards of 2 months at 55°C, and can be expressed as

$$C_r \propto \log (t + \theta)$$

where θ is very small, of the order of minutes. [The same relationship was found by others, for example Conway and Bourgault (74), who measured the oxygen evolved from the charged active material at 25°C]. Beyond about 40 days the relationship breaks down. Thus a linear plot C_r *vs.* t, from 10^3 to 10^5 min, discloses that the decay rate, $-\partial C_r/\partial t$, at long times is more or less constant [similar observations have been reported before (75)]. If C_r^o is defined as C_r at the first marked deviation from the linearity of the C_r *vs.* log $(t + \theta)$ curve, and if it is assumed that to a first approximation all C_r above this value is excess capacity over that due to $NiOOH/Ni(OH)_2$, that is, "overcapacity," one can analyze the decay of this overcapacity, $Q(\equiv C_r - C_r^o)$, by standard kinetic techniques. Figure 14 shows a linear plot of Q *vs.* stand-time. Tangential slopes ($-dQ/dt$) express the rate of decay, v, at various values of the excess capacity. If the order of the reaction with respect to concentration of overcapacity is n, then

$$v \propto Q^n$$

from which

$$\partial \log v/\partial \log Q = n$$

From plots of log v *vs.* log Q for all the results, n was found to be about 5 (consider the insensitivity of the log-log plot). Integration and introduction of the boundary condition that Q must have some well-defined value, Q_o, at the end of charge (*i.e.*, at a stand-time of zero) gives

$$Q = Q_o(1 + 4k\,Q_o^4\,t)^{-0.25}$$

where k is the specific rate constant for the decay. In Fig. 15 the charge retained after different times of charged stand is plotted up for four electrodes in a manner which displays the inverse quarter-power dependence upon time.

In the system under study here, an order of reaction of about five can be interpreted in at least two ways, neither of which directly results from the chemistry of the system:

1. An unknown concentration-dependent force may be operative when excess higher oxide material begins to accumulate. This could be a physical repulsion of oxygen (as O_2?; as OH?; as O?) trapped under high internal pressure (dU/dV) in distorted (stretched ?) crystallites; or possibly an electrostatic repulsion of trapped OH^- ions, since high orders of reaction are observed when strong repulsive forces can become operative.

2. An erosion reaction, very rapid at first, but slowing down quickly, may be operative, perhaps a recrystallization, or a "digestion," as suggested by

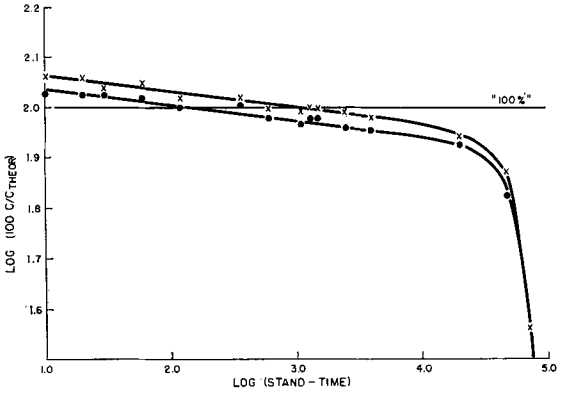

Fig. 12. Charge retention of thermally impregnated nickel hydroxide electrodes at 55°C, with no foreign ions added to the electrolyte, stand-time in minutes.

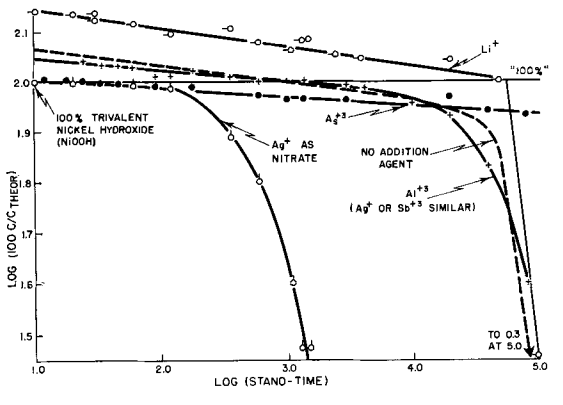

Fig. 13. Charge retention at 55°C, of thermally impregnated nickel hydroxide electrodes with foreign cations added to the electrolyte, stand-time in minutes.

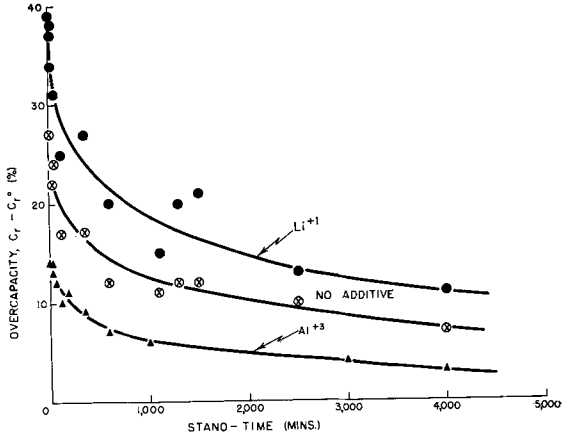

Fig. 14. Decay of overcapacity (C_r—C_r^o) of fully impregnated sintered plate nickel hydroxide electrodes at 55°C.

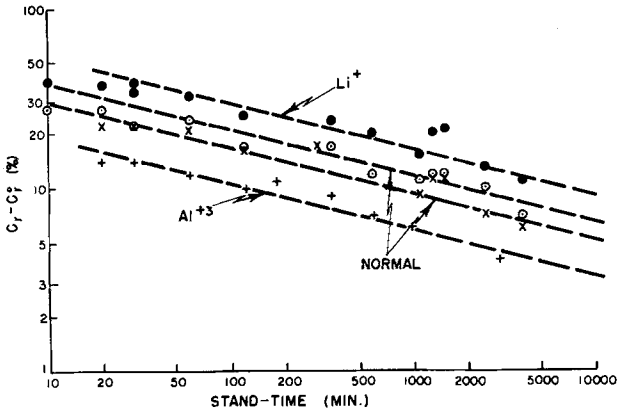

Fig. 15. Decays plotted as log ($C_r - C_r°$) vs. log (stand-time), with broken lines drawn in at slopes consistent with 5th order decay.

Seiger *et al.* (76). In this case the rate of decay of the overcapacity would simply follow the rate of the physical erosion of the mass, because it would be the erosion reaction which presents the overcapacity to the electrolyte.

On the assumptions that crystallites of charged active material have some particular (normal ?) size distribution, that little ones lose their extra oxygen faster (higher area/volume), and that Li^+ acts either by making the crystallites uniformly large or by helping to trap the extra oxygen in the crystallites, a study of the kinetics of loss of charge from very thin films, of the order of a few molecular layers in average thickness, has been started. Results on nickel wire, and then on nickel foil (Fig. 16) have shown, first, that the loss of charge is very much more rapid from open surfaces than from porous ones, and, second, that early in the decay from open surfaces the order of reaction with respect to overcapacity is only 2 not 5. We infer that the loss of charge from porous electrodes immediately after anodic oxidation is not controlled by an erosion reaction, but rather by the movement of trapped oxygen-containing species from the inside of the crystallites to the surface. The effect of the foreign cations, then, and of lithium in particular, can be ascribed to their modifying the elastic restoring forces, within the crystallites. This view is consistent with known modifications of lattice dimensions observed by Briggs (30) in 1957 in doped crystallites of nickel hydroxides.

Overpotential decay.—During studies of charge-retention of impregnated, sintered plate nickel hydroxide electrodes, the cell was allowed to stand on open circuit, and the open-circuit potential was traced as a function of time. The values so obtained were plotted in the manner introduced by Armstrong and

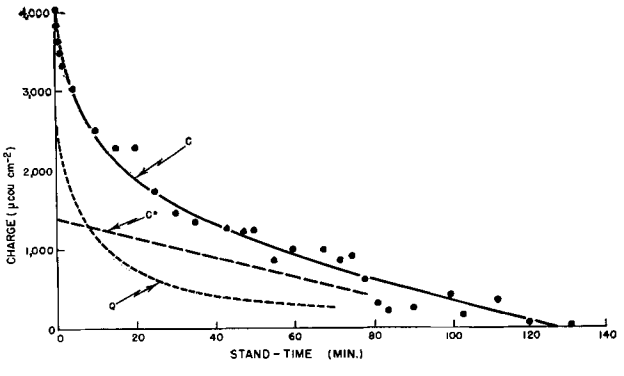

Fig. 16. Charge, C, delivered at 12 $\mu a/cm^2$ by oxidized nickel foil electrodes after various lengths of charged stand; $T = 30°C$; Q, overcapacity; C°, normal capacity.

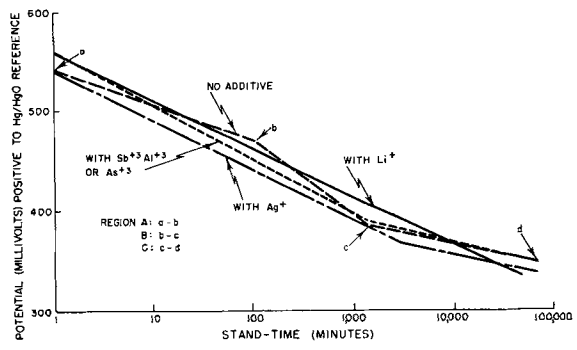

Fig. 17. Open-circuit decay of overpotential of nickel hydroxide electrodes, with and without foreign cations added.

Butler (77), *i.e.*, as E *vs.* log $(t + \theta)$. The slope, related [see ref (78), *e.g.*] to Tafel's "b" ($\partial E/\partial \log i$) could be evaluated. Figure 17 shows a typical plot. Three distinct regions A, B, and C are evident from inspection of the potential decay curves. Two of these regions, A and C, have been discussed rather fully by Conway and Bourgault (74); B is a transition region between A and C which has been examined by Seiger *et al.* (76). Average values of $\partial E/\partial \log t$ for the three regions are given in Table IV.

The three regions were not always observed in an electrode. For instance, plates containing Li^+ did not make the transition from A to B, and the C region was never observed. By contrast, plates with no additive spent most of their stand life in the C region. More or less complete loss of capacity did not further affect the open-circuit potential of the cells which had no additives: they remained in the C region.

As Conway and Bourgault, and earlier, Bockris, pointed out, if certain assumptions are made, the slopes, or b-values, may be interpreted in terms of specific rate determining steps in the self-discharge process. For instance, one can compare the value of 26 ± 2 mv for region C with the value of 25 (*i.e.*, 2.3 $2RT/5F$ at 55°C), which by Bockris' analysis is consistent with a rate-determining step in which HO_2 is being formed on the surface as follows

$$O_{ads} + OH^- \rightleftharpoons HO_2 + e^- \qquad [1]$$

However, the reaction

$$O_{ads} + OH_{ads} \rightleftharpoons HO_{2\ ads} \qquad [1a]$$

should give (78) a slope 2.3 $RT/3F$, or 22; which, although it is slightly less than our assignment of precision would allow (Table IV), would agree explicitly with the reaction assigned by Conway and Bourgault (74) to their values.[4]

Table IV. "b"-Values for different regions of self-discharge of nickel hydroxide electrode

		$b = -\partial E/\partial \log t$ (mv/decade of time)		
Decay	Region	No additive	Monovalent additive	Trivalent additive
Overcapacity	A	45 ± 8 (42 ± 0.2)*	50 ± 12	50 ± 12
	B	70 ± 5	None	None
	C	26 ± 2 (22 ± 0.3)*	None	22 ± 3
Normal capacity		Same as C	Same as C	Same as C

* Values given in parentheses are from reference (74) Table I, recalculated for 55°C. In our work individual decay plots did not give b-values (slopes) with high precision. However, repeated runs with the same electrode did not reproduce the value so exactly, and the accuracy reflects the variation observed.

[4] An undetected constant error is not impossible here although calibrations were done periodically to reduce the probability. The presence of Cd negatives may have made our decay slopes high. Further, the theoretical deductions of the numerical value of "b" invariably, and apparently quite arbitrarily for oxide electrodes, assume a "symmetry factor" of 0.5, which has not yet been unequivocally proven. With these reservations in mind, such an explicit statement of the reacting species gives the clue that it is O (and OH ?) which accounts for the overcapacity described earlier; and that self-destruction of NiOOH is slow.

Within the reproducibility in measurements, more than one deduced slope (said to be a characteristic of a certain step of the decay) can sometimes be made to fit the facts. The slope $-\partial E/\partial \log t$ of the reaction

$$OH_{ads} + OH^- \rightleftharpoons O_{ads} + H_2O + e^- \quad [2]$$

is said (78, 79) to be 2.3 $2RT/5F$, or 42 mv/decade of time at 55°C. This value falls within the range of values observed in the A region, and could be taken as an indication that this is the rate-controlling step early in the decay. Although such a reaction may exist under conditions of high overvoltage, the result on plates with Li^+ added show that this region of decay can continue to either the B or the C regions, and well below the overvoltage at which transition usually occurs. In this interpretation, Li^+ either promotes reaction [1] or inhibits reaction [2].

The B region has been given no assignment to date. It is short (a few hours) in solutions with no additives; it is absent altogether in weak caustic, and in solutions with additives (Fig. 17, Table III).

Milner's treatment [see ref (80)], and more recently Hale's (81), would involve diffusion processes, not necessarily activation processes alone, to explain the facts. Especially interesting is the fact that antimony and to a greater extent arsenic inhibit the loss of overcapacity. Perhaps arsenate is adsorbed on and poisons sites which would otherwise be involved in oxygen evolution.

Present status of the problem.—Many reported effects of cations on the measurable properties of the nickel hydroxide electrode are poorly founded in fact. Table I contains a summary of the claims and inferences drawn by various workers who have studied the question. Controlled experiments have been done in only a few cases, and the reported effects of others have to be considered more as lore than as scientific fact. This is understandable if the premise is accepted that the effect of a cation on the parameter being investigated is closely related to the physical condition of the nickel hydroxide (*viz.*, crystallite size distribution, defect structure, water content of the layer lattice, etc.) during the measurement. Reproducibility is bound to be poor. Of the reports on effects of 24 ions, reports on 7 draw particular attention: Li^+, Mg^{+2}, Zn^{+2}, Hg^{+2}, Co^{+3}, Sc^{+3}, and As^{+5}. The suppression of charge available from the electrode in the presence of Zn^{+2} and the increased charge available in the presence of both Hg^{+2} and Mg^{+2} ions require confirmation, for if the effects of divalent cations on coulombic capacity are as claimed (Table I), at least two interesting possibilities exist to account for the effects: (i) polarization of water of hydration might exist due to the strong electric field about the small Mg^{+2} ion (Doran's suggestion), and (ii) the layer-lattice crystallites might retain less water of hydration at the important defects occupied by large ions such as Hg^{+2} and Ba^{+2}.

Information on the transition metal cations is sparse and conflicting, with the exception of that on cobalt. Cobalt must exist as Co^{+3} even in the discharged nickel hydroxide material. There seems to be some agreement that Co^{+3} improves charge retention, stabilizes capacity during repetitive cycling, raises the charge and discharge voltages and increases the b-values, all indications that it promotes higher overcapacities. In this respect its effects resemble those of the Li^+ ion. The scandium ion seems to belong to this group also. However, its trivalent cousins (Fe^{+3}, Al^{+3}, B^{+3}), which have a strong tendency to form insulating oxides, clearly do not.

Arsenic and antimony, which must be present as pentavalent ions at the potential of the nickel hydroxide electrode, suppress the B region of potential decay and promote better charge retention; perhaps they adsorb, as AsO_4^{-3} or SbO_4^{-3}, on the oxygen evolution sites and inhibit the process. The fact that the arsenic ion can stabilize higher valence states of nickel (82), and increases the overpotential during charge and overcharge is supporting evidence.

Nickel hydroxide remains an enigma. As a semiconductor NiO will change conductivity by many orders of magnitude if it is doped with Li^+. The proton-transfer theory of ionic conduction seems well entrenched in the literature. Indeed the recent experiments on proton-penetrable Ni foil electrodes even permit the evaluation of the proton-transfer current during anodic oxygen evolution (83). (This current is highest in KOH, less in NaOH, and lowest in LiOH.) The present work emphasizes a possible movement of oxygen-containing species in the active mass, akin to mass transfer processes suggested for MnO_2, V_2O_5, and PbO_2 (84). Crystal deformation of the layer lattice can be effected by several cations (30), by carbonate (15) and probably by other anions such as nitrate. At the present time we may usefully consider nickel hydroxide to be a remarkable matrix through which electrons (or positive holes) and protons and oxygen-containing species can be forced, at relative rates which depend intimately on a time-dependent molecular structure, as well as on the nature of the applied force, or potential gradient. In this sense, nickel hydroxide may indeed be the most versatile, and *ipso facto* the most exasperating, member of the electrochemically active (hydr)oxide family.

General Summary

1. Electrodes were studied in which the electrochemically active material was supported within the pores of sintered nickel plaques. Detrimental effects of carbonate ion have been demonstrated on both the nickel hydroxide positive and cadmium negative electrodes.

2. On negative electrodes both permanent and transient effects occur, both of which lower the coulombic or ampere-hour output. The transient effects are a complicated function of the amount of carbonate in the electrolytes, and are dependent also on current density and temperature. Processes which seem to be involved are rate of conversion of primary reaction product into hydroxide or carbonate, specific volume of precipitate, and transport properties of electrolyte through the porous mass. Aging effects were demonstrated via the capacity *vs.* composition data.

3. On positive plates only transient carbonate effects were observed, quite complicated if the plate is heavily loaded.

4. Interpretations of these effects have been offered. Quantitative prediction of when they will occur is not yet possible. The possible roles of the hydroxycarbonates of cadmium and nickel as reaction intermediates are discussed.

5. The mechanism of the "nitrate shuttle" has been demonstrated. The nitrate-nitrite redox system within the cell seems to be unique in that it can be oxidized and reduced by the positive and negative, respectively. Since both species are soluble, it acts as an electronic short-circuit. A search for other systems which would do this was unsuccessful.

6. Prolonged (1-2 years) operation of pure nickel hydroxide electrodes at high temperature (55°C) resulted in a marked increase in the electrochemical capacity of the electrode. Analyses for soluble nickel showed that most of the increase could be attributed to oxidation of the sintered nickel matrix. However, there is evidence that the electrode gradually becomes able to be charged to a higher average oxidation state, especially in the presence of Li^+.

7. Practical conclusions from parts 1 to 6 include: (*A*) Nitrate from the processing of plates must be removed from cells, otherwise self-discharge may be rapid. (*B*) Special precautions must be taken to keep CO_2 from the air and carbonate from other sources (oxidation of separator ?) from processed plates and from assembled cells, otherwise the capacity may not be reproducible and the plates may show aging effects

and unpredictable outputs, especially at low temperatures. (*C*) Only extra high purity nickel powder should be used for the sintered matrix for nickel hydroxide electrodes, if corrosion of the matrix at high temperatures is to be avoided.

8. Loss of charge by charged nickel hydroxide seems to occur by two main processes: a rapid but convergent decay of the overcapacity, and a slower, linear decay of the normal capacity. The former may take days in a sintered plate, minutes on a nickel foil. The latter takes weeks in the sintered plate, hours on a foil.

9. Decay of the overcapacity consists of two, and perhaps three, consecutive steps, separable by analysis of the concurrent potential decay, and rather markedly affected by foreign cations. Possible controlling reactions are discussed. Kinetic analysis of the decay of charge, and analysis of the concurrent overpotential decay, suggest that the controlling reactions involve adsorbed oxygen atoms which are continuously supplied from within the crystallites.

10. Reported effects of foreign cations on the behavior of the nickel hydroxide electrode were collected and reviewed. The roles of certain uni- and trivalent positive ions on the nickel hydroxide electrode were investigated at length. None had any reproducible measurable effect on the ability of well-formed, charged nickel hydroxide to deliver its charge, even up to very high (20-min) rates, from 25° to −30°C. All promoted the oxidation of the sintered nickel matrix to active material at 55°C.

11. At 55°C Li^+ increased the overcapacity, and it also lowered the rate of loss of overcapacity. It blocked the onset of the second and third (B and C) stages in the potential decay which runs concurrent with the decay of overcapacity.

In an isolated, but interesting, instance, Al^{+3} blocked the reduction of a fully oxidized electrode, an effect that was finally broken by a strong anodic pulse of current. Arsenic, probably as As^{+5}, adsorbed on cathodic sites, affected the potential decays during loss of overcapacity, and then seemed to inhibit the protracted decay of the normal capacity which followed.

12. Inferences are drawn about the mechanisms of the various processes studied, and the present status of each is given.

Acknowledgments

Mr. D. G. Scraba, a summer student from the University of Alberta, did the nitrite analyses, and along with Mr. J. L. Lackner contributed technical assistance. Dr. J. R. Coleman, and Drs. I. H. S. Henderson and T. E. King who read the manuscript, offered many very helpful suggestions.

A special word of thanks is offered to the many friends in other laboratories who have encouraged the preparation of this paper.

Manuscript received Dec. 11, 1961; revised manuscript received Dec. 15, 1964. The manuscript is issued as DCBRL Report No. ———.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

SYMBOLS

equivalent % of carbonate:

$$\frac{\text{Equiv. of } CO_3^=}{\text{Equiv. of } OH^- + \text{Equiv. of } CO_3^=} \times 100$$

x = No. of moles of $CdCO_3$ contained in solid basic cadmium carbonate of general formula x $CdCO_3$ $Cd(OH)_2$.

C = measured electrochemical capacity, or charge, in ampere-hours per unit volume (cm^2 area x mm thickness of electrode)

C_{Theor} = theoretical capacity based on weight gain during impregnation of sintered plaque, it being assumed that all weight gain is due to $Cd(OH)_2$ (negative) or $Ni(OH)_2$ (positive)

C_r = reduced, or normalized, capacity = $100\ C/C_{Theor}$ (%)

c.d. = current density

C_r° = value of C_r at which the linear C_r *vs.* log $(t + \theta)$ relationship breaks down, denoting last of the overcapacity

$Q = C_r - C_r^\circ$ = overcapacity (normalized)

Q_o = overcapacity immediately at the end of charging

v = $-d(C_r - C_r^\circ)dt$, rate of decay of overcapacity

n = order of reaction (decay of overcapacity) with respect to overcapacity

k = specific rate constant for decay of charge

U = internal energy; V, specific volume; $\partial U/\partial V$, internal pressure

E = potential (mv) positive to Hg/HgO reference

b = $-\partial E/\partial \log t$ during open-circuit stand

Studies of the Oxidation of Nickel in the Temperature Range of 900° to 1400°C

Kazuo Fueki[1] and J. Bruce Wagner, Jr.

Materials Research Center and Department of Materials Science, Northwestern University, Evanston, Illinois

ABSTRACT

The parabolic oxidation of nickel has been studied between 900° and 1400°C at pressures from the dissociation pressure of nickel oxide to 1 atm of oxygen. The activation energies in various atmospheres were found to range from 36.3 to 43.6 kcal/mole. The usual equation for parabolic oxidation, $k_p = c[p_{O_2}{}^{1/n} - p_{O_2}{}^{1/n}$ (eq.)] did not hold over the entire pressure range because the value of $1/n$ varied with temperature. A marker study showed that the markers were located close to the metal-oxide interface. A method for obtaining the self-diffusion coefficient of the more mobile ionic species in the oxide is proposed.

The dependence of the parabolic constant of metal oxidation on the oxygen partial pressure can provide valuable information about ionic transport in the oxide and the mechanism of oxidation. In the early work of Wagner and Grünewald (1) on the oxidation of nickel, the parabolic constants were found to be proportional to $p_{O_2}{}^{1/5}$. The electrical conductivity of nickel oxide was found by von Baumbach and Wagner (2) to be dependent on $p_{O_2}{}^{1/4}$. On the basis of these results it was concluded that nickel oxide is a metal deficit p-type semiconductor and that the nickel oxide layer on nickel grows by the simultaneous diffusion of nickel ions via cation vacancies and of electron holes. Baur and his collaborators (3) carried out a study of the pressure dependence of nickel oxidation between 1000° and 1200°C at oxygen pressures from 6.5 x 10^{-3} to 20.4 atm. They found that the measured rates above 1 atm are insensitive to oxygen pressure and that the rates below 1 atm closely followed $p_{O_2}{}^{1/4}$. The pressure dependence was explained on the basis of Langmuir's adsorption isotherm and of vacancy creation by adsorbed oxygen. Since both oxidation studies and the measurements of diffusion (4, 5) and electrical conductivity (2, 6, 7) of nickel oxide have been confined to pressures above about 10^{-4} atm of oxygen, it has not been confirmed that the aforementioned mechanism still holds in lower oxygen pressures.

Marker studies are useful for identification of the predominant ionic species diffusion through oxides during metal oxidation. Sartell and Li (8) observed in their marker study that the nickel oxide formed on nickel consists of a black outer layer and a green inner one and that the markers were always located at the boundary between the two layers. They proposed a mechanism whereby the outer layer grows by the outward diffusion of nickel ions and that the inner layer grows by the inward diffusion of oxygen ions.

The results of von Baumbach and Wagner and of Baur and his collaborators are not consistent with that of Sartell and Li. To clarify further the ionic transport in nickel oxide, the present authors have studied the oxidation rate of nickel over a wide pressure range between the dissociation pressure of nickel oxide and 1 atm of oxygen. Marker studies have also been carried out. It is the purpose of this paper to report the results of these measurements and also to propose a method by which the self-diffusion coefficient is obtained as a function of oxygen partial pressure from oxidation data.

Table I. Analysis of nickel sheet*

	%
Silver	0.001
Aluminum	0.01
Cobalt	0.004
Chromium	0.001
Copper	0.002
Iron	0.02
Manganese	0.002
Molybdenum	0.001
Lead	0.04
Silicon	0.01
Tin	0.001
Titanium	0.001

* The above analysis was furnished by the Charles C. Kawin Company of Chicago, Illinois.

[1] Present address: Department of Industrial Chemistry, University of Tokyo, Tokyo, Japan.

Experimental and Results

Oxidation rate measurement.—Nickel sheet, 6 mil thick, containing impurities listed in Table I was used in these studies. Specimens, 1 cm wide by 2 cm long, were cut from the sheet, polished using 1/0, 2/0, 4/0 metallographic papers and using Linde "A" fine abrasive on a polishing wheel, washed with soap and water and with acetone, and then dried. The polished specimens were annealed in hydrogen at 550°C overnight to remove strain and to reduce any surface oxide.

The gravimetric measurements below 1190°C were carried out using an Ainsworth automatic-recording balance and its accessories described by Pettit and Wagner (9). Measurements above 1300°C were made using the weighing apparatus described by Pettit, Yinger, and Wagner (10) with modifications to the furnace and reaction tube. An ATT-type Globar tubular heating element, 1⅛-in. ID and 22-in. long, was used for the furnace. Through the hollow of the heating element an alumina reaction tube, 9/16-in. in ID and 36-in. long, was placed. There was a 3-in. section in the center over which the temperature was constant within ±3°C at 1400°C. The temperature was controlled at a given point within ±2°C by means of a platinum-10% rhodium thermocouple and a L&N Speedomax G.

The oxidizing atmospheres were oxygen of 1, 10^{-1}, 10^{-2}, 5 x 10^{-4}, and 1.35 x 10^{-4} atm, CO_2, and CO-CO_2 mixtures containing 0.25 and 0.50% CO at a total pressure of 1 atm. When a pressure of oxygen less than 1 atm was required, purified argon was used as the diluent gas. Flow rates of 0.9 and 2.7 cm/sec were employed below 1190° and above 1300°C, respectively.

Figures 1 and 2 show the parabolic plots of oxidation in various atmospheres at 1190°C. The slope changes with time during the initial oxidation period and eventually reaches a constant value. As seen from the comparison of two runs for 10^{-2} atm of oxygen, the rate for the later period is more reproducible than that for the initial period. Therefore, in this paper the parabolic constants were determined from the slope for the later period.

The Arrhenius plots of parabolic constants in various atmospheres are given in Fig. 3. The plots for oxidation in high oxygen pressures and in CO_2 are straight over the entire temperature range, but those

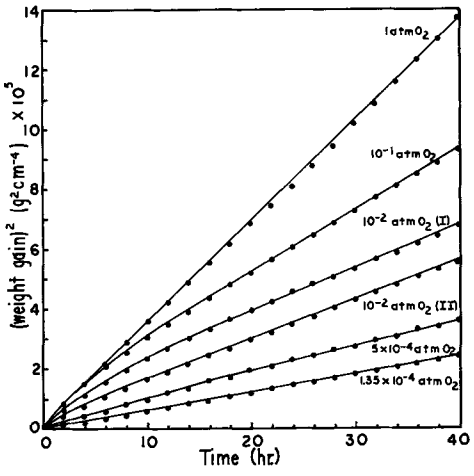

Fig. 1. Parabolic plot of oxidation at 1190°C

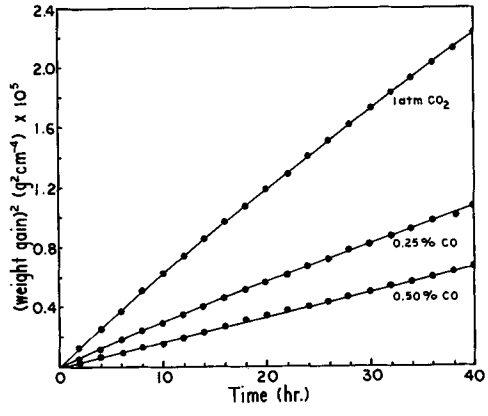

Fig. 2. Parabolic plot of oxidation at 1190°C

for low oxygen pressures and for CO-CO_2 mixtures are curved. The activation energies determined from the slopes of the straight-line portions are listed in Table II. For comparison, results obtained by previous investigators are summarized in Table III.

When an oxide with metal deficit and predominant electronic conduction is formed, the pressure dependence of parabolic constant is usually analyzed by the equation (16, 17)

$$k_p = c[p_{O_2}{}^{1/n} - p_{O_2}{}^{1/n}(\text{eq.})] \qquad [1]$$

where p_{O_2} and p_{O_2} (eq.) represent the oxygen partial pressures at the gas-oxide interface and at the oxide-metal interface respectively, c is a constant, and $1/n$ is a constant characterized by the mechanism of creation of a vacancy and electron hole(s), in this case, trivalent nickel. Figure 4 shows the plots of log k_p *vs.* log $[p_{O_2}{}^{1/n} - p_{O_2}{}^{1/n}(\text{eq.})]$ at constant temperatures. The oxygen pressures for CO-CO_2 mixtures were calculated assuming that the equilibrium of the reaction $2CO + O_2 \rightleftarrows 2CO_2$ was attained at the surface of nickel oxide. The value of n was chosen so that as many data points as possible could be located on a straight line with a slope of unity. As seen in Fig. 4 the data for low oxygen partial pressures deviate from the straight line except for the reactions at 1300° and 1400°C. A similar deviation has been reported by Pettit and Wagner for the oxidation of cobalt (9).

The data for oxidation in CO_2 were also plotted in Fig. 4. The oxygen partial pressures were calculated assuming that the equilibrium of self-dissociation $2CO_2 \rightleftarrows 2CO + O_2$ was attained on the surface of nickel oxide. These data, denoted by the symbol, *X*, are located close to the straight lines.

Marker study.—Platinum paste was put on a polished nickel specimen and heated at 900°C for 30 min

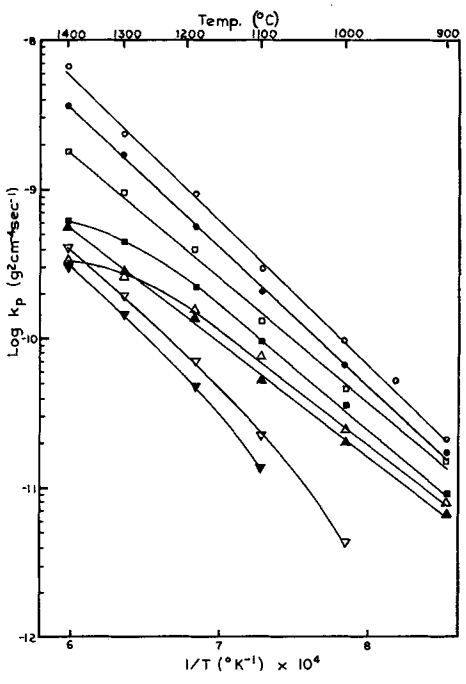

Fig. 3. Temperature dependence of parabolic constants in various atmospheres: ○, 1 atm O_2; ●, 10^{-1} atm O_2; □, 10^{-2} atm O_2; ■, 5×10^{-4} atm O_2; △, 1.35×10^{-4} atm O_2; ▲, 1 atm CO_2; ▽, 0.25% CO—CO_2; ▼, 0.50% CO—CO_2.

in a 1:1 mixture of CO-CO_2 to convert it into a thin and porous metallic film of about 1-2μ thickness. The specimen coated with the thin platinum layer was oxidized in oxygen of 1 atm or in carbon dioxide of 1 atm and cross-sectioned to examine the location of the platinum marker. Figure 5 shows the cross section of a specimen oxidized for 42 hr in 1 atm of oxygen at 1190°C. The oxide consists of a single layer and platinum markers are located close to the metal-oxide interface. When fine alumina powder was employed, markers were found to be located at the metal-oxide interface. The results of the present work clearly differ from those of Sartell and Li and show that nickel ions migrate much faster than oxygen ions.

Discussion

According to Wagner's theory of metal oxidation the rate constant for the formation of an oxide with predominant electronic conduction is given by the equation (16, 17)

Table II. Activation energies for the oxidation of nickel in various atmospheres in the present study

Atmosphere	Temperature range, °C	Activation energy, kcal/mole
1 atm O_2	900-1400	43.6
1×10^{-1} atm O_2	900-1400	42.5
1×10^{-2} atm O_2	900-1400	39.0
5×10^{-4} atm O_2	900-1190	37.7
1.35×10^{-4} atm O_2	900-1190	36.7
1 atm CO_2	900-1400	36.3

Table III. Comparison of activation energies

Investigators	Temperature range, °C	Activation energy, kcal/mole
Sartell and Li (8)	950-1200	67.0
Gulbransen and Andrew (11)	900-1050	68.3
Berry and Paĭdassi (12)	1000-1400	49.0
Frederick and Cornet (13)	800-1400	51.0
Baur, Bartlett, Ong, Jr., and Fassel (3)	1000-1200	50.0
Zima (14)	980-1260	45.1
Phillips (15)	700-1300	38.0

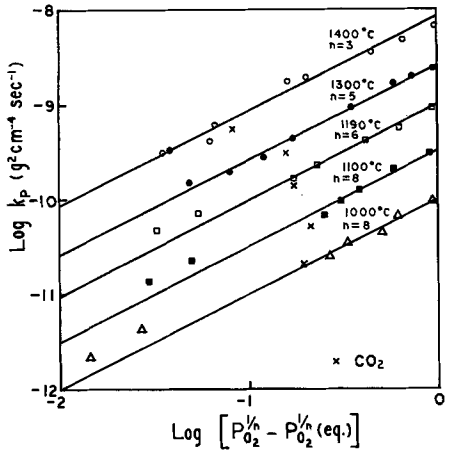

Fig. 4. Plots of log k_p vs. log $[p_{O_2}{}^{1/n} - p_{O_2}{}^{1/n}$ (eq.)]

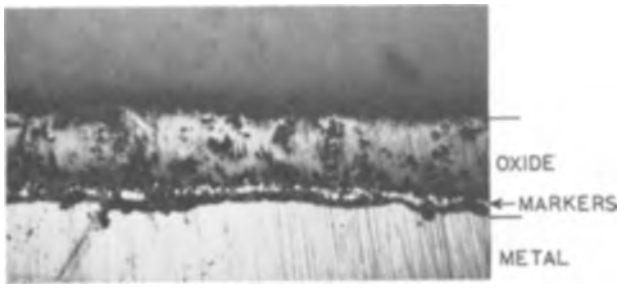

Fig. 5. Cross section of an oxide film with platinum markers. (1190°C, 1 atm O_2, 40 hr). Magnification 135X.

$$k_r = c_{eq} \int_{a_{x'}}^{a_{x''}} \left(\frac{Z_1}{|Z_2|} D_1{}^* + D_2{}^* \right) d \ln a_x \qquad [2]$$

where k_r is "rational rate constant" in equivalents per centimeter per second, $D_1{}^*$ and $D_2{}^*$ are the self-diffusion coefficients of cations and anions, respectively, Z_1 and Z_2 are units of charge on the cations and anions, respectively, a_x is the activity of nonmetallic element,[2] and c_{eq} is the concentration of ions in equivalents per cubic centimeter. Equation [1] is derived from Eq. [2] under the following assumptions: (*a*) oxidation is governed by the diffusion of cations via cation vacancies; (*b*) cation vacancies are created by a mechanism whereby n is independent of oxygen partial pressure, and (*c*) $D_1{}^*$ is proportional to the vacancy concentration. As shown above, Eq. [1] does not hold for the parabolic oxidation of nickel. Moreover, it is difficult to interpret a value of $n = 8$ for oxidation at 1000° and 1100°C. Therefore, a new method for the analysis of the pressure dependence of parabolic oxidation is proposed. As seen in Eq. [2], k_r consists of two kinds of terms, one of which is a function of a_x'' and the other a function of a_x'. a_x' is not a variable but a constant at a constant temperature. Therefore, k_r is differentiated by $\ln a_x''$ as follows,

$$\frac{Z_1}{|Z_2|} D_1{}^* + D_2{}^* = \frac{1}{c_{eq}} \cdot \frac{d k_r}{d \ln a_x''} \qquad [3]$$

In the case of the oxidation of nickel $Z_1/|Z_2|$ is unity and $D_2{}^*$ is eliminated because the marker study showed that cations migrate much faster than anions. Moreover, $d \ln a_x''$ is replaced by $\frac{1}{2} d \ln p_{O_2}$. Accordingly

$$D_1{}^* = D_{Ni}{}^* = \frac{2}{c_{eq}} \frac{d k_r}{d \ln p_{O_2}} \qquad [4]$$

c_{eq} is represented by the molecular weight M_{NiO} and the density ρ_{NiO} of nickel oxide (7.44 g/cc) as follows

$$c_{eq} = \frac{2 \rho_{NiO}}{M_{NiO}} \qquad [5]$$

[2] In the present case the single prime refers to the activity at the oxide-metal interface and the double prime that at the oxide-gas interface.

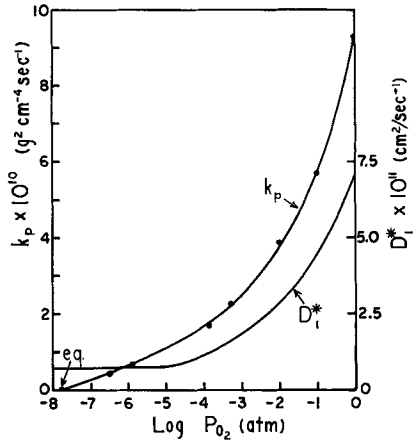

Fig. 6. Plots of k_p and D^*_1 as functions of p_{O_2} (1190°C)

For the present studies, the rational rate constant, k_r in units of eq/cm-sec, is related to the rate constant, k_p in units of $g^2 \cdot cm^{-4} \cdot sec^{-1}$, by an equation

$$k_r = \frac{M_{NiO}}{M_o{}^2 \rho_{NiO}} \cdot k_p \qquad [6]$$

where M_o is atomic weight of oxygen. Insertion of Eq. [5] and [6] into Eq. [4] yields

$$D_1{}^* = D_{Ni}{}^* = \left(\frac{M_{NiO}}{M_o \rho_{NiO}} \right)^2 \frac{d k_p}{d \ln p_{O_2}} = 0.1704 \cdot \frac{d k_p}{d \log p_{O_2}} \qquad [7]$$

Equation [7] shows that the self-diffusion coefficient of nickel ions is obtained as a function of log p_{O_2} by differentiating k_p with respect to log p_{O_2}. Figure 6 shows the plots of k_p *vs.* log p_{O_2} and of $D_1{}^*$ *vs.* log p_{O_2}. $D_1{}^*$ was obtained by differentiating the curve of k_p graphically and multiplying a factor of 0.1704. The plots of log $D_1{}^*$ *vs.* log p_{O_2} at different temperatures are given in Fig. 7. The value of log $D_1{}^*$ is independent of log p_{O_2} in the low-pressure range below about 10^{-6} atm and increases linearly with log p_{O_2} in the intermediate pressure range. The slopes determined in this range are given in Fig. 7. In the high-pressure range the slope appears to decrease gradually. In the intermediate

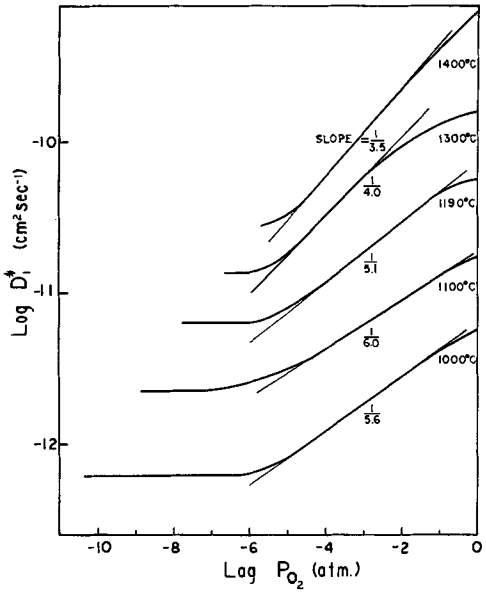

Fig. 7. Pressure dependence of self-diffusion coefficient D^*_1 calculated by the proposed method.

pressure range, the cation vacancies would be created by the following mechanisms

$$\frac{1}{2}O_2 \rightleftarrows [Ni_{\square''} \cdot \oplus] + \oplus + NiO \qquad (I)$$

or

$$\frac{1}{2}O_2 \rightleftarrows Ni_{\square''} + 2\oplus + NiO \qquad (II)$$

where $Ni_{\square''}$ is a cation vacancy and $\oplus$ is an electron hole. At 1300° and 1400°C the slope of the plot of log D_1^* *vs.* log p_{O_2} is about ¼. Mechanism (I) is inferred to predominate at these temperatures. Mechanism (II) would be predominant at 1000° and 1100°C. It is difficult to reconcile values of n in the pressure dependence of the parabolic rate constant (Fig. 4) and of the self-diffusion coefficient (Fig. 7) which decrease with increasing temperature. Such behavior would not be predicted on the basis of the ideal mass action law whereby the activities of each of the species are equated to their respective concentrations and whereby any trapping or association of electron holes onto vacancies would be expected to be more prevalent at the lower temperatures than at the higher temperatures.We do not have an explanation for this behavior. Additional data on the thermodynamics (activity coefficients of the respective species) are needed. The layers of NiO found in the present study were always adherent and free from pores under microscopic examination. While some oxygen transport in the NiO layers may aid in explaining the foregoing, the agreement of the present diffusion data with tracer diffusion studies (see below) suggests that the present analysis is correct.

There are no data available for the oxygen pressure dependence of the self-diffusion coefficient of nickel. One possible explanation for the apparent independence of D_{Ni}^* on oxygen pressure in the low-pressure range is as follows: In the low pressure range, the concentration of cation defects created by the excess oxygen would be small. Near the stoichiometric composition the defects would be created by a Frenkel mechanism,

$$\text{null} \rightleftarrows Ni_{\square''} + Ni_{O..} \qquad (III)$$

or by a Schottky mechanism

$$\text{null} \rightleftarrows Ni_{\square''} + O_{\square..} \qquad (IV)$$

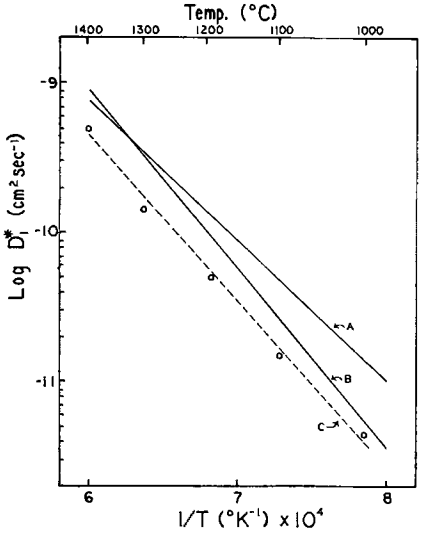

Fig. 8. Comparison of diffusion data: A, Shim and Moore, $D = 3.9 \times 10^{-4}$ exp (—44.2/RT) cm^2 sec^{-1}; B, Lindner and Åkerström, $D = 1.7 \times 10^{-2}$ exp (—56.0/RT) cm^2 sec^{-1}; C, This work, $D = 1.1 \times 10^{-3}$ exp (—50.3/RT) cm^2 sec^{-1}.

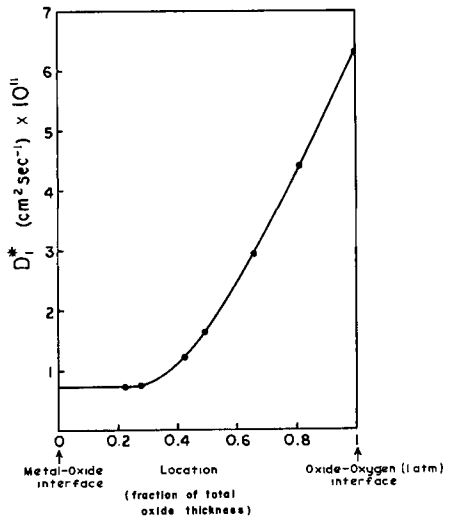

Fig. 9. Self-diffusion coefficient as a function of location in the oxide layer growing in 1 atm of oxygen at 1190°C.

where $Ni_{\square''}$ is a cation vacancy, $Ni_{O..}$ is an interstitial ion, and $O_{\square..}$ is an anion vacancy. If the concentration of defects created by mechanism (III) or (IV) greatly exceeds that created by the excess oxygen at low oxygen pressures, the mass action law yields

$$[Ni_{\square''}] \cdot [Ni_{O..}] = K_{III}(T) \qquad [8]$$

and

$$[Ni_{\square''}] \cdot [O_{\square..}] = K_{IV}(T) \qquad [9]$$

Since $[Ni_{\square''}]$ is equal to $[Ni_{O..}]$ or to $[O_{\square..}]$ as the case may be, the constant concentrations of cation vacancies and interstitial cations result in the self-diffusion coefficient being independent of oxygen pressure.

Baur and his collaborators found that the parabolic constant is insensitive to oxygen above 1 atm. In the present studies, the gradual decrease in the slope of k_p in the high-pressure range might be due to the transition to the pressure insensitive region. The Arrhenius plot of calculated D_1^* values at 0.2 atm is given in Fig. 8. The diffusion data of Shim and Moore (4), and of Lindner and Åkerström (5) are also plotted for comparison. The values of the self-diffusion coefficient of the nickel oxidation data agree well with those obtained independently using tracer techniques. This shows the self-consistency of the foregoing analysis.

The equilibrium oxygen pressure in a growing oxide decreases gradually from p_{O_2}, the oxygen partial pressure of ambient gas, to p_{O_2} (eq,), the dissociation pressure of the oxide. The location in the growing oxide where the equilibrium oxygen pressure is p_{O_2}' (p_{O_2} (eq.) $\leqq p_{O_2}' \leqq p_{O_2}$) is given by $(k_p'/k_p)^{1/2}$, where k_p' and k_p are the parabolic rate constants when the oxygen partial pressures are p_{O_2}' and p_{O_2}, respectively. Since the self-diffusion coefficient of nickel as a function of oxygen pressure is given in Fig. 7, one can obtain a relationship between the value of the self-diffusion coefficient and the location in terms of fraction of the total oxide thickness in the growing nickel oxide. Figure 9 shows the self-diffusion coefficient as a function of location in nickel oxide growing in 1 atm of oxygen at 1190°C. The linear gradient of D_1^* is seen in the outer portion of oxide and the independence of D_1^* on location is seen in the inner portion.

Summary

From the results of parabolic oxidation and of marker studies, the self-diffusion coefficient of nickel ions in nickel oxide is obtained as a function of oxygen partial pressure. The calculated self-diffusion coefficient is independent of oxygen pressure in the low

oxygen pressure range and is proportional to $p_{O_2}^{1/6}$ to $p_{O_2}^{1/3.5}$ in the intermediate pressure range. The dependence on $p_{O_2}^{1/4}$ is explained by the ionization of one electron hole from the cation vacancy while a $p_{O_2}^{1/6}$ dependence results if 2 electron holes are ionized. The calculated self-diffusion data at 0.2 atm of oxygen agree well with published tracer-diffusion values.

Determination of the Refractive Index and Thickness of Oxide Films on Anodized Zirconium from Transmission Interference Measurements

J. C. Banter

Oak Ridge National Laboratory, Oak Ridge, Tennessee

ABSTRACT

A method is described for the determination of the refractive index of thin oxide films stripped from anodized zirconium by dissolution of the metal. This new technique involves measurement of the interference patterns produced in the light transmitted through the films at various angles of incidence. The film thickness is also calculated from the data, and results show the refractive index does not vary with film thickness for films approximately 3000 to 5500Å thick. These films exhibit normal dispersion behavior over the ultraviolet, visible, and near infrared regions of the spectrum, with the refractive index varying from 2.07 to 2.50 at wavelengths of 1μ and 250 mμ, respectively.

In recent years, many experiments in the field of metallic corrosion have concerned the measurement of the optical properties and thickness of the thin oxide films formed in the early stages of corrosion. Frequently, reflection interference methods were used to make these measurements (1-4), but transmission measurements would serve just as well. This paper describes a transmission interference method applied to the determination of the refractive index and thickness of thin oxide films formed on zirconium. The technique was developed using anodically formed films with the hope of extending the measurements to films formed in other corrosive environments such as high-temperature water, air, and steam.

Theory

As the wavelength of light incident on a thin film is varied, the intensity of the transmitted beam exhibits alternate maxima and minima due to interference effects in the film. The wavelengths at which these extremes occur depend on the optical properties and thickness of the film as well as on the angle of incidence of the light. Vasícek (5) gives the equation describing the intensity, I_t, of light transmitted by a thin homogeneous film as

$$I_t = \frac{(1 - r'^2)(1 - r''^2)}{1 + r'^2 r''^2 + 2r'r'' \cos X} \qquad [1]$$

where r' and r'' are the Fresnel amplitude reflection coefficients for light incident from the same direction on the first and second surfaces of the film, respectively, and

$$X = 4\pi\eta_1 d_1 \cos\phi_1/\lambda \qquad [2]$$

η_1 and d_1 are the refractive index and thickness of the film, respectively, ϕ_1 is the angle of refraction of the light into the oxide, and λ is the wavelength of the incident light. Since $r'' = -r'$, the maxima occur at those wavelengths where $X = 2m\pi$; and the minima at those wavelengths where $X = (2m + 1)\pi$ with m, the order of interference, being an integer.

As the angle of incidence increases, the positions of the extremes for any given order of interference shift to shorter wavelengths in the spectrum. If the angle of incidence is increased sufficiently, the position of a given maximum or minimum can be shifted to the same wavelength as the minimum or maximum which was immediately adjacent to it at a lower wavelength at normal incidence. With known order numbers (which are easily determined) values for X as given by Eq. [2] can be calculated for both the extremes at normal incidence and those at the higher angle of incidence. Since $\cos\phi_1 = 1$ at normal incidence, the ratio of these two values of X yields $\cos\phi_1$ for the higher angle of incidence. The refractive index at this wavelength can then be calculated from Snell's law of refraction

$$\eta_0 \sin \phi_0 = \eta_1 \sin \phi_1 \quad [3]$$

where η_0 is the refractive index of the medium from which the light is incident on the film, and ϕ_0 is the angle of incidence of the light. The film thickness is determined by then substituting this value of η_1 into Eq. [2].

Experimental Procedure

Specimens ¾ in. x 1¾ in. were cut from 0.020-in.-thick zirconium foil and the surfaces chemically polished in a solution consisting of 50 ml lactic acid, 50 ml nitric acid, 20 ml water, and 10 ml hydrofluoric acid. Specimens were washed with copious amounts of water, dried, then anodized at constant voltages in a solution consisting of 40 ml glycerin, 20 ml lactic acid, 70 ml water, 120 ml ethyl alcohol, 10 ml phosphoric acid, and 4g citric acid. Specimens were anodized in such a manner that oxide film was formed on all surfaces. The film was then abraded from the center of one side of the specimen over an area approximately ⅜ x ⅝ in., and the metal in this area was dissolved by immersing the specimen in a 20% solution of bromine in ethyl acetate. This left a clear window of the oxide film supported by a surrounding frame of the undisturbed metal. The film and frame were then carefully washed in ethyl alcohol to remove all traces of bromine and dried in a stream of warm air.

The variation with wavelength of the intensity of light transmitted through these windows was measured in a Perkin-Elmer Model 4000 A spectrophotometer. For this purpose, two special specimen mounts were designed which allowed the rotation of the specimen about a vertical axis passing through the center of the spectrophotometer light beam. Figure 1 shows these two specimen mounts, one of which was used to make the measurements in air and has a specimen mounted in place. The second mount allows the measurements to be made with the specimen immersed in a liquid with refractive index higher than that of air. This mount was used with water as the immersion liquid in those instances where coincidence of the extremes could not be achieved at reasonable angles of incidence in air. The water immersion reduces the angle of incidence required to obtain coincidence of the extremes by increasing η_0.

Transmitted intensity measurements were first made on each specimen at normal incidence in the visible and/or ultraviolet regions of the spectrum, and then the angle of incidence at the appropriate wavelengths was gradually increased to obtain the angles required to produce coincidence of the extremes. Equation [2] was then applied to obtain η_1 and d_1 at each wavelength.

Results

Figure 2 shows typical interference patterns developed in the visible regions of the spectrum for one of the anodic oxide films and illustrates the shift to shorter wavelength of a given extreme as the angle of incidence is increased. At $\phi_0 = 60°$, maximum A has not shifted quite enough to come into coincidence with the position of minimum B at normal incidence,

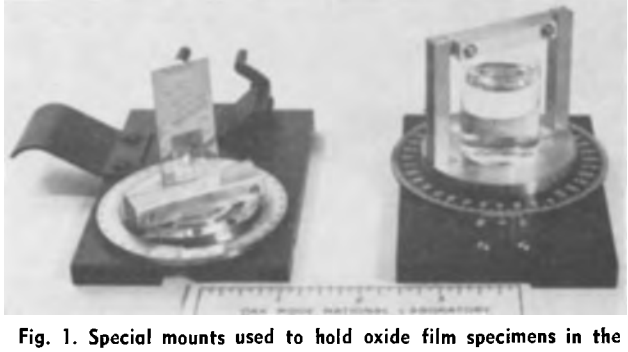

Fig. 1. Special mounts used to hold oxide film specimens in the spectrophotometer.

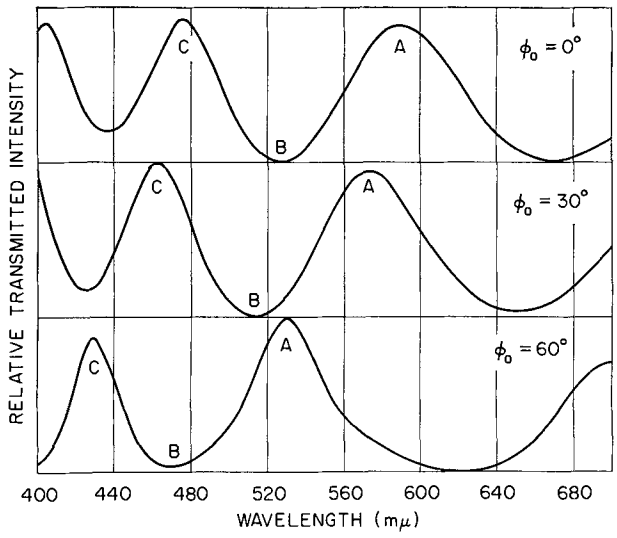

Fig. 2. Interference patterns developed in the visible regions of the spectrum at various angles of incidence by a film formed at 400v. A, 4th order maximum; B, 4th order minimum; C, 5th order maximum.

while minimum B has shifted beyond coincidence to a wavelength lower than that corresponding to the position of maximum C at normal incidence. Data for the calculation of η_1 and d_1 for this specimen in the visible region of the spectrum and the results of the calculation are listed in Table I. The average value for d_1 taken from this calculation was used in Eq. [2] to calculate values for η_1 at other wavelengths where extremes occurred outside the visible region. The calculated variation of the refractive index with wavelength of films formed at 200, 300, and 400v is shown in Fig. 3. The thicknesses of these films were calculated as 3159, 4318, and 5493Å, respectively.

Unfortunately, strong adsorption of light in the visible and ultraviolet regions of the spectrum obliterated the interference patterns of oxide films which were formed in high-temperature water and air to such an extent that this method could not be applied to them.

Discussion

Calculated values for both the refractive index and film thickness of the anodic zirconium oxide films are believed to be accurate to 1% or better, and within this limit the refractive index does not appear to change with film thickness. The refractive index of these films exhibits normal dispersion behavior with no appreciable absorption throughout the ultraviolet, visible, and near infrared regions of the spectrum, and varies from 2.07 at a wavelength of 1μ to 2.50 at a wavelength of 250 mμ. It should be noted, however, that the refractive index measured by this technique is not necessarily the same as that of the oxide film

in situ on the metal since the removal of the metal from the films tends to relieve certain strains existing in the film. These strains would be expected to affect the optical properties of the oxide. However, the calculated film thicknesses should not be appreciably different from those of the films in place.

The transmission interference method described here cannot, of course, be used with films such as the thermally formed films mentioned above which are strongly absorbing in both the visible and ultraviolet regions of the spectrum. The method is further limited by a lower limit on the thickness of the film for which coincidence of the interference extremes can be obtained at angles of incidence which are practically and accurately measurable. Proper choice of the liquid for use in the immersion mount can lower this limit considerably.

This method has one distinct advantage over the reflection interference methods often used for refractive index and thickness measurements. It completely eliminates the phase change occurring on reflection at the oxide-metal interface from the interference equations. This factor is often improperly treated. For example, Charlesby and Polling (6) developed interference equations for measurements similar to those reported using reflection techniques. Although these equations contained the phase change, its variation with angle of incidence was neglected completely in their use.

Furthermore, this method can undoubtedly be applied to other oxide films, both anodic and thermal, which can be separated from the substrate metal and which do not absorb strongly enough to obliterate the interference patterns normally developed.

Acknowledgment

The author wishes to express gratitude to Dr. M. L. Picklesimer for his many discussions of this project and his criticism of the manuscript.

The Role of Copper During the Oxidation of Transformer Oils

John J. Melchiore and Ivor W. Mills

Research Laboratories, Sun Oil Company, Marcus Hook, Pennsylvania

ABSTRACT

Air oxidation of two transformer oils, differing mainly in the fact that one contained metal deactivator, was studied at 95°C in the presence and absence of metallic copper. Power factor, hydroperoxide and carbonyl oxidation intermediates, and copper contents were measured as a function of time. In the absence of metallic copper, oxidation of the two oils is quite similar. Curves of power factor and oxidation intermediates show no striking differences. There appears to be a relation between power factor and carbonyl content in these cases. In the presence of metallic copper, the oil containing metal deactivator is capable of resisting the catalytic effects of copper. The oil without deactivator is grossly degraded by <0.2 ppm soluble copper which the oil rapidly dissolves. The relation between copper content, hydroperoxide content, and power factor is discussed in terms of a proposed mechanism.

It is well known that oxidative degradation of electrical oils results in the loss of electrical insulating properties of the oil. This has led to a search for electrical oils with superior oxidation resistance, especially in the presence of copper. A number of comparative accelerated laboratory tests have been devised, hopefully to predict what will actually happen to a transformer oil in service over a period of years. A particularly convenient and useful comparative test involves periodic measurement of the power factor of an oil at 95°C exposed to air and copper over a period of several days. Although the correlation of this test with actual oil performance in use has yet to be demonstrated, the mechanism of oil degradation should be the same, since in both cases the oil at elevated temperature is exposed to air and metallic copper. This test, described in detail in the Experimental Section, was used throughout the present study.

The mechanism of oil degradation in the presence of copper is not clear. Proposals for both heterogeneous and homogeneous copper catalysis have been made (1), but more convincing evidence has been reported supporting the homogeneous theory (2). Although transformer oils in service are reported to dissolve about 0.2-0.6 ppm copper, the ability of an oil to retain soluble copper apparently depends on many diverse factors (3). However, detailed quantitative data on copper solubility during the early hours of oxidation are lacking as well as the mechanisms responsible for copper solubilization. Similarly, the role of metal deactivators is another related aspect of the over-all problem. The work presently reported, there-

fore, was undertaken to help answer these questions, with particular emphasis on the processes occurring during the early hours of oxidation.

In this investigation, air oxidations of two transformer oils, A and B, were studied at 95°C in the presence and absence of metallic copper. Power factors of the oxidizing oils were recorded automatically each hour. From small aliquots withdrawn periodically, hydroperoxide and carbonyl contents were measured polarographically. The soluble copper content was determined by neutron activation analysis. Thus, data are available for plotting continuous curves of power factor, copper content, and oxidation intermediates.

Physical and chemical properties of oils A and B are summarized in Table I, with infrared and ultraviolet spectra given in Fig. 1 and 2. The most important difference between these oils is the fact that oil B contains a metal deactivator, that is, a material capable of significantly decreasing the catalytic activity of copper. This metal deactivator was derived

from naturally occurring sulfur compounds contained in oil A by the method detailed in the Experimental Section. The concentration of deactivator present in oil B is estimated to be about 100 ppm. Due to difficulties imposed by its low concentration, the exact chemical structure of this deactivator has not yet been determined. The effectiveness of deactivator is indicated in Fig. 3, which shows that deliberately introducing soluble copper does not markedly catalyze the oxidation of oil B, whereas the same quantity of copper grossly degrades oil A. Further evidence for the effectiveness of this deactivator is presented in Fig. 4, showing that a minor amount of oil B will protect oil A from the catalytic effect of soluble copper. These charts are presented simply to show the effectiveness of the deactivator when soluble copper is deliberately added to the oil to accelerate oxidation. In actual use, transformer oil is exposed to metallic copper and, in many cases, to air as well. Therefore, the studies described here were aimed at a better understanding of interactions between oil and metallic copper in the presence of oxygen.

Experimental

Generation of deactivator in situ.—Transformer oil A is obtained from a naphthenic distillate stock by treating the stock conventionally with sulfuric acid and

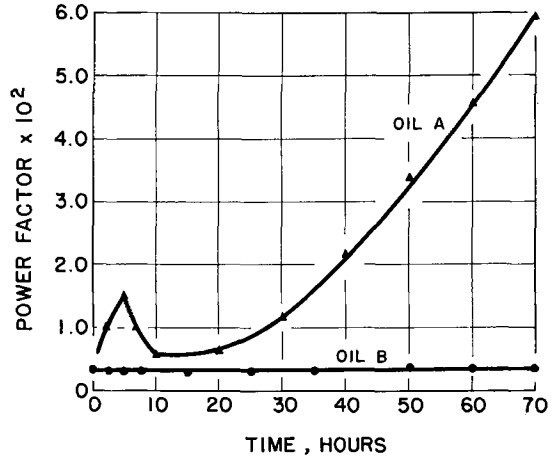

Fig. 3. Effect of 0.5 ppm Cu^{+2} and air on the power factor of conventional transformer oil (A) and oil containing metal deactivator (B) at 95°C.

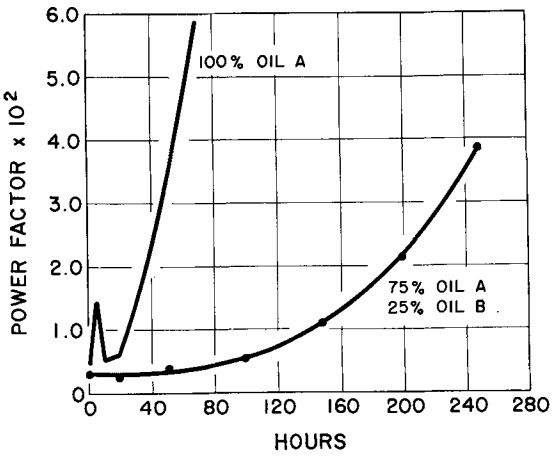

Fig. 4. Effect of 0.5 ppm Cu^{+2} and air on the power factor of blended transformer oils at 95°C.

adsorptive clay according to procedures widely used in the petroleum industry. When oil A is reacted with sodium isopropoxide, species capable of deactivating copper are generated in very low concentrations (~100 ppm). Specifically, the deactivated oil, oil B, is typically obtained by the following laboratory procedure.

A 1-liter Morton flask, equipped with thermometer, high-speed stirrer, reflux condenser, and gas inlet tube, containing 500 mls oil A and 2.3g sodium, is heated to 110°C under nitrogen with vigorous agitation in order to disperse the sodium. The contents are cooled to room temperature and 7g anhydrous isopropanol are added. The oil and sodium isopropoxide are reacted at 110°-140°C for 30 min, continuing good agitation. When cooled below 90°C, the contents are added carefully, with agitation, to 1 liter of cold distilled water. The oil phase is separated and thoroughly washed five times with equal volumes of water. After drying at 105°C under vacuum, 14g adsorptive clay are added and slurried with the oil for 20 min at 105°C. The oil is then filtered through paper and finally vacuum filtered through a 0.45μ millipore filter.

Oxidation procedure.—Before oxidation, each oil is refiltered through a 0.45μ millipore filter, and 250 ml of filtered oil is then preheated in an oven to 95°C. The oil is placed in a thoroughly cleaned test tube 11 x 2½ in. A stainless steel cell, containing two concentric electrodes, is immersed in the oil. This cell has an air capacitance of 47 x 10^{-12} farads or a measured capacitance of 105 x 10^{-12} farads using material of dielectric constant of 2.2. A coil containing 100 in. of 0.06 in. diameter copper wire is placed within the cell. An air delivery tube extends to the bottom of the oil, through the copper coil. The test tube containing the oil, electrodes, copper coil, and air delivery tube is immersed in a constant temperature oil bath maintained at 95° ± 1°C. Air is supplied to the oil according to the specifications of ASTM D1904. Once each hour, the d-c conductivity of the oxidizing oil is measured, amplified using a L&N #98360A amplifier and recorded using a Varian G-10 recorder. Current is allowed to flow only 5-6 sec each hour. Using an applied voltage of 2.7v from standard mercury cells and the measured current, the resistance of the oil is calculated from Ohm's law. The power factor is related to the resistivity through the equation

$$\text{Power factor} = \frac{1}{\sqrt{(2\pi fCR)^2 + 1}}$$

where f equals 60 cycles and C is capacitance (assumed constant).

Periodically during the oxidation, 3 ml aliquots are withdrawn. Using the Sargent XXI polarograph according to the method of Loveland (4), the hydroperoxide content is determined on a 1 ml aliquot from the half-wave potential in the —0.9v region and the carbonyl content measured from the half wave at —1.6v (*vs.* saturated calomel electrode). The copper content of the sample is determined from the remaining 2 ml aliquot, using neutron activation analysis (5).

Results and Discussion

Oxidation in the absence of copper.—Data on the oxidation of oils A and B with air at 95°C in the absence of copper are summarized in Fig. 5 and 6. The figures show that the power factors of the oils during the first 70 hr of oxidation remain low and essentially unchanged, indicative of little oxidative degradation during this period.

Also plotted on the same time scale are the relative concentrations of hydroperoxides and carbonyl compounds, namely, aldehydes and ketones. The rate of appearance of these oxidation intermediates is essentially the same for both oils. Within a few hours hydroperoxide is detected, rising to a maximum concentration of about 10 mmoles per liter and gradually falling to a steady state of about 4 mmoles per liter. Carbonyl compounds show a slow steady rise during this oxidation period.

Results are consistent with a generally accepted free radical autoxidation mechanism, with hydroperoxide as the first isolatable oxidation intermediate. Decomposition of hydroperoxide and subsequent rearrangement and oxidation of its fragments would result in the appearance of aldehydes and ketones, fol-

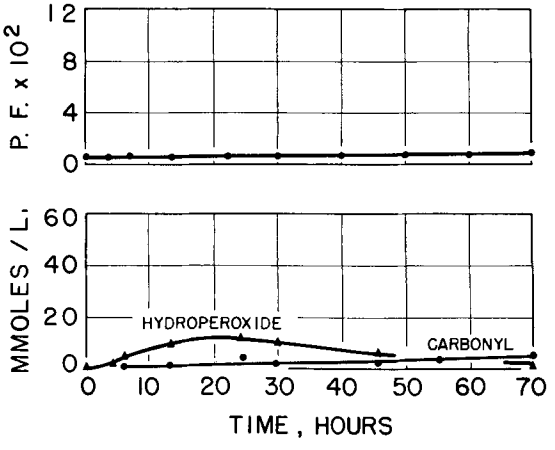

Fig. 6. Air oxidation of oil containing metal deactivator (B) at 95°C in the absence of copper. Power factor values and oxidation intermediates concentrations vs. time.

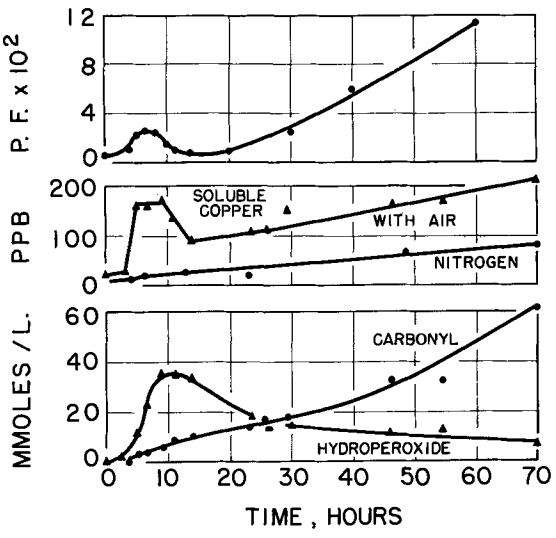

Fig. 7. Air oxidation of conventional transformer oil (A) at 95°C in the presence of metallic copper. Power factor values, parts per billion soluble copper, and oxidation intermediates concentrations vs. time.

lowed finally by the appearance of carboxylic acids. We can also reasonably conclude from the data that both oils, in the absence of copper, oxidize in a similar manner.

Figures 5 and 6 stop at 70 hr; however, if oxidation is continued longer, the power factor curves rise slowly. Although carboxylic acids and alcohols are known to make only small contributions to power factor (6), the parallel rise of power factor and carbonyl content suggests that they are related. Such a relation has not been previously reported, and we have not yet examined it in detail, but it is scheduled for further experimental studies.

Oxidation in the presence of metallic copper.—Power factor, oxidation intermediates, and copper solubility data for the air oxidation of oils A and B in the presence of metallic copper at 95°C are summarized in Fig. 7 and 8. It is immediately obvious that the oxidation of oil A is dramatically catalyzed by copper, whereas oil B is able to resist this copper catalysis.

Oxidation of oil A.—From a detailed examination of Fig. 7 the following observations are made:

1. Oxidative degradation of oil A is rapidly catalyzed by copper although the soluble copper content is less than 200 parts per billion (ppb) for most of the test period.

2. The power factor curve of the oxidizing oil exhibits a peak at 7 hr after which it falls nearly to its initial value before beginning a steady rise.

3. The copper content also rises to a peak between 5 and 10 hr, then drops before starting a gradual rise. The similarity between the power factor and soluble copper curves suggests that conductive copper in solution may affect power factor, particularly in the peak area. This copper solubility data is in sharp contrast to the copper solubility observed when the oil is maintained under nitrogen (Fig. 7). In this case, copper dissolves very slowly over a long period of time, never reaching the level of solubility obtained under oxidizing conditions. The power factor under nitrogen (not shown in Fig. 7) is low and flat over the entire test period.

4. The maximum hydroperoxide content of oil A during copper-catalyzed oxidation is about 3½ times greater than during the noncatalyzed oxidation (Fig. 5). It is interesting to note that maximum hydroperoxide content is achieved after the maximum amount of copper has entered solution, strongly supporting the hypothesis that soluble copper acts catalytically to accelerate hydroperoxide formation. From a comparison of the power factor and hydroperoxide curves, it is evident that hydroperoxides themselves make only a small contribution to the observed power factor.

5. The carbonyl content of the catalyzed oxidation becomes appreciable early in the oxidation and rises rapidly, greatly exceeding the carbonyl content of the uncatalyzed oxidation (Fig. 5) throughout the entire oxidation period, again indicating gross degradation of the oil.

The data are again consistent with a typical free radical chain autoxidation mechanism, catalyzed by soluble copper. The hydroperoxide and carbonyl curves are those that would be expected from such a mechanism. The copper solubility results summarized in Fig. 7 were somewhat unexpected and their interpretation warrants further discussion.

It is interesting to speculate on the nature of the processes occurring during the copper catalyzed oxidation of oil A at 95°C. This oil carried in it, before oxidation, 10-20 ppb soluble copper. Although processes initiating oxidation have received little attention and are not well understood, the initially contained soluble copper may be capable of initiating free radical chains according to previously proposed schemes (7). Once started, the first isolatable product of the oxidation will be hydroperoxides. It has been proposed that reaction of peroxides with metallic copper results in the solubilization of copper (8). It is generally accepted that copper forms an oxide film when exposed to oxygen (9, 10). It has recently been shown that at temperatures in the vicinity of 100°C, copper will form an oxide film having the unusual stoichiometry of $CuO_{0.67}$ (11). This film presumably is a gross defect structure of cuprous oxide. We propose, therefore, that solubilization of copper results from the reaction of hydroperoxide with this oxide film, which for simplicity we will simply consider as cuprous oxide as depicted in Eq. [1]. Possible disproportionation to the cupric salt is depicted in Eq. [2]

$$2ROOH + Cu_2O \rightarrow 2Cu^+(O_2R)^- + H_2O \quad [1]$$

$$2Cu^+(O_2R)^- \rightleftharpoons Cu + Cu^{+2}(O_2R)_2 \quad [2]$$

Metal salts of hydroperoxides, as proposed in reaction [1], are prepared by reaction of an appropriate metal oxide with hydroperoxide (12). The limited solubility of these salts in hydrocarbon media would depend on the nature of R, the ionic character of the salt, and any further organic material associated or complexed with it. From the coincidence of the power factor and copper solubility peaks of Fig. 7, it seems reasonable to conclude that the power factor peak observed at 7 hr is due largely to the conductivity of soluble copper.

For simplicity we have designated the first isolatable oxidation intermediate simply as hydroperoxide, ROOH. We do not imply that this is simply a hydroperoxide derived from a strictly hydrocarbon precursor. On the contrary, independent evidence indicates that sulfur and/or nitrogen containing organic compounds in the oil are the first to hydroperoxidize and it is these materials which we suspect tend to solubilize copper through reaction [1].

With the soluble copper present in solution, the typical catalytic reactions of metal ions with hydroperoxide would be expected according to Eq. [3] and [4], resulting in the formation of new chains and the appearance of carbonyl compounds from well-known reaction sequences (13).

$$ROOH + Cu^{+2} \rightarrow Cu^{+1} + H^+ + RO_2\cdot \quad [3]$$

$$ROOH + Cu^{+1} \rightarrow Cu^{+2} + OH^- + RO\cdot \quad [4]$$

In addition, the postulated copper salts would be expected to be unstable (14) and may decompose by Eq. [5] or [6].

$$Cu^+(O_2R)^- \rightarrow CuO + RO\cdot \quad [5]$$

$$Cu^{+2}(O_2R)^-_2 \rightarrow CuO + RO\cdot + RO_2\cdot \quad [6]$$

Consequences resulting from Eq. [5] and [6] would be initiation of new chains with subsequent appearance of hydroperoxides, alcohols, and carbonyl compounds, and a mechanism for removal of soluble copper from solution.

Alternate explanations for the observed net decrease in copper content (Fig. 7) are found in known reactions of hydroperoxides and their salts (15). Thus, hydroperoxide is known to react with its salt to produce an alcohol. Using the cuprous salt as an example, the reaction is summarized in Eq. [7].

$$Cu(O_2R) + ROOH \rightarrow ROH + O_2 + CuOR \quad [7]$$

Alternatively, primary and secondary alcohols are known to react with hydroperoxide salts according to Eq. [8].

$$Cu(O_2R) + RCH_2OH \rightarrow CuOH + ROH + R\text{-}CHO \quad [8]$$

The copper hydroxide produced would not be soluble in hydrocarbon media. The polar alcohol and carbonyl compounds produced via Eq. [7] and [8] or from the free radical chain autoxidation would be adsorbable on the copper oxide surface film, thus decreasing the rate of copper solubilization by reaction [1]. Eventually copper removal by Eq. [5], [6], or [8] predominates, resulting in a net decrease of soluble copper.

Although the experimental data clearly indicate a decrease in soluble copper content, visually we do not see any dispersed insoluble material, no doubt due to the extremely low concentration of soluble copper. The oxidizing oil and the aliquots withdrawn from it are perfectly clear. We do, however, observe the formation of varnish colored deposits on the copper coil and on the electrodes, after prolonged oxidation. The nature of these deposits was not investigated due to the minute quantities involved.

After passing through a minimum at about 14 hr, the copper content starts to rise again, probably due to the known solubilizing tendencies of carbonyl compounds and carboxylic acids (16).

Oxidation of oil B.—Oxidation data for oil B in the presence of copper, summarized in Fig. 8, is markedly different from oil A, since oil B contains material capable of reducing, but not completely eliminating, catalysis by copper. The oxidation is characterized by the following:

1. The power factor curve exhibits no peak early in the oxidation and rises only slightly over the entire oxidation period.

2. Oil B dissolves less copper than oil A. At equilibrium, oil B dissolves approximately 50 ppb soluble copper. Significantly, the copper concentration curve does not peak early in the oxidation, in good agreement with the lack of peak noted for the power factor curve.

3. The hydroperoxide curve approximates that found for oil B in the absence of copper. The carbonyl content is several times greater than that observed without copper, but still substantially less than that observed in oil A.

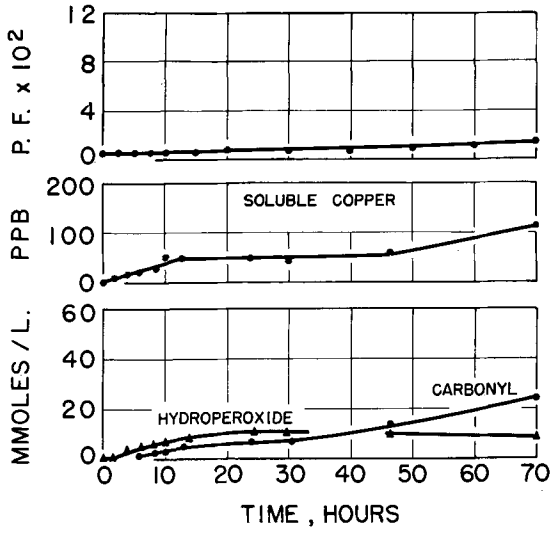

Fig. 8. Air oxidation of oil containing metal deactivator (B) at 95°C in the presence of metallic copper. Power factor values, parts per billion soluble copper, and oxidation intermediates concentrations vs. time.

The results clearly demonstrate that the catalytic effects of copper have been sharply reduced, but not completely eliminated. A striking difference is noted in the abilities of oils A and B to solubilize copper under oxidizing conditions. Oil B dissolves substantially less copper than oil A, although oil B oxidizes to produce appreciable hydroperoxide early in the oxidation. In fact, oil B after 4 hr of oxidation contains enough hydroperoxide to dissolve at least 70 ppm copper. Why then, if our postulated solubilization mechanism between hydroperoxide and copper oxide film is correct, does not more copper dissolve? A reasonable explanation is simply that the polar metal deactivator is adsorbed on the copper oxide surface, thus decreasing the solubilization of copper by Eq. [1]. Copper contained in solution, although at low concentrations, is capable of exerting some catalytic activity as evidenced by the increased carbonyl content over oxidation conducted in the absence of copper.

Therefore, based on this study, the function of metal deactivator appears to be twofold: (*a*) to coat the copper oxide surface and thus decrease the quantity of copper solubilized, and (*b*) to decrease the catalytic activity of solubilized copper, presumably by chelation.

Summary and Conclusions

This study of the processes occurring during the early hours of transformer oil oxidations has indicated that the oxidation rate of similar oils is slow and almost identical in the absence of copper, even though one contains metal deactivator. Dielectric loss, as measured by power factor, seems to be related to the carbonyl content of the oil in these cases.

The situation in the presence of copper is quite different. The oil without deactivator is rapidly degraded in the presence of metallic copper. The solubiltiy of copper rises quickly during the early hours of oxidation to a peak concentration of 170 ppb. The coincidence of this soluble copper peak and the observed power factor peak strongly suggests that copper enters solution in a conductive form contributing to power factor losses in the early stages of the oxidation. A mechanism of copper solubilization has been proposed, involving reaction of hydroperoxide derived from nitrogen and/or sulfur containing impurities in the oil, and a copper oxide surface film. The catalytic effect of the soluble copper is clearly demonstrated from the rate of appearance and concentration levels of hydroperoxide and carbonyl compounds.

In the presence of copper, a metal deactivator is very effective in preserving the oil. The quantity of copper dissolved is less, the rate of appearance and concentration of oxidation intermediates is also less. A twofold effect for the metal deactivator is apparent; namely, a coating effect on the metal which decreases copper solubilization and a decrease of catalytic activity of the soluble copper due to chelation.

Continuous power factor measurements have interesting but largely unexploited potential for following the oxidation of organic substances. Further fundamental work on factors contributing to observed power factor is needed to extend its usefulness. Particularly, quantitative correlations of power factor with oxidation intermediates and with valence and nature of soluble metal species are needed.

Finally, the present study emphasizes the effect of truly trace quantities of copper. The quantitative aspects of this effect could not have been appreciated were it not for the advent of neutron activation anal-

ysis, a superb tool for this and other trace element studies. It is hoped that this and later studies will contribute not only to a better understanding of oil oxidation as catalyzed by copper but to eventual significant improvement in the useful life of electrical oils.

Acknowledgments

The authors wish to acknowledge Mr. G. R. Dimeler and Mr. I. H. Johnson for their helpful assistance in polarographic analyses and power factor determinations, respectively.

Growth Mechanism of Thin Anodic Oxide Films on Tantalum

I. Self-Anodization Using an External Load Resistor

R. Dreiner, K. Lehovec, and J. Schimmel

Research Laboratories, Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

The growth of an anodic oxide film on tantalum metal immersed in diluted sulfuric acid has been investigated using potential and capacitance measurements. The tantalum metal was connected through an external resistance to a platinum electrode in the electrolyte. An analysis of voltage *vs.* time confirms the exponential field dependence of the ionic current for the later phases of oxide growth. Analysis of current (I) *vs.* time (t) measurements provides BF_o and λF_o where B is the field coefficient,[1] F_o is the initial field in the oxide, and λ is the growth rate per unit current, provided that the emf of the reaction, E, is known. E can be determined by matching the B-values derived from I *vs.* t to those derived from capacitance measurements. For sufficiently thin oxide films the growth rate exceeds the value expected from Faraday's law based on the external current which indicates the presence of internal electron currents for which the empirical expression

$$I_E = I_E^o \, e^{-d/l}$$

with $I_E^o \sim 3 \times 10^{-4}$ amp/cm^2 and $l \sim 3.0$Å, was obtained. There are indications that either the inverse Tafel slope, B, or the emf, E, varies with film thickness in the range where the internal electron current is appreciable.

It has been found (1) that the ionic current promoting the growth of anodic oxide layers depends exponentially on the field across the oxide. Determination of the constants involved in this relation usually requires the measurement of the oxide thickness by such techniques as capacitance-, optical-, or weight-measurement.

We have explored the applicability of the exponential field law for very thin anodic oxide films on tantalum. Since the determination of the oxide thickness becomes increasingly difficult the thinner the oxide film, a method was used which does not involve thickness measurements, namely, the analysis of the time dependence of the external current through a resistor connecting Ta and Pt electrodes in an electrolyte. This current arises from the electromotive force of the reaction of Ta with water and decreases with time as the oxide grows on the tantalum.

This general procedure of analysis could be applied also to cases where an external power source is placed in series with the external resistor. However, in order to investigate the growth of thin oxide films we must limit the external current to fairly small values to obtain a slow growth rate. Initially the oxide resistance is very low so that the current is limited by the external resistor. In this range the current *vs.* time relation is not sensitive to the oxide resistance. In order to investigate the properties of thin oxide films we must reduce the external resistor as much as possible which is incompatible with the former condition of a fairly small current if a large external voltage were employed. For this reason we have not applied an external voltage and have studied in detail the growth of thin anodic films by means of the emf associated with the formation of Ta_2O_5 (so-called self-anodization).

We have compared the experimental time dependence of the external current with a theoretical equation based on well-known relations valid for thick oxide films, but not necessarily applicable to the thin oxide films here investigated. By this comparison the numerical values of certain parameters for thin oxide films were determined and the following anomalies were discovered:

[1] Sometimes referred to as "inverse Tafel slope."

1. The presence of electron currents through the oxide which govern the growth of sufficiently thin oxide films, and
2. Some time or thickness dependence of the "emf" or of the "inverse Tafel slope" for the ionic current.

These anomalies have then been investigated in more detail using capacitance measurements.

Experimental Procedure

Tantalum foil of 99.9% purity supplied by Fansteel was degreased, chemically polished, leached in boiling deionized water for 10 min, "vacuum" annealed at pressures less than 10^{-4} Torr at 2100°C for 30 min, etched in hydrofluoric acid, briefly rinsed in deionized water, and immediately inserted in 0.1% (by weight) aqueous sulfuric acid at room temperature. The sample had a narrow neck extending out of the H_2SO_4 solution to provide an electric contact. The macroscopic contact area with the electrolyte was 18.8 cm^2. The tantalum was connected through a load resistor, R_L, to a platinum electrode immersed into the electrolyte, and the current through the load resistor was measured as a function of time. Resistors of 10^3 ohms were used to investigate the current decay over many orders of magnitudes within a reasonable time, *i.e.*, about one day. Resistors of 10^5 ohms were used when emphasis was placed on the capacitance measurements during the initial phase of oxide growth. The external resistors were large with respect to the electrolyte resistance so that the potential drop across the electrolyte could be neglected.

The voltage between the platinum electrode and the electrolyte (during a run) was monitored by using a saturated calomel electrode in the electrolyte. Except during the initial few seconds, no significant variation in polarization was observed. The voltage was about 0.6v with the platinum (Pt) positive with respect to calomel.

The initial voltage across the resistor was about 1v (tantalum negative) for freshly etched foils.

The equivalent series capacitance of the cell was measured at 1000 cps with a General Radio impedance comparator and a recorder. This permitted the continuous recording of the capacitance with time. The equivalent series resistance observed was approximately 50 ohms which agreed reasonably well with the specific resistivity of the electrolyte and the geometry of the electrolyte cell. From this capacitance an "oxide thickness," d^*, was derived by

$$d^* = S\epsilon\epsilon_0/C \qquad [1]$$

where S is the area, and ϵ is the dielectric constant of tantalum oxide. This procedure ignores capacitances of space charge layers in the electrolyte adjacent to the platinum and adjacent to the tantalum oxide. By investigating the equivalent series capacitances of gold *vs.* gold and gold *vs.* platinum in the electrolyte, we have found that the capacitance for the platinum electrode could indeed be ignored. The solution double layer capacitance adjacent to the tantalum oxide should remain fairly constant during the oxide growth, so that the true oxide thickness would be smaller than the oxide thickness, d^*, by a constant amount, Λ. The equivalent series capacitance of the arrangement Au-electrolyte-Au was found to be $C_S = 2.4\ \mu F/cm^2$.[2] If the solution double layer capacitance adjacent to the tantalum oxide were the same as that adjacent to gold, we would have $\Lambda = S\cdot\epsilon\cdot\epsilon_0/2C_S = 5.1$Å.

Since the capacitance depends somewhat on frequency, the significance of an "oxide thickness" as derived by Eq. [1] for capacitance measurements at the frequency of 1000 cps may be questioned. It has been observed on niobium oxide (3) that the frequency dependence between 60 cps and 8 kcps is the same for various oxide films of thicknesses ranging from a few tens of angstroms to several 1000 angstroms. If this is the case in our films, the correction factor for converting the apparent thickness (*i.e.*, that of Eq. [1], as calculated from C at 1000 cps) to the true thickness should be the same for all values of d, and the frequency dependence of the capacitance may be taken into account by a corresponding frequency dependence of the dielectric constant. When using the capacitance value at 1000 cps in Eq. [1], we must then use the dielectric constant at 1000 cps which was determined by Young (4) to be $\epsilon = 27.6$ based on the density $\rho = 7.93$.

[2] The equivalent series resistance per double layer Au/electrolyte was 20 ohms/1 cm^2 area.

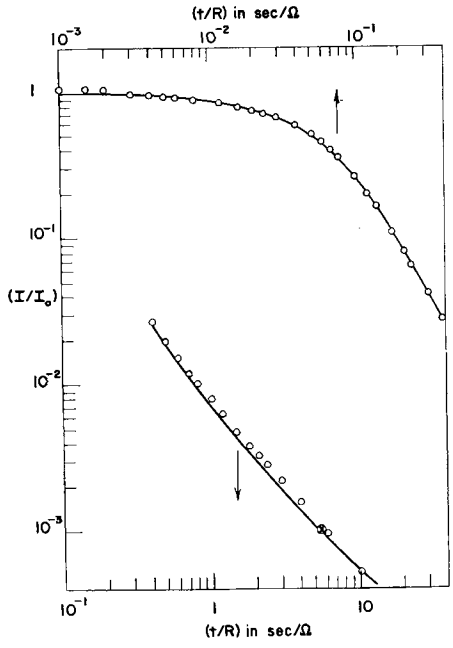

Fig. 1. Current decay during self-anodization of tantalum of area $S = 18.8\ cm^2$ in 0.1% aqueous H_2SO_4. Tantalum connected to a platinum electrode through a resistor $R = 1000$ ohms. Experimental points; Theoretical curve by Eq. [2] matched to the experimental points by using the following parameters: $I_o = 1.1$ ma, $E = 1.83$v, $BF_o = 35.6$, $\lambda F_o = 13.75$ v/coul.

Analysis of Current Density during Oxide Growth

Figure 1 shows the dependence of the current, I, in the external circuit on time. The ordinate is the ratio of the observed current to an extrapolated initial current, I_o, which was obtained by a procedure to be described later. The theoretical curve drawn represents the equation

$$\lambda F_o t/R = \left(1-\frac{1}{BF_o}\right)\ln\frac{I_o}{I} + \frac{E}{RI_o}\,\frac{BF_o}{[BF_o-\ln(I_o/I)]^2}\left(\frac{I_o}{I}-1\right) \qquad [2]$$

which follows from the accepted field dependence of the ionic current density

$$I_I = A\,e^{BF} \qquad [3]$$

with

$$F = (E-RI)/d \qquad [4]$$

and from Faraday's law

$$\frac{\partial d}{\partial t} = \lambda\cdot I_I \qquad [5]$$

with the ionic current I_I equal to the current, I, in the external resistor

$$I_I = I \qquad [6]$$

Equation [2] was derived as follows: Substitute d of Eq. [4] into [5], and replace $\frac{\partial F}{\partial t}$ by $\frac{1}{BI}\frac{\partial I}{\partial t}$ using [3] and [6] to obtain

$$\lambda I = \left[-\frac{R}{F}\left(1-\frac{1}{BF}\right) - \frac{E}{BF^2 I} \right] \frac{\partial I}{\partial t} \qquad [7]$$

Since F changes quite slowly (logarithmically) with I according to [3], we may treat F in Eq. [7] as a constant when integrating to obtain

$$\lambda t/R = \frac{1}{\bar{F}}\left(1-\frac{1}{B\bar{F}}\right)\ln\frac{I_o}{I} + \frac{E}{RI_o}\frac{1}{B\bar{F}^2}\left(\frac{I_o}{I}-1\right) \qquad [8]$$

where $\bar{F}$ is a suitable average value of F over the integration interval $0 \leq \tau \leq t$. Equation [2] was obtained by using the terminal value

$$F_{\tau=t} = F_o\left(1+\frac{1}{BF_o}\right)\ln\frac{I_{\tau=t}}{I_o} \qquad [9]$$

for $\bar{F}$ in the second term on the right of Eq. [8], since the largest contribution in the integration of Eq. [7] comes from the values near the boundary $\tau \approx t$. In the first term on the right of Eq. [8] $\bar{F}$ can be replaced simply by F_o since this term is important only in the range where $I_\tau \sim I_o$. The error committed by using [9] for $\bar{F}$ is estimated in Appendix I.

For $(I_o/I) - 1 << 1$ one may approximate $\ln (I_o/I) \approx (I_o/I) - 1$, showing that initially the ratio of the second term on the right of Eq. [2] to the first term is $\dfrac{E}{RI_o(BF_o - 1)}$. Since E/RI_o is of the order of unity, but BF_o is about 30, the first term dominates initially. It is interesting to note that the first term arises essentially without the aid of Eq. [3]. If we consider the field F in Eq. [4] as a constant, then it follows from Eq. [5] and [4] that $\lambda Ft/R = \ln I_o/I$ which is very approximately the first term of Eq. [2] since $BF_o >> 1$. Thus good agreement between Eq. [2] and the experimental data in the range $(I_o/I) - 1 << 1$ does not necessarily indicate that Eq. [3] is satisfied.

The second term on the right side of Eq. [2] results from the approximate variation of the field with thickness $F \approx E/d$, which is approached once $RI << E$, in conjunction with the exponential field dependence of the ionic current, Eq. [3], and Faraday's law, Eq. [5]. The second term on the right side of Eq. [2] is also pertinent to the decay of current with time when a constant voltage, V_A, is applied. The emf, E, is then to be replaced by $E + V_A$, and one obtains

$$I = \frac{B(E+V_A)}{[BF_o - \ln(I_o/I)]^2 \lambda t} \qquad [10]$$

Similar forms of the $1/t$-law of current decay during constant voltage formation have been previously derived (5, 6). However, Eq. [10] should be valid only if electron leakage currents through the sample are absent, if Faraday's law (5) and the field dependence (3) of the ionic current are fulfilled, and if there is no field distortion by space charges in the oxide.

Figure 2 shows a plot of $I(t)$ on a semilogarithmic scale. The straight line fits the experimental data well in the range $0.6 \lesssim RI \lesssim 1.05$v, *i.e.*, 400 sec $< t <$ 4500 sec. Such a straight line relationship is expected from Eq. [2]. Deviations of the experimental points from

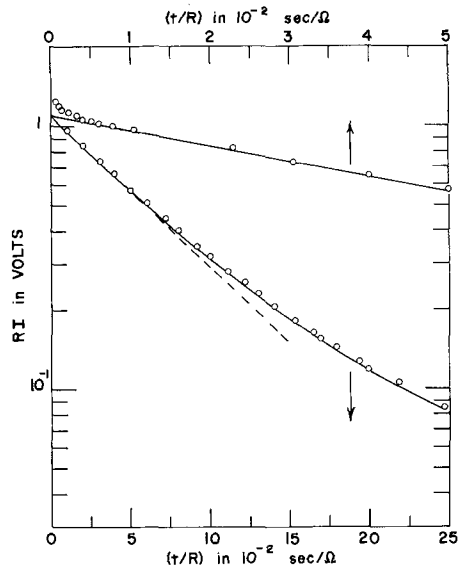

Fig. 2. Current decay during self-anodization of tantalum of area 18.8 cm² in aqueous 0.1% H_2SO_4 with $R = 10^5$ ohm connecting the tantalum to a Pt electrode. The straight line approximation provides $I_o = 1.1 \times 10^{-5}$ amps and $(\lambda F_o)^o = 13.2$ v/coul. Experimental points; —— theoretical curve Eq. [2] with $I_o = 1.1 \times 10^{-5}$ amp, $E = 1.83$v, $BF_o = 30.75$, $\lambda F_o = 13.48$ v/coul.

the straight line for $t \gtrsim 4500$ sec are expected due to the second term on the right side of Eq. [2]. The deviations of the experimental data from the straight line for $t \lesssim 30$ sec indicate that one or several of the Eq. [4]-[6] are not satisfied in this range. This will be discussed in more detail in conjunction with the capacitance measurements. Extrapolation of the straight line to $t = 0$ yields I_o, while its slope, according to Eq. [2] is

$$\left(\frac{\partial \ln (I_o/I)}{\partial\, t/R}\right)_{t\to 0} = \frac{\lambda F_o}{1+\dfrac{(E/RI_o)-1}{BF_o}} \equiv (\lambda F_o)^o \qquad [11]$$

As seen from Fig. 1, Eq. [2] fits well the entire range of experimental data $I(t)$ except for the initial range, as already mentioned. The constants BF_o and λF_o required to calculate the theoretical curve in Fig. 1 have been determined by matching the theoretical curve to the experimental data using the procedure described in Appendix 2.

Numerical values for BF_o and λF_o for four samples are listed in Table I, based on the value $E = 1.83$v. The value $E = 1.83$v was selected by comparing data of BF_o and λF_o derived from $I(t)$ with those derived from the capacitance measurements to be discussed in the next section. The values of λF_o differ very little among the four samples. The variation in BF_o is somewhat larger, which suggests that either B differs among various samples or that E might vary. The latter is not impossible considering that E in Eq. [4] is not only the emf but may include some contact potential.

Table I. Evaluation of the current vs. time relationship for self-anodization of tantalum oxide, assuming $E = 1.83$v

Sample	R, ohms	RI_o, v	BF_o	λF_o, v/coul	B/λ, farads	B^*, 10^{-6} cm/v	A^{**}, amp
1/21/63	10^6	1.1	35.6	13.75	2.59	8.03	3.8×10^{-19}
II	10^5	1.1	30.75	13.48†	2.28	7.07	4.9×10^{-19}
I	10^5	0.87	23.9	14.23	1.68	5.21	3.6×10^{-16}
1/16/63‡	10^4	0.45	27.1	14.02	1.93	5.98	7.6×10^{-17}

* Using $\lambda = 3.1 \times 10^{-6}$ cm/coul.
** $A = I_o e^{-BF_o}$.
‡ Sample remained unetched following the vacuum anneal.
† $\lambda F_o = 13.2$ using Eq. [11] and taking the denominator to equal 1.

Table II. Dependence of BF_o and λF_o on the choice of E for sample II

E, v	BF_o	λF_o, v/coul
1.7	20.08	13.45
1.83	30.75	13.48
1.9	31.61	13.50

To indicate the influence of the choice of E on the values of BF_o and λF_o of Table I, we have listed in Table II values of BF_o and λF_o for sample II, which would result from three different values of E.

Inserting the values of I_o and of BF_o into Eq. [3], the pre-exponential factor A has been calculated. These values scatter considerably. However, an error in BF_o by 10% would account for the large deviations of A from the mean value of about 10^{-17} amp.

Time Dependence of Capacitance

The time dependence of capacitance during oxide film growth was measured for the samples I and II listed in Table I. Self-anodization of these samples was carried out with the comparatively large resistance $R = 10^5$ ohm in order to slow down the initial oxidation rate so that fairly accurate capacitance measurements could be made.

As discussed in the previous section, the time dependence of the current is not strongly affected by relation [3] during the initial stages of oxide growth. However, the dependence of current on oxide thickness, obtained from Eq. [3], [4], and [6] is strongly dependent on the field dependence of the ionic current. Using the "apparent film thickness," d^*, derived from capacitance measurements by means of Eq. [1], and the external current, we have derived the field intensity as a function of current by means of Eq. [4] with $d = d^*$. These values are quite sensitive to the choice of the emf, E. In Fig. 3 these curves are plotted pertaining to the values $E = 1.9$, 1.83, and 1.7v, on a greatly expanded ordinate scale. The sample is the same as used for Fig. 2.

In spite of the scatter of the experimental points, three ranges of $F(I)$ are clearly apparent. The boundaries between these ranges correspond to the "apparent thicknesses" of 30 and 42Å, respectively. The middle range (b) becomes less pronounced for increasing E.

Range (a): For $d \gtrsim 42$Å, the field decreases linearly with the logarithm of current as expected from Eq. [3] with [6]. The straight lines fitting the experimental data of Fig. 3 in this range have slopes from which the values of B[3] (the first line of Table III) have been obtained. Extrapolation to $I = I_o$ of Table I provides F_o, and extrapolation to $F = 0$ provides the pre-exponential factor, A, of Eq. [3]. These values are listed in the second and last lines of Table III.

Comparison of BF_o values of Table III with the values derived from the analysis of $I(t)$ (Table II) shows that fairly good agreement exists for $E = 1.83$v. This value will be adopted, therefore, in the subsequent discussion of sample II. The value $E = 1.83$ has been used also for evaluating the $I(t)$ data of the other samples listed in Table I.

[3] B is defined as $\partial \ln I/\partial F$.

Table III. Evaluation of the straight lines in the region (a) marked in Fig. 3

	E = 1.7v	E = 1.83v	E = 1.9v
B (10^{-6} cm/v)	9.2	7.7	6.8
F_o (10^6 v/cm)*	3.61	3.94	4.13
BF_o	33.2	30.34	27.85
λF_o (v/coul)**	11.2	12.2	12.8
A (amp)	4.2×10^{-20}	5.1×10^{-19}	1.1×10^{-18}

* F_o is F extrapolated to $I_o = 1.1 \times 10^{-5}$Å.
** Using $\lambda = 3.1 \times 10^{-6}$ cm/coul.

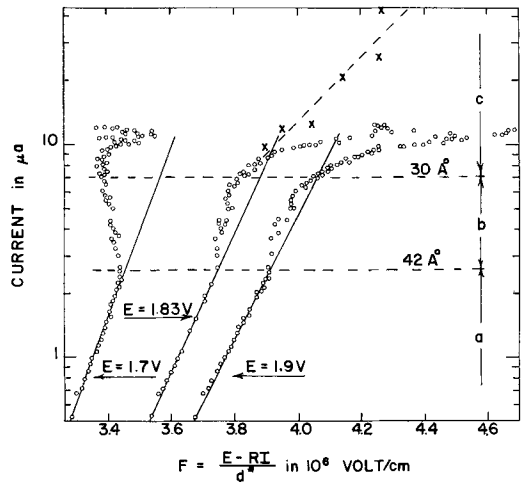

Fig. 3. Field intensity as a function of current, derived by Eq. [4] from current and capacitance measurements during self-anodization assuming three values of E. Values of Table III were derived from the straight line approximations in range (a).

Range (b): In the range corresponding to thickness between 30 and 42Å, the field derived by Eq. [4] changes much more slowly with current (*i.e.*, with time and thickness) than in the range (a).

Range (c): In the range $d \lesssim 30$Å, the field rises quite steeply with the external current.

It is obvious that for $d \lesssim 42$Å, at least one of the Eq. [3] to [6] ceases to be valid or, respectively, the parameters A, B, E, or λ in these equations are not constants but depend on t or d. For instance, the "emf" in this range might be a function of thickness or current density. Or else, the parameters A and B in Eq. [4] might not be constant; *e.g.*, B in the region (b) might be about twice the value in region (a). The region (c) could be explained by an ionic current which is much larger than the external electronic current due to internal flow of electrons so that Eq. [6] becomes invalid. Evidence for this interpretation of the region (c) will be discussed shortly. Lack of validity of Eq. [3] for $d \lesssim 42$Å should not significantly affect Eq. [2] since in the corresponding current range ($I \gtrsim 2 \cdot 10^{-6}$ amp), the condition $I > I_o/BF_o \approx 4 \times 10^{-7}$ amp prevails.

Using the external current, I, and the thickness, d^*, derived from capacitance by means of Eq. [1], we have calculated the "apparent growth efficiency"; *i.e.*, the growth efficiency based on the external current

$$\lambda^* = \frac{1}{I} \cdot \frac{\partial d^*}{\partial t} \qquad [12]$$

These values are plotted in Fig. 4 *vs.* oxide thickness. For thicknesses between 32.5 and 50Å, the average apparent growth efficiency was $\lambda^* = 3.2 \times 10^{-6}$ cm/coul. For smaller thicknesses, the apparent growth efficiency increases with decreasing current. Qualitatively, this accounts for the discrepancies between Eq. [2] and the experimental data in the range $t/R \lesssim 5 \times 10^{-3}$ sec/ohm of Fig. 2. For a given I and t, I_o of Eq. [2] would increase with an increase in λ.

The value $\lambda^*_\infty = 3.2 \times 10^{-6}$ cm/coul, approached by the apparent growth efficiency, λ^*, for $d^* \gtrsim 32.5$Å, is in reasonable agreement with the theoretical value $\lambda = \dfrac{M}{F \cdot \rho \cdot S \cdot 2z} = 3.1 \times 10^{-6}$ cm/coul, where the molecular weight of Ta_2O_5 $M = 442$, the Faraday constant $F = 96{,}500$ coul/g·equivalent, the density $\rho = 7.93$ g/cm^3, and the area $S = 18.8$ cm^2 have been used.

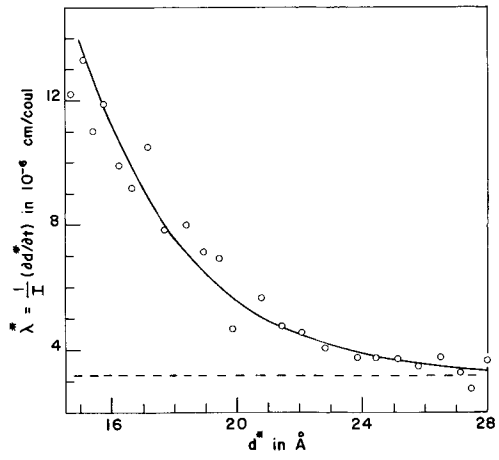

Fig. 4. Apparent current efficiency, λ^*; *i.e.*, current efficiency based on the external current, for oxide growth during self-anodization. Experimental points and theoretical curve from Eq. [13] with [14], assuming $I_E^o = 6.0 \times 10^{-3}$ amp, $l = 3.0$Å and $\lambda_\infty = 3.2 \times 10^{-6}$ cm/coul.

The fact that the apparent growth efficiency for $d^* \lesssim 32$Å exceeds significantly the value $\lambda = 3.1 \times 10^{-6}$ cm/coul can be explained by assuming that electrons flow through the oxide film together with the five-valent tantalum ions. This transfer may take place as an ionic current of tantalum ions of valency less than five (*i.e.*, one or several electrons attached to a five-valent ion), or else by electrons flowing through the oxide film unattached to tantalum ions.

Flow of a significant internal electron current, rather than transport by lower-valency tantalum ion, is indicated by the fact that the oxide also grows under open circuit conditions.[4] Considering the range of film thickness with which we are dealing, electron transfer is likely to occur by tunneling. Thus we shall refer to the electron current through the oxide tentatively as the tunnel current, I_E. The tunnel current has been obtained from

$$I_E = I \cdot \left(\frac{\lambda^*}{\lambda^*_\infty} - 1 \right) \qquad [13]$$

The full line drawn in Fig. 4 was calculated from [13] assuming an exponential dependence of tunnel current on thickness

$$I_E = I_E^o \, e^{-d/l} \qquad [14]$$

with $I_E^o = 6.0 \times 10^{-3}$ amp, $l = 3.0$Å and $\lambda = 3.2 \times 10^{-6}$ cm/coul. The data of Fig. 4 have been used to calculate the total ionic current, $I + I_E$ by means of Eq. [13]. If this total current would have been used as abscissa in Fig. 3 instead of the external current I, the points in the region (c) of the curve would have shifted to the left as indicated by the crosses for the case $E = 1.83$v. Thus correcting for the tunnel current removes much of the steep rise of the curves shown in Fig. 3 in the region (c).

However, the B-value derived by Eq. [3] for the range (c) in Fig. 3, after correction for the tunnel current, still remains significantly lower ($B \approx 3.3 \times 10^{-6}$ cm/v) than that in the region (*a*) ($B \approx 7.7 \times 10^{-6}$ cm/v).

Instead of the interpretation in terms of a constant E and a variable B, one might postulate a constant B [equal to that in region (*a*)] and a variable E, in the regions (*b*) and (c) which would be determined by the intersect of curves $E =$ const. with the extrapolated curve from the region (*a*). Assuming that $E = 1.83$v in the region (*a*), the E values would be higher in region (*b*) but lower in region (c). The changes in E required would be less than 0.1v.

[4] This will be the subject of the next paper in this series.

Discussion

The following discussion concerns mainly the validity of some of the basic equations used and the interpretation of certain parameters occurring in them.

Equation [4] expresses the electric field in the oxide in terms of the emf of the chemical reaction, E, the external voltage drop, RI, and the oxide thickness, d. Equation [4] implies that the electrical field is space independent throughout the oxide, *i.e.*, space charges are neglected. Actually, E is not only the emf of the reaction

$$2Ta + 5H_2O = Ta_2O_5 + 5H_2 \qquad [15]$$

but may include also electrostatic potentials which might exist between the metal and the electrolyte interface in analogy to the contact potential between two solids. This contact potential should be a function of surface states at the oxide-electrolyte interface as might arise from adsorbed ions. Thus E in Eq. [4] is not necessarily the true emf of chemical reaction [15], and its magnitude might change with current density and time during growth, contrary to the assumption of a constant E used in deriving Eq. [2] and the data of Fig. 3. Furthermore E might differ for different samples. The agreement between the value $E \sim 1.83$v derived from the experimental data with the theoretical emf 1.79v [Ta *vs.* Pt equal to Ta *vs.* $H_2 = 0.81$ (2) plus H_2 *vs.* Pt $= 0.98$] is therefore surprising.

Equation [3] contains also the tacit assumption that there is no overpotential during film growth across the space charge layer in the electrolyte adjacent to the oxide. In general, a fraction of the external potential RI might be required to modify the potential across this space charge layer when current flows, and only the remaining portion of RI would modify the field across the oxide.

We have already discussed the difficulties arising from the possible capacitance of the electrolyte space charge layer adjacent to the oxide for the determination of the true oxide thickness. Because of this difficulty the apparent oxide thickness d^* determined by Eq. [1] from capacitance measurements contains an unknown additive constant, Λ, the true oxide thickness being $d = d^* - \Lambda$. This constant, Λ, has been ignored in Fig. 3. The constant Λ has no effect on the effective growth efficiency λ^* of Fig. 4, and on the tunnel curcent, Eq. [14], derived from λ^*.

The determination of E by matching BF_o as obtained from $I(t)$ to BF_0 derived from capacitance measurements as shown in Fig. 3 is questionable for the following reasons: (*a*) if the apparent oxide thickness d^* is corrected by Λ to obtain the true oxide thickness, one has

$$\frac{1}{B_\Lambda F_\Lambda} = \frac{1}{BF} \cdot \frac{F_\Lambda}{F} + \frac{RI_\Lambda}{F\,d^{*2}} \cdot \frac{F_\Lambda}{F} \qquad [16]$$

where B_Λ, F_Λ are the values obtained from the corrected thickness, and B, F are those obtained from the uncorrected thickness ($\Lambda = 0$). The corrected product, $B_\Lambda F_\Lambda$, is smaller than the uncorrected one, since $F\Lambda/F > 1$. Thus the corrected values $B_\Lambda F_\Lambda$ would be less than those of Table III and by matching these corrected values to those of Table II a smaller value of the emf, E, would have been derived. Correcting d^* of Eq. [1] by Λ increases the field F by an amount which is larger for smaller d^*, so that the region (*b*) of Fig. 3 might be removed, and the region (*a*) would be enhanced.

For $E = 1.83$ and $\Lambda = 6$Å, region (*b*) in Fig. 3 would just about vanish. However, in order to match F_o and B from Fig. 3 (modified by $\Lambda = 6$Å) to the values obtained from $I(t)$, the value for the emf would have to be decreased to about 1.60v. Since region (*b*) becomes more pronounced by decreasing the value of E, the increase in Λ and the decrease in E would partially compensate and the region (*b*) would reappear. The sensitivity of various parameters to the choice of Λ is illustrated in Table IV. The values of BF_0 and λF_o

Table IV. Effect of the correction Λ for the oxide-electrolyte capacitance

Λ, Å	E, v	from $I(t)$				from $C(I)$			
		BF_o	λF_o, v/coul	B, 10^{-6} cm/v	F_o, 10^6 v/cm	BF_o	λF_o, v/coul	B, 10^{-6} cm/v	F_o, 10^6 v/cm
0	1.83	30.75	13.48	7.07	4.35	30.34	12.2	7.7	3.94
4	1.83	30.75	13.48	7.07	4.35	23.2	13.7	5.25	4.42
0	1.69	28.8	13.1	6.8	4.23	33.2	11.2	9.2	3.61
4	1.69	28.8	13.1	6.8	4.23	27.2	12.5	6.75	4.03

as determined from the analysis of $I(t)$ and $C(I)$ agree reasonably well for $\Lambda = 0$, $E = 1.83$ and also for $\Lambda = 4$, $E = 1.69$. However there is a large disagreement in BF_o obtained by the two methods for $\Lambda = 4$, $E = 1.83$ and for $\Lambda = 0$, $E = 1.69$.

The value λF_o of Table II is pertinent to the initial range of the $I(t)$ curve, while the value F_o of Table III is derived by extrapolation of F from the later ranges of current flow to the initial range using relation [3]. If this relation is not valid, as suggested by Fig. 3, the values of λF_o from Tables II and III cannot be expected to coincide.

The value of F_o derived from Table II with $\lambda = 3.1 \times 10^{-6}$ cm/coul should coincide with the F-value of Fig. 3 pertinent to the "initial current range," *i.e.*, the current range where the straight line approximation to the semilogarithmic plot of Fig. 2 is valid.

In view of all these difficulties, the B-values derived from Fig. 3 can be accepted only with great caution.

The B-values for region (a) as given in Table I are in reasonable agreement with those of the literature ($B \sim 5 \times 10^{-6}$ cm v^{-1}) (Young, p. 93).

Conclusions

1. The time dependence of the external current during self-anodization of tantalum in an electrolyte can be used to evaluate the combinations BF_o and λF_o of the "Tafel" slope, $1/B$, the growth efficiency, λ, and the initial field strength, F_o, provided that the emf, E, is known.

2. Combining the current *vs.* time measurements with those of capacitance *vs.* time, the emf, E, and the initial field can be derived. However, this evaluation involves some questionable assumptions.

3. For films of thickness $d > 40$Å the values of B and λ agree with those observed for the transport of five-valent tantalum ions.

4. At smaller film thicknesses, the following anomalies occur: (a) An electron current flows through the oxide film of magnitude $I_E^o \exp^{-d/l}$ with $I_E^o \sim 3 \times 10^{-4}$ amp/cm^2 and $l \approx 3.0$Å. (b) This simulates an effective growth efficiency, *i.e.*, a growth efficiency based on the external current which exceeds the value of Faraday's law for five-valent ions. (c) There is some indication that either the inverse Tafel slope of the ionic current varies in this range or else the emf, E, varies with film thickness.

APPENDIX 1

Estimate of Error in Eq. [2]

The error committed by using [9] for $\bar{F}$ can be estimated as follows. Since

$$F_{\tau=t} < \bar{F} < F_o \qquad [1.1]$$

we expect the relative error of the true t pertaining to the current I to be smaller than $(t_\tau - t_o)/t_o$ where t_τ is calculated from Eq. [8] using $\bar{F} = F_{\tau=t}$ and t_o is calculated from [8] using $F = F_o$. The error increases with decreasing I, and we shall be concerned, therefore, mainly with the range where the $\ln(I_o/I)$ term in Eq. [2] can be neglected *vs.* the I_o/I-term. Then

$$(t_\tau - t_o)/t_o \approx \frac{2}{BT_{\tau=t}} \cdot [\ln(I_o/I)] \cdot \left[1 + \frac{\ln(I_o/I)}{2BF_{\tau=t}}\right] \qquad [1.2]$$

Since the main contributions at the integration of Eq. [7] come from the I-values near the boundary $I_{\tau=t}$, we expect $F_{\tau=t}$ to be a better approximation to $\bar{F}$ than F_o. Thus the error by inserting [9] for $\bar{F}$ should be somewhat less than

$$(t - t_o)/2t_o \approx \ln(I_o/I)/BF_{\tau=t}) \qquad [1.3]$$

For $I_o/I \approx 10^3$ and $BF_{\tau=t} \approx 25$, the error in t by Eq. [2] should thus be somewhat less than 28%. The error can be bracketed closer by the relation

$$F_{\tau=t} < F < F_{\tau=t} + \frac{I - I_{\tau=t}}{BI_{\tau=t}} \qquad [1.4]$$

instead of [1.1] where the right side comes from the development of F as a function of I in the vicinity of $I_{\tau=t}$, $F_{\tau=t}$. For $E/RI_o = 1$, $BF_o = 30$ and $I_o/I = 10^3$, the following values are obtained: $\lambda t_o/BR = 1.33$ from Eq. [8] with $\bar{F} = F_o$; $\lambda t/BR = 2.09$ from Eq. [2]; and $\lambda t/BR = 1.69$ by integrating Eq. [7] with $\bar{F}$ replaced by the value on the right side of the inequality [1.4] prior to the integration. The exact value lies between 1.69 and 2.09.

APPENDIX 2

Determination of BF_o and λF_o by Matching Eq. [2] to Experimental Data $I(t)$

From a semilogarithmic plot as shown in Fig. 2, I_o and $(\lambda F_o)^o$ are obtained. Rearranging Eq. [2]

$$BF_o = 2\ln(I_o/I) - \frac{[\ln(I_o/I)]^2}{BF_o} + \frac{\frac{E}{RI_o}\left(\frac{I_o}{I} - 1\right)}{\frac{(\lambda F_o)^o}{R} t\left[1 + \left(\frac{E}{RI_o} - 1\right)/BF_o\right] - \left(1 - \frac{1}{BF_o}\right)\ln(I_o/I)} \qquad [2.1]$$

with $(\lambda F_o)^o$ defined by Eq. [11]. This form is convenient for calculating BF_o from a single experimental point of $I(t)$ in the range where the second term on the right side of Eq. [2] is dominant and assuming a suitable value of E. Equation [2.1] then becomes a good approximation

$$(BF_o)^{(o)} = 2\ln(I_o/I) + \frac{\frac{E}{RI_o}\left(\frac{I_o}{I} - 1\right)}{\frac{(\lambda F_o)^o}{R} t - \ln(I_o/I)} \qquad [2.2]$$

since the terms containing BF_o on the right side of Eq. [2.1] are only small corrections. By inserting $(BF_o)^{(o)}$ calculated from Eq. [2.2] on the right side of Eq. [2.1] and using an experimental point of $I(t)$,

one obtains the first order approximation $(BF_o)^{(1)}$; inserting $(BF_o)^{(1)}$ into the right side of Eq. [2.1], one obtains the second order approximation $(BF_o)^{(2)}$, etc.[5]

The series $(BF_o)^{(o)}$, $(BF_o)^{(1)}$, etc. converges so rapidly that we have found it rarely necessary to proceed beyond $(BF_o)^{(2)}$.

Using BF_o and $(\lambda F_o)^{(o)}$, one may calculate λF_o by Eq. [11].

SYMBOLS

I_I	ionic current
$I,(I_o)$	current (initial current) in the external resistor
A	preexponential factor in the ionic current-field relation
$F,(F_o),(\bar{F})$	field, (initial field), (time average of the field) across the oxide layer
B	field coefficient or "inverse Tafel slope"
λ	growth rate per unit current
λ^*	apparent growth rate as calculated from the external current
λ^*_∞	apparent growth rate for film thicknesses larger than 32Å
E	emf of reaction
I_E	internal electron current
$I_E{}^o$	preexponential factor in the electronic current-thickness relation
l	attenuation length of the internal electron current
d	true film thickness
d^*	film thickness as calculated from capacitances
Λ	(d^*-d)
C	capacitance
ϵ_o	permittivity of free space
S	area
R	external resistor
t	time
B_Λ,F_Λ	values of B and F after correcting for Λ

[5] Since BF_o is about 30, the first step in this procedure can be saved by inserting 30 for $(BF)^{(o)}$, instead of the value given by Eq. [2.2].

The Structure and Mechanical Properties of Electroless Nickel

Arthur H. Graham,[1] Robert W. Lindsay, and Harold J. Read

Department of Metallurgy, College of Mineral Industries,
The Pennsylvania State University, University Park, Pennsylvania

ABSTRACT

Effects of variations in phosphorus content of electroless nickel from 4.6 to 9.4 w/o on structure, strength, ductility, and hardness were studied. Electron diffraction proved the crystallinity of many as-plated alloys, and x-ray data established a conventional precipitation hardening mechanism during heat treatment. Changes in properties after heat treatment at 200°-750°C have been correlated with structural changes shown by x-ray diffraction and with those revealed in optical and electron back scatter micrographs. Abrupt changes in the structure, strength, and ductility of as-plated alloys and of alloys heat treated at 750°C occurred at phosphorus contents of about 7%.

Although electroless nickel plating has achieved considerable popularity in the somewhat more than a decade and a half since attention was drawn to its possibilities by the work of Brenner (1) and his colleagues, most of the literature on the subject concerns the process rather than the product. Some notice has been given to structure, but aside from hardness measurements, little has been done in the evaluation of mechanical properties.

Goldenstein, Rostoker, Schossberger, and Gutzeit (2) in their study of deposits containing 7-10 w/o (weight per cent) phosphorus concluded on the basis of x-ray diffraction and some other considerations that as-plated electroless nickel is amorphous. Other investigators reached similar conclusions. It is not impossible, however, to account for the typical diffraction patterns through a consideration of the combined effects of extremely small grain size, internal stress, and nonhomogeneous solid solution. Some hint of possible crystallinity in as-plated deposits appears in a paper by Zusmanovich (3), but he made no actual claim in this direction. The relationship between structure and phosphorus content of the deposits has not been studied, although the work of Brenner, Couch, and Williams (4) on electrodeposited nickel-phosphorus alloys contains evidence that phosphorus concentration is an important variable in determining structure.

More attention has been given to optical microstructure than to fine structure, but only a portion of the work has taken into account the phosphorus variable. The changes that take place on heat treatment have been extensively studied and most investigators have claimed that the final microstructure is a dispersion of Ni_3P in a nickel matrix (1, 2, 5, 6). Ziehlke, Dritt, and Mahoney (7) maintain, however, that heat treated, high-phosphorus alloys are dispersions of nickel in a matrix of Ni_3P. Because the mechanical properties would be markedly affected by the nature of the matrix, the effect of phosphorus on this variable needs further study.

The increase in hardness of electroless nickel as a result of heat treatment is a notable effect and has received much attention (2, 3, 5, 7). In general, agreement is good among investigators as to the effects of time and temperature on hardness, and the data resemble those for known precipitation-hardenable alloys. It has been generally assumed, therefore, that precipitation hardening is the mechanism that prevails in spite of the fact that the accepted theory of precipitation hardening, which requires a crystalline lattice, is not compatible with the amorphous structure that is also generally accepted. Only Goldenstein (2) and Ziehlke (7) and their colleagues recognized this point and postulated vague expedients to resolve it.

Almost nothing has been done on the determination of the strength of electroless nickel and most of the work on ductility has involved rather qualitative bend tests on composite samples of deposit and basis metal. Phosphorus content has not been regarded as an important variable, but Lee (5) as well as Ziehlke, Dritt, and Mahoney (7) published some observations that intimate that phosphorus content should not be ignored in work on mechanical properties.

The investigation described here had as its objectives (*a*) the study of the effects of phosphorus content on structure and mechanical properties, (*b*) correlation of changes in mechanical properties after heat treatment with structural changes, and (*c*) elucidation of the mechanism of hardening. Strength and ductility, as measured by the hydraulic bulge test, and microhardness were used to evaluate mechanical pro-

perties. Some preliminary findings on the crystallinity of electroless nickel have been reported previously (8).

Experimental Procedure

Specimen Preparation

Because of the large number of different electroless nickel plating processes that have been developed, it was not possible to select what might be considered a typical one. The selection of plating processes for this study was based principally on their ability to produce deposits that were free from internal stress and that did not contain macrovariations in phosphorus content across a thickness of 1 mil.[2] The microvariations in composition reported by Gutzeit (9) which occure over increments of approximately 0.02 mil in thickness could be tolerated. But, macrovariations in the average phosphorus content across the deposit would severely curtail, if not render impossible, the investigation of the effect of phosphorus on structure and mechanical properties. Internal stresses would also be detrimental to the objectives of this study because they would affect properties and influence the position and breadth of lines in diffraction patterns. The two processes selected for the preparation of specimens are specified in Table I.

Most of the specimens were prepared by alkaline-chloride processes that differ only slightly from the process developed by MacLean and Karten (10). Careful control of the periodic additions to the plating baths resulted in the formation of electroless nickel deposits that were free from internal stress, that is, they were not warped or distorted. Control of the periodic additions of sodium hypophosphite was based on the assumption that the amount required to maintain a constant rate of deposition would be sufficient to replace the amount consumed. The periodic additions of nickel chloride were determined by a calculation of the amount of nickel being deposited based on prior knowledge of the rate of deposition and the surface area of the basis metal.

As a result of the unavoidable changes in bath composition during 500 hr of plating from a particular alkaline-chloride bath, the average phosphorus content of the specimens deposited gradually increased from 4.6 to 9.4 w/o. Fortunately, the bath composition changed so slowly that the average phosphorus content, as indicated by electron-probe microanalysis, was constant across the thickness of deposits from a particular plating run.

The deposits from the acid-sulfate bath developed by Girard (11) were slightly stressed and had a phosphorus gradient that ranged from 5 w/o at the surface adjacent to the basis metal to 10 w/o at the outer surface. The increase in the phosphorus content during plating appeared to be related to the rapid decrease in the pH of the bath. A similar relationship between phosphorus content and the pH of acid electroless nickel baths has been observed by Gutzeit (9).

[2] All specimens were plated to approximately the same average thickness to avoid possible effects of variations in thickness on mechanical properties.

The electronprobe microanalysis traverses in Fig. 1 contrast the uniform distribution of phosphorus across a deposit from an alkaline-chloride bath with the steep phosphorus gradient across a deposit from the acid-sulfate bath. A limited number of specimens was prepared from the acid-sulfate bath to determine whether a significant difference in plating bath composition would affect the structure and the properties of the deposits.

The basis metal for bulge-test specimens was annealed copper sheet attached to a glass plate to give sufficient rigidity for handling. The surface of the copper sheet adjacent to the glass plate was coated with a stop-off lacquer. At the completion of a plating run, the stop-off lacquer was removed with acetone, and the copper substrate was stripped from the deposits in a solution of chromic acid (500 g/l) and sulfuric acid (50 g/l). Extensive experience with this stripping solution has shown that there is neither chemical attack nor mechanical disturbance of nickel or nickel-phosphorus deposits.

Strips of low-carbon steel served as the basis metal for hardness specimens.

Heat treatments were conducted at 200°, 400° 600°, and 750°C in a purified argon atmosphere. At the completion of a heat treatment, the specimens were cooled to below 100°C under the argon atmosphere before they were exposed to air.

X-ray Diffraction Studies

X-ray pinhole transmission patterns were taken of as-plated and heat-treated deposits to reveal the presence of any preferred orientation. Plated coatings with a preferred orientation usually have a fiber texture in which a certain crystallographic direction [hkl] of most of the grains is parallel, or nearly parallel, to an axis normal to the surface of the coating. To reveal the presence of any fiber texture in the electroless nickel deposits, it was necessary to tilt the specimen so that

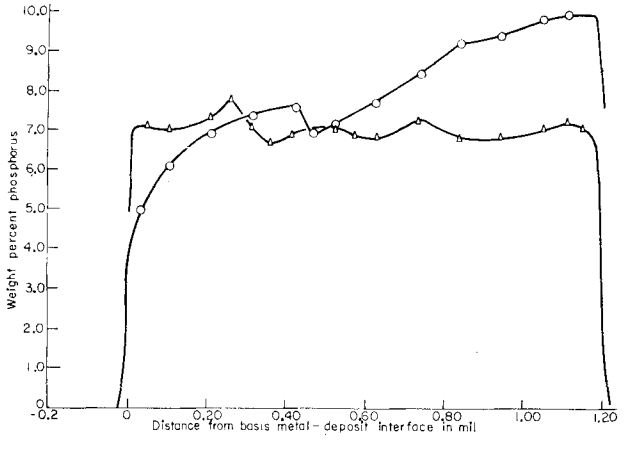

Fig. 1. Typical electron-probe microanalysis traverses of as-plated electroless nickel deposits. △—△, deposit from alkaline-chloride bath; ○—○, deposit from acid-sulfate bath.

the [hkl] fiber axis was not parallel to the x-ray beam. If the fiber axis is parallel to the beam, continuous Debye rings of uniform intensity will appear on the transmission patterns even though a strong preferred orientation exists (12). Preferred orientation will greatly diminish the intensity of many of the Debye rings on the pattern and might eliminate some of them.

An x-ray diffractometer study was conducted on the effect of phosphorus content on the position and breadth of the strong x-ray reflection from as-plated alloys. To compensate for instrumental errors in the diffractometer, the (220) reflection from a powdered-silicon standard was used as a reference for the calibration of the position of the electroless nickel reflection. The breadth of the reflection was measured at half maximum intensity.

The apparent grain size of as-plated electroless nickel alloys was estimated with the Scherrer formula which is based on diffraction broadening, as expressed in the following equation

$$t = \frac{0.9\,\lambda}{B \cos \theta_{hkl}}$$

where t is the apparent thickness of the grain in Å, λ is the wavelength of the radiation in Å, and B is the broadening of the reflection at half its maximum intensity in radians. The estimates of the grain size given by the Scherrer formula were compared with actual grain size measurements made on electron transmission micrographs.

Electron Diffraction Study

The deposits of electroless nickel for the electron diffraction investigation were thinned by electropolishing until they would transmit an electron beam accelerated by a potential of 75 kv. All the diffraction patterns were made with the electron beam perpendicular to the surface of the thin film.

Because excessive heating could cause the crystallization of an initially amorphous film, a finely focused beam and the smallest possible filament saturation current were used to minimize the heating due to electron bombardment. According to Thomas (13), such precautions can decrease the temperature rise of metallic specimens to approximately 20 centigrade degrees. As an additional precaution to insure that the structure of the specimens was not affected by electron bombardment, the beam was focused for diffraction before the specimen was moved into its path in the center of the microscope column. From the instant that the beam touched the specimens up to times as long as 1 hr, no change was observed in the diffraction patterns.

Because of the extremely small wavelength of the electrons (0.04Å), the radius of the Debye ring on a diffraction pattern is directly proportional to the magnitude of the reciprocal lattice vector for the reflection (d^*_{hkl}). A thin layer of polycrystalline nickel oxide or single crystals of nickel sulfate hexahydrate served as internal standards for the determination of the proportionality constant between the radius and d^*_{hkl}. The nickel sulfate hexahydrate crystals became attached to the electroless nickel films during the electropolishing of deposits in a sulfuric acid electrolyte with a high concentration of nickel ions. The thin layer of nickel oxide was intentionally formed on the films by electropolishing at low current densities.

Measurement of Mechanical Properties

The microhardness of the electroless nickel deposits was measured with a Tukon tester equipped with a Knoop indenter. Measurements were made on both the surface and the cross section of an adequate sample of as-plated deposits and heat-treated deposits. A 100-g indenting load was used on most of the specimens. For some specimens that had been heat treated above 400°C, the indenting load was decreased to 50g to avoid the anvil effect and to keep the indents well within the cross section of the deposit. Every hardness number reported is the average of measurements from at least 5 indents that were free from cracks and distortion.

A detailed description of the hydraulic bulge tester used to measure the strength and ductility of the electroless nickel deposits appears in an article by Read and Whalen (14). The theoretical and mathematical interpretation of the test results is presented in an article by Prater and Read (15). Strength is expressed as significant stress at fracture ($\bar{\sigma}$) and ductility is expressed as significant strain at fracture ($\bar{\delta}$). The only experimental data needed for the determination of $\bar{\sigma}$ and $\bar{\delta}$ are the oil pressure measured by appropriate gauges, and the bulge height determined by measurement of the travel of a microscope focused on the center of the bulge.

The significant strain was read directly from a master curve of $\bar{\delta}$ vs. bulge height experimentally determined by Prater.

The significant stress was calculated from the equation

$$\bar{\sigma} = \frac{PR}{2t_i}$$

where P is the pressure, R the radius of curvature of the bulge, and t_i is the instantaneous thickness of the specimen. Values for the instantaneous thickness were calculated by multiplying the original average thickness (t_o) by the ratio of t_i/t_o obtained from a curve determined by Prater.

Results and Discussion

Diffraction Patterns of As-plated Alloys

Although as-plated electroless nickel alloys have been considered to be amorphous by previous investigators, the electron transmission diffraction patterns in Fig. 2 and 3 provide definite evidence that the alloys are crystalline. There can be no doubt as to the crystallinity of the alloys with less than 7 w/o phosphorus because of the appearance of eight to eleven reflections in their diffraction patterns. Difficulties were encountered in the determination of lattice type and in indexing the patterns, but all the reflections could be attributed to nickel regardless of the lattice type assumed. Therefore, the as-plated alloys are supersaturated solid solutions of phosphorus dissolved in crystalline nickel.

Perhaps it should be made clear that as little as 2 v/o (volume per cent) of Ni_3P would produce lines in the diffraction patterns. A deposit with 7 w/o phosphorus would contain 50 v/o of Ni_3P if the phosphorus

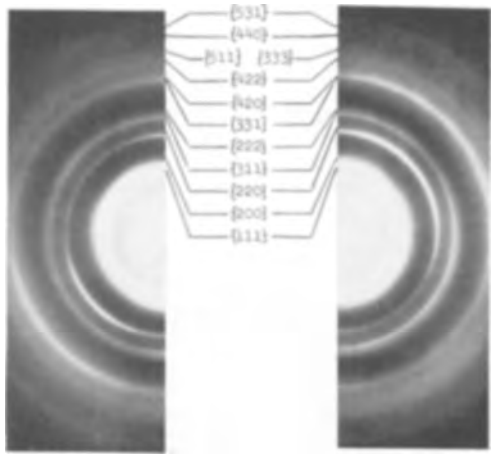

Fig. 2. Electron transmission diffraction pattern of as-plated electroless nickel from the alkaline-chloride bath, phosphorus content 5.0 w/o, indexed according to a fcc structure.

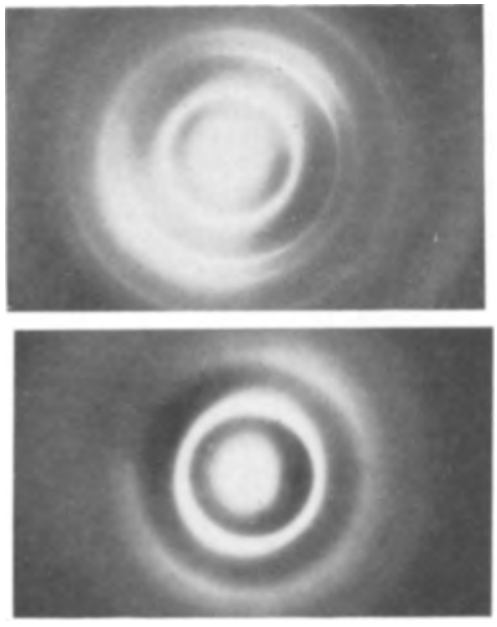

Fig. 3. Electron transmission diffraction patterns of as-plated electroless nickel alloys from the alkaline-chloride bath. (a) phosphorus content 6.6 w/o, (b) phosphorus content 8.6 w/o.

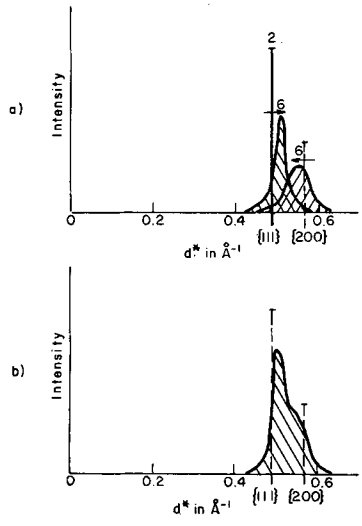

Fig. 4. Schematic sketch of the predicted effect of stacking faults on the {111} and {200} reflections from fcc nickel. (a) Effect on individual components of reflections, heavy vertical line represents unaffected components, shaded areas represent components that are broadened and shifted (after Paterson (16)). (b) Effect on over-all intensity profile.

were all combined with the nickel in the form of the compound. There is no indication that any compound other than Ni_3P is involved. Inasmuch as no compound lines were observed in the patterns, a supersaturated solid solution is indicated.

The patterns from the low-phosphorus alloys with less than 7 w/o phosphorus can be reasonably indexed according to either a hexagonal-close-packed (hcp) or a face-centered-cubic (fcc) structure (hcp nickel has often been reported). The most important factor in attempting to distinguish between the two possible structures is the {200} reflection for the fcc structure. The presence of a strong {200} reflection would be indicative of a fcc structure, whereas its absence would indicate a hcp structure. In all the electron transmission diffraction patterns, the {200} reflection was either absent or extremely weak. The difficulties in indexing can be attributed to stacking faults in the structure of fcc nickel.

The effect of stacking faults on the {111} and {200} reflections from a fcc structure as shown by Paterson (16) is illustrated schematically in Fig. 4a. The presence of stacking faults not only shifts all six components of the {200} reflection to a lower d^* value, but also diminishes their intensity by increasing their breadth. Although the (111) and $(\bar{1}\bar{1}\bar{1})$ components are not affected, the other six components of the {111} reflection are broadened and shifted to a higher d^* value. The predicted over-all intensity profile in the vicinity of the {111} and {200} reflections shown in Fig. 4 closely resembles the observed intensity profile on electron diffraction patterns of as-plated electroless nickel alloys. The d^*_{hkl} for the other reflections indexed in Fig. 2 is compatible with the assumption that the as-plated alloys consist of a single phase having the fcc structure of nickel with a high density of stacking faults. Evidence which might account for the presence of stacking faults in the as-plated alloys is presented in the section on the hardening mechanism.

As the phosphorus content of electroless nickel alloys increases from 7 to 9 w/o, all the reflections in the electron transmission diffraction patterns are severely broadened and many are destroyed. Only three or four reflections are discernible in patterns from alloys with more than 8 w/o phosphorus. However, these alloys still appear to be crystalline if their electron diffraction patterns are compared with patterns from glasses. Electron diffraction patterns of the amorphous structure of glasses have only one diffuse reflection that cannot be accurately located. On the negative of the diffraction pattern in Fig. 3b, which is typical of patterns from electroless nickel alloys with high phosphorus contents, four diffuse rings corresponding to the {111}, {220}, {311}, and {331} reflections are discernible.

Contradiction between Electron and X-ray Diffraction Results

The same specimens of as-plated electroless nickel that yield electron diffraction patterns indicative of a crystalline structure because of the appearance of eight to eleven reflections give x-ray diffractometer and x-ray pinhole transmission patterns that appear to be indicative of an amorphous structure because of the appearance of only one or two reflections. A strong {111} reflection and a weak {222} reflection were observed in diffractometer patterns from the alloys with less than 7 w/o phosphorus. As the phosphorus content increases from 7 to 9 w/o, the {111} reflection becomes less intense and the {222} reflection disappears.

Only the {111} Debye ring appears in x-ray pinhole transmission patterns produced with copper radiation. If an electroless nickel deposit is mounted so that the x-ray beam is perpendicular to its surface, the continuous {111} ring has a uniform intensity as shown in Fig. 5a. When a deposit with less than 7 w/o phosphorus is tilted so that the angle (β) between a normal to its surface and the x-ray beam is approximately 70°, a nonuniform intensity distribution indicative of a weak [111] fiber texture with an axis perpendicular to the surface of the deposit is revealed as shown in Fig. 5b. X-ray pinhole transmission patterns of the copper sheets that served as a basis metal reveal a random orientation; therefore, the preferred orientation in the electroless nickel deposits has no epitaxial relationship to the substrate. The electron transmission diffraction patterns in Fig. 2 and 3a also reveal the presence of the preferred orientation. In both the electron and the x-ray transmission patterns, the preferred orientation becomes weaker and eventually disappears as the phosphorus content increases above 7 w/o.

The detection of a [111] fiber texture in x-ray pinhole transmission patterns tends to support the electron diffraction evidence of crystallinity even though only one or two x-ray reflections are observed. A preferred orientation not only presupposes the existence of order, but also can cause the diminution of the in-

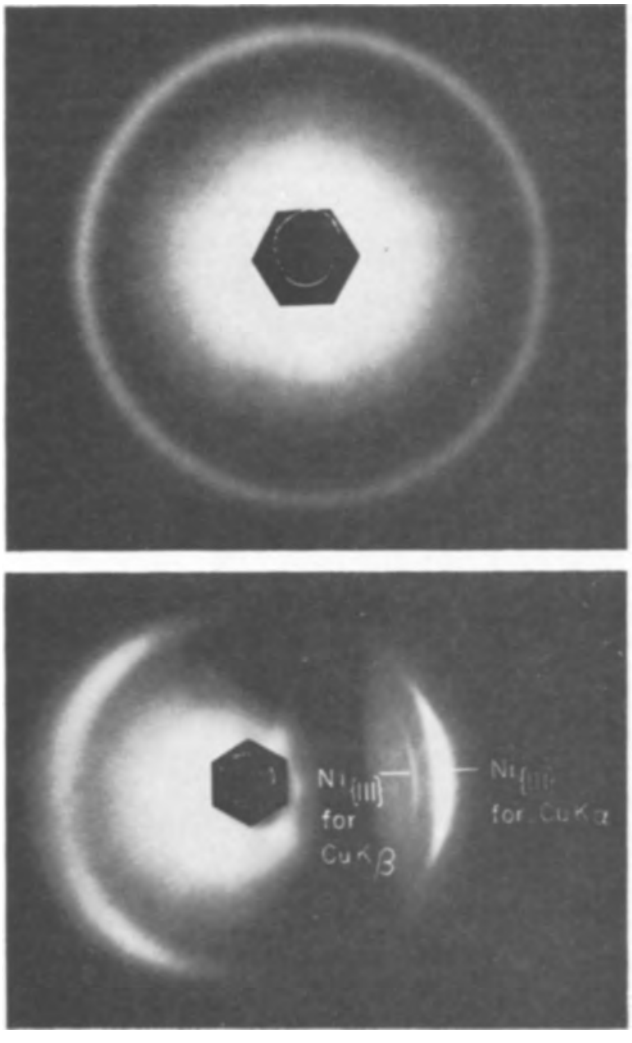

Fig. 5. X-ray pinhole transmission patterns of as-plated electroless nickel from the alkaline-chloride bath, phosphorus content 6 w/o, unfiltered copper radiation. (a) $\beta = 0°$, (b) $\beta = 70°$.

tensities of many x-ray reflections in diffractometer and pinhole transmission patterns. As a result of the basic design of conventional x-ray diffractometers, the crystallographic planes that are responsible for the appearance of a diffraction peak must be parallel to the surface of the specimen. An extremely strong [111] fiber texture perpendicular to the surface of a fcc metallic coating could cause the destruction of all x-ray reflections except those from the {111} planes and similar higher order planes because these would be the only planes parallel to the surface of the specimen. Although the weak [111] fiber texture in the low-phosphorus electroless nickel alloys would diminish the intensities of all the missing reflections in the diffractometer patterns, the preferred orientation is not strong enough to account for the absence of these reflections. The intensities of many reflections in the x-ray and electron transmission diffraction patterns would also be diminished by the weak [111] fiber texture if the beam of radiation were approximately parallel to the fiber axis.

The apparent contradiction between the x-ray diffraction results which led previous investigators to conclude that the structure of as-plated electroless nickel was amorphous, and the electron diffraction results which are indicative of crystallinity can be explained by a consideration of the effects of fine grain size and other factors that diminish the intensities of x-ray reflections. Reflections in x-ray patterns are broadened and become less intense as the grain size decreases to diameters less than 10,000Å. In electroless nickel, the

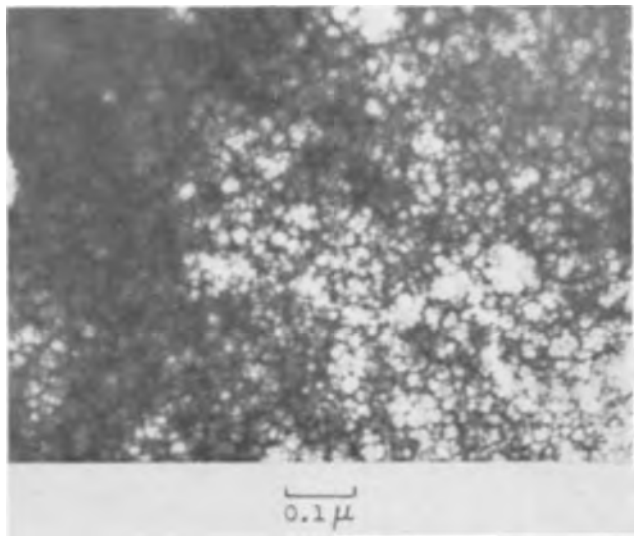

Fig. 6. Electron transmission micrograph of as-plated electroless nickel from the alkaline-chloride bath, phosphorus content 6.1 w/o, X 124,000.

apparent grain size, as indicated by electron transmission micrographs similar to that in Fig. 6, is of the order of 100Å; therefore, only the most intense x-ray reflections should appear. Although the x-ray diffraction pattern of a crystalline material with a particle size of 100Å should probably contain more than one or two reflections, the added effects of internal stress, solid solution, stacking faults, and preferred orientation on the diminution of the intensities of the reflections can reasonably account for the destruction of all but the strong {111} x-ray reflection from as-plated electroless nickel. In the x-ray diffractometer patterns of low-phosphorus alloys, the detection of a weak {222} reflection, which has not been observed by previous investigators, might be due to the absence of internal stress in the deposits prepared for this investigation.

Solution of the Scherrer formula (see section on experimental procedure) for the amount of broadening caused by fine grain size gives the equation

$$B = \frac{0.9\lambda}{t \cos \theta_{hkl}}$$

which indicates that the tendency of a fine-grained material to broaden reflections is greatly diminished as the wavelength of the radiation is decreased. The broadening is diminished not only because the numerator of the equation depends directly on the wavelength, but also because the cos θ_{hkl} term in the denominator increases as the wavelength decreases. The fine grain size of the electroless nickel does not preclude the production of electron-diffraction lines because the wavelength of electrons accelerated through a potential of 75 kv is almost two orders of magnitude smaller than the wavelength of x-rays used in diffraction work.

The existence of an abrupt change in the effect of phosphorus content at 7 w/o on the position and breadth of lines in diffraction patterns of as-plated electroless nickel alloys is clearly revealed by the graphs in Fig. 7 for the {111} x-ray reflection. The d_{111} and the peak breadth plotted for alloys deposited from the alkaline-chloride bath are averages of measurements made on the surface of the deposits adjacent to the basis metal and of measurements made on the outer surface. For alloys deposited from the acid-sulfate bath, the measurements from the two surfaces were plotted individually at phosphorus contents determined from electron-probe microanalysis traverses.

Variations in phosphorus content appear to have no significant effect on the position and breadth of the {111} reflection from alloys containing from 4.6 to

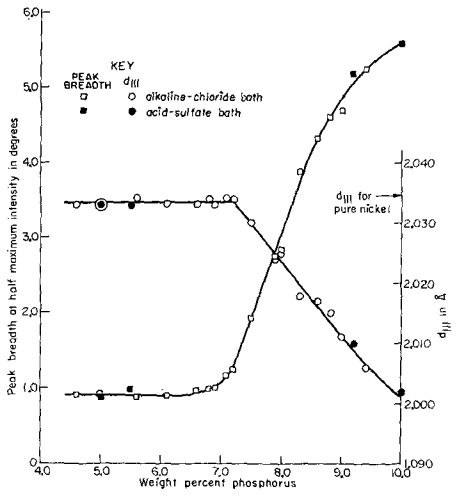

Fig. 7. Peak breadth of the {111} x-ray reflection and d_{111} for as-plated electroless nickel vs. weight per cent phosphorus.

7 w/o. As the phosphorus content increases from 7 to 10 w/o, d_{111} decreases and the reflection is broadened considerably. Both the shifting and the broadening of the reflection are associated with the development of an asymmetrical tail on the high-angle side of the {111} diffraction peak.

At present, the exact cause for the effects of an increase in phosphorus content above 7 w/o on diffraction patterns of as-plated electroless nickel alloys can only be the subject of speculation. Even though a decrease in grain size could contribute to the broadening of the {111} reflection, it would not result in asymmetry. Therefore, the observed increase in peak breadth with increasing phosphorus content must be caused by some phenomenon which can result in asymmetrical broadening, such as an increase in the density of stacking faults.

Goldenstein, Rostoker, Schossberger, and Gutzeit (2), in support of their contention that electroless nickel is amorphous, state that the apparent grain size obtained by measuring the breadth of the {111} x-ray peak and applying the Scherrer formula is only a few atomic diameters. The new data reported in Table II show that estimates given by the Scherrer formula are not valid indications of the actual grain size of alloys with more than 7 w/o phosphorus. In Table II, the Scherrer formula estimates, calculated from measured peak breadths that have been corrected for instrumental broadening, are compared with actual grain size measurements made on several electron transmission micrographs similar to that in Fig. 6. For the alloy containing 8.8 w/o phosphorus, the measured grain size is approximately five times greater than the estimate given by the Scherrer formula, which attributes all the broadening to fine grain size. The fact that the estimated grain size for alloys with 5.0 and 6.1 w/o phosphorus is fairly close to the measured value indicates that fine grain size makes a significant contribution to the total breadth of the x-ray reflections from the low-phosphorus alloys.

Table II. Comparison of estimated grain size given by the Scherrer formula with average grain size determined from electron transmission micrographs of as-plated electroless nickel

Weight per cent phosphorus	B radians	Grain size in Å: Estimate from Scherrer formula	Grain size in Å: Average of measurements on micrographs
5.0	0.0154	98	150
6.1	0.0153	98	150
7.5	0.0335	46	—
8.8	0.0803	19	100
9.4	0.0917	16	—

Effect of Heat Treatment on Preferred Orientation

An observed increase in the strength of the preferred orientation of the nickel phase of all electroless nickel alloys after heat treatments at temperatures ranging from 200° to 750°C is indicative of recrystallization and grain growth. Even the high-phosphorus alloys with more than 7 w/o phosphorus that seemed to have a random orientation in the as-plated condition develop a weak [111] fiber texture at temperatures as low as 200°C. After heat treatments at 200°C, the weak preferred orientation of the as-plated, low-phosphorus alloys is slightly stronger and a very weak {200} reflection appears on the x-ray pinhole transmission patterns. No evidence for the formation of a Ni_3P phase appears in electron or x-ray transmission diffraction patterns of alloys heat treated at 200°C for times as long as 240 min.

The initial particles of Ni_3P that form in alloys heat treated at 400° and 600°C also have a distinct preferred orientation. There seems to be no reason for this behavior unless the deposits are crystalline before heat treatment. This is one more bit of evidence for crystallinity of the as-plated deposits. In the low-phosphorus alloys, the preferred orientation of the Ni_3P phase is still strong after a heat treatment at 400°C for 120 min as shown by the {321} reflection in Fig. 8. An analysis of the preferred orientation in the Ni_3P phase and its implications concerning the hardening mechanism in electroless nickel will be presented in a subsequent section.

The strength of the [111] fiber texture in the nickel phase of all the electroless nickel alloys increases as the temperature of heat treatment increases from 200° to 600°C. At 750°C, the preferred orientation developed in the nickel phase of the high-phosphorus alloys is just as strong, if not stronger, than that developed in the same interval of time at 600°C. In the low-phosphorus alloys heat treated at 750°C for 120 min, the preferred orientation of the nickel phase is considerably weaker than that developed at 600°C, as shown by a comparison of Fig. 9 and 10a. Furthermore, the reflections from the nickel phase of the low-phosphorus alloys heat treated at 750°C are extremely spotty in character compared to the continuous reflections from the high-phosphorus alloys after a similar heat treatment. After heat treatments at 750°C, the differences in the character of the reflections and in the strength of the preferred orientation shown in Fig. 10 are indicative of recrystallization with excessive grain growth in the low-phosphorus alloys and recrystallization with restricted grain growth in the high-phosphorus alloys. Recrystallization is possible only if the as-plated deposits were crystalline.

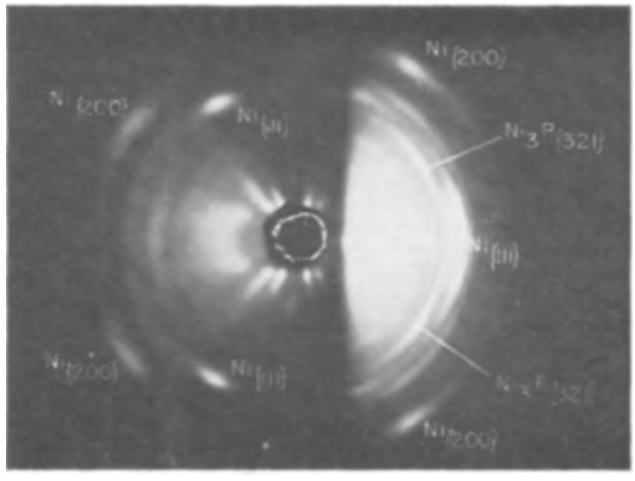

Fig. 8. X-ray pinhole transmission pattern of electroless nickel deposited from the alkaline-chloride bath and heat treated at 400°C for 120 min, phosphorus content 6.1 w/o, unfiltered copper radiation, $\beta = 70°$.

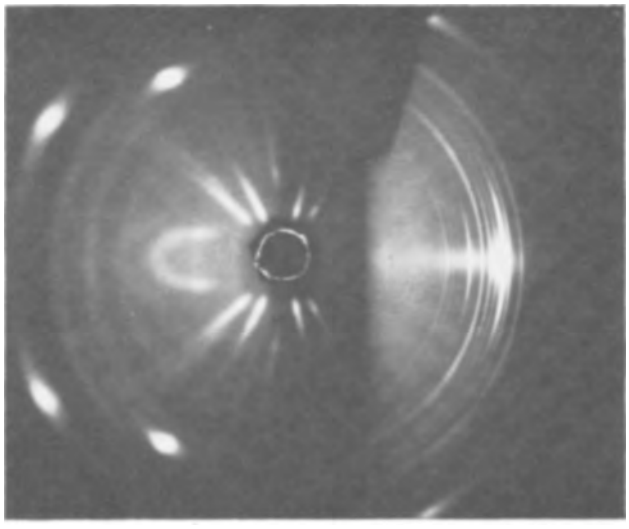

Fig. 9. X-ray pinhole transmission pattern of electroless nickel deposited from the alkaline-chloride bath and heat treated at 600°C for 120 min, phosphorus content 6.1 w/o, unfiltered copper radiation, $\beta = 70°$.

The results of the preferred-orientation study of electroless nickel alloys after heat treatments at temperatures ranging from 400° to 750°C are summarized in Table III. The qualitative estimates of the strength of the preferred orientation that appear in Table III were made on x-ray pinhole transmission patterns similar to those in Fig. 8, 9, and 10. The importance of inclining the specimen at various angles to the x-ray beam cannot be overemphasized, otherwise the variations in [111] fiber texture may not be detected.

Microstructure

The micrographs of as-plated electroless nickel in Fig. 11 and 12 show the lamellar structure observed by previous investigators and also reveal a significant difference in the thickness of the lamellae of deposits from the two plating baths. In the microstructure of the as-plated deposit from the alkaline-chloride bath shown in Fig. 11, the lamellar thickness is approximately 0.2 mil. The lamellae in the microstructure of the acid-sulfate deposit shown in Fig. 12, which closely resembles the appearance of micrographs published in the literature, are only about 0.02 mil thick.

After heat treatments at temperatures as high as 400°C, the microstructures of the electroless nickel alloys have the same lamellar appearance of as-plated alloys even though the supersaturated solid solution has transformed to the equilibrium phases of nickel and Ni_3P.

Heat treatments at 600°C for 120 min result in the disappearance of the lamellar structure, as shown by the micrograph in Fig. 13. The two equilibrium phases

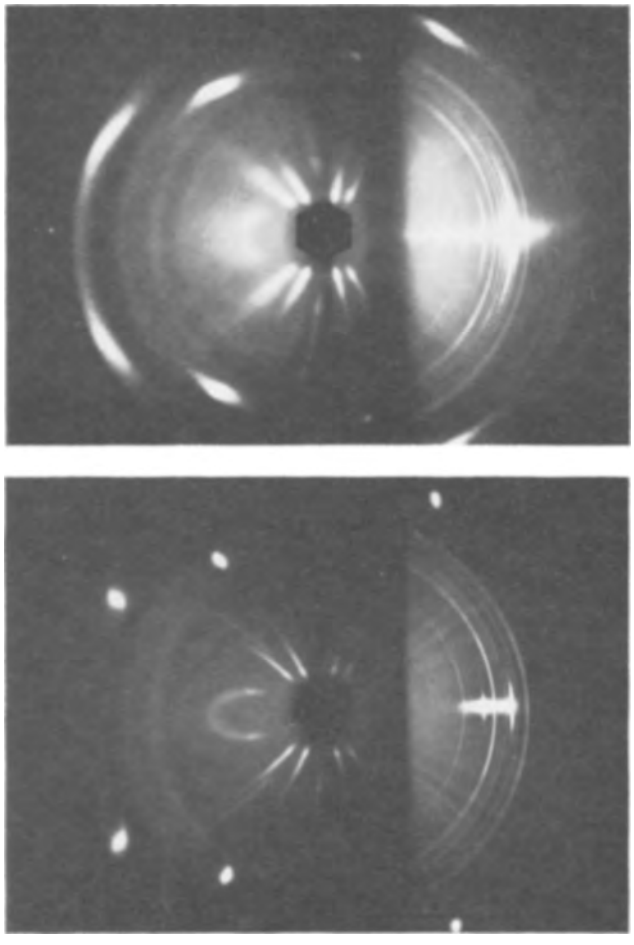

Fig. 10. X-ray pinhole transmission patterns of electroless nickel alloys deposited from the alkaline-chloride bath and heat treated at 750°C for 120 min, $\beta = 70°$, unfiltered copper radiation: (a) phosphorus content 5.0 w/o, (b) phosphorus content 8.8 w/o.

are evident in the micrograph, but the structure is too fine to be clearly resolved.

Optical micrographs of the electroless nickel alloys heat treated at 750°C for 120 min show clearly resolved particles dispersed in a matrix. The electron backscatter micrographs in Fig. 14 definitely establish that there is a change in the phase forming the matrix as the phosphorus content increases from 5.0 to 9.0 w/o. The intensity of electron backscattering diminishes with a decrease in mass density or with a decrease in the atomic number of the elements present. On the electron backscatter micrographs of electroless nickel, the Ni_3P phase should appear as a dark region not only because its mass density is less than nickel, but also because it contains 25 a/o (atomic per cent) of

Table III. Qualitative summary of preferred-orientation study of electroless nickel after heat treatments at temperatures ranging from 400° to 750°C

Phase	Plating bath	Weight per cent phosphorus	Strength of preferred orientation after heat treatment				
			at 400°C		at 600°C		at 750°C

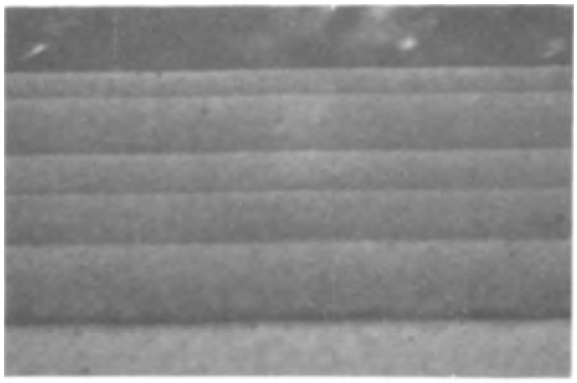

Fig. 11. Microstructure of as-plated electroless nickel from the alkaline-chloride bath, phosphorus content 7.1 w/o, NaCN-$(NH_4)_2S_2O_8$ etch, X 1000.

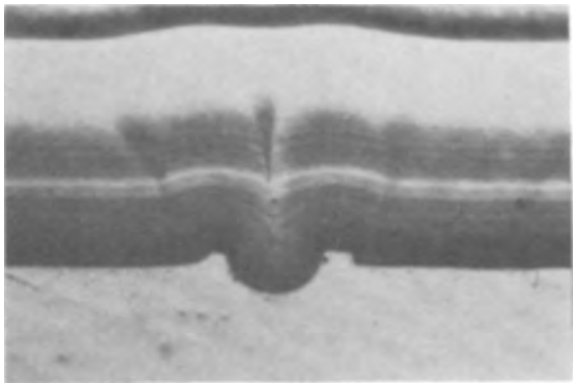

Fig. 12. Microstructure of as-plated electroless nickel from the acid-sulfate bath, phosphorus content varies from 5 w/o at surface adjacent to basis metal to 10 w/o at outer surface, NaCN-$(NH_4)_2S_2O_8$ etch, X 1000.

phosphorus, whose atomic number is considerably below that of nickel. Even though the particles of the dispersed phase are not clearly resolved, the electron backscatter micrographs indicate that the light nickel phase is the matrix in the alloys containing 5.0 w/o phosphorus and the dark Ni_3P phase is the matrix in the alloys containing 9.0 w/o phosphorus.

The evidence from x-ray pinhole transmission patterns for restricted grain growth of the nickel phase of high-phosphorus alloys heat treated at 750°C in contrast to the excessive grain growth in the low-phosphorus alloys can be attributed to the change in the phase forming the matrix as the phosphorus content increases. The continuous Ni_3P phase would act as a natural barrier to the growth of a dispersed nickel phase in the high-phosphorus alloys.

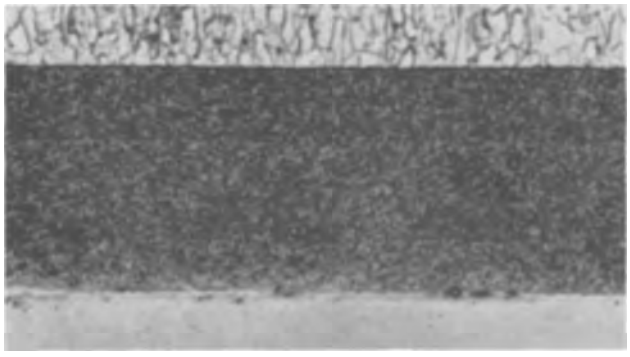

Fig. 13. Microstructure of electroless nickel deposited from the alkaline-chloride bath and heat treated at 600°C for 120 min, phosphorus content 9.0 w/o, NaCN-$(NH_4)_2S_2O_8$ etch, X 1000.

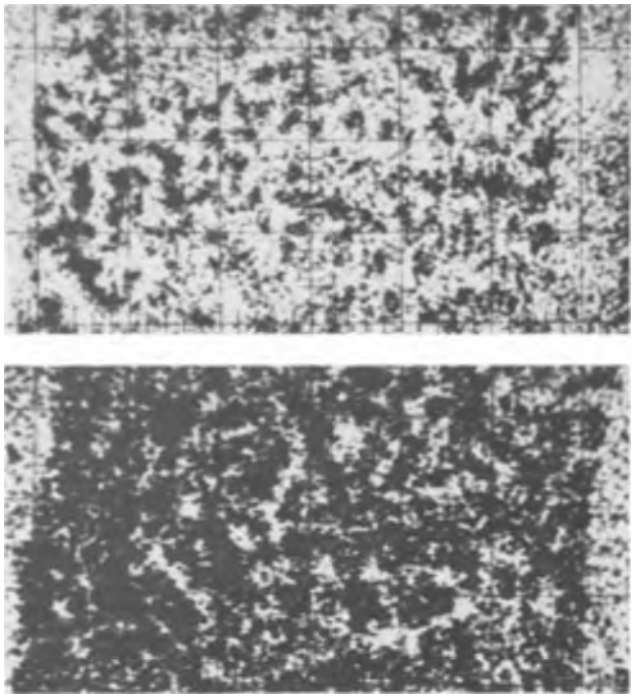

Fig. 14. Electron backscatter micrographs of electroless nickel alloys deposited from the alkaline-chloride bath and heat treated at 750°C for 120 min, unetched, X 2500. (a) phosphorus content 5.0 w/o, (b) phosphorus content 9.0 w/o.

The fact that the change in the phase forming the matrix occurs in the vicinity of 7 w/o phosphorus, which according to the equilibrium phase diagram corresponds to 50 v/o Ni_3P, can be ascertained from the series of micrographs in Fig. 15. The continuous nickel phase appears as light regions on the optical micrograph of the alloy with 5.0 w/o phosphorus in contrast to the gray regions representing the continuous Ni_3P phase in the micrograph of the alloy with 9.0 w/o phosphorus. In the microstructure of the alloy containing 7.1 w/o phosphorus shown in Fig. 15b, neither phase is continuous across the entire thickness of the deposit. The Ni_3P phase appears to be the matrix at the basis metal-deposit interface, whereas nickel seems to be the matrix near the outer surface. All optical micrographs in this section are oriented so that the basis metal is at the bottom.

Mechanical Properties

The bulge-test specimens deposited from the alkaline-chloride bath were grouped according to phosphorus content. As-plated specimens or specimens for a specific heat treatment were randomly selected from a group representative of a particular phosphorus content in order to eliminate any effect that plating conditions during a particular run might have on the properties of the deposits. The strengths and ductilities plotted on the graphs in this section are sample means or averages for measurements on several specimens. The limits of the averages indicated by dashed lines on some of the graphs are 90% confidence intervals for the true mean calculated from Student's "*t*" distribution.

For an adequate sample of as-plated specimens and heat-treated specimens, there was no significant difference between the hardness measurement on the surface of a deposit and the hardness measurement on its cross section. Therefore, it was not necessary to make two measurements on all specimens. If measurements were made on both the surface and the cross section, the Knoop hardness number (KHN) reported was the average of the two measurements. The maximum deviation of two measurements from their mean was less than 5%.

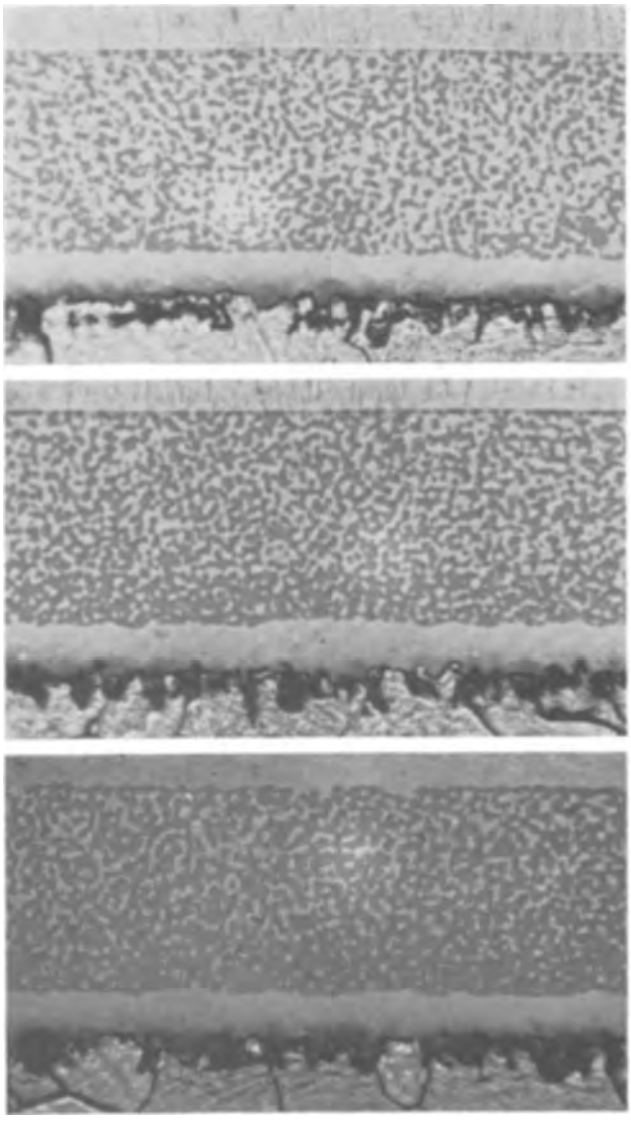

Fig. 15. Microstructure of electroless nickel alloys deposited from the alkaline-chloride bath and heat treated at 750°C for 120 min, NaCN-$(NH_4)_2S_2O_8$ etch, water rinse, 2% nital etch, X 1000. (a) phosphorus content 5.0 w/o, (b) phosphorus content 7.1 w/o, (c) phosphorus content 9.0 w/o.

The graphs in Fig. 16 indicate that both the strength and the ductility of as-plated electroless nickel alloys increase with a rise in phosphorus content. These results contradict qualitative observations of Brenner, Couch, and Williams (4) who reported a decrease in the strength and ductility of similar electrodeposited alloys with increasing phosphorus content. In the vicinity of 7 w/o, both the strength and the ductility of electroless nickel alloys rise abruptly and the strength appears to reach a maximum. The changes in strength and ductility are not reflected in the hardness, which remains practically constant as the phosphorus content increases.

The increase in the strength of the as-plated alloys can reasonably be attributed to either solid solution hardening or to the effects of localized coherency stresses in regions where phosphorus atoms are collecting and attempting to form a nucleus of the phosphide phase. At present, no reasonable hypothesis can be offered to explain the unusual direct relationship between strength and ductility with increasing phosphorus content of as-plated electroless nickel. A similar direct relationship was described by Read in his discussion of the effects of addition agents on the mechanical properties of copper and nickel electrodeposits (17).

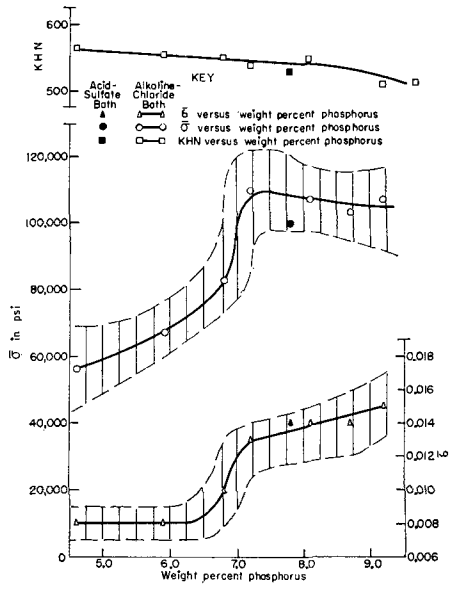

Fig. 16. Effect of phosphorus content on the mechanical properties of as-plated electroless nickel alloys.

The strength and ductilities reported in Fig. 16 for as-plated alloys containing 7 to 10 w/o phosphorus are in good agreement with those obtained by Jovanovic and Smith (18) for similar alloys. These investigators, whose method for analyzing bulge test results differs from that used in this investigation, report strengths at fracture ranging from 109,000 to 120,000 psi and strains at fracture ranging from 0.0069 to 0.0080. If the bulge test results of this study for alloys containing 7 to 10 w/o phosphorus were treated according to the method employed by Jovanovic and Smith, the average strength at fracture would be 106,000 psi and the average strain at fracture would be 0.0095.

Although heat treatments at 750°C for 60 and 120 min significantly improve both the strength and the ductility of the low-phosphorus alloys, they greatly decrease the strength and the ductility of the high-phosphorus alloys as shown by a comparison of the data in Fig. 16 and 17. The fact that alloys with greater

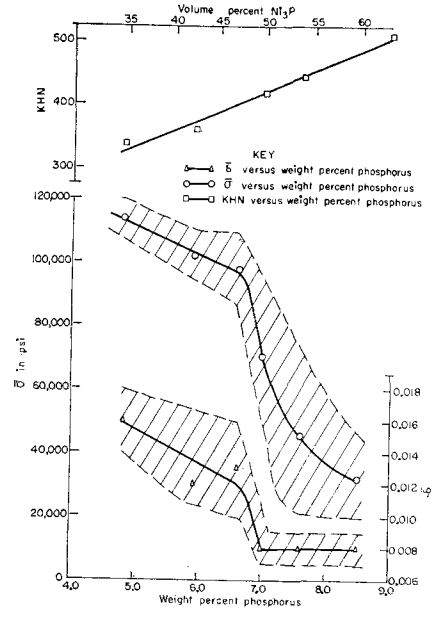

Fig. 17. Effect of phosphorus content on mechanical properties of electroless nickel alloys deposited from the alkaline-chloride bath and heat-treated at 750°C for 120 min.

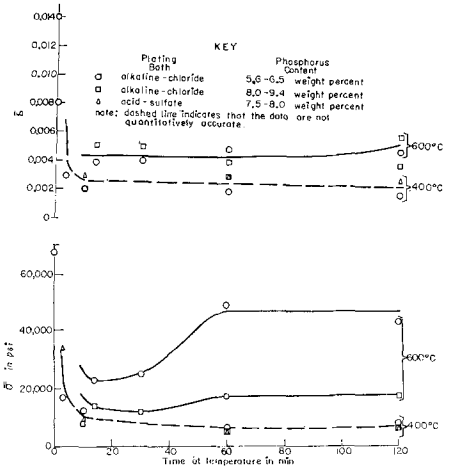

Fig. 18. Effect of heat treatments at 400° and 600°C on the strength and ductility of electroless nickel alloys.

than 7 w/o phosphorus are more brittle after heat treatments at 750°C than as-plated alloys of comparable phosphorus content confirms the qualitative observations of Brenner *et al.* for similar electrodeposited alloys and contradicts claims in the literature that prolonged heat treatments above 600°C improve the ductility of all electroless nickel alloys.

The graphs in Fig. 17 show that the strength and ductility of alloys heat treated at 750°C for 120 min decrease abruptly with increasing phosphorus content in the vicinity of 7 w/o. The abrupt loss in strength and ductility is indicative of the fact that a ductile nickel phase is the matrix in the low-phosphorus alloy and a brittle phosphide phase is the matrix in the high-phosphorus alloy. Once again, hardness measurements give no indication of the potent effect of phosphorus content in the vicinity of 7 w/o on strength and on ductility. The data plotted in Fig. 17 indicate that hardness is not only directly proportional to the weight per cent phosphorus in the alloys, but is also directly proportional to the volume per cent Ni_3P, as suggested by Ziehlke, Dritt, and Mahoney (7).

Heat treatments at 400° and 600°C result in a drastic decrease in the strength and ductility of all electroless nickel alloys as shown by the graphs in Fig. 18. After 10 min at 400°C, the alloys were so brittle that their strength and ductility could not be measured accurately even by the bulge test, which is particularly suitable for the determination of the properties of many brittle metallic coatings. The ductilities reported in Fig. 18 for the specimens tested are not quantitatively accurate because the bulge heights at fracture were far below the lower limit of the calibration graph for the bulge tester. At the lower limit, the curvature of the calibration graph changes rapidly so that precise extrapolation is not possible. Valid measurements of the strength were not obtained because the specimens fractured so early in testing that the oil pressure could not be accurately determined. For alloys heat treated at 400°C, phosphorus content seems to have no effect on the apparent strengths or the apparent ductilities which, at best, are only qualitative indications of these properties.

Even though the quantitative accuracy of the ductilities reported for alloys heat treated at 600°C is also questionable, the strength measurements are considered to be valid because all the specimens fractured at a measurable pressure. Heat treatments of the low-phosphorus alloys for more than 30 min result in the recovery of a significant portion of the original loss in strength. The high-phosphorus alloys are still extremely weak even after 120 min at 600°C.

There are probably many plausible explanations for the severe embrittlement indicated by the drastic decrease in the strength and ductility of electroless nickel after heat treatments at 400° and 600°C. One hypothesis could be based on the assumption that the Ni_3P phase initially precipitates as very thin platelets with edges that act as severe stress raisers. If this assumption were true, the recovery of the strength of the low-phosphorus alloys after prolonged heat treatments at 600°C could be attributed to the elimination of the stress raisers due to the natural tendency of the platelets to form spheroids and thereby decrease their surface energy.

A second hypothesis could be based on the assumption that many of the phosphorus atoms in as-plated electroless nickel alloys are segregated at grain boundaries. If this assumption were valid, the initial phosphorus-rich phase precipitated during heat treatments would form a continuous grain boundary network that could reasonably account for the embrittlement of the alloys. In the low-phosphorus alloys, a phosphide grain-boundary network would also tend to spheroidize during heat treatments at high temperatures. In the high-phosphorus alloys, the grain-boundary network would be stabilized due to the high volume percentage of the phosphide present.

There is some evidence on the x-ray pinhole transmission patterns of alloys heat treated at 400° and 600°C and on the micrographs of alloys heat treated at 750°C which would support both hypotheses suggested to account for the severe embrittlement. The observed preferred orientation of the phosphide phase in the x-ray pinhole transmission patterns suggests that some of the initial Ni_3P particles may precipitate as platelets with a particular crystallographic plane parallel to a habit plane in the parent nickel structure. The preferred orientation of the phosphide phase becomes stronger as the phosphorus content of the alloys decreases. However, even in the low-phosphorus alloys, the preferred orientation is not strong enough to preclude the existence of a randomly oriented precipitate at grain boundaries. The micrographs in Fig. 15a and 15b show irregularly shaped phosphide particles that appear to be the remnants of a grain-boundary network and also reveal small isolated phosphide spheroids which could have originally been platelets.

The data in Fig. 19 indicate that the embrittlement of electroless nickel after heat treatments at 400°C is accompanied by the substantial increase in hardness observed by previous investigators (2, 3, 5, 7). After 3 min at 400°C, the hardness of an alloy containing 6.1 w/o phosphorus is greater than that of an alloy containing 9.0 w/o. However, the hardness of alloys after heat treatments at 400°C for 10 min or longer is not significantly affected by phosphorus content. In Fig. 19, the stability of the maximum hardness developed at 400°C is compared with the rapid decrease in hardness during heat treatments at 600°C. The hardness

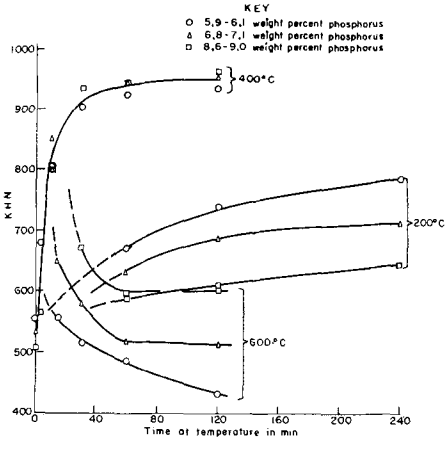

Fig. 19. Effect of heat treatment on the hardness of electroless nickel alloys deposited from the alkaline-chloride bath.

of alloys after identical heat treatments at 600°C appears to be directly proportional to the volume per cent of Ni_3P present.

After heat treatments at 200°C, an increase in the hardness was observed for all the electroless nickel alloys. In the low-phosphorus alloys, the rate of hardening was significantly greater than that in the high-phosphorus alloys as shown in Fig. 19. The observed dependence of the rate of hardening on phosphorus content partially accounts for the contradictory results of previous investigators concerning the tendency of electroless nickel to harden at 200°C. Goldenstein *et al.* (2), who reported no increase in hardness at 200°C, were studying high-phosphorus alloys. Zusmanovich (3) and Lee (5), who observed hardening, probably were studying low-phosphorus alloys.

In the high-phosphorus alloys, the relatively slow rate of hardening at 200°C seems to be indicative of the presence of an activation energy barrier, dependent on the phosphorus content, that retards the initial stages of the transformation and the hardening of the supersaturated solid solution. After a heat treatment at 400°C for 3 min, the low hardness of the alloy containing 9.0 w/o phosphorus compared to that of the alloy with 6.1 w/o phosphorus is further evidence for the existence of an activation energy barrier. If an activation energy barrier were not present, the high-phosphorus alloys should transform and harden faster than the low-phosphorus alloys because the instability of the solid solution and the free energy available for transformation should increase as the phosphorus content increases. Although in a few instances rate of precipitation may decrease with increasing solute concentration, we know of no reason to suspect that such a phenomenon should prevail here.

The strength and the ductility of the alloys heat treated at 200°C increase with a rise in phosphorus content as shown in Fig. 20. The measurements of strength of the alloys heat treated at 200°C for 120 min give a much more positive indication than hardness measurements that the low-phosphorus alloys start to transform before the high-phosphorus alloys. A comparison of the data in Fig. 16 and 20 indicates that a heat treatment at 200°C for 120 min decreases the strength of the low-phosphorus alloys by a factor of two but does not significantly affect the strength of the high-phosphorus alloys. The loss in strength in the low-phosphorus alloys resembles the embrittlement

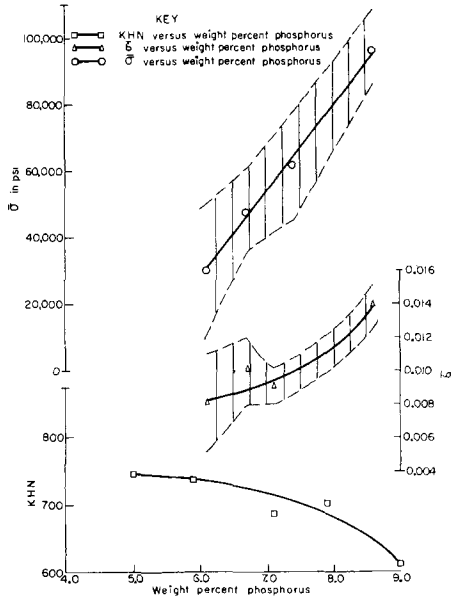

Fig. 20. Effect of phosphorus content on the mechanical properties of electroless nickel alloys deposited from alkaline-chloride bath and heat treated at 200°C for 120 min.

that accompanies the transformation of alloys during heat treatments at 400°C.

The decrease in ductility after heat treatments at 400°C is not observed after heat treatments at 200°C. Although the average values reported for the ductility of as-plated alloys and those reported for alloys heat treated at 200°C are almost identical, it is probably important to note that the scatter in the data for the low-phosphorus alloys heat treated at 200°C is much greater than that for as-plated alloys of comparable phosphorus content. Furthermore, changes in the mechanical properties of brittle materials are almost always indicated by variations in strength rather than in ductility because tests employed to measure strain are not sensitive enough. Even though the hydraulic bulge test is one of the most sensitive tests for detecting slight differences in the strain at fracture for brittle materials, its sensitivity is not very great at the strains at which electroless nickel deposits fracture.

Hardening Mechanism

The structural observations from x-ray pinhole transmission patterns and many of the characteristics of the increase in hardness after the heat treatment of electroless nickel tend to indicate the occurrence of conventional precipitation hardening. In the initial stages of precipitation hardening of a supersaturated solid solution, the atoms of the solute diffuse to a specific crystallographic plane with an atomic arrangement that resembles the array of atoms on a plane in the structure of the precipitate. As the atoms attempting to precipitate collect, they are forced to conform to the structure of the solvent. The forced coherency between atoms of the solvent and atoms attempting to form the structure of the precipitate causes severe, localized, elastic stresses that are responsible for the increase in hardness. When a sufficient number of solute atoms have collected, the structure of the precipitate is formed and the localized elastic stresses are relieved because the forced coherency no longer exists. After the formation of a significant number of precipitate particles at various locations throughout the specimen, the rate of hardening decreases and the hardness approaches a maximum.

The fact that there is no x-ray evidence for the presence of a phosphide precipitate in the low-phosphorus alloys that have been hardened by heat treatments at 200°C or by a heat treatment at 400°C for 3 min is in agreement with the established mechanism for precipitation hardening. After heat treatments at 400°C for more than 10 min, reflections from Ni_3P appear in x-ray diffraction patterns and the hardness approaches a maximum.

The strongest evidence obtained for the occurrence of conventional precipitation hardening in electroless nickel is based on the analysis of the relationship between the [111] fiber texture of the nickel phase and the preferred orientation of the Ni_3P phase, as revealed in the x-ray pinhole transmission pattern in Fig. 8. The presence of a preferred orientation in both the Ni_3P precipitate and the parent nickel phase implies the existence of a plane of coherency between the two crystal structures.

The habit plane on which a precipitate forms in the solvent is usually a plane of low indices. In the pattern in Fig. 8 and similar patterns, an analysis of the locations of the intense arcs on the {321} reflection of Ni_3P indicates that the {111} planes of fcc nickel are parallel to the {110} planes of Ni_3P, which has a body-centered-tetragonal structure with 32 atoms per unit cell. The arrangement of atoms associated with the $(\bar{1}10)$ Ni_3P plane shown in Fig. 21 bears a striking resemblance to the hexagonal array of atoms on the {111} planes of nickel. Furthermore, the average interatomic distance of 2.6Å on the {110} planes of Ni_3P is very close to the interatomic distance of 2.5Å in pure nickel. Therefore, the {111} planes of nickel

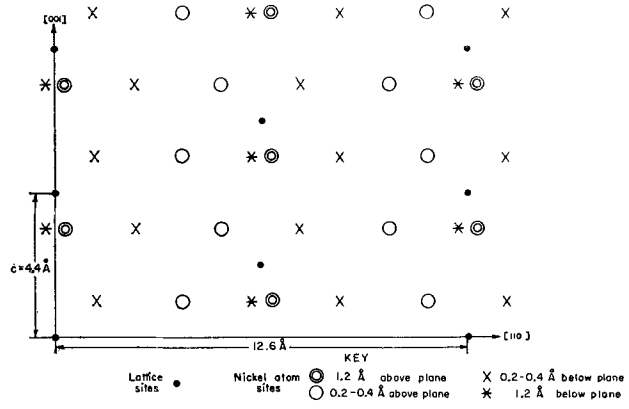

Fig. 21. Schematic sketch of the arrangement of atoms associated with the (110) plane of Ni_3P.

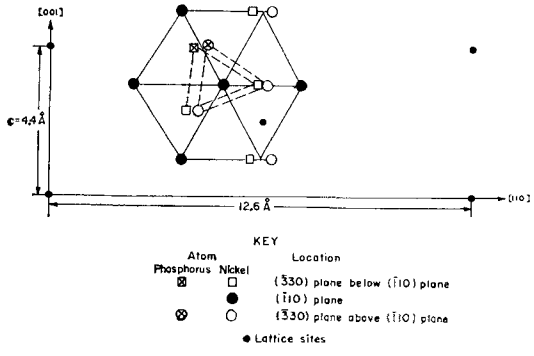

Fig. 22. Schematic sketch showing the pseudo hcp stacking sequence in the vicinity of a nickel atom on the (110) plane of Ni_3P.

satisfy all the requirements of a habit plane for the precipitation of Ni_3P.

The evidence that the {110} planes of the initial Ni_3P particles formed are parallel to the {111} planes of the nickel phase also tends to account for the existence of stacking faults in the as-plated deposits. In the Ni_3P structure, all of the phosphorus atoms may be considered to be located on a set of {330} planes which are immediately adjacent to the {110} planes. If one considers certain nickel atoms on {110} planes of Ni_3P and their nearest neighbors on adjacent {330} planes, a pseudo hcp stacking sequence is apparent, as shown in Fig. 22. This stacking sequence would correspond to a stacking fault in the fcc structure of the supersaturated solid solution in as-plated electroless nickel. If some of the phosphorus atoms in the as-plated alloy were segregated on {111} planes in the structure of the nickel solvent, they would tend to stabilize stacking faults because of the resemblance between the faults and a coherent structure of Ni_3P.

One important characteristic of the hardening of electroless nickel that is markedly different from conventional precipitation hardening is the inverse relationship between hardness and strength. In conventional precipitation hardening, an increase in hardness is accompanied by an increase in strength. The hypotheses that were proposed to account for the loss in strength during heat treatment of electroless nickel at 400°C do not explain why an increase in strength is not observed in the initial stages of hardening. In speculating on a plausible explanation for the unusual inverse relationship between strength and hardness in the initial stages of hardening, it is probably important to note that the established mechanisms and characteristics of conventional precipitation hardening are based on alloys with a grain size two to five orders of magnitude greater than that of as-plated electroless nickel. Very little is known concerning the relationships between strengthening mechanisms and the mechanical properties of extremely fine-grained alloys such as electroless nickel. Some of the characteristics of the hardening in fine-grained alloys might be different from those observed in alloys with a much coarser grain size.

Comparison of Alkaline-Chloride Deposits and Acid-Sulfate Deposits

No significant differences were observed between the x-ray diffraction patterns of alloys deposited from the alkaline-chloride bath and the patterns of deposits from the acid-sulfate bath. In the study of the effect of phosphorus content on the position and breadth of the {111} reflection from as-plated alloys, the data for the acid-sulfate deposits shown in Fig. 7 are extremely close to the curves established for the alkaline-chloride deposits. The data in Table III indicate that heat treatments have similar effects on the preferred orientation of the phases in alloys of comparable phosphorus content from the two baths.

In the microstructure of the as-plated deposits, the difference of one order of magnitude in the thickness of lamellae did not affect the mechanical properties shown on the graph in Fig. 16. However, it is possible that the steep phosphorus gradient across the acid-sulfate deposits obscures the effects on mechanical properties of differences in microstructure and plating bath composition. After heat treatments at 400°C, the mechanical properties of alloys deposited from the two plating baths were also similar, as shown by the data in Fig. 18.

Summary

An analysis of electron and x-ray diffraction patterns indicates that as-plated electroless nickel alloys are supersaturated solid solutions of phosphorus dissolved in crystalline nickel. An increase in phosphorus content above 7 w/o not only broadens and shifts electron and x-ray reflections, but also decreases the strength of a [111] fiber texture in the nickel-rich solid solution. Both the strength and the ductility of the as-plated alloys increase with a rise in phosphorus content whereas the hardness remains constant.

During heat treatments at temperatures ranging from 200° to 750°C, the development of a strong [111] fiber texture in the nickel phase is indicative of recrystallization and grain growth.

Differences in the mechanical properties of alloys after identical heat treatments at 200°C indicate that the phosphorus content affects the kinetics of the initial stages of transformation and hardening prior to the formation of a Ni_3P precipitate. The absence of a Ni_3P phase during the initial stages of hardening at 200° and 400°C is in agreement with the established mechanism for precipitation hardening. Additional definite evidence for the occurrence of precipitation hardening is the existence of a logical habit plane for the coherent precipitation of the Ni_3P phase.

Heat treatments at 400° and 600°C greatly decrease the strength and ductility of all the alloys. Low-phosphorus alloys heat treated for more than 30 min at 600°C recover a significant portion of the original loss in strength, but high-phosphorus alloys are still weak after 120 min at 600°C.

Heat treatments at 750°C that significantly improve the strength and ductility of low-phosphorus alloys greatly decrease the strength and ductility of high-phosphorus alloys. Hardness measurements give no indication of the abrupt changes in strength and ductility with increasing phosphorus content. The loss of strength and ductility in the vicinity of 7 w/o phosphorus indicates that a ductile nickel phase is the matrix in the low-phosphorus alloys, and a brittle Ni_3P phase is the matrix in the high-phosphorus alloys. Evidence in micrographs, x-ray diffraction patterns, and electron-probe microanalysis traverses confirms the change in the phase forming the matrix.

The x-ray diffraction patterns of alloys deposited from the acid-sulfate bath were similar to the patterns of alloys with comparable phosphorus contents deposited from the alkaline-chloride bath. The difference of one order of magnitude in the thickness of lamellae in the microstructure of as-plated alloys from the two plating baths has no apparent effects on mechanical properties.

Relationship between Deposit Thickness and Current Density during the Early Stages of Electrodeposition

Joseph B. Kushner[1]

Engineering School, Evansville College, Evansville, Indiana

ABSTRACT

Some experiments have been performed to determine how long it takes at a given current density to put a continuous copper deposit on a simple planar platinum cathode and what the average thickness of the copper deposit is at that time. The results indicate a hyperbolic power type of relationship between the current density and the time of full coverage and the current density and the deposit thickness at full coverage. A simple theory is proposed to explain the results obtained.

This is a preliminary report in connection with some experiments performed dealing with the origins of stress in electrodeposited metals. In a previous paper (1) the present author proposed that the stress in electrodeposited metals reaches a maximum value at the time the deposit becomes essentially continuous on the cathode. It is of interest therefore to determine for a given current density how thick the deposit is at the time continuity is achieved and how long it takes to arrive at this thickness.

At first glance this appears to be a rather elementary problem, but it is not as simple as it looks. If a deposit grows uniformly over the cathode surface, atom layer by atom layer, then at the time the cathode surface is continuously covered, the thickness of the deposit should be exactly one atom layer. But deposit growth does not occur like this. There is a certain amount of growth normal to the plane of the cathode as well as parallel to it. Furthermore it is well known that electrocrystallization on a cathode begins in many instances only after starting nuclei have formed. Evans and Shome (2) clearly demonstrated that in the case of a simple nickel plating bath growth starts from nuclei formed at the very beginning of the plating process and little or no additional nucleation occurs after that.

Electrocrystallization is very much similar to other kinds of crystallization, and thermodynamic reasoning leads one to the conclusion that the size of these starting nuclei should become smaller as the current density is increased. And since fewer atoms are required to form a nucleus there should be more of them at the start of plating at a higher current density than there would be at a lower current density. Furthermore, as current density is increased the rate of deposition is increased, and each of these starting nuclei grow at a faster rate. In accordance with this, therefore, it can be expected that at high current densities the cathode will be very quickly covered and the deposit thickness at that time will be very small whereas at low current densities, since less nuclei are formed, it will take longer to cover and the deposit will be thicker when full coverage is achieved. The purpose of the experiments described below was to determine what relationship, if any, existed between the current density used and the average thickness of the deposit at the time full coverage of a simple cathode surface occurred.

Experimental Equipment

The electrolyte used for the experiments was a 0.5M copper sulfate, 0.5M sulfuric acid solution. It was chosen because of its simplicity and because over a fairly wide range of current densities it is capable of producing microscopically resolvable deposits. Two liters of solution were made from analytical grade chemicals and distilled water. The solution was filtered through acid washed activated carbon and was preelectrolyzed using a strip of high-purity copper (99.-

[1] Also Director, Joseph B. Kushner Electroplating School, Evansville, Indiana.

999) as anode, as an additional purification. The solution was used in a specifically designed cell made of Lucite which held 16.4 ml of solution. The cell was drained after each test and filled with fresh solution for each succeeding test.

It is well known that exceedingly small amounts of impurities can have important effects in electrodeposition from acid copper sulfate baths, and no doubt the purification given the electrolyte was less than desirable, but it was felt that since each experimental bath would on the average contain the same kind and amount of impurities their effect on the deposit would be the same in all the experiments performed. The platinum strip was handled with considerable care to prevent bending and scratching of the surface beyond that already present in the as-received condition.

The cathode used was a thin strip of C.P. platinum (99.99+). Its dimensions were 0.01 in. thick, 0.25 in. wide and 4.00 in. long. The actual plating because of the cell design, occurred only on one side over a length of 1.00 in. so that the active cathode surface had an area of 0.25 in.^{2} (1.61 cm^2). Platinum was selected because it is known to give a reproducible surface (3, 6).

It has been shown quite convincingly that nucleation takes place at dislocation arrays such as polygonization boundaries, in the presence of impurities which at sometime during the previous history of the cathode have diffused to the dislocations (4, 5). For almost any other metal than platinum, surface cleaning would be sure to affect nucleation centers, leading to irreproducibility. In addition, the platinum surface gave a strong contrast to the pink colored copper deposit, a marked advantage in determining coverage.

The next question was how would continuity of the deposit be established? The criterion was the human eye, both unaided and with a microscopic amplification of 800 diameters. The plated cathode area was deemed fully covered when to the eye the deposit was uniformly spread over the surface and examination of random and selected areas at a magnification of 800 x showed no bare regions greater in area than 1/1000 of the total area of the field of view. Figure 1 shows a result in which the deposit was considered continuous. Figure 2 shows what was considered a discontinuous deposit. The human eye is amazingly sensitive to color, and some preliminary experiments indicated that the eye could detect films of copper only a few hundred angstoms thick.

The temperature of the plating bath was room temperature, 27°C + 1°. The cleaning procedure was as follows: The platinum strip, handled by tweezers at the nonplating end was heated in concentrated nitric acid for 2 to 3 min or long enough to remove the previous copper deposit. It was rinsed thoroughly in running distilled water and then anodically electrolyzed in a 10% solution of C.P. sulfuric acid using another platinum strip as cathode, at a potential of 6v so that there was copious oxygen evolution at the anode. This was followed by a distilled water rinse and then plating was started after permitting the strip to sit in the bath for 2 min without current.

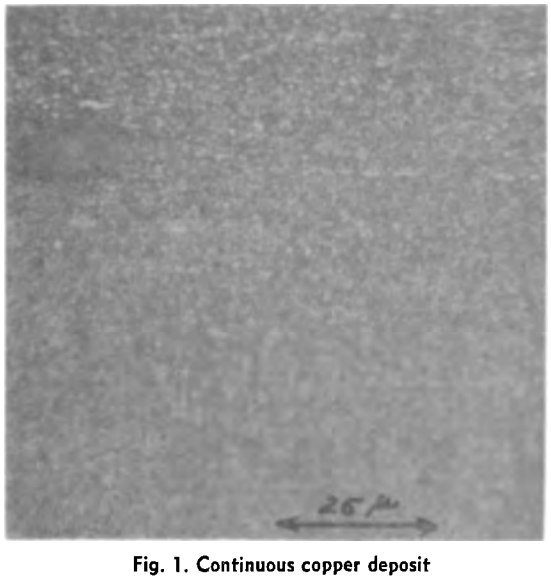

Fig. 1. Continuous copper deposit

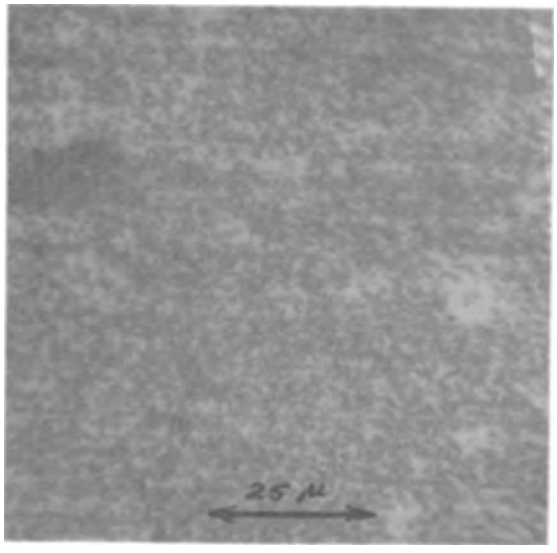

Fig. 2. Discontinuous copper deposit

It has been found by Becker (6) in the case of silver electrodeposition on platinum from a silver nitrate solution that random nucleation is produced whenever the platinum is given a cleaning treatment involving oxidation, such as dipping in nitric or sulfuric-chromate solution or flaming or anodic treatment in acid. He hypothesizes that oxygen is adsorbed on the cathode surface by these treatments, increasing the work of nucleation, and leading more or less to random nucleation. On the other hand he finds that cathodic treatment in nitric acid removes such an adsorbed oxygen layer, if formed, and leads to reproducible nucleation at easy nucleation sites with many many more nucleation sites available.

Use of a cathodic treatment in sulfuric acid was tried at first, but it was found that the hydrogen treatment led to nonuniformity of the copper deposit. Almost invariably for the same number of coulombs of electricity passed at several different current densities, the anodic treatment produced uniform coverage of the surface whereas the cathodic treatment resulted in bare areas. At this time no explanation is offered for this rather strange behavior. Possibly adsorbed hydrogen may be the cause of it. At any rate, on the basis of these tests, the anodic treatment was selected to help insure more random nucleation if this is what was occurring.

In order to determine the time of coverage as closely as possible, a pulse generator[2] producing an essentially square wave was used as the source of current. With this generator it was possible to produce either a single pulse or a series of pulses of known pulse width, spacing, and amplitude. The reasoning behind the use of a pulse generator was that the time element in the plating could be kept under closer control at the higher current densities when the time of plating was short. Thus, at higher current ranges full coverage might be obtained in a second or two with continuous current. With a pulse generator by using pulses of relatively small width compared to the pulse spacing the time factor could be magnified. For example, with a pulse spacing of 100,000 μsec and a pulse width of 10,000 μsec, the time of plating is magnified by a factor of 10.

Before using the pulse generator this way certain points had to be checked out. Basically these were:

[2] Servo Corporation of America, Model 3450D.

(*A*) Would the average thickness of the pulsed deposit be the same as for a continuous d-c deposit at the same number of coulombs? (*B*) Would pulse plating produce the same type of deposit, with reference to grain size, as continuous plating?

Regarding point *A*, it was found at once that some dissolution of the deposit took place during the off time particularly at low current densities. Thus at a current density below 4 ma/cm^2 the on-off ratio had to be 1 to 1 or better for an efficiency value as good as that for direct current. This was verified a number of times by plating the weighed platinum cathode with d.c. equivalent to the pulsed d.c. in terms of current density and coulombs passed. Efficiencies measured with the d.c. checked out very well with efficiencies at the same current density as measured by Turner (7) on an acid copper solution of similar composition. The efficiency with the pulsed current was likewise determined by weighing the platinum strip after a definite number of pulses producing the same current density and total number of coulombs was passed. These results came to within 2% or less of the d.c. results when the pulse width was at least one-half of the pulse spacing in the lower current density ranges. At higher current densities it was found possible to get results identical to the d.c. results with a wider pulse spacing; that is, a ratio of 1:10 could be used, thus magnifying the time by a factor of 10.

The attack on the copper deposit (and nickel in some other experiments) is no doubt due to the corrosive couple set up between the platinum and the copper. It appears that at relatively high plating current densities the interfacial film is depleted of ions or ion combination (most probably sulfate ions) that are capable of oxidizing the copper. The diffusion back to the interface of these attacking ions takes time and the next pulse puts on another layer of copper and retards the return of these ions. At lower current densities the attacking ions move only a short distance away from the cathode interface or are thinned out less extensively and, if the next pulse does not come quickly enough, some of the copper put on by the previous pulse is dissolved back into the solution, and the overall efficiency of the process becomes less than that of the d-c process. From the few pilot experiments tried, it appears that a considerable amount of information on diffusion and related subjects may be obtained by means of pulsing techniques.

With regard to the nature of the deposits, under the microscope the deposits produced by pulsed d.c. showed the same crystal size and general structure as those put down with the same number of coulombs of d.c. at the same current density. It may be that there are more subtle structure changes but these were not apparent to the eye.

It is also interesting to note that the copper deposits seemed almost invariably to nucleate along rolling lines, scratches, and other defects on the platinum strip. In most of the pictures taken a surface defect which can be seen in Fig. 1 and 2, was used as a landmark for positioning the surface so the same area could be photographed each time when desired. The circuit and apparatus layout is shown schematically in Fig. 3.

Table I. Time and deposit thickness at full coverage of platinum cathode

Actual plating time, sec, *t*	Coulombs passed, *Q*	Current density, ma/cm^2, *I*	Average thickness of deposit, Å, *T*
6.00	0.144	14.8*	329
17.5	0.280	9.88	638
30.0	0.360	7.41	822
80.0	0.640	4.94	1460
175.0	1.05	3.70	2400
400.0	1.60	2.47	3640
750.0	2.40	2.06	5470
1330	3.19	1.48	7280

* Measurements above this current density were not made due to difficulty in resolving crystal size.

The instantaneous current in the plating cell during pulses was determined from the measured instantaneous voltage drop across a precision resistor in series with the cell, as determined by means of a calibrated oscilloscope. Continuous direct current when used was produced by a constant current power source[3] and was measured by a precision Weston ammeter. During pulsed plating, the number of coulombs passed was determined by multiplying the number of pulses per second by the pulse width by the instantaneous current through the plating cell. The number of pulses (total) multiplied by the pulse width gave the actual plating time in seconds.

Data were obtained in the following way: At a given total current a known number of pulses were passed. The platinum strip was removed, rinsed in distilled water followed by a pure acetone spray, air dried and examined first with naked eye and then under the microscope at 800X. If the deposit showed bare areas, the strip was cleaned in hot nitric acid as previously described, given an anodic treatment in the 10% sulfuric, and plated again for a longer number of pulses and re-examined until finally the strip appeared to be fully covered (99.9%). The number of coulombs required for full coverage was determined by approaching full coverage from both the low coulomb side and the high coulomb side. The reproducibility of the method was good. It is estimated the maximum error is no greater than 10%. Each coulomb value (or time value) given in Table I is the result of at least two such determinations. The average thickness of each deposit was computed from the known number of

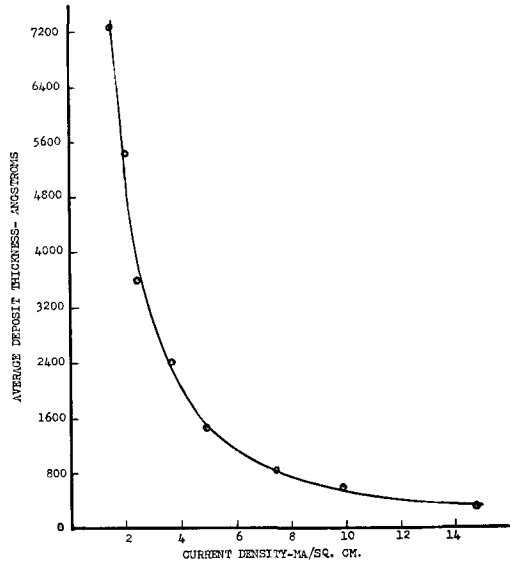

Fig. 4. Relationship between current density and average deposit thickness at time full cathode coverage is reached.

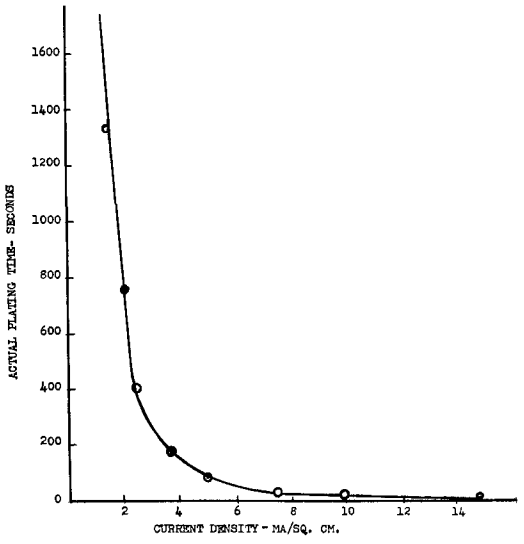

Fig. 5. Relationship between current density and time to reach full cathode coverage.

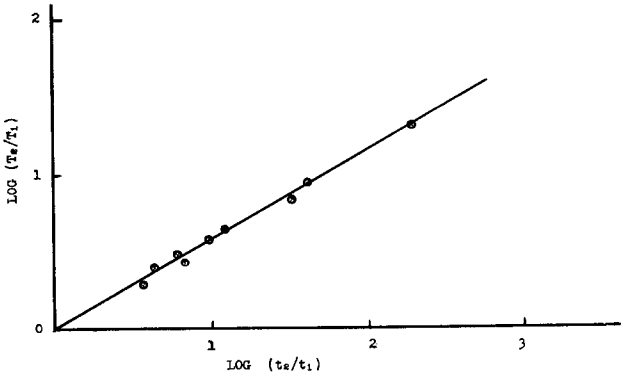

Fig. 6. Relationship between (T_2/T_1) and (t_2/t_1) at time full cathode coverage is reached.

coulombs passed, the nominal plated area, the electrochemical equivalent, and the bulk density of copper. Results for the copper solution described and the platinum strip used are given in Table I.

Three graphs have been plotted from the data. Figure 4 is a plot of the average deposit thickness *vs.* the current density used, at the time full coverage is reached. Figure 5 is a plot of the time to reach full coverage *vs.* the current density used and Fig. 6 is a plot of the log of (T_2/T_1) *vs.* the log of (t_2/t_1) where t_1 is the time in seconds to produce a deposit of average thickness T_1 angstroms, etc. Figures 4 and 5 show a hyperbolic type of relationship betweeen the thickness, time, and a power of the current density. Figure 6 gives what appears to be a straight line, with a slope of 0.57. The reason for this last plot will appear in the theory and discussion which follows.

Theory and Discussion

According to Evans and Shome (2) the area covered by a deposit on a flat cathode of area A_o in time t, is given by

$$A = A_o(1 - e^{-\pi v 2 t 2 N}) \qquad [1]$$

where v is the velocity of lateral spreading of the deposit (assumed constant for a given current density) and N is the number of nuclei originally formed. At the time of full coverage, assuming 99.9% to be full coverage, for different nucleation numbers, velocities, and times (different current densities) it can be said

$$\ln(1000) = \text{constant} = \pi v_1^2 t_1^2 N_1 = \pi v_2^2 t_2^2 N_2 = \pi v_3^2 t_3^2 N_3 \ldots \qquad [2]$$

What this series of equations is saying is that when coverage is complete, the lateral area of each grain deposited, multiplied by the number of grains (number of nuclei) is equal to the total area of the cathode surface A_o, or

$$A_1 N_1 = A_2 N_2 = A_3 N_3 = \ldots\ldots = A_o \qquad [3]$$

and

$$A_1/A_2 = N_2/N_1 \qquad [4]$$

Assuming all directions of lateral growth equally possible, the lateral growth that occurs from a given nucleus in time t must be equal to $a\sqrt{A}$, where a is a geometric constant. As a first approximation, the normal growth or thickness, T, can be assumed to be a simple linear function of the lateral growth. That is, $T = k\sqrt{A}$ where k is some proportionality constant. Solving for A gives $A = (T/k)^2$. Substitution of this value for A in [3] gives

$$(T_1/T_2)^2 = N_2/N_1 \qquad [5]$$

Electrocrystallization is very similar to other forms of crystallization, and by thermodynamic reasoning (8) it can be shown that the minimum radius of a crystal nucleus that will continue to grow is given by $R = Cs/G$ where C is a constant having to do with shape and interfacial relations, s is the surface energy (interfacial energy), and G is the free energy of the newly formed phase, all in consistent units.

In the case of electrocrystallization at a fixed temperature the interfacial energy is constant, and the free energy of the newly arriving metal ions will be measured by the difference between the energy they had as ions in solution and the energy they possess on sitting down on the substrate. This is given by the overpotential for deposition, e, the difference between the equilibrium potential and the actual potential required to produce deposition. Accordingly it can be said that

$$R = K/e \qquad [6]$$

where K is a new constant involving previous factors and the faraday.

If we consider the nucleus to be two dimensional at the start which is probably the case, and r is the radius of each individual atom of metal, then

$$\pi(K/e)^2 = bnr^2\pi$$

where n is the number of atoms in the nucleus and b is a constant having to do with the geometry of the arrangement. As a simple approximation in the case of copper, since the overpotential is relatively small, we can assume that the overpotential is directly proportional to the current density, I. This being so, the number of atoms forming a nucleus at a given current density, is proportional to one over the square of the current density, or

$$n \propto 1/I^2$$

Let m be the number of atoms deposited per unit of time per unit area which according to Faraday's law is proportional to I. Assuming the nuclei are formed in the first instant of time, the average number of nuclei formed at the start will be given by $m/n = N$. Thus N is proportional to $I/(1/I^2)$ or I^3. This line of reasoning, therefore, leads to the result that the number of nuclei formed at the start is proportional to the cube of the current density and as a result,

$$N_2/N_1 = (I_2/I_1)^3 \qquad [7]$$

Substitution of this value for N_2/N_1 in [5], gives

$$T_1/T_2 = (I_2/I_1)^{3/2}$$

or

$$T(I)^{3/2} = T_2(I_2)^{3/2} = T_1(I_1)^{3/2} = \text{a constant} \qquad [8]$$

But the average thickness of an electrodeposit varies directly with the number of coulombs $I\,t$, and accordingly,

$$T_1/T_2 = I_1 t_1 / I_2 t_2$$

If alternate substitutions are made for T and I in [8], using this last relationship, there results

$$t(I)^{5/2} = t_1(I_1)^{5/2} = t_2(I_2)^{5/2} = \text{a constant} \quad [9]$$

and

$$T_1/T_2 = (t_1/t_2)^{3/5} \quad [10]$$

If this theory is correct, we would expect that the relationship between current density and time and current density and thickness to take the forms shown in Eq. [8] and [9]. Likewise if a plot is made of the log of T_1/T_2 against the log of (t_1/t_2) the slope of the straight line, if it is a straight line, should be equal to 0.60 (3/5). The slope of the actual experimental line is 0.57 which is in excellent agreement with the theoretical value. A plot of Eq. [8] and [9] fits the experimental data fairly well but if $T(I)^{1.33}$ = a constant is plotted rather than $T(I)^{1.50}$ = a constant the smooth line through the experimental points shown in Fig. 4 is obtained and if $t(I)^{2.33}$ = a constant is plotted the smooth curve through the points of Fig. 5 results.

By assuming that the growth normal to the cathode is proportional to a power of the lateral growth, *i.e.*, $T = k(A)^{P/2}$ where p is an unknown power, and using the same type of procedure given above, we end up with the following relationships to replace [8], [9], and [10]:

$$T_1(T_1)^{3p/2} = T_2(I_2)^{3p/2} = \text{constant} \quad [8a]$$

$$t_1(I_1)\frac{3p+2}{2} = \text{a constant} \quad [9a]$$

$$T_1/T_2 = (t_1/t_2)\frac{3p}{3p+2} \quad [10a]$$

If $3p/3p + 2$ is set equal to 0.57, this gives $p = 0.883$ and substitution into [8a] and [9a] of this value gives $TI^{1.33}$ = constant and $tI^{2.33}$ = constant, with a better fit, as can be seen from the figures. It appears therefore on the basis of this evidence that the rate of growth normal to the cathode surface is almost but not quite a linear function of the rate of lateral growth. Because of possible errors in measurement and the appearance of exponential relationships, it may be that the first hypotheses is the correct one. Additional experiments will have to be performed in order to verify this. The hyperbolic power relationship shown here for copper is probably applicable to other deposits from simple solutions, at relatively low activation overpotentials. In the case of nickel which deposits at high activation overpotentials the number of nuclei formed will be very great (very fine crystals), and the technique used here for copper would be difficult to apply. Additional experiments are in progress in connection with the maximum stress in copper deposits in relation to these findings, which will be reported on in future papers.

Acknowledgment

The author would like to thank Mr. Wilfred Hung for assisting with the laboratory work, Mr. Russell Schoene for advice and assistance in connection with the electronic equipment, and Mr. Ed Reine for construction of the cell and other essential equipment.

Growth of Single Crystal Cuprous Oxide from the Melt and Luminescence of Cuprous Oxide

Richard S. Zucker

Astrionics Division, Aerojet-General Corporation, Azusa, California

ABSTRACT

A number of crucible materials were evaluated for melting Cu_2O. Only MgO appears to be sufficiently nonreactive for use in crystal growing. A melt of cuprous oxide contained in a magnesia crucible when cooled at a rate of 2.5°C per hour produced large single crystals. Attempts to accelerate growth by cooling at a rate of 13.5°C per hour produced only small polycrystals. A (100) seed cut from the single crystal along natural cleavage lines was used to pull a crystal from the melt by the Czochralski method. A tendency to grow off-axis resulted in beautiful subsurface facets of transparent ruby-red material. Two new forms of luminescence were observed during rapid cooling of solid cuprous oxide. From 1175° to 1145°C continuous light emission was observed in the yellow-green region. From 1125° to 975°C flashing points of light were observed in the same spectral region.

Polycrystalline cuprous oxide rectifiers have been in use since 1929 as instrument and power rectifiers because of their excellent frequency response, resistance to pulse damage, and exceptionally high reliability and long life. These have been prepared by partial oxidation of copper sheets of the desired shape. Recently large area single crystals have been formed by annealing of polycrystalline cuprous oxide (1). No reports of crystal growth from the melt have been observed in the literature. One observer in 1933 reported failure to obtain crystal growth by the Bridgman or hydrothermal techniques (2). This paper describes the growth of ingots of single crystal cuprous oxide by the Czochralski method and some interesting phenomena observed during these experiments.

Table I. Evaluation of crucible materials for melting cuprous oxide

Run No.	Crucible material	Results at 1230°C in presence of Cu_2O
1	Alumina[6]	Highly reactive, not satisfactory.
2	Tantalum	Highly reactive, not satisfactory.
3	Graphite	Highly reactive, Cu_2O reduced to Cu.
4	Molybdenum	Reactive, alloys with metallic copper.
5	Magnesia (sintered)[6]	Best of all materials tried, only slightly reactive with melt over long periods of time.
6	Crystolon 63[1] (silicon carbide, oxynitride bonded)	Wetting, partial reduction to Cu, scum on surface.
7	Cerac 4[2] (aluminum nitride 95% silicon carbide 5%)	Violet wetting occurs, N.G.
8	Cerac 6[2] (aluminum nitride 55% silicon carbide 45%)	Violet wetting occurs, N.G.
9	Magnesia (single crystal)[6]	Melting without wetting occurs for 5 minutes. May be OK.
10	Lecotherm ceramic[3]	Soaked right through crucible on melting.
11	Zirconium silicate[4]	Soaked right through crucible on melting.
12	Cerac 2[2] (boron disilicide)	Strongly reductive, glass binder in crucible reactive with melt.
13	Boron nitride[5]	Most violent reaction of all, evolution of gas and ejection of contents from crucible.
14	Thoria[3]	Entire contents reduced to copper, which permeated walls of crucible.
15	Calcium zirconate[3]	Entire contents reduced to copper, which permeated walls of crucible.
16	Quartz[7]	Violently reactive to form copper silicate.
17	Zirconia[6]	Wetting of crucible, but no violent reaction. Scum formation limits time available.

ture-set-point of the furnace controller) was used throughout this work. Baker Cu_2O powder was washed with benzene to remove the antioxidant (pine oil), dried, and weighed into the crucible. Argon (99.998%) or helium at 10 CFH was used for the furnace atmosphere. Subsequent experiments proved that the same results were obtained by weighing the unwashed Cu_2O directly into the crucible and removing the antioxidant by a vacuum heat treatment prior to melting. The crucible materials used are shown in Table I. About one-third reduction in volume of the powder is observed prior to melting, and a gradual change in color of the powder from ruby red to violet to black was noted. Norton RM-5480 Magnesia crucibles were used when pulling crystals using (100) seeds 5 x 5 x 25 mm cut from slow cooled runs. The seeds showed an approximate 70°32′ cleavage angle characteristic of (111) $\wedge$ (111) cuprite octahedrons. A natural crystal of cuprite may also be used as a seed. Slow cooling at a linear rate of 2.5°C per hour was easily obtained by automatic reduction of the power input to the furnace. Cooling at a rate of 13.5°C per hour produces polycrystalline material. At the melting point of cuprous oxide (1230°C) a change in apparent emissivity is evident, the melt appearing much brighter than the solid. The optimum pulling rate was found to be 1.75 cm/hr. The crucible was rotated at a speed of 10 rpm throughout all 28 runs in order to minimize uneven heating of the crucible. In addition, during some runs it became necessary to rotate the seed in an opposite direction at the same rate (10 rpm), making a total rotation rate of 20 rpm. The thermal fluctuations observed on the recorder during a typical run at equilibrium at the melting point of Cu_2O amounted to a maximum of 1.7°C, but the actual stepless controls of the furnace provide probably 0.2°C responsivity or better, if properly adjusted. A number of small crystals approximately 1 cm in diameter were easily grown using seeds. However, only one large irregular shaped crystal was grown which is shown in Fig. 4. The maximum diameter of this crystal was about 3 cm. The gross impurity in this crystal consisted of microscopic tree-like growths of metallic copper as determined by viewing a section of the crystal through a strong light. These apparently did not affect the single crystal of Cu_2O. In addition, some areas of this crystal were covered with a thin black surface layer of cupric oxide, CuO, which was easily removed in dilute hydrochloric acid before examination. No spectrographic or other methods were used to determine trace impurities, although from examination of the crucible attack after the run, it is strongly suspected that magnesium was picked up by the melt during a period up to several hours' contact with the molten cuprous oxide. The crystal, when viewed from the top during pulling, will show characteristic fourfold symmetry with light reflected off the (100) facets. These may not be present in all cases, as they seemed to predominate only when the crystal tended to grow off axis. Also, the crystal may tend to be lopsided due to freezing out of crucible reaction products on the crucible walls. Considerably more difficulty in growing cuprous oxide may be expected compared with silicon crystals due to the reactivity of the melt with magnesia. The single crystal character of the pulled crystal was confirmed by x-ray diffraction techniques (forward and back reflection Laue photographs).

After pulling is completed and during rapid cooling (approximately 100°C per min) of the remainder of the solid in the crucible, one or two luminescence phenomena may be observed, depending on the crucible material used. From 1175° to 1145°C the solid will instantaneously emit a burst of yellow-green light, L_1, which will diminish in intensity as the melt cools further, extinguishing at approximately 1145°C. No attempts were made to study the spectral characteristics of this high-temperature luminescence phenomenon, L_1. Over a much wider range of temperature (1125°-975°C) intermittent flashes of yellow-green light of 0.2-2 sec duration, L_2, will be observed. Cinespectrograph film measurements of the radiation of cuprous oxide over the temperature range 1125°-975°C show an absorption band in the yellow region of 0.56-0.60μ, and no emission lines or bands in this region are evident. The cinespectrograph used in this experiment consisted of a conventional slit, collimator, grating, lens, and film system. The film handling mechanism was a 35 mm cine camera permitting a sequence of spectra to be made at a rate of 10/sec. A lens in front of the slit serves as a light-gathering device for use with distant sources. It was not possible to focus this lens on the nearby source used in this experiment. Under these circumstances, therefore, emission lines from a blinking low-intensity point source on top of a 1200°-1300°K black body might easily have remained undetected. The emission wavelength is unknown at the present time. A more elaborate system would be required to determine the wavelength of emission of this radiation. These flashing lights appear at random throughout the solid and are especially intense wherever the Cu_2O has wetted (reacted with) the crucible walls. They remain of constant intensity throughout the above temperature range and then suddenly disappear at approximately 975°C. The high-temperature (continuous) light phenomena will be referred to as L_1, since it is the first to be observed on the cooling curve, and the lower temperature (flashing) light phenomena will be referred to as L_2 throughout the discussion. Both L_1 and L_2 can be repeated at will without any loss of intensity by reheating the contents of the crucible and cooling at the same rapid rate. Neither can be observed by cooling at a slow rate (10°C per min or less) or on the normal heating cycle.

Discussion

The best crucible materials are those which were compacted to the greatest degree during manufacture. To that extent the best results might be obtained from the use of single crystals of the respective materials, if available, by hollowing them out to form crucibles. On the basis of observed order of chemical reactivities with the melt, it might be predicted that crucibles made of beryllia would be less reactive than magnesia

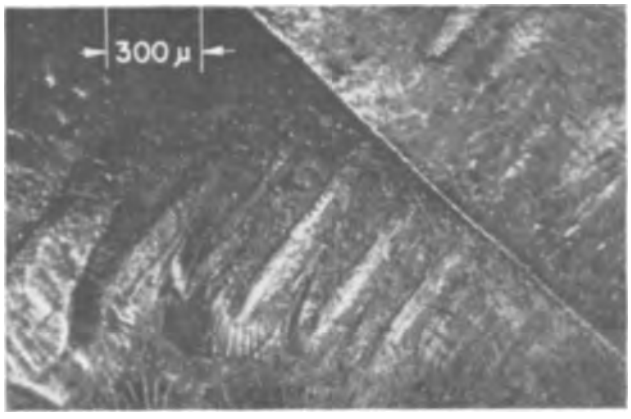

Fig. 1. Single crystal of cuprous oxide showing ridge along (100) sub-surface facet.

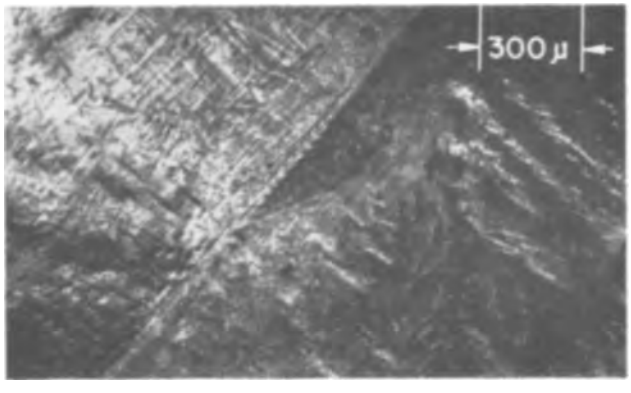

Fig. 2. Single crystal of cuprous oxide showing ridge along (100) sub-surface facet and light reflected off facet (left).

which is less reactive than alumina. Due to toxicity BeO crucibles were not tried, however. Crucibles made by pressing MgO slurries in a laboratory press were unsatisfactory due to porosity. However, use of a Pt crucible coated with MgO has been reported (3).

A microscopic view of the grown surface of a single crystal of cuprous oxide is shown in Fig. 1 and 2. The ridge along the edge of the facet is clearly shown here. The plane angle of the facet measured 90° ± ½°, characteristic of a (100) face (see Fig. 3). However, the vertex of this angle is inclined approximately 45° toward the seed axis indicating a shortening of the third cubic axis to form a rhombohedral pseudo-symmetry (4), although not clearly shown in Fig. 3 or 4. Cuprite (natural cuprous oxide mineral) belongs to the plagiohedral or gyroidal class of the isometric system because the faces of the general form (hkl) are arranged in spiral order. This class is rare among minerals and is represented, almost uniquely, by cuprite. It is interesting to note that because of this character, cuprous oxide may be expected to show circular polarization of light.

All material grown was p-type except one run made in a Ta crucible, which was strongly n-type and highly impure due to reaction of the melt with the tantalum crucible. It is suspected that almost degenerate doping with Ta resulted in this anomaly. Attempts to repeat this with 1% TaC (tantalum carbide) added to Cu_2O in a magnesia crucible resulted only in p-type material. Measurements made on typical crystals using silver paste to provide ohmic contacts are shown in Table II. These results show a hole mobility somewhat higher (about one order of magnitude) than that shown in the literature (5, 6).

A simple etch for revealing grain boundaries was 28% ammonium hydroxide for 5-30 min. For removing CuO deposits 3*N* HCl was found to be suitable.

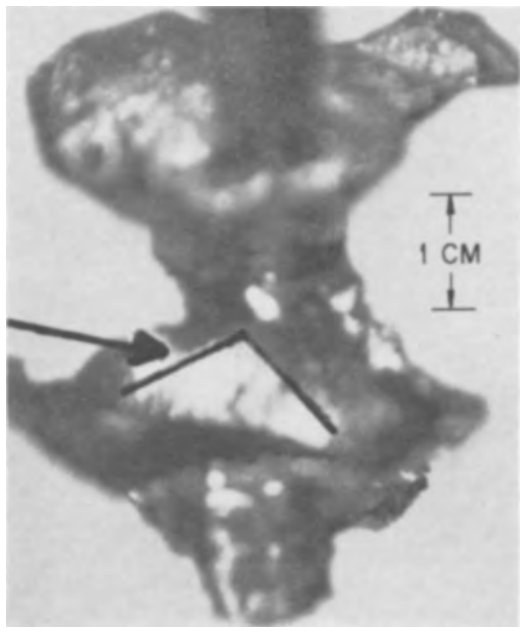

Fig. 3. Side view of pulled crystal of cuprous oxide showing light reflected off sub-surface (100) facet (arrow) and 90° plane angle (lines). Crystal was pulled out of melt rapidly to freeze the growth pattern, hence difference in diameter. The plane angle measured 90 ± ½°. Apparent distortion is due to perspective of the camera.

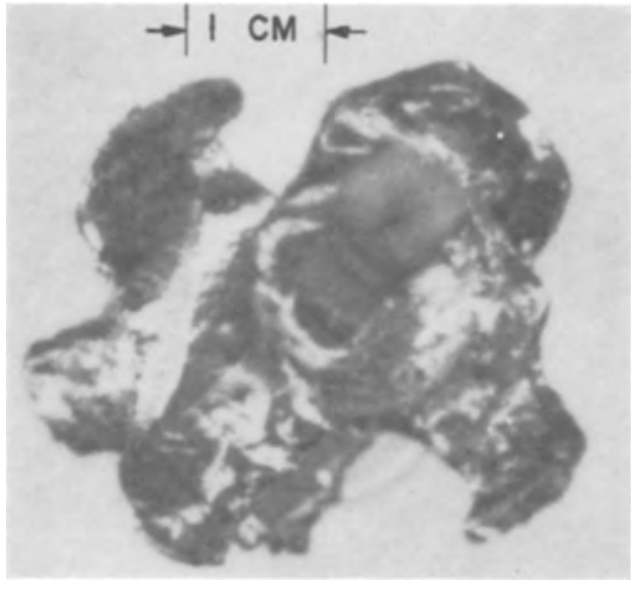

Fig. 4. Top view of Cu_2O crystal showing (100) seed

Luminescence

It is obvious from the limited data presented in this paper that a mechanism for the observed light emission cannot be put forth, particularly in view of the lack of data on the wavelength of emission. The two luminescence phenomena may not even be related in their mechanisms. Furthermore, both phenomena correspond to an "inverse thermoluminescence" since the emission is observed only on the cooling curve and not

Table II. Typical properties of single crystal cuprous oxide

Conductivity type	p
Resistivity, ohm-cm	4×10^3-16×10^3
Hall constant, cc/coulomb	2.1×10^6-2.2×10^7
Mobility, cm²/volt-sec	480-1300
Carrier concentration, carriers/cm³	3×10^{11}-3×10^{12}

on the heating curve. This is exceedingly difficult to explain. One is therefore forced to look for less obvious reasons such as possible phase changes in the system or the excitation of an impurity in the material. A brief review of the literature given below may be of interest at this point.

1. An anomalous vapor pressure curve has been reported for cuprous oxide (7, 8), because of the formation of a eutectic with cupric oxide. The vapor pressure of oxygen in equilibrium with liquid Cu_2O at 1230°C (mp of Cu_2O) is 0.6 Torr. This vapor pressure increases to 402 Torr in cooling to 1080°C (CuO-Cu_2O eutectic). Since the observed emission of L_2 is in the range of 1125°-975°C, this emission may in some cases be related to the CuO-Cu_2O eutectic at 1080°C, since it is known that CuO is present at least on the surface of the melt.

2. A rapid cooling rate of over 100°C per min is certainly a nonequilibrium condition, which may under these circumstances allow electronic transitions to occur which might otherwise be forbidden (9, 10).

3. Differential thermal analysis is indicated to explore the region 400°-1300°C to correlate light emission with perhaps extremely minute changes in the localized rate of cooling. No high-temperature phase changes have been reported for Cu_2O. However, crystallographic changes between 25° and 400°C have been reported (11) for cuprous oxide and similar changes for cuprous chloride (12).

4. The photoconductivity of Cu_2O is very complex (13), a maximum occurring at 0.57μ but complicated by "steps" in the absorption edge due to multiple level transitions, particularly in the yellow and green series of exciton absorption spectra (14) at 77.3°K. It is not known how this might affect the results observed.

In conclusion, it may be said that more precise measurements of the radiation observed will be required to resolve the exact nature of this luminescence. This may be rather difficult, in view of the transient as well as high-temperature nature of the phenomena.

Acknowledgments

The author is pleased to acknowledge the technical discussions of Dr. P. N. Russell and Dr. R. H. McFee. Interpretations of the cinespectrograms by Mr. Carleton W. Clench are greatly appreciated.

Poisoning and Gettering Effects in Silicon Junctions

E. J. Mets

Rectifier Components Department, General Electric Company, Auburn, New York

ABSTRACT

A study was made to obtain an understanding of the factors involved in the "poisoning" phenomena which are responsible for high reverse currents in silicon junctions. A tentative model has been proposed which describes the conditions by which fast diffusing metal impurities can precipitate within junction regions under certain high-temperature ambients and yet not under others. Oxygen appears to be a significant factor which can control the degree and location of such metal precipitation. The role of oxygen was investigated in its relation to impurities and defects in silicon. Its importance was demonstrated by copper-oxygen reactions, oxygen tie up complexing to form SiO_4^+ donor states, and by the effect of induced dislocations.

Considerable effort has been applied to the study of soft reverse characteristics of p-n junctions as indicated by excess reverse current below their normal avalanche breakdown voltage. The origin of this high leakage current is believed to be localized high electric fields caused by precipitated metal particles within the junction region. Goetzberger and Shockley (1, 2) have shown that metals with temperature dependent solubilities in silicon, such as Cu and Fe, can form precipitates through which current flows by Zener tunneling as a result of the high fields. However, certain diffusion processes do yield devices which have good electrical characteristics whereas other high-temperature processes cause degradation of junctions. Prior to this work no explanation as to why and how these precipitates occur in the bulk and junction regions of Si has been offered. As these undesired impurities are introduced into silicon to some degree by all such processes, there must be some controlling factors which reduce or prevent these impurities from collecting in junction regions in some cases but not in others. It is the purpose of this study to investigate those conditions which lead to the poisoning phenomenon and to establish a tentative model by which such precipitates locate in bulk silicon.

Previous observations.—It has been observed that diffused p-n-p structures as formed by Ga sealed-tube techniques yield "hard" breakdown (*i.e.*, devices which show negligible poisoning effects but exhibit avalanche breakdown characteristics). Subsequent oxidation procedures cause these reverse characteristics to become "soft" or poisoned. Typical characteristics are shown in Fig. 1.[1] Later phosphorus diffusion generally causes a poisoned unit to return to its original characteristics. The following discussion of the effects of each of these

[1] All devices were surface contoured to confine the avalanche regions to the body rather than the surface of the device. Further information concerning this technique can be found in a paper by R. L. Davies and F. E. Gentry entitled, "Control of Electric Fields at the Surface of p-n Junctions," *IEEE Transactions on Electron Devices*, July, 1964.

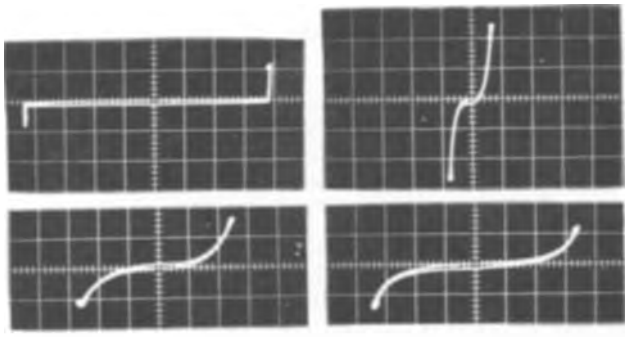

Fig. 1. Typical reverse characteristics of Ga diffused p-n-p junctions showing relative effect of cooling rate exposure to oxygen ambient at 1200°C: Vertical axis 5 ma/div; Horizontal axis 200 v/div. (a) (top left) as diffused; (b) (top right) furnace cool, 250°C/hr; (c) (bottom left) slow cool, 15°C/hr; (d) (bottom right) quenched.

three high-temperature operations results in a model which describes mechanisms that affect precipitation of these impurities in junction regions.

The formation of p-n-p structures by the normal sealed tube technique employs a Ga source along with silicon wafers which are sealed in a quartz capsule and back filled with argon through a liquid nitrogen trap. Avalanche-type electrical characteristics are ascribed to three possible effects. (*A*) The system is clean, free of poisoning impurities; (*B*) simple, glassy phase gettering occurs on the silicon surface; (*C*) fast diffusing impurities are removed by surface reactions which occur due to a lower partial pressure of oxygen in the sealed tube. In practice the first two are not probable. Deliberately poisoned Ga p-n-p structures, sealed in argon and heat-treated without a Ga source, are brought back to their original sharp characteristics with a significant increase in minority carrier lifetime. As no liquid phase is present, some other mechanism than glassy phase gettering must take place. This is probably the same means by which good p-n-p structures are originally formed. At the diffusion temperature (1250°C), metallic impurities are considered to be present from the source, quartz, gas ambient and on or in the silicon. The solid solubility of these impurities in silicon will be in equilibrium with phases present (such as oxides or gas) and dependent on temperature. On cooling, precipitation of these metallic impurities can occur because of decreasing solubility. A driving force to the surface is necessary to prevent precipitation in the vicinity of the junction. Such surface reactions can take place under a low partial pressure of oxygen by forming stable compounds of an oxygen complex. It has been shown by Schwuttke (3) that impurities such as copper will locate preferentially at regions of high oxygen concentration. This migration of residual oxygen in the silicon toward the surface would be a sufficient driving force for the removal of these fast diffusing impurities.

Under conditions of open-tube oxidation, silicon is exposed to temperatures 1100°-1250°C under wet or dry oxygen ambient to form an oxide phase on the silicon surface. Simultaneously, oxygen diffuses into the silicon along with undesired impurities. On cooling, precipitation of these impurities will occur at structural defects in the bulk with the size and location of the precipitates governed to some degree by the cooling rate. Sites of high oxygen concentrations can be formed in the bulk, thus preventing the mechanism of transport of fast diffusing impurities to the surface.

In fabricating p-n-p-n devices, phosphorus diffusion of the n-type emitter junctions often will restore p-n-p units which have been previously poisoned by the oxidation-mask step. In this two-step phosphorus diffusion process, first a phosphorus-silicate glass is formed under nitrogen or oxygen. Here an apparent liquid phase gettering effect (1) takes place. Normally, after this first predeposition step, the glass formed is removed prior to a higher temperature diffusion anneal under oxygen. It can be assumed that under these conditions liquid phase gettering is not present but rather some other mechanism is responsible for the prevention of downgrading. This might be explained by high surface doping concentrations which strain the lattice and thereby form dislocations at the surface. Prussin (4) and Quiesser (5) have shown that the stress introduced by solute contraction of phosphorus and boron in silicon is sufficient to generate dislocations. With these dislocations present, a "sink" can be formed, trapping fast diffusing impurities as "atmospheres" of the dislocations or by complexing with oxygen in these regions.

A poisoning model.—The model suggests that a controlling relationship exists between the gas ambient (particularly oxygen) and the type of diffused donor or acceptor impurity in silicon. It appears that the degree and location of such precipitation of fast diffusing metal impurities is influenced by the oxygen movement in the silicon. Clustering or precipitation of these impurities will occur at sites of high oxygen concentration, forming oxygen complexes and thus reducing the metal impurity level in other regions of the silicon. Oxygen will form atmospheres around diffusion induced dislocations thus depleting adjacent areas of oxygen and metallic impurities. Considerable evidence has been obtained to support this concept. These experiments have been based on copper-oxygen reactions, oxygen complexing to form SiO_4^+ donor states and surface induced dislocations.

Experimental

In an effort to determine the source of contamination, various parameters of the open tube systems were evaluated. Ga-diffused p-n-p wafers were chosen for this initial study. These structures offered good initial reverse avalanche-type characteristics which are sensitive to the poisoning phenomena.

Gallium diffused p-n-p structures, which were formed in chemically polished 20-22 ohm-cm n-type Si, generally had a junction depth of 3 mils and a base region of 3 mils so that avalanche voltages of 700-900v were obtained. Wafers were pelletized to a diameter of 0.640 in. and subsequently edge beveled to a 6° angle to eliminate surface effects. In all tests only avalanche type p-n-p wafers were selected for evaluation. Cleaning prior to heat-treatments were kept the same for all tests, except when specifically altered to study the effect of different cleaning cycles. This standard cleaning consisted of hot solvents, hot alkaline cleaning; HF:HNO_3 etch modified with iodine, and HNO_3 boil. Each step was followed by a large number of deionized water rinses.

From these initial experiments it was established that poisoning of the reverse characteristics of Ga p-n-p's could be accomplished at temperatures greater than 700°C under an oxygen ambient. With increasing temperatures, up 1250°C, there appears to be no significant correlation between temperature and the degree of electrical characteristic softening. This effect is observed regardless of prior pellet cleaning treatments and special care observed to prevent contamination by the furnace and the quartz tube, the latter being coated with a sodium-silicate glass to form a gettering sink on the surface. The use of an ultra-pure ambient oxygen did indicate some improvement in reverse currents.

Under a given set of experimental conditions, cooling rate of the p-n-p structures from 1250°C in oxygen did show pronounced effects in the degree of softening observed. Typically, a quenching rate such as 500°C/min in an oxygen ambient causes the least degree of poisoning whereas a furnace cool of 250°C/hr from 1250° to 900°C resulted in the highest degree of poisoning. By approaching equilibrium conditions with a cooling rate of 3-7°C/hr from 1250° to 900°C, harder avalanche breakdowns resulted than the furnace cool.

These typical reverse characteristics are shown in Fig. 1. Interrupted cooling was carried out by furnace cooling from 1250° to 1000°C and holding for 15 hr, then moderately quenched to room temperature by pulling the pellets out of the furnace slowly. The purpose of this experiment was to form SiO_2 precipitates as described by Kaiser (6); these precipitates should serve as complexing sites for metallic impurities. This process did result in considerable improvement over the normal furnace cool with reverse characteristics similar to that obtained by rapid quenching.

The most significant parameter was that effect observed by different gas ambients. No downgrading resulted at any temperature up to 1200°C when exposed to an argon ambient and allowed to furnace cool. On quenching some small degree of softening occurred. From these results it was felt that downgraded units could be "gettered" back under these conditions. Such p-n-p units obtained from various conditions of heat-treatment were sealed in a quartz ampoule under argon, heated at 1200°C for 1 hr, and allowed to furnace cool. In every case avalanche type characteristics were obtained with voltage 10-20% less than the original values. Lifetime values were increased by a factor of two to four above the initial values immediately following diffusion (hereafter defined as "as diffused"). Poisoning was also prevented by exposure of the p-n-p's in a hydrogen ambient at 1000-1100°C. However, electrical characteristics previously softened by oxidation treatments were severely poisoned on exposure to hydrogen. Under nitrogen at temperatures above 800°C, significant softening occurred.

Effect of Oxygen with Impurities and Defects in Silicon

The results from preliminary experiments indicated the oxide phase and/or oxygen ambient have some influence in the transport mechanism of impurities in Si. Motivated by these results, further investigations were made to determine the role of oxygen and its relation to impurities and defects in Si. In these experiments the behavior of oxygen was evaluated by converting the dissolved oxygen into SiO_4^+ donor states. The effects of diffused Cu and surface induced dislocations during oxygen diffusion and the subsequent effect on this oxygen-formed donor level was the basis of evaluation.

Oxygen complex (SiO_4^+).—Oxygen when diffused into Si can form donor states under suitable time and temperature conditions (7). These donor states, SiO_4^+, appear to form by association of groups of four oxygen atoms with one Si atom at a temperature of 450°C and reach a maximum level in about seventy hours. The degree to which the donor level will form is dependent on the dissolved oxygen. Logan and Peters (8) report the maximum solubility of oxygen in Si at 1250°C to be 3×10^{17} at./cm^3, which offers a maximum donor level of 1×10^{15}/cm^3 (8).

Experimentally, oxygen was diffused into polished p-type Si slices of 30-100 ohm-cm resistivity (net impurity concentration less than 3×10^{14} at./cm^3). One half of this lot was sealed in a quartz ampoule under argon, and the other half was used as a control lot. In the sealed tube, a portion of the slices had the oxide removed, and the other half the oxide was left intact. These were heat treated at 1250°C for the same periods of time as they were originally oxygen diffused, *i.e.*, 30 min to 3 hr. After this heat-treatment they were annealed at 450°C for 72 hr along with control slices which were not heat treated previously in argon.

From microscopic examination of stained cross sections, n-type layers were observed on the control slices to depths up to 1.5 mils depending on resistivity of the starting material. Those slices which were argon heat-treated with the oxide removed did not show any conversion. Silicon with the oxide left on converted, but to a lesser degree.

This effect was also observed when cooling rates that approached equilibrium conditions were used following open tube oxidation. In an earlier investigation, we had found that cooling rates of 3-15°C/hr, from 1250° to 900°C, prevented the formation of SiO_4^+ complexes. From these results it was postulated that this cooling rate would permit oxygen to form stable precipitates (SiO_2) or possibly diffuse to the surface of the slice. Under these conditions, therefore, the oxygen is tied up or reduced to level below which the conversion to donors is detectable.

Role of copper and oxygen.—The relationship between oxygen and the poisoning impurity should be determined. It appears that some residual oxygen is required to form favorable sites for nucleation and precipitation of such impurities away from the junction region but near or at the surface. The presence of an oxide phase on Si (always prevalent under an oxidizing ambient) would allow such precipitation to occur internally within the Si at many possible structural defect sites. The size of such precipitates would be governed by the precipitation kinetics of the species involved.

Some idea of these kinetics may be gleaned by examining the effects of Cu and oxygen such as offered by the investigations of Schwuttke (3). Results from that study show Cu to precipitate at regions of high oxygen concentrations with the possible formation of copper-oxygen complexes. It was also shown that dissolved oxygen will form atmospheres around dislocations thereby depleting adjacent areas of oxygen. Therefore, the presence of high concentrations of diffused oxygen should be a favorable location for the precipitation of impurities such as Cu during cooling.

As the normal impurity level of a species such as Cu is too low to be resolved by infrared examination, Cu was diffused into Si to decorate dislocation (9) sites with and without diffused oxygen. By observing the degree of decoration, as to size and shape, and to the level at which it occurs, a correlation with diffused oxygen appeared possible.

Chemically polished 20 ohm-cm n-type Si was oxygen diffused at 1250°C with a maximum surface concentration of 3×10^{17} at./cm^3. The time of diffusion was adjusted so that complementary error function gradient of probable oxygen would result in a level $\sim 1 \times 10^{14}$ at./cm^3 at a distance of three mils from the surface. A shallower diffusion was also made to the same level one mil from the surface. Along with controls containing only residual oxygen, Cu was diffused at 900°C for 10 min and rapidly quenched to room temperature.

By polishing in 0.2 mil increments from the surface and examining the slices with infrared, Cu was found to be precipitated in the high oxygen concentration regions near the surface. Unlike the control slices which showed fine dispersion of decorated dislocation tails, the samples containing oxygen were decorated by copper in the form of star-like clusters. This is similar to that observed by Schwuttke.

Effect of dislocation traps.—Realizing the effect of dislocations as trapping sites for oxygen and impurities such as copper, it was felt that such a site, if it can be introduced at the surface during diffusion, would offer a sink for fast diffusing impurities. The effect of cold working, introducing a stress, and subsequent heat-treatment to elevated temperatures would result in the formation of dislocations. Such line defects must be terminated, either by a surface, a grain boundary, or they may form closed loops. We could expect that in single crystals they would either propagate through the crystal, or form a loop with one surface. If such terminated loops could be produced at the surface, trapping at elevated temperatures of these impurities with an affinity for forming "atmospheres" with dislocations would appear possible.

It is known that a certain amount of damage is introduced into the surface of Si by impact loading, resulting in a stressed surface condition. On heating to some specific temperature, this stress will be re-

lieved with some resultant plastic deformation and subsequent formation of dislocations. Beveled Ga-diffused p-n-p pellets were stressed in this manner by sandblasting the surfaces lightly with a fine grit of 10μ size. Alternate surfaces and both surfaces of beveled pellets were sandblasted to evaluate directional effects of gettering. These units, along with control pellets were exposed to the standard oxidizing conditions of 1200°C for 30 min and furnace cooled. Etching the pellets first in HF to remove the oxide followed by 20 sec in CP-6 modified with iodine was sufficient to obtain the original avalanche characteristics on all the sandblasted units, regardless of the side on which the dislocations were introduced. Control pellets were badly downgraded.

Further experiments were made under longer oxidizing conditions up to 5 hr at 1250°C, always resulting in unpoisoned units. If the sandblasted pellets were quenched very rapidly from any of the oxidizing conditions, downgraded characteristics were obtained. However, reheating at 1200°C in oxygen for 30 min and furnace cooling restored the original electrical characteristics.

To evaluate trapping ability of the introduced dislocation "sponge" at the surface, Ga diffused p-n-p wafers were Cu diffused at temperatures of 900°-1200°C under oxygen and furnace cooled. No poisoning occurred with those pellets having surfaces in a lapped or sandblasted condition. By infrared examination, Cu precipitation effects could not be observed whereas the control slices always showed a large degree of either finely dispersed or gross precipitates in the crystal. Quenching of Cu diffused p-n-p wafers from 900°-1200°C under oxygen always resulted in severely poisoned units. Fine dispersed decorated dislocations were always present in the crystal and subsequent removal of this precipitation was accomplished to a large degree by reheat-treating at 1200°C followed by a furnace cool.

The rapid mobility of copper was first demonstrated by the following experiment: One side of a p-n-p wafer was chemically polished and the other side was finely sandblasted. Then drops of $CuNO_3$ solution were placed on the polished side with care being exercised to keep the sandblasted side free of copper. Next the slice was heat treated in oxygen at 1000°C for 30 min and quenched at a rate of 500°C/min. No downgrading of the reverse characteristics resulted. Moreover, after chemically polishing the sandblasted side, no copper precipitation was observable by infrared examination. However, p-n-p slices that were chemically polished on both sides and subjected to the same process had electrical characteristics which were badly softened and also showed heavy copper precipitation throughout the slices.

Surface induced dislocations on copper and oxygen.— It has been shown in this study that surface induced dislocations have a definite effect in preventing the downgrading phenomena, both in the formation and oxidation of p-n-p units. Copper decoration and infrared examination showed that impurities such as Cu are removed to a very significant degree by dislocation effects. However, it is possible that oxygen also contributes to this mechanism by forming atmospheres around these dislocations sites at the surface.

Oxygen was diffused into p-type Si having chemically polished, sandblasted and lapped surfaces with resistivities of 30, 54, 63, and 100 ohm-cm for 3 hr at 1250°C under wet O_2. One lot was allowed to furnace cool (250°C/hr) and the second lot was quenched to room temperature. After removing the oxide, both lots were annealed at 450°C for 84 hr. These were cross sectioned and stained to reveal any n-type conversion caused by oxygen-silicon interaction to form SiO_4^+. These results are illustrated in Fig. 2. Typically, n-layers were formed in the polished wafers, in some cases with a thin p-layer at the surface. In the lapped and sandblasted wafers, a thin 0.1-0.2 mil but nonuniform n-layer formed at the surface. This thin surface n-region was delineated by a p-type layer and another deeper n-region. Only a p-region more highly doped than the base was observed under the shallow n-surface layer in the sandblasted samples. In the resistivity range tested, no significant difference was observed between the type of structure formed by quenching or furnace cooling. By re-annealing at 575°C for 20 hr, the deep n-type conversion layers formed in the polished and lapped slices were removed. Under these conditions, the SiO_4^+ complex is disassociated. The thin n-surface layer on the lapped and sandblasted slices could not be annealed out at this temperature.

Fig. 2. Typical effect of various surface treatments on the formation of the SiO_4^+ complex from oxygen diffused into 54 ohm-cm p-type Si at 1250°C for 3 hr, 250°C/hr cooling rate; after 72 hr anneal at 450°C; beveled X-section depth magnified 10X. Microscope 60X.(a) Chemically polished surface.

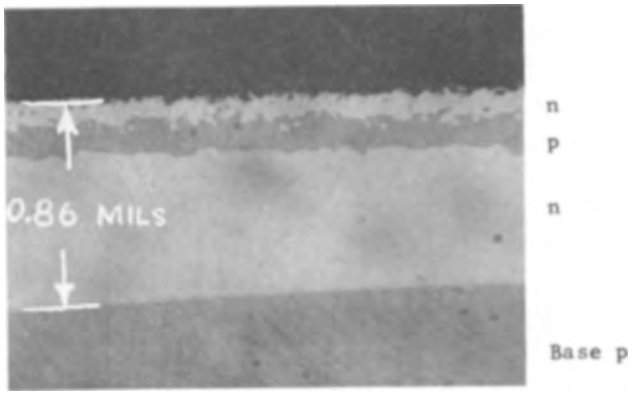

Fig. 2b. Lapped surface

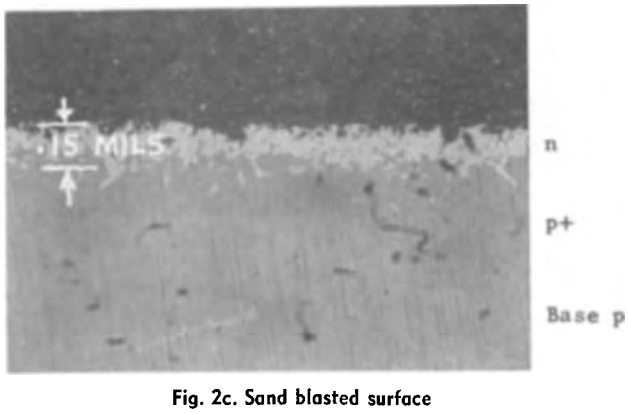

Fig. 2c. Sand blasted surface

The previous experiments were repeated except that Cu was diffused into the oxidized Si prior to annealing at 450°C. The diffusion of Cu was carried out under two temperature conditions; one at 900°C for 15 min and another at 1200°C for 20 min, to obtain different copper solute levels in the Si. A sig-

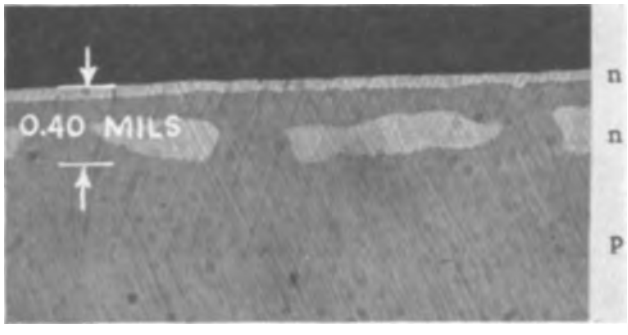

Fig. 3c. After Cu diffusion, 1200°C, quenched

nificant effect of Cu was observed in the donor formation after annealing at 450°C.

Typical results are shown in photomicrographs of Fig. 3. Directly after Cu diffusion from 1200°C, both quenched and furnace cooled polished slices showed an n-layer ~ 0.1 mil deep not observed on slices diffused with Cu at 900°C. After annealing at 450°C, n-layers formed on polished control slices (no Cu) and were partially eliminated on those which were Cu diffused. The effect was more pronounced when the Cu was quenched from diffusion temperatures. No significant effect of Cu on the oxygen formed donor level was found between sandblasted and lapped wafers as compared to polished control slices.

Oxygen-transport concept.—The concept of fast diffusing impurities locating at the silicon surface during nonoxidizing heat-treatments was further tested qualitatively. Wafers of 20 ohm-cm n-type silicon were prepared in three lots having chemically polished, lapped, and sandblasted surface finishes. These were oxidized in wet O_2, forming 12,000Å of oxide on their surfaces. The oxide was removed from one half of each lot and, along with control wafers which were not previously oxidized, they were Ga diffused in the standard sealed tube process. Typically, p-n-p junctions formed through the oxide on the polished slices showed downgraded reverse characteristics. Those formed without an oxide present had hard breakdowns, but the breakdown voltages were slightly less than the standard control slices. Sandblasted and lapped wafers with the oxide left on showed the same hard avalanche voltage breakdown as the control slices; whereas, those units with sandblasted surfaces from which the oxide had been removed, showed slightly higher voltages.

Discussion

The purpose of this investigation was to show that a relationship exists between oxygen, the oxide phase, and fast diffusing metal impurities in terms of both the degree and location of metallic precipitation in silicon. The effects of Cu used as an example in these experiments does not necessarily indicate that other fast diffusing metal impurities behave in the same manner. Dash (10) has shown that Au does not offer any observable precipitation. The precipitation kinetics of other metals such as Fe and Ni can be different than that of Cu. However, results have been obtained here which show that such precipitation in the bulk can be effectively prevented without glassy-phase surface gettering. The experiments with Cu and its effects in repressing the SiO_4^+ donor complex indicates ion-pairing as a possible mechanism. The SiO_4^+ donors formed as a result of diffused oxygen can be used as a sensitive measure of the oxygen level and can indicate effectively changes that take place within the silicon.

The effect of Cu on oxygen donor formation on chemically polished slices may be explained as follows. From photomicrographs of Fig. 2a and 3a, we can see the typical donor layer which is formed by oxygen conversion with no added Cu present. In some cases a p-layer has formed on the surface. This can be depicted by the concentration profile diagram of Fig. 4.

From the appearance of the layers formed, the p-type surface layer is assumed to be the result of boron pile-up during oxidation. If this pile-up at the surface exceeds the concentration of donors formed, a p-layer will predominate.

With Cu subsequently diffused into the Si, depending on its solubility level, and whether it was quenched or furnace cooled, the original donor level would be reduced by the tie-up of diffused oxygen and Cu. The p-layer which forms in the lapped wafers can be attributed to boron pile-up. The formation of the shallow n-type surface layer on both the lapped and sandblasted surfaces is probably due to the reaction of oxygen and dislocations. Thus an indication of the depth of damage and of the magnitude of dislocation formation was provided. Sheet resistance measurements indicate this level to be ~ 5 x 10^{15}/cm^3. The absence of oxygen-formed donors in sandblasted specimens might be the result of greater boron pile-up to a level high enough to exceed the donor formation.

To examine more closely the effect of damage to the surface of Si, 2000 ohm-cm, p-type polished wafers were scribed with a diamond pencil leaving a number of scratches on the surface. These were oxidized and annealed at 450°C. As shown in Fig. 5, the depth of

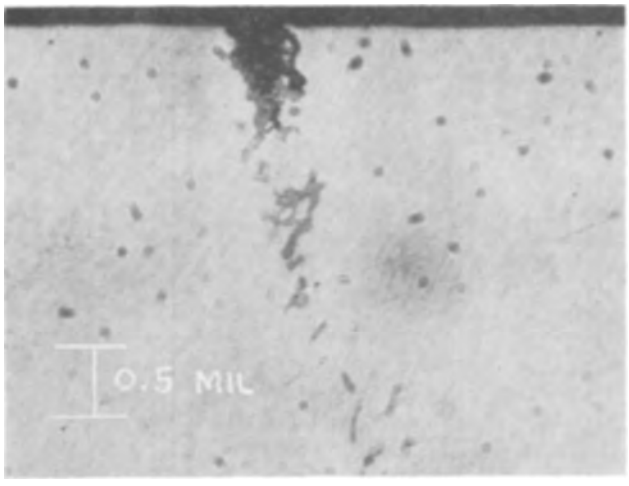

Fig. 5. Photomicrograph showing effect of damage due to scribe mark on polished 2000 ohm-cm p-type Si; after 1 hr oxidation at 1250°C and 450°C anneal for 72 hr; beveled X-section depth magnified 10X. a. Dark p-type regions within oxygen diffused and converted n-region. 75X.

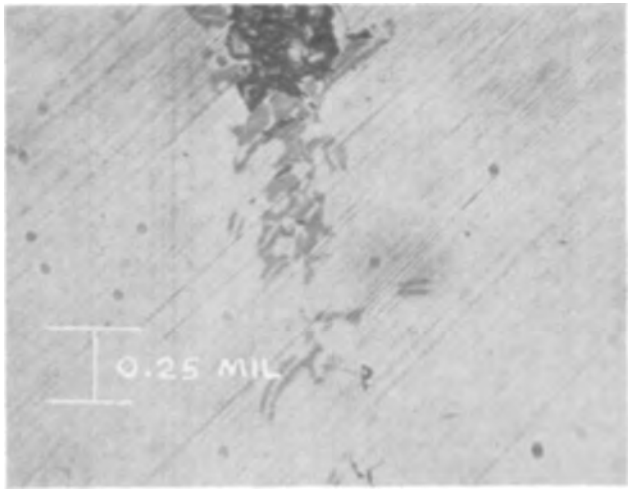

Fig. 5b. Enlarged view showing probable dislocation loops of high oxygen content within depleted dark stained regions. 150X.

the scribe mark was approximately 0.5 mil, but damage and subsequent dislocation formation extended to 2.5 mils. In this region of damage, darkly stained p-regions are present in the background of the n-type region where the latter is obtained because of oxygen conversion. These p-regions are assumed to be areas depleted of oxygen and are adjacent to dislocation loops containing atmospheres of oxygen removed from the depleted regions. From this observation, it is possible that the p-layer, assumed to be due to pile up, is also formed by the depletion of oxygen by reaction with surface induced dislocations.

The evidence indicates that oxygen can react with dislocations thereby forming shallow nonuniform n-type layers on the sandblasted and lapped surfaces. Further, there seems to be a reaction of Cu with oxygen as shown by their effects on the SiO_4^+ complex in polished wafers.

With the effect of a dislocation "sponge" at the surface, reheat-treating under oxygen of previously quenched wafers is of considerable interest. First it indicates that the introduced dislocations are not annealed out even with repetitive temperature cycles up to 1250°C. In addition the recovery of quenched and poisoned p-n-p units shows that fast diffusing impurities are responsible for the downgrading phenomena. A period of time, slower than rapid quenching, is needed to permit the diffusion of these impurities to the dislocation "sponge." As oxygen cannot out-diffuse in the time of cooling evaluated and because the SiO_2 phase is always present on the Si surface, the introduced dislocations must be the major influence in the prevention and recovery of poisoned p-n-p structures.

It was also shown that a metal impurity such as copper can be transported from bulk Si, probably to some surface layer by heat-treatment under argon ambients. Such an ambient also resulted in depletion of the diffused oxygen level from the body of the silicon. The recovery of the reverse characteristics of Cu poisoned p-n-p junctions by this argon treatment would indicate that oxygen-copper complexing or tie-up occurs at or near the surface. Infrared examination of these structures support this view.

An explanation may be offered concerning the effect of cooling rate in an oxygen ambient. In quenching, impurities can precipitate at sites throughout the wafer in a more dispersed form. Under a moderate cooling rate such as a furnace cool, metal impurities can coalesce because of their rapid mobility; however, oxygen levels would not be significantly affected by precipitation or agglomeration. A cooling rate approaching equilibrium conditions affects the oxygen level either by outdiffusion or by precipitation as indicated by the absence of oxygen formed donors. Although the metal impurity level in the bulk Si can be assumed to be the same in all these cases, the resulting reverse leakage currents are not. The lower leakage observed with quenched samples indicates that the over-all effect of more finely dispersed precipitates is less than that of larger coalesced precipitates. If equilibrium cooling resulted in a depletion of oxygen levels by outdiffusion (because of precipitation as SiO_2 at the surface), a significant reduction in reverse currents should be achieved. Therefore, it appears that coalescence of oxygen occurs within the bulk during such a slow cool thus permitting oxygen-metal impurity complexing. Similar reverse currents are obtained to those of slow cooling by holding the slices at 1000°C for long periods of time. Precipitation of oxygen as SiO_2 here causes a reduction in oxygen level within the body of the silicon.

Under nitrogen ambients, downgrading is probably due to a nitride formation. No explanation is offered for the serious poisoning effect of hydrogen on p-n-p slices which have been exposed to oxygen.

Acknowledgments

The author wishes to acknowledge the effort of R. I. Jurgensen, who helped plan and carry out the many experiments in this study and to F. E. Gentry for many helpful discussions and for reviewing this work.

Manuscript received Oct. 22, 1964. This paper was presented at the Washington Meeting, Oct. 11-15, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

The Preparation of Homogeneous and Reproducible Solid Solutions of GaP-GaAs

M. Rubenstein

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

Solid solutions of GaP-GaAs were prepared using the sealed tube iodine transport method. The initial charge was iodine, powdered GaP, and powdered GaAs. These powders were ground and treated with aqueous hydrochloric acid to remove the damaged layers. The resulting GaP-GaAs solid solutions were more homogeneous than other such series of solid solutions which are described in the literature. Polycrystalline sound masses as well as single crystals with reproducible and predictable compositions can be produced using these treated powders.

Solid solutions of two or more compounds or elements can offer a method of changing many characteristics of either of the original constituents. It has been shown that silicon and germanium exhibit continuous solid solution and continuous variation of energy gap over the entire range of compositions (1-4). This type of semiconductor investigation was extended to the III-V compounds (5-10). Investigations on the system GaP-GaAs began in 1955 with Folberth's work (5) and were continued by other workers (11-15).

This paper demonstrates that solid solutions having formula $GaP_{(1-x)}As_x$ (the system GaP-GaAs) can be prepared more homogeneously than previous papers have indicated (13, 14), and the primary reason for this homogeneity is due to the use of powders as the initial charge. The solid solutions prepared in this work involved the sealed tube iodine transport technique (11-17).

Preparation of $GaP_{(1-x)}As_x$

First, the preparation of the solid solutions with formula $GaP_{(1-x)}As_x$ will be sketched quickly since this method has been described in detail (13, 14). Then a detailed description of the preparation of the charge (the powdered GaP and GaAs) will be presented.

The initial charge consists of iodine, GaP, and GaAs. The amount of iodine is such that a maximum pressure of 3 atm would be reached in the ampule if the average temperature were 1000°C, if all the iodine were converted to iodine atoms, if the iodine atoms underwent no reactions, and if no iodine were lost during the evacuation of the ampule. The GaAs and GaP powders (a total of 2g) and I_2 were placed in the ampule (having a volume of about 70 cc) as indicated in Fig. 1. The ampule with the charge was evacuated using a mechanical pump. The ampule was cooled using an ice-water bath to prevent excessive loss of I_2 during evacuation. A liquid nitrogen trap was placed between the pump and ampule to prevent hydrocarbons from getting into the ampule. The pressure in the ampule was about 4×10^{-2} Torr.

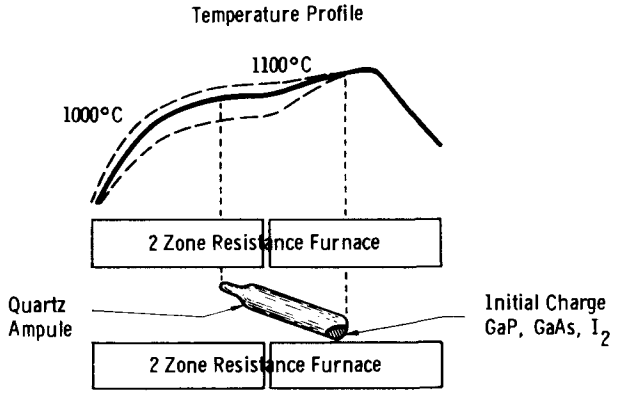

Fig. 1. Diagrammatic representation of ampule in furnace with temperature profiles.

The ampule was sealed off and placed in a temperature gradient such that the maximum temperature was 1100°C and the minimum temperature was between 1090° and 900°C. The time for transport varied between 15 min to four days. No attempt was made to seed the transported material.

Preparation of the Powdered GaP *and* GaAs

The GaP used in the charge for the iodine transport of $GaP_{(1-x)}As_x$ was material grown from a stoichiometric or nearly stoichiometric melt (this GaP was horizontally zone refined at about 1500°C at phosphorus pressures between 10 and 20 atm). The GaP was then crushed in a Plattner's diamond mortar and pestle, ground in a porcelain mortar and pestle, sieved, and then treated with aqueous hydrochloric acid (HCl) to remove contaminants introduced in crushing and sieving and to remove the damaged layer.

Since phosphine is produced when one grinds GaP (this compound is easily identified by its odor), the gallium (or the GaP) must undergo some change. Either Ga_2O_3, Ga_2O, or $GaPO_4$ is formed. Of course, any combination of these three could be produced. Some of the possible reactions which can be written are as follows

$$2GaP + 3H_2O \rightarrow 2PH_3 + Ga_2O_3 \quad [1]$$

$$2GaP + 3H_2O \rightarrow 2PH_3 + Ga_2O + O_2 \quad [2]$$

$$GaP + 4H_2O \rightarrow GaPO_4 + 4H_2 \quad [3]$$

$$GaP + 2\,O_2 \rightarrow GaPO_4 \quad [4]$$

Although GaP is usually considered a rather inert solid, one or more of these reactions could proceed at a damaged layer especially since grinding can produce large local thermal spikes in a material. It is also possible that GaP seems to be rather inert because the oxidized surface film protects the layers under this film.

It is difficult to prove which of these reactions most accurately describes this system since the grinding of GaP does not produce much product. It is fortuitous that a change in body color of the GaP on grinding is quite noticeable to the eyes, and it is also fortuitous that the olfactory nerves are quite sensitive to PH_3. The limit of perceptibility to PH_3 is 1.5-3 ppm, the limit for "serious effects after several hours" is 7 ppm, and the threshold limit is 0.05 ppm (19).

The treatment of the GaP with concentrated hydrochloric acid is an interesting reaction chemically. GaP is attacked very slowly by concentrated hydrochloric acid. GaP which has been ground is attacked at a much faster rate; there is an evolution of bubbles and a change in body color of the GaP. The color change is from brown to red-orange or yellow-orange (de-

pending on the particle size of the GaP).

Table I shows some information about the particle distribution used as well as the treatment used in preparing the GaP powders. In Fig. 2 the diffuse reflectance is presented for all four treatments (as indicated in Table I) for the finest distribution of particles. Figure 3 shows the diffuse reflectance for all four treatments for the coarsest distribution of particles.

The difference between treatments III and IV (Fig. 2) is a slurrying operation. This operation consists of mixing the powder with water and decanting the water. The very fine particles are removed by this operation. The difference between treatments I and II is the same as between III and IV. The difference between treatments I and III is the hydrochloric acid treatment. The same may be said concerning treatments II and IV. This HCl operation increases the diffuse reflectance over the entire range of wavelengths. The change from yellow-orange to brown on grinding GaP can be seen in Fig. 2 and 3 by noting that the diffuse reflectance for the brown material falls off at wavelengths from 0.65 to 0.57μ. At these same wavelengths, GaP which has been treated with hydrochloric acid has a much higher diffuse reflectance.

There is one other observation which was made on GaP which did not have the slurrying and decanting operation. Not only did the coarser particle distributions (after sieving) contain some of the very fine particles, but these larger particles were coated with these very fine particles. Perhaps an electrostatic attraction holds these very fine particles to the coarser particles even during the entire sieving operation. The sieving operation may even be the cause of the electrostatic build-up of charge. The slurrying and decanting operation allows one to obtain samples having particle distributions without the very fine particles.

When one grinds a crystal using a mechanical force, a damaged layer is produced. This damaged layer is composed of a variety of disorders such as a deformed layer, sharp edges, cracks, an increase in the dislocation and vacancy densities, and a reactive surface. Such grinding also produces thermal spikes. These thermal spikes together with a reactive surface could produce a reaction with the surrounding atmosphere. Some of the reactions of GaP with H_2O and/or O_2 mentioned earlier might take place. Grinding GaP produces such a damaged layer which can be observed visually and nasally. There is another technique which can be used to observe a difference between this damaged layer and GaP without this damaged layer, the rate of dissolution. The rate of dissolution of this damaged layer is much larger than the rate of dissolution of GaP without this damaged layer. Any analysis of this rate would include all types of disorders, but since there obviously is a chemical reaction associated with the formation of this damaged layer, it will be assumed that a new compound is, at least, partially covering the surface of the ground GaP.

GaP was ground, slurried, decanted, and sieved. The particle distribution was 0.149-0.125 mm in diameter. Several samples were treated in the following manner. A weighed amount (about 2g) of GaP was placed in aqueous concentrated HCl (about 250 ml) and the mixture was slowly stirred. After 3 hr the GaP was washed with water, dried, and weighed. This weighed sample was returned to the HCl for three more hours, washed, dried, and weighed. This operation was repeated again and again. The curve in Fig. 4 labeled "3 hour runs" is typical of such an experiment. Note that the rate of dissolution of the ground GaP is still falling after a total of eighteen hours of HCl treatment. The curve in Fig. 4 labeled "24 hour runs" was treated in the same way as described above for the "3 hour runs" except the

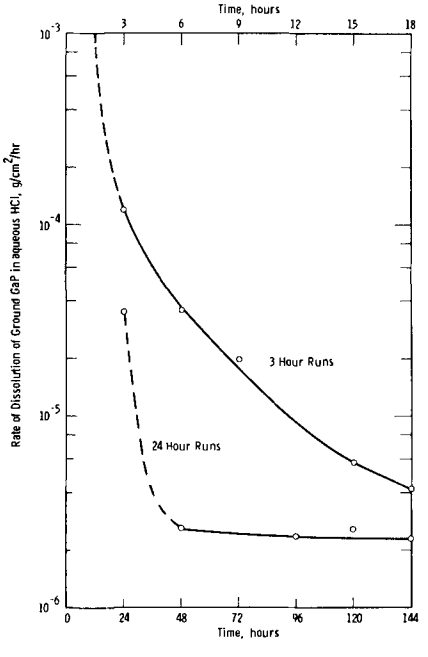

Fig. 4. Rates of dissolution of ground GaP vs. time

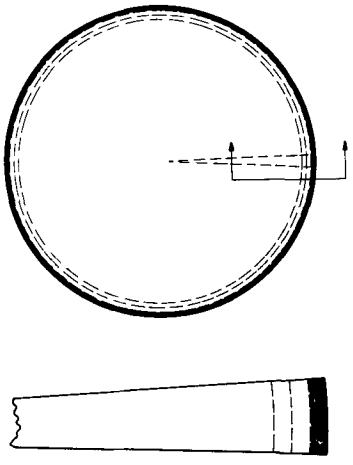

Fig. 5. Diagrammatic cross section of a particle of GaP with a damaged layer (top); (below) portion of sector of cross section of particle with damaged layer.

samples were treated for 24-hr periods instead of 3-hr periods. After 48 hr (two 24-hr HCl treatments) the rate of dissolution of the ground GaP does not fall appreciably. Figure 5 shows diagrammatically what the above experiments show. A particle has a damaged layer but this damaged layer is not a uniform one. It is most damaged on the outer periphery, and as one leaves the surface toward the interior of the particle this damaged layer shows less and less damage. The GaP in Fig. 4 shows a high rate of dissolution initially and a smaller rate of dissolution as more and more of the damaged layer or layers are removed. In the case of the curve labeled "3 hour runs" at the end of 18 hr, all of the damaged layers are not yet removed. In the case of the curve labeled "24 hour runs" at the end of the first 24-hr period the rate is greater than 18 total hr of 3-hr periods because this rate is a combination of higher rates and some lower rates of dissolution. Therefore, the room temperature dissolution rate of GaP with a damaged layer (caused by grinding) is greater than 1×10^{-4} g/cm^2/hr. The room temperature dissolution rate of GaP (without a damaged layer) in aqueous concentrated HCl is 2.3×10^{-6} g/cm^2/hr. The thickness of the damaged layer for several samples were calculated from the weight loss and rate of dissolution experiments to be about 2μ on a radius of about 70μ. After about 20 hr in HCl, GaP is removed at the rate of about 0.01 μ/hr. Initial rates of removal of GaP which has a damaged layer are about two orders of magnitude greater. This discussion may be concluded by saying that the rate of dissolution is not a constant since the degree of damage along a radius of a particle is not constant. It should also be pointed out that the calculation for the area of the particles assumes that these particles are spheres. Since these particles are not spheres, the real surface area is larger than calculated. This would mean that the true dissolution rates are smaller than those presented in this paper.

One other observation may be made correlating damaged layers with visual observation. As one treats ground GaP with HCl, there is a decided color change which one may easily observe from brown to red-orange or to yellow-orange. When the color change is noted, the most damaged material has been removed, and the rate of dissolution has fallen appreciably. The less damaged layers do not have diffuse reflectance much different from GaP without damaged layers and the dissolution rate in HCl of these layers is not much different from GaP without damaged layers. A good discussion on damaged layers and their chemical reactivity may be pursued in ref. (18).

GaAs in many respects is similar to GaP. Although their chemical reactivity is similar, GaAs is somewhat more reactive than GaP with respect to halogens, hydrogen halides, aqueous hydrogen halides, aqua regia, and nitric acid. GaAs powders were prepared in exactly the same way as the GaP powders. The discussion on damaged layers would equally apply to GaAs.

Results

$GaP_{(1-x)}As_x$ samples were prepared where $x = 0.1, 0.2, 0.3, \ldots, 1.0$. Table II contains lattice constants for 48 samples prepared in 28 independent preparations in this solid solution system GaP-GaAs. The samples were taken from single crystals and polycrystalline deposits. The samples were taken from preparations in which all of the GaP-GaAs was transported and in which as little as 28% of this material was transported. The time of transport varied from four days to 15 min. The difference in temperature between source and deposit varied from 10° to 200°C. The lattice constants in Table II are plotted in A of Fig. 6.[1] Whether the particle size of the source material had diameters between 0.177-0.149 mm or less than 0.074 mm no differences could be noticed in the material transported or material which did not transport. The length of time of the transport experiments (whether 4 days or 15 min) does not in any way affect the transported or non-transported material, other than the amount which transported. These lattice measurements were made using the Debye-Scherrer technique, a 57.32 mm radius of Straumanis-type camera with nickel filtered copper radiation. A trigonometric extrapolation was used to obtain the precision lattice constants (21).

[1] The lattice constants for GaP and GaAs at 18°C are 5.4505 ± 0.0001Å and 5.6534 ± 0.0002Å respectively (20).

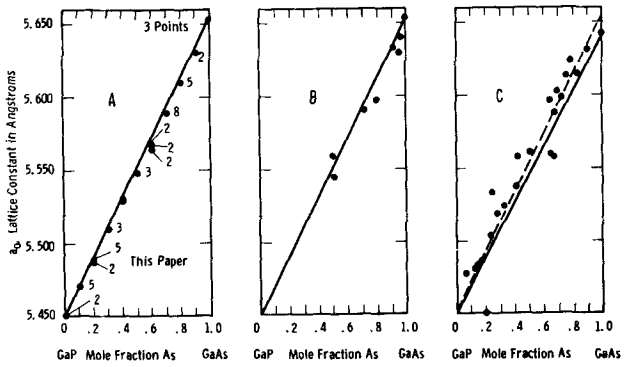

Fig. 6. Lattice constants of $GaP_{(1-x)}As_x$ *vs.* composition. "A" curve is from data obtained in this paper: "B" curve and "C" curve are from ref. (14) and (13), respectively.

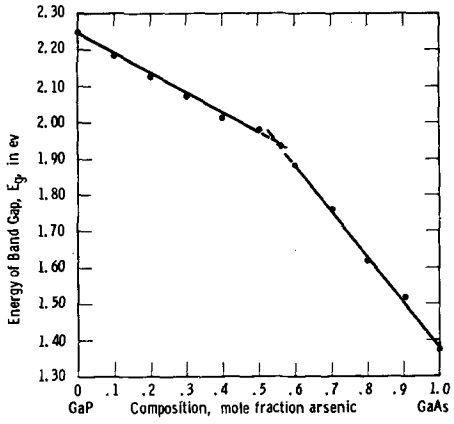

Fig. 7. Energy band gap *vs.* composition for the system $GaP_{(1-x)}As_x$

These points in Fig. 6, Curve A, lie quite close to the line connecting the lattice constants of pure GaP and GaAs; Vegard's law is followed quite well. Also plotted in Fig. 6 are two other curves from the literature (13, 14). The scatter of the points from data in this paper is much less than the scatter observed in data taken from the other two papers. One can observe in Table II that the so-called nontransported material has lattice constants which are either identical with or very close to the lattice constants of the transported material. This was observed not only in these samples listed in Table II, but in a number of other samples. One may conclude that the nontransported powders in these experiments did not remain as GaP and GaAs powders, but rather quickly formed the solid solution under the influence of iodine at a temperature of 1100°C.

Also included in this paper is a plot of band gap energy *vs.* composition, Fig. 7. The data was obtained from room temperature optical transmission measurements on samples which were about 0.4 mm thick. There are enough points plotted in this figure to merit the drawing of 2 straight lines with different slopes rather than a curved line as others have drawn for similar data (5, 13).

Conclusions

GaP and GaAs form a complete range of solid solutions obeying Vegard's law quite well. All of the points in A of Fig. 6 are below the line drawn (assuming Vegard's law is obeyed) indicating slight negative departures from Vegard's law.

One can obtain samples of $GaP_{1-x}As_x$ which are relatively homogeneous and reproducible as indicated in A of Fig. 7 by using crushed GaP and GaAs as the source of an iodine transport experiment.

When one crushes GaP and GaAs a damaged layer is produced. This layer may be removed by treatment with HCl. This treatment not only removes the damaged layer, but also any contaminants introduced on crushing and sieving.

Other workers were not able to obtain, in a reproducible manner, homogeneous solid solutions primarily because they did not know the composition of their solid solutions (their points show a scatter off the Vegard's law line). If they used large pieces of GaP and/or GaAs as their initial charge, the rates of GaP and GaAs leaving the sources and entering the gas phase were determined by the surface area of the source materials. If they crushed the source materials and did not remove the damaged layer, the source materials had already lost phosphorus and/or arsenic, formed oxides and/or phosphates (or arsenates), and were contaminated by impurities on crushing.

The author of this paper has noted (from the lattice constants of nontransported material) that before any solid solution is transported, the solid solution is formed at the source position when powdered GaP and GaAs are used as source material. This is experimental confirmation of a postulate previously set fourth (13). It is easier to understand the homogeneity and reproducibility of the solid solution presented in this paper, if the source material before transport were the solid solution already.

Acknowledgment

The author would like to thank Mr. Donald Sestrich for his help in the experimental efforts in this paper.

Manuscript received Sept. 16, 1964; revised manuscript received Nov. 27, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

Thermal Oxidation of Heavily Doped Silicon

B. E. Deal and M. Sklar

Research & Development Laboratory, Fairchild Semiconductor, Palo Alto, California

ABSTRACT

Oxidation characteristics of heavily doped silicon were investigated in dry and wet (95°C H_2O) oxygen ambients over the temperature range 920°-1200°C for oxide thicknesses of 0.10-1.0μ. Silicon uniformly doped with boron (1×10^{16} to 2.5×10^{20} cm^{-3}) or phosphorus (4×10^{15} to 1.5×10^{20} cm^{-3}) was studied, as well as silicon surfaces predeposited with these two elements. Boron concentrations greater than 1×10^{20} cm^{-3} cause an increase in oxidation rates at all temperatures, the greatest effect occurring in dry oxygen. Above 1000°, no such rate increase occurs for phosphorus doped silicon. At 920°C, however, phosphorus concentrations of 1×10^{19} cm^{-3} or more result in a significant increase of oxidation rates. The latter effect is most pronounced in wet oxygen. The results can be explained satisfactorily by considerations which take into account redistribution of impurities during thermal oxidation of silicon. These considerations also enable a tentative prediction of the effect of heavy doping concentrations of other impurities on the oxidation rate.

Silicon reacts in various oxidizing atmospheres at elevated temperatures to form silicon dioxide (SiO_2). The kinetics of this thermal oxidation of single crystal silicon has been the subject of several recent papers (1-5). The authors of these papers reported no dependence of oxidation rate on bulk impurity concentration over the concentration ranges investigated. These concentrations extended from very low values (intrinsic silicon) to as high as approximately 1×10^{20} cm^{-3} acceptor and donor impurities. It has also been noted, however, that when silicon having surface impurity concentrations greater than 10^{20} cm^{-3} is oxidized, deviations from the standard values of oxidation rate constants are encountered (6, 7). For the most part these deviations have been found with samples subjected to diffusion processes used in device fabrication.

Recently, silicon oxides have assumed an increasingly important role in the development of surface controlled devices and integrated circuits, and the close control of oxide thickness has become of vital interest (8, 9). A study was undertaken therefore to determine the effect of impurity doping, if any, on thermal oxidation rates. This study included both p-type (boron doped) and n-type (phosphorus doped) silicon oxidized in dry and wet oxygen (95°C H_2O) in the temperature range 920°-1200°C. Samples of both uniformly doped crystals and diffused surfaces were examined.

Experimental

Silicon used in this program was obtained from the Kollstan Semiconductor Elements Company, Westbury, New York. It was in the form of circular slices, cut from Czochralski crystals, and lapped to 250μ thickness. In all cases, surface orientation was (111). Material used for subsequent diffusion processing was 1.3-1.5 ohm-cm, either p-type (boron doped) or n-type (phosphorus doped) silicon. Dislocation count was specified to be less than 100 cm^{-2}. For the heavily doped p-type silicon, material with boron concentration of 1×10^{20} and 2.5×10^{20} cm^{-3} was used. Similarly, the heavily doped n-type silicon contained 3.7×10^{19} and 1.5×10^{20} cm^{-3} phosphorus. For both types, the higher values represent the maximum concentration available for boron and phosphorus. In examining these materials some segregation of impurities was noted, especially at the edges of the slices. However it was possible to obtain a sufficient number of slices with large areas of uniform impurity concentration which could be used in this investigation.

Apparatus

The oxidation system was similar to the one described in ref. (3). Both dry oxygen and wet oxygen ambients were used. The latter consisted of oxygen bubbled through deionized water at 95°C. The resulting partial pressure of water vapor in the ambient was assumed to be 634 mm Hg, the vapor pressure of water at 95°C. For the dry oxygen, the gas was dried and purified using a molecular sieve trap. Furnace temperature was controlled to ±1.0°C in the range 920°-1200°C. Silicon slices were placed flat on a thin quartz boat during oxidation. Separate quartz tubes were used for n-type and p-type silicon.

Procedure

The silicon slices were mechanically polished on one side to assure optimum conditions for oxide thickness measurements. Previous experiments had demonstrated no difference in oxidation kinetics between chemically and mechanically polished surfaces for the thickness range studied in this program (3). The slices were cleaned, and resistivity measurements were made on the lapped side. Immediately prior to oxidation, they were carefully cleaned again. The cleaning procedures involved prolonged rinses in organic and inorganic solvents using ultrasonic agitation.

Each particular run, representing a certain oxidation condition, included a standard silicon slice, *i.e.*, $C_B = 1 \times 10^{16}$ cm^{-3}, and two slices of higher impurity concentration. Thickness measurements of the oxides produced were obtained using multiple-beam interferometric techniques. Accuracy and reproducibility of this method is estimated to be ±40Å. Results of the standard sample were compared with corresponding oxides prepared in a separate furnace. The run was repeated if any deviation was noted, although agreement among standard oxides produced in the same furnace with heavily doped crystals and those prepared separately was generally very good.

Dry oxidation characteristics of predeposited[1] silicon were also examined in this program. In these experiments the surfaces were first prepared in regular predeposition furnace systems (9). For boron doped surfaces, methyl borate [$(CH_3)_3BO_3$] and boron tribromide [BBr_3] sources were used. In the case of phosphorus the sources were phosphorus pentoxide [P_2O_5] and phosphorus oxychloride [$POCl_3$]. Surface concentrations of these predeposited surfaces were estimated by measuring junction depths and sheet resistance, and using calculated relationships of the kind presented in ref. (10). A complementary error function-type impurity distribution was assumed. Surface concentration values calculated by this method ranged from $5\text{-}8 \times 10^{20}$ cm^{-3}. The samples were then oxidized at 1200°C. On

[1] "Predeposition," according to common usage, denotes a relatively short diffusion step (the impurity being present in the ambient) usually resulting in a high surface concentration of the impurity (9).

some samples the oxide glass formed during the predeposition step was removed by HF treatment before oxidation; on others it was left on. A standard slice was included in each oxidation, and thicknesses of oxides produced were measured as described above. Again, thicknesses of these standard oxides agreed quite closely with those of corresponding oxides prepared alone in a clean system. Thicknesses of the oxide glasses produced during the predeposition step were also determined.

Results

The oxidation results of silicon uniformly doped with boron or phosphorus are presented graphically in Fig. 1-4. These graphs are log-log plots of oxide thickness *vs.* oxidation time for dry and wet oxygen. Four different oxidation temperatures are included, with data obtained with three different impurity concentrations for each temperature. The lower line for each temperature represents oxidation characteristics of the standard, and these values agree quite closely with previous data (3). The deviation from the standard oxidation rates for more heavily doped boron or phosphorus under certain conditions is readily noted. The significance of these differences is discussed in the following section. In general, experimental values were reproducible to within 100Å, close to the accuracy of the oxide thickness measurement technique.

Oxidation rates obtained using predeposited samples (with the glass removed) were compared with the results in Fig. 1-4. With the exception of the methyl borate samples, the rates fell on the line corresponding to heaviest doping in both the boron and phosphorus cases, *i.e.*, C_B(boron) = 2.5 x 10^{20} cm^{-3}, C_B(phosphorus) = 1.5 x 10^{20} cm^{-3}. The oxides produced on the methyl borate predeposited surfaces were nonuniform in thickness, indicating nonuniform surface concentrations.

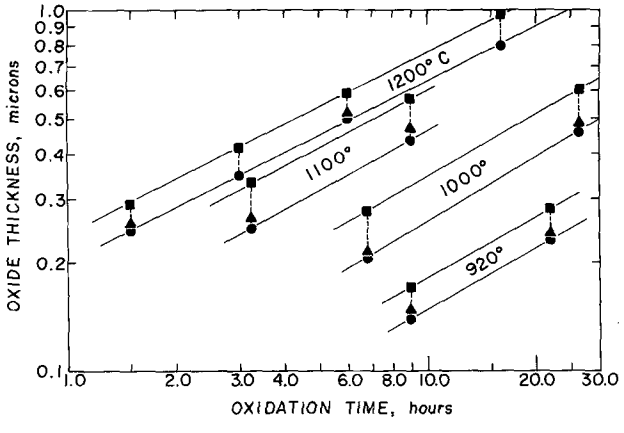

Fig. 1. Oxidation of boron-doped silicon in dry O_2 for three different boron concentrations at four oxidation temperatures: ■, C_B = 2.5 x 10^{20} cm^{-3}; ▲, C_B = 1.0 x 10^{20} cm^{-3}; ●, C_B = 1.0 x 10^{16} cm^{-3}.

Discussion

Boron doped silicon.—In order to interpret the results of Fig. 1 and 2, we must first consider the nature of silicon oxidation. It has been demonstrated (1, 2, 11) that oxidation proceeds by diffusion of some oxidizing species through the oxide already formed to react at the silicon surface. At temperatures above 1000°, the oxidation rate is limited by this diffusion process resulting in the parabolic relationship

$$w = Kt^{1/2}$$

where w is oxide weight or thickness, t, oxidation time, and K is the rate constant, It follows that a change in the oxide structure may affect the oxidation characteristics. By purposely changing the structure, one may observe this effect. The experiments described above concerned with oxidation of predeposited surfaces with boron glass left on the silicon provided an indication of what effect the presence of boron in SiO_2 could provide on further oxidation.

Let us assume a boron glass of thickness 0.2μ is already present on a silicon surface. Then let the sample be exposed to a dry oxygen ambient for 6 hr at 1200°C. Several possibilities arise as to the resulting oxide formation, some of which are shown in Fig. 5. First, if there was no glass present originally, the resulting thickness-time plot would be represented by curve (A) with a final oxide thickness of 0.5μ. Second, if the

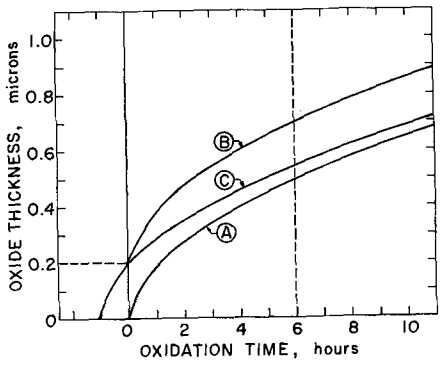

Fig. 5. Possible variations in subsequent oxidation characteristics due to 0.2μ glass formed on silicon surface during predeposition.

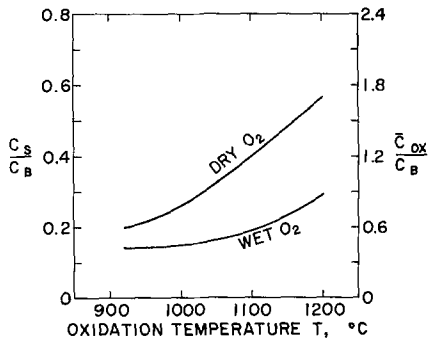

Fig. 6. Predicted boron concentration at the silicon surface (C_S) and in the oxide ($\bar{C}_{ox}$) due to impurity redistribution during thermal oxidation in two ambients at various temperatures.

diffusion of any oxygen species through the glass was much faster than through SiO_2, curve (A) would merely be displaced 0.2μ up along the thickness axis and curve (B) would result. Here the final oxide thickness would be the sum of two thicknesses, *i.e.*, 0.7μ.

The other simple case would exist if both the original glass and the final oxides produced had identical structures, *i.e.*, the diffusion coefficients of oxygen would be the same in both. This case is represented by curve (C), where the additional oxidation starts at the 0.2μ point of the original curve. In other words the original curve is shifted along the time axis so that 0.2μ coincides with 0 min. It can be observed that the final oxide thickness of this case will be 0.55μ. Of course other intermediate possibilities exist where the oxygen diffusivity through the original glass may be greater or less than through the final oxide.

Experiments involving subsequent oxidation of boron predeposited surfaces were performed in several variations. In a typical case the oxidation was conducted in dry oxygen for 90 min at 1200°C. Prior to this oxidation a borate glass was produced by BBr_3 predeposition in an oxygen-nitrogen atmosphere.

The results are: thickness of borate glass, 0.082μ; thickness of oxide on predeposited surface, borate glass removed, 0.294μ; thickness of oxide on predeposited surface, borate glass not removed, 0.372μ; thickness of standard SiO_2, 0.248μ.

It can be noted that the sum of the oxide thickness for the predeposited surface and the borate glass thickness (0.294μ + 0.082μ) is essentially equal to the total oxide thickness where the glass was not removed (0.372μ). Thus the latter result corresponds to case (B) of Fig. 5, and it follows that the borate glass presents very little resistance to the diffusion of oxygen. This effect has been noted previously by Thurston (12) and is in agreement with other comparisons of oxygen diffusion coefficients in glasses (13). The boron probably produces defects in the SiO_2 lattice, resulting in a structure which provides an increase of oxygen diffusion rate.

We are now in a position to discuss the increase of oxidation rates shown in Fig. 1 and 2 for uniformly doped silicon containing high concentrations of boron. These increases can be explained on the basis of the above results if boron is incorporated into the oxide during thermal oxidation. Results of experiments involving redistribution of impurities due to thermal oxidation indicates that this indeed does occur (14, 15). Figure 6 based on considerations of ref. (14, 15) shows the ratio of the boron concentration in the silicon, near the oxide-silicon interface, to the bulk concentration (C_S/C_B) for dry and wet oxygen oxidations as a function of temperature. Since a depletion of boron from the silicon takes place, this ratio is less than one. If a segregation coefficient[2] of 0.33 for the system is also assumed from ref. (14), the average boron concentration in the oxide can also be plotted in Fig. 6 as $\bar{C}_{ox}/C_B$ (see Appendix). At the higher temperatures, there is a considerable amount of boron in the oxide, especially in the dry oxygen case. This boron could cause a weaker bond structure and permit a more rapid oxidation, (assuming that diffusion through the oxide is the rate-determining step at the oxidation temperature). The boron concentration in wet oxides is less according to Fig. 6, and the increase in oxidation rate for heavily doped silicon accordingly should be less pronounced. This is indeed true as shown by comparing Fig. 1 and 2.

Figure 6 also indicates that as oxidation temperature decreases the average boron concentration in the oxide decreases. Thus, the effect of heavy doping should be less pronounced at lower temperatures. This is not observed from Fig. 1 and 2 perhaps because of the change in oxidation mechanism in the vicinity of 1000°C (see ref. 3).

Calculations indicate a dry oxide produced at 1200°C on silicon having a boron concentration of 2.5 x 10^{20} cm^{-3} should contain approximately 1% boron. Gravimetric analysis of such an oxide did show greater boron content than for a standard silicon oxide (C_B(std) = 1 x 10^{16} cm^{-3}), but the method was not sufficiently accurate for quantitative results. Much more significant results were obtained using an infrared examination. Samples were prepared by oxidizing to a thickness of 1.0μ. Using the photoresist and chlorine etch technique (1), a hole was etched through the silicon from the back side. A window of oxide, supported by a frame of silicon, remained on top for infrared transmission examination. Figure 7 shows spectra in the range 6.5-13.5μ wavelength for four different samples. (Total range examined was 2-15μ with no structure indicated beyond the limits included in the figure.) The spectrum for the standard oxide (either wet or dry oxygen) prepared from silicon whose bulk concentration is 1 x 10^{16} cm^{-3} is shown by curve (1). The characteristic absorption peak for fused silica (16) is shown at 9.2-9.3μ. A second peak attributed to an SiO bond, also exists at 12.5μ. Curve (4) represents a wet oxide also on 1 x 10^{16} cm^{-3} material, but covered with a borate layer produced in a methyl borate predeposition system. Additional peaks are now observed at 7.5 and 11.1μ. According to Jellyman and Proctor (17), these peaks are representative of a B_2O_3 glass.[3] Finally, curves (2) and (3) of Fig. 7 are for wet and dry oxygen oxides on 2.5 x 10^{20} cm^{-3} boron doped silicon. The peaks at 7.5μ have shifted slightly to the left (7.2μ) which is more typical of a mixed SiO_2-B_2O_3 system (17). Also present are the boron peaks at 11.1μ. The most significant fact about the two peaks at 7.2μ is the ratio of dry oxygen boron absorption to the wet oxygen value (about 2:1). This same ratio of boron concentration in the oxide is

[2] Segregation coefficient = m = $\frac{\text{equilibrium concentration of impurity in silicon}}{\text{equilibrium concentration of impurity in oxide}}$

[3] The data of ref. (17) are based on reflection spectra, but we as well as other investigators have found reasonable agreement between absorption and reflection data.

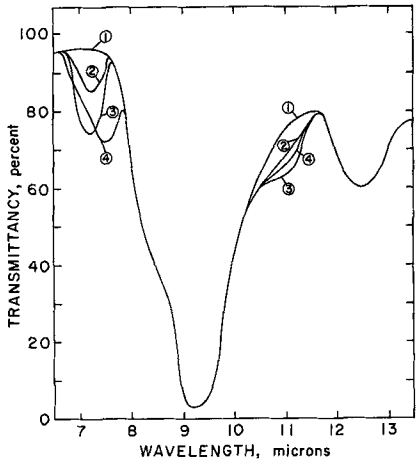

Fig. 7. Infrared absorption spectra of various silicon oxides: 1, standard dry and wet oxide, $C_B = 1 \times 10^{16}$ cm^{-3}; 2, wet oxide, $C_B = 2.5 \times 10^{20}$ cm^{-3}; 3, dry oxide, $C_B = 2.5 \times 10^{20}$ cm^{-3}; 4, wet oxide plus borate glass, $C_B = 1 \times 10^{16}$ cm^{-3}.

predicted from Fig. 6 (at 1200°C, $\bar{C}_{ox}/C_B$ for dry $O_2 = 1.7$, $\bar{C}_{ox}/C_B$ for wet $O_2 = 0.85$). Thus the presence of boron in the oxide is clearly verified by independent means.

Phosphorus doped silicon.—The phosphorus data of Fig. 3 and 4 may be analyzed in a manner similar to the heavily doped boron results. First, experiments involving oxidation of silicon covered with a phosphate glass indicated an increased diffusion rate of oxygen through the glass, although not to the same extent as with the borate glass system. The diffusion coefficient through the glass was estimated to be about 5 times that of pure SiO_2. This finding agrees with the results of Thurston who also noted that phosphorus in fused silica causes an increased rate of oxygen diffusion through the structure, but in a different manner than boron (12). If the phosphate glass data are applied to Fig. 5, the resulting curve would be somewhere in between curves (B) and (C).

Examination of Fig. 3 and 4 reveals that between 1000° and 1200°, a high bulk concentration of phosphorus causes little change in oxidation rates. This is consistent with results of ref. (14, 15): Phosphorus "piles-up" slightly at the silicon surface, and its concentration in the oxide is low. This effect is shown in Fig. 8. Even at 920°, the concentration of phosphorus in a wet oxide (the maximum case) is less than 0.2 that of the bulk. As a result the oxide produced will be essentially SiO_2 and subsequent oxygen diffusion through it will not be significantly affected. However, Fig. 3 and 4 show a marked increase of oxidation rate at 920°C, especially in wet oxygen. This apparent contradiction can be readily explained, however, if the mechanism of silicon oxidation is considered. It has been proposed that below 1000°C, thermal oxidation is no longer completely diffusion controlled, but depends considerably on the reaction at the silicon surface (3). The "pile-up" of phosphorus, especially in wet oxygen, could cause a change in the surface reaction rate and thereby affect the oxidation rate. From Fig. 8 this effect should be more pronounced in wet oxygen, and Fig. 3 and 4 indicate that this is indeed the case.

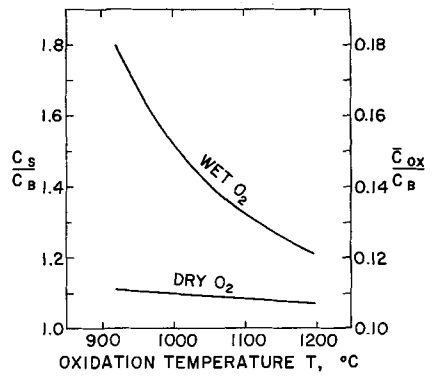

Fig. 8. Predicted phosphorus concentration at the silicon surface (C_S) and in the oxide ($\bar{C}_{ox}$) due to impurity redistribution during thermal oxidation in two ambients at various temperatures.

Table I. Relationship of parabolic oxidation rate constants for heavily doped silicon to standard values

Oxide ambient	Oxidation temp, °C	Rate constant K_{std}, $\mu/\sqrt{hr}$	Boron-doped silicon* K_B/K_{std}	Phosphorus-doped silicon† K_P/K_{std}
Dry O_2	1200	0.206	1.21	1.02
Dry O_2	1100	0.155	1.29	1.03
Dry O_2	1000	0.093	1.31	1.03
Dry O_2	920	(0.050)	1.20	1.18
Wet O_2 (95° H_2O)	1200	0.840	1.11	1.00
Wet O_2	1100	0.675	1.10	1.00
Wet O_2	1000	0.480	1.11	1.09
Wet O_2	920	(0.325)	1.13	1.30

* K_B is the rate constant for $C_B = 2.5 \times 10^{20}$ boron at./cm^3; K_{std} is the rate constant for $C_B = 1 \times 10^{16}$ boron at./cm^3.
† K_P is the rate constant for $C_B = 1.5 \times 10^{20}$ phosphorus at./cm^3; K_{std} is the rate constant for $C_B = 4 \times 10^{15}$ phosphorus at./cm^3.

Thus far, it has not been possible to establish the presence, or perhaps in this case, absence of phosphorus in the oxide by infrared examination. The only P_2O_5 absorption peak (over the wavelength range investigated) falls at 9.2-9.3μ, that of SiO_2. The latter completely masks any effect due to phosphorus.

Correlation of all data.—A general comparison of both boron and phosphorus results may now be made. Table I contains a partial summary of the data plotted in Fig. 1-4. Oxidation rate constants for the silicon with the heavier concentrations of boron and phosphorus ($C_B = 2.5 \times 10^{20}$ and 1.5×10^{20} cm^{-3}) expressed as K_B and K_P, are compared with the standard values, K_{STD}. It should be kept in mind that oxidation at the lower temperatures and for thiner oxides is not truly parabolic. However rate constants are still listed in terms of $\mu/\sqrt{hr}$ for the thicker oxides at each temperature for purposes of comparison. Table I shows a reasonable correlation with Fig. 6 and 8, in that at higher temperatures the concentration of boron in the oxide (Fig. 6) determines the amount of increase in oxidation rate. At 920°C, where the reaction has been proposed to be more surface controlled, wet oxygen oxidation of phosphorus-doped silicon results in the highest surface concentration and also the highest oxidation rate.

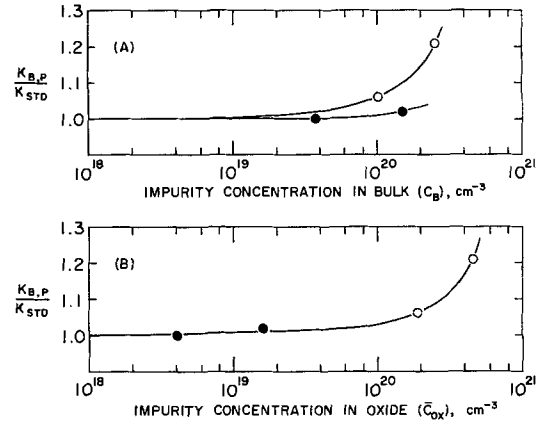

Fig. 9. Dependence of oxidation rate constants for heavily doped silicon on: (A) impurity concentration in the bulk; (B) impurity concentration in the oxide. Data are based on oxidation in dry oxygen at 1200°C; ○, boron; ●, phosphorus.

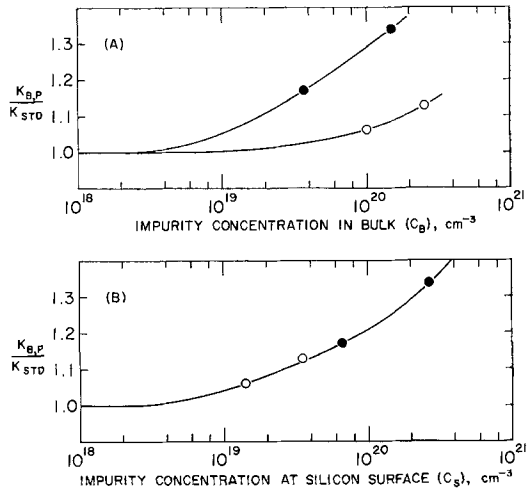

Fig. 10. Dependence of oxidation rate constants for heavily doped silicon on: (A) impurity concentration in the bulk; (B) impurity concentration at the silicon surface. Data are based on oxidation in wet oxygen (95°C H_2O) at 920°C; ○, boron; ●, phosphorus.

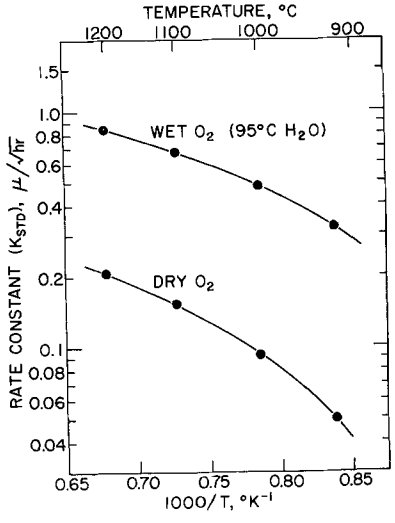

Fig. 11. Log of rate constant, $K_{STD} \equiv w/\sqrt{t}$, plotted against reciprocal of absolute temperature for dry and wet O_2 oxidation of silicon (C_B = 1 x 10^{16} at./cm^3).

In Fig. 9A, the K_B/K_{STD} and K_P/K_{STD} ratios for dry oxygen oxidation at 1200°C are plotted against bulk impurity concentration C_B. Two separate curves result. However, if the ratios are plotted against average impurity concentration in the oxide, $\bar{C}_{ox}$, one curve is obtained in Fig. 9B. Similarly, 920°C wet oxygen data are plotted in Fig. 10. In this case, whereas ratios of K_B/K_{STD} and K_P/K_{STD} plotted against C_B again result in two curves (see Fig. 10A), a plot of the ratios against surface concentration C_S gives one continuous curve. In this case if the results were plotted against $\bar{C}_{ox}$, the resulting curves would be even more divergent than Fig. 10A.

The above two cases (dry oxygen at 1200° and wet oxygen at 920°C) were selected as examples since they represent the two extremes in the effects of heavy doping on oxidation characteristics. It should be noted that wet oxygen data at 1200°C could be included in Fig. 9 (and dry oxygen data at 920°C in Fig. 10) with reasonable agreement with the existing curves. These results further indicate that the oxidation rate of heavily doped silicon is chiefly dependent on the impurity concentration either in the oxide (above 1000°C) or at the surface (below 1000°C).

A plot of the logarithm of parabolic rate constant versus the reciprocal of absolute temperature is shown in Fig. 11 for dry and wet oxygen silicon oxidation. The points represent the data from Table I for standard rate constants (K_{STD}). The curves help to illustrate the change in oxidation mechanism from one primarily diffusion controlled ($w = K_1 t^{1/2}$) to that where a reaction at the silicon oxide-silicon interface at least partially controls the oxidation rate ($w = K_2 t$). Above 1000°C the curves (based on parabolic rate constants) are more linear while below this temperature a more rapid change in slope is noted. The best fit of a straight line through the points in the 1000° to 1200° region in Fig. 11 will give activation energies of 14.75 and 10.25 kcal/mole for dry and wet O_2, respectively (where $K_{STD} \equiv w/\sqrt{t}$). These values correspond to 29.5 and 20.5 kcal/mole (for $k \equiv w^2/t$) which are in close agreement with previous results (3).

The fact that the curves in Fig. 11 are not strictly linear but have continuously changing slopes indicates that there is no sudden change in oxidation mechanism at any particular temperature. If we consider some concepts of oxidation mechanisms proposed by Evans (18), the nature of these results can be better understood. In the case of silicon, oxidation will depend on two main processes: the diffusion of the oxidizing species through the oxide and the reaction of this species with the silicon at the oxide-silicon interface. The slower of the two processes will be the actual rate-determining step. Temperature will be an important factor in determining the comparative rates and thus the relative importance of these two processes. This is indicated by the changing slopes in Fig. 11. The results described in this investigation involving oxidation rates of heavily doped silicon are also in agreement with this concept.

Mention should be made of the relationship of these results to the few data that have already been presented concerning oxidation of heavily doped silicon. Yeh (6) indicated that the oxidation rate of silicon with an estimated diffused phosphorus surface concentration of 2 x 10^{21} cm^{-3} increased if the oxidation occurred at 970°C in steam. The only data presented in support of this was a plot of oxide thickness *vs.* square root of time. The slopes and thus the oxidation rate constants, of the two plots (C_S = 2 x 10^{21} and 2 x 10^{16} cm^{-3}) were identical, while the intercepts were different. This indicated an initial porous oxide might have been present on the diffused surface, causing a shift of the type shown in Fig. 5 from curve A to curve B. According to the results of the present investigation, Yeh should have obtained a significant increase of oxidation rate in steam at 970° for the surface concentration indicated. Yeh did present data for a boron diffused surface (estimated C_s = 5 x 10^{18} cm^{-3}) which if plotted in a manner similar to the phosphorus data indicates a rate constant increase of about 10%. This increase would be of a magnitude similar to the boron results given in this paper, but such increases were found only when the boron surface concentration was at least 5 x 10^{19} cm^{-3}. The difficulty of accurately determining diffused surface concentrations might account for Yeh's results.

The other finding that heavily doped surfaces provide an increased oxidation rate was reported by Ligenza (7). Silicon with a phosphorus surface concentration of 10^{21} cm^{-3} was oxidized at 650°C for 1 hr in 120 atm steam. An oxidation rate five times that of high resistivity silicon was obtained. For this type of oxidation, the oxide thickness-time relationship is entirely linear which means the oxidation is controlled completely by a reaction at the silicon-silicon oxide interface. Such an increase in oxidation rate would therefore be expected from the results and considerations of the present investigation.

Conclusions

It has been shown that the thermal oxidation rate of heavily doped silicon (C_B of boron and phosphorus $\geq$10^{20} cm^{-3}) at temperatures above 1000°C depends on

the amount of impurity in the oxide. This finding is consistent with the diffusion-controlled mechanism of thermal oxidation in this temperature range. The amount of impurity in the oxide in turn is a function of the redistribution characteristics of the impurity and the oxidation ambient. Little effect is noted unless the impurity concentration in the oxide is greater than 10^{20} cm^{-3}.

At 920°C, where thermal oxidation is partially controlled by a surface reaction the rate of oxidation is a function of the impurity concentration at the silicon surface. This concentration, determined by redistribution phenomena, must be at least 10^{19} cm^{-3} before an appreciable change in rate occurs.

The effect of other impurities (for $C_B \geqq 10^{20}$ cm^{-3}) on oxidation rates may also be predicted, provided their redistribution characteristics are known. These predictions can be based on the four cases of the redistribution process as presented in ref. (14). Where the oxide rejects impurities and diffusion of these impurities in the oxide is slow (case 2A, ref. 14) such as phosphorus, antimony, and arsenic, no increase in oxidation rate should occur above 1000°C. However the rates should increase below 1000°C. If the oxide takes up an impurity, and again the impurity diffuses slowly in the oxide (case 1A), an increase of oxidation rate should occur at least at temperatures above 1000°C, and possibly below, as with boron. Gallium, aluminum, and indium, which deplete at the silicon surface and also probably diffuse rapidly through the oxide (either case 1B or 2B) should not cause an increase in oxidation rates at any temperature even at high bulk concentrations.

APPENDIX

The Average Impurity Concentration in the Oxide Layer

Because of the redistribution process taking place during thermal oxidation, some of the impurities which were originally in the silicon substrate will end up within the silicon dioxide film. The resulting average concentration of impurities within the oxide can be readily calculated on the basis of the redistribution theory (14), as follows.

The total amount of impurity (per cm^2) contained within the oxide layer is given by

$$Q_{ox} = \int_o^{z_o} C_1(z,t)\,dz \qquad [A\text{-}1]$$

where z_o denotes the oxide thickness, and $C_1(z,t)$ denotes the concentration of the impurity within the oxide film. [The notation follows that of ref. (14).] Incorporating Eq. [15] of ref. (14) into equation [A-1], and performing the integration yields the average concentration of the impurity in the oxide film

$$\bar{C}_{ox} \equiv \frac{Q_o}{z_o} = C_o + \left(\frac{C_s}{m} - C_o\right)\left[1 + \frac{\text{ierfc}(K/2\sqrt{D_1}) - 1/\sqrt{\pi}}{K/2\sqrt{D_1}}\right] \qquad [A\text{-}2]$$

where ierfc indicates the integral of the complementary error function and is tabulated in ref. (19). C_o denotes the concentration of the impurity at the outside surface of the oxide layer (this concentration is very small if the impurity has a tendency to leave the solid); C_s denotes the concentration of the impurity in the silicon near the oxide-silicon interface; and m is the segregation coefficient. The bracketed term has been evaluated and is shown in Fig. 12 as a function of $K/2\sqrt{D_1}$, the ratio of the parabolic oxidation rate constant to the square root of diffusivity of the impurity in the oxide layer. It can be noted that the limits of very small and very large diffusivities, Eq. [A-2] reduces to

$$\bar{C}_{ox} = C_s/m, \quad K/2\sqrt{D_1} \to \infty \qquad [A\text{-}3]$$

$$\bar{C}_{ox} = C_o, \quad K/2\sqrt{D_1} \to 0 \qquad [A\text{-}4]$$

The first of these equations corresponds to the case of boron and phosphorus; the second to gallium. These are the approximations used in the text of the present work.

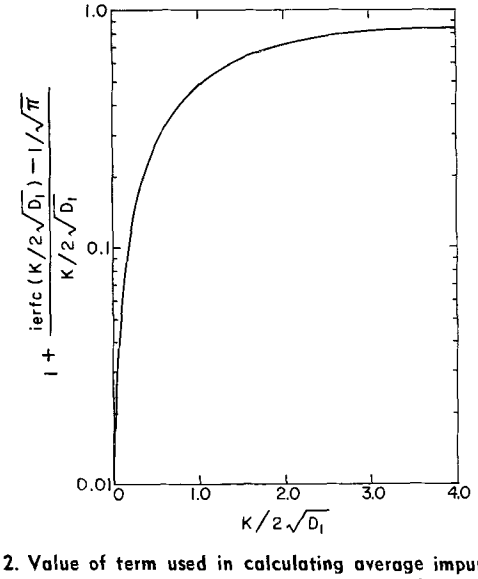

Fig. 12. Value of term used in calculating average impurity concentration in oxide as a function of the ratio $K/2\sqrt{D_1}$.

The Effects of Substrate Orientation on Epitaxial Growth

S. K. Tung

Bell Telephone Laboratories, Incorporated, Allentown, Pennsylvania

ABSTRACT

The effect of substrate orientation on the quality of silicon epitaxial layers was studied in terms of deposition rate and surface topography. The layer was deposited by the hydrogen reduction of silicon tetrachloride. Deposition rate was determined from the time of deposition and from the layer thickness obtained by angle lapping and staining. Deposition rate was lowest on accurately oriented <111> substrates and increased as the degree of misorientation from the <111> direction increased. The frequently observed surface pyramid defect was found to be a function of (*a*) deposition rate and (*b*) substrate orientation. These pyramidal defects were not observed for low deposition rates, and when the substrate was misoriented from the <111> direction. These observations are consistent with the proposal that the deposition rate used in practice is determined by two fundamental rate processes, namely, (*a*) reaction rate and (*b*) growth rate.

During the development of epitaxial deposited silicon layers, there has been interest in the effect of the orientation of the silicon substrate and in the change of orientation after surface processing and layer deposition. This paper reports a study of these effects on the quality of the silicon epitaxial layer in terms of deposition rate and surface topography.

Experimental Procedure and Results

Orientation change during silicon substrate processing.—A silicon substrate surface was lapped and chemically polished before epitaxial deposition. The surface orientation was measured by x-ray goniometry after each processing step, *i.e.*, lapping, chemical polishing, and epitaxial layer deposition. The precision of the employed technique was estimated to be within ± 10 min of arc. The data of this study are summarized in Table I. It is concluded that there was no substantial orientation change of the silicon surface through the orientation range investigated, either after chemical polishing or after layer deposition. The small orientation difference seen in Table I is believed to be experimental error.

Substrate orientation related to deposition rate.—To study the effects of substrate orientation on deposition rate a silicon layer was deposited on a polycrystalline silicon substrate whose surface was mechanically polished. This substrate contained two or three large grains. The orientations of these large grains were determined by the Laue back-reflection technique. An epitaxial silicon layer was deposited by the hydrogen reduction of silicon tetrachloride using a vertical type machine similar to that reported previously (1, 2). This deposition was normally done at a slice temperature of 1200°C and a 0.2 vol % concentration of silicon tetrachloride. After the layer deposition, the grain boundaries were delineated by the differences in thickness of silicon deposited on each grain. Figure 1 shows such a silicon wafer surface after epitaxial layer deposition. The grain boundaries can be seen clearly in this picture, but they could not be located before deposition because the wafer surface had been mechanically polished. The difference in layer thickness is further illustrated in Fig. 2 by an angle-lapped section. In this case the two large grains had <111> and<115> orientations. The layer thickness on the <111> grain was 11.2μ, and on the <115> grain it was 13.0μ. Because the two adjacent grains were deposited in the same run, other deposition parameters such as temperature, silicon tetrachloride vapor concentration, and flow rates were the same. The difference in layer thickness on different grains was thus due to the variation in orientation.

Figure 3 is a plot of deposition rate at 1200°C as a function of substrate orientation. Deposition rate was determined from the time of deposition and from layer thickness obtained by angle lapping and staining. The data of this plot were obtained from depositions on individual single crystal silicon substrates with different orientations. It is of interest to note that the deposition rate increased as misorientation from the <111> direction increased. Also, the curve shows that the <111> orientation had the lowest deposition rate of all low index orientations, while the <110> orientation had the highest deposition rate. These results were similar to those reported by Mendelson (3).

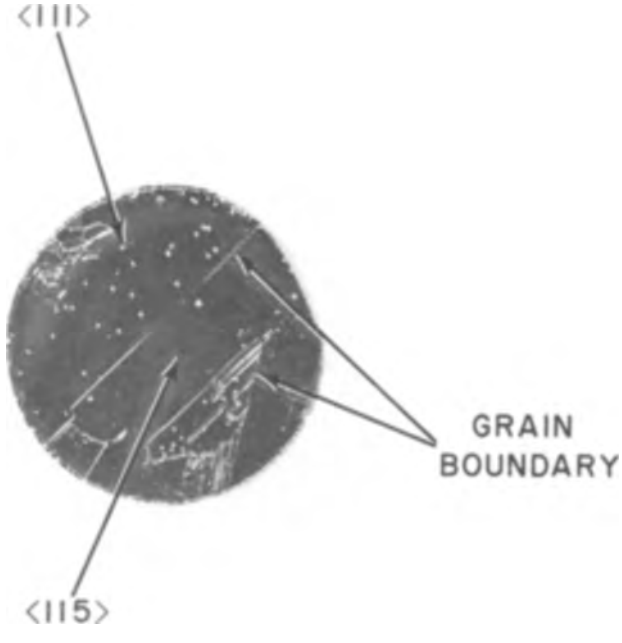

Fig. 1. Surface of silicon layer on polycrystal silicon substrate

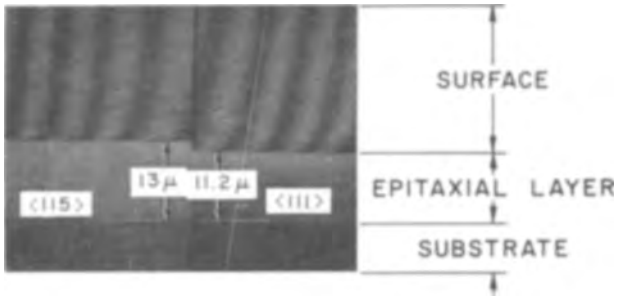

Fig. 2. An angle-lapped picture showing different layer thickness

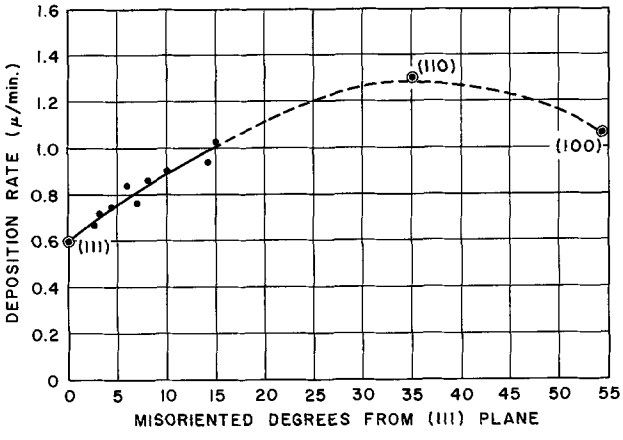

Fig. 3. Deposition rate vs. substrate misorientation

He observed a minimum growth rate and a high stacking fault density on <111> substrates.

Because the deposition rate depends strongly on other processing parameters (2), the orientation effect discussed here can be differentiated only when other process parameters are held substantially constant.

Substrate orientation and surface layer topography.— A surface defect of "pyramidal" shape was found in depositions upon <111> oriented substrates when the deposition rate exceeded a critical value (4). This type of surface defect is shown in Fig. 4. In general, this defect is a prominence on the surface and has a ridgelike tail associated with it. The size of the pyramids varied as the growing conditions changed. Normally, they are easily seen with the unaided eye.

A tetrahedral growth defect has been observed by Miller *et al.* (5) who attributed such a defect to the presence of silicon carbide. It should be emphasized that the type of surface defect observed here developed only when the deposition rate exceeded a critical value for that particular substrate orientation. That is the surface defect is a combination effect of both the substrate orientation and the deposition rate. Impurities play a less determining factor. For example, pyramids grew on a substrate with <111> orientation but no pyramids grew on a substrate with <115> orientation when both the substrates were deposited simultaneously at 1200°C with a deposition rate of 1.4 μ/min. In another experiment pyramids did not grow on either <111> or <115> oriented substrates because a lower deposition rate of 0.4 μ/min was used at the same deposition temperature. The deposition rate was adjusted by varying silicon tetrachloride concentrations. In general one can conclude that the pyramids were grown at a certain deposition rate for a particular substrate orientation. In this paper this deposition rate is called the "critical deposition rate" for that orientation.

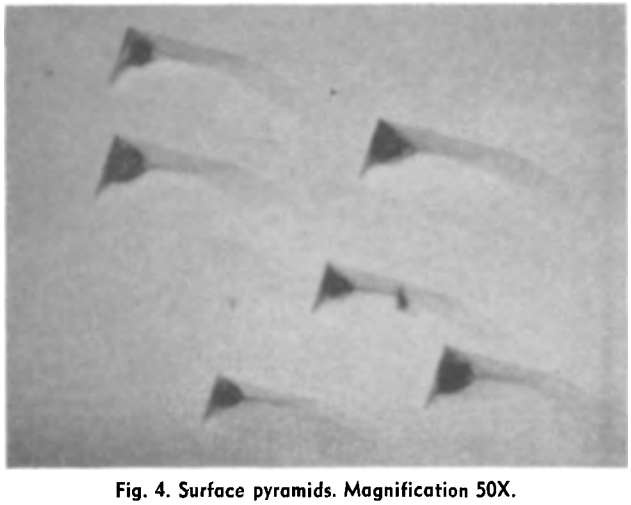

Fig. 4. Surface pyramids. Magnification 50X.

Table II. Summary of data

Substrate orientation	Critical deposition rate
<111>	1.0μ/min ±25%
½° from <111>	1.5μ/min ±25%
2° from <111>	3.5μ/min ±25%

Because the deposition rate is a function of the substrate orientation, it was expected that the critical deposition rate for pyramids grown depended on the substrate orientation. Experimental results showed that on a silicon substrate which had been misoriented from the <111> direction, a high deposition rate could be utilized without pyramids growing on the surface. Also, when a silicon substrate surface was closely oriented to the <111> direction, pyramids might develop on the surface unless a deposition rate less than the critical deposition rate was used.

The critical deposition rates for various misorientations from the <111> direction were found experimentally. Table II shows the critical deposition rate at 1200°C to be about 1 μ/min for a substrate oriented on the <111> direction, about 1.5 μ/min for a substrate with a ½ degree misorientation from the <111> direction, and about 3.5 μ/min for a substrate with a 2 degrees misorientation from the <111> direction. It should be pointed out that the critical deposition rate is also dependent on the depositing system and the data discussed was derived from the system described in a previous publication (2).

Discussion

One may ask "What is the critical deposition rate?" In answering this question it will be convenient to discuss the results in terms of heterogeneous rate reaction theory (6). In general the over-all deposition process can be separated into two main steps: (*a*) the reaction or series of reactions which take place on or near the substrate surface; this rate will be called the reaction rate; (*b*) the addition of atoms to proper sites of the substrate surface; this will be called the growth rate. These two rate processes complement each other during deposition. The slower process will control the over-all deposition process. Thus the observed deposition rate is either controlled by the reaction rate or by the growth rate. The controlling rate depends on how the deposition process is carried out and how the process parameters are arranged.

Figure 5 shows a schematic drawing of the observed deposition rate *vs.* silicon tetrachloride concentration. One may visualize that the growth rate or the rate at which atoms are added to the substrate surface is dependent on the substrate surface plane. Consequently the growth rate is a strong function of substrate orientation. On the other hand, the reaction rate should not depend too much on substrate orientation. Thus the critical deposition rate on a perfect substrate surface plane can be assumed to be the growth rate. Also, the deposition rate, whether controlled by the reaction rate or by the growth rate, depends on other process parameters in the deposition.

The theoretical treatment of surface structures in crystal growth from the vapor was given by Cabrera

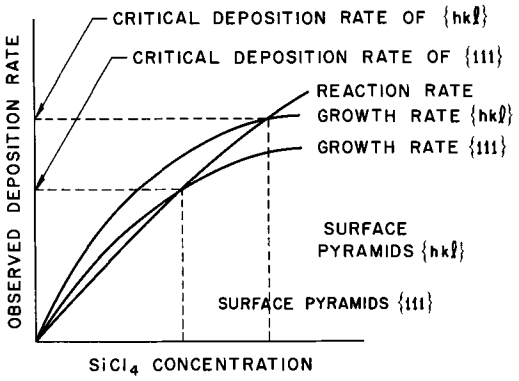

Fig. 5. Schematic drawing of the observed deposition rate vs. silicon tetrachloride concentration.

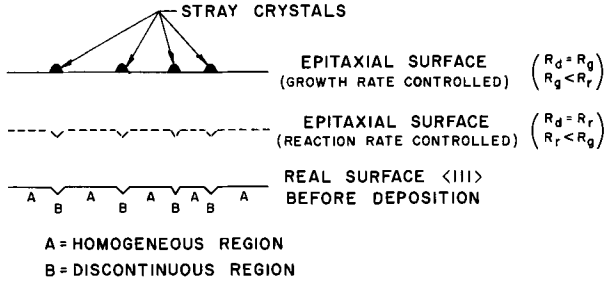

Fig. 6. Schematic drawing of a <111> surface after deposition

Fig. 7. Schematic drawing of a misoriented <111> surface

and Coleman (7). Assume a real surface to be almost homogeneous everywhere but with some inhomogeneities or discontinuities at several locations. These inhomogeneities will also have local orientation changes. It is predicted (7) that the growth rate at such discontinuities will be greater than the growth rate on the homogeneous region because nucleation will occur more readily at the discontinuities than at the homogeneous region. Figure 6 shows a schematic drawing of the epitaxial layer growth on a real surface having <111> orientation. If the deposition process is reaction rate controlled, then the over-all process is not orientation dependent. Consequently there are no differences in the growth features on the homogeneous regions and the inhomogeneous regions. The resultant epitaxial layer surface is merely an image of the substrate surface on which the layer was deposited. This result normally can be accomplished by depositing at a low silicon tetrachloride concentration. However, if the deposition process is growth rate controlled, then the over-all process is strongly orientation dependent and the reaction rate is greater than the growth rate. The difference between the reaction rate and the growth rate is shown by forming a stray crystal at an inhomogeneity at which the growth rate is greater than at other homogeneous regions on the surface. As shown in Fig. 3 the <111> oriented surface had the lowest growth rate when compared to other orientations. Consequently a "pyramid" on the surface is formed. In general, this result can be observed by depositing at a high silicon tetrachloride concentration.

The same general arguments can be applied for the case of a substrate surface which has an orientation other than the <111> orientation. Thus it is proposed that the atomic configuration of a misoriented {111} plane can be resolved into many steps which are parallel to the original {111} plane surface. This is shown schematically in Fig. 7. Such a misoriented {111} plane surface can have a greater growth rate than the {111} plane surface since it is expected that nucleation will occur more readily at the step corners formed by the {111} plane surfaces. Consequently the difference between the reaction rate and the growth rate on a misoriented {111} plane surface is less than the difference between the reaction rate and the growth rate on a {111} plane surface if the reaction rate is considered unchanged. Thus a substrate surface misoriented from the <111> direction can tolerate a higher deposition rate without developing pyramids on the surface.

Conclusions

The deposition rate was found to vary with substrate orientation. The deposition rate increased to a limit as the substrate was misoriented from <111> orientation. The <111> oriented substrate had the lowest deposition rate when compared to other major orientations, *i.e.*, <110> and <100>.

A pyramidal surface defect was found to be a function of both the deposition rate and the substrate orientation. The pyramidal defects were not observed when the deposition rate was slow, and/or when the substrate was misoriented from the <111> direction. These observations were explained by a proposed mechanism in which the deposition rate used in practice is considered to be composed of two fundamental rate processes reaction rate and growth rate which complement each other during the actual deposition.

Acknowledgment

The author wishes to thank Mrs. M. H. Read, Bell Telephone Laboratories, Murray Hill, for her x-ray work in determining the crystal orientations. Also, he is indebted to Dr. R. E. Caffrey for his valuable discussions.

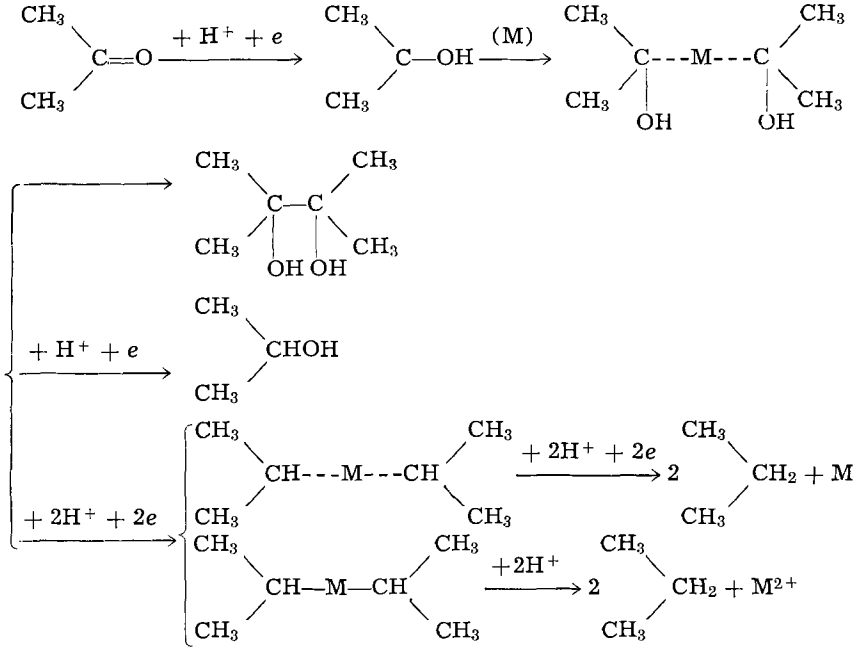
Mechanism of Hydrocarbon Formation in the Electrolytic Reduction of Acetone in Aqueous Sulfuric Acid

Taro Sekine, Akira Yamura, and Kiichiro Sugino

Department of Applied Electrochemistry, Tokyo Institute of Technology, Tokyo, Japan

ABSTRACT

A tentative mechanism or hydrocarbon formation is proposed which, by combining the usual mechanism of pinacol and isopropanol formation, will contribute to one clarification of the over-all electrode process of acetone reduction.



The main point lies in the fact that the radical $(CH_3)_2\dot{C}OH$ is further reduced with dehydration of propane through the isopropyl radical which is combined with the cathode metal. In certain cases (mercury and lead, etc.) the reaction products with metal (organometallic compound) can be isolated in a relatively stable form. Generally speaking, cathode material having a negative standard electrode potential tends to follow this hydrocarbon formation process.

In the electrolytic reduction of aliphatic ketones in acidic medium it is known that pinacol, secondary alcohol, and hydrocarbon are obtained as the main products. In the case of acetone, the reduction products were pinacol, isopropanol, and propane (1). Depending on the kind of cathode used, the amounts of the products obtained will differ considerably; at cadmium (1) and amalgamated zinc (2), the hydrocarbon was mainly obtained.

It is still not clear, however, why the use of different kinds of cathodes produces different types of products. It is impossible at this time to establish a complete mechanism of the electrolytic reduction of aliphatic ketones, although attempts have been made.[1]

The authors have undertaken this study in order to clarify the over-all electrode process of acetone reduction by trying to solve the problem of why the different kinds of cathodes cause the formation of different types of products, and in particular why the hydrocarbon is obtained.

Experimental

Assembly of the apparatus.—Arrangement of the electrolysis equipment and cell design are shown in Fig. 1. Two different types of cell, cylindrical and H type cell, were utilized for the convenience of preparative study and accurate gas analysis.

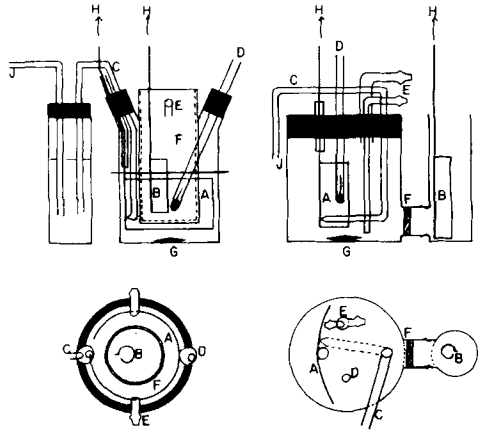


Fig. 1. Cell design: A, cathode; B, anode; C, salt bridge; D, thermometer; E, gas outlet to buret; F, diaphragm; G, stirrer (magnetic drive); H, to controlled potential electrolyzer; J, to saturated calomel electrode.

[1] Recently, S. Swann, Jr. reviewed the electrolytic reduction of keto groups to methylene groups in aliphatic compounds and he showed a tentative mechanism in which the metal of the cathode takes part in the reaction (3). This was originally put forth by Schall *et al.* (9).

Preparation of electrolyte.—Acetone was purified by distillation after standing for several days with potassium permanganate. HCl-KCl buffer solution (*p*H 1.55) and 0.2*N* sulfuric acid solution were used for the background solution of polarographic measurement.

Pretreatment of electrodes.—With the exception of mercury, which was carefully distilled before use, lead, cadmium, zinc, aluminum, nickel, tin, and copper cathodes were washed successively with dilute hydrochloric acid and water. The fresh electrodes were used immediately in the following experiments.

Analysis of the products.—A gas chromatographic technique (4) was utilized to determine the products which were formed during the electrolysis and those formed by the decomposition of organo-metallic intermediate.

The conditions of gas chromatographic analysis used are condensed in Table I.

At the same time, pinacol was separated from the electrolyte and determined by the following procedure.

The catholyte was neutralized with anhydrous potassium carbonate, filtered, and the resulting solution was distilled at reduced pressure to remove acetone and 2-propanol. The residue was extracted with ether and after drying, the ether solution was evaporated. Colorless needles were obtained having a melting point of 38°C.

With the exception of mercury, the ions of metals such as lead, cadmium, zinc, aluminum, nickel, tin, and copper in the electrolyte or in the decomposition product or organo-lead intermediate were determined polarographically at 20° ± 1°C after 5-30 min of deoxygenation by nitrogen. Mercury was determined by E.D.T.A. titration (5).

To confirm the structure of organo-metallic intermediate, the I.R. spectroscopic method was tried by using "Shimadzu I.R. spectrophotometer Type IR-27" at 35°C.

Results and Discussion

Current density-cathode potential curve.—A plot of current density *vs.* cathode potential was made in the catholyte described below by using controlled potential electrolyzer (Yanagimoto EV-3). Figure 2 shows the current density *vs.* cathode potential curves which were measured in a cylindrical cell at mercury, lead, cadmium, zinc, aluminum, nickel, tin, and copper cathodes, respectively. All measurements were carried out at 20° ± 1°C.

Polarographic measurement[2] was also carried out for the catholyte containing 1-10 x 10^{-3} mole/liter acetone in 0.2*N* H_2SO_4 or a HCl-KCl buffer. Polarograms of acetone are shown in Fig. 3. Current increases at mercury in Fig. 2 and 3 were seen at about —1.20v and are considered to be the reduction potential of acetone in sulfuric acid.

Although no noticeable reduction wave (showing half-wave potential) was observed on the polarogram of acetone reduction,[3] the interesting results were observed when the "controlled potential electrolyzer" was used on current-potential curve measurement. That is, at lead, cadmium and aluminum, a negative shift of current-potential curves was induced when

[2] Yanagimoto's High Sensitive Polarograph PA-201 was used.

[3] Nearly the same result was reported by Shikata and Tachi (6) and Zuman (7) for the same conditions.

acetone was added to the electrolyte, and at mercury, zinc, nickel, tin, and copper, a positive shift resulted.

Controlled potential electrolysis at various cathodes.—A controlled potential reduction of acetone in sulfuric acid was carried out at a reference potential of −1.375v, at various cathodes (mercury, lead, cadmium, zinc, aluminum, nickel, tin, copper) and was followed by the accurate determination of the products. The condition of electrolysis and its results are shown in Table II.

It was found that even when the reduction potential was the same, the types of products as well as the amounts differed substantially with the cathode used. For example, at mercury, 95% isopropanol, 3% pinacol, and 2% propane were obtained with a current efficiency of 73%. At lead, reduction occurred with a current efficiency of 86%, but the amount of isopropanol decreased to 68% while pinacol and propane increased to 7 and 25%, respectively. In these cases, aside from these reduction products, a small amount of organo-metallic compound which is considered to be reaction product of an intermediate and the cathode, was obtained. On the other hand, at cadmium, zinc, and aluminum cathodes, propane was the only product of electrolysis. At cadmium, reduction, for example, occurred with a current efficiency of 90% and formed 100% yield of propane. The current efficiency for propane formation *vs.* cathode potential is shown more clearly in Fig. 4.

Propane is formed at a potential more negative than −1.10v at a rapid rate and is accompanied by a slow evolution of hydrogen.

At nickel, tin, and copper, current efficiency was very much lower because of the low hydrogen overvoltage and film formation.

To obtain more insight into the mechanism of hydrocarbon formation, the electrolytic reduction of pinacol and 2-propanol was carried out at various cathodes under similar conditions and found to yield no propane.

Isolation of organo-metallic compounds and their decomposition.—The above results give no clue to the mechanism of the hydrocarbon formation and only indicate that a more negative electrode is necessary for the formation of hydrocarbon.

The observation that hydrocarbon formation was accompanied by pitting of the cathode suggested that the electrode had been attacked by a free radical.

This type of reaction was substantiated further by an interesting discovery during our experiments using mercury and lead cathodes. When the catholyte was allowed to stand after the electrolysis, there was a gradual formation of gas which turned out to be propane. Meanwhile, as previously reported (8), the above electrolyses produced also a small amount of oily substances which were considered to be organo-metallic compounds. Therefore, it seems to us that this propane might be formed as a result of the decomposition of the above-mentioned organo-metallic compounds.

To confirm this further, the catholyte containing the oily substance was taken out from the cell after the electrolysis and added to a saturated sodium chloride solution. The rate of decomposition and the composition of gas produced were then determined by gas buret and gas chromatography. The results are plotted in Fig. 5 and are listed in Table III.

As evident from the table, the oily substances seem to be the intermediate for propane formation.[4] Therefore, an attempt was made to isolate organo-metallic compounds and to clarify their properties. Although difficult, we succeeded in obtaining almost pure organo-mercury and organo-lead compound by careful procedure.

[4] An organo-metallic compound was postulated as an intermediate for the first time, by Schall and Kirst (9), in the electrolytic reduction of menthone to menthane.

Isolation of organo-metallic compounds.—The separation and purification of the oily substances were carried out in the glass apparatus shown in Fig. 6. The crude oily substance collected on filter paper by filtration of the catholyte was dissolved in ether and the solution was quickly introduced to "reservoir A" with anhydrous potassium carbonate. The atmosphere in the system was then completely replaced by nitrogen. After standing for about 10 min in the dark, the solution was transferred into "container B" through a glass filter attached at the bottom of the glass pipe inserted in "A." Evaporation of ether in "B" was then carried out by bubbling nitrogen gas in the dark and gave a pure organo-metallic compound. The decomposition of this compound was also carried out in the same vessel "B."

The mercury compound thus obtained had properties (b.p. 118°C, 125mm Hg, $d_4^{20} = 2.125$, $n_D^{20} = 1.526$) which were identical with those of diisopropyl mercury (10). The infrared absorption spectrum of this compound pointed to the presence of only methyl and methane groups and excluded the presence of any oxygen groupings. These data confirmed the structure of the compound as diisopropyl mercury. This structure was further verified by the identification of its decomposition products. For the lead compound, the measurement of physical contents was difficult due to its instability in air. Its composition as diisopropyllead was clearly indicated from the results of the decomposition study.

Decomposition of organo-metallic compounds.—The decomposition of the mercury compound under the exposure of mercury lamp was carried out in a nitrogen atmosphere. The results are shown in Table IV.

The rate of decomposition of the lead compound seemed to be more rapid than that of the mercury compound. The results are shown in Table V. The products confirmed the structure as diisopropyl lead.

The results indicate that the organometallic compounds are the source of the propane in the electrolysis. Decomposition in the presence of 20% sulfuric acid is accelerated by light and gives practically a quantitative yield of propane and metallic ions.

The formation of propane and propylene under other conditions points to the formation of an isopropyl radical which undergoes disproportionation. This reaction apparently occurs to a slight extent in acidic medium.

The sensitivity of the organometallic compounds to light is in agreement with the work done on lead tetramethyl and mercury dimethyl by Leighton and Mortensen.

of hydrogen from the ether by an isopropyl radical with the formation of ethyl radicals.

Attempts to isolate an organocadmium compound in the electrolysis at a cadmium electrode, which produces a quantitative yield of propane, was not successful in agreement with the sensitivity of the compounds to acid.

In the absence of light this electrolysis gave large amounts of hydrogen and a current efficiency for propane formation of 37%. The results are shown in Table VI.

Transpiration in an Open Tube GaAs/HI/H_2 System

G. Hellbardt

IBM Laboratories, Boeblingen, Germany

ABSTRACT

Etching rates and deposition rates have been measured in an open tube GaAs/HI/H_2 system for various iodine concentrations, flow rates, and temperatures between 500° and 850°C. Etching as well as deposition reactions are close to equilibrium at the surface of the solid GaAs. However, the amount of material of the vapor phase coming into contact with the solid is different in the two cases. At low flow rates the total flux through the tube takes part in the etching reaction whereas a certain fraction only takes part in the deposition reaction. It is suggested that different diffusion processes in the vapor phase cause this difference.

It has already been shown (1, 2) that etching rate measurements in open tube systems may yield results concerning the reaction mechanism.

Now the method of etching as well as deposition rate measurements has been applied to the system GaAs/HI/H_2. Whereas the thermodynamic data for the systems GaAs/H_2O/H_2 and GaAs/HCl/H_2 investigated in (2) had not been sufficiently and reliably known, in the system GaAs/HI/H_2 all the species in the gas phase and their mutual reactions are well known from thermodynamical equilibrium studies by Silvestri and Lyons (3) as well as by spectroscopic measurements by Richman (4). Furthermore, Leonhardt (5) calculated from these equilibrium data the partial pressures of all species in the vapor for a wide range of temperature. Thus we were able to compare immediately the results of our measurements with the equilibrium data. The question to be answered was how close to equilibrium the chemical reactions occur under the conditions of actual open tube vapor growth experiments.

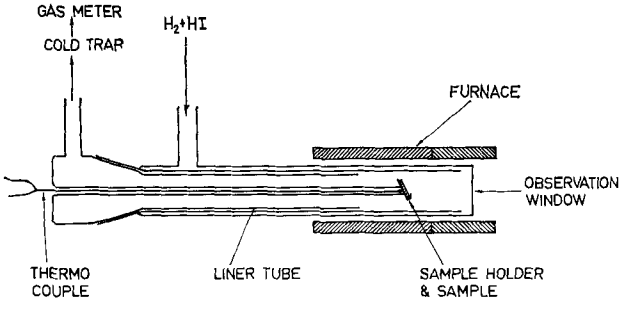

Fig. 1. Vapor etching apparatus

Experimental

Etching rate measurements.—The apparatus used in these experiments is shown in Fig. 1. Highly purified hydrogen is loaded with iodine in a U-tube filled with iodine and quartz granules and heated by a water bath to a temperature of $T_I = 50.3° \pm 0.1°C$. Additional experiments ascertained that the hydrogen/iodine mixture leaving the U-tube is saturated with iodine for all flow rates between 10 cm³/min and 500 cm³/min. The partial pressure of iodine which we found at the above mentioned temperature was $p_{I2} = 2.01$ mm Hg. The H_2/I_2 mixture is then passed through a reaction chamber containing platinized quartz wool at 450°C approximately after which the vapor consists of H_2 + HI only. This mixture is led into the double walled apparatus in which it is heated before it reacts with the GaAs sample. The reaction products leave the apparatus through a linear tube which is exchanged after each run and which prevents severe contamination of the reaction chamber.

All reaction products plus the unreacted HI are condensed in a liquid nitrogen cooled cold trap. The total volume of the pure H_2 leaving the cold trap is measured in a precision gas meter.

The face of the GaAs sample exposed to the vapor is the chemically polished (111) oriented Ga side.

Deposition rate measurements.—These experiments have been done in a simple connected tube apparatus (Fig. 2). In the first (lower) tube the seed is heated under the protection of pure H_2. In the meanwhile H_2 + HI stream over the source basket containing polycrystalline GaAs as source material. As soon as

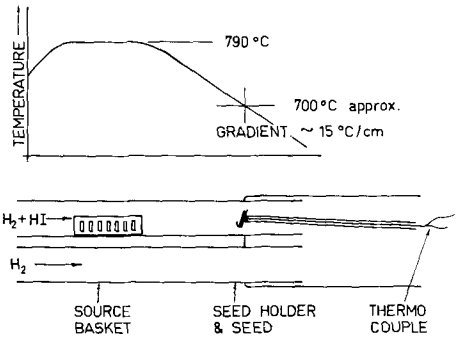

Fig. 2. Schematic sketch of the vapor deposition apparatus

the seed reaches the proper temperature it is pulled out of the lower tube and pushed into the upper one. The apparatus permits this operation to be done without opening a tube. Growth begins immediately.

The temperature profile which is the same in both tubes is such that the temperature in the source basket region is uniform within ±2°C, and the temperature gradient is constant in the vicinity of the seed. It is about 15°C/cm. Source temperature T_s and the temperature of the wafer T_w are measured by thermocouples during the run. Here, too, the exposed face of the sample is (111) oriented, Ga side.

Results

Etching rates.—Figure 3 contains all results of our etching rate experiments. The ratio of the total flux of gallium atoms in the vapor phase to the total flux of iodine atoms

$$y = \frac{n_{Ga}}{n_I} \qquad [A]$$

is plotted *vs.* the temperature of the wafer T_w. Since n_I is constant for a constant flow rate and n_{Ga} is proportional to the etching rate (cf. Eq. [1]) y itself is proportional to the weight loss per unit of time w/t in etching rate experiments. The full lines represent the theoretical values of y calculated by Leonhardt (5). The parameter is

$$\frac{P_I}{P_{tot}} = \frac{2 \times \text{partial pressure of iodine}}{\text{total pressure}} \qquad [B]$$

as measured in the iodine generator. P_{tot} used in that calculation is $P_{tot} = 1$ atm $= 735$ mm Hg, whereas we have a total (atmospheric) pressure of 720 mm Hg. We neglected this difference of 2% and calculated

$$\frac{P_I}{P_{tot}} = \frac{2 \times 2.01}{720} = 0.0056$$

This is between the values of $P_I/P_{tot} = 0.0025$ and 0.0125 available from the data of Leonhardt.

Most of the points are below the two curves. Apparently this is due to an effect of flow rate. Figure 4 shows this effect for two temperatures $T_w = 650$°C and $T_w = 800$°C; y decreases with increasing flow rate.

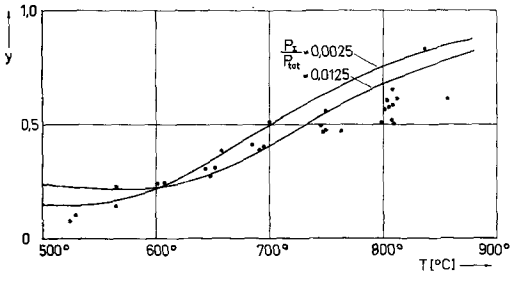

Fig. 3. Ratio of the total amount of gallium in the vapor phase to the total amount of iodine in etching experiments.

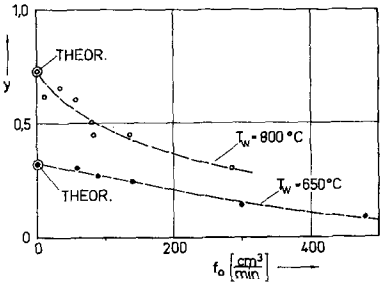

Fig. 4. Dependence of the etching rate on flow rate

The flow rate on the abscissa is in standard cm³/min. The linear velocity at $f_o = 100$ cm³/min and $T_w = 800$°C is $v = 138$ cm/min.

The theoretical values plotted at zero flow rates have been found by interpolation from the two theoretical curves in Fig. 3. Two lines can be drawn from these values through the experimental points of $T_w = 800$°C and 650°C, respectively. It appears that there is a dependence of the etching rate on the flow rate, but that for low flow rates the etching rates approach the equilibrium values.

Deposition rates.—For two different iodine concentrations corresponding to two different iodine generator temperatures T_I deposition experiments have been made. The iodine vapor pressures as determined in separate experiments were

$$T_I = 50.3, \quad P_{I_2} = 2.01 \text{ mm Hg}$$

$$T_I = 60.3, \quad P_{I_2} = 3.94 \text{ mm Hg}$$

The experimental deposition rates have been calculated from

$$g_{exp} = \frac{\Delta w}{M \cdot t \cdot A_w} \qquad [C]$$

where Δw, gain in weight of the wafer; M, molecular weight of GaAs; t, duration of the run; and A_w, area of the wafer.

The drawn curves (Fig. 5) represent values calculated according to

$$g_{calc.} = n_I[y_{T_s} - y_{T_w}]/A_T \qquad [D]$$

where n_I is the number of moles of iodine flowing through every cross section of the apparatus per unit of time, T_s the source temperature, T_w the wafer (seed)

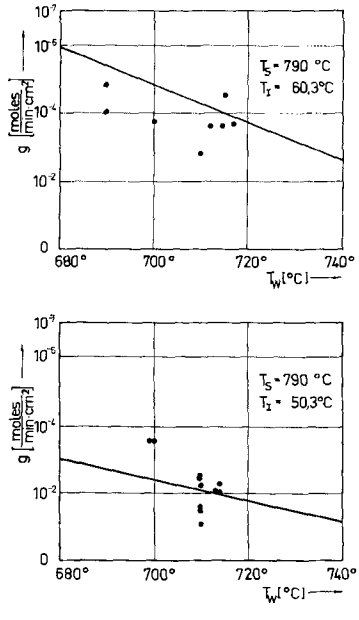

Fig. 5. Deposition rates for two different iodine concentrations

temperature, and A_T the area of the reaction tube. n_I can be calculated from the partial pressure of iodine in the iodine source and the flow rate.

For $T_I = 50.3°C$ with $P_I/P_{tot} = 0.0056$ $y_{theor.}$ has been taken from the curve of $P_I/P_{tot} = 0.0025$, while for $T_I = 60.3°C$ and $P_I/P_{tot} = 0.011$ the values have been taken from the curve of $P_I/P_{tot} = 0.0125$. In view of the scatter of the experimental points no serious error should be introduced by this approximation. The experimental points are scattered around the theoretical curves.

Discussion

Two diffusion effects have to be considered in etching rate experiments.

The first one has already been discussed in principle by Wagner and Stein (6) and others. If there is a concentration gradient along the axis of transportation, transport of the considered species will take place not only by linear flow but by diffusion also.

To calculate the magnitude of this effect in our etching rate experiments we assume the reaction

$$GaAs_s + HI_g \rightleftarrows GaI_g + \frac{1}{2}H_{2g} + \frac{1}{4}As_{4g} \qquad [1]$$

to take place.

Neglecting the partial pressure of GaI_3 is at least justified at 800°C. The mass action equation is

$$K = \frac{P_{GaI} \cdot P^{1/2}_{H2} \cdot P^{1/4}_{As4}}{P_{HI}} \qquad [2]$$

Furthermore, we write down an equation expressing the conservation of iodine during this reaction. HI enters the system at a partial pressure P^1_{HI}. Behind the GaAs the partial pressure of HI is constant and equal to P^o_{HI}. Consequently, no diffusion effects enhancing the transport of HI take place behind the GaAs. The amount of HI used up in the formation of GaI is given by

$$F = \frac{w \cdot q}{RT}(P^1_{HI} - P^o_{HI}) \qquad [3]$$

The flow F' of GaI from the GaAs is

$$F' = \frac{q}{RT}\left[-D\frac{dP_{GaI}}{dx} + wP_{GaI}\right] \qquad [4]$$

with D the diffusion constant of GaI in H_2, q the cross section area of the tube, x the coordinate parallel to the axis of the tube, and w the linear velocity of flow.

Under the conditions of steady state $F = \text{const}$ and $P_{GaI} = P^o_{GaI}$ at $x = 0$, *i.e.*, at the site of the GaAs, and $P_{GaI} = 0$ at a distance L behind the GaAs, Eq. [4] yields an expression for P_{GaI} as has been shown by Wagner and Stein (6).

$$P_{GaI} = \frac{P^o_{GaI}}{1 - \exp -\frac{w}{D}L}\left(1 - \exp -\frac{w}{D}(L - x)\right) \qquad [5]$$

$F = F'$ means the conservation of iodine and yields

$$P^1_{HI} - P^o_{HI} = P^o_{GaI}\frac{1}{1 - \exp -\frac{w}{D}L} = P^o_{GaI} \cdot \alpha \qquad [6]$$

With $P_{H_2} \approx \text{const} \approx 1$ atm and

$$P_{GaI} = 4P_{As4}$$

we get from [2] at $x = 0$

$$\frac{P^{o\,5/4}_{GaI}}{P^o_{HI}} = \frac{K}{0.707} = K' \qquad [7]$$

From [6] and [7] we arrive at

$$P^{o\,5/4}_{GaI} + K' \alpha P^o_{GaI} - K' P^1_{HI} = 0 \qquad [8]$$

The value of α is 1 with no diffusion going on. If α is varied by $d\alpha$ P^o_{GaI} is varied by dP.

We then get

$$\frac{F + dF}{F} = \left(1 + \frac{dP}{P^o_{GaI}}\right)\left(1 + \frac{d\alpha}{\alpha}\right) \qquad [9]$$

From [8] we obtain

$$\frac{dP}{P^o_{GaI}} = -\frac{1}{1 + 5P^{o\,1/4}_{GaI}/4K'}d\alpha \qquad [10]$$

With $T = 800°C$, $D = 1$ cm²/sec,[1] $f_o = 20$ cc/min, $q = 3$ cm², $L = 10$ cm, $d\alpha$ becomes $d\alpha = 0.01$. Since it is $P^o_{GaI} = 0.0019$ atm and $K = 0.45$ at 800°C (5) we get

$$\frac{dP}{P^o_{GaI}} = -0.007$$

The change in transport rate is

$$\frac{dF}{F} = 0.003$$

At lower temperatures w/D becomes larger, since it is $w \sim T$ and $D \sim T^{3/2}$, so that diffusion effects become still less important. Consequently, the partial pressures of GaI and GaI_3 are still less changed by diffusion drain from the GaAs source.

The second diffusion effect concerns the transport of reactants from the gas stream to the surface of the GaAs. The etched or grown surfaces on the wafer very often show striations not necessarily crystal oriented which can be explained as sort of flow patterns. These could not exist if the flow in the neighborhood of the wafer were turbulent. If, however, the flow is laminar, we must assume that a diffusion process is responsible for the mass transport from the vapor to the surface of the solid GaAs. Due to this effect the etching rate should decrease as the quantity w/D increases.

A quantitative model should be able to explain Fig. 4. It should also give different magnitudes of this diffusion effect at the source and at the seed because of the different numbers and types of species diffusing to and from the surface of the GaAs. However, we have not pursued this idea to a point where we can give quantitative answers.

Since the first diffusion effect has been shown to be negligible at least at flow rates above 20 cc/min, Fig. 4 means that the concentrations approach the equilibrium values in the vicinity of the solid GaAs with decreasing flow rates. In other words, almost all of the material passing the solid GaAs in our system reacts with the GaAs to equilibrium at 20 cc/min. We therefore assume that at higher flow rates there is also equilibrium at the surface of the solid. However, not all of the material in the gas phase can get to that surface in time before it passes by. This causes a decrease in the etching rate.

A similar thing happens at the seed. Since the same reactions take place at the source and at the seed, and the temperature region is about the same, we have no reason to assume that there is no equilibrium at the surface of the solid GaAs seed. However, the diffusion of material to and from the seed can be different as explained above. Therefore, the ratio of the amount of material reacting with the GaAs to the amount of material passing by unreacted is different.

Comparison of Eq. [C] and [D] shows that in calculating the experimental g values we referred to the wafer area whereas we calculated the theoretical values referring to the cross-sectional area of the tube.

[1] This diffusion constant has been assumed to be valid at 800°C for this estimate of the diffusion effect. Assuming the $T^{3/2}$ dependence on temperature this corresponds to a value of 0.13 cm²/sec at 0°C, which is about right if one compares it with the diffusion constant of metals in H_2 (7). One has to take into account that the molecule of GaI is larger than the metal atoms, *e.g.*, Hg.

Since we used a relatively large amount of polycrystalline GaAs as source we are sure from our etching rate experiments that we are in equilibrium there. Then the coincidence of the theoretical and experimental values (Fig. 5) actually means that the ratio as quoted above is equal to the ratio $A_w:A_T$ and that very little diffusion transport takes place.

Conclusions

Etching rate as well as deposition rate measurements in the GaAs/HI/H_2 open tube system showed that chemical reactions in vapor growth experiments go on close to equilibrium at the surface of the solid GaAs in the source region as well as in the seed region. However, the amount of material from the vapor which comes into contact with the solid depends on linear flow velocities. It is much higher in the source region than at the seed.

With the results of these experiments it is possible to predict deposition rates and efficiencies of vapor growth experiments in the open tube GaAs/HI/H_2 system. However, for a better understanding of the different kinetics at the source and the seed it is highly desirable to know more about the diffusion processes taking part in open tube experiments.

Acknowledgments

The author wishes to express his appreciation of the stimulating discussion with W. Kappallo and M. Michelitsch as well as his thanks to H. Leonhardt for furnishing the tabulated results of his calculations and for permission to publish these. The help of Miss G. Fritsche and Mr. M. Schlack in the experiments is gratefully acknowledged.

Manuscript received Mar. 2, 1964; revised manuscript received Nov. 27, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

The Thermodynamic Properties of Dilute Solutions of Oxygen in the Liquid Binary Cu-Ni Alloys

E. S. Tankins, J. F. Erthal, and M. K. Thomas, Jr.

Naval Air Engineering Center, Aeronautical Materials Laboratory, Philadelphia, Pennsylvania

ABSTRACT

Thermodynamic properties of dilute solutions of oxygen in the Cu-Ni systems have been studied by means of the hydrogen-water vapor equilibrium The following reaction

$$H_2\ (g) + [O]_{soln} = H_2O\ (g)$$

was studied for which an equilibrium ratio can be written

$$K = \frac{P_{H_2O}}{P_{H_2}[a/o\ O]} \qquad [1]$$

where P_{H_2O} and P_{H_2} are the partial pressures of water vapor and hydrogen and [a/o O] is the amount of dissolved oxygen in atomic per cent. The equilibrium reaction [1] has been investigated over a wide temperature range and also for various composition ranges. Equations are presented which show the variation of the equilibrium constant [1] as a function of composition and temperature. Equations are also presented which show the variation of the standard free energy of solution of oxygen as a function of temperature for various compositions. Evidence is presented which shows Henry's law is obeyed by oxygen within experimental error over a substantial composition range.

The copper nickel system forms a series of very important commercial alloys. Pure nickel and pure copper are resistant to oxidation. The Cu-Ni equilibrium diagram (1) shows only one solid solution and the only solid-state change is the magnetic change in the high nickel end of the diagram.

Data on the reaction between liquid metal and gases are of great practical importance to the process metallurgist as well as to the theoretical metallurgist who is trying to develop a dilute solution theory to make predictions of properties of the various multicomponent systems.

Alcock and Richardson (2, 3) have discussed the dilute solutions of molten liquids and alloys. They applied the quasi-chemical model with some success to the Cu-Ni-S system. Recently, Oriani and Alcock (4) reviewed some simple models of solution.

The object of this investigation was to determine equilibria in the following reaction from 1400° to 1600°C at the high nickel end

$$H_2\ (g) + [O]_{soln} = H_2O\ (g)$$

$$K = \frac{P_{H_2O}}{P_{H_2}[a/o\ O]} \qquad [1]$$

where P_{H_2O} and P_{H_2} are the partial pressures of water vapor and hydrogen and [a/o O] is the amount of dissolved oxygen in atomic per cent.

Experimental Procedures

Materials.—The metals used in the investigation in the equilibrium apparatus were high-purity Mond Nickel Pellets and Spectrographic Purity Copper. There was no detectable nitrogen and the initial oxygen contents were less than 0.0050 weight per cent (w/o).

Two high-purity argon-hydrogen mixtures were used with hydrogen contents of 1.02 and 0.20 in volume per cent (v/o). Further purification of the gas mixtures was effected by passing them through magnesium chips held at 630°C in a stainless steel tube furnace.

Equilibrium apparatus.—The purified hydrogen-argon mixture was led via a capillary type flow meter through a water presaturator to a condenser system submerged in a thermostatically controlled water bath. The resulting gas mixture was led through heated glass tubing to a vertical resistance heated, equilibrium furnace. Within the equilibrium furnace, the gas mixture was led through a ⅛ in. bore alumina inlet tube to the surface of the melt which was held in a pure alumina crucible, ¾ in. in diameter and 2 in. high. The pedestal which supported the crucible allowed the surface of the melt to touch the alumina inlet tube. A detailed description of the apparatus and associated electrical system has been published elsewhere (5, 6).

The temperature in the uniform temperature zone of the furnace was measured principally by a L&N Optical Pyrometer sighted through an optical flat onto the crucible pedestal. A Pt-Pt-10% Rh thermocouple was inserted from time to time into the alumina tube which supported the crucible pedestal; this served as a means of calibrating the optical pyrometer and as a double check on the temperature.

The water bath temperature was controlled by means of a mercury thermostat to better than ±0.1°C, the temperature being measured on a calibrated mercury thermometer which could be read to 0.1°C.

Analysis.—The samples were prepared for oxygen analysis by splitting the entire solidified ingot, usually vertically, with a hack-saw and then grinding at least 1/32 in. off the outside. If there were any blow holes in the sample, they were carefully ground out to ensure that any oxide which might have been formed during the quenching operation was removed and to make certain that no abrasive materials were trapped. Only the high copper alloys exhibited such blow holes. The samples were numbered, degreased, weighed, and kept in a dessicator until analyzed. Care was taken to avoid manual contact with the samples once they had been cleaned.

The oxygen analysis was by an improved vacuum fusion method which has recently been described (7). The major alloying elements were not determined since previous analysis of other alloy systems indicate that the desired composition was very close to the actual.

Procedure.—The apparatus was prepared for an experiment by replacing the alumina inlet tube, cleaning the sight window, adjusting the thermostat temperature, setting the furnace in the desired temperature range, and starting the gas flow in order to purge the system. The presaturator was adjusted until excess water precipitated in the condenser at the rate of a few cubic centimeters per hour. A pure alumina crucible was charged with a 10g heat and placed on the crucible pedestal in the bottom of the furnace tube. The pedestal was then slowly raised until the crucible was in the constant temperature zone of the furnace. When the charge had melted, the pedestal was further raised until the inlet tube was just touching the surface of the melt and a back pressure of 1-4 cm was indicated on a small water manometer placed in the gas train. The pedestal support tube was then clamped in position.

The in-flow pressure of water corresponding to the temperature of the saturator was taken from the published tables (8), and the P_{H_2O}/P_{H_2} ratio derived in the usual manner from the composition of the in-going hydrogen-argon gas mixture, with the necessary corrections for barometric pressure and the small back pressure within the apparatus. No fugacity corrections were made, as it was considered that these were too small to be significant within the experimental error.

Results and Discussion

The reactions investigated in this work may be represented by

$$H_2\ (g) + O\ [\text{in Ni-Cu}] = H_2O\ (g)$$

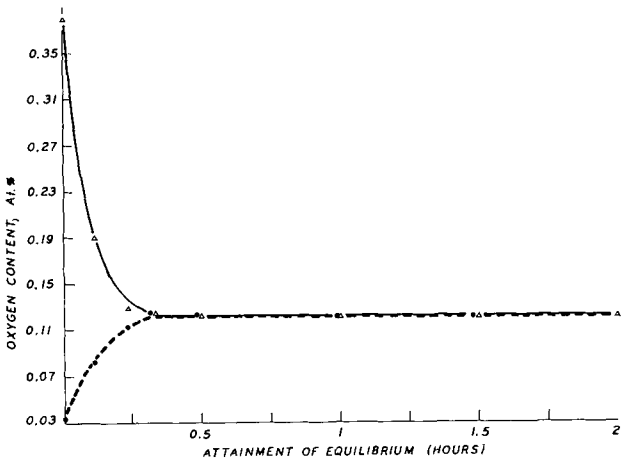

Fig. 1. Attainment of equilibrium for a 50Cu-50Ni alloy with a fixed gas composition, 1550°C: △ ——, initial oxygen 0.3800 a/o; ● - - - -, initial oxygen 0.0305 a/o.

$$K = \frac{P_{H_2O}}{P_{H_2}[\text{a/o O}]} \qquad [2]$$

where K is the equilibrium constant. The experimental results and their discussion are presented in the ensuing sections.

Attainment of equilibrium.—The attainment of equilibrium for a 50Cu-50Ni alloy with a fixed gas composition is shown in Fig. 1. The results show that in all cases except in the top line corresponding to a high oxygen content, equilibrium was reached in less than 30 min. The higher oxygen contents reached equilibrium in 30 min. The initial points on the curve probably are not as accurate because the control of temperature at the beginning is not as close as later on during each experiment. The results are also tabulated in Table I.

The melts were held at temperature with a gas flow rate of approximately 120 cc/min for at least 40 min. Earlier work on the pure metals (6) had shown equilibrium was attained in 20 min for this particular arrangement. It was assumed that copper behaved similarly to nickel, but as a further check, several duplicate runs were carried out for longer times for an alloy at the higher copper end. There was no significant change in oxygen content.

Equilibrium results for 1550°C.—In order for the derived value of K to be meaningful, either the dissolved oxygen must obey Henry's law, or a suitable extrapolation to the infinitely dilute solution must be made. It has been shown in earlier work (6) that oxygen obeys Henry's law over a substantial composi-

tion range for pure Fe, Co, and Ni at 1550°C. Table II and Fig. 2 show the experimental results over a wide range of oxygen contents in the 50Cu-50Ni binary alloy at 1550°C. The independence of the equilibrium constant relative to the oxygen content is shown in Fig. 2. All the additional experimental runs were carried out at the lower oxygen content to insure compatability with Henry's law. A comprehensive discussion of possible discrepancies in Henry's law has been made (6).

Equilibrium results for various temperatures.—The results for various compositions of the nickel-copper alloy system are shown in Table III. The results can be represented in the usual form $\log_{10}K$ *vs.* $1/T$.

Experimental results were obtained with a computator for the least mean square calculation. Probable errors in the slopes and intercepts of the derived straight lines were calculated by the methods of Birge (9). The resulting equation for $\log_{10}K$ with probable error, are listed in Table IV.

The standard energy change for the reaction

$$H_2\ (g) + \tfrac{1}{2}\ O_2\ (g) = H_2O\ (g) \qquad [3]$$

was taken as

$$F^\circ = -59{,}905 + 13.78T \qquad [4]$$

The straight line equations for $\log_{10}K$ were converted to standard free energy equations for reaction [2] by application of the relationship

$$F^\circ = -RT \log K \qquad [5]$$

The derived equations were subtracted from Eq. [4] to yield a series of equations representing the standard free energy change, $F^\circ\%-F^\circ$ for the reaction

$$\tfrac{1}{2}\ O_2\ (\text{gas}) = [O]\ \text{soln} \qquad [6]$$

Table IV lists the derived equations; no account was taken of possible error in Eq. [4] in the listed probable errors.

The free energy of solution for the three are very close to 22 kcal at 1550°C. This means that the maximum solubility of oxygen is probably about the same in this range of alloys. The activity coefficient of oxygen due to the presence of copper in the nickel matrix is relatively constant over the 20-60% range.

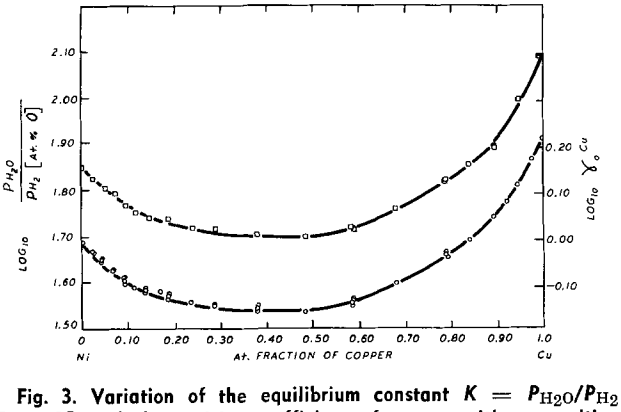

Fig. 3. Variation of the equilibrium constant $K = P_{H_2O}/P_{H_2}$ [a/o O] and the activity coefficient of oxygen with composition in the Ni-Cu alloys at 1550° (□—□—□—) and 1500°C (○—○—○—).

Table IV. Equations representing equilibrium constant and standard free energy of solution as a function of temperature

Copper w/o	$\log_{10} k$	F° $\frac{1}{2}O_2$ (g) = O soln.
20	$\frac{10{,}439\ (\pm 29)}{T} - 4.146\ (\pm 0.0165)$	$-12{,}136\ (\pm 133) - 5.192\ (\pm 0.076)T$
40	$\frac{10{,}355\ (\pm 25)}{T} - 4.138\ (\pm 0.0142)$	$-12{,}521\ (\pm 116) - 5.155\ (\pm 0.065)T$

From the consideration of the maximum uncertainties in the temperature, water ratio and oxygen analysis, one of the authors earlier suggested (6) a maximum probable error of about ±5% on the derived value of K; in general, the experimental scatter reported in this paper is consistent with this view. Analyses of many alloys in previous work for various binary alloys chosen at random showed no significant deviation in metal content (0.3%) from the stated compositions; this was ignored in considering the probable errors. The probable errors listed in Table IV suggest that the maximum probable error in the standard enthalpies of solution is of the order of 1 kcal.

Equilibrium results for binary alloys at 1550° and 1500°C.—Additional equilibrium runs are tabulated in Table V and are shown plotted in Fig. 3 for 1500° and 1550°C. There are additional runs above 60 w/o (weight per cent) Cu in order to see how the curve goes; however, the emphasis is being placed on the high nickel end of the system.

The copper-nickel system is a unique series. These alloys form a face-centered cubic lattice. The copper atom contains one more electron than the nickel atom, and to a first approximation, if a nickel atom is replaced by a copper atom in the alloy, the lattice is unaltered except that an electron is added which will raise the surface of the Fermi distribution and the lattice parameters show only slight changes.

Since the phase diagrams of the Cu-Ni system show an almost ideal solid solution alloy, one would suspect that Raoult's law for the liquid state would be obeyed and that the activity coefficient would be unity or close to unity. The conclusion to be drawn is that the free energy of solution would be a linear function of alloying addition for the dissolved oxygen. Figure 3 shows that this is not the case. The excess free energy of solution of dissolved oxygen is a function of the equilibrium constant. The value of $\log_{10}K$ decreases with the addition of Cu to the nickel matrix, and after reaching a minimum value remains almost constant over a wide range of composition. At the high copper end, there is a rapid increase in $\log_{10}K$ which has been observed in other binary systems. At the present time, there is no theoretical explanation for this behavior.

The equilibrium constant for the pure nickel is from an earlier publication (6). Two runs were made with pure copper to see how the results compare with Girardi and Siebert (10) and Sano and Sakao (11). The results are somewhat lower than those of Siebert or Sakao's; however, they are sufficient to show the trend of the curve. There is no explanation at present for the discrepancy, and an intensive investigation on pure copper is forthcoming in the near future.

Figure 3 shows the change in the activity coefficient of oxygen at the high nickel end, and then a constant range and at 0.6 copper the activity coefficient of oxygen changes. This behavior is very similar to what Alcock and Richardson (2) noted for the Cu-Ni-S system. It is interesting to note that at the corresponding composition in the solid state the alloy changes in magnetic properties.

Alcock and Richardson (2) discuss the work of Himmler (12) on the electronic effects and applied their results on the dissolved sulfur in various alloys to the model. Himmler assumed that the chemical potential of the free electrons increased as the ratio of the free electrons to atom ratio in the alloy increased. There was an excellent correlation for the chemical potential of hydrogen; however, Alcock and Richardson's work with sulfur in the several alloy systems showed that the behavior of sulfur could not be explained solely in terms of the electron to atom ratio. The electronic effect may have some effect on the dissolved oxygen and may be important, but at present there is insufficient data to make any correlation and to separate the electronic effects from other effects. The quasi-chemical model as described in great detail by Alcock and Richardson (3) was applied to the present work. The model gives the proper sign and shape to the curve for the activity coefficient of oxygen. To apply the equations that Alcock and Richardson derived (3), accurate data are needed for the activities of copper and nickel in the Cu-Ni alloy system. If one assumes Raoult's law to hold over the entire composition range for the Cu-Ni system, then the calculated values for the activity coefficient of oxygen is greater than the experimental results plotted in Fig. 3. It is interesting to note that, if one considers that the copper-nickel system exhibits positive deviation from Raoult's law, then the calculated results for the activity coefficient for oxygen will be in closer agreement with the experimental results.

Activity and interaction parameter studies.—It is convenient to use a reference state which can be defined for the infinitely dilute solution of oxygen in nickel, where $a_o = 1$. The oxygen activities in the Cu-Ni alloys, therefore, are based on an activity relative to that in pure nickel.

The equilibrium for the reaction studied may be rewritten in the form

$$K_1 = \frac{P_{H_2O}}{P_{H_2}} \cdot \frac{1}{N_o{}^a \gamma_o{}^a} \qquad [7]$$

where $N_o{}^a$ is the mole fraction of oxygen in the alloy and $\gamma_o{}^a$ is the activity coefficient of oxygen in the alloy. By taking logarithms of Eq. [7] and rearranging the following expression is obtained

$$\log \gamma_o{}^a + \log K_1 = \log \frac{P_{H_2O}}{P_{H_2}} - \log N_o{}^a \qquad [8]$$

The expression on the right hand side is the experimentally determined quantity, but K_1 cannot be determined directly because of the lack of information on oxygen activity. A new equilibrium constant K_2 is defined as

$$K_2 = \frac{P_{H_2O}}{P_{H_2}} \cdot \frac{1}{N_o{}^a} \qquad [9]$$

$$\log K_2 = \log P_{H_2O}/P_{H_2} - \log N_o{}^a \qquad [10]$$

or

$$\log N_o{}^a = \log P_{H_2O}/P_{H_2} - \log K_2$$

Comparing Eq. [8] with Eq. [10], the following expression is obtained

$$\log \gamma_o{}^a = \log K_2 - \log K_1 \qquad [11]$$

Since K_2 is constant with composition, the activity coefficient is constant and, therefore, $\log K_1 = \log K_{Ni}$. Log $\gamma_o{}^a$ can be computed from the following equation

$$\log \gamma_o{}^a = \log K_2 - \log K_{Ni} \qquad [12]$$

Values for log K_2 were the experimental values determined in this study, and log K_{Ni} is obtained from earlier work (6). A plot of log K as composition, Fig. 3, will give log $\gamma_o{}^a$ which is parallel to the curve for log K with its zero at the pure Ni end of the curve.

Figure 4 shows an expanded view at the high nickel end of the diagram. Results are tabulated in Table V.

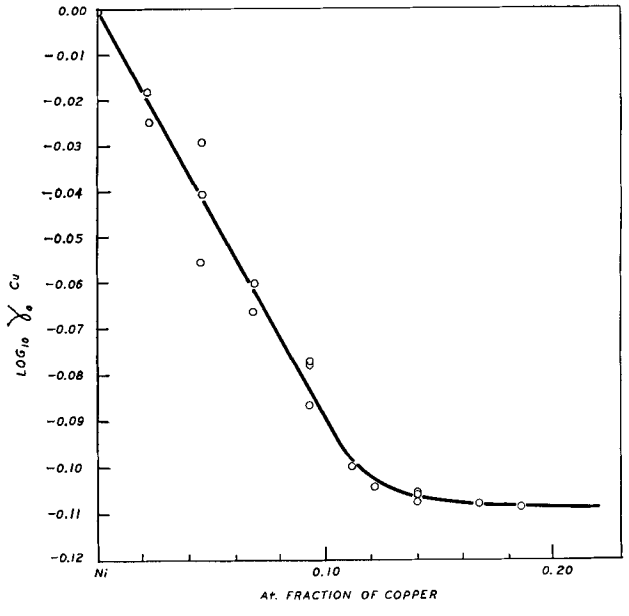

Fig. 4. Expanded view of the activity coefficient of oxygen at the nickel end of the Ni-Cu alloys at 1550°C to show the effect of Cu on the activity coefficient of oxygen in Ni.

A useful quantity can be derived from a measure of the terminal effects. The interaction parameter due to Wagner (13) can be obtained by differentiating the natural log of the activity coefficient of oxygen with respect to the mole fraction.

$$\epsilon = \left(\frac{\partial \ln \gamma_o{}^a}{\partial \text{Ni}} \right)_{\text{as Ni} \to 0} \qquad [13]$$

where ϵ is the interaction parameter, $\gamma_o{}^a$ the activity coefficient of oxygen in the alloy, and N the mole fraction of copper. From Fig. 4, one obtains a value of

$$\epsilon = -2.07$$

This value is valid up to 10% copper in nickel. The interaction parameter will allow one to calculate the excess free energy of solution.

Summary

A number of related thermodynamic equations, *e.g.*, $\Delta F°$, for the transfer of oxygen in the liquid Cu-Ni alloys have been investigated in great detail. The experimental results are represented as linear functions of $1/T$, and the related standard free energy changes are expressed as linear functions of temperature. It has been established that the dissolved oxygen in these metals follows Henry's law well within experimental errors.

The equilibrium relationships for dissolved oxygen have been investigated over a wide range of compositions for the copper-nickel alloys at two temperatures.

The interaction parameter has been determined at the high nickel end of the Ni-Cu alloy system.

Acknowledgments

Financial support for the work was from Foundational Research Project No. 9. The authors would like to thank Mr. J. Thompkins from AML for his assistance and Mr. J. Ryan for the computer work. The authors also would like to acknowledge the technical assistance of Mr. J. Hirl from AML.

Hydrogen Adsorption on Platinum Single Crystal Electrodes

I. Isotherms and Heats of Adsorption

Fritz G. Will

Research Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

The adsorption of hydrogen on the three main faces (100), (111), and (110) of platinum single crystal electrodes has been studied in 8*N* H_2SO_4 at different temperatures with the voltage sweep method. As on polycrystalline platinum electrodes, hydrogen adsorbs on each of the faces in two distinctly different binding states which present themselves as two pronounced maxima in the current-voltage sweep curves. There are indications for a third binding state giving rise to a third, less pronounced maximum. The potentials at which the maxima occur are essentially the same for polycrystalline and for each of the three single crystal electrodes. However, the relative heights of the maxima are different in each case. The adsorption isotherms and the heats of adsorption are also notably different on the three faces. Under the usual assumption of one hydrogen atom adsorbed per platinum surface atom, initial roughness factors of 1.0-1.9 result which increase to 1.9-2.4 during the experiments. The results suggest that, in fact, each of the crystal faces exposes more than one crystal plane. The left pronounced maximum is assigned to a (110) plane, the right pronounced maximum to a (100) plane, and the third small maximum to a (111) plane. Different proportions of these planes determine the different shape of the curves obtained on the different nominal faces and on polycrystalline electrodes.

The adsorption of hydrogen on polycrystalline platinum electrodes has been studied extensively in the past. Three different methods are available for these studies, (*a*) charging curves (1), (*b*) polarization with an alternating current (2), and (*c*) polarization with a triangular voltage sweep (3) also referred to as cyclic voltammetry or surface coulometry. All these methods are based on the fact that a change of the electrode potential in a certain range causes a change of the coverage of the electrode surface with hydrogen atoms. The adsorption-desorption process occurs through the charge transfer reaction

$$M\text{—}H \leftrightarrows M + H^+ + e^- \qquad [1a]$$

$$M\text{—}H + OH^- \leftrightarrows M + H_2O + e^- \qquad [1b]$$

in acid and alkaline solutions, respectively. For polarizations larger than about 50 mv, the charge transfer reaction [1] is much faster (4) than the dissociation-recombination reaction

$$H_2 + 2M \leftrightarrows 2M\text{—}H \qquad [2]$$

Hence, for a given polarization, a certain coverage of the surface with hydrogen atoms is established and maintained by fast discharge of hydrogen ions or hydroxyl ions according to the discharge reaction[1].

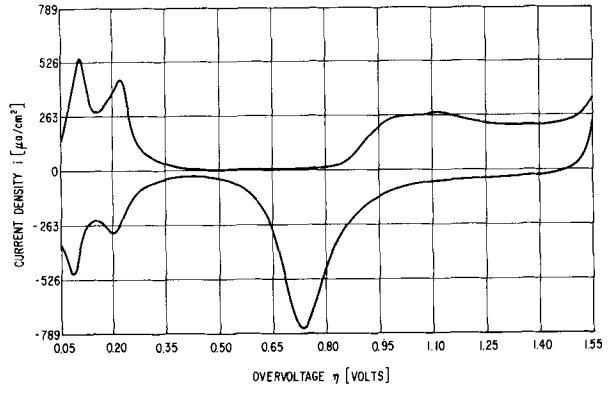

Fig. 1. Current-voltage sweep curve on polycrystalline platinum, obtained earlier (3). Sweep range 50-1550 mv, sweep rate 0.1 v/sec; surface area of electrode 0.19 cm².

The partial pressure of molecular hydrogen near the electrode surface which corresponds to that given polarization, on the other hand, is established much slower due to the slower rate of the dissociation reaction [2]. For any given polarization, the partial pressure of molecular hydrogen can be calculated from Nernst's law. At 0 volt (1 atm hydrogen pressure), the platinum surface is nearly saturated with hydrogen; at 0.4v ($\approx 10^{-14}$ atm), the surface is essentially free of hydrogen. It can thus be seen that a change of the electrode potential has the same effect on the hydrogen coverage of the surface as a change of the partial pressure of molecular hydrogen. In contrast to the latter method, however, the first method does not depend on the slow dissociation equilibrium [2].

In general, adsorption isotherms obtained on "active" polycrystalline platinum electrodes with either of the three methods exhibit three inflection points. These manifest themselves in two waves in the charging curves (5-7), and in two distinct maxima and one minimum in the differential capacity curves (8,9) and in the current-voltage sweep curves (3,10). Figure 1 shows a typical curve obtained on polycrystalline platinum with the sweep method. Apparently, hydrogen adsorbs on platinum preferentially at two distinct voltages or hydrogen pressures, *i.e.*, hydrogen exists in a strongly and a weakly bound state. Increasing voltage corresponds to decreasing hydrogen pressure, and hence the left maximum corresponds to weakly bound hydrogen and the right maximum to strongly bound hydrogen. Little conclusive information is available about the nature of the two states of adsorption.

Slygin and Frumkin (6,11) measured the amounts of anions and cations which are adsorbed on platinum as a function of the potential. They found that these amounts are influenced notably by the adsorption of hydrogen and interpret (12) their results as the adsorption of negatively polarized hydrogen at larger potentials (small coverages) followed by the adsorption of positively polarized hydrogen at smaller potentials (large coverages). Wicke and Weblus (8) found that the right maximum is influenced by the nature of the anions in the electrolyte while the left maximum does not show such a dependence. From this Eucken and Weblus (8) believe that the two maxima are not due to adsorption on two different crystallographic planes of the platinum but are due to adsorption on bare platinum (right maximum) and on oxygen atoms (left

maximum). Böld and Breiter (13) found values for the heat of adsorption of hydrogen on platinum in excess of 10 kcal/mole H_2 for coverages smaller than 0.5. This indicates that the strongly bound hydrogen is adsorbed as atoms. Kinetic considerations lead Breiter (14) to believe that the weakly bound hydrogen is also adsorbed as atoms.

Studies of hydrogen adsorption on platinum in the gas phase have also revealed the existence of strongly and weakly bonded hydrogen. Disagreement exists concerning the polarity of the two types of hydrogen and whether the weakly bound hydrogen is adsorbed as atoms or as molecules. Mignolet (15) measured the changes in the work function of a clean platinum film, which occur as a function of time, when hydrogen is being adsorbed at —190°C. Using both the condenser and the thermionic method, he found that the first 40% of the hydrogen which adsorbs increases the work function by 0.11v while the remaining 60% decreases the work function of the clean metal by 0.23v. At 20°C, under vacuum, only the initial 40% hydrogen which increases the work function remains adsorbed. These findings suggest that the initially adsorbed hydrogen is strongly bonded and negatively polarized and the subsequent 60% hydrogen weakly adsorbed and positively polarized. Mignolet also found that a volume of carbon monoxide almost equal to that of the weakly bonded hydrogen could be adsorbed in addition to the strongly bonded hydrogen. From this he believes that the weakly bonded hydrogen is adsorbed as molecules. It has been shown (16), however, that carbon monoxide displaces the weakly and strongly bonded hydrogen from the surface. Hence, the foregoing contention does not seem to be valid. Rootsaert *et al.* (17) adsorbed and desorbed hydrogen on a platinum tip in a field emission microscope by changing the temperature at a constant hydrogen pressure of 10^{-7} mm Hg. They found in agreement with Mignolet that on adsorbing hydrogen the work function first increases, passes through a maximum at a coverage of about 0.4, and then decreases with further increasing coverage. Pliskin and Eischens (18) obtained two absorption bands in infrared spectra of hydrogen adsorbed on alumina-supported platinum. When working with hydrogen and deuterium mixtures, they could not find any band corresponding to H — D^+ bonds. From this they deduce that the weakly bonded "positive" hydrogen is not adsorbed as molecules. Toya (19) showed that the two absorption bands correspond to a difference in heats of adsorption of only 0.8 kcal/mole H_2. This small difference makes it unlikely that the strongly and weakly bonded hydrogen discussed earlier is identical with the two types causing the two absorption bands. For the former, differences in heat of adsorption are found (10,20) which are of the order of 8 kcal/mole H_2.

The following study was undertaken to find out more about the nature of the two states of hydrogen adsorption. In particular, this study is concerned with the question whether the two states are due to adsorption on two different crystallographic planes preferentially exposed by the polycrystalline platinum. In order to test this possibility, the adsorption of hydrogen on the three main faces (100), (111), and (110) of platinum single crystals was studied. The voltage sweep method was applied because it affords a convenient and accurate way to determine the quantities of adsorbed hydrogen (3).

Experimental

The platinum single crystal was obtained by zone melting a platinum rod of 99.999% original purity in an electron beam. After orientation the crystal was cut with a diamond cutting wheel to give single crystals presenting the main faces (100), (111), and (110). These faces were then polished to optical flatness using for the final finish a 0.1μ alumina powder. The three single crystals were subsequently annealed in vacuum at 680°C for 24 hr and finally sealed into lime glass so that only the three faces of interest remained uncovered. The geometric surface areas were 0.181 cm^2 for (100), 0.328 cm^2 for (111), and 0.225 cm^2 for (110). The three crystals were symmetrically arranged in one cell compartment opposite the counter electrode. A hydrogen reference electrode was located in a second cell compartment which communicated with the main compartment via a capillary. All potentials are referred to this hydrogen electrode. The 8*N* H_2SO_4 used in the experiments was prepared with ultrapure water (21) and pre-electrolyzed for 15 hr. Although the measurements were carried out without gas-bubbling, the electrolyte was periodically flushed with prepurified argon to remove traces of hydrogen and oxygen.

Despite the cleaning procedures, reproducible results could be obtained only by applying a periodic sweep of such an amplitude that an oxide layer was formed and reduced during each sweep (compare Fig. 1) prior to the adsorption and desorption of the hydrogen layer. A sweep range of 50-1550 mv was chosen to achieve this and at the same time, hold the formation of molecular hydrogen and oxygen to a minimum. The applied sweep rate was 0.1 v/sec and, hence, the duration of one sweep was 30 sec. A modified (22) Hewlett Packard Function Generator 202A in conjunction with a potentiostat was used to apply the voltage sweeps. The resulting current-voltage (or time) curves were displayed on a Tektronix 502 x-y oscilloscope. For each face and each given temperature, photographs were taken of the first four sweeps and every 5 min thereafter for 20 min. A 35 mm "ROBOT" automatic transport and rewind camera was used for this purpose. The integration of the enlarged curves was performed graphically with an "Ott" planimeter No. 144 to a precision of 2%. Measurements on the three crystal faces were made at 0°, 10°, 25°, 40°, 60°, and 80°C. A specially designed circulating air thermostat allowed the temperature to be controlled within ±0.1°C.

While one particular face was being studied, the other two faces were kept in the solution on open circuit. When proceeding to the next face, a potential of 50 mv was always applied for 3 min before starting the periodic sweep from this potential. During the experiments which are reported here, each face was subjected to some 240 sweeps. In preceding preliminary experiments, about 160 sweeps had already been applied to each individual face.

Results

Current-voltage sweep curves.—As mentioned before, hydrogen desorbs from polycrystalline platinum electrodes preferentially at two different potentials corresponding to two distinct maxima in the current-voltage sweep curve. Figure 1 shows one such curve which was previously (3) obtained on polycrystalline platinum wires under conditions similar to those in the present study. The ratio of the currents of the "first" (less anodic) and "second" maximum I_1/I_2 is 1.2. Figure 2 shows curves which were obtained on the (100), (111), and (110) faces of platinum single crystals at 25°C. The curves correspond to sweep 260 and were photographed 10 min after starting the periodic sweep. The two striking features of the curves for (100) and (111) are: (*a*) as on a polycrystalline electrode there are still two distinct desorption maxima, and (*b*) while for the (100) face the first maximum is smaller than the second, the opposite is true for the (111) face; in fact the ratio I_1/I_2 is 0.8 for (100) and 1.5 for (111). The curve for the (111) face exhibits a small third maximum which degenerates to a shoulder in the curve for the (100) face. The curve obtained on the (110) face looks strikingly similar to the curve for (111), and the ratio I_1/I_2 is essentially the same for the two faces. However, the current densities i_1 and i_2 corresponding to the two maxima of the (110) curve are some 30% smaller than i_1 and i_2 for (111).

The effect of temperature on the curves is such that with increasing temperature the height of the maxima increases and their position is shifted toward less anodic

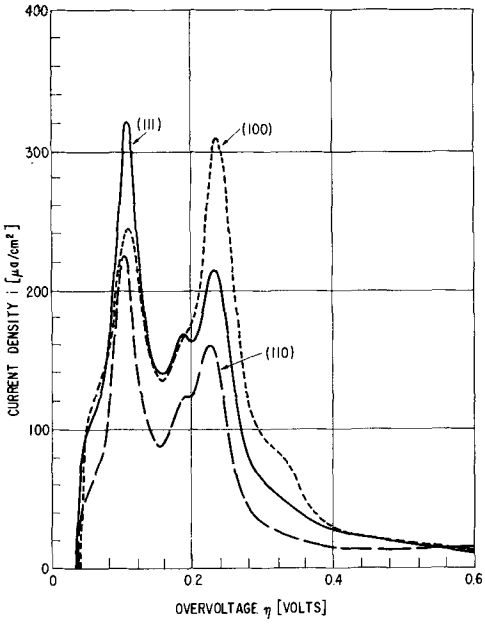

Fig. 2. Current-voltage sweep curves on platinum single crystal faces (100), (111), and (110) at 25°C. Sweep range 50-1550 mv, sweep rate 0.1 v/sec.

potentials. Both effects are larger for the first maximum.

During the 20-min duration of one experiment, the shape of the curves from the fourth sweep on remained essentially unaltered. The first curve and, to much lesser extent, the second and third curve always looked quite different from the succeeding curves.

The effect of the number of sweeps on the shape of the curves was quite pronounced, however, during the first 20 or 30 sweeps that were applied to the virgin crystal faces. Figure 3 shows this effect for the (110) face, where it is most pronounced. Curve I resulted when the 10th sweep was applied to the virgin surface. Curve II is identical to the (110) curve in Fig. 2 and was obtained after about 250 sweeps had been applied to the (110) face. While maximum 1 did not change too much, maximum 2 increased considerably with increasing number of sweeps. In fact, maximum 2 is smaller than maximum 3. After 10 sweeps, the ratio of the maxima currents I_1/I_2 is 2.9, and after 260 sweeps this ratio is 1.45. The corresponding figures for the (111) face are 2.1 (10 sweeps) and 1.5 (260 sweeps) and for the (100) face 0.79 and 0.80.

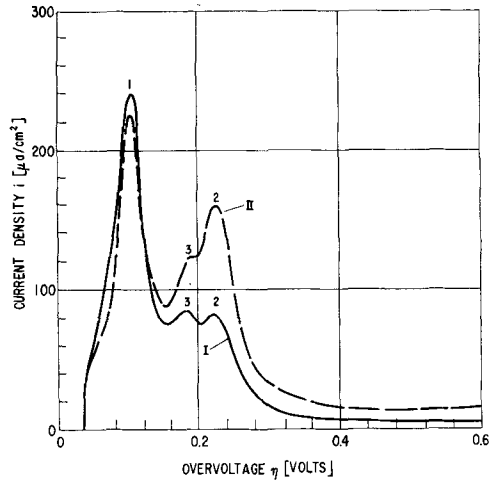

Fig. 3. Current-voltage sweep curves on the (110) face at 25°C after 10 sweeps (curve I) and after 260 sweeps (curve II).

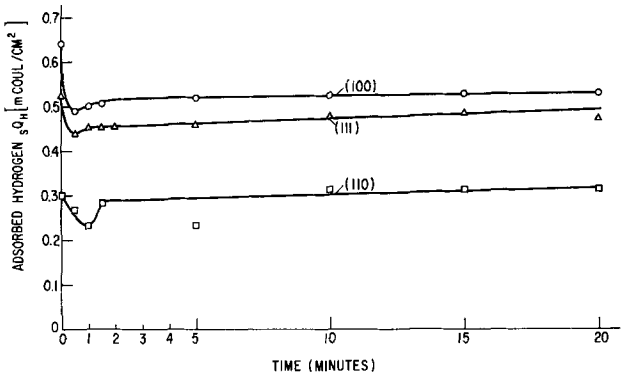

Fig. 4. Saturation amounts of hydrogen adsorbed on the three faces at 25°C.

Saturation concentration of adsorbed hydrogen.—Since a voltage is applied which changes linearly with time, the current-voltage curves in Fig. 1 and 2 also represent current-time curves. Hence, an integration of these curves yields the charge corresponding to the amount of adsorbed hydrogen plus the charge of the double layer capacity. The double layer capacity is almost constant between 50 and 400 mv (11). Its charge is only about 2% of the charge of adsorbed hydrogen and shall be neglected. The small current above potentials of about 400 mv is mostly due to the charge of the double layer (3). Below 50 mv the current decreases steeply. Therefore, the saturation concentration of hydrogen $_sQ_H$ adsorbed on the surface can be determined by integrating the curves from 50 to 400 mv. This was done for different times in the temperature range of 0° to 80°C. The result at 25°C for sweeps 240 to 280 is plotted in Fig. 4. During the first two or three sweeps of each experiment, erratic values are found for $_sQ_H$. From then on, $_sQ_H$ changes but slightly with time. This finding agrees with the finding concerning the changes in the shape of the curves with time.

For the first 10 sweeps that were applied to the virgin faces, considerably smaller amounts of hydrogen were found. The $_sQ_H$ values for 10 sweeps are 0.39 m-coul/cm² for (100), 0.23 for (111) and 0.24 for (110).[1] The corresponding values after 260 sweeps are 0.51 m-coul/cm² for (100), 0.46 for (111), and 0.30 for (110).

For the first sweep of each experiment, the total anodic charge, *i.e.*, adsorbed hydrogen plus oxygen, is always between 14% and 34% larger than the total cathodic charge. However, for the succeeding sweeps, the total anodic charge is consistently smaller than the cathodic charge, namely, by 1 to 12%.

Except for the (110) face, temperature has no systematic effect on the $_sQ_H$ values. For the (110) face, $_sQ_H$ stays roughly constant between 0° and 40°C and then decreases by about 20% from 40° to 80°C.

Adsorption isotherms.—The sweep curves obtained after 10 min for different temperatures were integrated in intervals of 50 mv between 50 and 400 mv. The degree of coverage $\theta = Q_H/{}_sQ_H$ at, *e.g.*, 300 mv, is the ratio of the charges resulting from an integration between 400 mv and, *e.g.*, 300 mv, and between 400 mv and 50 mv. The resulting adsorption isotherms for the (100) face are presented in Fig. 5. Applying Nernst's law and correcting for the vapor pressure of the sulfuric acid, the overvoltages are converted into partial pressures of molecular hydrogen. As one would expect for an exothermic process, the degree of coverage decreases with decreasing hydrogen pressure and increasing temperature. The curves display three inflection points in accordance with the three extrema

[1] Note added during revision of manuscript: According to a private communication on October 12, 1964, Dr. J. E. Oxley, Leesona Moos Laboratory, in similar experiments on Pt single crystals obtained $_sQ_H$ values of 0.30 mcoul/cm² for (100), 0.29 for (100), and 0.21 for (110). The results were obtained at a sweep rate of 18 v/sec.

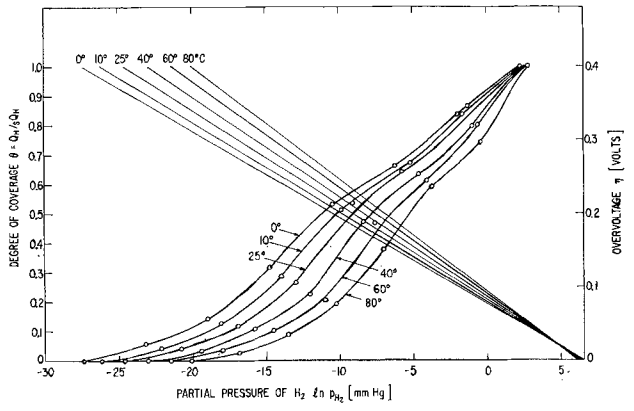

Fig. 5. Adsorption isotherms on (100) face. Straight lines relate voltage on right ordinate to partial pressure of hydrogen.

of the current-voltage sweep curves. Figure 6 shows the adsorption isotherms for the three crystal faces at 0° and 80°C. For constant hydrogen pressure, the degree of coverage decreases distinctly in the whole temperature range in the order (100)>(111)>(110). The effect is more pronounced at lower temperatures.

Heats of adsorption.—The Clausius-Clapeyron equation

$$dp/dT = \Delta H/T\Delta V \quad [3]$$

(ΔH, ΔV enthalpy and volume change on transferring 1 mole of hydrogen from the gas phase into the adsorbed phase) may be written as

$$d \ln p_{H_2}/dT = W/RT^2 \quad [4]$$

if one assumes ideal conditions in the gas phase and neglects the volume of the hydrogen in the adsorbed phase. The heat of adsorption $W \equiv \Delta H$ is negative for an exothermic process. If the heat of adsorption is temperature independent the integration of equation [4] gives

$$\ln p_{H_2} = -W/RT + \text{const.} \quad [5]$$

In a plot ln p_{H_2} against $1/T$ straight lines should result whose slope is proportional to the heat of adsorption (10, 13). While this is indeed the case for the (100) and (111) faces, the heat of adsorption increases noticeably with increasing temperature for the (110) face at temperatures above 40°C.

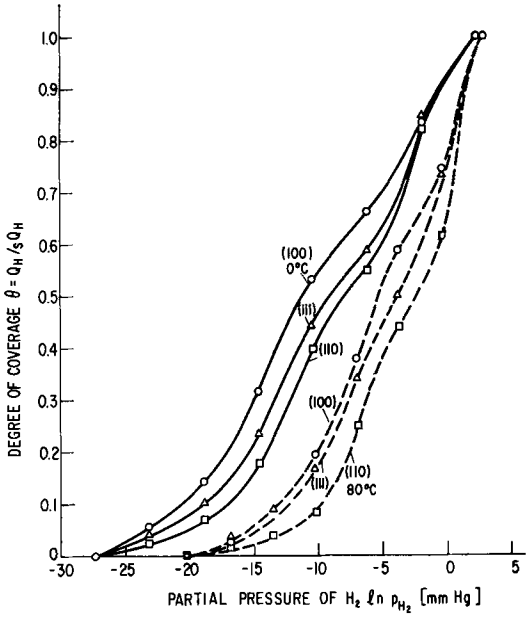

Fig. 6. Adsorption isotherms on (100), (111), and (110) at 0° and 80°C.

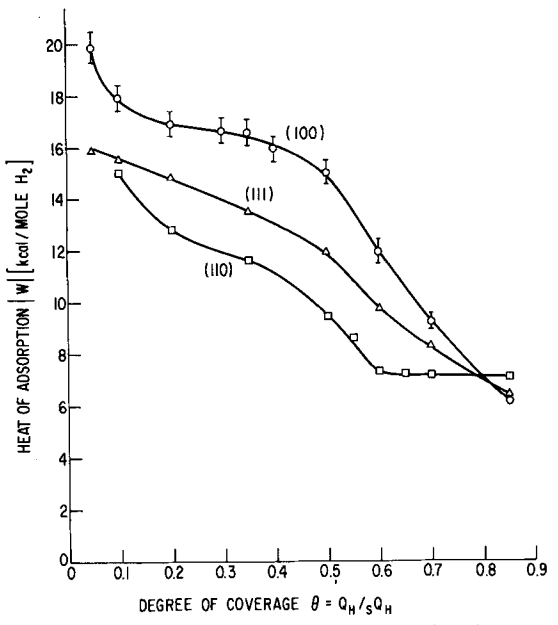

Fig. 7. Heats of adsorption of hydrogen on the three crystal faces as a function of coverage.

The heats of adsorption for the three crystal faces are plotted in Fig. 7 as a function of the degree of coverage. For the (110) face the temperature-independent values of W between 0° and 40°C are shown. For all three crystal faces, the heat of adsorption decreases substantially with increasing coverage. This agrees with results obtained on polycrystalline platinum in electrolytes (10, 13) and in the gas phase (20). Especially in the curve for the (110) face one can clearly distinguish between strongly and weakly bonded hydrogen; the latter prevails at $\theta > 0.6$ and has a heat of adsorption of about 7 kcal/mole. An increase of θ from 0.1 to 0.85 causes a decrease in the heat of adsorption of 66% for (100), 59% for (111), and 53% for (110). The other noteworthy finding is the comparatively large difference in the heats of adsorption for the different faces. Except for coverages larger than 0.8 the heats of adsorption decrease in the order (100)>(111)>(110). At coverages larger than 0.8, near saturation, this order is reversed. For coverages smaller than 0.6 the difference in W between the three faces averages between 2 and 3 kcal. For $\theta = 0.5$ the heats of adsorption are 15 kcal/mole H_2 for (100), 11.9 for (111), and 9.4 for (110).

Discussion

Roughness of the surface.—The number of platinum atoms in the surface planes of the three crystal faces are $1.5 \cdot 10^{15}$ atoms/cm^2 for (111), $1.3 \cdot 10^{15}$ for (100), and $0.92 \cdot 10^{15}$ for (110). If one makes the usual assumption that one hydrogen atom is adsorbed per platinum surface atom, the corresponding charges are 0.24 mcoul/cm^2 for (111), 0.208 for (100), and 0.147 for (110). The amounts of hydrogen that are found are considerably larger, particularly after the faces have been subjected to a large number of sweeps. This may be interpreted as a large initial roughness of the virgin faces which further increases with the number of sweeps applied. For the (100) face, for example, the roughness factor would be 1.87 after 10 sweeps and 2.45 after 260 sweeps. With such a large surface roughness, it is probable that the surface exposes more than one crystal face. The fact that the current maxima on all three faces occur to within ±5 mv at the same potentials (compare Fig. 2) could indicate that each of the faces is, in truth, a mixture of essentially two faces with a small fraction of a third face, particularly in the case of the nominal (111) and (110) face.

Effect of sweep on curve shape.—The effect of the number of sweeps on the shape of the curves (com-

pare Fig. 3) might be explained as follows. Initially (curve I), the nominal (110) face exposes a large fraction of (110) (maximum 1) and small fractions of (111) (maximum 3) and of (100) (maximum 2). After 260 sweeps have been applied (curve II), the amount of (110) has decreased slightly, the fraction of (111) stayed almost constant, but the fraction of (100) increased sharply. The periodic voltage sweep might cause the formation of etch pits with the exposure of preferred crystal faces. In this connection, it is interesting to note that the development of low-index planes by chemical etching is a standard technique in the determination of the orientation of various metal crystals (23).

The curve obtained on the (111) face (compare Fig. 2) looks always quite similar to that on the (110) face. This implies that the nominal (111) face exposes, in fact, always a large fraction of (110) (maximum 1), a considerable fraction of (100) and only a small fraction of (111). In order to rationalize this conclusion one has to assume that a thin surface layer exhibits a polishing and recrystallization texture which exposes the preferred orientations that are found. Indeed, a preferred orientation has been found on cold rolled and of polished copper and gold, with (110) planes lying parallel to the surface (24). The recrystallization texture on annealing may or may not resemble the polishing texture, depending on the severity of the surface damage and the particular annealing conditions (23). As mentioned before, the platinum crystals were annealed at 680°C for 24 hr. On platinum single crystals that had been annealed at 1100°C for 48 hr, Tucker (25) did not find evidence for faceting. However, the detection of crystal facets smaller than about 100Å in diameter is beyond the sensitivity of the slow electron diffraction apparatus.

Adsorption isotherms and heats of adsorption.—In the preceding discussion, maximum 1 has been assigned to a (110) plane, maximum 2 to a (100) plane, and maximum 3 to a (111) plane. This assignment is based on the relative heights of the current maxima for the different nominal faces in Fig. 2. It implies that the hydrogen bond is weakest on the (110) plane and strongest on the (100) plane. This agrees with the heats of adsorption for the three faces shown in Fig. 7, which increase in the order (110)<(111)<(100) for coverages smaller than 0.8. Based on considerations involving the number of nearest neighbors and their degrees of unsaturation, one would argue, however, that the bond should be weakest on the (111) plane and strongest on the (110) plane. More experiments are needed to solve this apparent contradiction.

Qualitatively, the different adsorption isotherms for the different faces can be understood with the proposed assignment of the current maxima. Since, for example, the nominal (110) face exposes a much smaller surface fraction of (100) than the nominal (100) face, it is evident that at smaller partial pressures of hydrogen, where (100) adsorbs preferentially, the surface coverage is smaller for the nominal (110) face than for the nominal (100) face. On a similar basis, the difference in heats of adsorption can be understood.

Current-voltage curves on polycrystalline wires.—The two pronounced maxima of current voltage curves obtained on polycrystalline platinum wires (compare Fig. 1) occur at essentially the same potentials as those obtained on the single crystal faces. The texture of cold-drawn wires of face-centered cubic metals, like platinum, is usually a double fiber texture with a [111] and a [100] direction parallel to the wire axis (23). With the possibility of so many different crystal planes exposed it seems surprising that only two maxima are observed. This difficulty can be reconciled by postulating that the wire surface becomes etched in the usual pretreatments of the electrodes prior to the experiments. In this etching process, the low-energy main faces are expected to develop at the expense of the large number of high-index planes.

Conclusions

The finding that the maxima have different heights for the different faces, but occur at almost the same potentials, suggests that each of the nominal faces exposes, in fact, several crystal planes in different proportions. Such an interpretation is consistent with the assumption that the large measured amounts of adsorbed hydrogen are due to a considerable surface roughness. The left pronounced maximum has been tentatively assigned to a (110) plane, the right pronounced maximum to a (100) plane and the third small maximum to a (111) plane. This implies that the bond strength of hydrogen and, hence, its heat of adsorption is smallest on (110) and largest on (100). This has been actually found. The two adsorption states of hydrogen that exist on polycrystalline platinum electrodes are also likely to be due to adsorption of hydrogen on two different crystallographic planes. The two current maxima occur within ±5 mv at the same potentials as the two pronounced maxima on the single crystals. Hence, it is concluded that cold-worked, polycrystalline platinum electrodes expose mainly crystallites with {110} and {100} planes. This conclusion is in agreement with the fact that the texture of all cold-rolled face-centered cubic metals is one in which {110} planes are parallel to the rolling plane (23). To reconcile the occurrence of only two or three current maxima on cold-drawn platinum wires with their texture of [111] and [100] parallel to the axis, one has to assume etching of the surface during the process of "activating" the electrodes. Studies with better defined crystal planes and under extreme clean conditions are needed to confirm these tentative conclusions.

Acknowledgments

The author gratefully acknowledges the loan of the platinum single crystals by C. W. Tucker which were prepared by J. W. Rutter and V. J. DeCarlo.

Manuscript received July 20, 1964. This paper was presented at the Toronto Meeting, May 3 to 7, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

Technical Notes

The Preparation and Luminescence of Molybdenyl Phosphate

V. Chiola and C. D. Vanderpool

Chemical and Metallurgical Division, Sylvania Electric Products Inc., Towanda, Pennsylvania

In 1955, Schulz (1) reported the preparation and x-ray identification of molybdenyl phosphate, $MoO_2(PO_3)_2$, as one of several crystalline compounds isolated from the binary system, $MoO_3 \cdot P_2O_5$. Kierkegaard (2) investigated and proposed a crystal structure for $MoO_2(PO_3)_2$ and a number of other molybdenum phosphate compounds having low Mo:P ratios (3). In this laboratory, recent investigations of molybdenum trioxide-phosphoric acid systems led to the isolation of a crystalline product identified as molybdenyl phosphate, $MoO_2(PO_3)_2$. In the course of examining this material, it was discovered that molybdenyl phosphate, $MoO_2(PO_3)_2$, is a phosphor responding to irradiation by 3650 and 2537Å. It was found also that the same phosphor possesses electroluminescent properties. The purpose of this note is to report the preparation and properties of molybdenyl phosphate as a luminescent and electroluminescent material.

Schulz (1) prepared $MoO_2(PO_3)_2$ by heating a five-fold excess of P_2O_5 with MoO_3 to about 500°C in a steel bomb. The reaction was complete in 3-4 hr. A light-blue to light-green crystalline product was recovered after leaching the glassy reaction mixture with water to remove excess P_2O_5. Kierkegaard (2) prepared $MoO_2(PO_3)_2$ by autoclaving a mixture of 1.5 g MoO_3 and 6.6g P_2O_5 in a platinum crucible at 500°C for one week. The reaction mixture was washed and filtered to recover crystals.

Molybdenyl phosphate was prepared in this laboratory by heating one mole of MoO_3 with six moles of phosphoric acid in a silica crucible to 450°C while agitating the mixture. Crystalline $MoO_2(PO_3)_2$ began precipitating at 325°C, but a glassy mixture was formed on cooling. A bluish-white product was recovered by aqueous leaching to remove excess phosphoric acid, filtering and drying at 110°C.

An alternate procedure involved heating one mole of MoO_3 with two moles of phosphoric acid to 600°C for 1 hr to form a solid, white crystalline mass. After cooling, soluble matter was removed by leaching, and the molybdenyl phosphate product was recovered by filtration, washing with water, washing with 7% ammonium hydroxide solution, and drying at 110°C.

The typical impurity content of the molybdenyl phosphate prepared by the above procedures was determined by spectrographic qualitative analysis as follows: Al, 1-10 ppm; Ca, 1-10 ppm; Cu, 1-10 ppm; Fe, 1-10 ppm; Mg, 1-10 ppm; Mn, <10 ppm; and Si, 100-1000 ppm.

X-ray diffraction films were taken on a Philips Norelco unit having a camera diameter of 114.6 mm and using Ni-filtered CuKα radiation of 1.542Å wavelength.

Observed $1/d^2$ values agreed very well with $1/d^2$ values calculated from cell parameters furnished by Kierkegaard (2) for the compound, $MoO_2(PO_3)_2$. The observed 2θ values agree with those given by Schultz (1) for the compound having the stoichiometric composition $MoO_3 \cdot P_2O_5$.

The emission spectra were obtained with a Perkin-Elmer spectrofluorimeter (4). The spectral response of molybdenyl phosphate under 3650Å radiation is a broad-band emission which peaks at 6100Å (Fig. 1). Under 2537Å excitation a similar broad-band emission between 6100 and 6300Å is observed. Response is significantly greater at 3650 than at 2537Å radiation.

The fluorescent intensity of molybdenyl phosphate under 3650Å excitation is 79% greater than that measured on a standard calcium silicate phosphor, JEDEC No. P-25, (Sylvania No. 156). Under 2537Å radiation, the intensity is only 33% of that measured on the standard.

Electroluminescent brightness measurements were obtained using cells having dimensions of 1 x 1 x 0.006 in. and a castor oil dielectric. The electrode materials were brass and transparent conductive glass. A Photovolt Model 520 Photometer was used in conjunction with a photomultiplier detector. Figure 2 shows a semi-logarithmic plot of brightness *vs.* the reciprocal of the square root of the voltage. Although the level of brightness was low, it varied linearly with $v^{-1/2}$ from about 400 to 900v. At 400v, brightness was about 0.2% of that measured for a conventional ZnS:Cu,Cl phosphor.

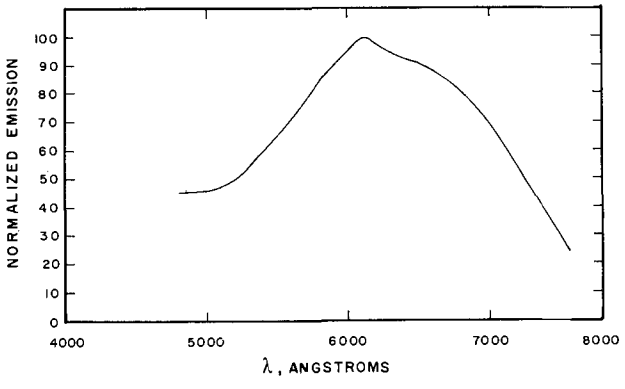

Fig. 1. Spectral response of $MoO_2(PO_3)_2$ to 3650Å excitation

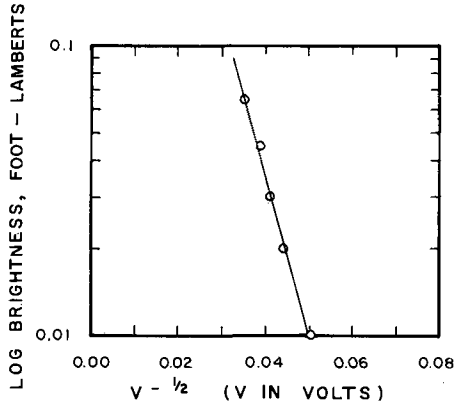

Fig. 2. Log brightness *vs.* (voltage)$^{-1/2}$

Molybdenyl phosphate electroluminesces blue-green at 60 cycles and blue at 6 kc. The results show that $MoO_2(PO_3)_2$ can be prepared from molybdenum trioxide-phosphoric acid reaction mixtures and that $MoO_2(PO_3)_2$ possesses luminescent and electroluminescent properties.

Acknowledgments

The authors wish to thank S. Faria for performing the spectral emission and electroluminescent brightness measurements and for helpful discussions concerning luminescent materials and their properties. They are also indebted to Dr. C. W. W. Hoffman and E. A. Wesley for x-ray diffraction measurements and to Dr. R. W. Mooney for advice and encouragement.

Manuscript received Aug. 18, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

The Correlation between Water Contact Angle and KPR Adherence on SiO_2 Surfaces

A. A. Bergh

Bell Telephone Laboratories, Incorporated, Allentown, Pennsylvania

Kodak Photo Resist (KPR) is used in the processing of silicon planar transistors to protect selected areas of oxidized silicon surfaces from etching. KPR is an organic solvent solution of an ultraviolet-sensitive plastic. When applied to the oxide surface a thin coating is formed, and the areas where the oxide is to be protected are exposed to ultraviolet light. The nonexposed areas developed in organic solvents leaving a resist pattern that offers chemical resistance to oxide removal etchants. The oxide is usually 0.5-1.2μ thick, and the width of unprotected areas varies from a few microns to several mils. The resolution of the oxide edges depends on the adherence of the KPR to the oxide during etching. "Adherence" cannot be measured quantitatively, and it is best defined by the current of undercutting during etching as shown in Fig. 1. The sharp lines show good resolution, and the interference fringes indicate undercutting. The photoresist is not attacked by the etchant; it is only lifted at the edges. The instructions to apply KPR (1) recommend a high degree of cleanliness for both the silica surface and the photo resist solution and low relative humidity ambient to achieve good adherence. These conditions yield good results only on oxides heated to temperatures exceeding 850°C during or after oxidation. Undercutting was observed on oxides partially removed with an etchant containing fluoride ions, on oxides grown at lower temperatures, and on some deposited oxides. All the above oxides are wetted by water to a greater extent than those yielding good KPR resolution after etching.

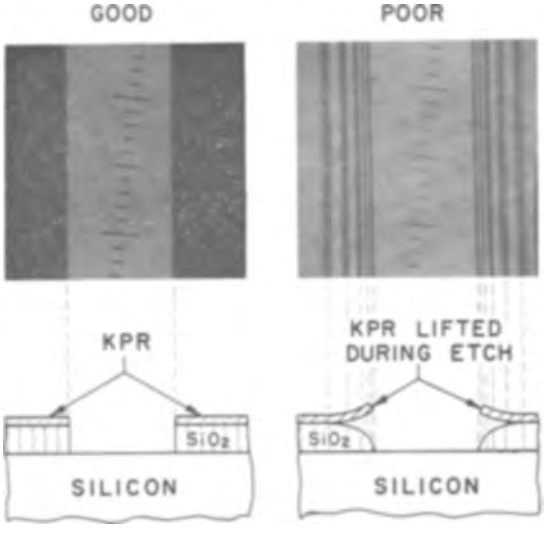

Fig. 1. Effect of KPR adherence on resolution (KPR has been removed before taking the photographs). Scale, 10 microns/division.

Experimental

One inch diameter, 5-6 mils thick, and 0.01 to 2 ohm-cm n-type silicon slices were used throughout the experiment. Oxides in the range of 0.6-1.0μ were produced under the following conditions: (*a*) 1 atm steam at 1050°C (1050°C-oxide); (*b*) 1 atm oxygen bubbled through 95°C water at 1050°C;(c) 120 atm steam at 650°C (650°C-oxide); (d) CO_2-oxide, deposited from a gas phase reaction at 1200°C (CO_2-oxide) (2); (*e*) reactive plasma sputtering at ~450°C (RPS-oxide) (3).

Water contact angles were measured with a reflection goniometer (4) using 4 x 10^{-3} ml size drops of high-purity water from a glass-Teflon micrometer syringe. KPR was applied over various patterns and unprotected areas of the oxide were removed with buffered HF solutions containing 15 ml of HF (49%) per 100 ml of a stock solution of 17M NH_4F. The etching rate of pure, amorphous SiO_2 is approximately 0.1 μ/min. The rate rapidly increases with increasing contamination of the oxide.

A minimum of six slices were taken from each group and contact angles were measured within 30 min after oxidation. Following this measurement slices were kept in hot concentrated HNO_3 for 10 min, rinsed in deionized water, and dried in a dust-free ambient at temperatures lower than 100°C. This treatment was used to remove any surface contamination and to evaluate the effect of water rinsing on the contact angle. (Boiling for 20 min in D.I. water produces the same change in θ.) Contact angles were measured on dry slices, KPR was applied, and the unprotected areas were etched away. The results of both readings and KPR adherence are listed in Table I. Oxides produced in atmospheric steam and wet oxygen at 1050°C showed identical values of θ and they are listed at "1050°C-oxide." Among the rinsed slices only the first group, average θ = 24°, gave good resolution.

Table I. Contact angles after oxidation and after rinsing

Type of oxide	θ After oxidation		θ After rinse		After rinse
	Average	Range	Average	Range	KPR adherence
1050°C-oxide	32	26-36	24	18-32	Good
650°C-oxide	3	0-8	3	0-8	Poor
CO_2-oxide	21	11-38	4	3-12	Poor
RPS-oxide	32	19-38	7	5-12	Poor

Table II. Change in θ after sequential treatments

Type of oxide	Treatment before heat	θ before heat	θ after heat*	θ after rinse**
1050°C-oxide	Buffered HF	4	36	24
650°C-oxide	None	<3	36	19
CO_2-oxide	HNO_3, H_2O	4	36	9
RPS-oxide	HNO_3, H_2O	13	35	9
Quartz plate	H_2O_2, H_2O	7	37	14

* 90 Min exposure to dry O_2 at 1200°C.
** 20 Min rinse in boiling DI water.

Correlation between low contact angles and poor KPR adherence was substantiated by another series of experiments. Different types of freshly oxidized slices were exposed to a buffered HF for 30 sec (etch rate~ 0.1 μ/min), rinsed in D.I. water and dried. All contact angles were lower than 6°, and poor adherence was observed on all slices with KPR.

A method to produce a low contact angle on any oxide has thus been established; different ways were tried to achieve the opposite effect. Heat-treatment in dry oxygen proved to be effective as shown in Table II. Similar results were obtained in vacuum and N_2, but O_2 is preferred because it prevents organic (usually hydrophilic) contamination. A limiting contact angle of $\theta = 40 \pm 5°$ was observed on all oxides after high-temperature baking.

Discussion

The significance of water contact angle on the structure and chemistry of SiO_2 surfaces will be discussed in detail in a forthcoming paper (5). The conclusions necessary to understand the adherence of KPR are listed below:

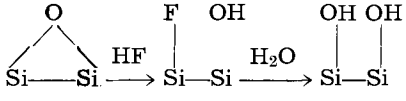
1. Low contact angles ($\theta < 3°$) indicate a strong adherence of water to SiO_2. Minimum contact angles are observed on completely hydroxylated surfaces.

2. The limiting value of $\theta = 40° \pm 5°$ observed on all oxides after exposure to high temperatures indicate a relatively weak bond between water and the SiO_2 surface. Heating removes water from the surface converting the silanol groups (Si — OH) into siloxane bridges (Si-O-Si). Siloxane is more hydrophobic ($\theta = \sim 40°$) than silanol ($\theta < 3°$).

3. The following can be said concerning the reaction

$$2Si{-}OH \leftrightarrows Si{-}O{-}Si + H_2O$$

(*a*) It can be completely shifted to the right at temperatures in excess of 850°C; (*b*) It can be shifted to the left only partially by boiling in water (or HNO_3). Deposited oxides hydrate easier than grown oxides (Table II, last column). (c) Complete hydration can be achieved (reaction shifted to the left) by breaking the siloxane bridges with HF, and hydrating the fluorinated silicon atoms, *i.e.*,



This accounts for the low contact angles after exposure to buffered HF and rinsing in water.

Table III. Effect of etch rate on the adherence of KPR

Etch rate, A/min	Etching time, min	Hydrophobic oxide	Hydrophilic oxide
4000	2.5	Not undercut	Slight undercut
1000	10	Not undercut	Undercut
330	32	Not undercut	Heavy undercut
140	70	Undercut	All oxide removed

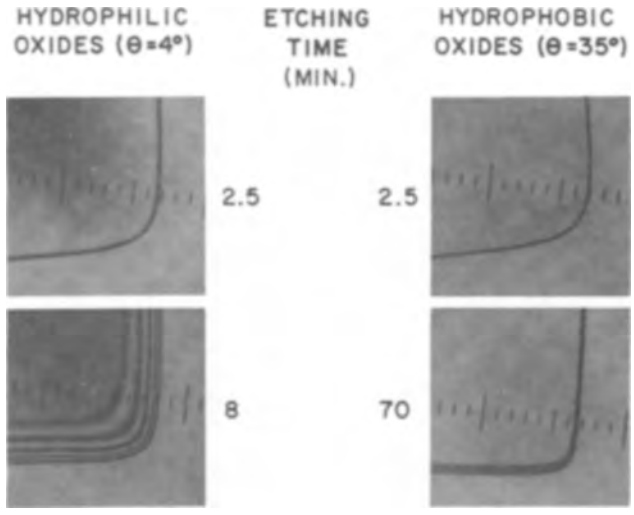


Fig. 2. Effect of etching time on undercutting. Scale, 10 microns/division.

A mechanism to explain that KPR is lifted during etching on hydrophilic surfaces can be obtained by considering the relative bond strengths at the KPR-oxide and water-oxide interfaces. Low contact angles indicate stronger, and high contact angles indicate weaker water-oxide bonds.

The contact angle of KPR, on the other hand, is nearly identical ($\theta \sim 20°$) on both hydrophilic and hydrophobic surfaces. In other words, the relative bond strengths between water-SiO_2 and KPR-SiO_2 is shifted in favor of the water on hydrophilic surfaces. Consequently, water has a greater tendency to penetrate the KPR-oxide interface on hydrophilic oxides. In view of this theory, two conditions enhance undercutting: (*a*) strong bonds at the water-oxide interface and (*b*) long exposure to aqueous solutions, *i.e.*, slow etching rates and excessive rinsing. A series of experiments were carried out, therefore, employing low and high contact angle oxides and different exposure times by changing the *p*H and thus the etch rate of the oxide removal etch. Results are shown in Table III, and some of the resolutions are illustrated in Fig. 2. Good agreement with theory can be observed. It is also evident that *p*H has an effect on the water penetration. The lifting of KPR increases with decreasing *p*H's faster than would be expected from the exposure time.

It can be concluded that the important effect of hydrophobic oxides is not in a better coupling between resist and silicon oxide, but in the decrease in the tendency of water to penetrate the resist-oxide interface.

Strain Patterns in $GaAs_{(1-x)}P_{(x)}$ Alloy Overgrowths

R. Rosenberg

State University of New York, Stony Brook, New York

and M. Kozlowski, W. J. McAleer, and P. I. Pollak

Merck, Sharp and Dohme Research Laboratories,
Division of Merck & Company, Incorporated, Rahway, New Jersey

The objective of this note is to illustrate the occurrence of a particular type of strain pattern characteristic of $GaAs_{(1-x)}P_{(x)}$ alloy overgrowths on GaAs single crystal wafer substrates. The ultimate importance of such a strain field lies in its effect on the light emission characteristics of the heterojunction region because of disruption of crystal regularity and distortion of energy bands. Overgrowths were produced by vapor transport from GaAs and GaP charge chips to the substrate surface in an iodine ambient. The growth direction was <111>, the growth rate about 400Å/sec, and the growth surface gallium in all cases. Preparation of the wafers for observation in the <111> direction after growth consisted of removing the GaAs substrate base by lapping with a fine grit abrasive and then polishing opposite faces of the overgrowth with 0.25μ diamond paste. The strain patterns were observed by the birefringence technique and in the case of compositions transparent only to infrared lighting polaroid HR IR filters were used as polarizer and analyzer and observations made with an IR image converter tube.

Representative birefringence strain patterns are illustrated in Fig. 1 for a $GaAs_{0.8}P_{0.2}$ overgrowth. No strain was observed in pure GaAs overgrowths when viewed either parallel or transverse to the growth direction; that is, the fields were uniformly black under polarized light. The strain pattern produced in the alloy overgrowth when viewed in the <111> direction, as shown in Fig. 1a, consists of a regular block-type array of discontinuous lines which extends uniformly over the entire cross section. Figure 1b shows the strained region to extend from the original growth interface to the surface (the GaAs substrate is shown to be strain free.)

The strain was observed as a function of deposition temperature, overgrowth thickness, and overgrowth composition. Growth at 660°C (normal temperatures exceeded 800°C) did not eliminate the strain pattern, but increased the average block size suggesting a decrease in strain magnitude. Changes in overgrowth thickness did not appear to affect the strain pattern within limits of reproducibility between tests. Chem-

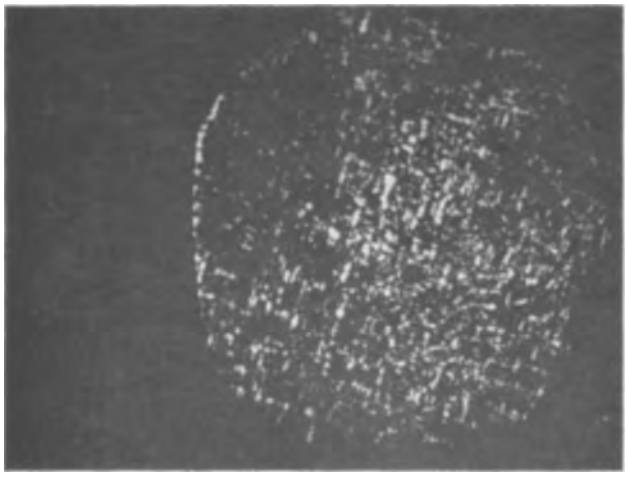

Fig. 1a. Strain pattern in $GaAs_{0.80}P_{0.2}$ alloy overgrowth produced by birefringence using polarized infrared light. Observation in <111> direction (growth direction).

Fig. 1b. Cross-section transverse to <111> direction

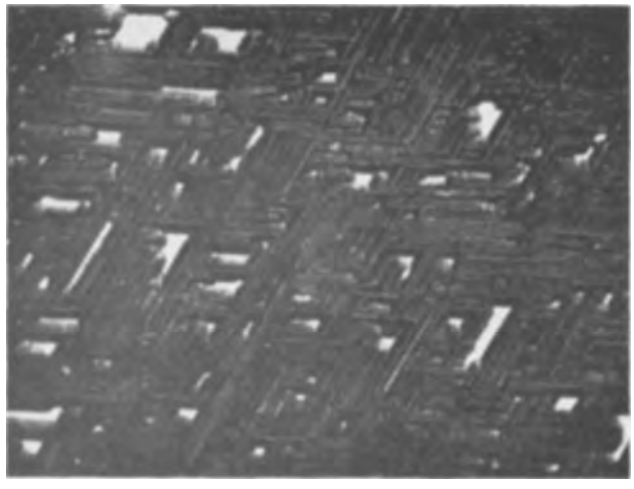

Fig. 2a. Etch-pit structure at the surface of alloy overgrowths. Slip line configuration in sample > 1 mm in thickness. Magnification approximately 100X.

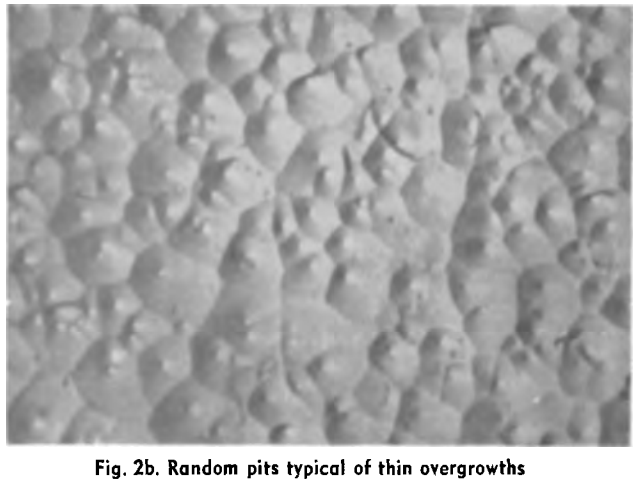

Fig. 2b. Random pits typical of thin overgrowths

ical etching of overgrowth surfaces revealed slip line configurations such as those of Fig. 2a in samples with overgrowths greater than 1mm thick, but random etch pit patterns in thinner samples, Fig. 2b. There did not seem to be a connection between the occurrence of slip and the birefringence pattern. Midrange overgrowth compositions, $0.40 < x < 0.60$, showed a tendency to fracture on cooling, with slight reduction in the observed residual strain. This was especially prevalent at low growth temperatures where release of elastic energy by deformation cannot readily take place. The strain pattern was already clearly defined in a 10% GaP alloy.

Relative rotation of the polarizer and analyzer with respect to the samples caused individual birefringence lines to be intermittently light and dark. This suggests a homogeneously distributed strain over the entire area rather than just within the observed pattern lines; the lines reflect the anisotropy produced in the crystal structure by the strain field.

Discussion

Three possible explanations can be suggested for formation of the strain pattern: lattice mismatch, thermal stresses and slip, and segregation. The lattice mismatch at the substrate overgrowth interface does not appear to be the most significant factor on several counts. First, the difference in lattice parameter between pure GaAs and pure GaP is about 4%; therefore the 10% GaP alloy has about a 0.4% mismatch (Vegard's law applies). Since the observed transition region in composition between substrate and overgrowth was found by x-ray analysis to be sufficiently broad to spread the mismatch over tens of micron distances, the resulting strain should be negligible. Second, the substrate was removed prior to observation so that the interface region was not present when observing strain patterns such as those depicted in Fig. 1a. Third, the transverse observation of Fig. 1b shows the field to extend over macroscopic distances, several orders of magnitude greater than expected on the basis of interface mismatch.

Stresses arise from thermal gradients during the cool-down period as the surface contracts more rapidly than the interior. The resulting tensile stresses, if sufficiently large, can produce slip structures such as those in Fig. 2a, or fracture in cases where slip is difficult. A recent observation by Gershenzon and Mikulyak (1) on a "pure" GaP overgrowth on GaAs showed a strain pattern similar to Fig. 1a. They attributed the pattern to the slip lines produced by the thermal stresses on cooling, relating the pattern to the familiar birefringence striations characteristic of bent crystals; also, it was argued that the strain lines were of the same orientation as slip plane traces. Several observations appear to indicate that cooling stresses were not the major cause of the strain patterns in the present work.

1. Strain patterns produced by cooling stresses usually take on a gross appearance, much like the fourfold symmetry birefringence as shown by Lederhandler (2) in silicon. The patterns in the sample of Fig. 1a and the rectangular-shaped specimen of Gerhenzon and Mikulyak were homogeneous over the entire cross section, including corners which should be most susceptible to stress concentration.
2. In the present work in which the growth direction was <111>, the strain pattern did not correspond to slip plane orientations.
3. The maximum effect of cooling should be at the outer surface of the overgrowth where the stresses are maximized. From Fig. 1b, however, it is apparent that the strain is uniform over the entire thickness of overgrowth.
4. Under exactly the same conditions of growth and cooling, pure GaAs overgrowths showed no strain patterns whereas alloy overgrowths did.
5. The GaAs substrate was found to be strain free even though the overgrowth was highly strained (see Fig. 1b). Both surfaces of the wafer were subject to approximately the same cooling rate.

The major cause of the observed strain as deduced from the findings seems to be a segregation effect. The presence of segregated impurities in silicon crystals was shown by Lederhandler (2) and Dash (3) to produce a fine striated birefringence pattern which was homogeneous with respect to the specimen cross section, much like the pattern found in the present work. As indicated by the strain-free GaAs overgrowths, the segregation effect was not produced by an impurity in the ambient or in the charge material; thus, it appears that it is the segregation of the alloy species As and P which occurs during growth (Ga segregation is probably not influential, again relying on the strain-free GaAs overgrowth). The segregation taking place must necessarily be of a local nature to give rise to the fine uniform strain pattern, and of small dimension as indicated by the homogeneous strain field suggested in a prior discussion concerning the effects of rotating the polarizer and analyzer. Segregation at sub-boundary walls is improbable on the basis that none were observed in the etch pit patterns of either the substrate or overgrowth. Also, it is difficult to conceive of segregation at individual dislocation sites causing the massive strain observed under polarization of IR or visible radiation. Two further possibilities are segregation of the species on specific habit planes, and short range ordering in the form of coherent islands, each island being consistent in composition and distribution within itself but differing from its neighbor such that a coherency strain would exist at the interfaces between islands; the sum of the local strains then appear as a long range strain. No direct evidence is available on which to base a mechanism at this time although it would seem that the driving force for segregation on habit planes should be low in this completely miscible system. Local ordering can be a result of the nucleation problem on the <111> growth surface. If it can be assumed that As, P, and Ga arrive at the surface at the same rate, then easy nucleation would give rise to a random distribution. In this case, however, the 4-atom, 2-layer triangular nucleus needed results in a nucleation problem. [Over-all growth of the nucleus occurs readily in a lateral <112> direction in the form of <110> zigzag chain units, as per Sangster (4)]. The number of stable nuclei will control the rate of growth of the surface layer. If the most stable nucleus is one which contains three atoms of P or As (the growth surface is Ga) rather than a composite, then the growth face will contain islands of GaAs and GaP nuclei. Lateral growth would then produce regions either high in As or P, with high stresses resulting in the planes of intersection between islands from lattice mismatch and differences in elastic thermal contractions on cooling. The stressed areas would be randomly oriented with respect to the growth surface and found throughout the thickness of the overgrowth, which seems to be the case. Since deposition is controlled by a chemical reaction of the growth surface, growth at low temperatures is characterized by fewer stable nuclei, slower growth, and larger and more uniform islands, resulting in a reduced strain field. Also, at the lower temperature the temperature gradients on cooling are less, decreasing contraction strains. Although experimental evidence directly confirming the above mechanisms is not available, the dependence of the strain pattern on segregation appears to be a reasonable explanation of the observations presented.

Thermal Expansion of GaSb at High Temperatures

J. C. Woolley

Department of Physics, University of Ottawa, Ottawa, Canada

Most of the available data on the thermal expansion of GaSb is for temperatures close to room temperature or below. Welker and Weiss (1) give a temperature coefficient α of 6.9 x 10^{-6}/°C without indicating the relevant temperature range; Sirota and Golobov (2) quote a mean expansion coefficient of 5.7 x 10^{-6}/°C over the range —100° to +20°C, whlie in a more detailed study Novikova and Abrikosov (3) have determined α as a function of temperature in the range 20-340°K and have shown a change in α from a negative value below 52°K to an almost constant value of about 6.5 x 10^{-6}/°C at 250°K and above. At temperatures above room, Bernstein and Beals (4) using an interferometric method with samples a few millimeters dimensions, give a value of α of 6.0 x 10^{-6}/°C up to 300°C. However they report that α increases rapidly above 300°C and they were unable to determine the expansion at 436°C.

It has been found (5) in electrical measurements on GaSb that the standard plot of log np/T^3 *vs.* $1/T$ shows a change in slope at approximately 450°C indicating different values of energy gap E_0 above and below this temperature. It was thought therefore that a change in α at this temperature could indicate some phase change in GaSb, which would cause the change in E_0. Although x-ray powder photographs of GaSb taken at 560°C still showed a zinc blende type of line distribution (5), this did not rule out the possibility of some transition such as that from a zinc blende structure to a defect antifluorite structure, since both structures would give the same pattern of lines in a powder photograph and would differ only in the relative intensities of the lines (6).

In order to check the results of Bernstein and Beals and to extend them to higher temperatures, x-ray powder photographs have been obtained for GaSb samples in the temperature range 25°-600°C, a Unicam 19 cm high-temperature camera being used with CuKα radiation. From these photographs the change in lattice parameter of GaSb relative to its value at 25°C has been determined. Figure 1 shows the variation of δ as a function of temperature where $\delta = a_T - a_{25}/a_{25}$, a_T being the lattice parameter at temperature T and a_{25} the parameter at 25°C. It is seen that within the limits of experimental error the graph is linear, showing a constant expansion coefficient of $+(6.7 \pm 0.1)$ x 10^{-6}/°C in the temperature range 25°-600°C. There is no indication of any anomalous behavior in the range 300°-450°C and no evidence of any structure change.

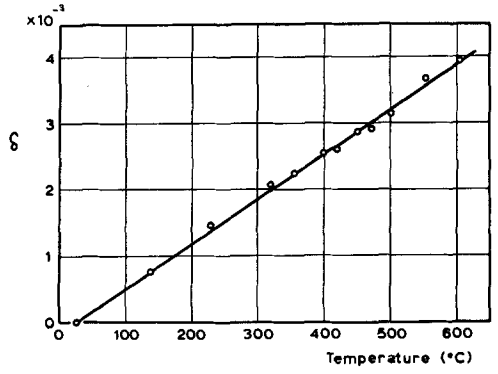

Fig. 1. Variation of δ as a function of temperature where $\delta = \frac{a_T - a_{25}}{a_{25}}$, a_T being the lattice parameter at temperature T and a_{25} the parameter at 25°C.

The Heats of Fusion of InSb, InAs, GaAs, and InP

D. Richman and E. F. Hockings

RCA Laboratories, Princeton, New Jersey

During a study of the thermochemical properties of III-V compounds (1), information about their heats of fusion was needed. Only two compounds InSb (2, 3) and GaSb (2) have been measured by standard calorimetric methods. A rapid semiquantitative method has been used here to obtain the heats of fusion of InAs, GaAs, and InP. The application of standard techniques to these compounds is complicated by the high vapor pressures existing over the melts. This high pressure also necessitates making the measurements during the heating cycle, since quenching does not produce homogeneous, single phase materials.

The heats of fusion for the III-V compounds InSb, InAs, GaAs, and InP have been measured by a differential thermal analysis technique using apparatus of the type described by Gasson (4). Temperatures and temperature differentials were measured with Pt-Pt 13% Rh thermocouples whose outputs were displayed on an x-y recorder. Differential signals were amplified to provide a chart sensitivity of 20 μv/in. Heats of fusion were obtained from the areas of the DTA peaks after calibration with materials having known heats of fusion.

Table I. Properties of III-V compounds

Compound	Melting point, °C	Heat of fusion, kcal/mole This work	Other
InSb	525 ± 3	9 ± 3	12.2 ± 0.5 (2) 11.2 ± 0.4 (3)
InAs	942 ± 3	26 ± 3	
GaAs	1245 ± 5	21 ± 5	
InP	1058 ± 3	12 ± 3	15.2 (5)

The III-V compounds examined were in the form of crushed samples of single crystal, high-purity materials which had been prepared from stoichiometric melts. Heats of fusion and the melting points of these compounds are shown in Table I.

The heats of fusion for InAs and GaAs are higher than those for the other III-V compounds by an amount which exceeds the experimental error and the entropies of fusion for the arsenides are also high with respect to the other compounds. At their melting points the solids all have the zinc blende crystal structure. The liquids above the melting points can be considered as mixtures of group III atoms with monatomic and polyatomic group V species. The higher values for the entropies of fusion of the arsenides arise from differences in degree of association between arsenic and the other group V elements in these melts. Thus the observed heat of fusion of a III-V compound can be considered as composed of a heat of melting and a heat of association of the group V element.

Brief Communication

A Simplified Calculation of Tafel Slopes for Successive Electrochemical Reactions

G. H. Fraser[1] and R. G. Barradas

Lash Miller Chemical Laboratories, Department of Chemistry, University of Toronto, Toronto, Ontario, Canada

An electrochemical reaction may be a sequence of several elementary reactions involving one or more intermediates. To calculate the Tafel slope, if a particular step in the sequence were rate determining, the commonly employed method is to assume "quasi-equilibrium" for all preceding steps and thus to obtain the concentration of the intermediates as a function of overpotential (1, 2).

In an alternative treatment, Parsons (3) considered the passage of the representative point of a system over a series of free energy barriers. He derived the following expressions for the Tafel slopes of cathodic and anodic reactions, respectively

$$b_c = (\partial\eta/\partial \ln i)_{T,a_i} = -(\nu RT/\beta nF) - [(1-\beta)\nu/\beta nF](\partial p/\partial \ln i)_{T,a_i} - (\nu/nF)(\partial q/\partial \ln i)_{T,a_i} \quad [1]$$

$$b_a = (\partial\eta/\partial \ln i)_{T,a_i} = (\nu RT/(1-\beta)nF + (\nu/nF)(\partial p/\partial \ln i)_{T,a_i} + [\beta\nu/(1-\beta)nF](\partial q/\partial \ln i)_{T,a_i} \quad [2]$$

where a_i is the product of the activities of the reagents of the over-all reaction, n is the number of electrons involved in the over-all reaction, the stoichiometric number ν is the number of times the rate-determining step occurs when the over-all reaction occurs once, p and q are electrical work terms and η, i, β, R, T, and F have their usual significance.

In calculating Tafel slopes, most workers have preferred to use the quasi-equilibrium analysis rather than Parsons' treatment (*loc. cit.*), possibly because of uncertainty in handling the terms p and q. We shall show that these terms are really quite simple and that the method of Parsons is just as easy to use as the quasi-equilibrium treatment.

[1] Present address: Johnson, Matthey and Mallory Ltd., Toronto, Ontario, Canada.

Calculations of Tafel Slopes

For the general electrochemical reaction

$$xX + gG^{+z} + ne = wW + cC^{+(gz-n)/c} \quad [3]$$

to occur, the electrochemical systems must pass over a series of free energy barriers (3, 4). Four states must be considered: namely, the initial state I, the final state F, the state P immediately before the highest free energy barrier and the state Q immediately after. The standard electrochemical free energies of these states are given by

$$\overline{G}_I^\circ = (x/\nu)\mu_x^\circ + (g/\nu)\mu_G^\circ + (gz/\nu)\phi_s F + (n/\nu)\mu_e^\circ - (n/\nu)\phi_M F \quad [4]$$

$$\overline{G}_F^\circ = (w/\nu)\mu_W^\circ + (c/\nu)\mu_c^\circ + [(gz-n)/\nu]\phi_s F \quad [5]$$

$$\overline{G}_P^\circ = \mu_P^\circ + (gz/\nu)\phi_s F - (n/\nu)\phi_M F + p \quad [6]$$

$$\overline{G}_Q^\circ = \mu_Q^\circ + [(gz-n)/\nu]\phi_s F + q \quad [7]$$

where ϕ_M is the inner potential of the electrode and ϕ_s that of the solution. p and q are the electrical parts of the standard free energies required to transfer the system from the state I to the state P and from the state F to the state Q, respectively. From these equations Parsons derived [1] and [2].

There are two sources of work in the terms p and q; namely, work done in the physical adsorption of an ion into the Helmholtz double layer, where it can be discharged, and work done in discharging an ion. The former is proportional to ψ, the potential of the Gouy-

Helmholtz boundary of the double layer and the latter to $\Delta\phi$, where

$$\Delta\phi = \phi_M - \phi_s \quad [8]$$

Generalizing the analysis of Parsons, one derives

$$p = k^1\psi F + kF\Delta\phi; \qquad q = l^1\psi F + lF\Delta\phi \quad [9]$$

where k is the number of electrons which must be taken from the electrode to permit the rate-determining step to occur once and $(-l)$ is the number which must be removed to permit the products formed by the occurrence of one rate-determining step to be transferred to the final state F. k^1 and l^1 are defined in an analogous manner for the physical adsorption of ions. When

$$\eta = 0, \quad \Delta\phi = \Delta\phi_R$$

$$\eta = \Delta\phi - \Delta\phi_R \quad [10]$$

Therefore

$$(\partial p/\partial \ln i)_{T,a_i} = kF(\partial\eta/\partial \ln i)_{T,a_i} = kFb$$

and

$$(\partial q/\partial \ln i)_{T,a_i} = lFb \quad [11]$$

For a process occurring on a cathode [3], the Tafel slope associated with any step proceeding in the forward direction is

$$b_c = -(RT/F)[k + \beta(l - k + n/\nu)]^{-1} \quad [12]$$

from [11] and [1]. Similarly, from [11] and [2], the Tafel slope associated with any step in a cathodic reaction proceeding in the reverse direction is

$$b_a = (RT/F)[(1-\beta)(l - k + n/\nu) - l]^{-1} \quad [13]$$

For processes occurring on anodes, the direction of the forward reaction is the opposite to that of cathodic processes, *i.e.*, anodic reactions proceed from the state formerly designated as F to the state I. We must now define l as the number of electrons which must be removed from the electrode to permit the rate-determining step to occur once, *i.e.*, to move the system from state F to state Q. Accordingly, $(-k)$ is the number of electrons which must be removed to permit the products of one occurrence of the rate-determining step to be transferred to the final state, namely to move the system from the state P to state I.

Using these new definitions of k and l, the Tafel slopes associated with any elementary reaction in an anodic process proceeding in the forward and reverse direction can be again given by [13] and [12], respectively. However, it is conventional to use the symbol β for the symmetry factor of the forward reaction (1). Therefore, for processes occurring on anodes, [13] is rewritten as

$$b_a = (RT/F)[\beta(l - k + n/\nu) - l]^{-1} \quad [14]$$

and by analogy, [12] as

$$b_c = -(RT/F)[k + (1-\beta)(l - k + n/\nu)]^{-1} \quad [15]$$

k and l are not necessarily integers. Consider the reaction scheme proposed by Conway and Bourgault (5) for the evolution of oxygen

$$M + OH^- = MOH + e \quad [16]$$

$$MOH + OH^- = MO + H_2O + e \quad [17]$$

$$MO + MOH = MHO_2 + M \quad [18]$$

$$MHO_2 + MOH = 2M + H_2O + O_2 \quad [19]$$

The [MOH] formed in [16] is converted to the final products in three ways: by [17] followed by [18] and [19], by [18] followed by [19], and by [19] alone. The first path involves an electron; the next two require no charge transfer. The average number of electrons required is 1/3, *i.e.*, $k = 1/3$. The analysis of this reaction scheme is shown in Table I as an example of the application of this method. The results agree with those of the quasi-equilibrium analysis performed by Conway and Bourgault (5).

Table I. Kinetic parameters

Rate-determining step	n	ν	l	k	b_a
[16]	4	3	0	1/3	$RT/\beta F$
[17]	4	1	−1	2	$RT/(1+\beta)F$
[18]	4	1	−3	1	$RT/3F$
[19]	4	1	−4	0	$RT/4F$

Thus the Tafel slope for an electrochemical reaction can be calculated by noting the number of electrons appearing before and after the rate-determining step.

The above treatment has, of course, the same limitations as Parsons' original treatment. It is applicable only when low-coverage Langmuir kinetic equations can be used, and when the current does not depend on ψ.

General Equivalence of the "Electron Count" Analysis to the Quasi-Equilibrium Analysis

$(n/\nu) - (k - l)$ is the number of electrons involved in the rate determining step. Let this quantity be m (m may be zero). For a rate-determining step in a cathodic reaction

$$i = A([I_1]^{x1}[I_2]^{x11}[I_3]^{x111}\ldots)\exp(-m\beta\eta F/RT) \quad [20]$$

where A is a constant made up of the rate constant and the activities of the reagents, the I's represent intermediates formed by the discharge of reacting ions, and the x's represent the numbers of the corresponding intermediates appearing in the rate-determining step. The terms involving the intermediates may be symbolized by $[I]^X$. Therefore

$$i = A[I]^X \exp(-m\beta\eta F/RT) \quad [21]$$

In the quasi-equilibrium analysis, one obtains $[I]^X$ as a function of overpotential. The assumption of quasi-equilibrium implies that $\bar{G}_I = \bar{G}_P$, where these electrochemical free energies are no longer defined for the standard state. $\bar{G}_P$ can be obtained by adding a term $x(RT)\ln[I]$ to Eq. [6].

$$\bar{G}_P = \mu_P^\circ + x(RT)\ln[I] + (gz/\nu)\phi_s F - (n/\nu)\phi_M F + p \quad [22]$$

The activities of the reagents are considered to be constant. Therefore $\bar{G}_I$ differs from [4] only by constants. Thus

$$p = \text{constants} - x(RT)\ln[I] \quad [23]$$

From [23], [9] and [10]

$$[I]^X = (\text{constant})\exp(-\eta kF/RT) \quad [24]$$

Therefore

$$b_c = -(RT/F)(k + \beta m)^{-1} \quad [25]$$

which is identical to [12].

Similarly for anodic reactions

$$i = A[I]^X \exp(\beta\eta mF/RT) \quad [26]$$

$$q = \text{constants} - x(RT)\ln[I] \quad [27]$$

$$[I]^X = (\text{constant})\exp(-l\eta F/RT) \quad [28]$$

and therefore

$$b_a = (RT/F)(\beta m - l)^{-1} \quad [29]$$

which is identical to [14]. Thus the method of analysis developed in the previous section leads to the same Tafel slopes as in the quasi-equilibrium analysis.

Summary

The kinetic analysis of electrochemical reactions consisting of several steps, which was derived by Parsons, has not been widely used. By an extension of his treatment we have derived expressions by which

it is possible to calculate Tafel slopes merely by counting the number of electrons which are involved in various parts of the reaction, *i.e.*, those that appear before and those that appear after the rate-determining step, as well as the total number of electrons involved in the reaction. The stoichiometric number of each step must also be known. The general equations for the Tafel slopes of cathodic and anodic reactions, which we have derived, make Parsons' treatment just as convenient as the better known quasi-equilibrium analysis. It is shown that both treatments predict the same Tafel slopes.

Manuscripts and Abstracts for Fall 1965 Meeting

Papers are being solicited for the Fall Meeting of the Society, to be held at the Statler-Hilton Hotel in Buffalo, N. Y., October 10, 11, 12, 13, and 14, 1965. Technical sessions probably will be scheduled on: Batteries (including Symposia on Charging Characteristics of Batteries and Characteristics of Electrodes during Charging), Corrosion, Electrodeposition (including Symposium on Thin Film Technology), Electronics-Semiconductors, Electrothermics and Metallurgy (including a Symposium on Zirconium and Its Alloys).

To be considered for this meeting, **triplicate copies of the usual 75-word abstract, as well as of an extended abstract of 500-1000 words** (see notice on page 112C of this issue), must be received at The Electrochemical Society, 30 East 42 St., New York, N. Y., 10017, *not later than May 17, 1965.* (Papers solely sponsored by the Corrosion Division **do not** require an extended abstract.) *Please indicate on 75-word abstract for which Division's symposium the paper is to be scheduled, and underline the name of the author who will present the paper.* No paper will be placed on the program unless one of the authors, or a qualified person designated by the authors, has agreed to present it in person. Clearance for presentation of a paper at the meeting should be obtained before the abstract is submitted. An author who wishes his paper considered for publication in the JOURNAL or ELECTROCHEMICAL TECHNOLOGY should send triplicate copies of the manuscript to the Managing Editor of the appropriate publication 30 East 42 St., New York, N. Y., 10017. Concerning papers to be published in the JOURNAL, see notice on per page charge on page 105C of this issue.

Presentation of a paper at a technical meeting of the Society does not guarantee publication in the JOURNAL or ELECTROCHEMICAL TECHNOLOGY. However, all papers so presented become the property of The Electrochemical Society, and may not be published elsewhere, either in whole or in part, unless permission for release is requested of and granted by the Editor. Papers already published elsewhere, or submitted for publication elsewhere, are not acceptable for oral presentation except on invitation by a Divisional program Chairman.

The Catalysis of the Electrochemical Oxidation of Formaldehyde and Methanol by Molybdates

J. A. Shropshire

Process Research Division, Esso Research and Engineering Company, Linden, New Jersey

ABSTRACT

The electrooxidation of formaldehyde and methanol on platinum has been shown to be catalyzed in sulfuric acid solution by the presence of molybdates. Decreased polarization has been shown to result from a cycle involving chemical reaction of the fuels with an oxidized molybdate species with subsequent electrooxidation of the reduced molybdate. The process requires the adsorption of molybdate at the electrode surface throughout the entire cycle.

The existence of catalytic currents during the electrochemical reaction of a variety of substances is well known (1). Catalytic currents in general arise when the product of an electrochemical reaction reacts with another species in solution in a subsequent chemical step, thus to regenerate the original form. The net observed result is an increase in the effective concentration of the electroactive species near the electrode and a corresponding increase in the observed current due to its reaction. In many cases this unique feature has been found useful in improving the polarographic determination of trace constituents in solution (1, 2).

An interesting variation of this principle has been investigated in the course of a recent study of the electrochemical oxidation of low molecular weight alcohol and aldehyde fuels for fuel cell use. This variation involves the catalytic reaction of HCHO or CH_3OH with a molybdate species at a platinum black electrode in H_2SO_4. In this case the molybdate species apparently is adsorbed and remains adsorbed at the electrode surface during both the electrochemical and chemical reaction steps.

This "surface redox" reaction, as it will be referred to hereafter, has been of particular interest in fuel cell studies on HCHO and CH_3OH. Through its use the electrochemical oxidation of these fuels to CO_2 may be carried out at a considerable decrease in polarization over that normally found on platinum based electrodes. A series of studies has been carried out to define the advantages and limitations of this system and to determine if in fact a catalytic mechanism is responsible for the observed improvements.

Experimental Techniques and Equipment

All electrochemical measurements in these systems were carried out in conventional glass "H" cells with anode and cathode compartments separated by glass frits. Voltage measurements were made against commercial saturated calomel reference electrodes through Luggin capillaries containing H_2SO_4 of concentration equal to that in the cell proper. All measurements were made using Keithley 610 A or 610 electrometers. Acid solutions were prepared from reagent grade 96% H_2SO_4 and deionized water of conductivity $< 10^{-6}$ mho/cm. Due to the practical necessity of high conductivity for fuel cell electrolytes, studies were carried out in 3.7M H_2SO_4, a solution exhibiting near-optimum conductivity. Absolute methanol and sodium molybdate were reagent grade chemicals. Formaldehyde was obtained as USP Formaldehyde solution (37% in water with a small amount of CH_3OH added for stabilization). Due to the higher reducing activity of HCHO no effect of the added CH_3OH was ever observed.

Electrodes used in this study were of two types. For performance studies (polarization-log current) of CH_3OH and HCHO in molybdate-containing electrolytes, the electrodes were prepared by pressing powdered platinum black into platinum screens. The platinum, prepared by the reduction of H_2PtCl_6 by $NaBH_4$ in aqueous solution, was found to have high surface area and to provide high activity for this purpose. In the chronopotentiometric studies on this system, small platinized platinum electrodes of about 0.25 cm^2 apparent area were used.

In one phase of this study oscilloscopic chronopotentiograms were obtained on the 0.25 cm^2 platinized electrode. Constant current for these transients was obtained from a 30v regulated d-c supply through a high series resistance. Transients were displayed on a Tektronix 545 A oscilloscope with type-D plug-in preamplifier and photographed with the aid of a Dumont type-453 A Polaroid attachment. Potentiostatic studies, where indicated, were carried out using the Duffers Model 600 potentiostat. Other pertinent experimental details will be found in the text where necessary. All polarizations in this study are referred to a hydrogen electrode in the same acid solution (NHE) or to the saturated calomel electrode (SCE), measured difference in these reference voltages being 0.194v at 25°C in the systems involved.

Oxidation of CH_3OH and HCHO on Pt in the Presence of Molybdate

The electrochemical oxidation of CH_3OH or HCHO on platinum black in strong acid media is a highly irreversible process. Passage of practical currents with either fuel is accompanied by polarizations up to 0.6v from the thermodynamically calculated potentials. Both fuels react at about the same potential level on platinum despite a computed difference of about 0.14v in theoretical potential ($E°_{25}CH_3OH = +0.03$v, $E°_{25}$HCHO (g) $= -0.11$v *vs.* NHE). This behavior has led to widespread belief that oxidation of both fuels involves a common slow step. The product of the oxidation of either fuel in acid has been shown by several investigators to result in essentially 100% production of CO_2 at steady state (3-5). Typical measured performances of 1M CH_3OH and 1M HCHO on $NaBH_4$-reduced platinum black in 3.7M H_2SO_4 at 82°C are shown in Fig. 1. Tafel slopes of about 0.06 v/decade are commonly found for oxidation of these fuels on platinum catalysts.

The addition of Na_2MoO_4 to the electrolyte before fuel addition results in a significant alteration of the performance curves (Fig. 1). The polarization at low current densities decreases by as much as 0.3v from that observed with platinum alone. Furthermore, the similarity of HCHO and CH_3OH performance largely disappears with HCHO in this system capable of sustaining currents 100 times as great as CH_3OH at the improved voltage. Also, neither fuel shows evidence of a well-defined Tafel behavior. Instead, the low polarization region exhibits a limiting current, beyond

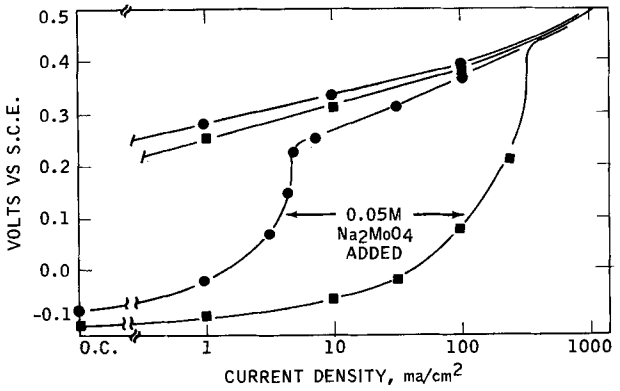

Fig. 1. Effect of Na_2MoO_4 on oxidation of CH_3OH and HCHO on Pt black ($NaBH_4$ reduced); 3.7M H_2SO_4, 82°C; •, 1M CH_3OH; ■, 1M HCHO.

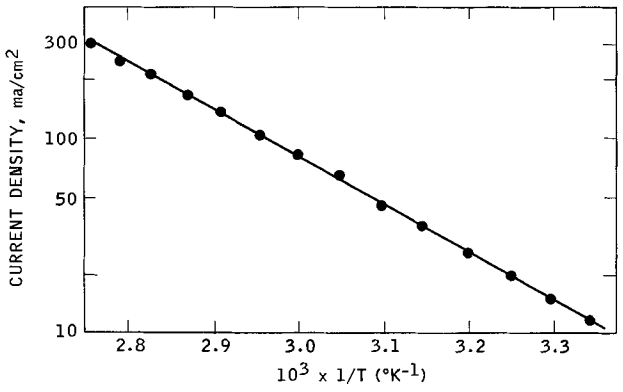

Fig. 2. Effect of temperature on reaction of HCHO on Pt black in presence of Na_2MoO_4. 1M HCHO; 0.05M Na_2MoO_4; 3.7M H_2SO_4; E = 0.1v vs. SCE; ΔE^* = 11.4 kcal/mole.

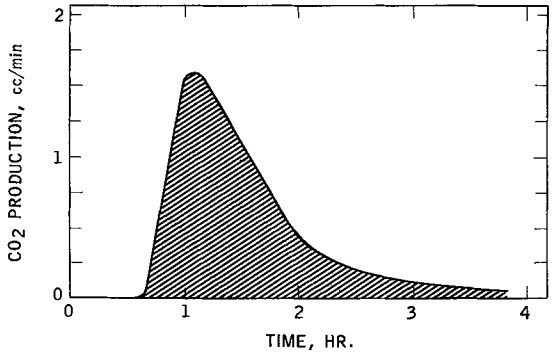

Fig. 3. Chemical reaction of CH_3OH with Na_2MoO_4 in presence of Pt black. 1M CH_3OH, 82°C; initial Na_2MoO_4 = 0.025 mole; 0.42g Pt black catalyst; total CO_2 = 0.0045 mole.

which polarization increases in both cases approximately to the level of the original platinum system. It was found that, if current was decreased following severe polarization of the system, the voltage followed the behavior found on platinum black in the absence of molybdate. This hysteresis was not evident until the limiting current of the initial plateau was exceeded. Thereafter, anodization of the electrode in fresh electrolyte without fuel was necessary to restore activity. It is significant to note that decreased polarization requires that the molybdate be added before the fuel is present. This point will be discussed in a later section.

An activation energy was obtained for the electrode reaction using 0.05M molybdate and 1M HCHO fuel at +0.10v *vs.* SCE using potentiostatic control. This voltage level lies in the region of the curve near the initial reaction limit, but not yet in a region where the normal reaction of HCHO on platinum black would be expected (see Fig. 1). Currents were measured at constant voltage in the temperature range 25°-90°C. The activation energy (Fig. 2) was about 11.4 kcal/mole, much too high to be indicative of a mass transport limitation.

Chemical Reaction of Molybdate with CH_3OH and HCHO

With these early indications of catalytic currents, it was discovered with some surprise that the chemical reaction between molybdate and these hydrocarbon fuels required a catalyst. It was found that with no catalyst present no significant reaction occurred between molybdate and CH_3OH or HCHO in 3.7M H_2SO_4. In the presence of platinum, however, reaction appeared to occur readily with the formation of a product which colored the strong acid solution red-brown. The molybdate equivalent in the reaction with CH_3OH was determined by monitoring the CO_2 production during the complete reaction of 0.025 moles of Na_2MoO_4 with CH_3OH in the presence of 0.42g of Pt black powder (82°C, 3.7M H_2SO_4). The CO_2 produced from the reaction was carried by a fixed flow of nitrogen to the absorption cell of a Liston-Becker Model 15A IR analyzer calibrated at a fixed wavelength for CO_2 analysis. The continuous record of CO_2 production versus reaction time is reproduced in Fig. 3. The peak CO_2 production corresponds roughly to a current of 14 ma/cm² on the type of electrode discussed previously. Although this value is undoubtedly subject to some error caused by lag in the nitrogen carryover system, it indicates a rough rate to be expected from the initial system. Integration of the entire CO_2 production *vs.* time curve was used to establish the moles of molybdate required to produce 1 mole of CO_2. This value was found to be about six, indicating a valence change of one for the reacting molybdate, in view of the six electron oxidation of CH_3OH to CO_2.

Although a similar complete curve was not recorded and analyzed for the reaction of molybdate with HCHO, the peak CO_2 production at the start of that reaction corresponded to about one half the value found for CH_3OH. In view of the greater reducing power of HCHO, this observation would seem inconsistent. An explanation of this result will be reserved to a later section.

Coulometry

As mentioned earlier, the product of the molybdate chemical reaction with fuel in 3.7M H_2SO_4 forms a red-brown solution. It was found that solutions identical in appearance were formed by electroreduction of an acid solution containing Na_2MoO_4 at a platinum electrode at 0.0 *vs.* SCE. (This voltage is about 0.2v negative to $E_{1/2}$ recorded in Fig. 4.) Since the chemical equivalent of molybdate to CH_3OH determined in the previous section would be wrong if CO_2 were not the sole product in the chemical reaction, an independent test of the valence change was made. Two coulometric determinations were carried out for reduction of the molybdate in 3.7M H_2SO_4 to equilibrium on a platinum basket held at 0.0v *vs.* SCE. This voltage level was fixed by means of a potentiostat and current *vs.* time recorded from the voltage drop across a fixed precision resistor in the auxiliary electrode lead. Auxiliary electrode was segregated using an agar plug to minimize bulk mixing of the electrolyte compartments. The data obtained leaves no doubt that a one electron reduction of the molybdate takes place.

Run	Coulombs calc. for 1 electron	Coulombs observed
1	571	573
2	398	390

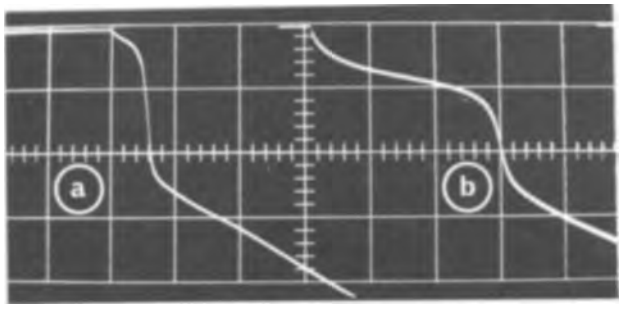

Fig. 4. Chronopotentiograms on platinized Pt in (a) 3.7M H_2SO_4; (b) 3.7M H_2SO_4-0.05M Na_2MoO_4. Top line, 0.0v *vs.* SCE, 300 mv/div (positive downward), 1 sec/div (left to right), 40 ma/cm^2, 25°C.

An attempt was made to confirm the equivalence value in run No. 1 by complete reoxidation of the reduced molybdate at potentials up to +0.8v vs. SCE. Such attempts were completely unsuccessful, however, resulting in very low current production over long periods of time. It appears that the pentavalent species is combined in solution in some relatively inert form, and reoxidation currents are limited by a slow release of the electroactive species.

Chronopotentiometry on Platinized Platinum

A typical anodic chronopotentiogram for a platinized platinum micro-electrode (0.25 cm^2 apparent area) in 3.7M H_2SO_4-0.05M Na_2MoO_4 at 25°C is shown in Fig. 4b. The electrode was polarized to 0.0v *vs.* SCE immediately prior to recording the voltage transient produced by impressing a constant current of 40 ma/cm^2 on the electrode. Under the conditions observed here, a well-defined wave is formed, with $E_{1/2} \simeq$ 0.2v *vs.* SCE (one-quarter wave). Formation of platinum oxide is evident when the voltage reaches +0.7v *vs.* SCE.

Since it was apparent that the over-all reaction of CH_3OH and molybdate involved other than a free molybdate species in solution, an attempt was made to use this well-defined transient to study the factors involved in molybdate adsorption on platinized platinum. Information on both molybdate and formaldehyde adsorption was obtained at 25°C by the anodic stripping technique originally used by Pavela (6). In this method, the preconditioned electrode was placed in the solution of adsorbate for a desired interval, removed rapidly to a 3.7M H_2SO_4 rinse solution to remove excess bulk solution, then placed in a cell containing 3.7M H_2SO_4 and the (anodic) stripping transient recorded. While this technique suffers the drawback of permitting determination of only the material strongly adsorbed, it nonetheless allows the separation of the independent factors in molybdate and fuel adsorption.

The 0.25 cm^2 platinized electrode used for this study was preconditioned by evolving H_2 and O_2 successively a few times (in H_2SO_4 solution) with final equilibration at 0.0v *vs.* SCE before removal to adsorbate solutions. Adsorbate solutions referred to in the following paragraphs are 1M HCHO in 3.7M H_2SO_4 and 0.05M Na_2MoO_4 in 3.7M H_2SO_4 in all cases not otherwise noted. Anodic transients, with the exception of Fig. 9, were recorded in pure 3.7M H_2SO_4.

It was found that a second immersion of this platinized electrode in 3.7M H_2SO_4-0.05M Na_2MoO_4 with no fuel present was sufficient to produce a tenaciously held layer of molybdate, yielding about 40 millicoulombs/cm^2 in the subsequent anodic stripping, Fig. 5b. The blank transient, also shown in Fig. 5a, clearly shows the initial regions of pseudocapacitance from oxidation of chemisorbed hydrogen atoms, the steep so-called double layer region, followed by platinum oxide formation at more positive voltages. By comparison, the electrode with adsorbed molybdate retained much of the initial pseudocapacitance of oxidation of adsorbed hydrogen, indicating that the adsorbed molybdate is not seriously blocking hydrogen sites. This single chemisorbed layer of molybdate was found to be sufficient to produce steady-state performance in a subsequent test with HCHO fuel, in 3.7M H_2SO_4, provided excessive polarization was avoided.

Immersion of the platinized electrode in 3.7M H_2SO_4-1M HCHO with no molybdate results in the rapid formation of a layer of tightly bound HCHO with an oxidation transient as shown in Fig. 6. Oxidation of this strongly held HCHO appears to occur only at or near voltages at which platinum oxidation occurs. Note the marked decrease in double layer capacity in the presence of this adsorbed HCHO, as evidenced by the very steep rise of voltage between 0.0 and +0.3v *vs.* SCE compared to the blank in Fig. 6. Absence of hydrogen pseudo-capacitance is taken as an indication that formaldehyde occupies the majority of the surface, including sites normally held by adsorbed hydrogen atoms. While HCHO was used as the fuel in this and subsequent studies of transients on platinum, the observations made apply in a general way to CH_3OH as well. Due to a stronger adsorption of HCHO, however, effects with that fuel are somewhat more pronounced and therefore have been used to illustrate the behavior.

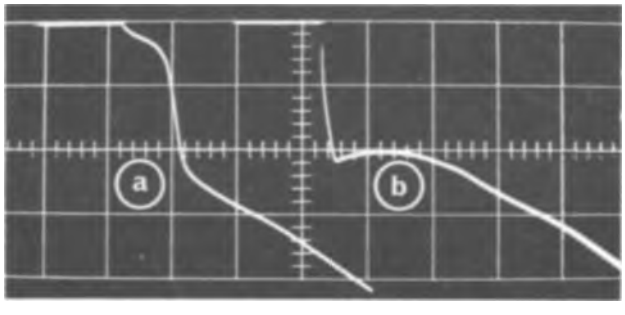

Fig. 6. Chronopotentiograms on platinized platinum in 3.7M H_2SO_4 (a) blank; (b) after 2-min dip in 1M HCHO-3.7M H_2SO_4 and rinse. Coordinates and conditions as in Fig. 4.

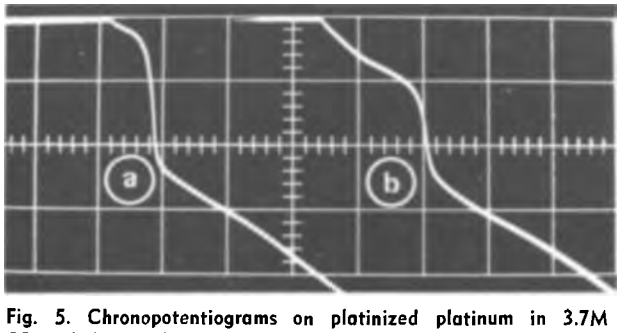

Fig. 5. Chronopotentiograms on platinized platinum in 3.7M H_2SO_4 (a) blank; (b) following 2-min dip in 0.05 Na_2MoO_4-3.7M H_2SO_4 and subsequent rinse in 3.7M H_2SO_4. Coordinates and conditions as in Fig. 4.

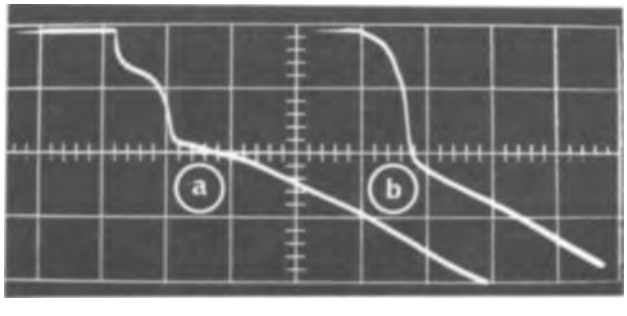

Fig. 7. Chronopotentiograms on platinized platinum in 3.7M H_2SO_4 (a) after 2-min dip in acid-molybdate solution, rinse, 2-min dip in acid-formaldehyde solution and rinse; (b) first subsequent transient on same electrode.

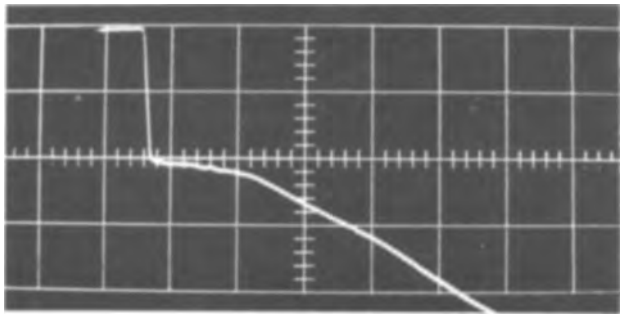

Fig. 8. Chronopotentiogram on platinized platinum in 3.7M H_2SO_4 following 2-min dip in acid-formaldehyde solution, rinse, 2-min dip in acid-molybdate solution, rinse. Coordinates and conditions as in Fig. 4.

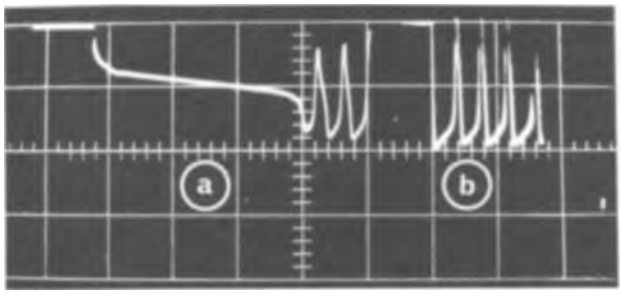

Fig. 9. Chronopotentiograms on platinized platinum in 1M HCHO-3.7M H_2SO_4 (a) after 2-min dip in acid-molybdate and rinse (3.7M H_2SO_4); (b) first subsequent transient on same electrode. Coordinates as in Fig. 4 except 2 sec/div (left to right).

If the electrode is immersed in molybdate solution, rinsed, and then immersed in formaldehyde, both components occupy the surface simultaneously as evidenced by the presence of both characteristic waves in the transient of Fig. 7a. The quantity of molybdate adsorbed appears to be only slightly less than that adsorbed in the previous case of Fig. 5, and absence of adsorbed hydrogen pseudocapacitance makes it seem probable that the strongly adsorbed formaldehyde is present on the hydrogen-type sites not occupied by molybdate.

It is important to recognize in this sequence that the molybdate oxidation wave is not catalytically enhanced through interaction with the HCHO that is strongly adsorbed on the surface. This is evidenced by the fact that the adsorbed HCHO remains on the surface until electrooxidized (Fig. 7a). As shown in Fig. 7b, however, a single anodic transient here serves to eliminate essentially all molybdate as well as formaldehyde.

If the electrode is treated in the reverse order (*i.e.*, contacted with HCHO first) no chemisorbed molybdate is found on the electrode (Fig. 8). The preadsorbed HCHO layer is apparently completely impervious to replacement by molybdate. (This is not completely true in the case of CH_3OH.) Thus, once the formaldehyde layer is formed at the platinum surface in a formaldehyde-containing solution, the electrode must be removed to a plain acid solution and adsorbed HCHO anodized off before the electrode once more is active for molybdate adsorption.

In contrast, anodic stripping of the preadsorbed molybdate layer in the presence of the 1M HCHO-H_2SO_4 solution at 25°C results in a sevenfold increase in transition time before voltage increases to the oscillatory level characteristic of constant current oxidation of HCHO on platinum in these solutions at 25°C (4, 7). This catalytic enhancement of the molybdate oxidation wave is shown in the transient of Fig. 9a. The second transient, Fig. 9b, shows no trace of remaining molybdate, only the oscillating trace of HCHO electrooxidation.

Proposed Mechanism

Based on the foregoing observations, the Pt-molybdate-HCHO (CH_3OH) interaction in H_2SO_4 would seem best summarized as follows:

Chemical reaction:

$$n[Mo^{+6}]_{(ads)} + \left\{\begin{matrix}HCHO\\CH_3OH\end{matrix}\right\} \rightarrow n[Mo^{+5}]_{(ads)} + CO_2 + (n-1)H_2O \text{ (slow)}$$

Electrochemical reaction:

$$n([Mo^{+5}]_{(ads)} + (H_2O) \rightleftarrows [Mo^{+6}]_{(ads)} + H^+ + e^-) \quad \text{(potential determining)}$$

Irreversible failure (to normal Pt levels)

$$[Mo^{+6}]_{(ads)} \rightarrow [Mo^{+6}]_{(soln)} \text{ (near PtO Levels)}$$

$$\left\{\begin{matrix}HCHO\\CH_3OH\end{matrix}\right\}_{(soln)} \rightarrow \left\{\begin{matrix}HCHO\\CH_3OH\end{matrix}\right\}_{(ads\ strongly)}$$

Thus, this reaction differs from a normal catalytic current-producing reaction in that the active intermediate must be fixed at the surface in order to be effective. This characteristic has given rise to the designation "surface redox" or "immobilized redox."

In this scheme no pretense of knowledge is made as to the exact nature of the adsorbed molybdate species. Based on the decrease in transition times for coadsorbed HCHO, however, it appears that strongly held molybdate occupies less than half the electrode surface, primarily those sites not involved in the (most anodic) hydrogen atom adsorption. Fuel on the other hand, especially HCHO, is capable of occupying the entire surface, blocking molybdate adsorption.

Based on the lack of Tafel behavior and dissimilarity of CH_3OH and HCHO performance, the slow step in this catalytic mechanism would seem to arise in some phase of the chemical reaction. Recalling that strongly adsorbed HCHO does not appear to react with adsorbed molybdate, it would seem that the observed rates are determined by the chemical reaction of adsorbed molybdate and nonadsorbed fuel. The high (limiting) activation energy is in accord with this reasoning. In this connection, adsorbed fuel refers to that fuel strongly chemisorbed and does not eliminate the possibility that a weaker, perhaps physical, state of adsorption exists for reactive fuel molecules. Mass transport considerations are eliminated by the fact that the molybdate can be fixed at the electrode, and HCHO (CH_3OH) diffusion is capable of supporting much higher currents (as shown by the subsequent reaction on Pt alone). The difference in performance, then, of HCHO and CH_3OH reflects the true difference in reducing power toward molybdate in the chemical step. If the Nernst equation can be assumed to apply to the surface species involved here, it would appear that Mo^{+5} concentration on the surface is very high during this reaction. Thus, for example, in order to operate at 0.0v *vs.* SCE with $E_{1/2}$ = 0.2v, a Nernst ratio for Mo^{+5}/Mo^{+6} of over 1000 would be required.

It would seem possible, since all molybdate is removed during anodization in the presence of fuel solutions, that the irreversible failure step might involve complexing surface molybdate with a product formed during the direct electrooxidation of HCHO (CH_3OH). Alternatively the absorbed molybdate layer may be forced off by formation of platinum oxides as the potential moves in a positive direction. In any event, once molybdate is lost from the surface, rapid and essentially irreversible replacement by the organic molecule occurs. Thus, as pointed out in a previous section, the sequence of contacting the electrode with molybdate and fuel becomes all important.

The proposed mechanism makes it apparent that the chemical reaction rate observed between fuel and molybdate need have no relation to the electrochemical rates which may be achieved in the "surface redox" process. Thus, the observed chemical reaction requires the desorption of reduced (pentavalent) molybdate in order to perpetuate the reaction, while

the electrochemical cycle does not. If this desorption process is slow, or readsorption of fuel in preference to molybdate occurs, the rates may differ widely. Thus, as pointed out previously, the low apparent chemical rate for reaction of HCHO with molybdate is not inconsistent with the mechanism, but indicates high coverage of the surface with formaldehyde and the inability of molybdate to replace it at a reasonable rate. In the case of CH_3OH this displacement does occur more readily and higher apparent rates are observed.

Summary

The use of molybdates as cocatalysts in the complete oxidation of HCHO and CH_3OH on platinum in acid electrolyte can result in a higher efficiency of this reaction. This improvement has been shown to arise from the catalytic chemical reaction of the fuel with an adsorbed (oxidized) molybdate species with subsequent electrooxidation of its reduced form. To remain operative the molybdate species must remain adsorbed at the electrode surface. Molybdate is lost from the surface under conditions of excessive polarization where HCHO is directly electrooxidized and performance subsequently is characteristic of the levels found with platinum alone. Strong adsorption of fuel under these operating conditions makes the failure irreversible.

The molybdate-fuel-platinum interaction outlined here is probably of little interest for a practical fuel cell system since HCHO is not at present a practical fuel and current densities for CH_3OH reaction are too low to be of interest. The surface redox concept, however, may have broad implications in the search for new fuel cell catalysts. Thus, other compounds may exist which would undergo this same type of redox reaction with fuel and whose adsorption at the electrode interface is not irreversible in the sense described above.

The Solubility and Diffusivity of Oxygen in Electrolytic Solutions

Keith E. Gubbins and Robert D. Walker, Jr.

Department of Chemical Engineering, University of Florida, Gainesville, Florida

ABSTRACT

Measurements of the solubility of oxygen in sulfuric acid, phosphoric acid, and potassium hydroxide are reported, together with values of the diffusivity of oxygen in potassium hydroxide solutions at 25°C. It is shown that for the electrolyte concentrations commonly employed in fuel cells the solubility and diffusivity of oxygen may each be reduced to as little as 2% of their corresponding values for pure water.

It seems probable that in some cases the current obtainable from fuel cells is limited by diffusion of the reacting gas through the liquid (electrolyte) phase to active sites on the surface of the electrode. Under these conditions it follows from Fick's law that the limiting current that may be drawn from a given electrode will depend on the concentration of the gas in the bulk electrolyte and on its diffusivity. In order to enable calculations concerning the performance of such electrodes to be made experimental measurements of solubilities and diffusivities of oxygen in fuel cell electrolytes have been carried out.

Experimental

Solubility.—Gas chromatography was used to determine the solubilities; a diagram of the apparatus is shown in Fig. 1. A sample of electrolyte was equilibrated with oxygen in a constant temperature bath controlled to ±0.1°C. A sample of known volume was withdrawn by means of a syringe and injected into a glass gas stripping cell. This cell contained a medium porosity glass frit and had a volume of about 7 ml; it was also equipped with an injection point consisting of a rubber serum cap. The sample size used was 5 ml. Helium carrier gas passed through the reference side of the thermal conductivity detector and into the sample cell; dissolved gases were rapidly and completely removed from solution by the dispersed carrier gas, and the gas mixture passed through drying tubes before entering the molecular sieve column. Since there was only one component to be analyzed the separating column was not really necessary; however it was included as an experimental convenience in providing a

suitable time interval between sample injection and the arrival of the peak. The peaks obtained by this method were somewhat broader than normal, but there was no excessive "tailing." The gas chromatograph was calibrated for oxygen by injecting a sample of pure water saturated with oxygen at 25°C. The solubility in this case has been accurately determined by chemical methods.

Diffusivity.—The diffusivity of oxygen in potassium hydroxide solutions was obtained by a polarographic method involving measurement of the limiting current during the reduction of the oxygen to hydrogen peroxide at the dropping mercury electrode. The apparatus was similar to that used by Lingane and Laitinen (7). A well-defined limiting current region was observed over the voltage range —0.2 to —1.0v *vs.* a saturated calomel electrode; this wave corresponds to reduction of oxygen to hydrogen peroxide. The second oxygen wave, corresponding to the reduction of hydrogen peroxide to hydroxyl ion, was less well-defined; in addition the mass flow rate and drop-time vary fairly rapidly with change in voltage in this region. The diffusivity (D) was therefore calculated from measurements made on the first wave, using the modified Ilkovic equation (8, 11)

$$i_d = 607\, n\, D^{1/2}\, C\, m^{2/3}\, t^{1/6} \left(1 + \frac{A\, D^{1/2}\, t^{1/6}}{m^{1/3}} \right)$$

where A is a constant; n the number of electrons involved in reaction = 2; i_d the limiting diffusion current, μa; C the concentration of oxygen, millimoles/liter; m the mass flow rate of mercury electrode, mg/sec; t the drop time of mercury electrode, sec.

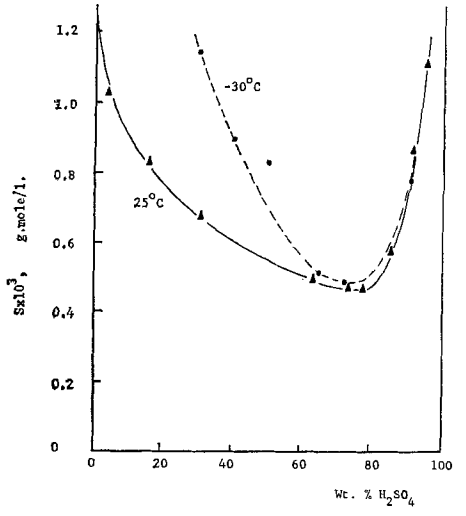

Fig. 3. Solubility of O_2 in H_2SO_4 at 25° and —30°C

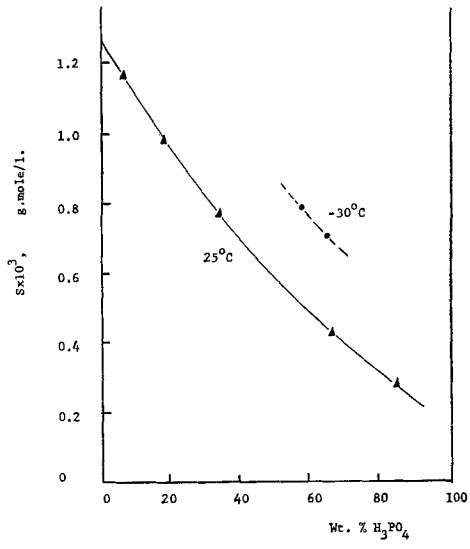

Fig. 4. Solubility of O_2 in H_3PO_4 at 25° and —30°C

The limiting current depends on both the solubility and the diffusivity. However, since the solubility was known from independent measurements, the diffusivity could be calculated from measurements of the limiting current. Different workers have given somewhat different values for the constant A. Strehlow and von Stackelberg (11) predicted the value 17 theoretically and claimed that this value was supported experimentally; Lingane and Loveridge (8) predicted a value of 39 from theory and found values of 31.7 and 33.5 by experiment. Meites and Meites (9) give the value of 31.5. Since experimental evidence supports the higher values for A (5) the value 31.5 given by Meites and Meites was used. Under normal experimental conditions the value obtained for D is not highly sensitive to changes in the value of A; thus changing the value of A from 31.5 to 39 produces a change in the value of D obtained of only about 4%. Jordan (4) has used polarography to determine the diffusivity of oxygen in glycerol-water mixtures and aqueous sucrose solutions

Results

Solubility.—The solubility of oxygen in sulfuric acid, phosphoric acid, and potassium hydroxide solutions has been determined. The results for 25°C are shown in Fig. 2. The solubility values plotted are gram moles of oxygen per liter for a solution equilibrated with oxygen gas at 1 atm pressure (*i.e.*, excluding water vapor pressure). The reproducibility of these results was of the order ±2%.

Figure 2 shows that the solubility of oxygen falls off rapidly and continuously with increasing concentration of potassium hydroxide or phosphoric acid. The solubility in sulfuric acid solutions shows a pronounced minimum at about 75 w/o (weight per cent) H_2SO_4, however. Bohr (1) has reported data for the solubility of air in sulfuric acid at 21°C; these data also show a minimum solubility in the range 70-80% H_2SO_4, and the values are in good general agreement with those shown in Fig. 2. Geffcken (2) has presented data on the solubility of oxygen in dilute solutions of potassium hydroxide (up to 2N); these results are in quite good agreement with those shown in Fig. 2.

Figure 3 compares solubilities in sulfuric acid at —30° with values at 25°C; at concentrations less than about 35% or greater than 90%, solid freezes out of solution at —30°C. Figure 4 shows the solubility in phosphoric acid at —30° compared with values at 25°C. Some additional experimental difficulties occurred at low temperatures owing to the high viscosity of the

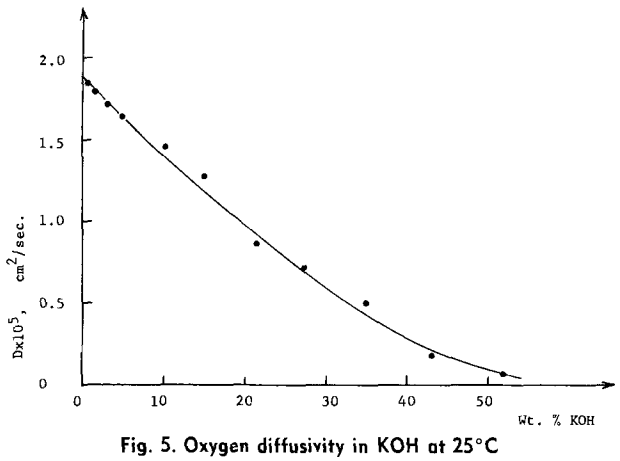

Fig. 5. Oxygen diffusivity in KOH at 25°C

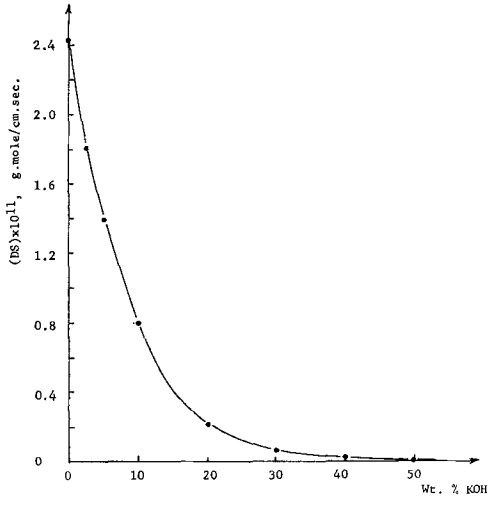

Fig. 6. Rate of diffusion, KOH at 25°C

solutions; this caused difficulty in saturating the solution with the gas and in transferring solution by means of a syringe.

Diffusivity.—Figure 5 presents diffusivity values for oxygen in potassium hydroxide at 25°C. Extrapolation of the curve back to zero concentration gives a value of 1.90 x 10^{-5} cm^2/sec for the diffusivity of oxygen in water at 25°C. This is in good agreement with values determined by other workers (3); thus Kreuzer (6) gives 1.90 x 10^{-5}, Semerano (10) gives 1.87 x 10^{-5}, and Jordan (4) gives 2.12 x 10^{-5}. Taking into consideration the uncertainty in the value of constant *A*, and experimental errors in the measurement of the variables in the Ilkovic equation, it is estimated that the maximum error of the diffusivity values reported is about ±6%.

Discussion

Figures 2 and 5 indicate that both the solubility and diffusivity of oxygen in potassium hydroxide decrease rapidly with increase in concentration. The rate of mass transport of dissolved oxygen to an electrode is proportional to the product of the diffusivity and the solubility. Figure 6 shows this product for potassium hydroxide at 25°C. From this figure it is seen that for a 35% KOH electrolyte the oxygen mass transport rate is less than 2% of that obtainable in pure water. Calculations of the current expected from a mass transport-limited fuel cell in which data for pure water are assumed will therefore give current values that are much too high.

Scaling of Fe-26Cr Alloys at 870°-1200°C

D. Caplan and M. Cohen

Division of Applied Chemistry, National Research Council, Ottawa, Ontario, Canada

ABSTRACT

The oxide layers formed on Fe-26Cr alloy are wrinkled, porous, and blistered, and the metal/oxide interface markedly roughened. This is interpreted as evidence that compressive stresses are generated continuously in the growing oxide, hence that anion diffusion participates in the growth process. Smooth oxidation curves are observed if the wrinkled scale is adherent, even though non-uniform. However, when blistering and cracking occurs, as with electropolished specimens, the weight-gain/time curves are irregular. Similar irregularities occur wih Fe-26Cr-0.5 Si, Fe-26Cr-1Mn, type 446 and pure Cr. Manganese decreases oxidation resistance.

An earlier publication (1) described the oxidation of Cr at 980°, 1090°, and 1200°C. In this paper the oxidation of an Fe-26Cr alloy is examined under the same experimental conditions in a continuing program to investigate the physical nature and mechanism of growth of protective oxide scales. Also included are some experiments with Fe-26Cr containing additions of Mn or Si and with a 26% Cr commercial alloy.

The literature on the oxidation of Fe-Cr alloys has been reviewed recently by Seybolt (2, 3), Kubaschewski and Hopkins (4), Lai *et al.* (5), and most extensively by Wood (6). It is evident that a large effort has gone into investigating this system, but the accumulated information is in many cases contradictory and poorly reproducible. A wide range of scaling rates and a variety of oxide phases is observed. The reviewers

Scaling of Fe-26Cr Alloys at 870°-1200°C

D. Caplan and M. Cohen

Division of Applied Chemistry, National Research Council, Ottawa, Ontario, Canada

ABSTRACT

The oxide layers formed on Fe-26Cr alloy are wrinkled, porous, and blistered, and the metal/oxide interface markedly roughened. This is interpreted as evidence that compressive stresses are generated continuously in the growing oxide, hence that anion diffusion participates in the growth process. Smooth oxidation curves are observed if the wrinkled scale is adherent, even though non-uniform. However, when blistering and cracking occurs, as with electropolished specimens, the weight-gain/time curves are irregular. Similar irregularities occur wih Fe-26Cr-0.5 Si, Fe-26Cr-1Mn, type 446 and pure Cr. Manganese decreases oxidation resistance.

An earlier publication (1) described the oxidation of Cr at 980°, 1090°, and 1200°C. In this paper the oxidation of an Fe-26Cr alloy is examined under the same experimental conditions in a continuing program to investigate the physical nature and mechanism of growth of protective oxide scales. Also included are some experiments with Fe-26Cr containing additions of Mn or Si and with a 26% Cr commercial alloy.

The literature on the oxidation of Fe-Cr alloys has been reviewed recently by Seybolt (2, 3), Kubaschewski and Hopkins (4), Lai *et al.* (5), and most extensively by Wood (6). It is evident that a large effort has gone into investigating this system, but the accumulated information is in many cases contradictory and poorly reproducible. A wide range of scaling rates and a variety of oxide phases is observed. The reviewers

Table I. Composition of specimen materials (weight per cent, w/o)

	Fe-Cr	Fe-Cr-Si	Fe-Cr-Mn	Type 446
C	0.022	0.022	0.012	0.18
Mn	0.003	0.004	1.00	0.75
Si	0.02	0.55	0.01	0.86
Ni	0.02	0.02	0.02	0.32
Cr	26.2	26.2	25.7	25.9

see two main causes. One is the complexity created by experimental variations including alloy composition, impurities, specimen shape, specimen preparation, atmosphere, and procedure in carrying out the oxidation runs. The other is mechanical and structural: pores, blisters, cracks and plastic flow due to stress, local attack and non-uniform scales, phase changes caused by selective oxidation and loss of adhesion are superimposed on the scaling process and obscure the effect of the variables being investigated.

The particular object of the present work was to compare the results to the scaling of unalloyed Cr already carried out and thus disentangle the effects of composition variations in metal and oxide. Further, it was hoped to reduce confusion by using a high-purity Fe-26Cr alloy, oxidizing in purified oxygen, and giving considerable attention to surface preparation and experimental procedure. Since the only oxide formed on Fe-26Cr is Cr_2O_3 containing a small amount of Fe_2O_3 in solution, oxidation behavior similar to that of Cr metal is to be expected; spinel does not form unless surface metal were to become depleted below 13% Cr (2).

As will be seen, clarification was achieved only in part. The structural-mechanical factors are an intrinsic part of Cr alloy scaling and cannot be eliminated. Metallographic cross sections demonstrated their nature and permitted an interpretation of their origins.

Experimental

A high-purity, vacuum-melted Fe-26Cr alloy was used for most of the work. In addition, two similar alloys containing 0.5% Si or 1% Mn and a 26% Cr type 446 commercial steel were oxidized at 1090° only. Table I shows the composition of the four specimen materials. Rectangular specimens 1.1 x 0.5 x 4 cm were machined from 1.3 cm diam rolled rods. A few runs were made with cylindrical specimens 0.6 cm diam x 4 cm long and sheet specimens 1.1 x 0.035 x 5 cm, machined or rolled from the same rods.

The specimens were smoothed by abrading through 600 grit SiC paper and a 10μ layer of metal electropolished off in glacial acetic-70% perchloric acid (20 to 1) to remove surface contamination. They were then annealed for structural stability at 1100°C in purified argon at 20 Torr and electropolished to remove a further 10μ layer of metal. The second polish removed the Cr-depleted surface layer caused by preferential evaporation of Cr and any contaminant that formed during annealing; a precipitate of Cr carbide that apparently nucleated at the surface during cooling also was removed. Some specimens were not annealed, in which case the second electropolish was omitted. After electropolishing, the specimens were either rinsed in water and methanol and blotted dry or immediately etched for 15 sec in 1.38*N* HF (7), or in deoxygenated 4*N* HCl for 45 sec with the specimen polarized cathodically at 10 $\mu a/cm^2$ (1).

The oxidation runs were carried out at 870°, 980°, 1090°, and 1200°C in a vertical tube furnace in flowing oxygen from which CO_2 and moisture had been removed (1). Details of the experiments are included in Table II. For experiments in wet oxygen the gas was saturated with moisture at 25°C corresponding to a P_{H_2O} of 24 Torr. Weight increase was recorded continuously on an automatic balance. The open-insertion method was used in which the cold prepared specimen is lowered quickly into the hot reaction tube with oxygen flowing. Specimens required 0.5-3 min to reach temperature depending on cross section, and weight recording began at about 0.5 min. It is of prime importance to make an accurate estimate of the specimen weight at zero time. This differs from its weight in still air at room temperature by a factor involving convection, buoyant force, a piston effect, and a magnetic correction. It cannot be predicted and may take as long as 5 min to reach a steady state. The weight recording is most uncertain at the very beginning when, unfortunately, the weight is changing most rapidly. Satisfactory correction factors, accurate to 0.01 mg/cm^2, could be obtained from facsimile experiments with nonoxidizing specimens and by other means (1). Different correction factors were obtained if the specimen hung inside a Cr_2O_3 baffle crucible which was sometimes used at the higher temperatures to minimize volatilization of Cr oxide (1, 8).

After removal from the furnace the specimens were observed microscopically as they cooled under argon

Results

Figure 1(a) summarizes the oxidation data for 11 etched Fe-26Cr specimens in 1 atm dry oxygen at 870°, 980°, 1090°, and 1200°C, and Fig. 1(b) the data for 9 electropolished specimens at 980°, 1090°, and 1200°C. The dashed lines are the oxidation curves for pure Cr metal at 980°, 1090°, and 1200°, etched or electropolished, repeated from an earlier publication (1).

Comparison of Fig. 1(a) and 1(b) shows that electropolished Fe-26Cr oxidized more rapidly than the etched alloy. [Cr had shown the same E.P. effect to an even greater degree (1). The etched alloy oxidizes as fast or faster than Cr; after electropolishing, Cr oxidizes faster than the alloy.] The etched specimens yield smooth oxidation curves but those of electropolished specimens all show irregularities near the beginning of the runs as evident in the sub-plot inset in Fig. 1(b). Usually, two such early waves occur between 0.2 and 2 hr. In general, the weight gain before the breaks increases and the time at which they occur decreases with increasing temperature (last two columns of Table II).

Scale structure on etched Fe-26Cr.—Figures 2 to 5 show the structure of the scale formed on the etched Fe-26Cr alloy. The outer surface is wrinkled and the metal surface very roughened, sometimes scalloped in high-crested waves; *e.g.*, compare Fig. 3(c) or 4(d) with the smooth metal as prepared for oxidation [Fig. 2(b)]. The oxide layer is blistered and porous and contains islands of metal [Fig. 3(b), 3(c), and 5(b)] that give the appearance of having been dragged from the metal surface. [The thin scale formed at 870° (Fig. 2) has developed only some of these characteristics and that at 1200° (Fig. 5) is incomplete, much of it having spalled during cooling after the run.] The rugged metal/oxide interface cannot be the result of local or intergranular attack since the oxide is too thin in the metal troughs in relation to the trough depth; it is often thicker over the metal projections instead of where least metal remains. A related phenomenon is shown in Fig. 5: at temperatures and run durations great enough to develop thick scale, the edges of

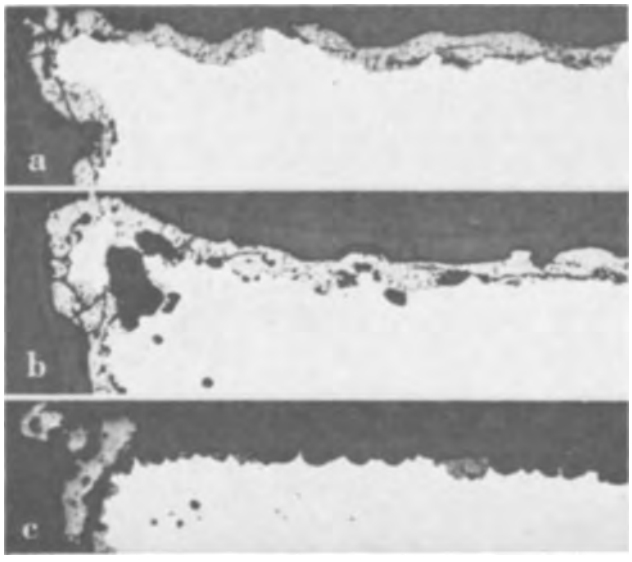

Fig. 5. Section through etched Fe-26Cr oxidized 70 hr at 1200° (curve 11). Scale layer not complete; approximately 50% lost by spalling during cooling at end of run. Magnification 120X.

the rectangular specimens showed a sharply peaked ridge of oxide. In cross section, the metal of the corners also may show a peak [Fig. 5(a)], whereas before oxidation the corners had been smoothly rounded by electropolishing. Measurements of the diagonal distance of the metal core after scaling showed an increase over the original dimension rather than the decrease expected due to metal having been consumed; *e.g.*, in run 11, the diagonals increased by 75μ while, on the average, 32μ of metal were oxidized. It follows from these observations that oxide and metal have been subjected to considerable lateral plastic flow, probably as a result of compressive stresses generated in the oxide layer by the growth process.

Scale structure on electropolished Fe-26Cr.—The scales formed on electropolished Fe-26Cr at 980°, 1090°, and 1200° are illustrated in Fig. 6 to 8. All show an outer separated layer and a more solid inner layer. The early waves in the weight-gain/time curves appear to be related to the outer blistered layer. Usually only one blistered layer is observed even though the oxidation curves show two waves; presumably the two sides of the specimen fail at different times. Figure 6(a) is a plan view of the oxide formed in 0.8 hr at 980°; the layer is poorly adherent and wrinkled or blistered but has not yet failed since no irregularity has occurred in the oxidation curve. Figure 6(b) and (c) are sections through the scale formed in 24 hr under the same conditions; the second layer of adherent, nonblistered scale formed when gaseous oxygen

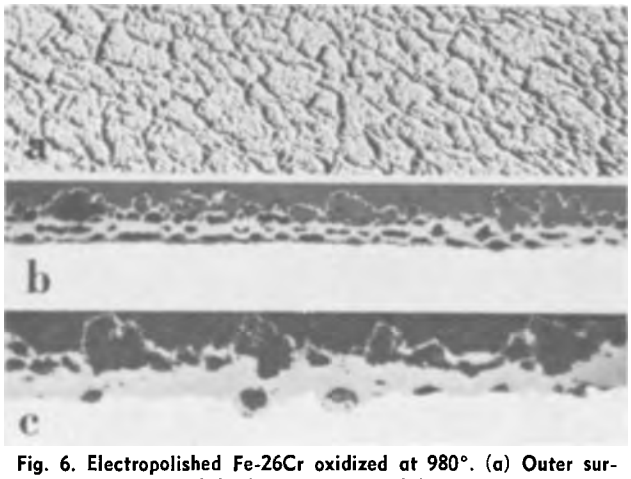

Fig. 6. Electropolished Fe-26Cr oxidized at 980°. (a) Outer surface of oxide after 0.8 hr (run 12); (b) and (c) cross section after 24 hr (curve 15). Some pores next to metal may be artifact. Magnification (a), 80X; (b), 400X; (c), 800X.

Fig. 8. Section through electropolished Fe-26Cr oxidized 0.6 hr at 1200° (curve 20). Magnification 400X.

was admitted to the bare metal by failure of the outer, wrinkled, first-formed layer at 1.7 (or 3.1) hr. At 1090° the outer blistered layer is less evident, especially after 100 hr [Fig. 7(b)], even though the weight gain before the break was no less than at 980° (last column of Table II); this might be accounted for by the increased sintering and evaporation of oxide (8) that would occur at the higher temperature and longer time. In the 0.6 hr run at 1200° (Fig. 8) the outer ballooned layer is much in evidence, consistent with the greater weight gain before the break and too short a time for significant sintering and evaporation to have occurred.

X-ray diffraction of Fe-26Cr.—The only oxide detected by x-ray diffraction was $(Cr,Fe)_2O_3$. Thermodynamically, a spinel is possible if the surface metal were to become depleted in Cr below 13% (2). Attempts to induce spinel by scaling for short times at high temperatures, under which conditions the reaction rate and hence Cr depletion would be greatest, were unsuccessful; no spinel was detected. The lattice parameter of the oxide corresponded to pure Cr_2O_3 which signifies an Fe_2O_3 content of less than 3% [based on the 0.01% accuracy of the x-ray method used and the known lattice parameter of the Fe_2O_3-Cr_2O_3 solid solution (9)].

Chemical analysis of Fe-26Cr.—The Fe_2O_3 content found by chemical analysis ranged from 0.4 to 2.5%, consistent with the x-ray result. There was a tendency for oxide formed at more rapid rates (electropolished, high temperatures, and short times) to contain more iron, but this could not be confirmed because of the difficulty of sampling thin oxide layers without contamination by the substrate metal.

Moisture.—Three runs were carried out in wet oxygen as duplicates to dry oxygen runs, etched and electropolished at 980° and etched at 1100° (see Table II). The oxidation curves were little different from the dry oxygen runs except at the higher temperature after the first several hours. The presence of moisture increases the rate of evaporation of Cr oxide (8) which decreases the weight gain but increases the consumption of metal. As the rate of weight gain slows due to increasing oxide thickness, the loss in weight caused by evaporation of Cr_2O_3 becomes relatively important especially if not suppressed by use of the Cr_2O_3 baffle crucible. Hence, the curve of the last 80 hr of run 29 was essentially flat and the final weight gain only half that of run 10 in dry oxygen.

Other alloys.—Figure 9 compares the 1090° oxidation curves of the Fe-26Cr alloy, etched and electropolished, with the three other Fe-26Cr alloys, the compositions of which are shown in Table I. The 1090° curves for Cr are included for reference.

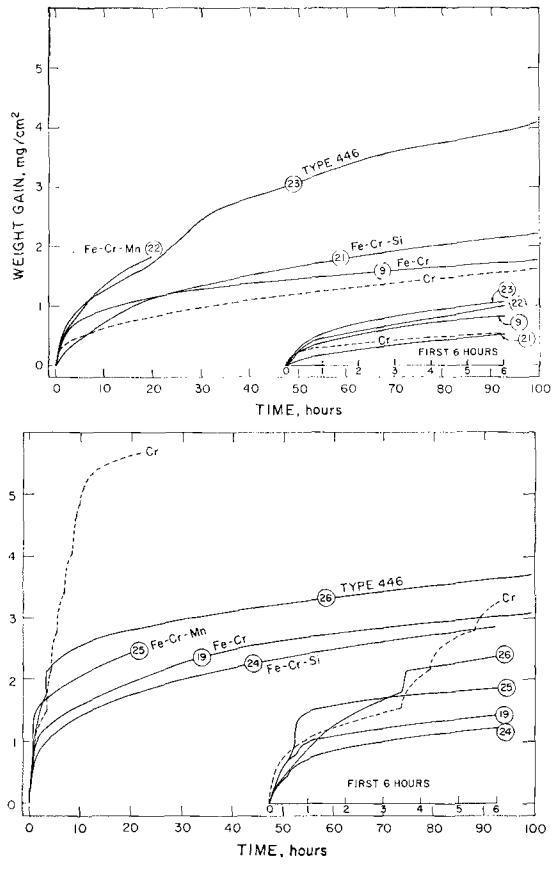

Fig. 9. Oxidation of Fe-26Cr, Fe-26Cr-0.5Si, Fe-26Cr-1Mn, type 446, and pure Cr at 1090° in 1 atm dry oxygen; (a) etched; (b) electropolished.

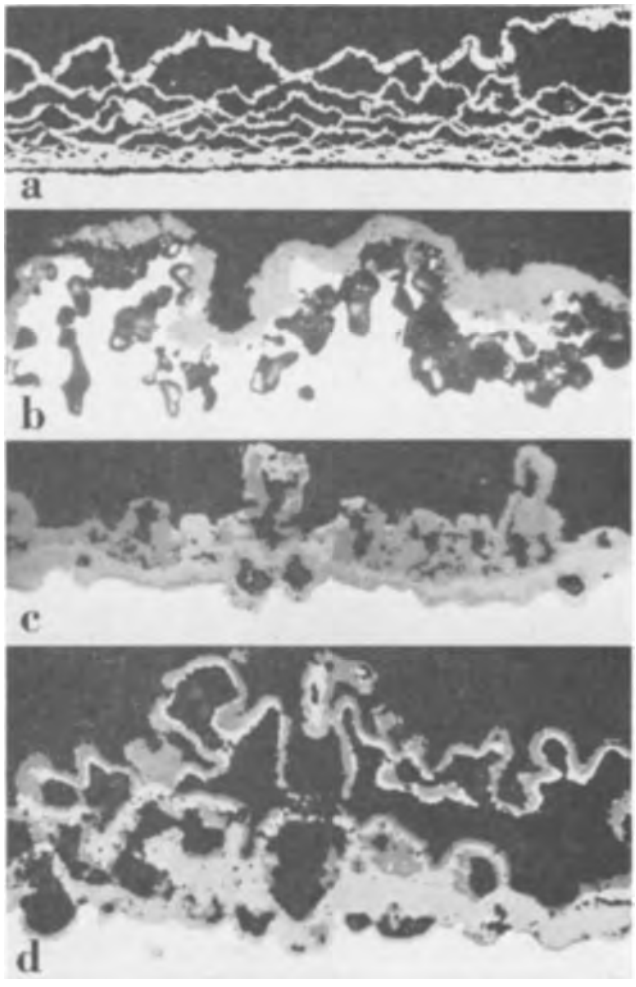

Fig. 10. Sections through Cr, Fe-26Cr-0.5Si and Fe-26Cr-1Mn oxidized at 1090°, illustrating irregular scale structures. (a) electropolished Cr, 21 hr. (Black gap between metal and scale is artifact.) Magnification 200X. (b) etched Fe-26Cr-0.5Si, 117 hr; islands of internal oxide in metal are mainly silica. Magnification 800X. (c) etched Fe-26Cr-1Mn, 20 hr (curve 22). Darker oxide is spinel; lighter oxide is M_2O_3. Magnification 800X. (d) electropolished Fe-26Cr-1Mn, 20 hr (curve 25). Darker oxide is spinel; lighter oxide is M_2O_3. Magnification 800X.

The increase in rate of oxidation due to electropolishing, which was observed with Cr and Fe-26Cr binary alloy, also occurs with Fe-26Cr-0.5Si, Fe-26Cr-1Mn, and type 446. For all five materials the initial reaction rate is faster after electropolishing than after etching, and all five show early breaks or waves after electropolishing [Fig. 9(b) inset] but not after etching [Fig. 9(a) inset]. The two alloys containing Mn oxidize faster than the others.

Scale structures are shown in Fig. 10. Highly irregular layers are formed. The multiple layers of Cr_2O_3 in Fig. 10(a) correspond directly to the segments of the Cr oxidation curve of Fig. 9(b). In the Fe-26Cr-0.5Si alloy, Si oxidized preferentially to form silica islands or subscale [Fig. 10(b)] below the outer layer of $(Cr,Fe)_2O_3$. Mn also oxidizes preferentially but forms a $MnO{\cdot}Cr_2O_3$ spinel (10) [Fig. 10(c), 10(d)] at the expense of some of the $(Cr,Fe)_2O_3$.

Discussion

The general oxidation behavior of the Fe-26Cr alloy is similar to that of Cr in regard to scaling rate and general topography of the scale.[1] Both of these are markedly affected by stress formation in the oxide and the prior chemical preparation of the surface, particularly electropolishing. All five specimen materials show a faster initial oxidation rate after electropolishing. [Pure Fe, on the contrary, oxidizes at the same rate whether electropolished or etched (11).] The compressive stress generated in the oxide leads to wrinkling and separation of the scale and to distortion and roughening of the surface metal.

[1] It is not unreasonable that Cr and Fe-26Cr should exhibit similar oxidation behavior since the 74% Fe content changes the system surprisingly little. The alloy is a substitutional solid solution, b.c.c. like Cr, and of nearly identical lattice parameter. The only oxide phase formed is the solid solution of rhombohedral $(Fe,Cr)_2O_3$ containing less than 3% Fe_2O_3 and indistinguishable in lattice parameter from the rhombohedral Cr_2O_3 on Cr. A spinel phase would develop between metal and $(Fe,Cr)_2O_3$ if preferential oxidation were to deplete the surface metal below 13% Cr (2) but no spinel was detected by x-ray diffraction. Attempts to produce spinel in short runs at high temperature, where depletion might be a maximum, were unsuccessful. In one instance spinel did form after a very long, hot run (500 hr at 1200°) when no baffle crucible was used to suppress volatilization of Cr oxide: boils of spinel as large as 3 mm were found at the bottom (upstream) corners where Cr depletion would be greatest.

Scaling Mechanism

The scaling mechanism proposed for Fe-26Cr is closely allied to that deduced for the oxidation of Cr. To account for the observed compressive flow it appears necessary to infer, as with Cr, that oxygen diffusion participates in film growth causing oxide to form below the oxide/gas boundary. Since evidence exists that Cr diffuses in the rhombohedral oxide on Fe-Cr alloys (2), it is assumed that both cations and anions participate in the diffusion process. Thus the zone of oxide formation is within the body of the growing oxide, reasonably accounting for the observed compressive stress.

Plastic flow of the oxide layer on the etched specimens induces extensive deformation in the adherent surface metal. The consequent rugged oxide/metal interface is observed at temperatures as low as 870° (Fig. 2) and at 1200° the effect is sufficient to cause gross deformation of the specimen (Fig. 5). With pure Cr, adhesion between oxide and metal appeared to be weaker since less flow of the metal surface was observed. The explanation for this is not known but some speculations are possible. The hot strength of

metal and oxide will be decreased by the presence of Fe. This will not only make the metal more readily deformable but will facilitate subsidence of the oxide on to the retreating metal to lessen loss of adhesion. Adhesion would be improved further by collapse of pores via plastic flow of the oxide and annihilation of cation vacancies at suitable sinks, *e.g.*, by dislocation climb. The effect of Fe on the defect structure of the oxide is unknown. If anion diffusion becomes relatively favored, as in α-Fe_2O_3, the zone of stress generation would shift toward the oxide/metal interface. Greater metal creep would then be expected. Whatever the reason, the result observed is a very rugged metal surface and peaked edges.

With the alloy, enhancement of diffusivity due to stress and continuing plastic strain is not directly apparent as was the case with Cr where nodule formation was explained in this way. Nevertheless, it is reasonable to assume its existence because the oxides are similar and stress so apparent. The effect of enhanced diffusivity on reaction kinetics should be a maximum initially and decrease progressively as the reaction rate slows.

The early waves in the E.P. oxidation curves can also be explained by the development of compressive stress. The fastest oxidation rate, hence the highest rate of stress generation, is with an electropolished specimen at the start of a run. Stress relief by creep normal to the surface will then be least effective and the stress can come to exceed the force of adhesion between oxide and metal. As a result, the oxide layer blisters away from the metal. A contributing or perhaps alternative cause of loss of adhesion is the higher rate of arrival at high oxidation rate of cation vacancies at the metal/oxide interface which may decrease adhesion by condensing into pores. The scaling process can continue in spite of separation between oxide and metal by transfer of Cr at points of contact and as vapor through the vacuum of the gap (1). Whereas with Cr the blistered layer could persist unbroken for 100 hr or more, with Fe-26Cr it fails in 2 hr or less, creating the early waves. The earlier failure might be because the oxide has lower hot strength than pure Cr_2O_3 or because the vapor pressure of Cr for the alloys is too low, especially after the metal surface becomes depleted in Cr. When the blistered layer perforates at some point, oxygen at 1 atm rushes into the vacuum gap and a second layer of oxide begins on the bare metal; the second layer does not blister because the surface on which it forms is no longer electropolished. The cause of the E.P. effect is believed to be related to the prior oxide produced during electropolishing having a higher concentration of lattice defects or of leakage paths for easy diffusion. This same speculation was proposed for pure Cr.

Oxidation Kinetics

The electropolished specimens are not considered because of the mechanical failure of the blistered first layer. The photomicrographs have shown that the oxide formed on the etched specimens is highly irregular with a rough outer surface, nonuniform thickness, rugged oxide/metal interface and containing blisters, pores and islands of metal. The effective area differs from the geometric area, not all the oxide participates in the protective process, and these factors change nonsystematically with time. As a result, meaningful analysis of the oxidation kinetics is not possible. It is surprising that the oxidation curves, at least of the etched specimens, are so smoothly well-behaved and the reproducibility as good as it is; apparently, despite so many processes operating simultaneously, local events are on a fine enough scale not to perturb the weight-gain/time record perceptibly.

Plotted on parabolic coordinates, $(\text{weight})^2$ *vs.* time, the oxidation curves generally are concave downwards. Possible reasons for this type of deviation from normal parabolic behavior are some oxide being nonparticipating, increasing cavity formation, loss of Cr oxide by volatilization, and improvement of the barrier by sintering; if, as postulated previously, plastic deformation resulting from compressive stress enhances diffusion, the effect would decrease as the reaction slows with time.

Double log plots of the oxidation data (log W *vs.* log t) yield good straight lines, in some cases over the entire time period of 0.1 to 100 hr, with slopes indicating values of n (in the relation $W^n = kt$) usually less than 3 and as low as 2.3 ($n - 2$ for parabolic). Nevertheless, this treatment has even less significance than the parabolic plot. The markedly nonideal character of the barrier layer precludes a systematic treatment and renders derivation of rate constants and consequent activation energies pointless. With Cr it was possible to estimate a local rate constant from areas on the metallographic cross sections where short lengths of ideal barrier layer could be found (1); no such areas of smooth, single-layer, nonporous oxide appeared on the alloy.

Moisture

The companion runs in wet oxygen demonstrate as with Cr that moisture does not significantly change the protectiveness of the M_2O_3 scale. This is in contrast to earlier observations on commercial stainless steels where gross increases and decreases were found depending on alloy type (12, 13). Much of the differences were due to mechanical factors: the huge breaks were obviously the result of separation and cracking of the barrier layer. Certainly moisture can be expected to change the sinterability of the oxide and hence affect plastic deformation and cracking. But increased plasticity cannot explain all the results. The moisture effect still is unexplained.

Other Alloys

In the ternary alloys, Si and Mn both oxidize preferentially and form second oxide phases. The silica formed under the $(Cr,Fe)_2O_3$ scale on the Fe-26Cr-0.5Si alloy does not develop into a continuous layer and for this reason has no appreciable effect on oxidation resistance. The protectiveness of the $(Cr,Fe)_2O_3$ layer is not affected. If the Si content were higher or the experimental conditions different, a continuous layer could form and isolate the Cr oxide from the substrate (12). The oxidation resistance would be increased temporarily until mechanical failure of the isolated layer occurred and rapid oxidation resumed.

The Fe-26Cr-1Mn ternary and the 446 stainless alloy, also containing Mn and 26% Cr, scale more rapidly than Cr, Fe-26Cr and Fe-26Cr-0.5Si. The $MnO \cdot Cr_2O_3$ spinel forms as a continuous layer, in part replacing the $(Cr,Fe)_2O_3$. The reaction rate is higher because diffusion is faster in the spinel (10) and also because Mn promotes excessive blistering, hence nonparticipating oxide.

Summary

The wrinkled and blistered oxide layers, peaked corners and roughened metal surface indicate that compressive stresses develop continually in the growing oxide. This points to anion diffusion as one of the processes contributing to film growth, resulting in a zone of formation of new oxide within the oxide layer. The consequent compressive stress causes the oxide and metal to deform plastically, creating highly irregular structures and mechanical failure of the barrier layer.

The nonuniformity of the scale structure interferes with the analysis of the reaction kinetics even when smooth oxidation curves are obtained. No rate constants or activation energies were deduced. The several complicating factors, including porosity, nonparticipating oxide, unknown effective area and varying oxide thickness, themselves change nonsystematically with time. If diffusion is enhanced by the continuing plastic flow, as is believed, diffusion coefficients in the oxide also would slow with time.

The oxide formed on Fe-26Cr is the same as the Cr_2O_3 formed on Cr except for a minor Fe content, and the oxidation rates are similar. Addition of 0.5% Si to Fe-26Cr leads to the formation of silica islands under the $(Fe,Cr)_2O_3$ layer but has no appreciable effect on the oxidation resistance. Fe-26Cr-1Mn and type 446, both containing Mn, form spinel layers as well as M_2O_3 and show greater weight gains. Mn is apparently deleterious in oxidation-resistant Fe-Cr alloys.

The oxidation of Fe-26Cr is highly sensitive to surface preparation. The initial rate is especially rapid after electropolishing. The three other Fe-26Cr alloys and Cr behave similarly. As a result the oxide layer blisters away from the metal surface, fails mechanically and a second layer forms below. Corresponding irregularities appear in the oxidation curves.

Moisture appears to have no effect on the oxidation resistance of Fe-26Cr except that it enhances the volatilization of Cr oxide thus thinning the layer and decreasing the weight gain but increasing the amount of metal consumed.

For best results in the utilization of high temperature alloys which rely on Cr for oxidation resistance it should be advantageous to prepare the metal surface carefully, arrange moderate oxidation conditions for the first exposure, and avoid gas flows that would aggravate oxide evaporation. Mn should be avoided; no doubt certain other alloying additives would be beneficial.

Acknowledgment

The authors are grateful to Mrs. Alma Harvey for skillful assistance with the oxidation experiments and Mr. P. E. Beaubien for the metallography.

Studies on the Oxygen Gradients in Oxidizing Metals

III. Kinetics of the Oxidation of Zirconium at High Temperatures

J. P. Pemsler

Ledgemont Laboratory, Kennecott Copper Corporation, Lexington, Massachusetts

ABSTRACT

The oxidation of zirconium was studied in the temperature range 840°-1100°C. Film growth and oxygen solution processes were separated experimentally. Oxygen solution obeys diffusion kinetics and remains parabolic for sufficiently thick samples. Film growth does not obey normal rate laws; an exceedingly rapid initial rate is followed by a period of slower growth. The over-all weight gain curve is explained in terms of the separate film growth and oxygen solution processes. At temperatures $\geq$975°C voids form in the oxide; they act as diffusion blocks and promote formation of a duplex layer. The mechanism of void formation is discussed in terms of a condensation of oxygen vacancies. The effect of orientation, pressure, surface preparation, and initiation temperature are discussed.

The kinetics of the oxidation of zirconium has been extensively investigated over a wide range of temperatures. Authors variously report the rate as cubic transforming to linear or parabolic transforming to linear. There are relatively few measurements at high temperatures where oxygen dissolution in the metal represents a significant quantity of the total oxygen absorbed. The high-temperature data are for the most part of short duration and exhibit poor reproducibility from sample to sample. High-temperature studies have in general relied on thin coupons which are not amenable to long term observation of the kinetics for two reasons: (i) Spalling and cracking at the edges after relatively short times prevents accurate assessment of the weight gains; and (ii) the meeting of the oxygen gradients in the center of the sample alters the rate of dissolution of oxygen in the metal, so that the kinetic curve is dependent on the thickness of the sample.

There has been only one group of investigators which has attempted to separate quantitatively the contributions of film thickness and oxygen dissolution to the kinetics of the high-temperature process. Wallwork, Smeltzer, and Rosa (1) oxidized 2 mm-thick zirconium coupons for times up to 200 hr at 850°C. They report that both the oxide film and over-all weight gain conform to parabolic kinetics. Rosa and Smeltzer (2) oxidized similar samples for times up to 100 hr at 950°C. They report that after an initial deviation both oxide film thickness and total weight gain conform to parabolic kinetics.

In a recent investigation (3) the author has shown that the oxygen gradient beneath the oxide film on zirconium oxidized at high temperatures may be measured experimentally and is in good agreement with values from a theoretical expression involving the diffusivity, time, and oxide film thickness. Furthermore, it was noted that with coarse grained samples the oxide film thickness at 850°C did not conform to a parabolic rate of growth, but rather grew at a very rapid rate for the first several hours, and thereafter, at a greatly reduced rate.

It is the purpose of this work to attempt: (i) to obtain accurately and reproducibly kinetic data for the oxidation of zirconium at high temperatures for long periods of time; (ii) to separate quantitatively the film growth and oxygen dissolution processes; and (iii) to investigate the mechanism of the film growth process.

Experimental

The zirconium used in this investigation was obtained in the form of 1.9 cm diameter rod, and the analysis is given in Table I. Spheres of 1.74 cm diameter were machined from the rod with a tolerance of 25μ on the diameter. The spherical shape was chosen to eliminate the effects of edges and corners as a source of initiation of oxide failure and spalling. Furthermore, the spherical shape enables precise calcula-

tion of the quantity of oxygen dissolved in the metal; the situation is far more complex with other sample shapes such as parallelopipeds where gradients from different directions overlap.

Spheres were etched in an aqueous solution of 50% nitric and 5% hydrofluoric acids, rinsed, dried, and suspended by a thin platinum wire in an Ainsworth continuous recording semi-microbalance of 0.01 mg sensitivity and 400 mg weight gain capacity. The balance was evacuated, and the sphere was annealed for 1 hr at the temperature at which the oxidation was to take place. After annealing, the furnace was removed and the sample allowed to cool to room temperature. High-purity grade oxygen whose analysis is given in Table II was then admitted to the sample tube and the furnace repositioned around the sample tube. A continuous record of the weight gain was obtained throughout the course of the oxidation. In the two runs of less than 1 hr at 910°C, the oxygen was admitted while the sample was at temperature in order to define the exposure time more precisely. At the conclusion of the oxidation run spheres were removed from the balance, imbedded in bakelite mounts, and machined to within 0.25 mm of the diameter. A final polish for 60 sec on a napless cloth was used to prevent rounding of the oxide film. Photographs of the oxide film were taken at suitable magnification at eight areas equidistant around the circumference of the circle of polish. The thickness of the oxide film at each area was obtained from the photographs by measuring the area of the oxide film with a planimeter.

Since the diffusion coefficient of oxygen in zirconium is highly temperature dependent, and at the temperatures under consideration in this study the quantity of oxygen dissolved in the metal represents a considerable portion of the total oxygen absorbed, it is necessary to control and measure the temperature accurately. The initial experiments at 840°C were performed using a rate-proportioning galvanometer controller. In this instance the temperature varied by ±2.5° from the control point. In subsequent experiments at higher temperatures, a 1 mv potentiometric controller with an external solid-state zero suppression reference together with a proportioning current adjuster were used to control the temperature of the furnace. A calibrated measuring thermocouple placed along side of the suspended zirconium sphere and read on a 670 μv full-scale potentiometric recorder was used to monitor the temperature continuously throughout the course of the oxidation. The controlling and recording thermocouples were led directly to an automatic ice-point reference system and thence to the controller and recorder. During the course of the oxidations temperatures were maintained constant to better than ±0.5°C.

Diffusion Equations

Below α/β transformation.—Calculation of the oxygen gradients beneath the film on oxidized metals necessitates the solution of a moving interface diffusion problem with the oxidation rate as a boundary condition. The solution to this problem for the case of alpha zirconium has been derived elsewhere (3, 4).

The oxygen concentration C at a distance x from the oxide/metal interface is given by the expression

$$C = C_s \frac{\operatorname{erfc}(x/2\sqrt{D_\alpha t})}{\operatorname{erfc}(s/2\sqrt{D_\alpha t})} \quad [1]$$

where C_s is the oxygen concentration in zirconium coexisting with ZrO_2, D_α is the diffusion coefficient of oxygen in zirconium at the experimental temperature, s is the distance of the oxide/metal interface from the position of the initial surface, and $x = x' + s$.

Integration of Eq. [1] gives the total quantity of oxygen present in the metal beneath the oxide film

$$M = 2C_s\sqrt{D_\alpha t}\left[\frac{\exp(-s^2/4D_\alpha t)}{\sqrt{\pi}\operatorname{erfc}(s/2\sqrt{D_\alpha t})} - \frac{s}{2\sqrt{D_\alpha t}}\right] \quad [2]$$

where M is the quantity of oxygen dissolved in the metal per unit area of surface.

The use of spherical samples necessitates the solution of the above case in spherical coordinates. In a sphere of radius a with an initial oxygen concentration of zero, the boundary conditions are

$$C = 0 \text{ at } r > 0, t = 0 \quad [3]$$

and

$$C = C_s \text{ at } r = a - s \quad [4]$$

where s is defined as above.

The concentration C at a distance r from the center of the sphere is given by

$$C = C_s \frac{1 + \frac{2a}{\pi r}\sum_{n=1}^{\infty}\frac{(-1)^n}{n}\sin\left(\frac{n\pi r}{a}\right)\exp\left[-\frac{D_\alpha n^2\pi^2 t}{a^2}\right]}{1 + \frac{2a}{\pi(a-s)}\sum_{n=1}^{\infty}\frac{(-1)^n}{n}\sin\frac{n\pi(a-s)}{a}\exp\left[-\frac{D_\alpha n^2\pi^2 t}{a^2}\right]} \quad [5]$$

Integration of Eq. [5] gives the total quantity of oxygen contained in the metal sphere of radius $a-s$ beneath the oxide film.

$$M = C_s \frac{\frac{4}{3}\pi(a-s)^3 + \sum_{n=1}^{\infty} 8\pi(-1)^n\left(\frac{a}{n\pi}\right)^3\left(\sin\frac{n\pi(a-s)}{a} - \frac{n\pi(a-s)}{a}\cos\frac{n\pi(a-s)}{a}\right)\exp\left[-\frac{D_\alpha n^2\pi^2 t}{a^2}\right]}{1 + \frac{2a}{\pi(a-s)}\sum_{n=1}^{\infty}\frac{(-1)^n}{n}\sin\frac{n\pi(a-s)}{a}\exp\left[-\frac{D_\alpha n^2\pi^2 t}{a^2}\right]} \quad [6]$$

The necessity of performing summations makes the equation most conveniently evaluated by computer methods.

The diffusion coefficient of oxygen in alpha zirconium has been measured by the author (5) and subsequently by several additional authors (6-9). The value in the alpha phase is considered to be known with high accuracy and expressed by

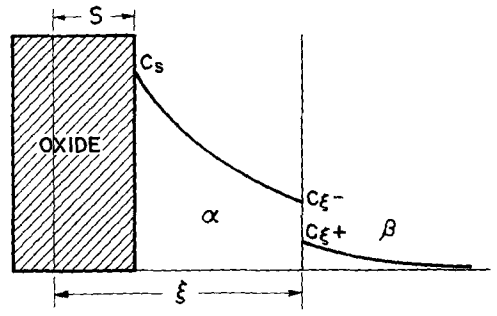

Fig. 1. Schematic diagram of zirconium oxidized at temperatures above the α/β transition temperature.

$$D_\alpha \text{cm}^2/\text{sec} = 5.2 \exp[(-50{,}800 \pm 870)/RT] \quad [7]$$

The saturation value of oxygen in alpha zirconium coexisting with zirconia was taken as $C_s = 0.456$ g/cm^3 (10, 11). The quantity of metal s consumed in generation of an oxide film of thickness l was taken as $s = 0.666l$.

For spheres of 1.74 cm diameter oxidized at 840°C, the value of M calculated for a sphere from Eq. [6] was about 4% less than values for a semi-infinite sample as calculated from Eq. [2].

Above α/β transformation.—Oxygen is a strong alpha stabilizer and at temperatures above the α/β transformation (862°C) a more complex situation exists, as shown in Fig. 1. Beneath the oxide film there exists a solution of oxygen in alpha zirconium for a distance ξ from the original metal interface, until an oxygen concentration of $C_{\xi-}$ is reached. At this position there is a plane of discontinuity where the concentration falls to $C_{\xi+}$, the saturation value of oxygen in the body centered cubic β zirconium. Thereafter, the concentration falls to a value of C_0, the initial oxygen content of the metal. The boundary conditions for a semi-infinite sample are expressed as

$$C = C_0 \text{ at } x > 0\ t = 0 \quad [8]$$

$$C = C_s \text{ at } x = s\ t > 0 \quad [9]$$

$$C = C_{\xi+} \text{ at } x = \xi - 0 \quad [10]$$

$$C = C_{\xi-} \text{ at } x = \xi + 0 \quad [11]$$

The particular integrals satisfying Eq. [8] through [11] are

$$C_\alpha = C_s + \frac{(C_s - C_{\xi-})\left[\text{erf}\left(\frac{s}{2\sqrt{D_\alpha t}}\right) - \text{erf}\left(\frac{x}{2\sqrt{D_\alpha t}}\right)\right]}{\text{erf}\left(\frac{\xi}{2\sqrt{D_\alpha t}}\right) - \text{erf}\left(\frac{s}{2\sqrt{D_\alpha t}}\right)} \quad [12]$$

and

$$C_\beta = \frac{C_{\xi+}\left[\text{erfc}\left(\frac{x}{2\sqrt{D_\beta t}}\right)\right]}{\text{erfc}\left(\frac{\xi}{2\sqrt{D_\beta t}}\right)} \quad [13]$$

The mass flow across the boundary ξ is given by

$$(C_{\xi-} - C_{\xi+})\frac{d\xi}{dt} = -D_\alpha\left(\frac{\partial C}{\partial x}\right)_{\xi-0} + D_\beta\left(\frac{\partial C}{\partial x}\right)_{\xi+0} \quad [14]$$

where D_α is the diffusion coefficient of oxygen in alpha zirconium and D_β is the diffusion coefficient in beta zirconium.

Setting $\gamma = \xi/2\sqrt{Dt}$ and $\phi = D_\alpha/D_\beta$, and integrating Eq. [14] we obtain

$$C_{\xi-} - C_{\xi+} = \frac{C_s - C_{\xi-}}{\left(\text{erf}\gamma - \text{erf}\frac{s}{2\sqrt{D_\alpha t}}\right)\gamma\sqrt{\pi}}\exp[-\gamma^2] - \frac{C_{\xi+} - C_0}{\gamma\sqrt{\pi\phi}\,\text{erfc}\,(\gamma\phi^{1/2})}\exp[-\gamma^2\phi] \quad [15]$$

from whence ξ can be calculated.

The total quantity of oxygen contained in the alpha and beta phases are obtained by integrating Eq. [12] and [13], respectively.

$$M_\alpha = C_s(\xi - s) + \frac{C_s - C_{\xi-}}{\text{erf}\left(\frac{\xi}{2\sqrt{D_\alpha t}}\right) - \text{erf}\left(\frac{s}{2\sqrt{D_\alpha t}}\right)}\left[(\xi - s)\,\text{erf}\left(\frac{s}{2\sqrt{D_\alpha t}}\right) - \xi\,\text{erf}\left(\frac{\xi}{2\sqrt{D_\alpha t}}\right) - \frac{2\sqrt{D_\alpha t}}{\sqrt{\pi}}\exp\left[-\frac{\xi^2}{4D_\alpha t}\right] + s\,\text{erf}\left(\frac{s}{2\sqrt{D_\alpha t}}\right) + \frac{2\sqrt{D_\alpha t}}{\sqrt{\pi}}\exp\left[-\frac{s^2}{4D_\alpha t}\right]\right] \quad [16]$$

$$M_\beta = \frac{C_{\xi+}\,2\sqrt{D_\beta t}}{\sqrt{\pi}}\,\frac{\exp\left[-\frac{\xi^2}{4D_\beta t}\right]}{\text{erfc}\left(\frac{\xi}{2\sqrt{D_\beta t}}\right)} - C_{\xi+}\xi \quad [17]$$

The increase in the quantity of oxygen in the metal during oxidation is then equal to the amount of oxygen in the alpha phase plus the amount in the beta phase minus the initial oxygen content.

$$M = M_\alpha + M_\beta - \frac{4}{3}\pi a^3 C_0 \quad [18]$$

No attempt was made to solve Eq. [16] directly for the spherical case. The oxygen content of the alpha phase M_α was evaluated for a semi-infinite sample from Eq. [16] and the result decreased by 4% (see above) to correct for spherical geometry. The evaluation of M_β for the sphere is analogous to the evaluation of M according to Eq. [6], where now s is replaced by ξ, and computer methods used.

Values of C_s, D_α, and s are obtained as in the preceding section. Values of D_β are obtained from the work of Mallett *et al.* (6).

$$D_\beta = 0.0453 \exp[(-28{,}200 \pm 2400/RT)] \quad [19]$$

and are known only to within about a factor of two.

Values of $C_{\xi-}$ were estimated from the phase diagram (10, 11) and are probably correct to within a 30% error. Since it was difficult to estimate values of $C_{\xi+}$ from the phase diagram, it was determined experimentally at one temperature. A cylinder 0.5 cm in diameter x 1.5 cm long was oxidized at 967°C for 64 hr, after which the oxygen concentration at the center was calculated to be $0.69C_{\xi+}$. The oxide film and alpha phases were machined from the sample and the remaining transformed β-phase analyzed for oxygen. The value of $C_{\xi+}$ at 967°C was obtained in this manner, and values at the other temperatures were estimated by assuming that values of $C_{\xi+}$ are linear with temperature near the transformation temperature (in agreement with the shape of the phase diagram). Values of D_β, $C_{\xi+}$, and $C_{\xi-}$ are listed in Table III.

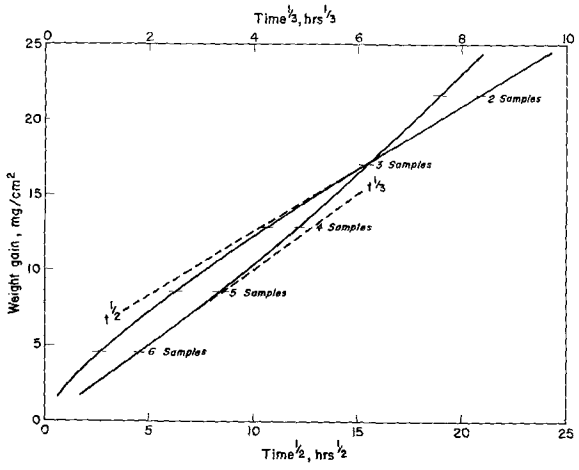

Fig. 2. Total weight gain of zirconium oxidized at 840°C

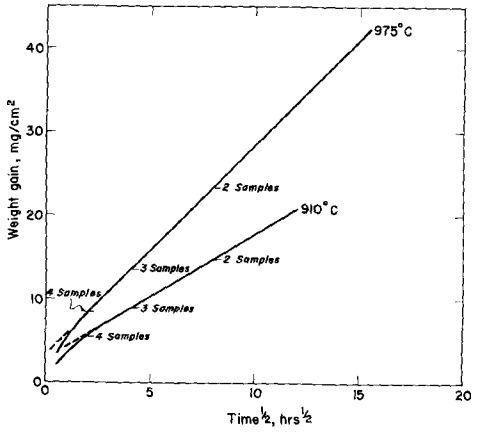

Fig. 3. Total weight gain of zirconium oxidized at 910° and 975°C

Results and Discussion

Weight gain.—Data for the total weight gain at 840°, 910°, and 975°C are given in Fig. 2 and 3. Data at 840°C are presented in the form of both parabolic and cubic plots. Solid lines indicate the continuous weight gain curves, and dashed lines represent extrapolation of parabolic and cubic portions. The reproducibility of the data was excellent, and all sample points fall within the breadth of the line representing the data. Since samples were to be used for further measurements, separate experiments were concluded at varying periods of time; therefore, the data presented in Fig. 2 are derived from seven samples for a duration of 7 hr, six samples for a duration of 40 hr, etc., as indicated on the figure. It is apparent from examination of this figure how a discrepancy may arise in reporting high-temperature kinetic data in terms of parabolic and cubic rates. The rate conforms quite well to a cubic relationship up to about 80 hr after which it bends off toward the ordinate, indicating that the weight gain rate is now more rapid than that represented by a cubic relationship. It should be noted that the cubic curve extrapolates well through the origin. Furthermore, if the data are plotted on logarithmic coordinates, which by their nature emphasize the early time data, a straight line is obtained whose slope equals 0.375, close to the cubic value. Investigators who performed experiments for times not far beyond 80 hr at this temperature would be inclined to report their data as conforming to a cubic relationship.

Examination of the parabolic plot indicates that there is a rapid initial weight gain which does not conform to the parabolic law, and only after about 150 hr does the weight gain increase parabolically. One would have to ignore a large initial portion of the curve to conclude that the weight gain data obeys a parabolic behavior. In any case further analysis will show that the total weight gain curve has little theoretical significance since the total weight gain curve is the sum of the film growth and oxygen dissolution processes which themselves have different rate behaviors.

Table IV. Oxide film thickness for various times at 840°, 910°, and 975°C

	Time, hr	$\Delta x_a \pm d_a$, μ	Min-Max, μ
840°C	7.0	20.1 ± 0.7	18-21
	40.0	29.8 ± 0.8	28-31
	113.0	38.0 ± 1.2	35-40
	234.0	44.9 ± 1.0	44-47
	435.0	52.7 ± 1.1	52-56
	601.5	59.8 ± 0.8	58-63
910°C	0.25	10.9 ± 0.3	9-13
	0.75	13.9 ± 0.3	12-15
	4.0	19.3 ± 0.3	17-21
	17.0	25.8 ± 0.4	23-28
	63.7	35.1 ± 0.5	33-38
	146.0	43.7 ± 0.7	42-47
975°C	4.0	25.9 ± 0.5	21-35
	16.7	30.7 ± 1.2	26-39
	63.7	42.8 ± 1.7	36-49
	237.5	67.1 ± 5.9	60-71

Δx_a is average oxide thickness; d_a is average deviation from mean; Min is minimum oxide thickness; Max is maximum oxide thickness.

Data at 910° and 975°C are also highly reproducible and are presented in Fig. 3 as parabolic plots. At these temperatures the region of conformity to cubic kinetics is small so that no cubic plot is given. After relatively short times, representing however considerable weight gains, the total weight gain curves conform closely to parabolic rates. The reason for this will become clear in the following sections where the separate processes are analyzed.

Oxidation behavior was also investigated at 1025°, 1050° and 1100°C, but no total weight gain curves were obtained since the capacity of the continuous weighing balance was exceeded after relatively short periods of time.

Film thickness.—Data for the growth of oxide films at 840°, 910°, and 975°C are presented in Table IV and Fig. 4. At 840° and 910°C the films are of relatively uniform thickness, differing by a maximum of 3-5μ at different areas. At 975°C the oxide/metal interface becomes irregular and the films differ in thickness by 10-15μ from point to point (see section on Metallography). Very little difference exists between the rate of growth of oxide at 840° and 910°C; however, at 975°C the film grows appreciably more rapidly than at 910°C.

Data at the two lower temperatures where the oxides appear dense and pore-free are presented in parabolic cubic, and quartic form in Fig. 5. The parabolic plot is inadequate at both short and long times; conformity begins at about 4 hr and ends at about 100 hr at these temperatures. The cubic plot fits the data quite well except for times less than about 4 hr. The quartic

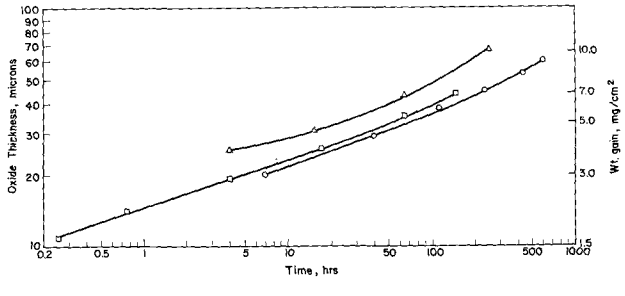

Fig. 4. Logarithmic plot of the oxide film growth on zirconium oxidized at 840° (○), 910° (□), and 975° (△).

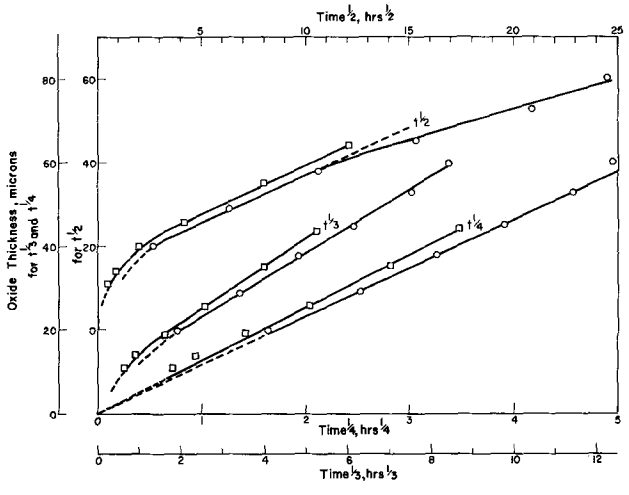

Fig. 5. Parabolic, cubic, and quartic plot of oxide film growth on zirconium oxidized at 840° (○) and 910°C (□).

plot appears to conform to the data rather well even at very short times with the exception of the last point at 840°C for 600 hr, which is slightly above the line. Figure 5 should however at this time remain an exercise in curve fitting, since quantitative information on the structure and transport properties through the oxide is necessary in order to understand, rather than rationalize, the data which does not conform to any established rate law. A qualitative explanation for the rapid initial growth followed by a slower growth will be offered in the section on Mechanism.

Data for growth at 1025°, 1050°, and 1100°C are presented in Table V. The rate of film growth continues to increase greatly at these higher temperatures. At 1025°C the oxide/metal interface becomes highly irregular and the oxide thickness varies by a factor of two to three from place to place. Little additional growth is observed between 16 and 77 hr. At 1050°C after the first 5 hr the film is of fairly uniform thickness, and irregularity commences by 18 hr. At 1100°C there was widespread localized attack in the vicinity of the platinum support wires. The thickness of the unaffected areas was relatively uniform.

Oxygen in the metal.—A knowledge of the total weight gain and measurement of the oxide film thickness enables the computation of the quantity of oxygen dissolved in the metal substrate beneath the oxide film. Furthermore, the latter quantity can be calculated according to Eq. [6] for temperatures below the α/β transformation and by Eq. [16], [17], and [18] above the α/β transformation. Calculated and experimental data for oxygen dissolved in the metal below the α/β transformation are plotted as a function of the square root of time in the lower curve in Fig. 6. Here the solid line represents calculated values, and separate experimental points are indicated in the figure. At 840°C

Table V. Oxide film thickness for various times at 1025°, 1050°, and 1100°C

	Time, hr	Δx_{Max}, μ	Δx_{Min}, μ
1025°C	4.0	90	45
	16.3	125	45
	77.2	125	60
1050°C	5.3	190	180
	18.5	380	250
	64.0	630	250
1100°C	31.0	650	610

Δx_{Max} is maximum oxide thickness; Δx_{Min} is minimum oxide thickness.

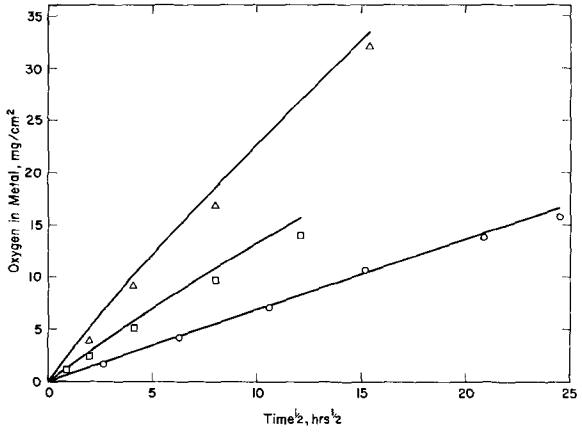

Fig. 6. Oxygen in solution in zirconium oxidized at 840° (○), 910° (□), and 975°C (△).

Fig. 7. Zirconium sphere oxidized for 17 hr at 975°C showing α/β phase boundary. Magnified approximately 60X; polarized light.

there is excellent agreement between calculated and observed oxygen content of the metal. Data are parabolic as demanded by diffusion theory.

Metallographic examination of samples oxidized above the α/β transition temperature clearly reveals the position of the α/transformed β boundary (Fig. 7). Measurement of the distance of the α/transformed β boundary from the oxide/metal interface and the previously evaluated oxide thickness enables calculation of the parameter ξ. It is also possible to calculate ξ from Eq. [15]. However, uncertainties in the values of $C_{\xi+}$, $C_{\xi-}$, and D_β do not permit the calculation of ξ with great accuracy, and a comparison of observed and calculated values of ξ is not too rewarding. For example, examination of a sample oxidized for 64 hr at 910°C gave an observed value of $\xi = 5.54 \times 10^{-2}$. Calculation using maximum and minimum estimates of $C_{\xi+}$, $C_{\xi-}$, and D_β gives values ranging from 4.88×10^{-2} to 5.60×10^{-2}.

Agreement between calculated and experimental data at 910° and 975°C as shown in Fig. 6 are not as good as at 840°C. This may be due to two factors: (*a*) As discussed above there are appreciable uncertainties in the values of the solubility parameters at the α/β interface and the diffusion coefficient of oxygen in the β-phase; and (*b*) the formation of voids at the metal/oxide interface (see section on Metallography) may act as discontinuities in the Zr/ZrO_2 diffusion couple so that the flow of oxygen to the metal is interrupted.

The calculated curve at 910°C is initially linear when plotted against $t^{1/2}$, and then curves downward toward the abscissa. This is due to the fact that after about 50 hr the gradients in the β-phase meet at the center of the sphere, thereafter slowing down the rate of ab-

sorption of oxygen into the β-phase. The calculated curve at 975°C is again initially linear with $t^{1/2}$ representing a maximum rate of diffusion. After a few hours at this temperature, the gradients begin to meet in the center of the sphere causing the line to bend toward the abscissa. Shortly thereafter, the β-phase becomes saturated with oxygen, and the rate again becomes parabolic representing the increase of oxygen in the α-phase.

Kinetics.—Having previously examined the film growth and oxygen diffusion kinetics, we are now in a position to understand the over-all weight gain curves as a summation of the two separate processes. In the initial stages the rapid film growth coupled with oxygen dissolution gives rise to an approximately cubic rate of growth. As the reaction proceeds, the rate of film growth decreases markedly, and the relative quantity of oxygen in the metal compared with oxygen in the film increases. Since the oxygen dissolution process is parabolic, it is not surprising that at longer times the over-all kinetics tends toward a parabolic process. Furthermore, the activation energy for the dissolution process is much higher than for oxide growth so that at the higher temperatures the oxygen dissolution process represents a larger part of the over-all weight gain. Consequently, the time necessary to approach parabolic kinetics decreases with increasing temperature.

It must be borne in mind that the depth of oxygen penetration into the sample is quite appreciable at these temperatures and the thickness and geometry of the specimen are exceedingly important in determining the shapes of the kinetic curves. A thin sample may rapidly become saturated with oxygen, and the film growth will then be paramount in determining the kinetics. Conversely, a thick sample will continue to dissolve oxygen at a parabolic rate, while the film growth will proceed comparatively slowly.

At the temperatures under consideration in this study the over-all kinetic curve is of little theoretical significance. The oxygen dissolves in the metal according to diffusion theory, and its contribution to the over-all kinetics is entirely predictable according to equations previously discussed. It remains then to understand the film growth law in terms of the structure and transport properties of the film.

Metallography.—The film formed at 840°C appears dense and adherent and exhibits a fine, columnar structure. In all samples except the one with the longest exposure time there was no evidence of cracking in the oxide or accelerated growth. However, the sample exposed for 601.5 hr developed several thin lines of white oxide around the circumference of the sphere. The fine cracks probably develop due to the accumulation of stresses caused by the oxide growth. This process may be enhanced by thermal cycling, and a specimen with a thick oxide film which has been rapidly cooled and reheated to temperature in oxygen shows a network of such cracks around the sample.

Careful examination of the structure of the sound film formed at 840°C indicates some difference in the structure of the oxide near the oxide/metal interface compared with the oxide further out toward the oxide/gas interface. In order to reveal this more clearly it is necessary to polish perpendicular to the fine columnar grains so that they are viewed in the direction of growth. This is best achieved on a spherical sample by polishing at the circumference through the oxide film until the metal is just reached. In addition, appreciable magnification of the oxide is achieved since this technique is similar to polishing a flat oxide at a low angle. Examination of the sample prepared in this manner indicates that the outer oxide consists of a somewhat coarser structure than the fine inner oxide.

The oxide film formed on samples exposed at 910°C is quite similar to that observed on the samples formed at 840°C. The oxide again appears dense and adherent. Differences in structures of the outer and inner oxide are more pronounced at 910° than at 840°C.

At 975°C the duplex nature of the scale becomes more pronounced than at lower temperatures. After the initial exposure (4 hr), voids are visible at the oxide/metal interface; at later times they become buried in the oxide by further growth, while new voids continue to originate at the metal/oxide interface (Fig. 8-11). These voids act as diffusion blocks preventing further oxidation of metal below them and necessitate that further oxidation occur around them. Voids also appear to enhance the tendency toward formation of the duplex oxide layer. Beyond the voids toward the oxygen/oxide interface, there are ovals of oxide with a milky white appearance under polarized light; the fine columnar structure is retained between the void and oxide/metal interface. The whitening of the oxide may be logically explained by the action of the void in preventing access of the oxide above it to the demand for oxygen from the oxide and metal below it. The nonstoichiometric oxide would then tend to be oxidized toward the stoichiometric composition by oxygen from the gas phase.

The presence of second phase particles in the metal enhances the formation of voids, and a Zr-0.5 w/o (weight per cent) B alloy containing particles of ZrB_2 exhibits void formation at temperatures as low as 840°C. At higher temperatures voids selectively nucleate at the second phase particles.

At 1025°C after the first exposure time of 4 hr the film is highly irregular and contains many voids. The duplex oxide layer becomes quite pronounced. By 16 hr the oxide whitens appreciably, and by 77 hr the entire oxide appears milky white.

At 1050°C after the first exposure of 5 hr, the film is quite uniform in thickness. There appears to be a distribution of fine voids throughout the oxide, but it

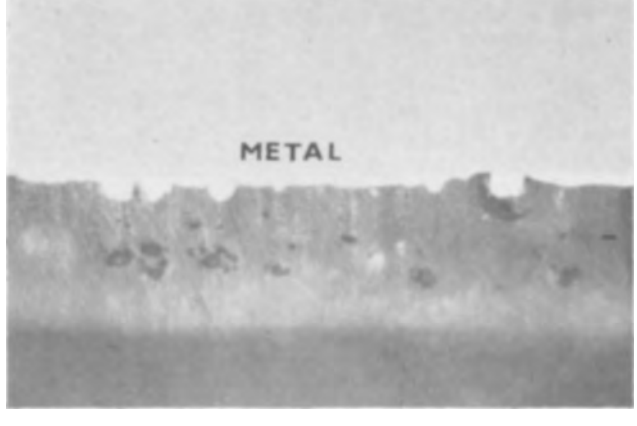

Fig. 8. Zirconium sphere oxidized for 64 hr at 975°C showing voids at metal/oxide interface and in the oxide. Magnified approximately 525X; bright light.

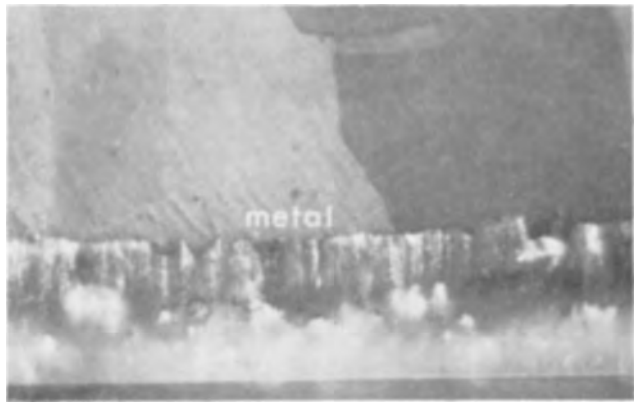

Fig. 9. Same as Fig. 8 but viewed under polarized light.

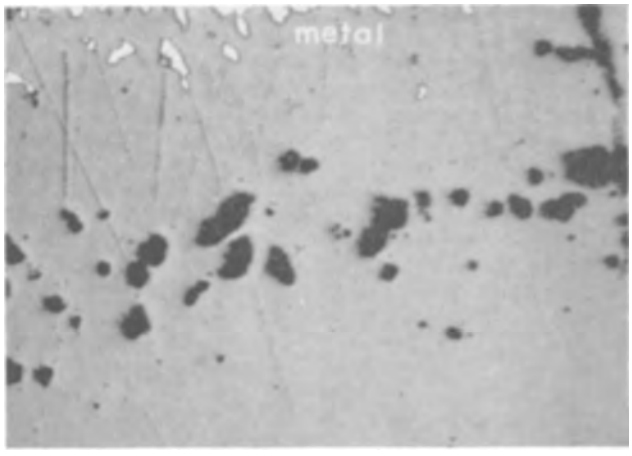

Fig. 10. Perpendicular taper section of sample in Fig. 8. Bright light. Areas of metal near the top of the picture are due to an irregular metal/oxide interface combined with a tapering polish.

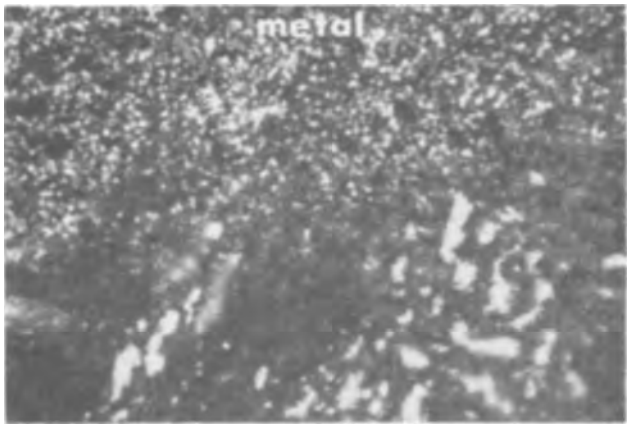

Fig. 11. Same as Fig. 10 but viewed under polarized light

is difficult to be certain of this due to the tendency of the columnar grains of oxide to be pulled out during polishing. There is no evidence of the development of the larger voids or the duplex layer characteristic of samples oxidized at lower temperatures. However, by 18.5 hr the oxide has become irregular, larger voids are forming at the metal/oxide interface, and there is a tendency toward the formation of a duplex layer. Several areas of accelerated oxidation due to gross cracking of the oxide were observed. After 64 hr areas of accelerated oxidation were widespread. In other areas the oxide consisted of a duplex oxide containing voids.

At 1100°C after an exposure of 31 hr, accelerated attack occurred in those areas where the sample was in contact with the platinum support wire. In other areas the oxide was uniform in thickness and as yet showed no tendency toward large void formation or a duplex layer.

Various authors have noted that the onset of accelerated oxidation at high temperatures is accompanied by the formation of a duplex layer. It appears on the basis of this work that the development of the duplex layer is gradual and dependent on time and temperature. At 840° and 910°C for the times investigated in this study, the duplex layer appears to be developing slowly. Voids are not observed, but their presence on a micro scale is not precluded and may even be inferred by the early stages of duplex layer development as observed. Accelerated corrosion at these temperatures appears to be due to gross cracks developing in the oxide film. At higher temperatures and simultaneous with the appearance of voids in the oxide film, the duplex layer undergoes a more rapid development. The development of stoichiometric ZrO_2 as an outer

Table VI. Effect of pressure on oxide thickness on ½ in. spheres oxidized for 64 hr at 910°C

Pressure, Torr	Average thickness and deviation, μ	Maximum, μ	Minimum, μ
1	35.5 ± 0.6	36.5	34.8
14	35.1 ± 0.6	36.0	34.0
100	36.3 ± 1.0	38.5	35.2
730	37.3 ± 0.7	39.2	35.9
730*	35.1 ± 0.5	36.0	34.4

* ¾-in. sphere.

layer is accompanied by an accelerated growth of the total oxide. It therefore appears that the outer stoichiometric layer becomes nonprotective.

Orientation effect.—The thickness of the oxide film formed on coarse grained zone refined zirconium oxidized at 910°C for 64 hr was found to vary somewhat from grain to grain. The variation of the oxidation rate of zirconium with orientation has been reported previously (3). Its persistence to the thick film region is noted in this study. Variation of thickness with orientation is much less pronounced for zirconium than for hafnium (12). In the latter case wide deviations from stoichiometry have been noted in those grains oxidizing more slowly. Thus, the oxidation rates may involve unequal rates of formation of vacancies from crystal faces of different orientations. This phenomenon is under further investigation in this laboratory using single crystal material.

Pressure.—One-half inch diameter spheres were oxidized at 910°C for 64 hr at pressures ranging from 1 to 730 Torr. Results of the oxide thickness measurements are given in Table VI which includes the average value, average deviation, and maximum and minimum values at each pressure. For comparison, data from the ¾ in. diameter sphere is listed. The variation in thickness from sample to sample appears to be within the experimental reproducibility, so that pressure in the range investigated does not affect the oxidation rate.

Surface preparation.—In order to determine the effect of surface preparation on film growth and total weight gain, spherical samples were oxidized in both the as-machined condition and as shot-blasted with fine-grit sand. Samples were oxidized at 840°C for 24 hr. The weight gain curve paralleled those of the chemically polished samples, but the ordinate was displaced higher by several per cent. Metallographic examination indicated that, with the exception of small protrusions at the surface, the oxide thickness was identical with that observed on chemically polished samples. The differences in weight gain must then be due to the small protrusions from the irregular surface which were oxidized during the initial stages of the oxidation. Therefore, at 840°C for times beyond the initial stages of the reaction, it does not appear that the surface treatment has any effect on the kinetics. However, the possibility cannot be excluded that at much later stages of oxidation the surface irregularities may act as sites for initiation of cracks in the film.

Initiation temperature.—Experiments were performed to determine whether there is an effect of exposing the sample to oxygen while at temperature as opposed to the technique used in nearly all of these experiments of allowing the sample to cool before admitting oxygen. At 840°C beyond the very early stages of the reaction (~15 min), the weight gain curves were identical.

Mechanism.—Zirconium dioxide exhibits a complex dependence of conductivity on oxygen partial pressure (13, 14). Conduction is considered to be largely ionic with n-type conductivity predominating at low oxygen partial pressures ($<10^{-20}$ atm) such as would exist within a sound oxide film growing on the metal substrate. Oxygen vacancies and possibly interstitials

are believed to be the mobile species. At higher oxygen partial pressures ($>10^{-8}$ atm) such as would be encountered in a cracked ZrO_2 film, the p-type oxide may predominate (14), and cation migration cannot be excluded.

The oxidation process is generally pictured as occurring by the formation of an oxygen ion vacancy at the metal/oxide interface

$$Zr_{(metal)} = Zr^{+4}{}_{(s)} + 2\square_{O}{}^{=} + 4e^{-}$$

where $Zr_{(metal)}$ represents a zirconium atom in the metal lattice, $Zr^{+4}{}_{(s)}$ represents a Zr^{+4} ion on a lattice site in the oxide, and $\square_{O}{}^{=}$ represents an oxygen ion vacancy in the oxide lattice. The electrons may be bound to the oxygen vacancy, present as a defect associated with $Zr^{+3}{}_{(s)}$ ions, or mobile in the lattice. In order for oxidation to proceed, $\square_{O}{}^{=}$ and electrons must diffuse through the oxide to the oxygen/oxide interface where they are consumed in the reaction

$$O_2 + 2\square_{O}{}^{=} + 4e^{-} = 2O^{=}{}_{(s)}$$

where $O^{=}{}_{(s)}$ is an oxygen ion in the oxide lattice.

It is suggested here that the formation of voids at the metal/oxide interface encountered during oxidation at the higher temperatures of this study ($\geqslant$975°C) may be considered to result from a condensation of oxygen vacancies. It is also possible that at 840° and 910°C voids are forming on a microscale too fine to be viewed with optical microscopy. These voids may act as diffusion blocks preventing the access of oxygen ions to the metal/oxide interface, thereby retarding the oxidation rate.

In the initial phase of oxidation the film is forming at an exceedingly rapid rate, leading to a highly defect-rich oxide. As time passes, the oxygen vacancies may cluster and eventually condense to form voids. This may occur most readily at the oxide/metal interface or at an inclusion if it is present to aid the nucleation. One then may consider oxidation to occur through an oxide containing blocked diffusion paths. At the higher temperatures where the voids occur on a gross scale, oxidation of the outer oxide toward the stoichiometric value becomes more complete, and the duplex layer more pronounced. The near stoichiometric outer layer is apparently nonprotective. This may be due to the fact that a p-n junction may develop within the oxide at the meeting of the two oxide layers. The outer scale may then allow migration of Zr^{+4} ions which could account for its lack of protectiveness.

Any theory explaining the oxidation of zirconium and hafnium must account for the orientation dependence of the oxidation rate in the thick film region. For this reason, studies using single crystal material have been initiated in this laboratory. Further work on the structure and transport within the oxide films is also in order.

Acknowledgment

The author is again indebted to J. K. Litchfield for experimental assistance and suggestions through the course of this study; thanks are expressed to E. J. Moreau for extensive metallography. Valuable discussions on the diffusion equations were held with Drs. A. L. Loeb, S. H. Gelles, and G. Kemeny, and on nonstoichiometry with Dr. G. G. Libowitz.

Manuscript received Nov. 12, 1964. This paper was presented at the Washington Meeting, Oct. 11-15, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

Tantalum Films Deposited by Asymmetric A-C Sputtering

F. Vratny and D. J. Harrington

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

The new technique of asymmetric a-c sputtering has been evaluated for the deposition of tantalum films in argon, oxygen-argon, and nitrogen-argon gas mixtures. This method utilizes a lower sputtering potential on the tantalum substrate holder every half cycle compared to the potential on the tantalum cathode. At an optimum current ratio, tantalum films of three to five times that of bulk resistivity are obtained compared to twenty to forty times bulk resistivity for normal d-c glow discharge sputtering. The reactive sputtering experiments confirm that the normal high resistivity of sputtered tantalum films are caused by impurities gettered during the deposition and that the greater tolerance to reactive gas pressure with asymmetric a-c sputtering may be due to ion and electron bombardment during deposition. Further work is required to confirm this latter supposition.

Present methods for the deposition of tantalum films rely upon evaporation methods (1, 2), *i.e.*, electron beam evaporation, or d-c sputtering from a tantalum cathode (3-6). With some exceptions, the sputtering technique when used with initial background pressures of 10^{-6} Torr produces films with specific resistivities of 100 to 300 μ-ohm-cm and temperature coefficients of resistance in the range of $\pm$200 ppm/°C (7). The high resistivity in sputtered films is indicative of 5-10 a/o (atomic per cent) of oxygen impurity (6) assuming the latter is the prime component gettered during deposition. Evaporated films have been obtained with

values of 15 μ-ohm-cm and +3000 ppm/°C (1, 2, 3, 8) under conditions of ultra high vacuum and/or very high deposition rates. By careful control over sputtering variables it has been possible to obtain sputtered films with resistivities of only 50 μ-ohm-cm and temperature coefficients of +1500 ppm/°C (4, 6) although the basic criteria for obtaining such films routinely have not been rigorously established.

The advent of asymmetric a-c sputtering (9-11) offers the possibility of obtaining routinely tantalum films of high purity without the necessity of ultra high vacuum techniques. Frerichs (9-11) reported that superconducting tantalum films were obtained with a transition region from 4.45° to 4.3°K, compared to a value of 4.38°C for bulk tantalum. The purity of the film was ascribed to argon bombardment of the surface of the sample and a decrease in rate of incorporation of residual gases from the vacuum system.

The sputtering of tantalum has provided an important method of preparing thin film components and integrated circuits (12-14) especially when utilized with reactive gases to deposit a tantalum nitride film. The asymmetric a-c sputtering technique could provide a means of obtaining relatively pure films which would serve as a reproducible starting material for reactive sputtering, provided reactive gas molecules can be incorporated in the film under asymmetric a-c deposition conditions. A comparison of the properties of films prepared by reactive sputtering both with a normal d-c and the asymmetric a-c method should provide a pertinent test of the proposed method of purification.

Method

Asymmetric a-c sputtering is performed by applying a partially rectified 60 cycle a-c potential to two identical tantalum electrodes. The substrate is placed on the electrode with the lower bombarding potential. In anology with the geometry used for film deposition in normal d-c sputtering, the latter electrode, the substrate electrode, will be designated the anode in this paper. With a completely symmetrical voltage wave form, the anode and cathode collect equal numbers of energetic argon ions, and no net deposition occurs. However, by using a smaller average potential (E_2) at the substrate electrode (see Fig. 1) more tantalum arrives from the cathode than can be removed by ion bombardment at the anode. Concurrent with the ion motion in the plasma there is also electron transport. This is indicated by curve C which represents the inverse of curve B. Thus, if curve B represents the field affecting the ion density at the substrate and B' represents the field affecting the ion density at the cathode, then curve C represents, respectively, the field affecting the electron density at the cathode while C' represents the field affecting the electron density at the substrate. Frerichs (9) reported that a favorable degree of asymmetry is a cathode to anode current ratio of five to ten. To obtain a wide range of anode to cathode current ratio a supply was used with silicon rectifiers and a variable resistance (R) in one arm of a bridge network (Fig. 2). The output from a high-voltage transformer is placed across the anode and the current limiting network which in turn is connected to the cathode. The cathode current I_c, is controlled by the

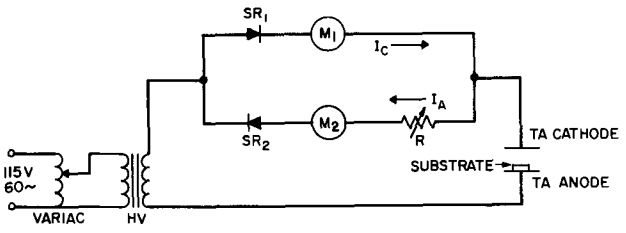

Fig. 2. Asymmetric a-c power supply. SR1, SR2, high voltage diodes; M1, Mw, milliammeter; R, variable resistance 2K to 1 meg; HV, high voltage transformer 10 kv.

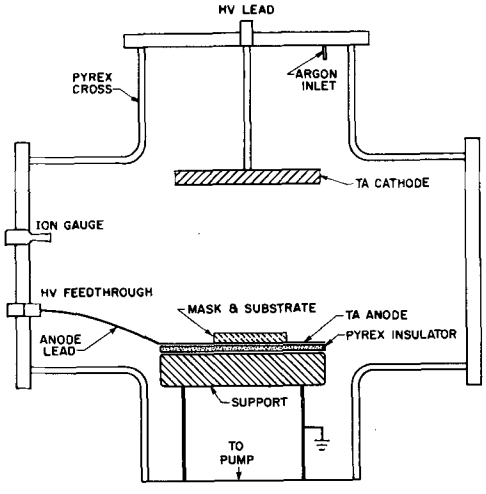

Fig. 3. Schematic of the sputtering chamber

plasma impedance and a small resistive drop across the diodes while the anode current, I_A, is diminished further by the resistance, R. By varying the resistance, R, a range of anode to cathode current ratios (I_A/I_c) is obtained of approximately 0.05 to 0.35.

The cathode and anode were high-purity tantalum plates 4 in. in diameter and ¼ in. thick. These were mounted in a 6 in. ID "Pyrex-cross" sputtering chamber (Fig. 3). The cathode was suspended from a high voltage feedthrough while the anode was mounted on a Pyrex spacer. All experiments were performed at a cathode potential of 4 kv and a cathode current density of 0.25 ma/cm^2 at an argon pressure of 20 x 10^{-3} Torr. Tantalum was deposited on 1 by 3 in. Corning 7059 glass through mechanical masks covered by a thin layer of tantalum. These substrates were cleaned by a succession of washes in detergents, water, hydrogen peroxide, and deionized water. They were dried in a nitrogen stream at 110°C and placed in the vacuum chamber. The system was evacuated by means of a 300 l/sec diffusion pump with a liquid nitrogen cooled baffle. An ultimate pressure of 2 x 10^{-6} Torr and a nominal leak rate of 0.05 1 atm/sec are typical for this machine. Tantalum films with specific resistivities of 150-200 μ-ohm-cm and temperature coefficients of resistance of ±200 ppm/°C are conventionally produced by d-c sputtering in this system

Results

In the process of asymmetric a-c sputtering argon ion bombardment occurs at both the cathode and anode. If we consider the two extreme cases, it is evident that for an identical potential at both electrodes there will be no deposition at the anode, yet due to the high intensity of ion bombardment this condition will produce the maximum cleaning at the surface. Correspondingly, for normal d-c cathode sputtering the deposition rate will be large at the anode, yet due to minimal bombardment, the substrate will be ineffectively cleaned. Between these two extremes there is a compromise of effective deposition and cleaning. To

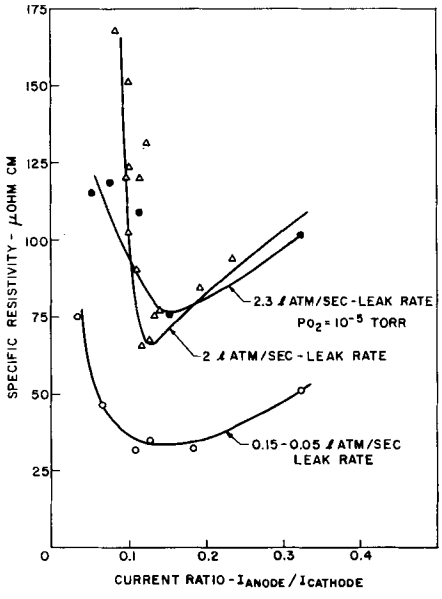

Fig. 4. Specific resistivity as a function of current ratio

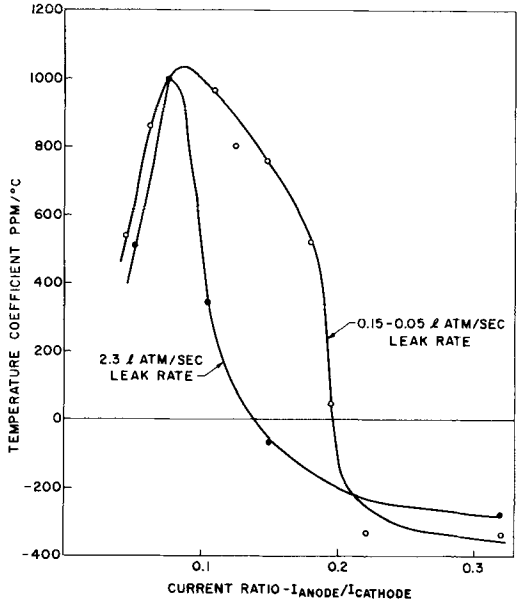

Fig. 5. Temperature coefficient of resistance as a function of current ratio.

explore this method of sputtering, the deposition rate, resistivity, and temperature coefficient of tantalum films were evaluated as a function of the current ratio to determine the optimum conditions. Due to the direct correlation between resistivity and impurity level (6) the specific resistivity can also be used as an indication of the purity of the deposited film.

The measured deposition rate, using a constant cathode potential of 4 kv (rms) was a direct function of the current asymmetry ratio. The sputtering pressure was 20μ while the pressure before sputtering was typically $\sim 2 \times 10^{-6}$ Torr. At an anode to cathode current ratio of 0.25 the deposition rate was ~30 Å/min, and at a current ratio of 0.1 it was ~60 Å/min. Further data indicated that a linear correlation exists between the deposition rate and the difference in power (Δw, in watts) supplied to the cathode and anode (Eq. [1]).

$$\text{Deposition rate (Å/min)} = 5.1\ (\pm 0.6)\ (\Delta w) - 100\ (\pm 10) \quad [1]$$

This equation shows that for a constant flux of tantalum atoms arriving from the cathode, less tantalum remains deposited on the substrate with increasing power supplied to the anode. This result tends to confirm that bombardment-sputtering occurs at the anode with increasing current ratio.

The increased bombardment at the anode reflects itself in increased purity of the resultant tantalum film as manifested in the resistivity and temperature coefficient of resistance despite the lower deposition rate. The resistivity drops to a minimum value with increasing current ratio from 0 to 0.15 (Fig 4) while further anode current beyond a ratio of 0.15 causes an increase in resistivity. The resistivity change at a background pressure of $\sim 2\text{-}5 \times 10^{-6}$ Torr (0.05 to 0.15 liter-atm/sec virtual leak) from 200 μ-ohm-cm for d-c sputtering to a minimum of ~37 μ-ohm-cm represents a change from ~10 a/o oxygen to ~3 a/o oxygen if the change in resistivity is due to this impurity (6). The increase in resistivity with anode current ratio above 0.15 will be discussed later.

The change in resistivity with increasing current ratio to ~0.15 exhibits a sensitivity to residual impurities in the vacuum system. At a leak rate of residual gases of ~2 liter-atm/sec the resistivity minimum corresponds to ~65 μ-ohm-cm while a deliberate oxygen leak rate of 10^{-5} Torr (2.3 liter-atm/sec) gives a nearly identical current ratio profile with a resistivity minimum at ~75 μ-ohm-cm. The temperature coefficient of resistance of these films similarly exhibits a sensitivity to the current ratio and gaseous impurity (Fig. 5). It is noteworthy that the maxima in the temperature coefficient curve occur at a lower current ratio than the minima in the resistivity curve. This difference indicates that the film properties that determine the resistivity and temperature coefficient have a different dependence on the anode-cathode current ratio.

It is evident that the ability to obtain low resistivity films by this technique is a function of the level of the residual gases in the system during sputtering. Thus, it is possible to sputter reactively by this method. The main advantage of this technique is that it provides a reproducible low resistivity film as a starting point for the controlled modification of its electrical properties. During reactive sputtering it would have the effect of diluting the contribution of undesired reactive gases in the system An evaluation of the process of reactive sputtering and a study of the quality of the resultant film components have been carried out. Gerstenberg (6) and Pendergast (15) have prepared tantalum nitride and tantalum oxide films. The tantalum oxide films exhibit a monotonic increase in resistivity with increasing oxygen content and a monotonic decrease in the temperature coefficient. The tantalum nitride films have a specific resistivity of 200 μ-ohm-cm which is nearly independent of the nitrogen partial pressure over a pressure range corresponding to the formation of the compound Ta_2N and TaN. In the same nitrogen partial pressure range, the temperature coefficient of resistance has a value of —50 to —100 ppm/°C. Due to the inherent leak rate of vacuum systems and other d-c deposition variables it has not been possible to completely reproduce the exact pressure dependence reported by Gerstenberg (6) although the Ta_2N and TaN phases always occur with approximately the same electrical properties.

Experiments were performed at varying nitrogen and oxygen partial pressure in argon to assess the suitability of the asymmetric a-c process for controlled deposition by reactive sputtering. Reactive sputtering was carried out at a current ratio of 0.13, a cathode potential of 4 kv and cathode current of 20 ma (~0.25 ma/cm^2) at an argon pressure of 20μ. Sputtering in oxygen-argon gas mixtures produced an increase in resistivity with increasing oxygen partial pressure (Fig. 6) for both the a-c and d-c technique. However, the resistivity is always lower at a given oxygen pressure in the a-c sputtering technique. As an example, at a background pressure of 2×10^{-6} Torr there is a re-

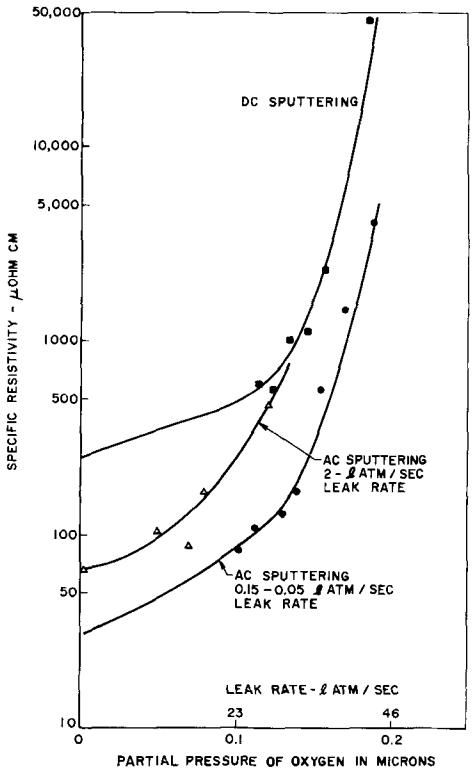

Fig. 6. Specific resistivity as a function of oxygen partial pressure

sistivity differential of ~200 μ-ohm-cm. This constitutes a decreased sensitivity to oxygen of 4-7 a/o (6). At higher oxygen pressures the curves tend to merge. This difference is also apparent in the temperature coefficient of resistance for these films. They are generally higher by 600 to 800 ppm/°C for the asymmetric a-c method (Fig. 7). Correspondingly, it was possible to sputter in argon-nitrogen gas mixtures and reproduce d-c results which were obtained only by using extreme care to control sputtering parameters and residual gases (see Fig. 8 and 9).

Discussion

The basic model employed by Frerichs (9-11) to explain purification of films deposited by the asymmetric a-c sputtering technique is the argon ion bombardment of the film during deposition. The degree of cleaning given the depositing film on the anode is determined by the degree of current asymmetry. The latter factor establishes the ion flux to the surface while the energy and flux density of incident ions determines the probability of removal of matter from the film. An additional feature which we will consider below is the effect of electron bombardment of the substrate.

In considering a model of film cleaning by argon ion bombardment it is necessary to evaluate three factors: the probability of collision between the individual incident ions and impurity atoms; the fraction of energy available to an impurity atom as a result of collision; and the probability of desorption of an impurity atom. If we assume that an impurity atom has the same cross section as a tantalum atom, we can calculate the probability of collision between the incident ions and atoms on the surface. In this way we can obtain an estimate of the probability of reducing an impurity level (excluding secondary processes).

When tantalum is deposited at a rate of 50 Å/min, the arrival rate or the collision rate of tantalum is ~6 x 10^{14} at./sec/cm^2 while the impurity level at a background pressure of 10^{-6} Torr and 300°K is 3.6 x 10^{13} molecules/sec/cm^2 (taken for the case of oxygen[1]) with a sticking coefficient of 0.1. Although it is known that sticking coefficients can be as large as 1.0 for fresh reactive surfaces (17) and as small as 10^{-5} for dirty surfaces (18) or physically adsorbed states at high temperatures (19). For physically adsorbed states at modest temperatures or clean surfaces a sticking coefficient of 0.1 is a reasonable approximation (17, 19). For this sticking coefficient, the impurity level corresponds to about 12 a/o of monatomic oxygen which will be incorporated in the film. Thus, the total flux corresponds to 88% tantalum and 12% impurity. Since an impurity atom (as oxygen) which is present at low surface coverage will probably sit on a

[1] It is recognized that many residuals exist in conventional vacuum systems. In the system under consideration it is estimated that the residuals are made up of 20% oxygen, 60% nitrogen, 5% carbon as CH_4 and CO, 15% others. During deposition the oxygen level drops to a very low level, nitrogen drops by about 20% and the hydrogen level increases to ~10^{-6} Torr (16).

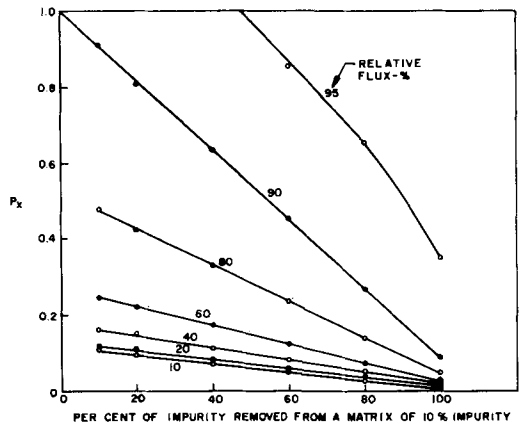

Fig. 10. Probability of surface cleaning as a function of relative incident flux.

tantalum lattice site there will be an equal probability of collision between an argon ion and either tantalum or oxygen assuming equal cross section. With the initial assumption that an impurity atom is the same size as a tantalum atom and occupies a random tantalum lattice site the probability of collision between an argon ion and surface impurity was calculated for a variable argon ion flux and for a constant surface density of 10% impurity atoms and 90% tantalum atoms (Fig. 10). The probability of collision between the argon ion flux and the surface density of impurity flux is large above a relative ion flux of 92% while the probability drops appreciably at lower flux densities. If the collision probability is interpreted in terms of removal then the probability of removal of 10% of the impurities, *i.e.*, reducing the total level from 10 to 9% is appreciable in the range of 95-100% relative ion flux, but decreases rapidly as the flux density decreases.

In addition to the collision probability it is necessary to consider the relative size of the impurity atom and tantalum as well as the probability of their removal. It is known that the relative cross section of oxygen and tantalum is quite different and that the cross section may vary with the energy of the incident ion (20). It may be estimated that at rest energy an oxygen ion has a larger relative cross section than tantalum by 5.45 (21). As a result, the collision probability would be larger by a proportionate factor. On impact, an argon ion is able to impart ~98% of its energy to an oxygen molecule while tantalum will receive roughly 59% of the energy of the incident argon ion as a result of momentum conservation in a diatomic collision. However, this energy is distributed in the lattice. It can be approximated that tantalum has a sputtering threshold between 25 and 30v (22) with reported values as large as 120v (23-25). The lattice surface displacement energy is ~4.79 ev (26) while oxygen on tantalum has a dissociation energy of roughly 9 ev (27). If the lattice energies and momentum conservation processes are interpreted in terms of sputtering yields, we can combine energy transfer and surface desorption effects and estimate (28) a relative sputtering ratio (S_O/S_{Ta}) of 0.78 with a range of 0.35 to 1.5 depending on the upper and lower limits of the threshold. If we include the relative cross section of oxygen and tantalum (5.45), we obtain a sputtering ratio S_O/S_{Ta} of 4.25 with a range from ~2.1 to 8.5, *i.e.*, oxygen desorption is more probable. When this is applied to the collision probability (Fig. 10) we may see that a 60% relative ion flux corrected by the above sputtering ratio will be as effective as 92% relative flux *i.e.*, a single projectile will be 4.25 times as productive on oxygen as on tantalum.

In establishing an argon ion flux to the sample, it is evident that argon can respond to the 60 cycle changes in the anode-cathode potential as it is able to traverse 8-16 cm (29-34) between these changes. The measured current ratio of anode current to cathode current then gives an indication of the relative degree of surface bombardment. In Fig. 4 we initially have 10 a/o impurities at a zero current ratio and 2-3 a/o at the resistivity minima or 70 to 80% removal of impurities. At this point the argon flux is ~1.5-3 x 10^{14} or 25-50% of the deposition flux. This corresponds to a collision probability with a 10% surface impurities coverage of ~0.1-0.42. When modified by the difference in sputtering yield this represents a probability of at least 0.2 but no more than 3 with a mean value of 0.8. This is a marginal proof of effective cleaning by argon bombardment for the most probable yield is less than one. Further, this model also requires a continuous improvement in resistivity at a higher asymmetry current ratio due to the enhancement of the argon ion density. However, we obtain an increase in the film resistivity at a higher anode current as seen by the rise in resistivity above a current ratio of 0.15.

Because of these anomalies we feel this deposition mechanism is inadequate. This may suggest a coexisting mechanism of argon incorporation at high argon ion flux density, for it is known that a bombarding particle will have an effective penetration depth from about 2 to 200 Å/kev (35). This produces incorporation of the neutralized species at a rate of 10^{14} to 10^{15} at./cm^2/kev (36) or between 1 and 10% of the deposition flux. Films analyzed for argon place the argon content in this range (37). This will reduce the effective electron mean free path and thus increase the resistivity and reduce the temperature coefficient. These factors are insufficient to explain the ability of the incident argon ion flux to clean the sample to the implied degree exhibited by the resistivity current-ratio profile of Fig. 4. An additional mechanism we wish to propose is the clean up by the presence of an intense electron flux at the substrate surface. It should be noted in Fig. 1 that as the potential alternates between the cathode and substrate the argon ion and electron flux density to the substrate also change. In the first half of the potential cycle, the argon ion flux to the substrate is low while the electron flux to the cathode is also low. In the latter half of the potential cycle the electron flux to the substrate is large while the argon ion flux to the cathode is also large. It is felt that the electron flux to the substrate contributes to an additional degree of cleaning. This phenomena has been observed by Peterman (38), Moore (39), and Redhead (40). Further work is in progress to clarify the deposition mechanism in asymmetric a-c sputtering (41).

Conclusions

Our results agree with earlier work which has demonstrated that deposition of thin films by asymmetrical a-c sputtering can lead to an improvement in film purity as demonstrated by the lower resistivity and higher temperature coefficients of resistance.

It was also pointed out that the background pressure has a pronounced effect on the ultimate purity of the deposited film. This was demonstrated by the variation in resistivity and temperature coefficient of resistance as a function of doping conditions.

It was proposed that the removal of these impurities is due to argon ion bombardment. This is suggested by the reduction in deposition rate which occurs at high anode currents. Secondary mechanisms are proposed to expand on this mechanism. One proposal was that the increase in resistivity at higher asymmetry ratio I_A/I_C is due to argon incorporation. A further proposal is that electrons which are generated in the plasma play a significant role in the deposition process.

It has been shown that deposition of thin films by a-c asymmetric sputtering can offer a reproducible base for controlled reactive sputtering. Evaluation of passive components prepared by this technique is presently in progress and appears to be favorable.

Vapor Transport Reactions Related to Halophosphate Phosphor Formation

Jacob G. Rabatin and George R. Gillooly

Luminescent Materials Laboratory, General Electric Company, Cleveland, Ohio

ABSTRACT

A double crucible technique has demonstrated that the principal phosphor forming reactions may involve particle-particle interaction between $Ca_2P_2O_7$ and CaF_2 leading to direct formation of apatite and POF_3. The POF_3, or vapors of similar composition, react with $CaCO_3$ also forming apatite. The transport of vapors containing fluorine, phosphorus, oxygen, and antimony has been demonstrated. Activation of the phosphor above 1000°C occurs by a reaction of Sb_2O_4 vapor with apatite.

The ease of formation of apatites from solid-state reactants commonly used in the preparation of halophosphate phosphors belies the complexity of the system from which these products are derived. Some general reactions of the usual starting materials, investigated by the use of differential thermal analyses and thermogravimetric analyses, have been reported along with isolated chemical and x-ray diffraction studies (1-6). These data reveal such a multiplicity of possible intermediate reactions as to preclude interpretation of the kinetics or mechanism of apatite formation. Thus it is sometimes assumed that apatite formation and activation proceed by solid-state diffusion processes (7, 4).

Based on earlier studies (8, 9) it has been postulated that, with the usual starting material, $CaHPO_4$, $CaCO_3$, CaF_2, $CaCl_2$, etc., halophosphates form by a two-step solid-state process. In the first step, $Ca_3(PO_4)_2$ is formed by the reaction

$$Ca_2P_2O_7 + CaCO_3 \rightarrow Ca_3(PO_4)_2 + CO_2 \qquad [1]$$

It is further assumed that $CaCO_3$ dissociates to CaO before reaction [1] begins. The subsequent apatite-forming reaction is also a solid-solid type, namely;

$$3Ca_3(PO_4)_2 + CaF_2 \rightarrow [Ca_3(PO_4)_2]_3CaF_2 \qquad [2]$$

Mixed apatites can be obtained by varying any of the above ingredients (8, 9).

The possibility of vapor transport as a mechanism accelerating apatite formation was first indicated by the work of Daubree (10) who obtained apatite by passing vapor of phosphorus trichloride over red-hot lime. More recently, Montel (11) has studied in detail

the reaction between $Ca_2P_2O_7$ and CaF_2 showing that apatite and the vapor, POF_3, are the two products according to the reaction

$$18Ca_2P_2O_7 + 14CaF_2 \rightarrow 5 \text{ apatite} + 6POF_3 \quad [3]$$

Since both $Ca_2P_2O_7$ (formed by low-temperature decomposition of $CaHPO_4$) and CaF_2 are normally employed as solids in the manufacture of halophosphate phosphors, the presence of POF_3 or a vapor of similar composition may play a role during the synthesis. The present study further indicates that the vapor transport of P, O, Sb, and halogens does play an important part in the formation of halophosphate phosphors.

Methods

Two simple techniques were used for the studies reported herein. The first involved the use of a small crucible placed inside a larger covered crucible as is illustrated in Fig. 1. Firings were made at various temperatures and for several times. Appropriate mixtures were placed in each crucible, thus permitting reaction between crucible contents only by vapor transport mechanisms. As indicated by undisturbed surfaces, there was no evidence in any case of solid material transfer by gas entrainment. Further, in most cases no evidence for a liquid phase was found; thus any possibility of liquid creep from one vessel to another can be discounted.

After firing, the contents of each crucible were identified by standard x-ray diffraction methods using an XRD-5 GE x-ray diffraction apparatus. ASTM x-ray data file together with comparisons of original x-ray patterns were used to identify the various phases present. Although this technique is qualitative, since some vapor may escape, the appropriate choice of reactants and trapping materials enables definitive demonstration of vapor transport from one crucible to the other. Relative line intensities of the x-ray diffraction patterns were used to estimate the amounts of the products present.

The second technique makes use of a quartz tube with a constriction at the center which allows the flow of gas from one compartment to the other. A quartz wool plug was also placed in the constriction. Appropriate materials were placed in each compartment; then the tube was evacuated and sealed. Firings were also performed for various times and temperatures. After firing, the products were examined by x-ray diffraction and chemical methods. Since this is a closed system, quantitative data can be obtained about vapor transport and mechanisms.

Results and Discussion

Apatite Forming Reactions

Reaction of $Ca_2P_2O_7$ *with* CaF_2.—In order to confirm Montel's (11) work, several proportions of $Ca_2P_2O_7$ and CaF_2 were blended and fired at temperatures from 700° to 1100°C. The major product in every case was fluorapatite. When excess $Ca_2P_2O_7$ was used over that shown in reaction [3], x-ray diffraction showed the presence of $Ca_2P_2O_7$. When CaF_2 was used in excess of that shown in reaction [3], CaF_2 was present in the product.

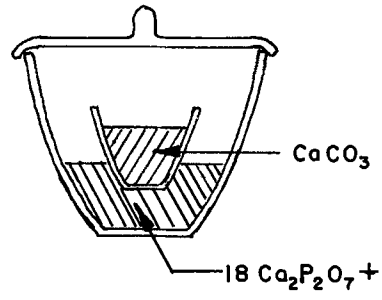

Fig. 1. Double crucible arrangement for vapor transport experiments

To show the presence of POF_3 (or vapors of similar composition) as one of the products of reaction [3] the following double crucible experiment was performed: The outer crucible contained Montel's mixture (reaction [3]); the inner crucible contained $CaCO_3$. After firing at 1000°C for 1 hr, the product in the outer crucible was fluorapatite. The products of the inner crucible were fluorapatite and CaF_2. It can be readily concluded that F, O, and P were all transported to the inner crucible where the most probable reaction was

$$18CaCO_3 + 6POF_3 \rightarrow [Ca_3(PO_4)_2]_3CaF_2 + 18CO_2 + 8CaF_2 \quad [4]$$

The product of the outer crucible was fluorapatite as expected from Montels' reaction (reaction [3]). If reactions [3] and [4] are combined and divided by 6 the following equation results.

$$3Ca_2P_2O_7 + 3CaCO_3 + CaF_2 \rightarrow \text{Apatite} + 3CO_2 \quad [5]$$

Reaction [5] has the usual proportions of reactants used in phosphor formulations.

When the mixture for reaction [5] was placed in the outer crucible and $CaCO_3$ was placed in the inner crucible, on heating 1 hr at 1000°C, the products in the inner crucible were CaO and a trace of CaF_2. These results indicate that, in an intimate mixture of the reactants, the vapors liberated by the solid-solid reaction of $Ca_2P_2O_7$ with CaF_2 will react quickly and completely with the nearest $CaCO_3$. Thus no vapor escapes to react with the $CaCO_3$ in the inner crucible.

Reaction of HF *with* $Ca_2P_2O_7$.—Since hydrolysis of POF_3 may occur to some extent and, thus, free HF and P_2O_5 may be reactants, the following double crucible experiment was performed. $Ca_2P_2O_7$ was placed in the outer crucible, and in the inner inverted crucible NH_4HF_2 (as a source of HF) was placed. The crucibles were heated for ½ hr at 900°C, and the products of the outer crucible were examined (the inner crucible was empty because of the volatility of NH_4HF_2). Both unreacted $Ca_2P_2O_7$ and fluorapatite were present. The following reaction is proposed.

$$5Ca_2P_2O_7 + 2HF \xrightarrow[\frac{1}{2} \text{ hr}]{900°C} \text{apatite} + 2P_2O_5\uparrow + H_2O \quad [6]$$

Vapor-solid reactions of this type would be expected to lead to a more rapid and complete dispersion of reactants than the usual solid-solid diffusion processes.

Reaction of P_2O_5 *with* CaF_2.—When the outer crucible containing CaF_2 and inner inverted crucible containing $(NH_4)_2HPO_4$ (as source of P_2O_5) were heated ½ hr at 900°C, the products of the outer crucible were fluorapatite and some unreacted CaF_2. The reaction leading to apatite formation is in balanced form

$$10CaF_2 + 6P_2O_5 \xrightarrow[\frac{1}{2} \text{ hr}]{900°C} \text{apatite} + 6POF_3\uparrow \quad [7]$$

This reaction along with [4] and [6] is of the gas-solid type. The liberation of POF_3 by this reaction would lead to a further repeat of reaction [4] whereever POF_3 came in contact with $CaCO_3$. The fact that a gaseous phosphorus-fluoride product did form according to reaction [7] was demonstrated by the use of a third small crucible containing $CaCO_3$ placed in the crucible setup mentioned above. After heating at 900°C for ½ hr, this third crucible now contained CaF_2 and $Ca_2P_2O_7$ with some apatite again illustrating the vapor transport of P and F.

Reaction of POF_3 *with* $Ca_3(PO_4)_2$.—Since there is a possibility that in a phosphor mix some $Ca_3(PO_4)_2$ may form according to reaction [1], the following double crucible experiment was performed. The outer crucible contained a mixture of $Ca_2P_2O_7$ and CaF_2 as a source of POF_3 (reaction [3]). The inner crucible con-

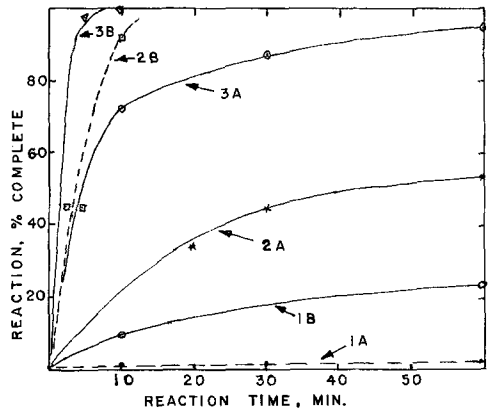

Fig. 2. Rate of formation of products at A, 800°C; B, 900°C for the reactions.

1. $Ca_2P_2O_7 + CaCO_3 \rightarrow Ca_3(PO_4)_2$
2. $3Ca_3(PO_4)_2 + CaF_2 \rightarrow$ apatite
3. $18Ca_2P_2O_7 + 14CaF_2 \rightarrow 5$ apatite

tained $Ca_3(PO_4)_2$. The setup was heated 1 hr at 900°C. The products of the inner crucible were fluorapatite and $Ca_2P_2O_7$. The probable reaction is

$$14Ca_3(PO_4)_2 + 2POF_3 \xrightarrow[1\text{ hr}]{900°C} 3\text{ apatite} + 6Ca_2P_2O_7 \quad [8]$$

These results once again illustrate the great tendency toward apatite formation whenever the ions Ca^{+2}, P^{+5}, $O^{=}$, and F^{-} are present.

Reaction Rates for Apatite Formation

It may be argued that reactions [3], [4], [6], [7], and [8] occur only under very special conditions, but that in actual practice apatite forms only by a stepwise process involving reactions [1] and [2]. To answer this more definitely, kinetic studies were performed on mixtures according to reactions [1], [2], and [3] at 800° and 900°C. Samples were heated in 5 ml crucibles at these temperatures for the desired times. The products were analyzed by standard x-ray diffraction techniques involving the measurement of line intensities. The completely reacted product line intensities were used for the 100% values of apatite for reactions [2] and [3], and β $Ca_3(PO_4)_2$ for reaction [1]. Although some error will arise due to line broadening for very small crystallites formed during the initial stages of reaction, the results are sufficiently accurate to determine relative rates of formation. Results are presented in Fig. 2. The data could not be fitted to either first order or parabolic rate curves. Thus only qualitative estimates of relative rates are indicated in the discussion.

The results demonstrate that at 800°C apatite formation by reaction [3] is much more rapid than its formation by the stepwise process involving reactions [1] and [2] since reaction [1] [formation of β $Ca_3(PO_4)_2$] is a relatively sluggish rate-determining step. Reaction [3] is several times more rapid than reaction [2] and about 100 times more rapid than reaction [1]. Even at 900°C reaction [3] is still the most rapid. Thus it can be concluded that in apatite mixes reaction [3] would be the dominant reaction.

Other Vapor Reactions

Reaction of apatite with Sb_2O_4.—During the formation of fluorescent apatites, solid solution of Sb^{+3} ions occurs in the apatite structure. To determine how apatite might react with antimony compounds, the following double crucible experiment was performed. The inner crucible contained a mixture of 10 fluorapatite + $2Sb_2O_4$. Antimony tetroxide was chosen because of its low volatility at high temperatures. The outer crucible contained $CaCO_3$. The system was heated at 1100°C for 1 hr and the products analyzed. The inner crucible contained a luminescent apatite (indicating the solid solution of Sb^{+3} ions in fluorapatite) plus a minor phase of $Ca(SbO_3)_2$. The outer crucible (originally $CaCO_3$) now contained CaF_2, $Ca_2Sb_2O_7$, and CaO. The proposed sequence of reactions to explain these results is as follows, (assuming a solid solution of 0.1 mole Sb^{+3} per mole of apatite).

The solid solution of antimony in apatite appears to require the removal of F^{-} and Ca^{++} ions from apatite. The Ca^{++} ions react with Sb_2O_4 to give $Ca(SbO_3)_2$. The F^{-} ions form an antimony halide, perhaps SbOF, as indicated in Eq. [9].

$$10[Ca_3(PO_4)_2]_3CaF_2 + 2Sb_2O_4 \xrightarrow[1\text{ hr}]{1100°C} 10[Ca_3(PO_4)_2]_3 0.9CaF_2 \cdot 0.1SbOF + Ca(SbO_3)_2 + SbOF\uparrow \quad [9]$$

The outer crucible trapped this vapor to give (in air)

$$3CaO + 2SbOF + O_2 \rightarrow Ca_2Sb_2O_7 + CaF_2 \quad [10]$$

Reaction of $Ca_2P_2O_7$ *with* $Ca(SbO_3)_2$.—According to Butler *et al.* (3) the Sb_2O_3 usually used as the starting antimony compound rapidly reacts to form $Ca(SbO_3)_2$. To determine how $Ca(SbO_3)_2$ may enter into phosphor formation, the system $Ca_2P_2O_7$ + $Ca(SbO_3)_2$ was studied at several temperatures together with the reaction of $Ca_3(PO_4)_2$ with Sb_2O_4. The results are as follows.

1. Below about 1100°C (in air)

$$Ca_3(PO_4)_2 + Sb_2O_4 + \tfrac{1}{2}O_2 \rightarrow Ca_2P_2O_7 + Ca(SbO_3)_2 \quad [11]$$

2. Above 1100°C (open crucibles)

$$Ca_2P_2O_7 + Ca(SbO_3)_2 \rightarrow Ca_3(PO_4)_2 + \text{volatile products} \quad [12]$$

Presumably Sb_2O_4 is the volatile product. Kinetic studies were performed on mixtures according to reaction [12] at temperatures of 1000°, 1100°, and 1200°C. Results are presented in Table I.

The theoretical weight loss for reaction [12] is 49.0%. Thus the results in Table I confirm that this reaction did occur above 1100°C. Since Sb_2O_4 is a product of this reaction, presumably as a vapor, it can now react according to reaction [9] leading to solid solution of Sb^{+3} in apatite.

Vapor transport of F *and* Cl *from apatites.*—To determine if high-temperature vapor transport of F^{-} and Cl^{-} ions may occur, possibly by means of a water cycle, the following sealed tube experiments were performed. Chlorapatite was placed in one compartment, fluorapatite in another. The systems were evacuated, sealed, and heated at 1200°C for 20 and 72 hr, respectively. Chemical analysis for chlorine was made on the products of each compartment. X-ray diffraction analyses of the products after 72 hr firings show the product of each compartment were fluorchlorapatites of almost identical patterns. The chloride analyses are listed in Table II. The results lead to the conclusion that both Cl^{-} and F^{-} ions were involved in a vapor transport mechanism, possibly through a water cycle as indicated.

$$[Ca_3(PO_4)_2]_3CaX_2 + 2HOH \rightleftarrows [Ca_3(PO_4)_2]_3Ca(OH)_2 + 2HX\uparrow \quad [13]$$

Table I. Weight losses for reaction of $Ca_2P_2O_7 + Ca(SbO_3)_2$

Reaction time, hr	% Wt loss 1000°C, %	1100°C, %	1200°C, %	Product at 1200°C
1	0	1.5	4.9	β $Ca_3(PO_4)_2 + Ca_2P_2O_7 + Ca(SbO_3)_2$
2	0	3.0	12.0	β $Ca_3(PO_4)_2 + Ca_2P_2O_7 + Ca(SbO_3)_2$
23	3.0	5.2	50.0	β $Ca_3(PO_4)_2$

Table II. Chloride content of sealed tubes fired at 1200°C

Compartment	Chloride Content Wt % 20 hr	72 hr
Fluorapatite	1.8	2.9
Chlorapatite	5.3	2.5

Table III. Decomposition of $CaCO_3$ at high pressures of CO_2

Mixture	Pressures of CO_2, psi	Temp, °C	% Wt loss	Theory wt loss %
$CaCO_3$	90	1100	15.0	44.0
$CaCO_3$	120	1000	1.2	44.0
$6CaHPO_4 + 3CaCO_3 + CaF_2$	120	700	15.2	15.6

By simple gaseous diffusion the hydrogen halides could diffuse to the opposite chamber resulting in the mixed fluorchlorapatites. At 1200°C the equilibration by direct vapor transport of $CaCl_2$ and CaF_2 might also be considered.

Vapor transport of CaF_2.—Measurable vapor pressure of CaF_2 at 1200°C has been reported (12). To determine if this vapor may react with β $Ca_3(PO_4)_2$, a sealed tube experiment was performed at 1200°C. One compartment contained CaF_2 and the other β $Ca_3(PO_4)_2$. After heating the system for 20 hr, the products were examined by x-ray diffraction. The $Ca_3(PO_4)_2$ compartment now contained a major phase of fluorapatite plus minor unreacted phases of $Ca_3(PO_4)_2$ and CaF_2. These results confirm that a vapor transport of F did occur. Although these results may be only of passing interest to the study of the usual processes for apatite formation, they do illustrate once again that unusual vapor transport phenomena can exist at high temperatures.

Apatite Formation under CO_2 Pressures

A pressure vessel similar to that previously described for DTA (13) was used to study the effect of pressure of CO_2 on the tendency for apatite formation. If it is assumed that the two-step process of apatite formation occurs according to reactions [1] and [2], then reaction [1] should be greatly depressed in a CO_2 atmosphere if free CaO is essential to the process as has been assumed by other authors (2, 6). Various mixtures were placed in the pressure vessel and heated for 1 hr at the indicated pressure and temperatures. Weight losses were determined on the cooled samples. The results are presented in Table III. The results in Table III clearly indicate that $CaCO_3$ dissociation can be greatly depressed in CO_2 even at 1100°C, yet apatite formation is essentially complete even at 700°C. It is highly unlikely therefore that the usual dissociation of $CaCO_3$ to CaO is necessary to apatite formation. This is additional evidence that the principal apatite forming reaction is pressure insensitive as would be expected from the reaction of $Ca_2P_2O_7$ with CaF_2 (reaction [3]). The second most important apatite forming reaction is between POF_3 and $CaCO_3$ (reaction [4]), which can be considered an acid-base-type reaction and therefore insensitive to CO_2 pressure.

High-Temperature X-ray Diffraction Studies of Halophosphate Mixes

Phosphor mixes composed of $CaHPO_4$, $CaCO_3$, CaF_2, $CaCl_2$, Sb_2O_3, and $MnCO_3$ in proportions used for phosphor manufacture were examined by high-temperature x-ray diffraction methods using the GE-XRD-5 unit together with a Tem-Press furnace assembly. X-ray diffractometer traces were made at various temperatures. The results are in general agreement with the thermogravimetric data of Wanmaker and Verheyke (2) namely that:

1. beginning at about 450°C
$$2CaHPO_4 \rightarrow \gamma Ca_2P_2O_7$$
2. beginning at about 500°C
$$Sb_2O_3 + \tfrac{1}{2}\, O_2 \rightarrow Sb_2O_4$$
3. beginning at about 650°C, fluorchlorapatite forms.

In no cases were any diffraction lines detected for $Ca_3(PO_4)_2$ to indicate its presence even in small amounts. These results also tend to indicate that in phosphor mixes apatite formation probably occurs primarily by reactions [3] and [4].

Summary

The present studies have permitted a simplification of the potential reactions involved in the preparation of halophosphate phosphors from the usual starting materials ($CaHPO_4$, $CaCO_3$, CaF_2, Sb_2O_3). The principal apatite forming reaction involves the interaction of $Ca_2P_2O_7$ particles with CaF_2 particles beginning at about 600°-700°C leading directly to formation of the apatite plus a vapor phase of POF_3 (11). The second most important apatite forming reaction is between POF_3 and $CaCO_3$ which also proceeds by a direct reaction that does not require free CaO, thus being pressure insensitive. These studies demonstrate that vapor transport plays a dominant role in the formation and activation of halophosphate phosphors.

Microstructures in CdS:Au Single Crystals

Arthur Dreeben

RCA Laboratories, Radio Corporation of America, Princeton, New Jersey

ABSTRACT

The incorporation of gold in CdS crystals grown from the vapor phase results in the formation of two types of precipitates. Type I, probably a CdAu phase, consists of small (2.5-7μ) hexagonally shaped platelets throughout the crystal oriented to reflect the CdS crystal symmetry. Type II are much larger hexagons (160μ) apparently of elemental gold in localized positions, and with an orientation rotated 30° with respect to the small ones. Type I precipitates have been found to decorate a unique, highly symmetrical network of dislocations associated only with Type II hexagons. The dislocations are generated in a critical strain field developed around hexagons of sufficient size. Strain birefringence has been observed around these hexagons in polarized light.

In a previous investigation (1), it was demonstrated that extraneous phases precipitate in CdS crystals containing the acceptor elements Cu, Ag, or Au. The precipitates involving Cu and Ag were thought to be sulfide phases, whereas gold was found to segregate as the element together with a CdAu phase. It was shown that each of the precipitates had a characteristic shape and crystallographic orientation. The sulfides formed needles, rods, or disks, but the gold phases formed hexagonal platelets.

In this paper, additional results of direct optical observations of precipitates in CdS:Au crystals are presented. The principal findings include the identification of two kinds of hexagonal platelets, which differ in size and crystallographic orientation, and the observation of a unique, decorated imperfection network associated with the larger hexagons.

Experimental

The crystals used in this work were cut from large boules of CdS:Au which were grown from the vapor phase, oriented, and polished as previously described (1). The powder charge from which the boules were produced, contained 5 mole % of gold as gold (III) sulfide prepared by precipitation from a solution of chloroauric acid, trihydrate. With this amount of gold, globules of the metal, formed by thermal decomposition of the sulfide during crystal growth, are found in contact with the boule. During growth, therefore, molten gold is present, and this condition promotes its incorporation in the crystal. The polished samples were examined under the polarizing microscope using transmitted, incident and dark field illuminations.

Observations

As previously noted (1), discrete hexagonal platelets lying in a (0001) basal plane had been found to segregate in CdS:Au crystals. In the present samples, the average size of this species (hereafter called type I) ranges from about 2.5 to 7μ. However, in Fig. 1A, some giant hexagons (hereafter called type II) up to 160μ across can also be seen in localized sites which are at various distances below the surface of the crystal. Transmitted polarized light disclosed a strain birefringence around these large precipitates clearly seen as the white areas radiating outward from the type II hexagons in Fig. 1B. The "specks" in these photomicrographs are the smaller, type I precipitates.

In addition to their size, type II hexagons are also distinguished by a surrounding array of unique, highly symmetrical, decorated dislocations. This network in the CdS crystal consists of two distinct patterns as seen in Fig. 2. One of these is superimposed over the hexagon in the form of an asterisk whose arms are directed through and extend beyond the vertices of the large hexagon. The other decoration is a peripheral, open hexagonal array with sides paralleling those of the precipitate at a distance of about 40-45μ. The asterisk and the peripheral hexagon both consist of many individual, aligned type I precipitates.

The photomicrograph in Fig. 2 was taken with the aperture diaphragm of the microscope condenser stopped-down to increase the depth of field, thereby showing all features of the arrays together. However, the type II hexagon and the two decorated patterns are not coplanar, the composite consisting of the separate parts shown in Fig. 3. In this typical crystal, 0.7 mm thick, incipient formation of the asterisk is visible close to the surface (Fig. 3A), but the fully developed pattern is first seen at 0.17 mm below the surface of the crystal. The asterisk continues in a three-dimensional array and is still clearly seen at a depth of 0.25 mm where distinct outlines of the peripheral, open hexagon also appear (Fig. 3B). In fact at this focus, elements of an inner pattern (I in 3B) and outer pattern (O in 3B) can be seen. The peripheral hexagon is at last sharply defined at a depth of 0.32 mm, while the decoration forming the asterisk is beginning to diminish (Fig. 3C). Both patterns essentially terminate at about 0.47 mm below the surface. Finally, the type II hexagonal precipitate is brought into focus at a depth of 0.57 mm (Fig. 3D). Below this hexagon, there is a somewhat less distinct repeat pattern of the peripheral figure and the asterisk.

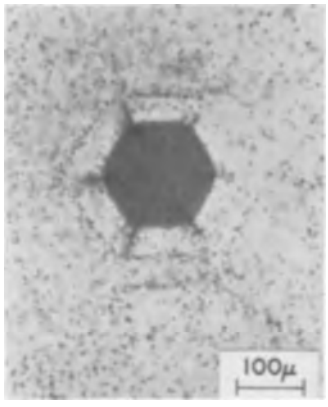

Fig. 2. Decorated dislocation arrays around hexagon No. 3 in Fig. 1

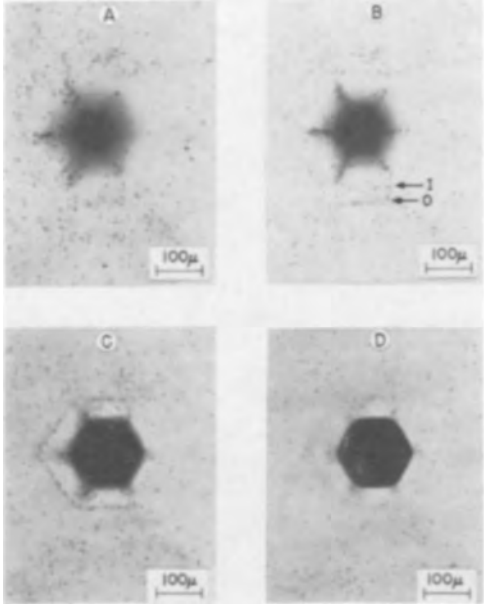

Fig. 3. Separate parts of the decorated array in Fig. 2, (A) near the crystal surface; (B) asterisk and outlines of peripheral rings, 0.25 mm below surface; (C) sharply defined ring, 0.32 mm below surface; and (D) type II hexagon, 0.57 mm below surface.

The interesting formation of the decorations above and below another type II hexagon is shown in Fig. 4. In this specimen, the asterisk and the peripheral hexagon (Fig. 4A) are seen above and essentially around the left side of the type II precipitate (Fig. 4B), while below the large hexagon, the patterns are around its right side (Fig. 4C). In Fig. 4D, a different portion of the peripheral hexagon appears at a level 0.07 mm below the position in Fig. 4C and also further away from the sides of the type II hexagon.

In the lower central portions of each illustration in Fig. 1, two asterisks (labelled 1 and 2 in 1A) can be seen without accompanying type II hexagons. Found at the surface of the crystal, they are the remnants of the typical systems already shown, but from which the other parts were removed during polishing. One of these is seen in greater detail in Fig. 5, which also clearly shows that these decorations consist of arrays of individual type I hexagons.

Crystallography of Precipitates

In (0001) planes, type I precipitates observed in many crystal slices from different boules always have the same orientation. They are bounded by $\{10\bar{1}0\}$ planes of the CdS with the a-axes directed through the vertices of the hexagons which have the same orientation as etch pits in the basal plane. This correspondence is shown in Fig. 6.

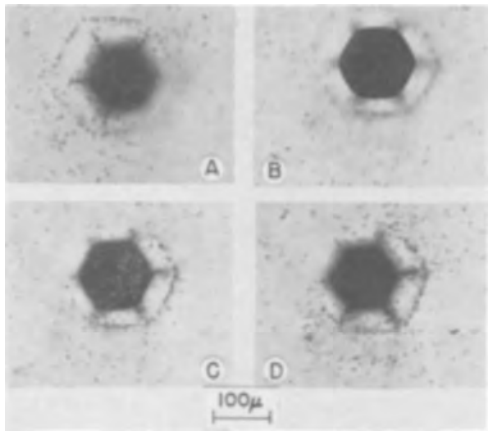

Fig. 4. (A) Dislocation array above hexagon; (B) type II hexagon; (C) dislocation array below hexagon; (D) 0.07 mm below field in (C), note outward displacement of peripheral ring.

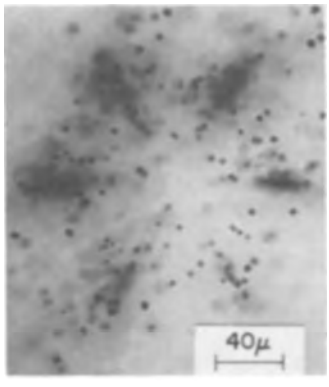

Fig. 5. Dislocation array after hexagon is removed. Note that decoration consists of individual type I hexagons.

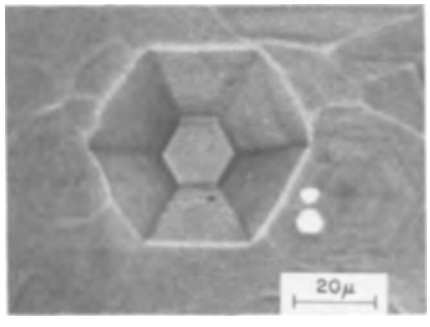

Fig. 6. Photomicrograph in incident light showing orientation of type I hexagons and etch pits in basal plane.

The large type II hexagons also have a self-consistent orientation, but it is different from that of type I. In Fig. 7, the outlines drawn around several of the type I precipitates make it readily apparent that the type II hexagon is rotated 30° with respect to the small ones. The relationship between the precipitates and the decorated dislocations with respect to the basal plane of CdS is summarized schematically in Fig. 8.

In all of the preceding photomicrographs, the precipitates have been seen as they are arranged in a basal plane. In Fig. 9 the arrangement in a (1010) plane is shown in transmitted, dark-field illumination. Type I hexagons appear as the short bright lines, while type II are the longer ones. X-ray methods established that the CdS C-axis ([0001] direction) is perpendicular to the lines in the plane of the picture and that the a-axis $[\bar{1}2\bar{1}0]$ is parallel to them. This illustration also shows arrays from asterisks and peripheral hexagons above and below the type II precipitates. However, the clear, undecorated regions directly around the pre-

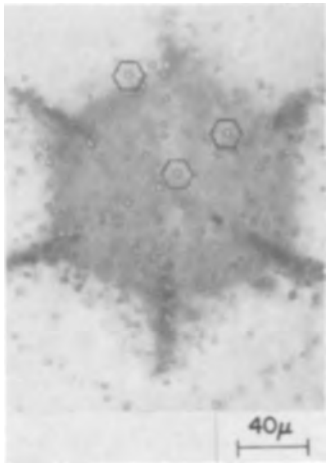

Fig. 7. Photomicrograph showing different orientations of type I (small) and type II hexagons.

cipitates confirm the earlier observation that the decoration patterns terminate at some distance from the large hexagons.

Other Decorations

In addition to the dislocation arrays surrounding the type II precipitates, there are often decorated lines that emanate from the type II precipitates, one of which can be seen in Fig. 1A between the positions labelled 2 and 3. Similar lines are also shown in Fig. 10 where it will be noted that many type I precipitates

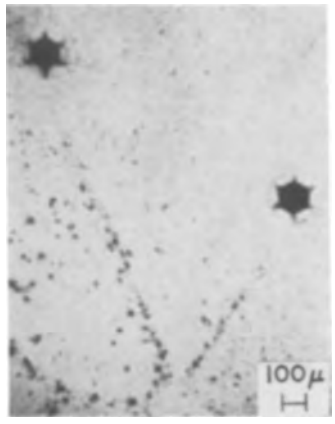

Fig. 10. Decorated boundaries emanating from type II hexagons

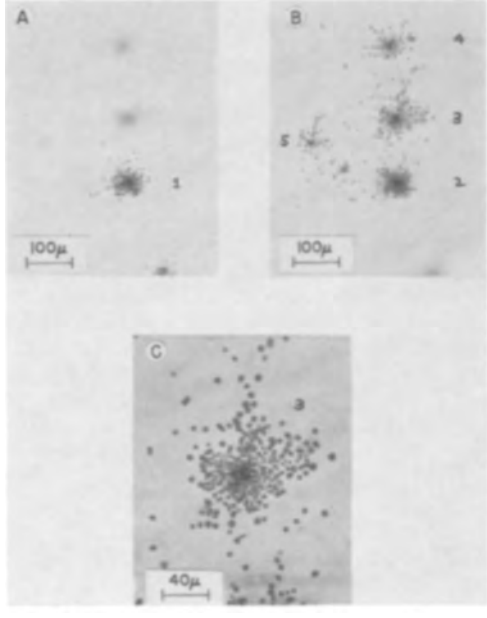

Fig. 11. Clusters of type I hexagons along boundaries shown in Fig. 10.

are grouped in clusters along and near the lines. The clusters, seen at higher magnification in Fig. 11, are arranged in a three-dimensional network. For example, group 1 in Fig. 11A is about 0.2 mm below the crystal surface, and the defocused outlines of other groups can also be seen. These appear in the same field, but at a depth of 0.4 mm as shown in Fig. 11B where the shadow of group 1 can be seen over group 2. Formations of this type are often associated with subboundaries.

Discussion

The two respective orientations of type I and type II precipitates suggest that they may be different chemical species. This is consistent with electron diffraction data indicating the presence of Au and CdAu phases in the CdS crystal. Gold has a face-centered cubic lattice and some CdAu phases have a hexagonal structure (2). In view of these structural differences, it is reasonable to expect the precipitates to have dissimilar epitaxial arrangements in the hexagonal CdS lattice. At present it has not been possible to obtain selected area electron or x-ray diffraction patterns of the precipitates. However, it is likely that the CdAu hexagonal structure would adopt the orientation bounded by the low index {10$\bar{1}$0} planes of hexagonal CdS and thereby reflect the crystal symmetry in the same way as the etch pits and type I precipitates shown in Fig. 6. On the other hand, the cubic Au, with {111} close packed planes, may well prefer the other ob-

served orientation of type II precipitates which are rotated at a 30° angle with respect to type I (see Fig. 7).

The different crystallographic orientations, and the probable separate identities of each precipitate, together with the fact that the dislocation arrays and boundaries are decorated with type 1 precipitates, suggest that different precipitation mechanisms are operating. One possible sequence for precipitation and decoration consistent with the observations is the following. Type II precipitates nucleate and grow at localized sites during the formation of the CdS boule while it is still at a high temperature. When these hexagons are sufficiently large, a critical strain field is established, and the symmetrical dislocation network is generated. In this connection it can be pointed out that the networks have never been observed around the small type I precipitates. In addition, the peripheral hexagonal loop is either very weakly defined or missing from type II precipitates well within the crystal, but which are less than about 100μ in size compared with 140μ for those associated with a complete array.

The CdAu phase, on the other hand, appears to have a greater solubility and remains in solution at or near the crystal growth temperature of CdS. As the crystal cools, type I hexagons precipitate randomly and on preferred sites for nucleation provided by the dislocations.

The decoration of sub-boundaries in the crystals was pointed out earlier (see Fig. 10 and 11). The other prominent dislocations in these crystals comprise the symmetrically decorated arrays around type II precipitates. The peripheral hexagons appear to be decorated prismatic loops (3) whose sides are on traces of $(11\bar{2}0)$ planes in the basal plane. It is also possible that the loop is part of a helical dislocation, an arrangement which could account for the displacement of the sides of the peripheral hexagon with respect to the type II precipitate as shown in Fig. 3B. 4C, and 4D. Two observations are of particular interest. One is that the network consisting of the precipitate, the asterisk, and the peripheral hexagon is not coplanar; the other is the situation shown in Fig. 4, wherein parts of hexagonal loops exist on opposite sides above and below a type II precipitate. The mechanisms leading to these formations are not yet completely known. However, the source of the dislocation network appears to be a type II precipitate of sufficient size to develop around it, a critical strain field which is observable in polarized light. The dislocation loops once formed may glide away from the source thereby tending to relieve the stresses and leave the precipitate relatively isolated (4).

Bourdon Gauge Determination of Chemical Equilibrium in the Ge-Cl_2 System

T. O. Sedgwick

Thomas J. Watson Research Center, International Business Machines Corporation, Yorktown Heights, New York

ABSTRACT

Bourdon gauge pressure measurements of samples of $GeCl_4(g)$ and $GeCl_4(g)$ plus Ge(s) have been made in the temperature range 300°-1300°K. The pressure change of pure $GeCl_4$ as a function of temperature indicates that it does not dissociate up to 1300°K. The pressure *vs.* temperature behavior of $GeCl_4(g)$ plus Ge(s) is described by the equilibrium

$$Ge(s) + GeCl_4(g) \rightleftarrows 2GeCl_2(g)$$

The standard enthalpy, ΔH°, and entropy, ΔS°, of reaction at 723°K were found to be 34.9 kcal and 46.7 eu, respectively.

In contrast to the Ge-H_2-I_2 and Si-H_2-Cl_2 epitaxial growth systems (1, 2) for which complete thermodynamic analyses have been made, there is insufficient thermodynamic data currently available for a similar analysis of the Ge-H_2-Cl_2 system. A complete thermodynamic description of this system would, for example, obviate the present speculation regarding the gas phase composition in $GeCl_4$ epitaxial growth and etching processes (3-5). As a first step toward this goal, the present work describes a quantitative determination of the equilibrium in the Ge-Cl_2 system using a Bourdon gauge.

As early as 1887 Nilson and Pettersson (6) noted the thermal stability of $GeCl_4$. By measuring the vapor density of $GeCl_4$ vapor they found that it was essentially undecomposed up to 1012°K at atmospheric pressure. In contact with solid Ge, however, it has been repeatedly postulated that an equilibrium with the dichloride obtains (3, 4, 7, 8)

$$Ge(s) + GeCl_4(g) \rightleftarrows 2GeCl_2(g)$$

Although both Dennis and Hunter (7) and Schwarz and Baronetzky (9) have obtained a solid reaction product with a Cl/Ge ratio of 2 from the action of gaseous $GeCl_4$ on solid Ge, it does not necessarily follow that the vapor phase species has either the same stoichiometry or the same degree of polymeric character (monomer *vs.* dimer, etc.). This is particularly true since it appears that the solid $(GeCl_2)_x$ phase is polymeric (10).

Although related Group IVA halide systems. *i.e.*, $Si-Cl_2$, $Ge-I_2$, $Ge-Br_2$, exhibit disproportionation type equilibria (11-13), there was the possibility that species other than $GeCl_2$ and $GeCl_4$ might be important in the present system. For example, both Ge_2Cl_6 and GeCl have been produced under nonequilibrium conditions in this system (9, 14-16).

Experimental

Bourdon gauge, pressure control, and measurement.—The Bourdon gauge (12) and furnace used in the present studies are shown in Fig. 1. Flag movements caused by pressure changes modulate a light beam passing through the light pipes. The resultant optical signal is used to actuate automatically the valves to both pressure and vacuum sources which control the pressure in the equalizing chamber to "null" the flag. The details of this automatic pressure control system have been described previously by Hochberg (17).

The pressure in the equalizing chamber was measured with a model FA 129 Wallace and Tiernan dial-type manometer which had been calibrated with a 13 mm diameter Hg manometer. Both the pressure control and accuracy are within ±0.2 mm Hg. The zero pressure point was checked frequently and, although its variation was normally within the above limits, an occasional deviation of 1-2 mm Hg was observed.

Chemical purity.—Sylvania "Special High Purity" semiconductor grade $GeCl_4$ was distilled under vacuum to remove all inert gases and transferred to the gauge in an all glass apparatus. Since 1-mg quantities of $GeCl_4$ were used, the glass apparatus was carefully cleaned and baked out before transfer of the $GeCl_4$. In sample 1, a 36 ohm-cm undoped Ge wafer was used. In samples 2 and 3, small wafers of 16 ohm-cm Ga doped Ge were used as the Ge solid phase. The wafers were etched in "white etch" and rinsed with deionized water and ethanol before use. The Bourdon gauge and wafer were baked out at 450°-700°C for more than 12 hr at a final pressure of 2×10^{-7} mm Hg (at the pump). The bake out tube (to vacuum) and the sample delivery tube were subsequently removed from sample chamber and are not shown in Fig. 1.

Experimental procedure.—The pressure of a total of four different samples was measured as a function of temperature. The pressure readings were taken over several cycles of increasing and decreasing temperatures. In the temperature region where a chemical reaction took place, it was necessary to wait for ½ hr ($T > 800$°K) to several days ($T < 600$°K) before chemical equilibrium was achieved, and no further change in pressure occurred as a function of time. The temperature was measured with a Pt-Pt 10 Rh or a Chromel-Alumel thermocouple both at the Ge wafer in the bottom of the sample chamber and at the top of the thermocouple well. The temperature in the furnace was adjusted so that the top of the Bourdon gauge was 2-10°C higher than the bottom (position of Ge wafer) to avoid condensation of solids on the spoon.

Results and Discussion

Thermal stability of $GeCl_4(g)$.—The pressure of a sample of gaseous $GeCl_4$ (59 mm Hg at 300°K) at constant volume was found to be a linear (within <1%) function of the temperature up to 1300°K. It was therefore concluded that $GeCl_4$ does not dissociate significantly over this range of temperature and pressure.

Equilibrium in the $GeCl_4$-Ge *system.*—The pressure *vs.* temperature data for three different samples of $GeCl_4(g)$ plus Ge(s) spanning a fivefold range in total pressure are shown in Fig. 2. In each sample the number of moles of solid Ge used was at least a factor of ten greater than the number of moles of gaseous $GeCl_4$. The presence of an excess Ge solid phase was confirmed visually up to ~800°K. During the measurements no solid phase other than Ge was observed with one exception.[1]

In all three samples the initial linear portion of the curves (up to ~570°K) is attributed to an ideal gas law pressure increase of $GeCl_4$ gas. From ~570°-950°K the increasing slope shows an increase in the number of gas molecules. In samples 1 and 3 the second linear region above ~950°K has a slope, P/T, twice the slope

[1] In one experiment using a different furnace arrangement, the sample temperature was dropped rapidly by cooling the bottom of the gauge with an air stream. In this case a yellow-green-gray solid was condensed on the chamber walls and the final pressure read 36 mm Hg instead of the expected 54 mm Hg. Presumably the color was due to a condensed chlorine containing phase similar to that described by Schwarz and Baronetzky (9). On recycling the system at a uniform temperature, the condensed phase disappeared, and the pressure returned to the expected value.

of the respective low temperature linear regions as indicated in Table I.

Postulation of an equilibrium model.—As possible models, we have considered all equilibria involving $GeCl_4(g)$, Ge(s), and the species $(GeCl_x)_y$ where $x = 1, 2, 3$ and $y = 1, 2$.

$y = 1$

$$3Ge(s) + GeCl_4(g) \rightleftarrows 4GeCl(g) \quad [1]$$

$$Ge(s) + GeCl_4(g) \rightleftarrows 2GeCl_2(g) \quad [2]$$

$$1/3Ge(s) + GeCl_4(g) \rightleftarrows 4/3GeCl_3(g) \quad [3]$$

$y = 2$

$$3Ge(s) + GeCl_4(g) \rightleftarrows 2Ge_2Cl_2(g) \quad [4]$$

$$Ge(s) + GeCl_4(g) \rightleftarrows Ge_2Cl_4(g) \quad [5]$$

$$1/3Ge(s) + GeCl_4(g) \rightleftarrows 2/3Ge_2Cl_6(g) \quad [6]$$

The observed doubling of the number of gas molecules in passing from low to high temperatures (see Table I), indicates that only the equilibria Eq. [2] and [4] are adequate models. In addition, there is a model involving two simultaneously operative equilibria, *i.e.*, Eq. [5] and [7], which is consistent with the observed doubling of molecules as discussed above.

$$Ge(s) + GeCl_4(g) \rightleftarrows Ge_2Cl_4(g) \quad [5]$$

$$Ge_2Cl_4(g) \rightleftarrows 2GeCl_2(g) \quad [7]$$

Although the three models Eq. [2], [4], and [5] and [7] are indistinguishable on the basis of Bourdon gauge measurements alone, the latter two models are considered unlikely since neither the species Ge_2Cl_4, Ge_2Cl_2, nor their analogs for any Group IVA-halide (carbon excepted) combination have ever been observed (18, 19). In the Ge-I_2 system, for instance, the complementary Bourdon gauge measurements of Lever (12) and weight-loss measurements of Jona *et al.* (13) specifically rule out the possibility that Ge_2I_2 and Ge_2I_4 are major constituents of the vapor phase. In the Ge-Cl_2 system Haq (20) has been able to observe only a single species which persists over the whole temperature range 473°-873°K (presumed to be $GeCl_2$). In the present study the onset of Ge etching has been observed visually to coincide with a measurable pressure increase, which indicates qualitatively that there is at most only a small concentration of Ge_2Cl_4 present. For the above reasons the model involving $GeCl_2$ has been chosen as the most probable description of the system, and the following analysis will be made on the basis of Eq. [2]

Test of the model.—In order to test the validity of the proposed model, Eq. [2], the functional dependence of the equilibrium constant, K_p, on temperature and pressure was determined.

$$K_p = \frac{P^2_{GeCl_2}}{P_{GeCl_4}} \quad [8]$$

The partial pressures of $GeCl_2$ and $GeCl_4$ were calculated by noting that

$$P_{total} = P_{GeCl_4} + P_{GeCl_2} \quad [9]$$

and since no chlorine containing solid phase was observed, the molecular conservation of chlorine in the vapor phase requires that

$$\frac{N_{Cl}RT}{V} = 4P_{GeCl_4} + 2P_{GeCl_2} \quad [10]$$

where N_{Cl} is the total number of moles of chlorine atoms in the gas phase.

Simultaneous solutions of Eq. [9] and [10] yield

$$P_{GeCl_4} = \frac{N_{Cl}RT}{2V} - P_{total} \quad [11]$$

$$P_{GeCl_2} = 2P_{total} - \frac{N_{Cl}RT}{2V} \quad [12]$$

The quantity $N_{Cl}R/V$ is a constant for each sample and was calculated from Eq. [11] for $T > 950°K$ where P_{GeCl_4} is essentially zero and from Eq. [12] for $T < 570°K$ where P_{GeCl_2} is essentially zero (see Table I).

The standard enthalpy $\Delta H°$, and entropy, $\Delta S°$, of reaction were obtained by the second law treatment using the relation

$$\log K_p = \frac{\Delta H°}{-2.303RT} + \frac{\Delta S°}{+2.303R} \quad [13]$$

where $\Delta H°$ and $\Delta S°$ are assumed independent of temperature.

Calculated values of $\log K_p$ *vs.* $1/T$ are shown in Fig. 3. The constancy of K_p with varying pressure at constant temperature and the linearity of the $\log K_p$ *vs.* $1/T$ are confirmation that the model Eq. [2] is a satisfactory description of the system. If significant quantities of GeCl, $GeCl_3$, or Ge_2Cl_3 were present, log

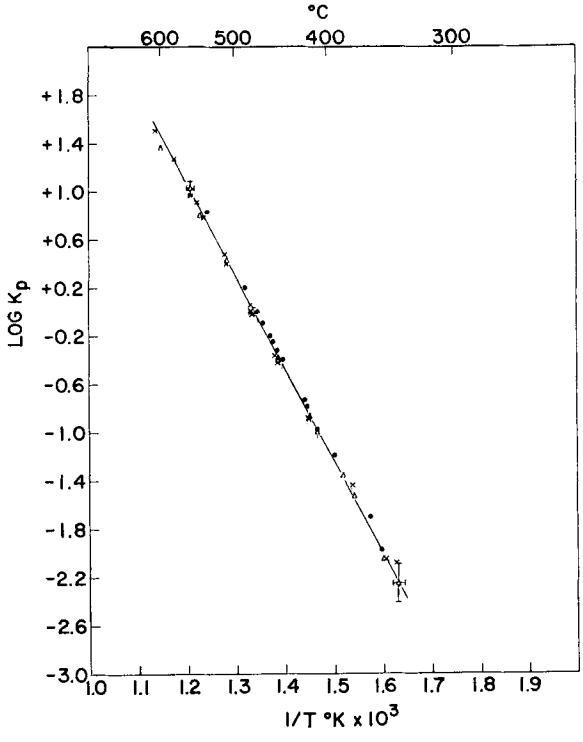

Fig. 3. log K_p *vs.* $1/T$ for the postulated equilibrium $Ge(s) + GeCl_4(g) \rightleftarrows 2GeCl_2(g)$. X, Sample 1; •, sample 2; △, sample 3.

Table II. Calculated thermodynamic properties of the reaction

	$Ge(s) + GeCl_4(g) \rightleftarrows 2GeCl_2(g)$	
	$\Delta H°_{723°K}$ (kcal)	$\Delta S°_{723°K}$ (eu)
Sample 1	34.1	45.6
Sample 2	35.5	47.7
Sample 3	35.0	46.7
Avg	34.9 ± 0.5	46.7 ± 0.7

Standard state 1 atm

K_p would not be constant with varying total pressure nor would it in general be linear with $1/T$.

Calculated values of $\Delta H°$ and $\Delta S°$ for each sample based on a least squares fit of Eq. [13] to the data are presented in Table II.

As a check on the experimentally determined value of $\Delta S°$, the entropy of reaction was calculated at 700°K from entropy values of Ge(s) and $GeCl_4(g)$ listed by Kelley (21, 22) and from a computed entropy of $GeCl_2(g)$ from estimated molecular constants and spectroscopic data described in Appendix I.

$$\Delta S°_{700} = 2S°_{GeCl_2(g)} - S°_{Ge(s)} - S°_{GeCl_4(g)}$$
$$\Delta S°_{700} = 2 \times 80.7 \pm 2 - 12.6 \pm 0.1 - 103.8 \pm 0.8$$
$$\Delta S°_{700} = 45.0 \pm 4 \text{ eu} \qquad [14]$$

The calculated value of 45.0 eu is in excellent agreement with the measured value of 46.7 eu and is well within the uncertainties in the entropy values indicated.

APPENDIX I

Calculation of the Entropy of $GeCl_2(g)$

The bond length of 2.1Å was taken to be essentially equal to the Ge-Cl bond length in $GeCl_4(g)$ (23). There is electron diffraction (23) and spectroscopic (24) evidence that the Group IV A dihalides are nonlinear. The bond angle of $GeCl_2$ was assumed to be the same as for $SiCl_2$ which was estimated by Sinke (25). The symmetric valence vibration frequency, ω_1, and the deformation vibration frequency, ω_2, for $GeCl_2$ were estimated by averaging the corresponding vibrational frequencies of $SnCl_2$ and $SiCl_2$ as measured by Asundi, Karim and Samuel (24). The asymmetrical valence vibrational frequency, ω_3, was estimated to be equal to 1.12 ω_1 since the nonlinear XY_2 molecules listed by Herzberg (26) in Table 37 exhibit on the average the property $\omega_3 \simeq 1.12\ \omega_1$.

Table III. Summary of the estimated and calculated molecular constants

Molecular weight	143.5g
Ge-Cl bond length	2.1Å
Cl-Ge-Cl angle	110°
Product of moments of inertia $I_AI_BI_C$	1.308×10^{-113} g²/cm⁶
Symmetry number	2
Vibrational levels [multiplicities]	
ω_1	450 cm⁻¹ [1]
ω_2	185 cm⁻¹ [1]
ω_3	505 cm⁻¹ [1]

The entropy was calculated from the data in Table III using the formulas given in the JANAF tables (27). Only the ground electronic state was assumed to be occupied in analogy to $SnCl_2$ and $SiCl_2$ (24, 25), and the usual assumptions of a rigid rotator and harmonic oscillator were made.

$$S°_{total} = S°_{electronic} + S°_{translation+rotation} + S°_{vibration}$$
$$= 0 + 72.6 + 8.1$$
$$S°_{total} = 80.7 \pm 2 \text{ eu} \qquad [15]$$

Deposition of Germanium Films by Sputtering

K. E. Haq

Thomas J. Watson Research Center, International Business Machines Corporation, Yorktown Heights, New York

ABSTRACT

Both n and p-type germanium films were deposited epitaxially by using asymmetric a-c sputtering. The quality of the films was found to be strongly dependent on the substrate temperature and the voltages during both the cleaning and the sputtering cycles. It was demonstrated that when the sputtering parameters were properly adjusted, the films deposited from n-type source material showed n-type conductivity, even when they were polycrystalline, indicating that the p-type conductivity observed previously in sputtered films was primarily due to impurities. Further, epitaxial films of the same type and conductivity and of approximately the same carrier concentration as the source material were deposited with substrate temperatures as low as 350°C.

There have been continuing efforts in the deposition of single crystal films of semiconducting materials epitaxially on various substrates. Considerable success has been achieved in obtaining good quality films by the halogen transport process. Although germanium and silicon films were deposited epitaxially by vacuum evaporation and sputtering techniques (1-5), the films, with the exception of a few cases, showed p-type conductivity, even though the source materials were heavily doped with n-type impurities. In those few instances (4-5) where the authors reported success in depositing n-type silicon films, the evaporations were conducted at a vacuum of 10^{-9} Torr. As for germanium there have been no reports of successful deposition of n-type films by either sputtering or evaporation. There has been considerable discussion in the literature as to why the films generally showed p-type conductivity (6-7). Some authors attributed this result to impurities, while others considered it to be due to imperfection in the crystalline structure of the films. Recently, it has been demonstrated in the case of silicon that the p character in conductivity is not entirely due to structural defects but due partially to contamination.

Frerichs (8) has reported that good quality superconducting metal films can be deposited by using asymmetric a-c sputtering. In the present investigation the same technique has been successfully used for the deposition of single crystal germanium films. It has been observed that even with the use of a system capable of obtaining vacuum in the high 10^{-6} range, both n- and p-type germanium films can be deposited on either type of germanium substrate, if the sputtering conditions are properly adjusted. In the present paper detailed conditions for depositing such films by sputtering and their properties will be reported.

Experimental

Apparatus.—The experimental apparatus consisted of a 14 in. glass bell jar system with a 2-in. oil diffusion pump and a liquid nitrogen trap. After overnight pumping, the system reached an ultimate vacuum of 7 x 10^{-6} mm Hg. The electrode geometry was as shown in Fig. 1. The electrodes were made of ¼ in. stainless steel rods surrounded with stainless steel shields. A spacing of 1/16 in. was maintained between the rod and the shield. A disk of polycrystalline germanium approximately 2 in. in diameter was used as a source material. It was prepared by casting pure germanium with a known amount of impurity. The disk rested on a molybdenum stage screwed to the top of the lower electrode. This arrangement precluded the use of any clips or screws for holding the source, and thus eliminated the problem of sputtering of undesirable impurities along with the source material. The germanium substrate was held with clips to a molybdenum disk which was screwed to the upper electrode with the substrate facing down towards the source.

One geometrical feature of the shields surrounding the source and the substrate should be pointed out. In the case of the source, the shield protruded approximately 1/16 in. beyond the level of the source. This arrangement confined the bombardment to the source alone, due to the repulsion of the positive ions by the shield. The substrate, on the other hand, protruded about the same distance beyond its shield. This configuration insured uniform bombardment of the substrate by the positive ions during the cleaning cycle.

The substrate heater consisted of a hollow doughnut shaped structure attached to the shield that surrounded the substrate holder. The heating of the substrate was accomplished by radiation. The temperatures of the substrate were determined in the following way: In an auxiliary experiment the temperatures of the substrate holder corresponding to different temperatures of the heater were measured by attaching one thermocouple to the heater and another to the substrate holder. A calibration curve was then plotted. During the actual run, the temperature of the heater was monitored. Using the calibration curve, the temperature of the substrate was determined.

An asymmetric 60 cycle a-c voltage was used for sputtering. The characteristics of the voltages applied to the source, the substrate, and the shields are shown in Fig. 2. Several features of the voltages should be

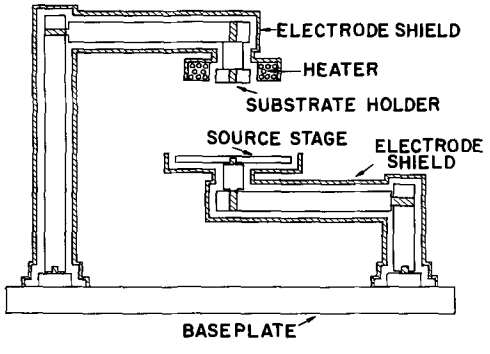

Fig. 1. Electrode geometry used for deposition of germanium film by sputtering.

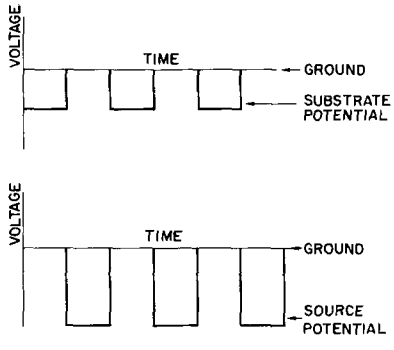

Fig. 2. Characteristics of voltages appearing on the source, substrate, and the shields during sputtering.

pointed out. First, the wave forms of the voltages appearing on the electrodes were square rather than sinusoidal. Second, when the source became negative, the substrate and the shields were at the ground potential. Similarly, when the substrate became negative, the source and the shields were at the ground potential. In this way, during sputtering the bombardment of all the undesirable parts of the system by positive ions was prevented. In the rest of the discussion, the negative voltages appearing on the source and the substrate will be referred to as the sputtering voltage and the cleaning voltage respectively.

Operational Procedure

The following procedure was used for the deposition of films. Germanium wafers, cut from a single crystal ingot, were first mechanically polished, and given a 5 min etch with CP_4. The wafer was then rinsed several times with deionized water and stored under alcohol until ready to be mounted. The source material was cleaned in the same way as the substrates. No further cleaning was done to the source between runs. After the source and the substrate were mounted, the system was evacuated to 7×10^{-6} Torr. The substrate heater was then turned on. Sufficient time was allowed for the substrate to come to a predetermined temperature equilibrium. A dynamic equilibrium pressure of approximately 45μ was then established in the bell jar by bleeding in ultra high purity argon through a needle valve, with the system open to the mechanical pump through a liquid nitrogen trap. It is essential that a cold trap be used between the bell jar and the mechanical pump to prevent the back-streaming of oil vapor from the mechanical pump. Experience has shown that unless such a precaution is taken, the properties of the film are adversely affected.

After the establishment of the argon pressure in the bell jar, both the source and the substrate were cleaned for 5 min with 1000v ions. At the end of the cleaning period, the source voltage was raised, while the substrate voltage was lowered to some predetermined values. The run was continued for a period of several hours, at the end of which time the system was opened to the diffusion pump and allowed to cool under vacuum before the film was exposed to air.

Results and Discussion

Since there has been considerable discussion in the literature as to why the evaporated and sputtered germanium films showed only p-type conductivity, part of the present investigation was devoted to determining the various deposition parameters which gave either n- or p-type films when n-type source material was used. After determining the conditions that gave reproducible n-type films, several such films were deposited on p-type substrates. The characteristics of the films and the p-n junction were then investigated. Germanium films were deposited on germanium substrates under various growth conditions. In all experiments the source to substrate distance was maintained constant at 2½ in. X-ray diffraction techniques were used to determine whether or not the films were epitaxial. The thickness of the films was determined by an interferometric method. The type of conductivity of the films was established from thermoelectric voltage measurements.

It has been observed that films deposited from a n-type source material show p-type conductivity unless several precautions are taken. First, after the system is pressurized with clean argon to a predetermined value, the sputtering must be immediately initiated. Second, the ion bombardment should be confined between the source and the substrate. Otherwise, impurities released from the electrodes and the fixtures during sputtering are incorporated in the film. Finally, the geometry of the electrodes should be such that uniform bombardment of the substrate during the cleaning cycle is insured. Otherwise, part of the film may show n-type conductivity, whereas the rest may be p-type. This phenomenon was observed during the early part of the investigation when proper precautions were not taken.

As the run proceeds the system slowly becomes heated and as a result, outgassing of the apparatus increases. If the run is continued for too long, the contamination from outgassed impurities may be so severe that the type of conductivity of the film may vary through the deposit thickness. It will be instructive, perhaps, to describe the result of a particular run, since it illustrates such an effect; and moreover, it gives an indication as to what might have been the chief reason for the general occurrence of p-type conductivity of sputtered and evaporated films deposited from n-type source material.

The experiment was designed to obtain a thick n-type film on a p-type substrate, therefore the run was continued for 8 hr, instead of the usual 3-4 hr. When examined, the film unexpectedly showed p-type conductivity. After a few upper layers were removed by flash etching, the film underneath was found to be n-type, indicating that the p-type impurity was incorporated in the layers that were deposited in the latter part of the run. We interpret this to be associated with system outgassing as the temperature of the supporting structures increases. This result would also imply that the chief cause of the generally observed p-type conductivity in films prepared by evaporation and sputtering from n-type sources is due to impurity rather than crystal defects. It should be noted that several of the deposited films during the present investigation showed n-type conductivity, even though they were found to be polycrystalline by x-ray analysis.

The crystalline quality of the films was found to be strongly dependent on sputtering parameters, namely substrate temperature, deposition rate (*i.e.*, the sputtering voltage) and the cleaning voltage. For a particular temperature of the substrate and cleaning voltage, the film may be epitaxial, polycrystalline, or amorphous, depending on the growth rate. At a low growth rate the film is epitaxial, while at an increasing growth rate the film becomes first polycrystalline and then amorphous. Similar dependence of crystalline properties of deposited films on substrate temperature and deposition rate was observed by Krikorian (9) in the case of d-c sputtering.

Films deposited from p-type source always showed p-type conductivity, whether or not the films were single crystal. On the other hand, the films deposited from an n-type source material showed p-type conductivity, unless the temperature and the voltage applied during the cleaning cycle were consistent with the sputtering voltage (*i.e.*, deposition rate). For example the films deposited with the substrate at 400°C and the cleaning voltage of 250v showed p-type conductivity when the sputtering voltage was 3000v. However, when the sputtering voltage was reduced to 2000v, the films deposited at the same substrate temperature and cleaning voltage showed n-type conductivity. Table I shows the highest sputtering volt-

Table I. Highest sputtering voltages at which n-type Ge films were obtained on p-type <111> oriented Ge substrates at various substrate temperatures and cleaning voltages

Substrate temp, °C	Cleaning voltage	Sputtering voltage	Deposition rate, μ/hr	Crystallinity
500	500	3700	1.0	Single
400	250	2000	0.32	Single
400	600	3000	1.1	Single
350	600	3000	0.9	Single
325	600	3000	1.5	Poly
300	600	3000	1.4	Poly

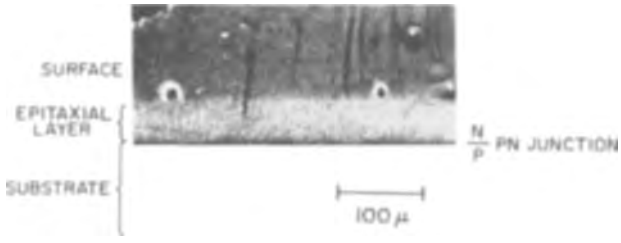

Fig. 4. Appearance of the junction after it was angle lapped and stained with copper.

ages at which n-type films were obtained at various substrate temperatures and cleaning voltages.

The films were examined in several ways to evaluate their properties. To do that, a polycrystalline n-type source doped with 2-3 x 10^{17} atoms/cc of antimony was prepared. Using this source, single crystal n-type films were deposited on p-type substrates.

Under microscopic examination, films deposited on substrates oriented in the <111> direction showed triangular pyramids, as can be seen in Fig. 3. From an n-type layer deposited on a p-type substrate containing 7-9.4 x 10^{18} atoms/cc of impurity, diodes were fabricated by mesa etching. The current voltage characteristics and the differential capacitance of the diodes were measured. A plot of $1/C^2$ *vs.* voltage showed a straight line indicating that the junction was abrupt. Further, from the slope of the straight line, the carrier concentration was estimated at 1.04 x 10^{17}/cc., which was approximately the doping level of the source material. The reverse bias breakdown voltage also agreed with the value calculated from the carrier concentration. To further examine the nature of the junction, a sample was angle lapped and stained with copper. The appearance of the junction at 250X, exhibited in Fig. 4, shows that the junction was fairly sharp. To determine the concentration and the mobility of the carriers, a sample was prepared by depositing n-type film on a 40 ohm/cm p-type germanium substrate oriented in the <111> direction. The previously described source material was used here also. The sputtering voltage, 3000v; substrate temperature, 360°C; cleaning voltage, 600v were used for deposition. A 100 mil square chip of the deposit was diced and contact was made at the four corners. The resistivity and the Hall voltage were measured at liquid nitrogen temperature by using the Van der Pauw method. The mobility and the carrier concentration, calculated from the above measurements were as follows:

$$\mu = 1930 \text{ cm}^2/\text{v sec}$$

$$N = 3 \times 10^{17}/\text{cc}$$

Thus the carrier concentration of the film is approximately equal to the doping level of the source material. This would indicate that in the sputtering process the transfer of material from source to substrate takes place without change of composition.

Fritzschi (10) made Hall voltage and resistivity measurements at liquid nitrogen temperatures on bulk samples with various carrier concentrations. The mobilities calculated from his data for carrier concentrations 2.7 x 10^{17}/cc and 1.3 x 10^{17}/cc are 1810 cm^2/v sec and 3230 cm^2/v sec, respectively, showing that the mobility of the carriers in the sputtered films is similar to that of the bulk material for the same range of carrier concentration. This would indicate that the films obtained by sputtering have fairly good crystalline quality.

Acknowledgment

The author expresses his appreciation to M. Cowher for making the Hall voltage and resistivity measurements and to Dr. F. Fang for differential capacitance data. He also thanks Dr. A. Reisman for his critical reading of the manuscript.

Manuscript received Dec. 2, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

On the Mechanism of the Deposition of Silica by Pyrolytic Decomposition of Silanes

Julius Klerer

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

The mechanism of formation of silica films produced by the thermal decomposition of ethyltriethoxysilane has been studied. It is proposed that the thermal decomposition of the silane results in the production of complex silicon-alkyl radicals which become chemisorbed on a hot surface and suffer further decomposition in order to form a silica film. Recombination of these radicals on a cold surface leads to the formation of organic polymers of silicon. A new technique for the production of thick silica films is also presented.

Thermal decomposition of organo-oxy-silanes has been reported to provide a method for the deposition of thin silica films. Jordan (1) used ethyltriethoxysilane vapor which was passed with argon as a carrier gas into a furnace at ≅ 700°C to accomplish film formation on a sample contained in the furnace at the same temperature. This is a closed tube technique. Klerer (2), utilizing the same experimental arrangement and conditions, allowed the gases from the furnace to contact a sample outside of the furnace in an open tube technique and obtained a film claimed to be silica.

The mechanism of formation of these films has been formulated and their properties measured. It is shown that the films produced by the technique of Jordan are probably pure silica and that those produced by the technique of Klerer are organic polymers of silicon.[1] A new technique for producing silica films is also presented.

Materials and Methods

Ethyltriethoxysilane was obtained from Union Carbide Silicones Division and redistilled to obtain the purified silane. This product was then used as the starting material for all of the investigations. Mass spectrographic analysis of the gases exiting from the furnace during the thermal decomposition of the silane was performed. Gases evolved on heating of the polymer film were also examined by the mass spectrograph. Infrared transmission spectra of both types of films were obtained. Density and refractive index of the films were determined by ellipsometric techniques.

Experiments and Results

Furnace films.—Utilizing the closed tube technique, argon was passed through ethyltriethoxysilane at 1 CFH and then through a furnace maintained at 725° ±5°C. A gas sampling tube was placed at the exit end of the furnace, and gases were allowed to pass through it for a period of 15 min; then the tube was sealed off. The composition of the gases were determined by the mass spectrograph. The principal gases observed and their relative amounts normalized to C_2H_4 were $CH_2 = CH_2$ [1], CH_4[0.75], CO [1], and H_2 [0.49]. Trace amounts of C_2H_6 and C_3H_8 [0.02] were also noted, and essentially no evidence of water was found.

Samples of chemically (CP-4) polished silicon (100 ohm-cm), when placed in the furnace at 725°C, were coated with a film. The infrared transmission spectra of these films were comparable to silica films produced by thermal (1200°C, dry O_2) and steam (975°C) oxidation of similar silicon wafers.

The furnace films, when heated to 825°C in air or in argon, appeared to become denser as evidenced by an increase in refractive index from 1.430 to 1.450. Similar results were reported by Pliskin *et al.* (3). Deposition of the furnace films at 825°C resulted in a silica film with a refractive index of 1.450, and further heat-treatment at 900°C did not result in any further change in the refractive index. Deposition of furnace films above 825°C resulted in cloudy films initially which were followed by whitish and grayish appearing films as the temperature was raised to 950°C.

One deficiency of the furnace films is that, unless they are properly annealed, cracking or crazing of the film occurs when the thickness exceeds 15,000-20,000Å (3). A new technique for depositing silica films was developed to overcome this difficulty. Wafers of silicon were placed on a hot stage at 900°C and ethyltriethoxysilane vapor, carried in a stream of nitrogen, was allowed to impinge on the heated silicon. Formation of a silica layer occurred. The refractive index was determined to be 1.455.

Further heating at higher temperatures did not change this value, and the infrared spectra agreed closely with that of thermally oxidized silicon. At a nitrogen flow rate of 2 CFH and a surface temperature of 800°C, 2000Å of silica were formed per minute. Clear and continuous layers up to 200,000Å have been formed which withstood temperature cycling from 900°C to liquid nitrogen temperature.

Polymer films.—A reinvestigation of the films produced by the open tube technique was initiated in order to characterize them with respect to the other silane decomposition techniques.

Table I. Infrared absorption bands of polymer films

Frequency, cm^{-1}	Intensity	Provisional assignment	Effect of heating on intensity, 300°C, air
3600	W	Free—OH	Appears on heating
3380	S	H_2O, Silanol, —OH	Diminishes
2960	M	$=CH_2$, $CH_2=CH_2$	No change
2880	W	$—CH_3$, $O—CH_3$	Diminishes
2240	M	Si—H	Diminishes
1637	VW	$CH_2=CH_2$, Opal	No change
1460	W	$R—CH_3$, CH Bend	Diminishes
1415	VW	$R—CH_3$, CH Bend	Diminishes
1395	VW	$R—CH_3$, CH Bend	Vanishes
1255	W	$Si—CH_3$, Si—C Bend	Diminishes
1170	SSh	≡Si—O—R, Opal	No change
1065	VS	Si—O stretch, Opal	No change
1013	WSh	Si—O—Si	No change
965	W	—OH deformation	Diminishes
940	W	—OH deformation	Vanishes
880	S	Si—C stretch Si—OH deformation	Diminishes
770	M	Si—O—C $Si—CH_3$	Diminishes and shifts to 800 cm^{-1}

[1] Jordan's silica films will henceforth be called "Furnace" films and the films produced by Klerer will be called "Polymer" films.

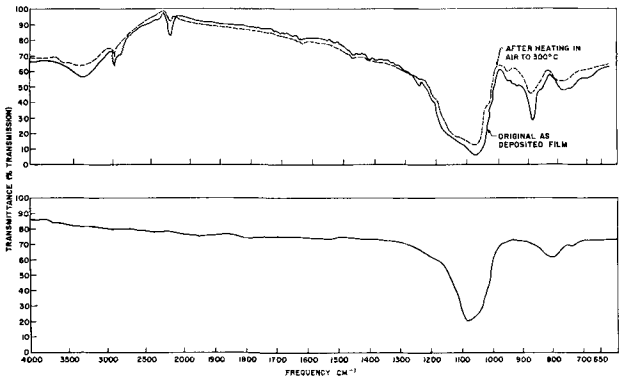

Fig. 1. Infrared spectra of polymer film before and after heat treatment (top) and typical spectra for a furnace produced (750°-825°C) film of silica. Perkins-Elmer model 221 with NaCl prism. Films were deposited on 100 μ-ohm-cm silicon wafers of 0.010 in. thickness. Film thickness was approximately 15,000Å.

Films produced by the open tube process in thicknesses below 3000Å had exhibited infrared transmission spectra similar to the furnace films (2). However, on examination of 15,000Å polymer films, absorption bands were readily observed indicating the presence of $\equiv Si-CH_3$, $\equiv Si-OCH_3$, $\equiv Si-OCH_2CH_3$, $\equiv Si-O-Si\equiv$, $\equiv SiOH$, $\equiv Si-H$, and $\equiv Si-CH=CH_2$ groups as well as bands similar to those in silica gel or opal. Heating of the polymer films above 175°C caused a decrease in magnitude of the absorption bands of $\equiv Si-OH$, $\equiv Si-OCH_3$, $\equiv Si-OCH_2CH_3$, $\equiv Si-H$ and $\equiv Si-CH_3$ with the appearance of some free —OH groups, the remainder of the infrared band structure being unaffected.

Table I lists the principal infrared absorption band positions and provisional assignments together with the change in intensity of the bands on heating of the polymer film to 300°C in air. The particular bands listed appear most frequently in the spectra of polymer films prepared under slightly differing conditions of gas flow and temperature. The principle changes in the spectra are in the different fine structure observed. Figure 1 presents the infrared absorption spectra of a typical polymer film (prepared at 720°C and gas flow of 1 CFH) before and after heat treatment as compared to the spectra obtained from a furnace deposited oxide.

Gases evolved on heating the polymer films were analyzed by the mass spectrograph. The principal gases found were CH_3CH_2OH, H_2, $CH_3CH_2CH_3$, and H_2O. The relative amounts of these gases varied from film to film. Since these gases differed from the thermal decomposition products obtained from the closed tube process, the question arose as to the influence of room air on the polymer film.

A long furnace tube was prepared in which a series wafer was placed from the center of the furnace (725°C) out to the cold exit end (95°C). To prevent back diffusion, the exit from the tube was arranged to bubble through silicone oil. On admitting the ethyltriethoxysilane and argon mixture, film formation was observed on those wafers in the temperature zone between 600°-725°C and on those wafers in the zone between 250°-95°C. The films formed at 600°-725°C were identical to the furnace films, and the films formed between 150° and 95°C were found similar to the polymer films by means of infrared spectral analysis and dissolution behavior in hydrofluoric acid solution. No film formation was observed on substrates in the temperature range between 250° and 600°C. The formation of polymer films in this controlled atmosphere indicated that the gases evolved on heating of the polymer film come from the structure of the film rather than the environment of deposition.

The effect of substrate temperature on the film formed utilizing the open tube technique was investigated. An open furnace was set up so that the gases exiting from the tube would impinge on substrates mounted on a hot stage. During the course of these experiments, the gas flow and temperature in the furnace were constant at 1 CFH and 720°C. Films were deposited on silicon wafers at room temperature to 700°C in 50° steps. No film deposition occurred in the temperature range 250° to 500°C. In addition, the rate of growth of the films decreased as the temperature of the substrate was raised to 250°C, no growth of the film occurred between 250° and 500°C, and then the rate of growth increased from 500° to 700°C. The films deposited in the range of room temperature to 250°C were identical to the polymer film, and the films deposited from 500° to 700°C were similar to the furnace coating.

One of the characteristics of the polymer film in contrast with the furnace film is that in thicknesses $>$ 20,000Å it will crack or spall off silicon or germanium surfaces when heated to $\cong$ 250°C. This can be attributed to a change in density and bonding characteristics upon heating the film to 250°C. Table II presents the results obtained on these films before and after heating together with data obtained for silica films produced by the different techniques.

Discussion of Results

Thermal Decomposition Mechanism

The thermal decomposition of metal alkyls of the type MR_X has been shown to result in the production of free radicals (6). In some cases, besides the normal formation of alkyl radicals, metal alkyl radicals have been proposed to explain the order of the reaction and to justify the end products of the decomposition. One such example is the thermal decomposition of silicon tetramethyl, $Si(CH_3)_4$, in which free radicals such as $Si(CH_3)_3$ and $Si(CH_3)_3CH_2$ have been proposed in the reaction mechanism.

A tentative mechanism for the thermal decomposition of ethyltriethoxysilane can be arrived at by a consideration of both the bond structure of the silane, $(CH_3CH_2)Si(OCH_2CH_3)_3$, and the gaseous products evolved during the decomposition; namely, C_2H_4, CO, CH_4, H_2, and traces of C_3H_8 and C_2H_6. The bond energies involved in the ethyltriethoxysilane would be as follows: Si—O (108 kcal); Si—C (60 kcal); C—O (86 kcal); C—C (83 kcal); C—H (96 kcal) (7). As the temperature is raised, it would be expected that initial bond rupture would occur in the group $\equiv Si-CH_2CH_3$ followed by attack on the group $\equiv Si-OCH_2CH_3$ to give the following possibilities: $(CH_3CH_2O)_3Si(CH_2CH_3)$

$$\rightarrow (CH_3CH_2O)_3Si + CH_3CH_2$$

$$\rightarrow (CH_3CH_2)Si(CH_3CH_2O)_2O + CH_3CH_2$$

$$\rightarrow (CH_3CH_2)Si(CH_3CH_2O)_2 + CH_3CH_2O$$

Table II. Properties of silica films prepared by different techniques*

Technique	Refractive index	Density	Dissolution rate in 1.8M HF, Å/sec
Thermal (dry O_2)	1.450	2.23 ± 0.02	3.3
Steam (high pressure)	1.475	2.32 ± 0.02	3.7
Anodic	1.362	1.80 ± 0.05	360.0
Furnace	1.430	2.14 ± 0.07	48.0
Furnace (after heating to 825°C)	1.450		12.0
Polymer	1.430	1.63 ± 0.04	550.0
Polymer after heating at 250°C	1.390	1.9 ± 0.02#	1200.0

* Measurements made by R. J. Archer and Miss R. E. Cox of these Laboratories.

Calculated from observed volume decrease of 30.6 ± 1.5% and weight decrease of 12.8 ± 4.1%.

Other conceivable reactions could, and quite possibly do, occur, but these shown are sufficient to justify the final products observed. The alkyl free radicals produced from the proposed reactions can then react further in the following well-known manner (6):

$$CH_3CH_2 \rightarrow CH_2{=}CH_2 + H$$

$$CH_3CH_2O \rightarrow CH_3CO + H_2$$

$$CH_3CO \rightarrow CH_3 + CO$$

$$CH_3 + H \rightarrow CH_4$$

$$2CH_3 \rightarrow CH_3CH_3$$

$$CH_3 + CH_3CH_2 \rightarrow CH_3CH_2CH_3$$

Although the formation of the gaseous products observed can be explained by these equations, the relative amounts found did not fit any stoichiometric relations that could be derived from these free radical processes.

The radicals such as R_3Si or R_2—Si—O where R can be CH_3CH_2— or CH_3CH_2O— should exist in the gas phase. These can combine with the radicals previously proposed or with themselves to condense out on cooler portions of the apparatus to form polymer films. This can be illustrated in the experiments, where a series of wafers were placed in the closed furnace. Polymer coatings were obtained at the cooler exit end of the furnace tube. In the hot zone of the furnace, the radicals were further decomposed, forming a silica coating.

The over-all reaction for the thermal decomposition of ethyltriethoxysilane can be simply stated as

$$(CH_3CH_2)Si(CH_3CH_2O)_3 \rightarrow \left[\begin{array}{l}\text{complex}\\ \text{silicon}\\ \text{alkyl radical}\end{array}\right] + CH_2{=}CH_2 + CH_4 + CO + H_2$$

Mechanism of Furnace Film Formation

In the hot zone of the furnace (600°-850°C) the complex silicon alkyl radicals in the gas phase can now proceed to build up silica layers. Radicals such as R_3Si or R_3Si—O can associate with a metal surface by attachment of the —O atom to the metal, or through the —Si atom coupling to a surface oxide by bonding with an oxygen atom. The organic fractions of the radical then can be thermally cracked to form new bonds to repeat the process, and film formation would continue to occur.

The changes in refractive index and etch rate of these films on heating suggest the presence of organic groups in the film. For films formed below 825°C, these groups can be removed by heating to >825°C. Deposition of the film at 825°C appears to result in organic free silica coatings. The presence of these organic groups in the silica films deposited below 825°C probably cause the crazing of the thicker films (>15,000Å), since they can alter the bonding characteristics and/or structural arrangement of the film. This can thus result in poor stress or strain release leading to discontinuous films. The thermal treatment of the film *in situ* (>825°C) results in producing thick craze-free films and is attributed to densification of the film (3).

The question of whether organic groups are occluded in the film or really part of the structure can be resolved by observations made on films which were deposited on the hot stage at ≧ 800°C. The hot stage technique illustrates direct thermal surface decomposition, with minimum chance for entrapment of gases. At temperatures below 800°C on the hot stage, films containing organic grouping were produced, implying that these organic groups are not occluded or entrapped in the film but are still attached to the silicon atom. If this is the case, it would lend supporting evidence to the existence of radicals such as those mentioned earlier in this section.

Mechanism of Polymer Film Formation

It is not surprising that the mechanism of film formation of the furnace and polymer films should differ. In one case, the silane is being thermally decomposed with simultaneous deposition on a hot surface, and in the other case the silane is being thermally decomposed and then deposited on a relatively cold surface. The difference in properties of these films is shown in Table II.

The behavior of the deposition rate of the polymer film on surfaces which were at different temperatures can be explained by the following mechanism.

The ethyltriethoxysilane is decomposed in the furnace to organic gas residues and the complex silicon alkyl radical. This radical emerges from the furnace tube and contacts a surface. There it undergoes physical adsorption and when another radical attachment occurs in its proximity, crosslinking can occur. Repetition of this process would lead to thicker and thicker layers. This process requires a finite time for the radical to remain on the surface until another radical approaches. As the temperature of the surface is raised, more kinetic energy is imparted to these radicals, and they tend to spend a shorter time on the surface, thus decreasing the probability of crosslinking with another radical landing nearby. Since there is probably a Boltzmann distribution of energy in the particles emerging from the open furnace, there should be a decrease in deposition rate as the temperature of the surface is raised because the more energetic particles spend less time on the surface. Ultimately, when the temperature is raised to a point such that the hot surface imparts sufficient kinetic energy to the least energetic radicals, sufficient physical adsorption on the surface cannot occur and deposition ceases. This situation remains in effect until 500°C is reached.

At this and higher temperatures, it is proposed that a chemisorption mechanism is initiated since there is now enough energy available so that bonding between the radical and the surface can occur. Initially, the more active sites on the surface react and then as the temperature is raised, more sites come into play until rapid formation of a coating occurs. After the first monolayer is complete, the other radicals can link up with this monolayer, etc. These coatings are similar to the furnace films, and essentially the same mechanism occurs there, namely, radical attachment to the surface and subsequent cracking of the radical to produce new bonds for further growth of the oxide.

The film layers deposited at the lower temperature must be organic polymers of silica. From the proposed mechanism presented on the thermal decomposition of ethyltriethoxysilane, the formation of a complex silicon alkyl radicals plus radicals such as CH_3CH_2, CH_3CH_2O, H, CH_3, and CH_3CO occurs in the heated zone of the furnace. As these radicals exit from the furnace, they can recombine on cooling on surfaces to form bonds such as ≡Si—CH_3, ≡SiOCH_3, ≡Si—OH and also to cross link on the surface to form polymers of varying lengths and linkages intermixed with small silica groupings. The low density and high dissolution rate of the polymer film demonstrates a fairly open network in the film. Its refractive index indicates that SiO_2 groupings are present in large concentration.

On heating, the film undergoes a shrinkage and rearrangement leading to a higher density. This shrinking and rearrangement are due to condensation and elimination reactions between neighboring silane groupings to eliminate H_2O, CH_3CH_2OH, H_2, and $CH_3CH_2CH_3$. The higher dissolution rate is due probably to increased porosity with change in structure. The decrease in refractive index serves to demon-

strate that a more open network was present. The films, however, remain coherent on heating at thicknesses less than 15,000Å, and their similarity in chemical properties to silica makes them an attractive coating for use in applications where high-temperature processing is not a factor.

Summary

It has been proposed that the thermal decomposition of ethyltriethoxysilane on a hot surface to form a continuous, amorphous, silica film is essentially a free radical process, involving an initial chemisorption on the surface. The chemisorbed radical suffers further thermal decomposition resulting in the formation of new bonds for attachment to other radicals, thus building up the layer.

Recombination of thermally produced radicals on a cold surface results in an organic polymer of silicon, which exhibits some of the properties of pure silica.

Thermal decomposition of silanes on a hot surface in air has been demonstrated and leads to a technique for growing thick films of pure silica.

Solid and Liquid Phase Miscibility of Calcium Metal and Calcium Fluoride[1]

Barry D. Lichter[2] and M. A. Bredig

Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

ABSTRACT

The solubility of Ca in solid CaF_2 was determined by vapor phase equilibration in the temperature range 1060°-1265°C in which it rises from 0.4 to approximately 2 mole %. This solubility is considered in an analysis of the melting point depression of CaF_2, which suggests that the ionization. $Ca^{++} = + 2e^-$, takes place in dilute solution. The equilibrium $2Ca^{++} + 2e^- \leftrightharpoons Ca_2^{++}$ is shifted toward the right, *i.e.*, molecule ion formation, by increasing metal concentration. Literature data for liquid solutions are reinterpreted in terms of complete miscibility of Ca and CaF_2 in the liquid state.

In studies of the phase equilibria and electrical conductance of one type of molten metal halide-metal system, the assumption has been made (1) that in dilute solutions the metal dissolves by being ionized in the ionic medium according to $M = M^{z+} + ze^-$. At higher concentrations, evidence was found (1, 2) in some systems of association of the electrons to form molecules or molecule ions such as Na_2 or $(Ca_2)^{2+}$. The latter species was thought by Rogers, Tomlinson, and Richardson (3) to exist even in dilute solutions of Ca in CaF_2; but in order to support this hypothesis, a heat of fusion of CaF_2 as high as 10 kcal/mole rather than 7.1 kcal/mole measured calorimetrically (4), as well as insolubility of calcium and of NaF (5) in solid CaF_2, has to be assumed. Since evidence for a rather unexpectedly high solubility of Ca in solid CaF_2 existed in the literature (6), determination of the true extent of such solid solution was made the objective of the work reported below.

Experimental Procedures and Results

Materials.—Calcium fluoride was in the form of large, high-purity, optical quality crystals (Harshaw).

Calcium metal (Nelco Metals, Inc.) was in the form of redistilled pellets (metallic impurities in ppm: 800 Mg, 5 Fe, 6 Mn, 40 Ni, and 10 Al). The calcium was kept under argon in a metal can with a tight-fitting lid. Attempts were made to select pellets having a minimum of surface oxide.

Armco iron crucibles (impurities in ppm: 80 C, 260 S, 90 P, 500 O, and 6 N) were used to contain Ca and CaF_2 during experimental runs.

High-temperature equilibration.—Experiments consisted of high-temperature annealing of CaF_2 crystals in an atmosphere of Ca vapor, followed by moderately rapid quenching to room temperature (100° min^{-1} initial cooling rate). The pressure of the Ca vapor was established as the equilibrium calcium vapor pressure of a saturated solution of CaF_2 in molten Ca metal at the experimental temperature.

Figure 1 shows the arrangement of materials in the iron crucible. The bottom compartment was charged

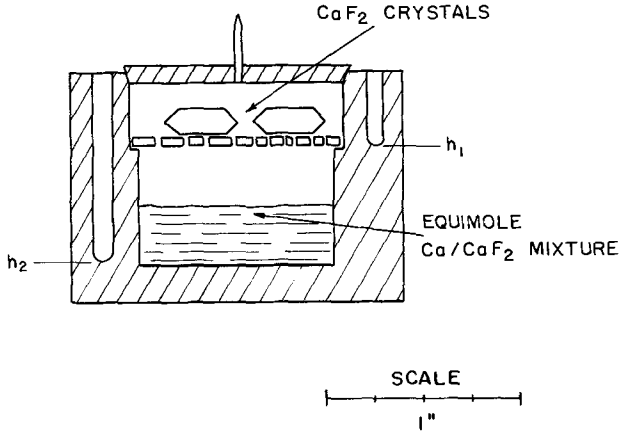

Fig. 1. Crucible assembly for high-temperature equilibrium.

[1] Research sponsored by the United States Atomic Energy Commission under contract with the Union Carbide Corporation.

[2] Present address: Division of Metallurgical Engineering, University of Washington, Seattle, Washington.

with a 2-3g approximately equimolar mixture of Ca pellets and CaF_2 powder. At the equilibration temperature, this mixture formed a saturated solution of CaF_2 in liquid Ca according to the phase diagram of Rogers, Tomlinson, and Richardson (3). The top compartment contained 2-5g of CaF_2 in the form of 2-8 mm thick platelets cleaved from a single crystal. The platelets were supported on a thin iron partition in which were drilled a number of small holes. The average composition of the combined systems varied in different runs from 0.2 to 0.5 mole fraction calcium, N_{Ca} = g atoms Ca/(g atoms Ca + moles CaF_2). Several experiments were attempted with the partition removed and the CaF_2 crystals in contact with the Ca-CaF_2 mixture. However, these experiments resulted in erroneously high values for the solubility of Ca, due to pitting-type attack of CaF_2 crystals by the melt. This phenomenon is discussed further below.

The lid was fusion-welded to the crucible in an inert gas dry box. The crucible was evacuated through a tube in the lid to a pressure of $<10^{-5}$ mm Hg, and the tube was crimped and welded shut. The crucible was contained in the furnace in a closed Inconel tube under 2 atm pressure argon, and the temperature was controlled with two Pt/Pt-10% Rh couples in series, using a L&N Micromax controller. The temperature was measured at positions h_1 and h_2 (Fig. 1) using Pt/Pt-10% Rh thermocouples. The variation of either couple during a run was $<\pm 1°C$. However, the measured temperature difference between h_1 and h_2 could not be reduced below $\pm 5°C$ at temperatures between 1060° and 1260°C.

The time to establish equilibrium was determined from results of duplicate runs and from results obtained with crystals of varying thickness in a given run.

Microscopic evidence for true solid solubility at elevated temperature.—Quenched CaF_2 crystals were translucent, appearing gray or rose-brown in color. However, crystals which were in contact with the melt were green. Microscopic examination under transmitted light revealed the following structures shown in Fig. 2:

(*a*) Metallic particles ranging from 1 to 10μ diameter were uniformly distributed in the crystal matrix.

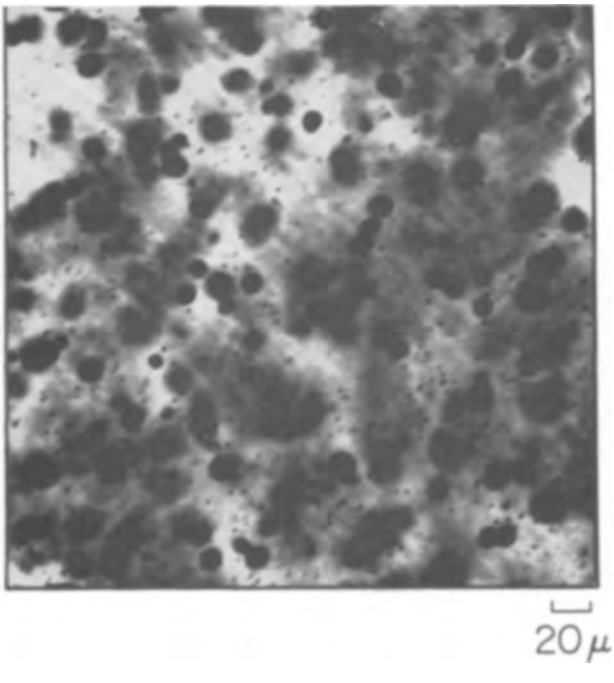

Fig. 2a. Structure of quenched CaF_2 crystals; Sample equilibrated through the gas phase.

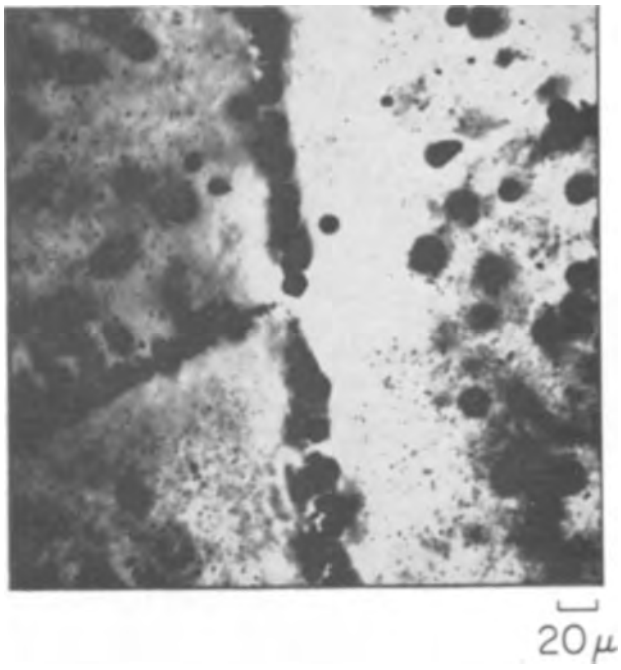

Fig. 2b. Sample equilibrated through the gas phase

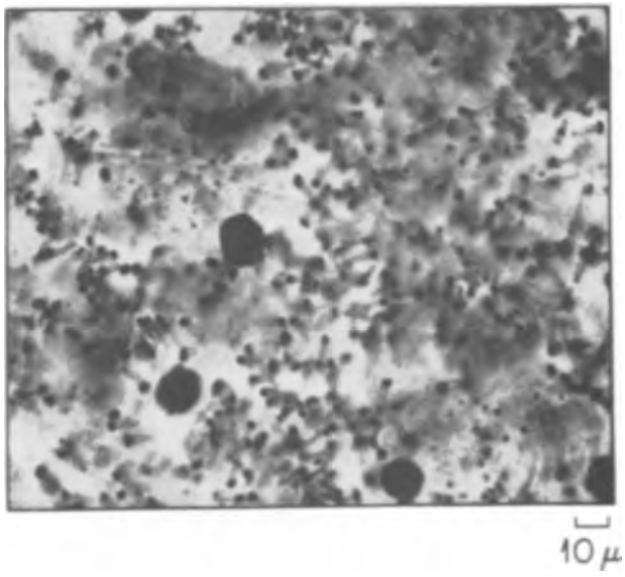

Fig. 2c. Sample in contact with the melt

The presence of submicroscopic colloidal particles was also indicated by the muddy appearance of the matrix.

(*b*) At certain locations in the crystal, presumably low-angle grain boundaries, the particle density was unusually high, while in immediately adjacent areas the particle density was low.

(*c*) Green crystals contained a larger amount of colloid as evidenced by lower transparency. In addition, a network of fine pits could be resolved at higher magnification.

The existence of isolated spherical particles in the single crystal matrix suggests that during quenching a true precipitation from saturated solid solution occurred, where the precipitating phase is a liquid. Areas of high particle density as shown in Fig. 2b are consistent with precipitation at preferential sites. However, for crystals in contact with the melt, dissolution of calcium in the crystal and dissolution of the crystal in the melt can occur simultaneously. Attack of the crystal presumably took place via the formation of small pits (Fig. 2c) which served to entrap excess calcium. The metallic content of green crystals was found to be about twice that of crystals equilibrated through the gas phase, and, in general, the results of

Table I. Solubility of calcium metal in solid CaF_2 between 1060° and 1265°C

Run No.	t, °C	N_{Ca} (s) × 100	Annealing time, hr	Sample thickness, mm
13	1265	1.70	42	8.2
12	1215	1.55	86	8.6
11	1175	1.00	51	6.4

5	1060	0.42	65	7.4

calcium analysis were less reproducible for green crystals.

Determination of excess calcium in quenched CaF_2 *crystals.*—Quenched crystals were ground to a fine powder, leached with distilled water, and the resulting solutions titrated against standard HCl and NaOH solutions. The amount of metallic calcium present was calculated from the measured basicity of the solutions on the reasonable assumption that, with the moderate quenching rate used, a negligible amount of calcium remained in supersaturated solid solution at room temperature.

No basicity was detected in crystals used in control experiments for which calcium was omitted from the crucible during high-temperature annealing. Crystals from the control experiments were transparent, uncolored, and free of any precipitate. Several additional sources of error were considered and evaluated as follows:

(*a*) Chromatographic analysis of the gas evolved from a sample during leaching revealed only hydrogen, and the calculated calcium content agreed to within 5% with results from the titration, thus ruling out significant contamination from soluble impurities (P, S, N, and O).

(*b*) Before grinding, quenched crystals were washed in distilled water. Titration of the wash water revealed less than 1% of the calcium present in the crystal, thus ruling out errors from calcium condensed on the crystal surface during quenching.

(*c*) The major possible source of error was found to be incomplete dissolution of colloidal calcium during leaching. The procedure adopted was to grind the crystal in a known volume of standard HCl solution, back titrate the mixture with NaOH, reacidify, regrind the mixture, and repeat the titration. After 5-10 grindings no subsequent calcium dissolution was detected.

Results are summarized in Table I. The partial and total phase diagrams for the system CaF_2-Ca are shown in Fig. 3 and 4 which include most of the data of Rogers *et al.* (3).

Discussion

Comparison with previous studies of phase equilibria in the system CaF_2-Ca.—The existence of solid subhalides (*e.g.*, CaF) in alkaline earth metal-metal halide systems as reported by Wöhler and Rodewald (7) has not been confirmed by more recent investigations (3,8,9). In particular, the main features of the system CaF_2-Ca were recently determined by Rogers *et al.* (3), and the results pertinent to the present discussion are given in Fig. 3, 4, and 5. These authors did not determine the solubility of calcium in solid CaF_2; however, their observations do not support the exceptionally high solubility previously reported by Mollwo (6). Mollwo's results are based on (*a*) optical absorp-

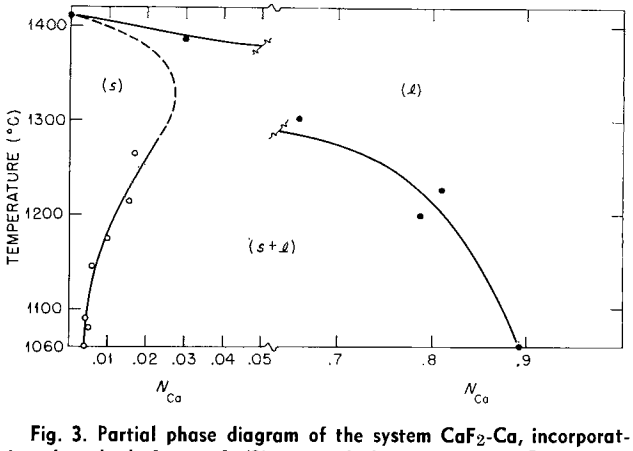

Fig. 3. Partial phase diagram of the system CaF_2-Ca, incorporating data both from ref. (3), •, and the present work, ○.

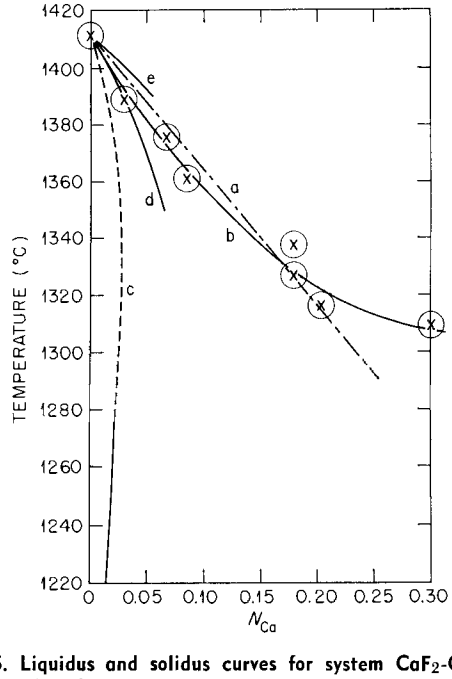

Fig. 5. Liquidus and solidus curves for system CaF_2-Ca: a, experimental liquidus, after Rogers, Tomlinson, and Richardson (3); b, experimental liquidus proposed by Lichter and Bredig for data of ref. (3); c, solidus; d, ideal liquidus, $T = T_m - (2\,RT_m^2/\Delta H_m)(N_{Ca}(l) - N_{Ca}(s))$ for $Ca \rightarrow Ca^{++} + 2e^-$; e, ideal liquidus, $T = T_m - (RT_m^2/\Delta H_m)(N_{Ca}(l) - N_{Ca}(s))$ for $Ca + Ca^{++} \rightarrow Ca_2^{++}$. Note identity of curves b and d for $N_{Ca}(l) < 0.02$ and increasing positive deviation of b from d at higher metal concentrations.

tion measurements of samples annealed in calcium vapor at 450°-600°C and then quenched; (b) measurements at 600° and 800°C of the velocity of color centers produced by application of a strong electric field; and (c) measurements of pycnometric density of samples annealed in calcium vapor at ~1000° and ~1100°C and then quenched. These results are an order of magnitude greater than the results of the present work which are felt to be accurate to ±10%. This disagreement is difficult to explain without further experimental details of Mollwo's measurements. In particular, microscopic observations of quenched samples used in optical absorption and density measurements are lacking, and the absence of colloidal calcium in quenched samples is not confirmed.

It will be noticed that in our diagrams we have rejected the notion of the existence in this system of a monotectic reaction and consequently of a consolute or critical solution temperature. The opposite conclusion reached by Rogers, Tomlinson, and Richardson, namely, that between 1290° ± 5° and 1322° ± 10°C equilibria between two liquid phases exist is not supported by their experiments. The new interpretation of these data is necessary because no thermal effect at the alleged monotectic temperature of 1290° was obtained for any of the six compositions below 20 mole % Ca that were studied. Particularly on heating, the differential thermal analysis would have shown a monotectic reaction, if present, even more distinctly than the liquidus. That the sensitivity of the method used was satisfactory is attested to by the appearance of the corresponding eutectic effects even in these mixtures containing relatively little Ca metal which also has a lower heat of fusion than CaF_2. Furthermore, the thermal effects which Rogers, Tomlinson, and Richardson reported for three compositions within the range of the alleged liquid-liquid reaction, namely, 29, 45, and 65 mole % Ca cannot possibly have been caused by this reaction which is characterized by a very small enthalpy change (or, more correctly, a very small change in the heating or cooling rate) while the far greater enthalpy change of a monotectic reaction remained unrecorded in these three and six additional compositions mentioned above. There can be no doubt that actually all five of the observed thermal effects within the alleged liquid-liquid separation range involved solid CaF_2 (liquidus curve), with a scattering of ±12°C which is actually less than two thirds the scattering (±20°) of the three points between 75 and 95 mole % Ca. (One notes that the scattering increased greatly in going from the salt-rich to the metal-rich ranges of the phase diagram, namely, from ±2° to ±20°. This may be at least partly connected with a parallel increase in the tendency to phase segregation during the quenching operation carried out by Rogers *et al.* before each differential thermal analysis run.)

The results reported by Rogers *et al.* as "solubility" from another series of experiments designed to preserve the alleged liquid-liquid equilibria by quenching are subject to grave doubt because of the inherent faults of the method that were pointed out by the authors themselves as well as one of us (Bredig); thus, they cannot be included in the discussion (two of the experimental solubilities, those at 1303°C, show deviations of as much as 16 and 31%).

With the new interpretation, the CaF_2-Ca system represents the first metal-halide pair outside of the alkali metal systems (Cs-CsX and Rb-RbBr) to exhibit complete salt-metal miscibility in the liquid state, *i.e.*, absence of liquid-liquid phase equilibria. In comparison with the other calcium metal-halide systems, this is to be ascribed principally to the high melting point of the fluoride. However, the shape of the liquidus is characteristic of a large deviation from Raoult's law and of a more than incipient tendency toward formation of two liquid phases.

Analysis of freezing point depression of CaF_2 by calcium.—The finding of limited solubility of calcium metal in solid CaF_2 gives rise to a modification of the interpretation of the liquidus curve advanced by Rogers *et al.* (3). In the other CaX_2-Ca systems (X = Cl, Br, I), Dworkin, Bronstein, and Bredig (1, 9) have interpreted the observed melting point depression of CaX_2 by Ca and the electrical conductivity of dilute solutions in terms of the dissociation (ionization) of Ca metal in the highly ionized medium which the molten salt represents, *i.e.*, according to $Ca = Ca^{++} + 2e^-$. The electrons are thought of as anion- or color-centerlike species (2, 10-12). With increasing metal (or electron) concentration, the reaction $2e^- + 2Ca^{++} = (Ca_2)^{++}$ was assumed to progress toward the right, *i.e.*, the formation of a molecule ion resembling somewhat in electronic structure the $(Cd_2)^{++}$ and $(Hg_2)^{++}$ ions and especially the Na_2 molecules proposed earlier for the NaX-Na systems (2). If one assumes that in dilute solutions Ca dissolves in the liquid phase in a similar manner as in solid CaF_2, namely, according to $Ca = Ca^{++} + 2e^-$, with electrons substituting in "ideal" mixtures for F^- ions, one obtains for the activity of CaF_2 in both the solid and liquid phases

$$a_{CaF_2} = X_{Ca++} \cdot X_{F-} \qquad [1]$$

where the Ca^{++} cation fraction = $X_{Ca++} = 1$ and the F^- anion fraction

$$X_{F-} = \frac{n_{F-}}{n_{F-} + n_{e-}} = \frac{2n_{CaF_2}}{2n_{CaF_2} + 2n_{Ca}} = N_{CaF_2}$$

Therefore

$$a_{CaF_2} = X^2_{F-} = N^2_{CaF_2} \qquad [2]$$

and the equation for the melting point depression becomes

$$T - T_m = \Delta T =$$

$$\frac{RT_m^2}{\Delta H_m} \cdot \ln \left(\frac{a^{(l)}_{CaF_2}}{a^{(s)}_{CaF_2}} \right) = \frac{RT_m^{\,2}}{\Delta H_m} \cdot 2 \ln \frac{N^{(l)}_{CaF_2}}{N^{(s)}_{CaF_2}} \qquad [3]$$

Thus, the melting point depression, ΔT, is proportional to twice the difference in the logarithms of the mole fractions of CaF_2 in the liquid and solid phases. At low concentration of Ca, $\ln N_{CaF_2} = (N_{CaF_2} - 1) = -N_{Ca}$, and Eq. [3] can be written

$$\Delta T = -\frac{2RT_m^2}{\Delta H_m} \left(N^{(l)}_{Ca} - N^{(s)}_{Ca} \right)$$

$$= -\frac{4 \times (1684)^2}{7100} (\Delta N_{Ca}) = -1600 \cdot \Delta N_{Ca} \qquad [4]$$

Figure 5 shows that it is possible at temperatures near T_m, *i.e.*, at small concentrations of calcium metal, to reconcile the experimental results obtained for the liquidus by Rogers *et al.* (3) and the estimated solidus from the present work with this equation: At T approximating T_m, curve d, the ideal liquidus corresponding to $Ca = Ca^{++} + 2e^-$ and to

$$T = T_m - \frac{2RT_m^2}{\Delta H_m} \left(N^{(l)}_{Ca} - N^{(s)}_{Ca} \right) \qquad [5]$$

with estimated $N_{Ca}(s)$ from curve c, approximates curve b, the curve drawn by us through the experimental point from ref. (3). At higher metal concentrations in the liquid phase, there occurs strong positive deviation from Raoult's law as one might expect with limited miscibility in the liquid phase and/or increasing reaction according to

$$2e^- + 2Ca^{++} = (Ca_2)^{++}$$

i.e., interaction and trapping of pairs of anion of F-centerlike electrons in the form of molecule ions.

Summary

1. Contrary to reports in the literature, solid CaF_2, in equilibrium with the calcium vapor over a saturated solution of CaF_2 in liquid calcium metal, dissolves near 1330°C a maximum of approximately 2.7 mole % calcium metal.

2. The depression of the melting point of CaF_2 by low concentration of Ca can be interpreted in terms of a solidus as estimated from the measurements and of the known calorimetric heat of fusion, with the assumption that the solution mechanism in the solid is the same as in the dilute liquid phase, namely, $Ca \rightarrow Ca^{++} + 2e^-$ (F centerlike electrons). With increasing metal concentration, the dissolution of calcium metal in molten CaF_2 follows $Ca + Ca^{++} \rightarrow (Ca_2)^{++}$, or $2Ca^{++} + 2e^- \rightarrow (Ca_2)^{++}$ to an increasing degree. The ionization according to $Ca \rightarrow Ca^{++} + 2e^-$ is thus believed to be similar to that in the calcium metal solutions in the three other CaX_2 melts (X = Cl, Br, I) where such ionization is supported by electrical conductance data.

3. The CaF_2-Ca system is the first metal-halide system outside of the alkali metal systems to exhibit complete metal-salt miscibility in the liquid state, *i.e.*, absence of liquid-liquid phase equilibria.

Some X-Ray and Thermoelectric Studies on Cubic Th_3X_4 Compounds

C. E. Price[1] and I. H. Warren

Department of Metallurgy, The University of British Columbia, Vancouver, British Columbia, Canada

ABSTRACT

Measurements of thermoelectric power and electrical conductivity have been made up to 950°C on Th_3P_4, Th_3As_4, Th_3Sb_4, and $Th_3(AsSb)_4$ solid solutions. Thermal conductivity data have been obtained near 30°C. X-ray and density measurements suggest that the compounds are stoichiometric.

A previous paper (1) indicated that Th_3As_4 may have interesting thermoelectric properties with a figure of merit comparable to the more widely investigated isostructural compound $Ce_{3-x}S_4$. It was shown that compounds having either n- or p-type properties could be prepared, and that appreciable quantities of Fe, Co, Ni, CaS, and BaS could be taken into solution. This investigation was limited by the purity of the thorium available (99%) and the presence of ThO_2 as a major contaminant in the products. The present study, using three grades of thorium metal and an improved preparational technique, reports thermoelectric and x-ray data on Th_3P_4, Th_3As_4, Th_3Sb_4, and $Th_3(AsSb)_4$ solid solutions.

Experimental

Materials.—Three grades of thorium were used: 99.0% metal from Dominion Magnesium Limited, 99.9% metal from Lindsey Chemical Corporation, and 99.99+% metal from Leytess Metal Corporation. All metals were received as fine powders; the Dominion and Leytess samples had been packed in sealed containers under an inert atmosphere. They were opened and stored in an inert gas glove box. A typical analysis quoted by the suppliers for Leytess metal, in ppm, was: oxygen, 30; nitrogen, 20; hydrogen, 5; carbon, 20; aluminum, 5; copper, 10; iron, 25; and all others, ±2. Iron was also the main metallic contaminant in the other thorium powders. Arsenic and antimony of 99.999% purity were obtained from Consolidated Mining and Smelting Company. The 99.9% purity phosphorus was from the Fisher Scientific Company.

Preparation of compounds.—The compounds Th_3P_4, Th_3As_4, and Th_3Sb_4 were prepared by heating the constituents together in sealed and evacuated Vycor or quartz capsules. Quantities of 20g were made at a time, the elements being weighed to within 0.002g of that required stoichiometrically by the formula. The heating rates were critical for a too rapid increase in temperature led to a violent exothermic reaction which fragmented the capsules. The samples of phosphide, arsenide, and antimonide were heated over a period of 100 hr to 450°, 620°, and 900°C, respectively. For the arsenide it proved essential to maintain the temperature below 350°C for the first 30 hr. No attack of the containers was observed. The capsules were opened, and the products (fine gray powders) stored in the

[1] Present address: Mackay School of Mines, University of Nevada, Reno, Nevada.

glove box. Attempts to prepare a compound Th_3Bi_4, isostructural to the known compound U_3Bi_4, were unsuccessful.

Fabrication.—Cylindrical compacts 0.9 cm in diameter and 1-2 cm long were prepared by hot pressing with induction heating, and under a helium atmosphere. Graphite dies and plungers were used, loading taking place in the glove box. During the heating cycle a pressure of 5000 psi was maintained continuously. The heating rates were approximately 150°/min. Temperature measurement was by a W- W/26% Re thermocouple placed down a 0.3 cm hole drilled almost to the bottom of the upper plunger. In some instances a molybdenum sleeve was used to separate the sample from direct contact with the carbon of the die. When solid solutions were prepared the powders were mixed beforehand in a mortar. Prior to the measurement of properties, the outer layers of the samples were ground away.

Analyses.—X-ray measurements, using a diffractometer in conjunction with a Geiger counter and chart recorder, were made on the powders and compacts. The powders were imbedded in a flat surface of vacuum grease to prevent oxidation. For angles greater than about 22° it was possible to separate the two peaks of the α_1-α_2 doublet in the CuK_α radiation used. Less than about 2% of ThO_2 (or a second phase) could not be detected by this method, but from metallographic examination it was estimated, through comparison with contaminated samples, that 0.1% of ThO_2 would be visible readily. In contaminated samples ThO_2 occurred as small white particles. Representative compacts were chemically analyzed to determine the thorium-arsenic ratios and carbon contents. Analyses for dissolved oxygen were not made because of ease of atmospheric contamination.

Property measurement.—Densities were measured by immersion in CCl_4. Thermal conductivity values (K) were obtained near room temperature by simultaneous absolute and comparative steady-state methods. Temperature gradients of near 10°, 20°, and 30°C were in turn maintained across the sample held under a vacuum of 10^{-5} mm Hg. Temperature measurements were made with copper-constantan thermocouples cleated into copper at each end of the sample. Indium amalgam was used to minimize thermal contact resistances (2). Agreement and reproducibility were to within 5%. Thermoelectric power (α) with reference to copper was determined from liquid nitrogen temperatures to near 1000°C *in vacuo*, using a 10°-20°C/cm temperature gradient. Electrical conductivity results (σ) of reproducibility to within 3% were obtained using stainless steel probes pressed against a side of the compact. These measurements have been described in more detail elsewhere (3).

Results and Discussion

The compacts which were all of a silver gray color tarnished very readily in air, dark surface films forming on antimonides and phosphides within 5 min. Although all measurements were done *in vacuo*, some exposure to air proved unavoidable during transfer and assembly. However, exposures of up to 1 hr appeared not to change the results. Samples placed clean and shiny in the apparatus showed a dark surface film after the high-temperature measurements. No reaction occurred with the copper end pieces. The materials were weakly diamagnetic.

Dense Th_3P_4 compacts could not be prepared, for on heating between 1200° and 1600°C the compound gradually decomposed giving the mono form. Th_3As_4 was stable up to 2050°C, densification started near 800°C and appeared to be complete by 1500°C. With Th_3Sb_4 a liquid phase appeared at about 1600°C, but dense compacts could be obtained at 1400°C.

X-ray measurements on the powders gave results, in Å ± 0.0005, of Th_3P_4 8.6530, Th_3As_4 8.8548, and Th_3Sb_4 9.3659. These figures differ slightly from the solely reported data of 8.617, 8.843, and 9.372, respectively, summarized by Pearson (4). Attempts to vary the 3Th:4X ratio of arsenide and antimonide compacts failed; monocompound formation or anion deposition on the fabrication container occurred with all arsenide and antimonide compacts exhibiting the same lattice spacing. With Th_3P_4 compacts the lattice spacing appeared to vary in the range 8.630-8.654Å; however, our inability to get dense compacts free of ThP precludes any conclusions in this instance. In the isostructural compound $Ce_{3-x}S_4$, however, the lattice size was reported to vary only slightly from 8.6250Å ($x = 0$) to 8.6347Å ($x = 1/3$), but this led to a density drop from 5.68 to 5.18 gm cc^{-1} as x went from 0 to 1/3 (5). As, in the present study, the lattice spacing was constant and the measured densities of arsenide and antimonide were within 1% of that required for a stoichiometric structure, it seems probable that departures from the formula Th_3X_4 are very small or nonexistent in these compounds. Chemical analyses gave carbon contents of 0.02-0.04% and thorium-anion ratios within 5% of ideal.

Table I. Thermoelectric data

Compact	Fabrication Time, min	Fabrication Temp, °C	α, $\mu V°C^{-1}$	σ, ohm-cm^{-1}	K, cals cm^{-1} sec^{-1} °C^{-1}	Density % theor.
Th_3P_4	15	1200	−223	1.5	0.0066	92
Th_3As_4	30	1900	−160	545	0.0130	100
Th_3Sb_4	15	1600	−52.5	3,370	0.0179	100

Thermoelectric data near room temperature for compacts based on the 99.99% purity thorium are summarized in Table I. The variation of thermoelectric power (α) and electrical conductivity (σ) with temperature for these materials are shown in Fig. 1 and 2. Changes in pressing temperatures between 1400° and 2000°C could shift by up to 50°C the temperature at which a given value of α was obtained. Thus, in Fig. 1 the temperature axis may be moved ± 25°C. As before (1) the trend was for a higher room temperature α with an increased pressing temperature. The reported electrical conductivities (Table I) were the highest obtained, lower pressing temperatures giving in some instances values down to 25% of these figures. The possibility of carbon contamination or inhomogeneity was considered by progressively grinding layers off some samples and remeasuring but no property changes were found.

Data for arsenide and antimonide compacts made from the less pure thoriums are shown in Fig. 3 and 4. The compacts were fabricated as for the purest metal and again α was found to be slightly influenced by pressing temperature. The impure compacts tend to maintain a positive α to a much higher temperature and in the case of the arsenides give subsequently a smaller negative value. As the major metallic impur-

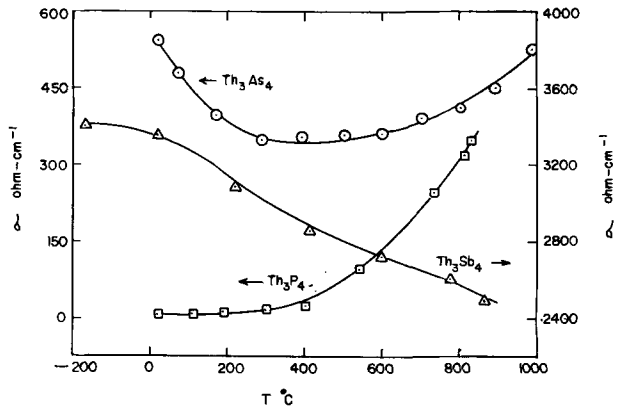

Fig. 2. Variation of electrical conductivity σ with temperature for compacts based on the 99.99% purity thorium.

ity in these compounds is iron it seems likely that the p-type behavior observed in these compounds is not intrinsic to the materials, but arises from the presence of iron and similar impurities providing acceptor levels at low temperatures. These impurity effects are very similar to those observed for metallic additions, nickel in particular, in the previous study.

One unexpected feature of this investigation concerned the behavior of Th_3As_4 compacts pressed in molybdenum lined dies, which were used to reduce the possibility of carbon contamination. Molybdenum diffused into samples pressed at 1800°-1900°C giving products which appeared to have partially melted. The properties of two specimens (using 99.99% metal) prepared in this way are shown in Fig. 5. One sample not only has a high p-type value near room temperature but, unlike any other compact studies here or previously (1), maintains a negative thermoelectric power

in excess of 200 μv/°C from 500° to 1000°C. Chemical analysis of this sample showed 0.14 w/o (weight per cent) molybdenum; the x-ray pattern was unaltered from Th_3As_4. In this instance, due to the size and shape of the samples, the electrical conductivities could only be measured approximately, but appeared to be between 150 and 450 $(ohm\text{-}cm)^{-1}$ over the temperature range.

The examination of the Th_3As_4-Th_3Sb_4 solid solutions was undertaken using the 99.9% thorium metal which was plentifully available. In Table II room temperature x-ray and thermoelectric data are summarized. The lattice spacing of the middle alloys is only approximate for line broadening occurred. The compounds were all pressed between 1500° and 1600°C which was very near to the melting point for antimony rich alloys. Annealing compacts for 50 hr at 1400°C *in vacuo* had no effect on the properties. Figures 6 and 7 illustrate the variation of α and σ with temperature, intermediate properties occurring for those compounds not shown. The electrical conductivity peak with the 75% antimonide sample is not understood, but was reproduced on a second specimen. It appeared from these results that the arsenide rich compounds had the best thermoelectric properties, accordingly an alloy of composition $Th_3(0.9\ As, 0.1\ Sb)_4$ was fab-

ricated using the 99.99% thorium metal. α and σ data for this compact (pressed for 30 min at 1550°C) are shown in Fig. 8.

These Th_3As_4 base compounds have possibilities as high-temperature n-type thermoelectrics. Exact figures of merit (Z) cannot be calculated but if, as in InAs and GeTe (6), K is assumed to halve between 30° and 800°C, then approximate values can be computed. The best Z obtained at 800°C is 0.5 x 10^{-3} $°C^{-1}$ for the $Th_3(As_{0.9}Sb_{0.1})_4$ of Fig. 8. The other materials studied give maximum figures of 0.1-0.4 x 10^{-3} $°C^{-1}$ up to 900°C. These values, which are almost certainly not the ultimate obtainable, are somewhat lower than the Z of 0.6 x 10^{-3} $°C^{-1}$ for InAs at 800°C and 0.9 x 10^{-3} $°C^{-1}$ for GeTe at 600°C (6).

Interpretation of the data obtained in this investigation is clearly restricted by the polycrystalline nature and limited purity of the compacts. They are conventional in that the electronegativity differences (7) Th_{IV}1.4, P 2.1, As 2.0, Sb 1.8 are suitable for semiconducting properties (8) and the increasing metallic behavior with temperature is in the correct order Sb-As-P. The fortuitous molybdenum contaminated samples show that n-type conductors of high thermoelectric power up to at least 1000°C can be produced. Phase diagrams of thorium-Group VB compounds are not available but the isostructural uranium compounds U_3Sb_4 (9) and U_3Bi_4 (10) break down below their melting point to give the mono compound. Reference to these diagrams and the observations here with the phosphide suggest that it will be difficult to take the investigation any further for zone refining will be inapplicable and single crystal growth techniques not straightforward.

Some Considerations on the Use of Platinum Electrodes in Chloride Solutions

R. P. Frankenthal and H. W. Pickering[1]

Edgar C. Bain Laboratory for Fundamental Research,

United States Steel Corporation, Research Center, Monroeville, Pennsylvania

ABSTRACT

As part of some studies on the passivity of iron-chromium alloys, experiments were performed to determine under which conditions platinum pre-electrolysis electrodes and auxiliary electrodes will dissolve anodically in chloride solutions and cause interference with subsequent measurements due to the cathodic redeposition on the alloy of the dissolved platinum. For these experiments potential-current relationships were measured and thin foils of the alloy were examined by transmission electron microscopy and by selected-area electron diffraction for the presence of deposited platinum. Even when the anolyte and catholyte were separated by a fine-porosity fritted disk during pre-electrolysis, platinum subsequently deposited on the working electrode. Platinum will also dissolve anodically from the auxiliary electrode when a net cathodic current flows at the working electrode; if the electrochemical measurements are not sufficiently fast, the dissolved platinum will diffuse to the working electrode and deposit on it. The presence of dissolved platinum can usually be detected electrochemically. However, an examination of the material under study by transmission electron microscopy and electron diffraction is the most certain means to determine whether platinum will redeposit under the conditions of the experiment.

In the course of an investigation of the passivity of iron-chromium alloys, it was deemed necessary to investigate the effect of pre-electrolysis of the electrolyte solution. The need for pre-electrolysis in electrochemical studies has been well established, particularly by Bockris (1, 2). The usual procedure (3) is to perform the pre-electrolysis either between two electrodes of the metal under study or between two platinum electrodes and under conditions more stringent than those in the actual experiment, thereby, hopefully, eliminating the impurities that could affect the experiment.

In the work with iron-chromium alloys it was not possible to do the pre-electrolysis between two electrodes of this alloy, since at the current densities required for the pre-electrolysis the anode would assume a potential at which chromium is oxidized to dichromate ion; this ion would then interfere with the passivity experiment. It was, therefore, decided to use platinum electrodes. However, since some of the work was to be done in solutions containing NaCl and since it is well known (4-6) that a platinum anode will dissolve in a chloride medium to give either the chloroplatinite or the chloroplatinate ion, an investigation was conducted into the possible side effects of this anodic dissolution. From a combination of electrochemical measurements and observations by transmission electron microscopy, we have drawn certain conclusions concerning the use of platinum electrodes in chloride media.

Experimental

The working electrode for the electrochemical measurements and the foils for the electron microscope specimens were prepared from a laboratory vacuum melt of high purity Fe-24% Cr alloy. Cylindrical electrodes (1 in. high and ¼ in. in diameter) were machined with a threaded hole for electrical connection at one end. The material for the foils was cold rolled to 0.003 in. Immediately prior to use, the electrodes and the foils were electropolished in a mixture of glacial acetic acid and perchloric acid (5:1) at 35v, rinsed in reagent-grade methanol, dried, and immediately inserted into the cell. Electrical contact was made to the electrode by means of a brass screw that was isolated from the environments by a Teflon sleeve. To obtain electrical contact with the foil, a thin platinum wire, covered by a glass sleeve, was spot-welded to one end of the foil. The opening at the weld area, as well as the weld, was sealed with polyethylene.

The studies were conducted in three solutions: 1*N* H_2SO_4, 1*N* H_2SO_4 + 0.1*N* NaCl, 1*N* H_2SO_4 + 0.01*N* NaCl. These were made from reagent grade chemicals and doubly distilled water with a conductivity of 3×10^{-7} mho-cm. Pre-electrolysis, when performed, was conducted for 24 hr at a current density of 15 ma/cm^2 between two platinum electrodes, each 10 cm^2 in area. Experiments were conducted with the anode and cathode in the same compartment and also with the electrode compartments separated by a fritted-glass disk (fine porosity). In the latter case, the electrolyte to be used in the passivity experiments was in the cathode compartment. All solutions were purged with prepurified helium before and during use.

The cell was constructed completely of Pyrex. Both water-wetted glass stopcocks and Teflon stopcocks were used. A Luggin capillary connected the cell to the reference electrode via a salt bridge. The auxiliary electrode was a platinum cylinder (40 mm diameter), concentric with the working electrode to insure uniform current distribution. The working electrode was inserted through a ball joint, so that the electrode could be properly placed with respect to the Luggin capillary. A hydrogen reference electrode was used when the electrolyte was H_2SO_4; a saturated calomel reference electrode was used when chloride was present in the solution. All potentials are reported relative to the normal hydrogen electrode (NHE). Prepurified helium was swept through the cell at all times. The potential-current curves were obtained with a Wenking potentiostat and a motor-driven potentiometer. The potential sweep rate was normally 100 or 200 mv/hr.

Bulk specimens and the foils were treated electrochemically in an identical manner, and the potential-current curves were always similar. The following polarization treatments were used:

1. Immersion at +0.475v *vs.* NHE (passive region, see Fig. 1); holding at this potential until the electrode was passive; sweeping the potential to —0.165v,

[1] On leave until September 1965 at the Max Planck Institut für Physikalische Chemie, Göttingen, Germany.

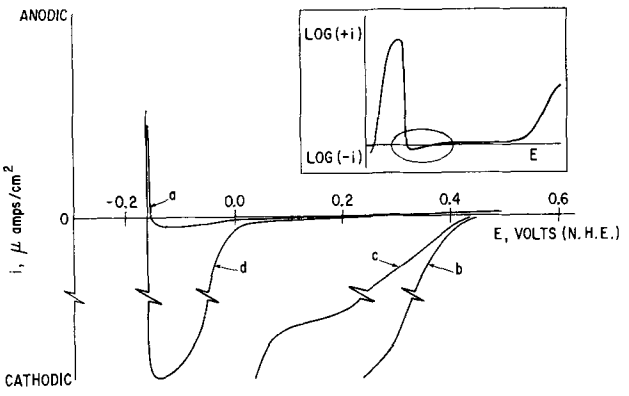

Fig. 1. Potential-current curves in the region of passivity and the Flade potential: (a) in 1*N* H_2SO_4 or in 1*N* H_2SO_4 + 0.1*N* NaCl with no interference from platinum; (b) in presence of large quantities of dissolved platinum; (c) in presence of intermediate amounts of dissolved platinum; (d) in presence of traces of dissolved platinum. Inset shows the over-all passivity curve; the circled area shows the portion plotted in main part of figure.

at which potential the anodic current is increasing sharply as passivity decays.

2. Immersion at —0.500v for 10 sec, at which potential hydrogen evolution proceeds vigorously, sudden switch to +0.475v, followed by the procedure outlined for treatment No. 1. This treatment should give an oxide-free surface prior to passivation.

3. Same as treatment No. 1, but potential is suddenly switched from +0.475 to —0.165v, instead of sweeping through this range.

When the foils reached the final potential, *i.e.*, —0.165v, they were pulled from the cell with the potential still applied, rinsed with reagent-grade methanol, and dried. Some foils were examined immediately in the electron microscope; others were stored in a desiccator until they were examined. There was no effect due to storage. Each foil was examined by transmission electron microscopy in a Siemens Elmiskop. In addition, selected-area electron diffraction allowed examination of regions of specific interest.

Solutions were chemically analyzed for platinum by evaporating the solution to a very small volume and adding a few drops of stannous chloride. A brownish-black precipitate indicated the presence of platinum.

Results and Discussion

Table I summarizes the experimental conditions for the various experiments.

Figure 1 summarizes the electrochemical findings in the form of potential-current curves for the alloy under the different conditions in the region of passivity and of the Flade potential ($E \approx -0.2$v). Curve a is for the series of experiments a_1 and a_2. In H_2SO_4 the potential-current relationship is essentially independent of pre-electrolysis, polarization sweep rate up to approximately 500 mv/hr, and polarization treatment. The cathodic loop has been explained by Edeleanu (7) and is due to hydrogen evolution prior to the breakdown of passivity. As soon as chloride is added to the solution, the other conditions become critical. In experiment a_2, conditions were such that the potential-current curve was the same as for experiment a_1, and the transmission electron micrographs of the foil showed no trace of platinum deposits.

Table I. Summary of experimental conditions

Experimental series	Solution composition	Pre-electrolysis	Polarization sweep rate, mv/hr	Polarization treatment
a_1	1*N* H_2SO_4	Yes, No	100-500	1, 2, and 3
a_2	1*N* H_2SO_4 + 0.1*N* NaCl	No	200	1
b	1*N* H_2SO_4 + 0.1*N* NaCl	Yes	200	1
c	1*N* H_2SO_4 + 0.1*N* NaCl	No	200	2
d	1*N* H_2SO_4 + 0.01*N* NaCl	No	100	1

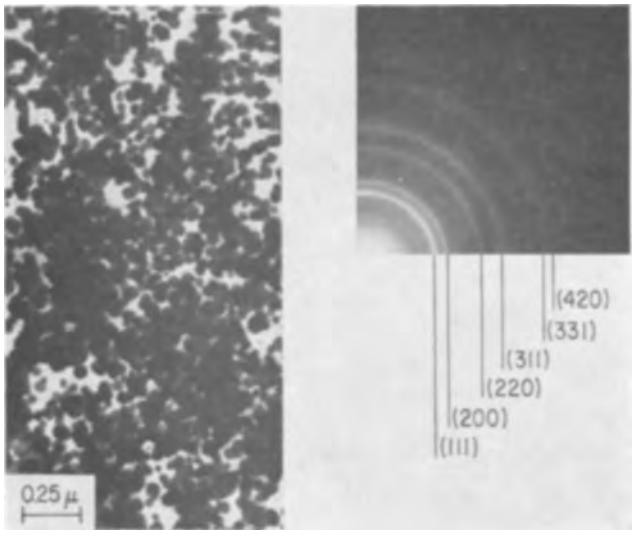

Fig. 2a. (Left) Transmission electron micrograph of platinum deposit at edge of foil after pre-electrolysis of chloride-containing solution between platinum electrodes. (b) (right) Selected-area electron diffraction pattern of area shown in (a) identifying the deposit as platinum.

In experiment b the same solution was used as in experiment a_2, but it was first pre-electrolyzed between two platinum electrodes in the same compartment; the potential-current relationship is given by curve b. It is obvious that a different cathodic reaction is occurring and that it is occurring at potentials corresponding to a strong oxidizing agent. Chemical analysis of the solution revealed the presence of platinum. A transmission electron micrograph (Fig. 2a) of an area at the edge of a foil that had been subjected to a sweep through this potential range shows a heavy deposit, which has been identified as platinum by selected-area electron diffraction (Fig. 2b).

Experiment c in which the alloy surface was initially cathodically reduced (polarization treatment 2) resulted in curve c. The initial cathodic current is again due to platinum deposition; a limiting current is observed, indicating that the concentration of dissolved platinum is considerably less than for the case represented by curve "b". The transmission electron micrograph (Fig. 3) of a foil shows deposits of platinum. The further increase in the cathodic current after the limiting current is due to hydrogen evolution. This hydrogen evolution begins at a potential about 100 mv more positive than that observed for case a. This results from a lowering of the hydrogen

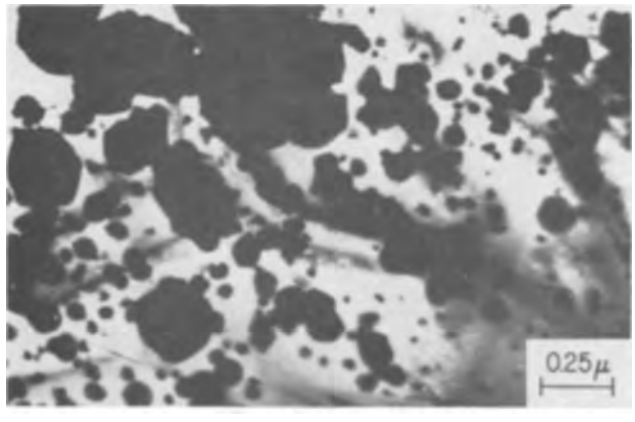

Fig. 3. Transmission electron micrograph of platinum deposit on a foil. Platinum dissolved from the auxiliary electrode during initial hydrogen evolution treatment to clean surface.

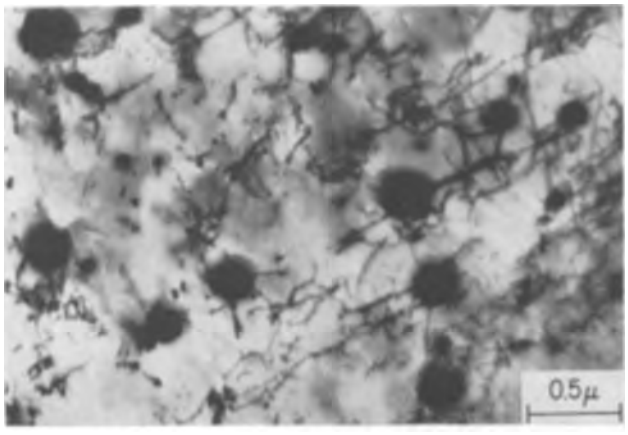

Fig. 4. Transmission electron micrograph of platinum deposit on a foil. Platinum dissolved from auxiliary electrode during potential sweep through cathodic loop. Lines in background are dislocations.

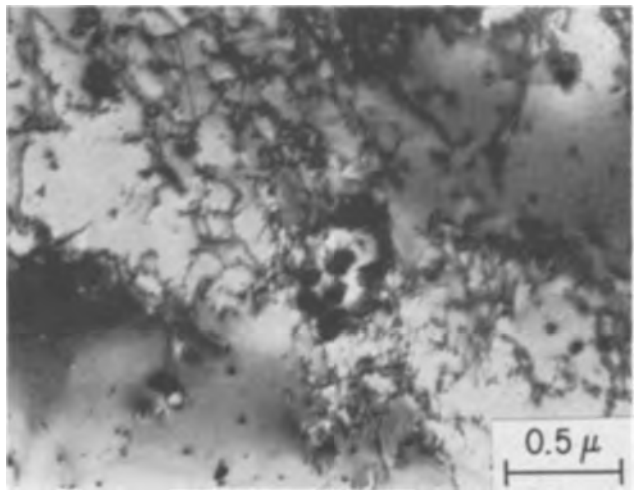

Fig. 5. Transmission electron micrograph showing deposit, which is presumably platinum, on foil exposed to H_2SO_4. Solution had been pre-electrolyzed between two platinum electrodes for 24 hr at 15 ma/cm^2. Foil was subjected to polarization treatment No. 1.

overpotential by the platinum deposit. Sweeping through the same potential range with a platinum electrode, the beginning of hydrogen evolution also occurred at the potential shown in curve c.

The deposition of platinum was also observed in experiment d in which more stringent precautions were taken to avoid the anodic dissolution of platinum and its redeposition, but in which a slower polarization sweep rate was used. A potential-current curve similar to a was expected. Instead, the potential-current curve showed a sharply increased cathodic current in the loop, as shown in curve d. The cathodic loop began at about the same potential as for curve a. A transmission electron micrograph (Fig. 4) of the foil shows deposits of platinum. The platinum, undoubtedly, came from the auxiliary electrode during the sweep through the cathodic loop, during which time this electrode had a net anodic current imposed on it. Because of the slow potential sweep rate, the dissolved platinum had time to diffuse to the working electrode, to deposit and to depolarize the hydrogen-evolution reaction. Integrating the area under the time-current curve (potential varied linearly with time) of the cathodic loop, it is estimated that the maximum amount of platinum that could have been dissolved is equivalent to ½ coulomb, assuming the complete absence of other anodic reactions such as chlorine evolution.

When the cathode and anode compartments were separated by a fine-porosity fritted disk during a 24-hr pre-electrolysis of a chloride-containing solution, sufficient dissolved platinum diffused through the disk to be detected qualitatively by chemical analysis. The presence of the dissolved platinum was also detected as a cathodic current when a platinum electrode was swept through the potential range from +0.5 to 0.0v in this solution. Although no foils were examined for this pre-electrolysis condition, the platinum undoubtedly would also have been found on them.

It has been determined that passivity curves in chloride solutions can best be measured by rapidly sweeping the sample through the desired potential range, a procedure which can lead to markedly distorted passivity curves (8), if the rate is too great, or by obtaining a point-by-point plot (polarization treatment No. 3), omitting regions in which the net current on the working electrode is cathodic; and by omitting pre-electrolysis and the initial cathodic reduction of air-formed oxide films. Work in H_2SO_4 showed no deleterious effects on the potential-current curves when pre-electrolysis and oxide reduction were omitted.

The authors are indebted to the reviewer for bringing to their attention the fact that platinum has been found to dissolve in H_2SO_4 (9). The dissolution of platinum by H_2SO_4 is also thought to have occurred in this work since micrographs of foils treated in H_2SO_4 showed deposits which looked like platinum (Fig. 5). This foil had been subjected to polarization treatment No. 1 after pre-electrolysis of the H_2SO_4 solution. Additional evidence in the form of electron diffraction data must be obtained before it may be unequivocally stated that platinum dissolves in H_2SO_4 under the conditions of our experiments. In this regard it should be noted that the test conditions were considerably more severe in the work of Hirano *et al.* (9) than they were in the work reported here. In their work an anodic current of 2 amp was imposed on a platinum wire (area, 5 cm^2) for 3 to 5 hr; analysis of the mercury cathode showed the presence of approximately 10 μg of platinum. If the deposits, such as those in Fig. 5, are platinum, it was not evident from the potential-current curves indicating that electron microscopy is a more sensitive technique.

The cathodic deposition of platinum appears initially as random deposits (Fig. 4), which grow with continued deposition; for the case in which large quantities of platinum are in solution, the deposits eventually impinge upon one another (Fig. 2a) to cover significant portions of the working electrode surface.

Conclusions

Great caution must be exercised when platinum electrodes are used in chloride-containing media. It has been shown that, whenever a platinum electrode is subjected to an anodic current, some dissolution will occur; if the electrochemical measurements are not sufficiently fast, the dissolved platinum will diffuse to the working electrode and deposit on it. The presence of dissolved platinum can usually be detected electrochemically. However, an examination of the material under study by transmission electron microscopy and electron diffraction is the most certain means to determine whether platinum does deposit under the conditions of the experiment. It has been determined that passivity curves in chloride media can best be measured by rapidly sweeping the desired potential range or by obtaining a point-by-point plot, omitting regions in which the net current on the working electrode is cathodic and by omitting pre-electrolysis and the initial cathodic reduction of oxide films.

Acknowledgments

The authors wish to express their thanks to the following members of this Laboratory: Dr. S. S. Brenner for editorial discussions while writing this paper; Mr. G. W. Momeyer for the chemical analyses; and

Drs. L. S. Darken and R. A. Oriani for their continuing encouragement.

Manuscript received Aug. 24, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

On the Equilibrium Properties of Single Crystalline Copper Electrodes

Leslie H. Jenkins and Ugo Bertocci

Solid State Division, Oak Ridge National Laboratory, Operated by Union Carbide Corporation for the United States Atomic Energy Commission, Oak Ridge, Tennessee

ABSTRACT

It is shown that, when true equilibrium conditions exist in the aqueous system studied, no single crystal orientation exposed to solution spontaneously changes with time. Also, under these conditions no differences in equilibrium potential can be measured between different orientations. Data are offered which suggest that some previous measurements possibly were not the result of equilibrium properties, but rather were produced by kinetic phenomena.

Previous studies to determine the equilibrium shapes of copper crystals exposed to aqueous solutions and/or to explore the possibility of the existence of thermodynamically more stable orientations have been reported. Getman (1) observed that in $CuSO_4$ solutions single crystalline copper exhibited an equilibrium potential about 3.5 mv greater than that of copper amalgam electrodes. Leidheiser and Gwathmey (2) reported that in acidic copper sulfate solutions copper single crystals with surfaces oriented (100) were anodic to the (111) orientation by approximately 7 mv in solutions exposed to the atmosphere. This difference dropped to ~2 mv in solutions from which air had been removed previously by boiling and which were under a hydrogen atmosphere. Annealing the crystals in hydrogen before exposure to air-saturated solutions caused the (111) to become anodic to the (100) by about 3 mv. However, Tragert and Robertson (3) concluded that only the (111) orientation was stable and capable of producing a reversible cell, and that in time all other orientations approached the (111) since they were metastable in $CuSO_4$ solutions. Since these and other published data are not in complete agreement, it seemed worthwhile to establish and attempt to understand, if possible, the reasons for disagreement.

Materials

Three different types of 99.999% pure copper single crystals were used. Coupons ~10 x 20 x 1 mm with the preferred orientation on the large 20 x 10 mm area were prepared in a manner described previously (4). Coin shaped crystals, 25 mm diameter x 7 mm thick, were cut with an acid saw from larger single crystal cylindrical slugs which had been grown by a modified Bridgman technique. Spherical crystals ~12 mm in diameter also were grown by the latter technique. Copper sulfate solutions were prepared from reagent grade $CuSO_4 \cdot 5H_2O$ and H_2SO_4. These solutions were prepared and maintained in a rack reservoir by methods previously described. All solutions reported in this study were 0.2M in $CuSO_4$ with pH adjusted to ~1 with sulfuric acid. Also, at the time of removal from the storage rack and admission to the systems of interest, the solutions, free of dissolved oxygen, were under a hydrogen atmosphere and at equilibrium with copper metal.

Experimental Method

Following normal mechanical preparation (4), coupon crystals were electropolished in an acid copper phosphate bath, rinsed in dilute phosphoric acid, washed in distilled water, and dried in a jet of oxygen. They were then suspended from one of the four glass hooks of the insert thimble of the test cell, as shown in Fig. 1. The entire apparatus was attached to the reaction rack through the side-arm standard glass joints with o-ring seals. After repeated evacuation and filling with hydrogen, a heater was placed about the lower portion of the flask, and the crystals annealed at 450°C

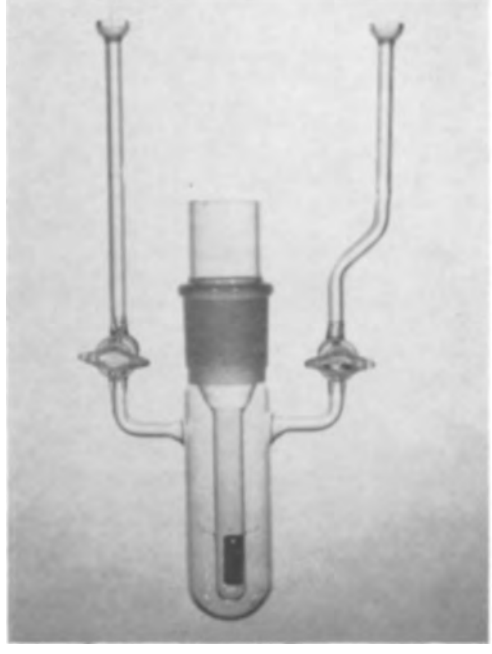

Fig. 1. Annealing cell for coupon crystals

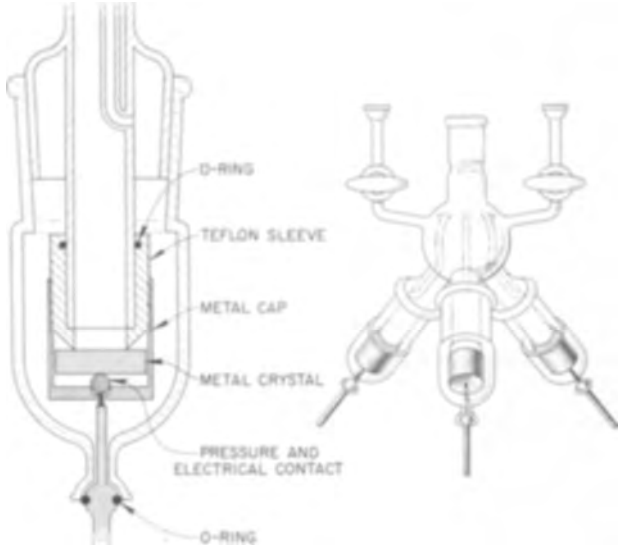

Fig. 2. Tripod cell permitting isolation of a single orientation

under H_2 for ~15 hr. When annealing had been completed and the crystals cooled to ambient temperature, the pre-equilibrated copper sulfate solution under a hydrogen atmosphere was admitted to the flask. The side-arm stopcocks were closed and the apparatus removed from the filling rack and immersed in a water bath at 25.04° ± 0.02°C. Periodic visual inspections could be made of the systems.

Cylindrical (coin shaped) crystals were first polished on a chemical polishing wheel to remove small surface irregularities introduced by the acid sawing process (5). The remainder of the polishing and washing procedure was identical to that given coupon crystals. After drying, the polished crystals were mounted on one of the three legs of a tripod cell in the manner shown in Fig. 2. A glass electrode which had been sealed vacuum-tight into a standard taper glass bushing with o-rings and epoxy resins was inserted in the standard taper joint at the top of the cell. Another entry port to the system, not shown in the illustration and hereafter referred to as the side port, was provided by a small standard taper joint located in the upper rear quadrant of the cell. A platinum wire sealed through the corresponding male member of the joint provided a means of electrical contact as well as a means of suspension of a polycrystalline 99.999% copper wire. When assembly was complete, this entire apparatus was also attached to the filling rack with o-ring seals at the standard joints on the side-arms of the cell. After repeated evacuations and filling with hydrogen, copper sulfate solution was admitted to the system and the side-arm stopcocks closed. Obviously, it was impossible to anneal the crystals. A constant temperature air bath, temperature 23.0° ± 0.1°C, was placed about the system and constant temperature maintained for the remainder of the experiment. Since the system was so massive, temperature fluctuations within the cell were small.

Potential differences between the glass electrodes and metal specimens were measured with a Beckman, model G, pH meter. Potentials between metal crystals were measured with a Cary, Model 31V, vibrating reed electrometer.

In all cases after experimentation was completed, the cells were opened quickly and the crystal hurriedly washed in distilled water, dried in a jet of oxygen, and examined with the optical microscope.

Experimental Results

Equilibrium Systems

Annealed crystals.—Four coupon crystals, oriented (100), (110), (111), and (321), respectively, were suspended from the glass hooks of the insert thimble. Systems were exposed to the copper sulfate solution for periods of 1, 3, 7, and 17 weeks. Visual inspection of the crystals showed no detectable changes in surface topography on all samples during this time. In every case, after removal from the cell, absolutely no evidence of change in surface structure could be observed microscopically. In one instance, rather than filling the flask to a level such that all samples were entirely immersed, as was normally done, only enough solution was admitted to cover half of each coupon. Upon opening, it was impossible to detect even where the solution level had been on these crystals. Also, determination of sample weights in two systems before and after exposure to solution showed no weight changes.

A spherical copper crystal[1] was suspended from a special insert thimble consisting of only one large vertical hook, annealed, and exposed to solution for two weeks in one case and four weeks in another. At the end of the indicated times no changes could be detected on any surface area in either case.

Nonannealed crystals.—To insure that the previous results were not due to the presence of undesired orientations on the edges of the coupon crystals, similar studies were conducted on cylindrical crystals in tripod cells since exposure to solution could be restricted to the orientation of interest. Coin shaped crystals with the large flat areas oriented (100), (110), and (111), respectively, were mounted one on each leg of the cell. After exposure to the copper sulfate solution at controlled temperature for periods varying from one week to four months, the cells were opened and the solution removed and saved for analysis. Examination of the crystal surfaces showed that in no case was there any detectable change in the surfaces exposed to the solutions.

Neither could a change be observed on any of these three orientations which in one system had been exposed to the solution for one year at ambient laboratory temperature, nor was any change in surface structure observed on a spherical crystal suspended from the glass electrode after a four months' exposure at controlled temperature of 23.0° ± 0.1°C.

Rest potentials.—The following observations were made only on nonannealed crystals in cells of the tripod type. It is difficult experimentally both to isolate an orientation and anneal the crystal, and it was judged to be unnecessary in this instance.

Immediately on admitting solution to the cells, a small initial potential difference (never exceeding 1.5 mv) could sometimes be measured between different orientations as well as a polycrystalline wire suspended through the side entry port. However, within 1 hr these differences had decreased to 0.2 mv, a value never exceeded during the remainder of the experiments and thought to be about the limit of experimental error in these systems. Since the magnitude and sign of both the initial and later potential differences varied from one orientation to another in different systems, they are not thought to be significant, and only one typical set of data are shown as system A, Table I.

Because the glass electrode had been subjected to vacuum treatment during preparation of the system, it usually required about 4 hr of exposure to solution before reliable results could be obtained. After that period a potential difference of ~300 mv was observed between the glass electrode and the copper crystals. The exact magnitude varied from one electrode and one system to another. Since aging and standardization of the electrode could not be accomplished after the vacuum treatment and prior to exposure to solutions, the absolute magnitude of the potentials observed is not significant. However, it is significant that other than the first few hours not only were no potential differences measured between crystals after one day or one year, but in every instance the potential measured

[1] Spherical 99.999% pure copper single crystals were kindly supplied by John V. Cathcart of this Laboratory.

Table I. Potential differences of various orientations

System	Potential of (100) mv vs. (110)	(111)	Time after solution admitted
(A)	0.75	0.62	0.1 hr
No O_2 leak	0.09	−0.27	1.0 hr
No residual O_2	0.02	−0.11	1.5 hr
	2.01	1.66	0.1 hr
(B)	2.26	2.01	1.0 hr
No O_2 leak	0.99	1.53	8.0 hr
Slight residual O_2	0.24	0.10	24.0 hr
	−0.10	0.14	48.0 hr
(C)	9.15	8.65	1 day
Constant O_2 leak	7.42	7.70	5 day
Equivalent to a corrosion current of ~10 μa/cm^2	5.98	6.84	15 day
	4.96	4.64	30 day
	4.48	3.47	60 day
	3.88	2.61	90 day

between the glass electrode and the crystals also did not change with time.

Nonequilibrium Systems

Since the experimental conditions described here were quite different from those of previous workers (1-3), it was understandable that the data were not in full agreement. However, a possible explanation of the cause(s) for disagreement was desirable. Fortunately, air inadvertently leaking slowly into a system under observation resulted in potential differences arising between electrodes and produced changes in surface topography which suggested a means of explaining these differences.

It has been shown (6) that surfaces being oxidized by oxygen dissolved in solution are attacked uniformly since the reaction rate is diffusion controlled. However, another reaction mechanism is possible in a system of copper metal exposed to a solution of its ions. If the system is originally at equilibrium, then the equilibrium constant of $\sim 10^{-6}$ is satisfied for the reaction

$$Cu^{2+} + Cu^{o} \leftrightharpoons 2Cu^{+} \quad [1]$$

If air slowly leaks into the system at a point far removed from the metal, equilibrium is destroyed by the reaction

$$2Cu^{+} + \tfrac{1}{2}O_2 + 2H^{+} \leftrightharpoons 2Cu^{2+} + H_2O \quad [2]$$

The equilibrium concentration of copper(I) ions can be restored only when copper metal is oxidized by copper(II) ions, as in reaction [1] proceeding to the right.

Controlled, constant leak rates in the systems could be obtained through faulty platinum-through-glass seals of the male standard joint at the side entry port. If a very limited reaction was desired, evacuation and flushing with hydrogen was limited so that a trace of air was retained in the system. The following data were all obtained using tripod cells.

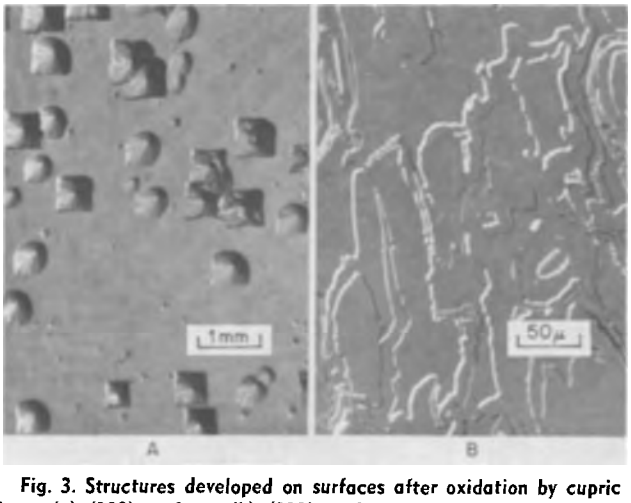

Fig. 3. Structures developed on surfaces after oxidation by cupric ions: (a) (100) surface; (b) (111) surface.

Figure 3 shows typical structures developed by cupric ion oxidation of the indicated surface. It is obvious that dissolution on the (100) and (111) occurred in highly restricted regions rather than uniformly over the entire surface. This phenomena was repeated in all systems at all reaction rates up to 30 μa/cm^2, the greatest rate studied. Facets developed on the (110) were more uniformly distributed, but their appearance and habit also were observed repeatedly in all systems not at equilibrium.

Table I records some typical potential differences measured in these systems. As previously stated, the first group of data in the table was collected from an experiment in which not only had the cell initially been well evacuated and flushed with hydrogen so that no residue of oxygen remained, but there was also no leak in the system. The experiment supplying the second group of data, System (B), had not been well evacuated and flushed so that a small residue of oxygen remained. However, there was no leak in the cell, and equilibrium was established within two days. Obviously the potential differences observed reflect the corrosion process occurring on the various orientations. Although the potentials are meaningful, when the system was opened and the surfaces examined the reaction generating the potentials had been so slight that surface changes could be detected only on the (100), and then only after extremely careful observation. Needless to say, no corrosion rate could be established since no detectable change in copper concentration occurred in solution.

System (C) in Table I had a constant leak of air into the system which resulted in a corrosion rate equivalent to approximately 10 μa/cm^2 geometric electrode area. The gradual decrease in potential differences reflects (among other things) changes in the crystal surfaces, for when the samples were removed after 111 days, very little of the original surface remained on any of the electrodes.

Discussion and Conclusions

The failure of all crystals (annealed or not; either coupon, spherical, or cylindrical) to develop facets spontaneously after exposure to oxygen-free copper sulfate solutions (initially at equilibrium with polycrystalline copper) for varying periods of time up to one year suggest that no crystal orientation is thermodynamically more stable than any other in the system studied. The data in Table I show that even small departures from equilibrium conditions generate a measurable and significant potential difference and suggest that, if at equilibrium a potential difference as little as ~1 mv existed between different orientations, facets of preferred orientation(s) would develop since mass transfer could occur.

Because equilibrium potentials were measured in a cell which did not permit annealing the crystals, it is probable that initial small potential differences sometimes observed between crystals was due primarily to the dissolution of oxide originally present on the electrode surface. Certainly in noncorroding systems no potential differences could be measured between unlike orientations or between the glass electrode and one orientation as compared with another. Therefore since any potential differences between orientations cannot be measured experimentally, and since spontaneous faceting does not occur over long periods of time, it is reasonable to conclude that no potential difference exists between different orientations under equilibrium conditions.

The nature of the pits developed on (100) surfaces and the formation of ledges on the (111), as well as the potential differences observed in cells containing dissolved oxygen, perhaps explain the variance of

these data with most of those in the literature. First of all, the physical dimensions of each leg of the tripod cell were equal, and geometric surface areas exposed to solution were the same for all crystals. It can be assumed then that over-all corrosion rates were equal in the legs of any one cell. The potential differences observed were not due to differences in corrosion rate, but reflect rather complex surface properties of the different crystals. These problems will be enlarged and treated in another paper.

None of the data discussed here was collected under conditions in which the corrosion current exceeded 30 μa/cm^2. Many observations were made on systems reacting at rates ~10 μa/cm^2, but most data were obtained with rates of 0.5-3 μa/cm^2. In all cases significant differences in potential could be measured, even at the slowest rates. The magnitude of the differences was generally proportional to the difference in corrosion rates from one system to another, and although the significance is not clear, the (100) was usually anodic with respect to the (111) and (110) in all corroding systems.

In summary, it has been shown that two conditions must be fulfilled before true equilibrium exists in a solution of copper sulfate exposed to copper metal: (*A*) No dissolved oxygen can be present or corrosion will occur as shown in Eq. [1] and [2]. (*B*) Even if no dissolved oxygen is present, the solution must be pre-equilibrated with copper metal before immersion of the test electrode, or reaction [1] will occur until equilibrium is established. It must be emphasized again that dissolution due to the latter cause is not inappreciable for the equilibrium concentration of copper(I) ions in solutions of copper (II) ions at unit activity is ~10^{-3}M. Finally, although not discussed here previously, Miller and Lawless (7) have shown that the *p*H of such systems is a factor in establishing equilibrium as defined by Eq. [1]. Their results need not be described at length, but clearly they demonstrate that, even in deaerated $CuSO_4$ solutions at all *p*H values above ~3.2, oxide films grew over the metal surfaces for periods of hours, and that in addition to the composition and growth forms of the films being complex, it was reasonable to assume that little, if any, metal surface is free of oxide under such conditions. Therefore, whatever the final equilibrium state in these latter systems, it is reached slowly, accompanied by a decreased *p*H of the solution, and certainly must involve some consideration of the presence of an oxide film. Obviously, in such a system an initial potential difference between electrodes which decreased with time possibly could be due only to the complex processes occurring on the surface rather than to differences in thermodynamic states of crystal orientations.

Then at the moment of immersion of a test electrode true equilibrium exists only in solutions which are free of dissolved oxygen, which have been pre-equilibrated with copper metal, and which exhibit a *p*H less than about 3.2. While the equilibrium results reported here were obtained under these conditions, the authors are unaware of any previous reports on the single crystal Cu-aqueous copper sulfate system in which all three requirements were satisfied. Therefore, it is possible that many previous measurements of others reporting crystallographic differences in equilibrium potentials were obtained from systems originally removed from equilibrium, and the potential differences observed were due to kinetic rather than thermodynamic phenomena.

Manuscript received Oct. 21, 1964; revised manuscript received Jan. 30, 1965.

Studies of the Electrochemical Kinetics of Indium

II. System Indium + Indium Sulfate at Higher C.D.

V. Markovac and B. Lovrecek

Institute of Electrochemistry and Electrochemical Technology, Faculty of Technology, University of Zagreb, Zagreb, Yugoslavia

ABSTRACT

In a previous paper the kinetics of the deposition and dissolution of indium was studied by a galvanostatic method of single current pulses. At c.d. higher than 2.5 x 10^{-3} amp/cm^2 a change in the mechanism of the deposition and dissolution of indium was observed. To study the phenomenon, the cathodic and anodic polarization in solutions of indium sulfate with *p*H 2.5, *p*H 1.56, and *p*H 1.0 was investigated as well as the deposition of hydrogen at cathodic polarization in equivalent sulfate solution without indium. After cathodic polarization at chosen c.d.'s, the polarographic investigation of the indium sulfate solution was done. Analysis of the experimental data obtained by cathodic polarization in indium sulfate solution at higher c.d. points to the reaction step $In^{3+} + 2e_0^- \rightarrow In^{1+}$ as rate-determining. For anodic polarization one can conclude that a disproportionation reaction occurs with increasing c.d., and that the first anodic reaction step $In^o - e_0^- \rightarrow In^{1+}$ becomes rate-determining.

In a previous paper (1) the kinetics of deposition and dissolution of indium in sulfate solution was studied using a galvanostatic method of single square-wave pulses.

In that paper it was mentioned that experimental $\eta_A - \log_{10} i$ curves for c.d.'s higher than 2.5 x 10^{-3} amp/cm^2 do not follow Tafel linear relation as found for the region of lower c.d.'s, but show reproducible deviations. The phenomena indicate the existence of some other processes which interfere in the processes previously described (1) and point to changes in the mechanism of deposition and dissolution of indium at higher c.d.'s.

These phenomena were investigated by a slightly modified experimental method (1). The expressions

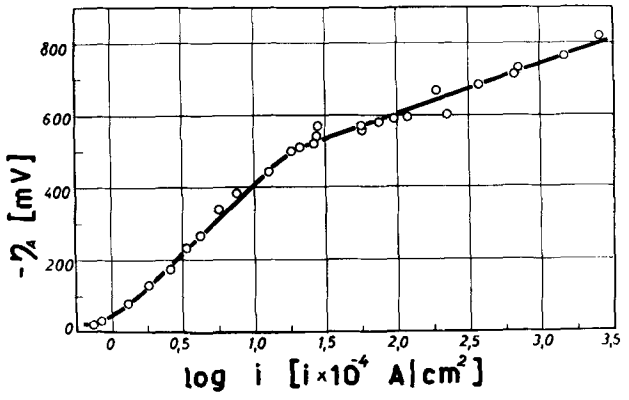

Fig. 1. η_A — log $_{10}i$ curve for cathodic polarization. Electrolyte: 0.116*N* $In_2(SO_4)_3$ + 0.5*N* K_2SO_4, *p*H 2.5.

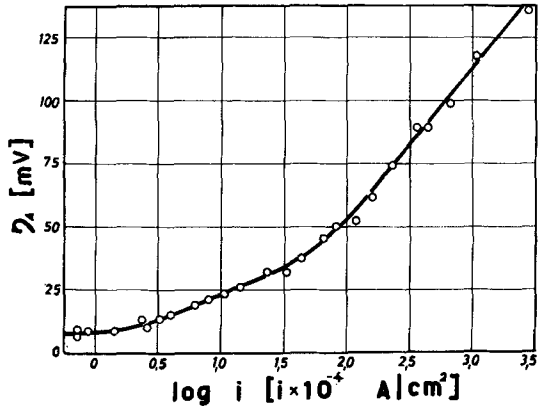

Fig. 2. η_A — $\log_{10}i$ curve for anodic polarization. Electrolyte: 0.116*N* $In_2(SO_4)_3$ + 0.5*N* K_2SO_4, *p*H 2.5.

for kinetics of "many steps" electrode reactions (2) were used.

Experimental

For cathodic and anodic polarization of indium (as 0.3% indium amalgam) with galvanostatic single pulses the same apparatus was used as described (1), with the exception that the electrolytical cell was placed in a wooden air thermostat provided with thermoregulator and ventilator that allows work at a constant temperature of 25° ± 1°C.

Polarization was carried out in the following electrolytes

0.116*N* $In_2(SO_4)_3$ + 0.5*N* K_2SO_4, *p*H 2.5

0.116*N* $In_2(SO_4)_3$ + 0.5*N* K_2SO_4, *p*H 1.56

0.116*N* $In_2(SO_4)_3$ + 0.5*N* K_2SO_4, *p*H 1.0

0.5*N* K_2SO_4, *p*H 2.5

Chemicals used were of analytical reagent grade and water was redistilled.

The experimental $\eta_t - t$ curves were obtained in the same way as previously described (1).

To test for the presence of ions of lower valency in the electrolyte after cathodic polarization, the electrolysis and polarography of indium sulfate solution were done in an analogous way as earlier (3).

Results

Activation overpotential-current density relationship.—The difference between the steady-state potential and the ohmic overpotential η_Ω represents the activation overpotential η_A (1).

When the values of activation overpotential (η_A) were plotted against the logarithms of c.d. ($\log_{10} i$), the curves (Fig. 1, 2) for cathodic and anodic polarization in 0.116*N* $In_2(SO_4)_3$ + 0.5*N* K_2SO_4 at *p*H 2.5 were obtained. Both curves are linear in the c.d. ranges 2.5 x 10^{-4} — 2.5 x 10^{-3} amp/cm² and 8.5 x 10^{-3} — 2.5 x 10^{-1} amp/cm².

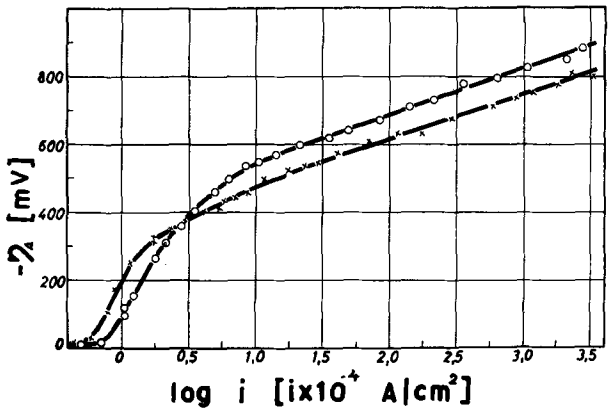

Fig. 3. η_A — $\log_{10}i$ curves for cathodic polarization. Electrolyte: 0.116*N* $In_2(SO_4)_3$ + 0.5*N* K_2SO_4; x, *p*H 1.0; ○, *p*H 1.56.

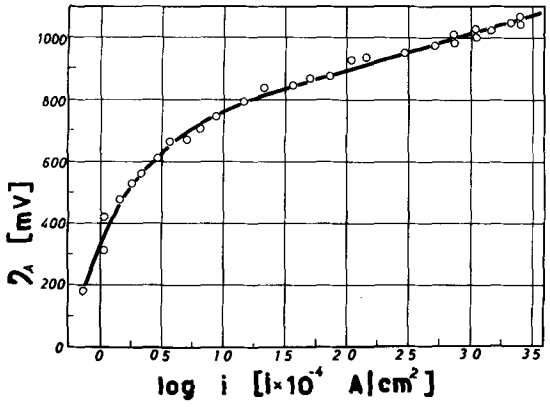

Fig. 4. η_A — $\log_{10}i$ curve for cathodic polarization. Electrolyte: 0.5*N* K_2SO_4, *p*H 2.5.

Figure 3 shows η_A — $\log_{10} i$ curves for cathodic polarization in 0.116*N* $In_2(SO_4)_3$ + 0.5*N* K_2SO_4 at *p*H 1.56 and *p*H 1.0, respectively. The curve corresponding to the solution with *p*H 1.56 is linear in the c.d. ranges 8.5 x 10^{-5} — 2.5 x 10^{-4} amp/cm² and 1.5 x 10^{-3} — 3.0 x 10^{-1} amp/cm² as is the curve in the solution with *p*H 1.0 in the c.d. ranges 7.0 x 10^{-5} — 1.2 x 10^{-4} amp/cm² and 1.5 x 10^{-3} — 3.0 x 10^{-1} amp/cm².

Figure 4 shows the η_A — $\log_{10} i$ curve for cathodic polarization in an electrolyte without indium (0.5*N* K_2SO_4 at *p*H 2.5). In the c.d. range 1.5 x 10^{-3} — 2.5 x 10^{-1} amp/cm² the experimental curve shows a marked linear relation with characteristics usual for the deposition of hydrogen. (Experimentally obtained parameters of Tafel-line are: $a = -0.666$v, $b = 0.114$v).

The linear parts of the experimental η_A — $\log_{10} i$ curves (Fig. 1, 2, 3, 4) that are in fact Tafel-lines are treated with a method earlier developed (2), using expressions for the slowest reaction step, *i.e.*, the rate-determining step.

$$\frac{\partial \log i_-}{\partial V} = -\frac{zF}{2.303\,RT}(n_c^* - \alpha) \qquad [1]$$

$$\frac{\partial \log i_+}{\partial V} = \frac{zF}{2.303\,RT}(n_a^* - 1 + \alpha) \qquad [2]$$

Since the left sides of Eq. [1] and [2] represent the slopes of the experimental Tafel-lines, it was possible to obtain from the experimental data n_c^*, n_a^*, and α.[1]

[1] n_c^* and n_a^* being the ordinal numbers of the slowest reaction step for the cathodic and anodic polarization (small integer), α the transfer coefficient ($0 < \alpha < 1$), and z the number of electrons involved in the slowest reaction step.

Table I. Kinetic parameters for cathodic polarization

Electrolyte	pH	Range of c.d., amp/cm²	$\partial \log_{10} i_{-}/\partial V$ #	α#	n_c*	z
0.116*N* $In_2(SO_4)_3$ + 0.5*N* K_2SO_4	2.5	2.5×10^{-4} to 2.5×10^{-3}	2.87	0.834	1	1
		8.5×10^{-3} to 2.5×10^{-1}	6.11	0.823	1	2
0.116*N* $In_2(SO_4)_3$ + 0.5*N* K_2SO_4	1.56	8.5×10^{-5} to 2.5×10^{-4}	1.44	0.917	1	1
		1.5×10^{-3} to 3.0×10^{-1}	7.20	0.792	1	2
0.116*N* $In_2(SO_4)_3$ + 0.5*N* K_2SO_4	1.0	7.0×10^{-6} to 1.2×10^{-4}	1.24	0.929	1	1
		1.5×10^{-3} to 3.0×10^{-1}	7.84	0.773	1	2
0.5*N* K_2SO_4	2.5	1.5×10^{-3} to 2.5×10^{-1}	8.74	0.494	1	1

Mean values derived from 2-7 complete experimental curves.

Table II. Kinetic parameters for anodic polarization

Electrolyte	pH	Range of c.d., amp/cm²	$\partial \log_{10} i_{+}/\partial V$ #	α#	n_a*	z
0.116*N* $In_2(SO_4)_3$ + 0.5*N* K_2SO_4	2.5	2.5×10^{-4} to 2.5×10^{-3}	48.0	0.803	3	1
		8.5×10^{-3} to 2.5×10^{-1}	14.99	0.869	1	1

Mean values derived from 4-7 complete experimental curves.

Results of the calculations are presented in Table I and Table II.

Polarographic investigations.—Figure 5 shows polarograms obtained before and after cathodic polarization of indium in sulfate electrolyte and a polarogram obtained in the corresponding sulfate electrolyte without indium. As it is seen (Fig. 5) there is no experimental curve with an anodic wave. Consequently after cathodic polarization it is not possible to prove the existence of ions of lower valency by polarography.

Discussion

Ohmic Overpotential

When the experimental values of the ohmic overpotential were plotted against the values of the current i, the linear relation was obtained with slope representing the resistance R (Fig. 6). The resistance R calculated on the ground of expression of Mattsson and Bockris (4) is in good accordance with values determined experimentally (Table III).

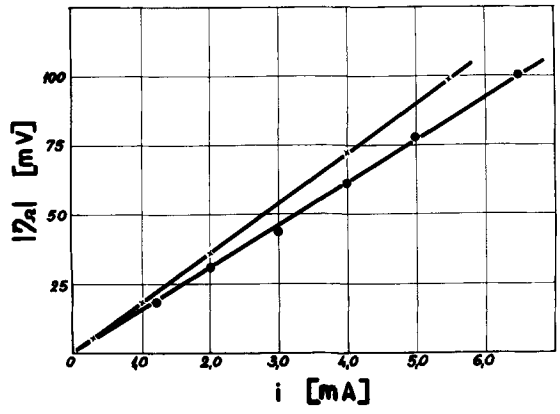

Fig. 6. $|\eta_\Omega|$ — i curves for electrolyte: 0.116*N* $In_2(SO_4)_3$ + 0.5*N* K_2SO_4; x, pH 1.56; O, pH 1.0.

Activation Overpotential-Logarithms of Current Density Curves

For the electrochemical deposition and dissolution of indium in the region of lower c.d.'s (Fig. 1, 2, Table I, II) it was found that the first step was the slowest one in the cathodic reaction and that the third step was the slowest one in the anodic reaction (1).

$$In^{3+} \xrightarrow[\text{slowest}]{+e_0^-} In^{2+} \xrightarrow{+e_0^-} In^{1+} \xrightarrow{+e_0^-} In^0 \qquad [3]$$

$$In^0 \xrightarrow{-e_0^-} In^{1+} \xrightarrow{-e_0^-} In^{2+} \xrightarrow[\text{slowest}]{-e_0^-} In^{3+} \qquad [4]$$

If the c.d. is increased over 2.5×10^{-3} amp/cm², η_A — $\log_{10} i$ curves do not follow earlier relations either at cathodic or at anodic polarization.

Cathodic curve at higher c.d.'s.—The curve for cathodic polarization shows a transition in the range of c.d.'s 2.5×10^{-3} — 8.5×10^{-3} amp/cm², but in the range of higher c.d.'s there exists again a linear relation with another slope (Fig. 1). Such an experimental fact points to the change in the mechanism of indium deposition at higher c.d.'s. To explain the significance of the linear part of the experimental η_A — $\log_{10} i$ curve at higher c.d.'s we have to consider the processes that might occur under given circumstances.

It might be assumed that the first step of the overall reaction, Eq. [3], at higher c.d.'s is so much accelerated that the over-all reaction is controlled eventually by the second or third cathodic step. The assumption is questionable because the linear part of the experimental curve has a slope that shows according to Eq. [1] that the first cathodic reaction step is the slowest one (Table I). Furthermore, after the cathodic polarization at chosen c.d.'s it was not possible to find oxidizable intermediates by polarography, *i.e.*, we did not succeed in recording the anodic wave (Fig. 5).[2]

[2] In an earlier investigation (3) it was possible to register ions of lower valency by polarography after anodic polarization.

Table III. Resistance calculated and experimentally determined for 0.116*N* $In_2(SO_4)_3$ + 0.5*N* K_2SO_4 at various pH values

pH	$R_{calc.}$	$R_{exp.}$
1.56	17.7	18.0
1.0	15.3	15.4

For corresponding data for electrolyte of pH 2.5 see ref. (1).

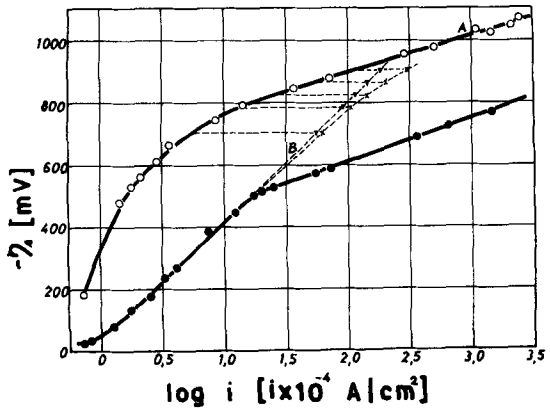

Fig. 7. •, cathodic η_A — $\log_{10} i$ curve for electrolyte: 0.116*N* $In_2(SO_4)_3$ + 0.5*N* K_2SO_4, *p*H 2.5. ○, Cathodic η_A — $\log_{10} i$ curve for electrolyte: 0.5*N* K_2SO_4, *p*H 2.5. ▾, Selected points at the lengthened linear part of curve of deposition of indium. x, Curve constructed by addition A and B.

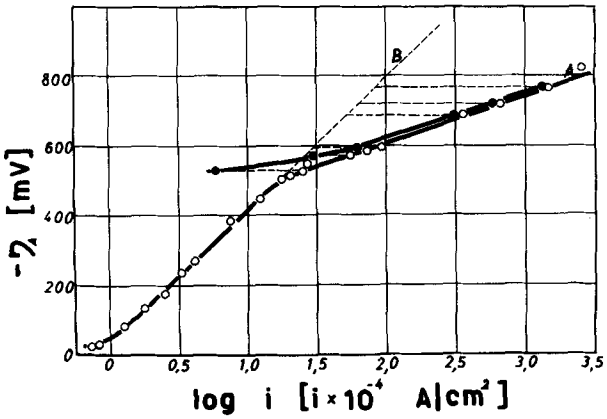

Fig. 8. ○, cathodic η_A — $\log_{10} i$ curve for electrolyte: 0.116*N* $In_2(SO_4)_3$ + 0.5*N* K_2SO_4, *p*H 2.5 •, Curve constructed by subtraction A and B.

According to other authors (5) it might be assumed that the deposition of hydrogen may influence the experimental curve at increased c.d.'s and low *p*H values. Actually, our experimental results (Fig. 3) show some changes with decreasing *p*H, although the general shape and characteristic slopes remain the same. To find the magnitude of the influence that hydrogen deposition might have at higher c.d.'s on the experimental η_A — $\log_{10} i$ curve, a parallel cathodic polarization was carried out using an equivalent electrolyte without indium. The curve obtained in such a way shows over a wide range a typical Tafel linear relation for hydrogen deposition as often reported in the literature.

To compare experimental η_A — $\log_{10} i$ curves at cathodic polarization in the presence and absence of indium, we applied the following procedure (Fig. 7). The linear part of the curve in the presence of indium at lower c.d.'s was lengthened, and at that part of the curve random points of c.d.'s were added to those of hydrogen discharge at the same overpotentials. In such a case, the constructed and experimental curve would coincide if the discharge of hydrogen is a simultaneous and parallel process to the deposition of indium at higher c.d.'s. However, this is obviously not the case (Fig. 7) and indicates that at higher c.d.'s some changes occur in the kinetics of deposition of indium itself, although under such conditions some deposition of hydrogen might be expected.

Let us therefore consider again the possible reaction steps of the over-all electrochemical process of deposition. There is no reason not to accept the possibility of the fusion of any two of the three possible reaction steps [3], especially in the range of higher c.d.'s; *i.e.*, the deposition of indium might proceed as follows:

$$In^{3+} \xrightarrow{+e_o^-} In^{2+} \xrightarrow{+2e_o^-} In^o \qquad [5]$$

$$In^{3+} \xrightarrow{+2e_o^-} In^{1+} \xrightarrow{+e_o^-} In^o \qquad [6]$$

Reaction [5] would hardly be possible because either the second cathodic step should be the slowest, or the linear part of the experimental curve at lower c.d.'s (Fig. 1) should have the same slope at higher c.d.'s too. However, the slope at higher c.d.'s does not show according to Eq. [1] that the second reaction step is the slowest one. It follows that only the reaction [6] may be considered as the possible ones.

Considering reaction [6], from the slope of the experimental curve at higher c.d.'s it can be calculated that the first cathodic reaction step is the slowest one (Table I). In addition, the reaction step

$$In^{1+} + e_o^- \rightarrow In^o \qquad [7]$$

was fast enough at lower c.d.'s too, and it would hardly be possible that the over-all reaction is influenced by it. In support of this is the fact that after cathodic polarization at chosen c.d.'s it was not possible to register oxidizable ions of lower valency by polarography.

On the basis of the shape of the experimental curve (Fig. 1) and earlier considerations it follows, that going from lower c.d.'s to higher ones, a change in the mechanism of the deposition of indium occurs. One mechanism is predominant at lower c.d.'s and the other at higher c.d.'s, while in the region between both processes are possible. The difference between the total experimental c.d. and the partial current of the interfering process is the c.d. to be used for the rate-determining process in the given range. Applying this principle in the higher c.d. range by subtracting the c.d. values of the lengthened Tafel-line (representing the rate-determining process at lower c.d.'s) from the c.d. values of the experimental curve at the same overpotential, one obtains a curve representing the rate-determining reaction step at higher c.d.'s. That curve differs very little from the experimental one in the range of higher c.d.'s (Fig. 8). From the slope of the constructed curve and Eq. [1] can be calculated that the first step is the slowest one of the over-all reaction [6]. All the mentioned facts and qualitative considerations point to the possibility of a reaction involving two electrons and one ion of In^{3+} at higher c.d.'s. Increasing the density of electrons at the cathode increases the probability of the simultaneous reaction of two electrons and one ion of In^{3+}, especially at higher concentrations of In^{3+} (concentration of the electrolyte) and low concentrations of In^{2+}. (In^{2+} was a product of the slowest reaction step at lower c.d.'s, and because of the faster subsequent reaction steps this ion would hardly be found near the cathode).

From these facts it can be concluded that the reaction

$$In^{3+} \xrightarrow[\text{slowest}]{+2e_o^-} In^{1+} \qquad [8]$$

is the slowest step in the cathodic polarization of indium in sulfate solutions at higher c.d.'s.

Anodic curve at higher c.d.'s.—At higher c.d.'s the experimental η_A — $\log_{10} i$ curve of the anodic polarization of indium does not follow the original Tafel linear relation. It changes slope. In the range of c.d.'s 8.5×10^{-3} — 2.5×10^{-1} amp/cm² it follows again a linear relation but with a different slope. The slope of this second part of the curve shows according to Eq. [2] that the first anodic step is now the slowest one

in the over-all electrochemical dissolution of indium (Eq. [4], Table II). That change in the mechanism of the dissolution of indium is possible to explain in following way: As the reaction step

$$In^{2+} - e_o^- \rightarrow In^{3+} \quad [9]$$

is the slowest one at lower c.d.'s, the ions of lower valency are accumulated as proved by polarography (3). By the accumulation of the ions less stable than In^{2+} there is the general possibility (6, 7) that they are removed by a disproportionation reaction as for instance

$$2In^{2+} \rightarrow In^{3+} + In^{1+} \quad [10]$$

An increase of c.d. increases the concentration of In^{2+} and therefore the disproportionation reaction [10] is accelerated. With such an accelerated disproportionation, the third step of the over-all electrochemical reaction of dissolution [4] has less and less influence. In addition, with the process accelerated according to reaction [10], other disproportionation reactions may be assumed, as of the type

$$3In^{1+} \rightarrow In^{3+} + 2In^{o} \quad [11]$$

In favor of reaction [11] are earlier observations (3) when small crystals of indium were found in electrolyte after anodic polarization.

Considering accelerated disproportionation reactions [10] and [11], it can be assumed that the over-all anodic reaction [4] is really controlled by the first reaction step

$$In^{o} - e_o^- \rightarrow In^{1+} \quad [12]$$

at higher c.d.'s as proved by the slope of experimental curve (Fig. 2, Table II).

Technical Notes

Preparation of Transition Metal Oxide-Metal Electrodes

Richard L. Every

Central Research Division, Continental Oil Company, Ponca City, Oklahoma

Recent interest has been evidenced in the formation of oxides on transition metals for various purposes. Electrodes of NiO on Ni are used in batteries (1) and fuel cells (2). Tantalum oxide on tantalum is used for electron emission (3), as an electrolytic rectifier (4), and for electrolytic capacitors (5-7). Titanium oxide on titanium has also been used as a capacitor (8). Oxides are used to protect the transition metals from corrosion and erosion (9, 10). Transition metal oxides have been used in catalysis (11) and electrochemistry (12-26). Various other workers have conducted miscellaneous studies of oxides on the transition metals, *i.e.*, Mo (27), W (28), Nb (29, 30), Nb and Zr (31), Zr (32), Ta (33), Ni (34-36), Pt (37-47), Pt and Pd (48), Pd (49, 50), Rh and Ir (51), Nb, Th, W, U, and Co (52), and Nb, U, V, Ti, Zr, and Ta (53).

The present study is concerned with the fabrication of metal oxide-metal electrodes of ZrO_2, α-Nb_2O_5, Nb_2O_5 (penta), Rh_2O_3, PdO, HfO_2, β-Ta_2O_5, Ta_2O_5 (penta), and PtO on their respective parent metals. (The α, β, and penta are ASTM designations.) The electrochemical characteristics of these electrodes are being studied and will be reported at a later date.

Experimental

All electrodes were about 0.038 x 1.3 x 3.8 cm. About two-thirds of the electrode (about 6.5 cm^2 of metal) was oxidized. The oxides formed were identified either by x-ray or electron diffraction.

The electrode metals were designated "commercially pure" by the manufacturer. All metals except platinum were abraded with fine emery cloth prior to each oxidation. X-ray diffraction patterns verified the removal of residual oxides with this treatment. The platinum electrode was preheated to redness for several seconds in order to remove residual oxides before depositing the platinum black (54). The oxides and the methods of formation are listed in Table I.

Many unsuccessful attempts were made to form the transition metal oxides before trying the general method of using the molten oxidizing salts with and without electrolysis. The exact temperature of the molten salt is apparently not critical in the formation of the oxide. As seen in Table I, typical temperature conditions range from 360° to 420°C. However, the use of electrolysis is important in the formation and growth of certain of the oxides.

To accomplish electrolysis, dry cell batteries were used in series with an ammeter and a rheostat. The current densities given in Table I represent maxima as controlled with the rheostat. The ability to maintain these maxima was limited. In each electrolysis the current density could be controlled for about 1 min before it slowly decayed to a minimum value. Using fresh batteries and established oxide films, these minimum current values could be repeated; this proved that the current decay was due to formation of the oxide film and was not due to the current drain on the battery.

Discussion

Films identified as the oxides were formed on Ta, Rh, and Hf without electrolysis. The thickness of the oxide films was increased with prolonged exposure to the molten salts. Upon microscopic examination of the films, the surface of the electrodes appeared slightly etched. Surprisingly, Ta was oxided in molten $KClO_3$ after only 30 min while it was apparently not oxidized after 3 hr in molten KNO_3.

Table I. Method of preparation of metal-metal oxide electrodes

Oxide	Condition	Appearance
ZrO_2	Anode in 400°C KNO_3 for 5 min with 6v. No current control.	Dark gray
α-Nb_2O_5 (high temp)	Anode in 360°-400°C KNO_3 or $KClO_3$ with 180v and current density controlled at a maximum of 31 ma/cm².	White
Nb_2O_5 (penta)	Anode in 360°-400°C KNO_3 or $KClO_3$ for 5 min with 90v and current density controlled at a maximum of 31 ma/cm². Electrode was then boiled in 96% H_2SO_4.	Silvery-gray
Rh_2O_3	Placed in 400°C KNO_3 or $KClO_3$ for 12 hr.	Dull
PdO	Anode in 400°C KNO_3 for 2 hr with 6v. No current control.	Gray
HfO_2	Placed in 400°C KNO_3 or $KClO_3$ for 1 hr.	Blue
Ta_2O_5 (penta)	Anode in 420°C $KClO_3$ for less than 5 min with 6-60v and current density controlled at a maximum of 2.3-23 ma/cm².	Yellow and blue-green
β-Ta_2O_5	Placed in 380°C $KClO_3$ for 30 min.	Dark blue
	Anode in 400°C KNO_3 or $KClO_3$ with 90v for 1 min. No current control.	Gray
PtO	Pt black (54) electrode placed in O_2 atmosphere at temperatures exceeding 465°C for several hours.	Black below 500°C; gray above 500°C.

Merely dipping the electrodes of Zr, Nb, and Pd into molten salt was not sufficient to form enough oxide for identification; however, the color of the Nb electrode did change to blue. This blue Nb had a few weak x-ray lines in common with Nb_2O_5 (ASTM Powder Diffraction File Card No. 5-0352), but the evidence was inconclusive.

The ZrO_2 formed in 400°C KNO_3 with 6v was a thick, gray coating and could be removed only with extreme difficulty. However, when Zr was made the anode in molten $KClO_3$ with 6v for 5 min, a white coating formed which flaked off and left a blue, deeply etched, and relatively oxide-free Zr surface.

The α-Nb_2O_5 (high temperature) formed as a thick, white adherent powder which could be scraped from the electrode with difficulty. The fact that it formed at 360°-400°C is a little surprising since the transition to the α structure is given as 1095°C (55). The electrical energy used to make this electrode may explain the unexpected appearance of the high-temperature form.

A somewhat less adherent gray coating with flecks of white was formed on Nb when the applied voltage was dropped from 180 to 90v. This coating was dissolved by placing it in hot H_2SO_4 for about 2 hr; this resulted in an etched Nb_2O_5 (penta) surface. The α-Nb_2O_5 was also dissolved by a similar treatment, but the resulting surface was severely eroded.

Niobium was also subjected to electrolysis in molten salts with 6 to 45v. The electrode color changed from blue to amber to gray as the voltage was increased. A study of the diffraction patterns indicated some Nb_2O_5 (penta) might have been present, but positive identification was doubtful.

Diffraction d-spacing values for Rh_2O_3 are not available from the ASTM data file. However, we were able to obtain 6 coincident peaks on comparison of x-ray diffraction patterns from commercial anhydrous Rh_2O_3 powder (Alfa Inorganic Inc.) and our own oxidation product.

When Pd was made the anode in 400°C $KClO_3$ with 6v, a heavy froth in the electrolyte forced the experiment to stop at the end of 5 min. A thick black coating had formed and was identified as PdO. The PdO formed in KnO_3 with 6v was a thick, gray adherent coating at the end of 2 hr. No problems with froth were experienced in KNO_3.

The forms of Ta_2O_5 are many, and as in the case of Nb_2O_5 the positive identification of any given structure is elusive. Ta_2O_5 (penta) (ASTM Card No. 7-231) was identified as the result of electrolysis in $KClO_3$ with 6v at a maximum current density (c.d.) of 2.3 ma/cm² and again with 60v at a maximum of 23 c.d. units. These thick adherent coatings were yellow and bluish-green to violet, respectively. Little success was realized in trying to form Ta_2O_5 (penta) with electrolysis in KNO_3. Some highly colored oxides were formed with various treatments, but identification was not positive.

β-Ta_2O_5 (ASTM Card No. 8-255) apparently may be fabricated in a number of ways. Thin films of this type were the result of heating Ta to redness in work preliminary to this study and also resulted from exposing Ta to molten $KClO_3$ for about 30 min. The β form was also obtained with electrolysis in both molten salts with 90v for about 1 min. This was an extremely adherent, thick gray coating. Under a microscope, it was found that scratches on the Ta surface had been smoothed over by the gray coating.

Mixed oxides of PtO_2 and PtO were identified spectrophotometrically from adherent films which were formed when Pt was placed in molten salts with and without electrolysis (56).

ASTM diffraction d-spacing values are also not available for PtO. It had been reported (57) that PtO should have the same structure as PdO. We found 7 coincident x-ray diffraction peaks on comparing our platinum oxide with ASTM data on PdO, and have therefore tentatively identified our product as PtO. The PtO made by exposing Pt black to O_2 at high temperatures is more tightly adherent than the original Pt black, but is still easy to remove by scraping.

Cobalt Phthalocyanine as a Fuel Cell Cathode

Raymond Jasinski

Tyco Laboratories, Incorporated, Waltham, Massachusetts

One of the necessary characteristics of an oxygen electrode is that it chemisorb oxygen without degradation of the catalytically active surface. Reversible absorption has been observed in aqueous solution for some metal chelates, *e.g.*, bis (salicylal) ethylene diamine cobalt (II), heme, and cobalt (II) histidine (1). The possible application of these soluble compounds as fuel cell cathode catalysts would lead to a complicated engineering system, even if the oxygen-exchange kinetics were favorable.

A number of insoluble metal chelates will also chemisorb oxygen; the most chemically stable of these are the metal porphyrins and the metal phthalocyanines. The molecules are square planar complexes (2) with the metal atom symmetrically surrounded by four nitrogen atoms. These nitrogen atoms are each members of ring systems, which in turn are connected by carbon atoms (porphyrins) or nitrogen atoms (phthalocyanines). The details of crystal structure, chemical properties, and methods of preparation have been summarized recently (3).

A number of these compounds are insoluble in most common solvents, acid (8M H_2SO_4) and base (7*N* KOH). Concentrated sulfuric acid is required to solvate cobalt and copper phthalocyanine (CoPc, CuPc). CuPc is reported to be stable to thermal decomposition at 500°C. No decomposition of CoPc has been observed at 120°C under oxygen. Further stability can be achieved by partially chlorinating the compound or by polymerization (4).

Copper phthalocyanines (CuPc) have been reported to be active catalysts for hydrogen reactions such as o-p conversion and H_2-D_2 exchange (5-7). More relevant to the present work are the properties of copper and cobalt phthalocyanines as oxidation catalysts. For example, both compounds have been used in the air oxidation of mercaptan sulfur to disulfides for the "sweetening" of petroleum products (3,8). A preliminary appraisal of CoPc as a fuel cell cathode catalyst has been discussed in a recent note (9). In the present paper, CoPc is more fully evaluated in a practical electrode configuration, and its catalytic activity is compared to that of other known catalysts measured under identical experimental conditions.

Experimental

IR-free voltage measurements were made with the interrupter technique, employing a transistorized sine wave commutator (10). The test H_2/O_2 fuel cells had end-plates machined from Teflon; a Teflon O ring was employed to prevent uncontrolled evaporation of water. The use of Teflon components obviates problems which could arise from the oxidation and/or corrosion of metal end-plates.

A platinum wire imbedded in the end-plates served as the electrical lead. The contribution of the Pt wires to catalytic activity was found to be negligible; thus the electrodes were the only electrochemically active materials in the system.

An electrolyte of 35% KOH, immobilized in an asbestos membrane, was used. The anodes, 5 cm^2 disks, consisted of 9 mg Pt/cm^2 plastic-bonded to a nickel screen (American Cyanamid Corporation).

The cell temperature was 80°C unless otherwise noted. A thermocouple was placed in one of the Teflon plates and positioned above the cathode.

Only total cell voltages were measured since it was difficult to insert a probe into the test set-up described. Platinum cathodes were therefore run in the same cell to establish a point of reference. Data for H_2/O_2 cells are apparently self-consistent to $\pm$ 0.015v, as the reproducibility of the cell performances indicates. The flow rate of oxygen was adjusted to remove the water produced by the cell reaction; the hydrogen was "dead-ended." Both gas pressures were kept at 2.08 atm (16 psig).

In previous work (9) a cathode had been used which consisted of a porous nickel plaque onto which a coating of CoPc had been slurried. These structures were effective electrodes only if O_2 was passed through the CoPc coating. Impregnating porous plaques was difficult because of the limited solubility of CoPc in com-

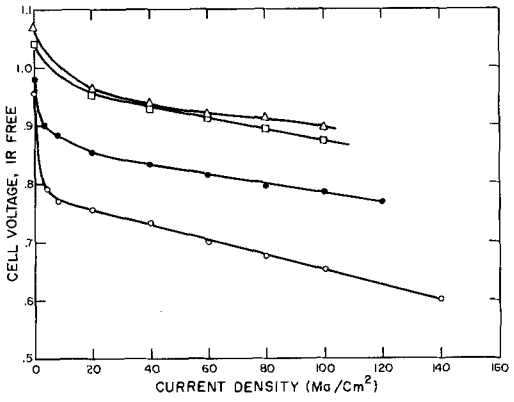

Fig. 1. Performances of H_2/O_2 fuel cells operating at 80°C with an electrolyte of 35% KOH, and a platinum black anode (9 mg/cm²). The cathodes are: 9 mg/cm² platinum (□); 40 mg/cm² silver (△); 14 mg/cm² CoPc (●); and 20 mg/cm² acetylene black (○).

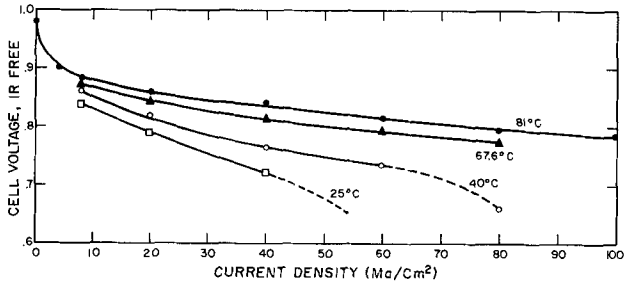

Fig. 2. Temperature dependence of the performance of H_2/O_2 fuel cells employing a CoPc cathode. The cell was operated with an electrolyte of 35% KOH and a platinum anode.

mon solvents. A more suitable electrode structure was formed by Teflon-bonding a mixture of 0.072g of CoPc and 0.048g of acetylene black to a 5 cm² nickel screen disk. Acetylene black cathodes were also prepared by Teflon-bonding 0.12g to nickel screen.

This method of electrode preparation is relatively independent of the particular material employed as the catalyst and has been used to investigate a variety of nonconductive metal chelates. After the electrode has been "activated" in the manner described below, a cell resistance of 0.022 ohm was obtained. This may be compared to a cell resistance of 0.018 ohm obtained for Teflon bonded platinum electrodes in the same cell. No attempt was made to reduce further the internal resistance.

Cobalt phthalocyanine, supplied by the National Aniline Division of Allied Chemical Corporation, was 99% pure and was used without further treatment.

Results

The chemical stability of CoPc under conditions approximating fuel cell operation was evaluated as follows. A sample was placed in 35% KOH and heated to 75°C. No discoloration of the liquid was noted. A second sample was placed in 30% H_2O_2. Again no discoloration occurred, although gas evolution was noted. Similar experiments with iron phthalocyanine resulted in considerable decomposition of the chelate, particularly in the presence of hydrogen peroxide.

Electrode activation.—The initial performance of CoPc cathodes was generally low, *e.g.*, 80 ma/cm² at 0.70v. However, it was found that if the cathode were polarized to H_2 evolution potentials, subsequent operation improved, *e.g.*, 80 ma/cm² at 0.81v. No decrease in output was noted after 10 hr of operation. The maximum performance which could be obtained is that shown in Fig. 1. The increase in electrochemical activity is accompanied by a change in appearance of the electrode. On dismantling the cell, it is found that the color of the catalyst mixture had changed from red-violet to brown-black. "Activation" also lowers the internal resistance of the cell. Typically, the resistance decreased from 0.05 to 0.02 ohm.

That this pretreatment is not a temporary charging effect is indicated by a comparison of the quantity of charge passed during activation with that passed on subsequent fuel cell operation. Activation is accomplished with 600 ma/cm² (3 amp), flowing for 2 min (0.05 amp-hr). Typically, the cell was then operated at 100 ma/cm² for 10 hr (5.0 amp-hr). This difference in charge of 10^2 can best be explained by postulating a permanent alteration in the structure of the catalyst.

Since activation was carried out at a current density of 600 ma/cm², significant IR heating occurred. Thus, the presence of oxygen and the generation of H_2 in the cathode cavity suggest at least five possible activation mechanisms: (i) the effect is electrochemical; (ii) the effect is thermal; (iii) the effect involves heat and O_2; (iv) the effect involves heat and H_2; (v) the effect involves an alteration of the physical structure of the electrode. *e.g.*, wetting characteristics.

Temperature measurements, made with the thermocouple placed above the cathode compartment, indicated that the cell temperature never rose above 90°C. Since heat transfer through Teflon is low, most probably the temperature at the electrode surface was somewhat higher during the current density flow of 600 ma/cm². To insure an adequate evaluation of the effect of temperature, the electrode was first heated to 350°C under argon before use in a cell. Since this did not activate the electrode, heating alone is not sufficient. Second, the electrode was heated in a hydrogen atmosphere up to 340°C. A number of inactive electrodes resulted, although the electrode had changed color to brown-black and the internal resistance was lowered. Therefore, mechanism (iv), IR heating plus H_2, is not the explanation. It should be noted that heating the electrode in H_2 at a higher temperature (370°C) did provide active cathodes. Activation under these conditions is presumed to be an alternate mechanism. Third, a cell was polarized so that O_2 was evolved at the CoPc electrode. Activation did not occur. Finally, activation was not noted for the acetylene black or the platinum black electrodes, indicating that the effect represented an alteration of CoPc.

Apparently the effect is electrochemical, indeed, an "arrest" in the time-potential curve is observed at a cell voltage of approximately — 1v. This occurs when activating the CoPc electrodes but not the acetylene black. The "arrest" was noted for only CoPc electrodes which were inactive initially, *i.e.*, those not activated by gaseous H_2 at 370°C. It is not possible with this limited data to offer a detailed description of the mechanism by which the electrochemically altered CoPc improves cathode performance.

Cell performance.—The performance of the CoPc cathode in a H_2/O_2 cell is compared in Fig. 1 to that for acetylene black, platinum black, and silver (40 mg/cm²). At a constant current density of 100 ma/cm² the cells performed as follows: CoPc cathode 0.79 ± 0.015v, acetylene black 0.65v, platinum black and silver 0.87v. Thus, it is apparent that CoPc functions as an oxygen electrode catalyst, although its performance is 0.08v poorer than that obtained with platinum black. This difference could be slightly greater if an equal loading, 15 mg/cm², of platinum were used. On the basis of relative cost, however, the use of CoPc becomes more favorable.

Cell performance as a function of temperature is summarized in Fig. 2. Some output is obtained at room temperature so that a fuel cell employing this catalyst could be considered as self-starting. An increase in temperature results in an increase in performance. The

temperature of 80°C was arbitrarily chosen as the operating point.

Discussion

It has been possible to form an oxygen electrode with a metal chelate, cobalt phthalocyanine, as the active catalyst. Sufficient electrical conductivity was achieved by mechanically blending the chelate with acetylene black. A stable electrode structure was formed by Teflon-bonding the mixture to a metal screen. Since a supported electrolyte was also used, no difficulty was noted due to variations in electrode uniformity across the face of the screen.

The electrochemistry (*e.g.*, activation, pretreatments) of the chelate compounds is different from that experienced with metal and oxide catalysts. The "activation" treatment, found with cobalt phthalocyanine, (which resulted in an increase in cell voltage of 0.1v at 100 ma/cm^2) was without noticeable effect when applied to acetylene black, platinum, and silver.

The activation step is a reductive procedure; chemical testing indicated the absence of free cobalt or cobalt oxide. A recent paper (7) on the activation of hydrogen by copper phthalocyanine has indicated three types of catalytically active sites: (*a*) the chelated metal atom, (*b*) unpaired electrons arising during heat treatments, (c) unpaired π electrons formed by the opening of double bonds. Furthermore, it is indicated that the hydrogen reaction rates are enhanced by catalyst polymerization due to an increase in the density and stability of unpaired electrons. It is possible that the electrochemical treatment induced polymerization and/or increased the density of unpaired electrons. It is also possible that Co(II) was reduced to Co (I). However, phthalocyanine complexes of monovalent metal atoms are generally unstable. A more rigorous explanation for this effect cannot be made until the mechanism for oxygen reduction is determined.

The current densities sustained with H_2/O_2 cells were sufficiently high (60-120 ma/cm^2), to be considered for application in practical fuel cell systems. The H_2/O_2 cell voltage is about 0.1v lower than can be obtained at present with either platinum or silver catalysts. Some metal phthalocyanines are relatively inexpensive and are employed commercially as dyes; for example, the copper compound is available at approximately $1.10/lb.

Effect of Oxide Hydration on Surface Potential of Oxidized P-Type Silicon

A. B. Kuper[1] and E. H. Nicollian

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

The n-type tendency of silicon surfaces under thick oxide has been known since the first work of Atalla, Tannenbaum, and Scheibner (1). In the present paper experimental evidence is presented showing that an important cause of this tendency is hydration of the oxide and that the effect is reversible. Temperature-humidity history is thus important in establishing the silicon surface potential of passivated structures. This effect has practical significance for oxidized silicon device performance and reliability.

Atalla *et al.* (1) showed that fast (close to the interface) donor-type states were present and observed the n-type surface tendency on diodes oxidized after diffusion. Sah (2) reported the n-type tendency on diodes where oxidation was done before diffusion. Kahng (3) used high pressure steam oxidation after diffusion and also found n-type surfaces. Edagawa *et al.* (4) found the n-type tendency using grown junction silicon diodes oxidized in wet O_2, dry O_2, wet N_2, and wet H_2.

Water is expected to be present in silica films grown in steam or after exposure to steam as shown by Ligenza and Spitzer (5, 6) who studied the exchange of oxygen between silica and steam and by Moulson and Roberts (7) who observed infrared absorption due to water in silica.

Diodes in the present work were conventional n^+p planar junctions with no metal contacts. Oxidation preceded diffusion. Preoxidation cleaning was similar to that used by Atalla *et al.* (1).

Planar diodes 3.6 x 10^{-4} cm^2 in area, approximately 8 mils in diameter, were made by diffusion of phosphorus into chemically polished (Appendix A) boron-doped pulled crystal silicon. Resistivities from 0.5 to 5 ohm-cm were used. To make the diodes, the silicon was given a final boiling nitric acid, boiling water cleaning (Appendix B) and oxidized in atmospheric pressure steam (Appendix C) at 1050°C for 1 hr, which formed 6000Å of oxide. Photoresist masking was used and holes were etched in the oxide. Phosphorus doped layers 4μ deep with a sheet resistance of 50 ohm/sq were then formed in the etched areas by predifusion at 740°C for 40 min followed after glass removal by 1 hr at 1230°C in dry nitrogen — 10% oxygen. Diodes in this "dehydrated" state had reverse dark currents in the nanoampere range. Diode reverse current results were qualitatively the same when the oxide was grown in dry oxygen.

Diodes then oxidized in unpressurized steam at 1050°C with consequent "hydration" of the oxide had

[1] Currently on leave of absence at Case Institute of Technology, Cleveland, Ohio.

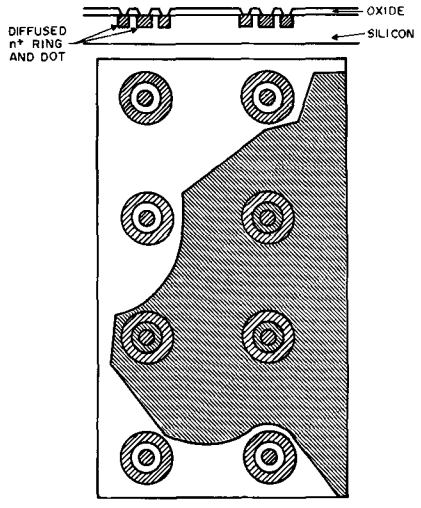

Fig. 1. Extent of n-channel under oxide after steaming ring and dot diodes 2 hr at 408°C. Silicon is 0.5 ohm-cm p-type. Shaded region indicates extent of channel measured by diode photoresponse. Outside diameter of devices is 15 mils, and center to center distance is 50 mils.

channel saturation currents in the milliampere range. If diodes were then heated for about 1 hr at 1000°C in dry ambient, reverse currents were reduced to the nanoamp range again. Dry air, oxygen, nitrogen, and argon as well as vacuum were found to be suitable for drying.

The channel that resulted when the oxide was hydrated was shown to be n-type extending over the p-region by measuring diode photoresponse using a small chopped light spot. The extent of one channel resulting from steaming a set of ring and dot diodes at 408°C for 2 hr is shown in Fig. 1. Here, hydration was stopped before the entire surface was inverted. The oxide was of uniform thickness. This patchy inversion (also suggested the spread of data in Fig. 2) suggests that localized conditions at the oxide-air or oxide-silicon interface may control the rate of inversion.

If the oxide were completely etched off in concentrated HF and the sample then rinsed thoroughly and dried, no channel was present, as has been reported (1). Results are summarized in Fig. 2. Hydrogen at 400°C also produced channels, in agreement with Blum *et al.* (8), but longer exposure time than with steam was required to produce a channel of the same strength. Exposure to other gases at 400°C did not produce channels as shown in Table I.

Reversible channeling was also seen by means of measurements of the diode capacity. In the dehydrated state for the case of 0.5 ohm-cm p-type there was negligible excess capacity. In the hydrated state, the presence of a channel was clearly indicated by excess capacity at low bias. This excess capacity went to zero at about the same reverse voltage at which the reverse current saturated.

Five ohm-cm p-type ($N_a = 2.5 \times 10^{15}$ cm^{-3}) silicon remained slightly inverted at the surface after 1000°C baking in dry nitrogen for 2 hr while 0.5 ohm-cm (4×10^{16} cm^{-3}) did not, suggesting that there was an effective donor concentration of the order of 10^{11} cm^{-2} in this experiment.

At 800°C, the current-voltage characteristic of the dehydrated state was found to reach equilibrium from the hydrated state in less than 1 min. Likewise, the heavily channeled state could be achieved at 1050°C in steam in less than 1 min. Reverse currents of diodes in the dehydrated state changed slowly when given wet-dry cycling at low temperatures as shown for 300°C in Fig. 3. Data of this kind generally indicated that hydration proceeded somewhat faster

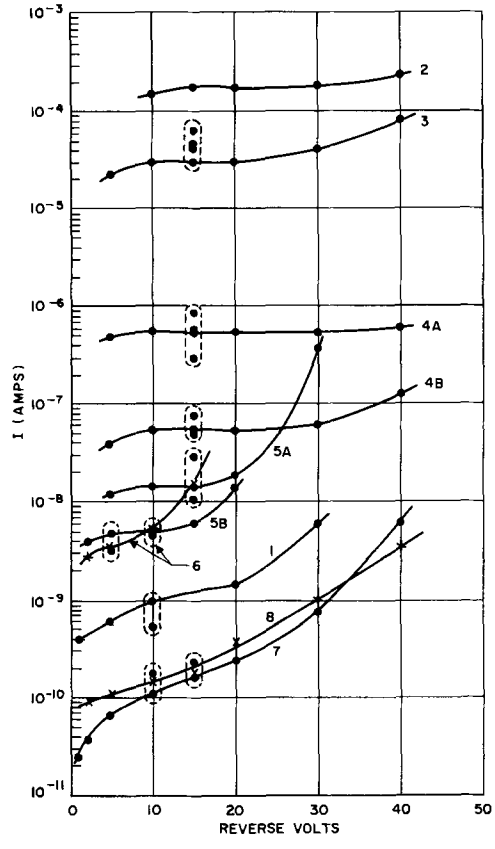

Fig. 2. Summary of reverse current vs. voltage on planar diodes from one diffused slab of 0.5 ohm-cm boron doped pulled crystal silicon. Each curve represents a group of diodes. Vertical box indicates the spread of current data. A and B refer to regions of a piece which showed a distinct grouping of currents after baking. Curve 1, initial state after phosphorus diffusion; curve 2, oxidized in 1 atm steam pressure at 1050°C for 1 hr after 1. Oxide over junction is approximately 8000Å thick; curve 3, baked 5 min in air at 460°C after curve 2; curve 4, baked 30 min in dry argon at 700°C after curve 2; curve 5, baked 30 min in dry argon at 750°C after curve 2; curve 6, baked 30 min in dry argon at 800°C after curve 2; curve 7, baked 1 hr in dry nitrogen at 1000°C after curve 2; curve 8, oxide etched off in concentrated HF after curve 2, dry nitrogen ambient. The "soft" characteristic of curves 5 and 6 is a typical result of heating an unclean sample and is not regarded as significant for this experiment.

than dehydration at the same temperature. Estimated relaxation times (time for reverse current to decrease by a factor 10) for baking temperatures between 200° and 700°C were consistent in many cases with the known rate of diffusion of water through silica glass (7).

The effect of water on diode reverse current observed in the present experiments is similar, except for longer relaxation times, to the effect of humidity at room temperature on diodes that have not been thickly oxidized. This suggests that the observed effects are due to water or a water-related species largely concentrated at the silicon-oxide interface.

To test this model, hydrated oxide was progres-

Table I. n^+p (1.5 ohm-cm) Planar diode aging

Aging temp, °C	Exposure time, hr	Gas at 1 atm	Saturation current, μa

390	3.5	H_2O	2000

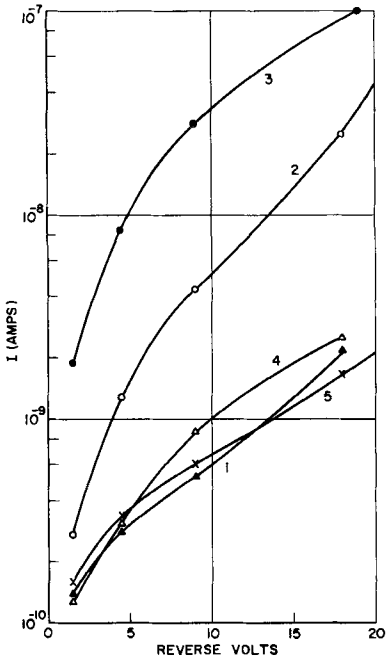

Fig. 3. Diode reverse characteristics. Low-temperature steam and bake cycle of a diode starting in the dehydrated state. The p-region resistivity is 0.5 ohm-cm. Oxide over junction is approximately 6000Å thick. Curve 1, start; curve 2, After 30 min in atmospheric pressure steam-oxygen mixture at 300°C; curve 3, after 52 min more as in curve 2; curve 4, after 40 min bake in air at 300°C after curve 3; curve 5, after 60 min more as in curve 4.

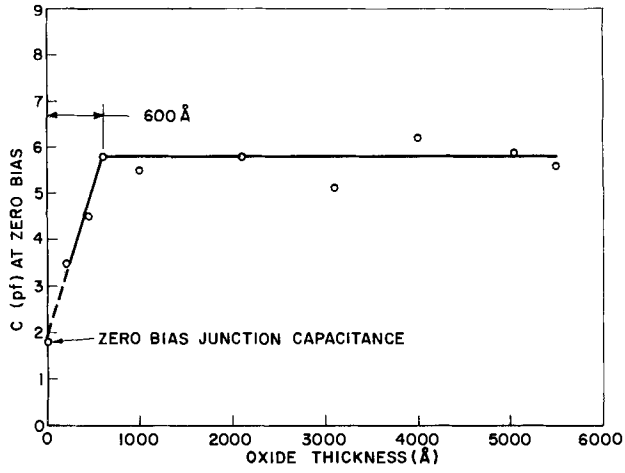

Fig. 4. Total zero bias capacitance of one channeled 0.5 ohm-cm diode measured at 100 kc as a function of oxide thickness on the inverted surface. Oxide thickness is measured by matching color to a standard whose thickness is known by ellipsometer measurement and is verified for each point by measuring the dielectric breakdown voltage of oxide on the slab.

sively etched off a channeled diode and the zero-bias capacity was measured. The result in Fig. 4 shows that the surface of the 0.5 ohm-cm silicon remained inverted until only a few hundred angstroms of hydrated oxide remained. (Oxide thickness less than 1000Å was obtained by controlled etching and checked by dielectric breakdown.) Figure 4 shows that a substantial number of ionized donors from hydration were in the oxide within 600Å of the silicon. The charge may be confined even closer because disappearance of the channel beginning at a thickness of 600Å may be a spurious result due to the fact that such thin oxide probably contains pinholes, and/or that states at the oxide-air interface become important.

The experiments suggest that hydration effects in steam depend on a water species acting as a donor localized on the oxide side of the oxide-silicon interface.

The Minimum in Molar Conductance of $CdCl_2$ in Water-Methanol

D. O. Johnston

Department of Chemistry, David Lipscomb College, Nashville, Tennessee

and P. A. D. de Maine

Department of Chemistry, University of California, Santa Barbara, California

Molar conductances of $CdCl_2$ in methanol (1) and in ethanol (2, 3) have been measured. Golben and Dawson (3) proposed that in ethanol $CdCl_2$ dissociates in the most dilute range as an uni-univalent electrolyte. For CdI_2 in methanol (4, 5) conductance values show a maximum, but no maxima have been reported for the chlorides. Hartley and Raikes (6) have reported the ionic mobilities of Cd^{++}, Cl^-, and other ions in methanol.

Conductance minima have been reported for methanol-water systems containing KCl, KOH, NH_4Cl, or HCl (7). The minima for the KCl and KOH systems

* As this table is traversed to the right, the $CdCl_2$ concentration increases by 3% because of the nonideality of water-methanol.

occur between 40 and 60 mole % water which coincide with maxima in the viscosity. At 25°C water-methanol mixtures show a maximum in viscosity at 73 mole % water (8). The pronounced conductance minimum at 5°C for HCl-methanol-water at 20 mole % water has been ascribed by Gurney (9) to partial suppression of proton jumps by the water molecules capturing protons from methonium ions since the methonium ion has a proton level higher than that of the hydronium ion. As the water concentration is increased, the conductance increases because of proton jumps between water molecules.

Experimental

General techniques of preparing solutions and measuring resistances with a General Radio Company Impedance Bridge (Type 1650A) at 5°, 20°, and 45°C have been described elsewhere (1, 10). The Fisher Spectrograde methanol had a specific conductivity of 9×10^{-7} ohms^{-1} cm at 20°C. The anhydrous Fisher Certified Reagent $CdCl_2$ assayed 99.1% $CdCl_2$, and chloride analysis showed a maximum deviation of 0.52% from stoichiometry. The water, distilled in an all-glass apparatus, had a specific conductivity of 3.5×10^{-6} ohms^{-1} cm at 20°C.

In Table I concentrations of $CdCl_2$ and water are given. In calculation of $CdCl_2$ concentrations solvent densities reported by Mikhail and Kimel (8) were used. The solutions were stable for at least 24 hr. Resistance measurements on 29 duplicate samples in the area of the minimum showed that resistances could be measured reproducibly to within 1%.

Results

For constant $CdCl_2$ concentrations the molar conductances of $CdCl_2$-water-methanol systems decrease with an increase in water concentration to about 4.5M (17 mole %) (Table I). Conductances then increase for higher water concentrations. This effect was observed for $CdCl_2$ concentrations from 0.005 to 0.0015M at 5°, and 0.0005M at 20°C, but was not noted for salt concentrations equal to or greater than 0.0005M at 45°C. Table I contains some of the data which illustrate these statements. Concentrations near 9M in water are required to achieve the conductance value obtained in anhydrous methanol at 5°C.

Discussion

If water complexing with the salt is important, the high local dipole moment of the water molecules should enhance and not decrease ionization. It appears that solvolysis products may be important in producing the minimum. At 5°C the minimum for the $CdCl_2$-water-methanol system occurs between 16 and 18 mole % water, while for HCl-water-methanol the minimum is at 20 mole % water. Decreased mobility of the Cd species formed by hydrolysis together with diminished proton jumps would account for a decrease in conductance as water is added to the system. The increase at higher water concentrations would result from increased ionization of the salt and from increased proton jumps.

However, the lack of a conductance minimum at 45°C and at higher salt concentrations indicates that besides solvolysis there may be other important effects such as basic solvent structure. Viscosity studies (1, 8) indicate that water increases structure in a solution more than methanol. Increased solvent structure might offer sufficient resistance to ions to effect a conductance decrease until ionization effects offset the structural resistance. Then conductance increases with higher water concentrations. At 45°C water would not add a sufficient increase in structure to counteract the greater production of ions.

Observation of Active Areas in Thin Films of Palladium

Steve Eisner

Materials Research Section, The Martin Company, Denver, Colorado

Active centers in catalysts have been attributed by other investigators to emergent dislocations (1, 2), and point defects (2). Other kinds of crystal imperfections may also function as active centers, such as stacking faults, sessile dislocations, and impurity atoms.

The palladium-hydrogen system was chosen for the further study of active catalytic centers because of the large amount of hydrogen sorbed (from 1000 to 3000 times the metal volume) by palladium at room temperature. Exposure of palladium to hydrogen yields an expansion of the palladium lattice of 0.2Å, *i.e.*, from 3.8Å to 4.0Å (3).

Experimental Methods

Films on thin transparent substrates.—Thin films were deposited in a vacuum chamber by vapor deposition of palladium on microscope cover glasses and on Mylar substrates. The glass substrate had previously been cleaned by glow discharge to provide adherent coatings.

The average thickness of the palladium deposit was measured by weight changes on known areas of substrate. Specimens having an average thickness of 570Å were chosen for the hydrogen experiments.

Before they were exposed to hydrogen, the coatings showed no palladium hydride lines in the x-ray diffraction pattern.

Films on iron crucibles.—Thin films were deposited on the outside of previously polished Armco iron analytical crucibles. The crucibles were then set up over a Unitron microscope so that changes in the surface films could be photographed as hydrogen diffused through the crucible and combined with the palladium.

The crucibles were filled with a 4% solution of H_2SO_4 containing As_2O_3 as a poisoning agent. A current of 1 amp/in.^{2} was passed through the electrolyte, the crucible being cathodic. Diffusion of hydrogen through the crucible to the palladium film on the underside was clearly evident in 2 hr by the formation of the rosettes on the film.

The relative rate of hydrogen sorption and desorption in both types of experiments was recorded by two methods: (a) by measuring the change in intensity of the palladium hydride x-ray diffraction lines during and after exposure to hydrogen; (b) by measuring the change in light transmitted through the glass substrate specimens during and after exposure to hydrogen.

Discussion

Changes in thin films on glass and Mylar substrates.—Hydrogen was passed over thin palladium films on Mylar and on glass. The formation of a palladium hydride was indicated by the curling of the palladium-coated Mylar, showing expansion of the films. Glass-based films crinkled as the film expanded with the formation of palladium hydride (Fig. 1).

Crinkling started from microscopically observable points or lines on the surface. With only 300X magnification, defect areas rather than individual defects were seen. Circular crinkle patterns developed around point areas and elliptical crinkle patterns around active line areas. Increase in the diameters of the circles or ellipses means that the hydrogen gas entered through the hydride phase or through the palladium at a highly stressed edge of the crinkled area.

When the hydrogen was shut off, visible uncrinkling began after a few minutes (Fig. 2). This continued until all crinkling disappeared.

More photographs (Fig. 3) were taken when the palladium film was exposed to hydrogen again, after the cycle of crinkling and uncrinkling shown in Fig. 1 and 2. Comparison of Fig. 1g and 3e shows that new active centers have been formed. Since no impurities have been added to the film, it is assumed that the new active areas are due to the cold work created by the crinkling process. [Recent work (2) has shown the relationship of cold work to catalysis in the case of ortho-para hydrogen conversion by nickel catalysts.]

After several cycles of crinkling and uncrinkling, the crinkling film changed its appearance from sharp-ridge crinkles to deformed or splayed-out crinkles, and occasional cracks also developed. This cracking, after frequent mechanical cycling, is reminiscent of fatigue cracking phenomena in metals.

Changes in films on iron substrates.—The effect of diffusing hydrogen by electrolysis for 2 hr through

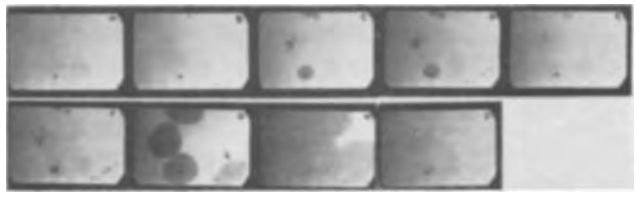

Fig. 1. (a through i). Approximately 160X micrographs taken 3 sec apart. Hydrogen gas was flowed over a palladium film evaporated on glass. Rosettes of crinkled area formed. When the flow was stopped (Fig. 1c) the rosettes disappeared. The flow was restarted again (Fig. 1e), and the rosettes grew until the entire surface was covered. It is interesting to note that active centers may be both in the form of points and lines (arrow).

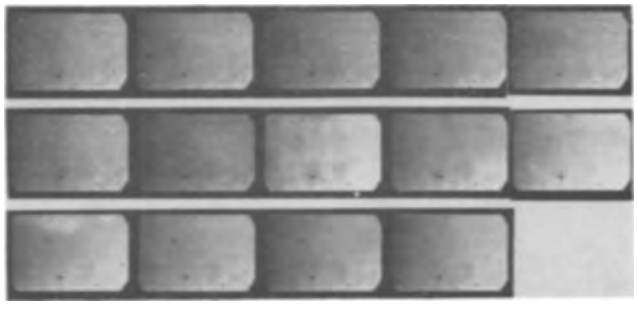

Fig. 2. Stream of hydrogen was stopped, and the crinkled surface was photographed every 3 sec. Uncrinkling was much slower than crinkling.

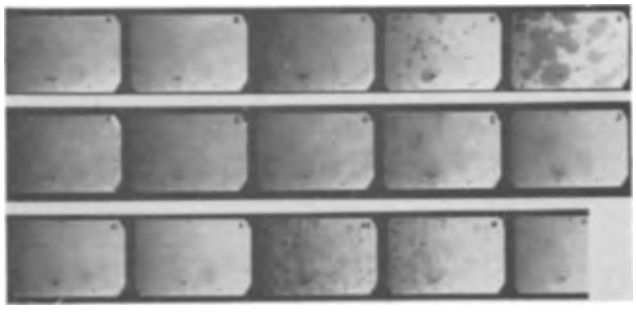

Fig. 3. (a through o). The flow of hydrogen was restarted. Figures 3c, 3d, and 3e show that new active centers are in evidence. These were generated by the cold work of the previous crinkling process. These centers are assumed to be crystal imperfections such as emergent dislocations or stacking faults. After several cycles of hydrogen pickup and release, the crinkles seem to lose their sharpness.

Fig. 4. Rosettes were formed on 500Å-thick palladium evaporated on an iron crucible which was hydrogen charged from the inside. Magnification 700X.

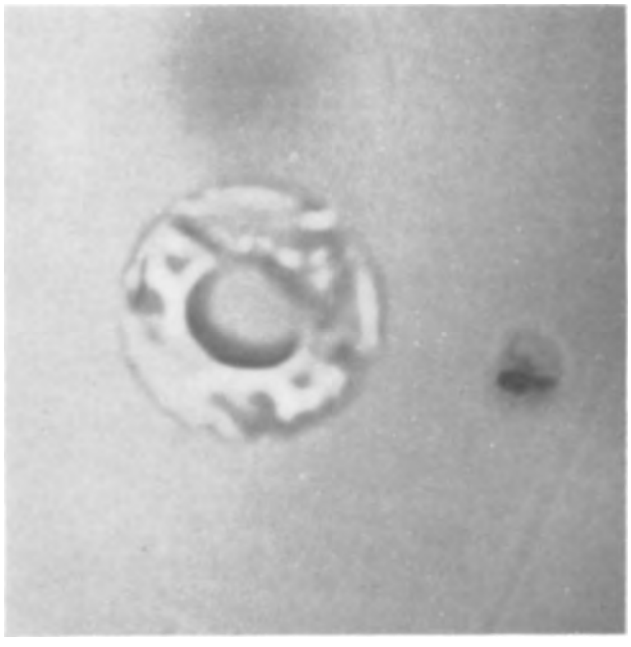

Fig. 5. Rosette shown in Fig. 4 deformed after a few hours. Magnification 700X.

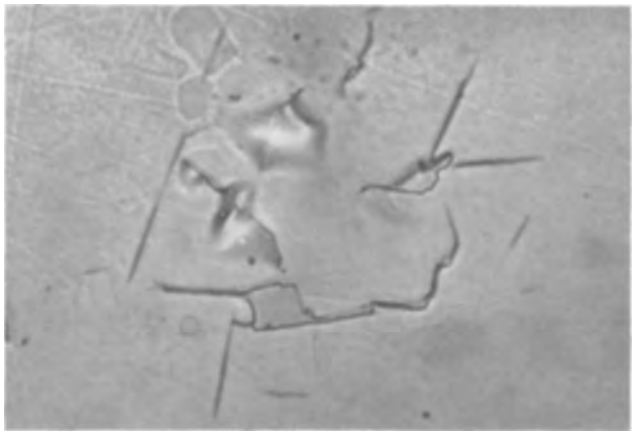

Fig. 6. Rosette shown in Fig. 5 and Fig. 6 cracked within 24 hr. Magnification approximately 800X.

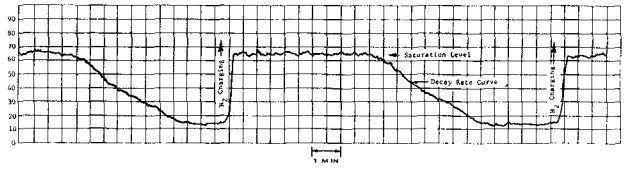

Fig. 7. Intensity of a single palladium hydride line changes with sorption and desorption of hydrogen. The sorption is quite rapid; the desorption is slow.

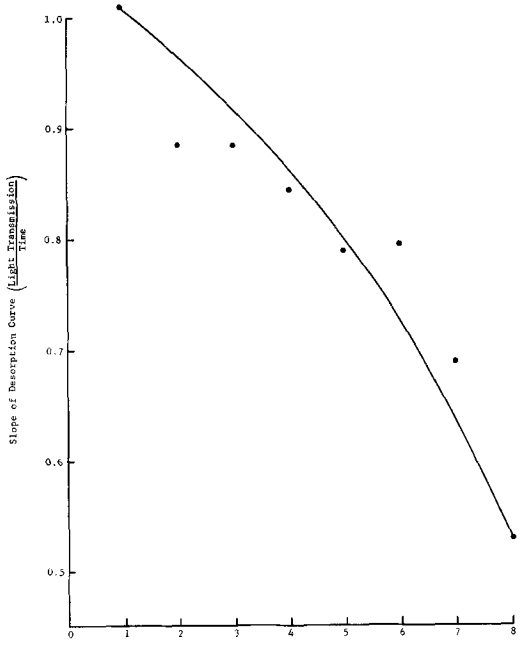

Fig. 8. Slope of the hydrogen desorption curve as measured by densitometry tends to decay with the number of charging cycles.

polished Armco iron crucibles was the creation of individual rosettes on the palladium film deposited on the outside of the crucibles (Fig. 4). The rosettes did not disappear with time as did the crinkles in palladium films on glass. Instead, the rosettes deformed (Fig. 5) and cracked (Fig. 6) within 24 hr.

Changes in x-ray diffraction line intensity.—The rapid increase and slow decay of x-ray diffraction line intensity (Fig. 7) for the palladium hydride lines can be related to the rapid crinkling and slow uncrinkling of the palladium film shown in Fig. 1 and 2. The rate of change in diffraction line intensity can also be related to the microcinematographs taken of the crinkling and uncrinkling phenomena. Saturation of the palladium film with hydrogen is indicated by the constant intensity level of the palladium hydride line (Fig. 7).

Densitometer readings.—Similar evidence was given by densitometer readings as light was transmitted through the thin palladium film during hydrogen sorption crinkling and desorption uncrinkling. The desorption curves have a smaller slope with each succeeding cycle of hydrogenation. The slopes of the desorption curves were obtained from the densitometer recordings.

The slopes of the desorption curves were measured from 0.1 to 1.0 min after hydrogen saturation of the palladium film, the curve being relatively straight during this time.

These slopes, when plotted against the number of hydrogenation cycles (Fig. 8), show a gradual decrease. This decrease in hydrogen escape from a thin palladium film with an increasing degree of cold work due to crinkling indicates that hydrogen traps are

formed by cold work. Such an assumption is not out of line with metallurgical investigations that show it is more difficult for hydrogen to diffuse through hard steels than through soft steels (4).

X-ray diffraction studies showed the rapid increase of palladium hydride line intensity under hydrogen exposure, but the slow decrease in this intensity after exposure. Visual confirmation was provided also in the rapid crinkling and slow uncrinkling of the palladium film by means of microcinematographs. Eventual saturation of the palladium film with hydrogen is indicated by the constant-intensity level of the palladium hydride line. The decrease of hydrogen escape shows that hydrogen traps are formed by cold work.

Conclusions

The following conclusions apply:

1. The active areas of the hydrogen-palladium thin film systems (as evidenced by mechanical crinkling) are due to impurities and/or crystal imperfections.
2. New active areas are created by cold working (due to crinkling) of thin palladium films. This indicates that the creation or interaction of dislocations is important in forming active areas.
3. Hydrogen traps are created by cold work in palladium thin films as shown by decay curves of palladium hydride lines in the x-ray diffraction pattern after repeated hydrogen exposure. Densitometer readings through the palladium film also support this conclusion.

Brief Communications

Recrystallization of Thin Films of Germanium and Silicon

S. Nielsen

Ministry of Aviation, Royal Radar Establishment, Great Malvern, Worcestershire, England

Recent work on thin alloy zone crystallization processes (1) has suggested the possibility of recrystallizing thin films of semiconductors. We report here some progress in recrystallizing films of silicon and germanium deposited on insulating substrates and comment on some of the difficulties experienced with these processes.

Recrystallization has been attempted by forming a thin liquid alloy zone in the film and driving this zone across the film using a temperature gradient. For example a layer of germanium 1μ thick was evaporated onto a sapphire substrate at room temperature and a stripe of aluminum, 100μ wide, evaporated on top of the germanium layer. The layer was then subjected to a temperature gradient for 8 hr by placing the sapphire on a molybdenum strip heater in a vacuum system at 10^{-5} Torr. Thermocouples on the heater indicated a gradient of 150°C/cm across the 100μ wide aluminum-germanium alloy zone and a zone temperature of 650°C ± 10%. Under these conditions the zone did not move (Fig. 1), but certain regions of the film adjacent to the zone (appearing white in Fig. 1) had recrystallized. The crystallite size in these regions is ~0.05 mm (Fig. 2) compared to ~100Å before recrystallization. The crystallites showed no preferred orientation with respect to the substrate or zone and were confirmed as silicon by x-ray microprobe analysis. Larger gradients and longer times did not significantly increase the area recrystallized.

Silicon films, 1μ thick, deposited on sapphire by reduction of trichorosilane also showed recrystallized regions (Fig. 3) when treated in the same way. Figure 3 shows a region near an aluminum zone, which had

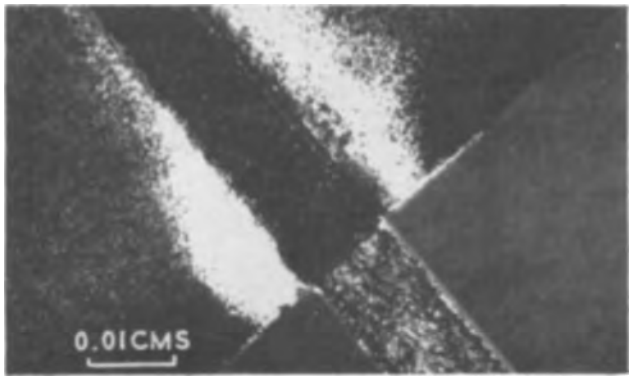

Fig. 1. Polycrystalline germanium film and aluminum alloy zone on sapphire substrate after heating for 8 hr in a temperature gradient of 150°C/cm.

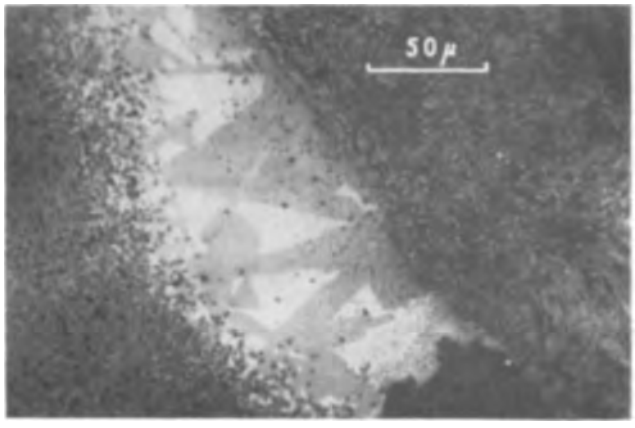

Fig. 2. Recrystallized region near aluminum alloy zone shown in Fig .1.

Fig. 3. Recrystallized region of a polycrystalline silicon film on sapphire.

been subjected to a temperature gradient of 100°C/cm at a zone temperature of 1000°C.

Zones of gold or tin alloys were used with germanium and silicon layers with various temperature gradients, but no zone movement was observed. In all cases the gold or tin diffused rapidly away from the zone, but produced no recrystallization. Attempts were also made to drive the gold or tin zones using an electric current (2); this produced very irregular movement of alloy, but again gave no recrystallization.

Experiments on the epitaxial deposition through thin liquid alloy layers (3) showed that epitaxy is possible through gold or tin alloy layers but not through aluminum layers. We attributed this to a coherent oxide skin over the surface of the aluminum alloy, the alloy then not being able to accept silicon from the vapor. We think that the recrystallization observed with aluminum zones in the above experiments is due to the removal of oxide from grain boundaries enabling the alloy to interact with the silicon crystallites. The gold or tin alloys do not remove this oxide and hence diffuse along grain boundaries without affecting the crystallites.

We conclude therefore that considerable recrystallization of silicon or germanium films by thin alloy zone crystallization processes is possible, but that difficulties are to be expected over the zone movement. These difficulties are probably enhanced by oxide contamination and must be overcome either by use of an oxide getter or perhaps by use of very steep temperature gradients such as is possible with electron beam processes.

Low-Temperature Epitaxy of Silicon by Sublimation onto Thin Alloy Layers

J. D. Filby and S. Nielsen

Ministry of Aviation, Royal Radar Establishment, Great Malvern, Worcestershire, England

The work of, for example, Carman *et al.* (1) on the regrowth of silicon from a silicon-gold eutectic, of Wagner and Ellis (2) on their V.L.S. process, and of Hurle *et al.* (3) on thin alloy zone crystallization processes, suggested that it would be possible to epitax silicon at low temperatures by evaporation onto a thin alloy layer. Results from recent experiments indicate that this is true, epitaxy of silicon having been obtained as low as 300°C.

The apparatus used is illustrated in Fig. 1. Silicon was sublimed from the source by heating it to 1300°C using induction heating. The substrate was heated by radiation from the source. The substrate temperature and the deposition rate were determined by the source-to-substrate distance and varied from 1100°C and 5 μ/hr to 500°C and ½ μ/hr. The substrate temperature was calibrated against the source temperature and source-substrate distance by using thermocouples in a blank run. At the start of each run the source temperature was determined with an optical pyrometer and the substrate temperature derived from it. This substrate temperature may be in error by ±50°C. The apparatus was pumped by a 10 l/sec ion pump which maintained a pressure of 5 x 10^{-8} Torr during the sublimation.

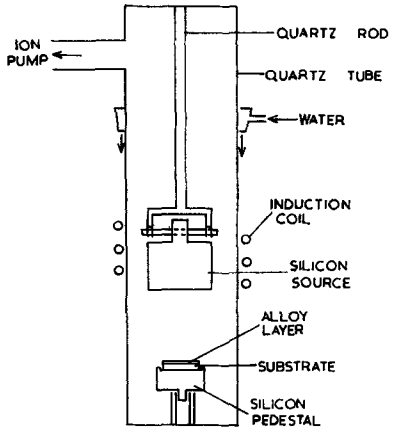

Fig. 1. Schematic diagram of sublimation apparatus

The substrate used in these experiments was a (111) silicon wafer which had been mechanically polished, degreased, and freed from oxide in HF. Before putting the substrate in the apparatus, a layer of metal 1-10μ thick was evaporated over part of the surface, the surface being near room temperature during the evaporation. The metal then alloyed with the silicon substrate to form a thin liquid layer at the deposition temperatures. Layers of gold, silver, copper, indium, and tin were alloyed in this way. After deposition, the layers were examined before and after removal of the alloy layer, and after bevel and vertical sectioning and etching, using optical microscopy and electron diffraction techniques.

The results from these experiments indicated that epitaxial silicon could be prepared by deposition through the liquid alloy layer. However, certain difficulties were experienced. First, the alloy layer showed a tendency to break up, the area covered by it

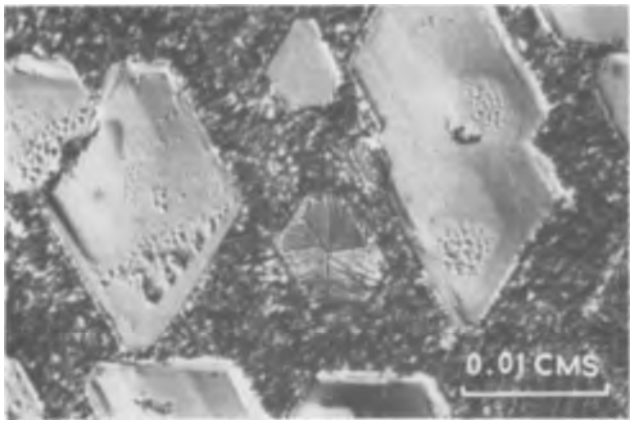

Fig. 2. Cellular silicon growth obtained under a gold alloy layer

depending on the constituents used and on the temperature. With gold alloy layers, for example, the layer broke up into droplets of 10-100μ diameter at temperatures above 1000°C. If radial temperature gradients were present, these droplets moved across the surface. At lower temperatures the droplet size increased, and at 700°C or lower the layer was substantially stable. Second, the silicon deposit underneath the alloy layers was often irregular. Figure 2 shows an example of this; a gold alloy layer has been removed and an irregular cellular type of growth revealed. This type of growth was observed under gold, silver, indium, and tin, but not copper alloys. The surface area of cells varied with the alloy and with the deposition temperature from 100 μ^2 to 0.5 mm^2. Sections through layers showing cellular growth also often revealed droplets of alloy trapped at the interface. We attribute this cellular growth to an irregular alloying caused by impurity on the substrate surface.

A polycrystalline deposit was observed on the surface of aluminum alloy layers; this we attribute to silicon depositing onto a coherent skin of oxide on the surface of the alloy.

Etching studies showed that the silicon deposited in the cells was usually more perfect than that deposited between them. A stacking fault density of 10^6/cm^2 within the cells was typical. An exception was the case of gold where no stacking faults were observed in the grown material unless a substrate with a heavily oxidized surface was used. For copper, where cellular growth was not observed, stacking fault densities of 10^3/cm^2 were obtained underneath alloy globules and in their immediate surroundings. We think that the stacking fault density is related to the oxygen concentration in the alloy.

One advantage of the sublimation process is that the temperature gradient through the alloy layer is such that the temperature of the alloy vapor interface is higher than that of the alloy substrate interface, the significance of this having been stressed recently by the authors (4).

So far our work has shown that epitaxial growth of silicon on silicon can be obtained at 850°, 800°, 500°, 400°, and 300°C using silver, copper, tin, gold, and indium alloys, respectively.

Microampere Multiple Constant Current Power Supply

Joseph B. Story[1] and Robert D. Wales

Materials Sciences Laboratory, Lockheed Missiles and Space Company, Palo Alto, California

A number of the more interesting anodic oxide thin films can be grown to potentials exceeding 100v. If it is desired to carry out this growth at a constant current, there is a problem in obtaining a suitable constant current source. The simple unit that is used for many purposes involves the use of a very large resistance in series with the cell, and a correspondingly high voltage across the combination. This makes the change in voltage across the cell small compared with the total and results in a correspondingly small change in the current. The voltage required for this apparatus is inconveniently large for use in thin film studies.

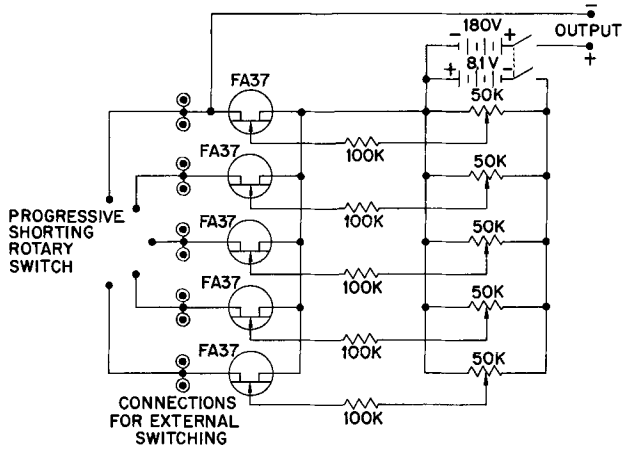

Fig. 1. Field effect transistor constant current power supply

One solution to this problem has been presented by one of the authors (1), who utilized the properties of a photomultiplier tube. It has now been found that a supply with smaller drift can be constructed using one or more field effect transistors in parallel (each individually adjustable). In addition, this arrangement offers the possibility of switching rapidly through a series of constant currents by using the transistors in various combinations. This rapid switching has been used by one of the authors (2) in investigating the mechanism of anodic germanium oxide film formation.

A circuit diagram of the power supply is shown in Fig. 1. The most critical factor involved is the stability of the biasing potential. For this purpose, six Mallory RM-42R mercury batteries (1.35v each) were used in series. It appears that a partial discharge of the batteries increases the stability. The FA 37 field effect transistors were of Amelco manufacture. Beckman

[1] Present address: University of Arkansas, Graduate Institute of Technology, Fayetteville, Arkansas.

precision potentiometers (50K) were used for adjusting the biasing potential.

Each of the FA 37 transistors is useful for currents up to 75 μa. The paralleling of transistors permits proportionately higher currents. It should also be possible to increase the current range by the selection of a different field effect transistor.

After a warm-up of 1½ hr, the drift over a period of 6 hr was 0.6% for currents up to 75 μa for one transistor. During this time there was usually a period of several hours during which the drift was about 0.01%. When the load is varied such that the voltage across it varies from zero to 100v, the current drops by 3.6%, 2.3%, and 1.8% for initial currents of 25 μa, 50 μa, and 75 μa, respectively.

Errata

On page 417 of the April 1965 issue of the Journal in the paper by Joseph B. Kushner "Relationship between Deposit Thickness and Current Density during the Early Stages of Electrodeposition," Eq. [8a], [9a], and [10a] should read

$$T_1 (I_1)^{3p/2} = T_2 (I_2)^{3p/2} = \text{constant} \quad [8a]$$

$$t_1 (I_1)^{(3p+2)/2} = \text{a constant} \quad [9a]$$

$$T_1/T_2 = t_1/t_2^{3p/(3p+2)} \quad [10a]$$

Manuscripts and Abstracts for Fall 1965 Meeting

Papers are being solicited for the Fall Meeting of the Society, to be held at the Statler-Hilton Hotel in Buffalo, N. Y., October 10, 11, 12, 13, and 14, 1965. Technical sessions probably will be scheduled on: Batteries (including Symposia on Charging Characteristics of Batteries and Characteristics of Electrodes during Charging), Corrosion, Electrodeposition (including Symposium on Thin Film Technology), Electronics-Semiconductors, Electrothermics and Metallurgy (including a Symposium on Zirconium and Its Alloys).

To be considered for this meeting, **triplicate copies of the usual 75-word abstract, as well as of an extended abstract of 500-1000 words** (see notice on page 121C of this issue), must be received at The Electrochemical Society, 30 East 42 St., New York, N. Y., 10017, *not later than May 17, 1965.* (Papers solely sponsored by the Corrosion Division **do not** require an extended abstract.) *Please indicate on 75-word abstract for which Division's symposium the paper is to be scheduled, and underline the name of the author who will present the paper.* No paper will be placed on the program unless one of the authors, or a qualified person designated by the authors, has agreed to present it in person. Clearance for presentation of a paper at the meeting should be obtained before the abstract is submitted. An author who wishes his paper considered for publication in the JOURNAL or ELECTROCHEMICAL TECHNOLOGY should send triplicate copies of the manuscript to the Managing Editor of the appropriate publication 30 East 42 St., New York, N. Y., 10017. Concerning papers to be published in the JOURNAL, see notice on per page charge on page 122C of this issue.

Presentation of a paper at a technical meeting of the Society does not guarantee publication in the JOURNAL or ELECTROCHEMICAL TECHNOLOGY. However, all papers so presented become the property of The Electrochemical Society, and may not be published elsewhere, either in whole or in part, unless permission for release is requested of and granted by the Editor. Papers already published elsewhere, or submitted for publication elsewhere, are not acceptable for oral presentation except on invitation by a Divisional program Chairman.

The Effect of Oxygen Pressure on the Oxidation of Zone-Refined Iron

W. E. Boggs, R. H. Kachik, and G. E. Pellissier

Applied Research Laboratory, United States Steel Corporation, Monroeville, Pennsylvania

ABSTRACT

The rate of oxidation of pure iron increases with decreasing oxygen pressure in the temperature range of 220°-450°C and the pressure range 100-0.01 Torr. Fe_3O_4 forms initially on the surface of the iron, and subsequently Fe_2O_3 nucleates in the surface of the Fe_3O_4. As the Fe_2O_3 layer becomes continuous, diffusion through the Fe_3O_4 layer is reduced, resulting in a substantial reduction of the oxidation rate. At low oxygen pressures (0.01 Torr), the rate of nucleation of Fe_2O_3 is low, resulting in relatively thick films of Fe_3O_4 and high oxidation rates, whereas at high oxygen pressures (100 Torr), the rate of nucleation of Fe_2O_3 is high, resulting in thinner Fe_3O_4 films, and lower over-all oxidation rates.

The technical literature contains more reports of investigations of the oxidation of iron and its alloys than of any other metal system (1, 2), presumably because of the great commercial and technological importance of ferrous materials. In the majority of studies reported, rates of oxidation of fairly pure commercial iron in oxygen or clean air have been determined for ranges of temperature and exposure time at a single gas pressure. Because of the greater practical interest in oxidation at higher temperatures, considerably more research has been devoted to the oxidation behavior of iron and its alloys at temperatures above about 600°C, where relatively thick oxide layers or scale form in a short time. The most recent information concerning the low temperature oxidation of relatively pure iron (200°-470°C and oxygen pressures of about 20 Torr) has been reported in a series of papers by Cohen and co-workers (3-8).

Some time ago, an investigation of the low temperature oxidation behavior of iron was undertaken by the present authors to provide background information for a larger research program directed toward obtaining a better understanding of the oxidation and corrosion behavior of commercially important alloy steels. The experimental pattern established in a recently completed study of the oxidation of tin (9-11) was followed, in that the effect of oxygen pressure as well as temperature was explored, and the constitution and morphology of the resulting oxide films were examined at various stages of film formation and growth. In an initial series of experiments carried out under oxygen pressures of 100, 10, 1, 0.1, and 0.01 Torr, at 270°C, it was found that the thickness of the resulting oxide films, for a given exposure time, increased quite substantially as the oxygen pressure was lowered. This unexpected finding prompted a more comprehensive study of the effects of pressure, temperature, and time of exposure on the oxidation kinetics and on the constitution and microstructure of the oxide films. The results are presented in this paper together with a proposed model for the mechanism of oxidation that appears to account satisfactorily for the experimental observations.

Materials and Experimental Work

Specimen purity.—Zone-refined iron was used in this investigation. According to the analysis provided by the source, Battelle Memorial Institute, the purity of the iron was about 99.99%, Table I. After the iron had been reduced to foil and electropolished in preparation for the oxidation experiments, it was analyzed by solid mass spectrometry and vacuum fusion. According to these analyses the purity of the iron foil was 99.94%, Table I.

Specimen preparation.—Half-inch-thick wafers of the zone refined iron were cold-rolled to a thickness of about 6 mils. Specimens of the rolled material were electropolished to clean and smooth the surface, vacuum-annealed at 10^{-6} Torr and 950°C for 4 hr, and then slowly cooled to room temperature (2°C/min). After this treatment, the foils contained relatively large grains (1 mm average diameter) that were free of deformation.

Surface preparation.—Great care must be taken in surface preparation prior to oxidation experiments. Ideally, the metal surface should be atomically flat and clean. Since mechanical polishing tends to distort and strain the surface layers, electropolishing is often employed to produce the desired smooth surfaces. Unfortunately, the resulting metal surfaces are usually covered by thin oxide films as a consequence of the electropolishing mechanism (12). The problem of removal of this electropolishing residue has not been solved satisfactorily. In the case of iron, hydrogen reduction is employed quite often, but it leaves

a residue of reduced iron and may result in surface rearrangement (12). Despite these anticipated disadvantages, electropolishing, followed by hydrogen reduction, was the method of surface preparation chosen for this investigation.

The following specimen preparation was found to yield fairly reproducible oxidation data. Specimens of the cold-rolled and vacuum-annealed iron foil were electropolished in a solution of 15% perchloric acid and 85% glacial acetic acid, washed, and dried. The foils were then transferred to a vacuum microbalance system and, after evacuation to 10^{-7} Torr, were reduced in pure hydrogen at a pressure of 10 Torr and a temperature of 400°C for 1 hr. The microbalance system was again evacuated to 10^{-7} Torr, the temperature was adjusted, and the system allowed to equilibrate; then pure oxygen was introduced to initiate an oxidation experiment.

Electron microscopic examination revealed that these electropolished and hydrogen-reduced iron surfaces were very smooth. There was no evidence of the gross surface rearrangement, such as faceting, that may occur in the course of hydrogen reduction at higher temperatures (12). A weight loss of the specimen corresponding to an iron oxide film 25-30Å thick was observed during the reduction.

To determine the nature of the electropolishing residues and the effectiveness of the hydrogen reduction, electropolished specimens were examined by reflection electron diffraction both before and after hydrogen reduction. The diffraction patterns (Fig. 1) consisted of elongated spots characteristic of the reflection electron diffraction patterns usually obtained from electropolished surfaces (13). Both patterns were identified as diffraction patterns of α-iron. Since available information suggests that a layer of contamination 25-50Å thick would completely obscure the low-angle diffraction maxima of a flat metal surface (14-16), the observed reflection diffraction pattern of iron, with marked refraction streaking and low background scatter, tended to confirm that the electropolishing treatment resulted in a film only 25-30Å thick on the iron surface. As is shown in Fig. 1, the refraction streaks are longer, and the background is lower, in the diffraction pattern of the hydrogen-reduced specimen than in the pattern of the electropolished specimen. Thus, it was concluded that the hydrogen reduction treatment had effected some cleaning of the surface. The physical condition of the iron produced by the reduction of the oxide film is not known.

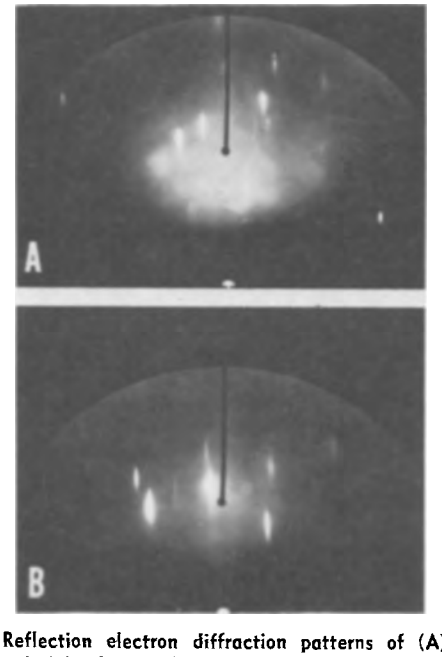

Fig. 1. Reflection electron diffraction patterns of (A) electropolished, and (B) electropolished and hydrogen-reduced surfaces of zone-refined iron.

Vacuum microbalance.—The Gulbransen-type vacuum microbalance (17) used in this investigation had been used in a previously reported study of the oxidation of tin (9). Because of radiometric and buoyancy effects (18), which are pressure and temperature dependent, it was necessary to apply corrections to the data obtained from the vacuum microbalance in the course of kinetic studies. These corrections involved making the initial and final measurements of the balance deflection while the specimen was at the oxidation temperature in high vacuum (9). Since the relative proportion of Fe_3O_4 in an oxide film containing both Fe_3O_4 and α-Fe_2O_3 will increase during evacuation at elevated temperatures at the expense of the α-Fe_2O_3 (19), it has been necessary to modify this procedure to obtain representative specimens of the oxide films for x-ray and electron-diffraction analysis and electron-microscopic examination. Separate specimens of iron were oxidized and then allowed to cool rapidly to room temperature before evacuation, to minimize the change in the composition of the oxide film. Thus, the kinetic data and the x-ray analytical data were obtained from the oxidation of separate specimens of iron foil.

Analysis of Iron oxide.—X-ray diffraction techniques were used in the estimation of the compositions of the stripped iron oxide films reported in this paper. These techniques are only qualitative. A minor constituent, comprising as much as 10% of the total film, might not be detected. Furthermore, it is difficult to distinguish between the two cubic oxides, Fe_3O_4 and γ-Fe_2O_3. In this work, all cubic oxide is reported as Fe_3O_4, and only the rhombohedral oxide, α-Fe_2O_3, is reported as a separate phase, although it is to be expected from the studies of Sewell and Cohen (8) that γ-Fe_2O_3 may form between the Fe_3O_4 and α-Fe_2O_3 phases.

Electron microscopy.—Specimens of oxide were removed from the metal using a dry stripping method which is a modification of the two-layer, plastic-replication technique used throughout the earlier studies of tin oxidation (10). The oxidized iron foil specimens were coated with a thin layer of formvar followed by a thick layer of parlodion. After the plastic was dry, the edges of the specimen were sheared, loosening the adjacent oxide; the plastic backing together with most of the oxide film was then peeled from the iron surface. After the thick parlodion film was dissolved in amyl acetate, the oxide, supported on formvar, was ready for examination by transmission electron microscopy and diffraction, or by x-ray diffraction. The disadvantage of the technique was that iron oxide films of thickness less than about 100Å adhered too tightly to the iron surface, and could not be stripped. Therefore, the earlier stages of iron oxide formation were not investigated. However, the metal surface at the oxide-metal interface could be replicated and examined after the oxide had been removed, since the metal surface was not damaged by the dry stripping technique. In most instances scattered fragments of the oxide remained attached to the metal after stripping. Replicas of these partially stripped surfaces were used to study simultaneously the topography of the top surface of the oxide and that of the metal at the oxide-metal interface. Replicas of the bottom surface were prepared by evaporating carbon on the underside of the stripped oxide, and then dissolving the plastic backing layer in amyl acetate. Much of the oxide was washed from the carbon replica when the plastic backing was being dissolved. Replicas of the interfaces were shadowed with platinum before examination in an electron microscope. The average film thicknesses calculated from the microbalance data were verified by measuring the

length of the shadows cast by the oxide fragments on the replicas of the oxide-metal interface.

Experimental Results

Kinetic Data

Plots of the microbalance data obtained from the oxidation of iron for 150 min at 220°C and oxygen pressures of 0.01, 0.1, 1, 10, and 100 Torr, respectively, are shown in Fig. 2. The data obtained at 1, 10, and 100 Torr are coincident, within the limits of experimental error. However, the data obtained at 0.1 and 0.01 differ significantly from the data obtained at the higher oxygen pressures. Thus, there appears to be an increase in the oxidation rate with decreasing oxygen pressure at 220°C. Another interesting feature of these data is that, although the curves for the iron oxidation at 0.1, 1, 10, and 100 Torr are either coincident or essentially parallel, the rate curve for the oxidation at 0.01 Torr goes through an induction period before crossing the other curves and proceeding at the highest rate.

Figure 3 is a plot of the microbalance data for the oxidation of iron for 150 min at 270°C, and oxygen pressures of 0.01, 0.1, 1, 10, and 100 Torr, respectively. Here, the effect of external oxygen pressure on the kinetics is clearly evident. The total weight increase was much greater at the low oxygen pressures than at the higher oxygen pressures. Again, the data obtained from the oxidation at 0.01 Torr exhibit an induction period, and then the reaction proceeds at the highest rate.

The effect of oxygen pressure on the rates of oxidation at 350°C is shown in Fig. 4. The greatest differences in the amounts of oxide formed at the different oxygen pressures were observed at this temperature. The oxidation appears to proceed in two stages: (i) an initial period of high oxidation rate, followed by

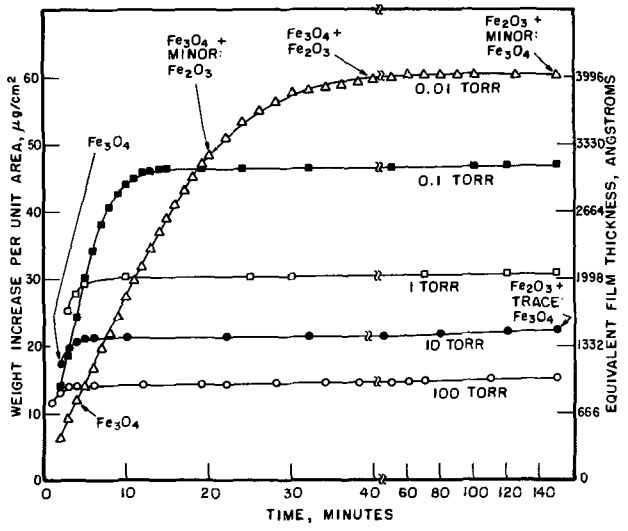

Fig. 4. Effect of oxygen pressure on the oxidation of zone-refined iron at 350°C, linear plot.

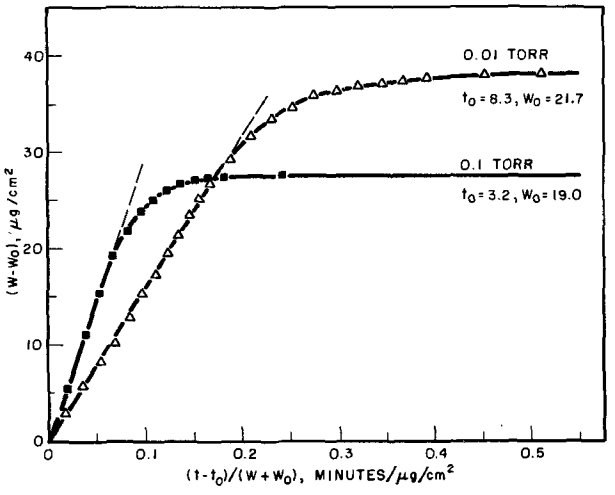

Fig. 5. Parabolic plot of data from the first stage of oxidation at 350°C, 0.1 and 0.01 Torr.

(ii) a rather sharp transition into a period of lower oxidation rate. The duration of the first stage, the period of high oxidation rate, was strongly dependent on oxygen pressure. However, the plots of the data obtained in the second stage of the oxidation are essentially parallel, an indication that there is very little oxygen pressure dependence in the second stage. The plot of the data obtained at 0.01 Torr crosses that obtained at the other pressures, as was observed at the lower temperatures.

These data, plotted in a parabolic manner, are shown in Fig. 5. The data from the first stage of the oxidation at 0.1 and 0.01 Torr, respectively, at 350°C, appear to conform to a parabolic rate law. The duration of this first stage at the higher oxygen pressures was too short to yield data that could be tested for this conformity. It appears likely that the early stage of the oxidation at 1, 10, and 100 Torr may also conform to a parabolic rate law. At the end of the first stage, oxidation proceeds through a transition period, and eventually enters a parabolic region having a much lower rate constant, Fig. 6.

The data obtained from the oxidation of iron at 450°C and at oxygen pressures of 0.01, 0.1, 10, and 100 Torr, respectively, are shown in Fig. 7. It is evident that the external oxygen pressure has very little effect on the oxidation rate at this temperature. The first parabolic region exists for a very short time, if at all, and the microbalance data shown in these

plots represent only the second region of the oxidation process.

X-ray Diffraction Analyses

The approximate crystalline constitution of the oxide films formed at 0.01 Torr and at 10 Torr and at temperatures of 220°, 270°, 350°, and 450°C, as estimated by x-ray diffraction analyses of the stripped oxide, are shown on the curves of Fig. 2, 3, 4, and 7, respectively. At 220°C, Fe_3O_4 was the only oxide phase detected during 150-min reaction time. At 270°C, Fe_3O_4 was the only phase detected after 30-min exposure at either oxygen pressure. As the reaction progressed at 10 Torr, increasing amounts of α-Fe_2O_3 were detected, until at 150 min the amount of Fe_3O_4 remaining in the stripped film was scarcely detectable. In contrast, Fe_3O_4 continued to be the major oxide phase formed at an oxygen pressure of 0.01 Torr, even after 150 min of oxidation.

As shown in Fig. 4, the rate curves for the oxidation of iron at 350°C are divided into an initial region of high oxidation rate and a later region of lower oxidation rate. The major oxide phase found in the first region was Fe_3O_4. Toward the end of this region of high oxidation rate, the α-Fe_2O_3 phase began to appear. As the reaction rate began to diminish, increasing amounts of α-Fe_2O_3 were detected, until after 150 min of oxidation, α-Fe_2O_3 was the major oxide phase found in the films. The weight gain, from the end of the period of high oxidation rate until the termination of the experiments at 150 min, corresponded approximately to the amount of oxygen that would be required to completely convert the Fe_3O_4 phase to α-Fe_2O_3.

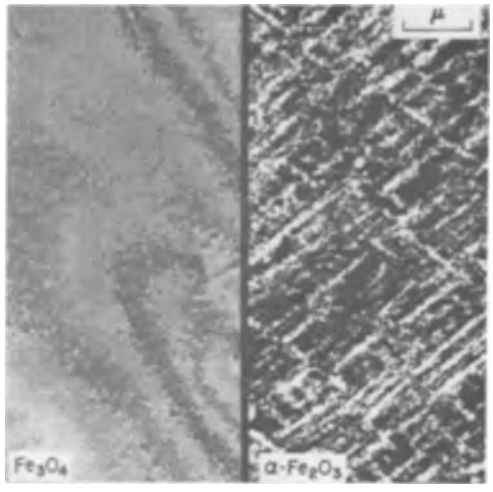

Fig. 8. Transmission electron micrographs showing the fine mottled texture typical of Fe_3O_4 films and the coarse "herringbone" texture typical of α-Fe_2O_3 films.

These data suggest that the initial region of high oxidation rate corresponds mainly to the growth of the Fe_3O_4 layer, whereas the later region of lower oxidation rate corresponds mainly to the growth of the α-Fe_2O_3 phase. The duration of the period of Fe_3O_4 growth appears to be strongly dependent upon the external oxygen pressure. This period of time was short at high oxygen pressures, and became longer as the oxygen pressure was decreased.

Approximately equal amounts of both oxide phases were detected in the oxide films formed at 450°C, irrespective of the external oxygen pressure. Evidently, the initial period of unhindered Fe_3O_4 formation was very short (or perhaps nonexistent).

Morphology of Iron Oxide Films

Electron micrographs of typical Fe_3O_4 and α-Fe_2O_3 films are shown in Fig. 8A. The Fe_3O_4 layer (Fig. 8A) has a very fine-grained texture as though it were composed of very small crystallites. Single-crystal electron-diffraction patterns were always obtained from these films. Thus, if the observed texture is indicative of a polycrystalline film, all crystals are very nearly of the same orientation. The typical α-Fe_2O_3 film has a rather coarse-grained, "herringbone" texture. Electron diffraction patterns of these films usually indicated that the α-Fe_2O_3 crystals occurred in several orientations. However, completely random orientation in this layer was seldom observed. The influence of temperature and oxygen pressure on the texture, or crystallite size, of the α-Fe_2O_3, as a function of oxidation time, is illustrated in Fig. 9, 10, and 11.

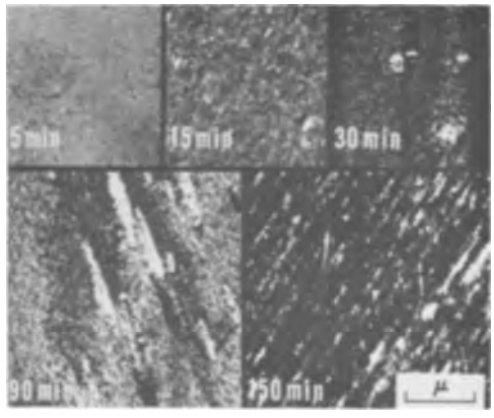

Fig. 9. Electron micrographs of the oxide formed on zone-refined iron at 270°C and an oxygen pressure of 10 Torr.

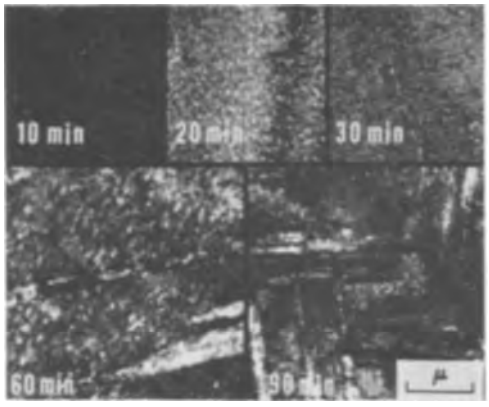

Fig. 10. Electron micrographs of oxide formed on zone-refined iron at 270°C and an oxygen pressure of 0.01 Torr.

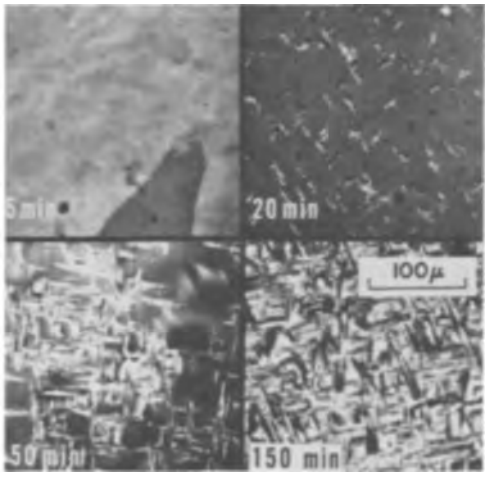

Fig. 11. Optical micrographs of oxide formed on zone-refined iron at 350°C and an oxygen pressure of 0.01 Torr.

Electron micrographs of stripped oxide films that had formed upon exposure at 270°C and an oxygen pressure of 10 Torr, for different times, are shown in Fig. 9. After 5 min, the oxide consisted of a fairly uniform fine-grained layer, typical of Fe_3O_4. After 15 min, a few irregularities (bright spots) appeared in the oxide film. These spots were better defined after 30 min, and after 90 min they had developed into small parallel acicular platelets. The film appeared to be composed almost completely of these platelets in the typical "herringbone" texture of an α-Fe_2O_3 film, after reaction with oxygen for 150 min.

Electron micrographs of the oxide films that had formed upon exposure at 270°C and an oxygen pressure of 0.01 Torr, for different times, are shown in Fig. 10. Little change from the typical fine-grained texture of Fe_3O_4 was apparent until the reaction had progressed for 60 min. After this time, the acicular platelets were observed growing in the surface of the Fe_3O_4 matrix, but they were fewer in number, larger, and farther apart than the platelets formed at 10 Torr in the same length of time. Even after 90 min of reaction, large areas of Fe_3O_4 remained between the platelets in the oxide formed at 0.01 Torr. Beyond 90 min of oxidation the oxide became opaque to the 50 kv electron microscope beam.

The oxide film formed at 350°C became too thick for examination by transmission electron microscopy in 5 to 10 min of oxidation. However, the changes in oxide morphology, as the films became richer in α-Fe_2O_3, could be observed by light microscopy at lower magnifications. A series of light micrographs of oxide films in situ that had formed upon exposure at an oxygen pressure of 0.01 Torr are shown in Fig. 11.

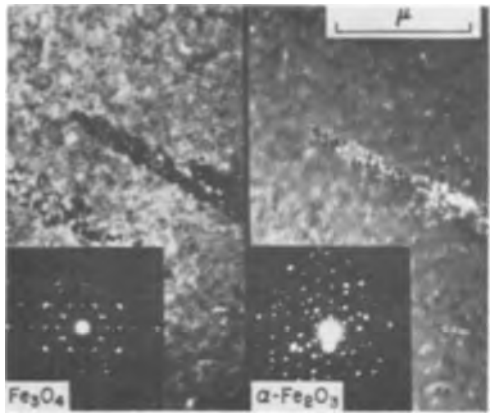

Fig. 12. Bright-field (left) and dark-field (right) electron micrographs and diffraction patterns of Fe_3O_4 matrix and α-Fe_2O_3 platelets.

After 5 min of oxidation, the film was composed mainly of Fe_3O_4, and very little microstructural detail was evident. After 20 min, the acicular platelets were visible in the Fe_3O_4, and these became quite profuse in some grains after 50 min of oxidation. Finally, after 150 min of oxidation, the oxide film consisted of a profusion of closely interlocked platelets, arranged in a Widmanstätten pattern. This type of structure in iron oxide films has been observed by other investigators (20-22).

A detailed study of these oxide films using both bright-field and dark-field contrast electron microscopy, coupled with selected-area electron diffraction analysis, revealed that the acicular crystals were composed of α-Fe_2O_3, apparently nucleated in the surface of the Fe_3O_4 layer. This is demonstrated by the electron micrographs and diffraction patterns of Fig. 12. An α-Fe_2O_3 crystal appears as the diagonal dark platelet in the mottled gray background of the bright-field micrograph. The electron-diffraction pattern of Fe_3O_4 in the inset was obtained from the matrix area surrounding the platelet. The same crystal appears in bright contrast in the dark-field micrograph. This dark-field electron micrograph was obtained by using the (100) reflection of the α-Fe_2O_3 electron diffraction pattern shown in the inset. The orientation of these α-Fe_2O_3 platelets is believed to be related to the crystallographic orientation of the iron substrate through the lattice of the intervening Fe_3O_4 layer. For example, a Widmanstätten pattern consisting of rectangles and squares probably indicates that the substrate iron was oriented with a (100) plane parallel to the surface (20, 21).

Replicas of partially stripped surfaces revealed the topography of both the metal surface at the oxide-metal interface and the oxide at the oxide-gas interface, and provided an independent means of estimating the thickness of the oxide. For example, the average thickness of the oxide film formed on a specimen of iron in 150 min at 350°C and 10 Torr was estimated to be 1525Å from the length of shadows on a replica of the partially stripped iron surface. The thickness of this film calculated from the microbalance data was 1460Å. Similarly, the thickness of an oxide film formed in 60 min at 350°C and 0.01 Torr was estimated to be 4051Å by the shadow-casting method, compared to 4289Å obtained by calculation from the microbalance data.

Figure 13 is an electron micrograph of such a replica obtained from an iron specimen oxidized at an oxygen pressure of 10 Torr and a temperature of 350°C for 5 min. The iron surface (A) remained relatively smooth, whereas slight changes in the topography of the top surface of the oxide (B) were observed, which corresponded to α-Fe_2O_3 crystals. The

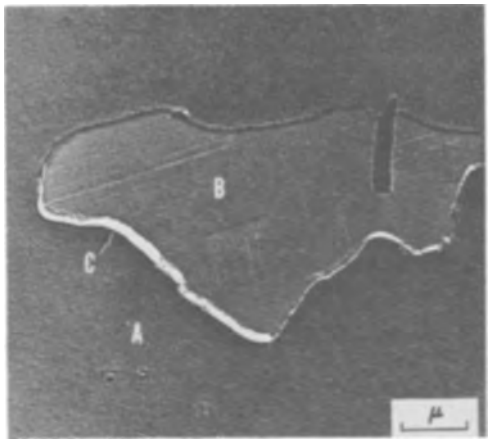

Fig. 13. Electron micrograph of platinum-shadowed replica of (A) metal at oxide-metal interface and (B) oxide at oxide-oxygen interface after oxidation for 5 min at 350°C and a pressure of 10 Torr, showing shadow (C) used for calculation of oxide thickness.

thickness of this oxide film, as calculated from the length of the shadow (C), is 1150Å, whereas a thickness of 1250Å was calculated from the weight-gain measurements. The oxide surface at the oxide-metal interface (not shown) was about as smooth as the metal surface (A) shown in Fig. 13.

A roughening of both surfaces occurs with further oxidation, but the oxide-metal interface remains much smoother than the oxide-oxygen interface. Figure 14 is an electron micrograph of a replica of a partially stripped iron surface that had been oxidized at 10 Torr and 350°C for 120 min. Striations in the replica of the metal surface (A) appear to correspond to striations in the replica of the top surface of the oxide (B). The locations of the replica shadows relative to these striations indicate that the striations represent indentations (grooves) in the oxide at the oxide-oxygen interface, or ridges in the metal at the oxide-metal interface. The grooves in the top surface of the oxide appear to correspond to the earliest formed segments of α-Fe_2O_3 platelets. Thus, the ridges in the metal, and the grooves in the oxide, may be evidence of a decreased transport of iron from the metal substrate into and through the oxide, in the area immediately beneath the spreading α-Fe_2O_3 platelets.

The change from a predominantly Fe_3O_4 to a predominantly α-Fe_2O_3 surface texture, upon oxidation at 350°C and an oxygen pressure of 0.01 Torr, is illustrated by the electron micrographs of surface replicas shown in Fig. 15 and 16. Both the surface of the metal

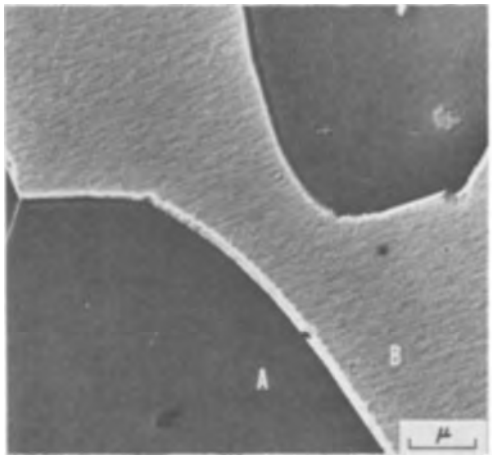

Fig. 14. Electron micrograph of platinum-shadowed replica of (A) iron at the oxide-metal interface, and (B) oxide at the oxide-oxygen interface after oxidation for 120 min at 350°C and a pressure of 10 Torr.

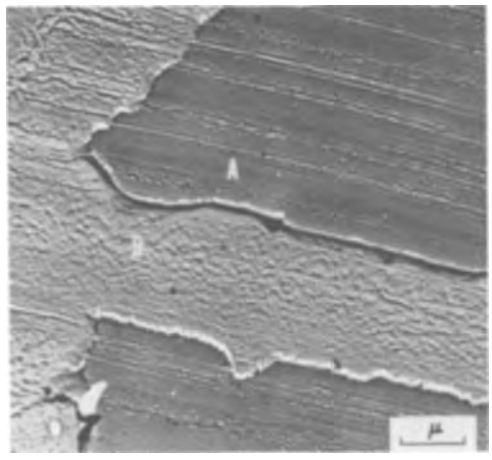

Fig. 15. Electron micrograph of platinum-shadowed replica of (A) metal at oxide-metal interface, and (B) oxide at oxide-oxygen interface after oxidation for 5 min at 350°C and a pressure of 0.01 Torr.

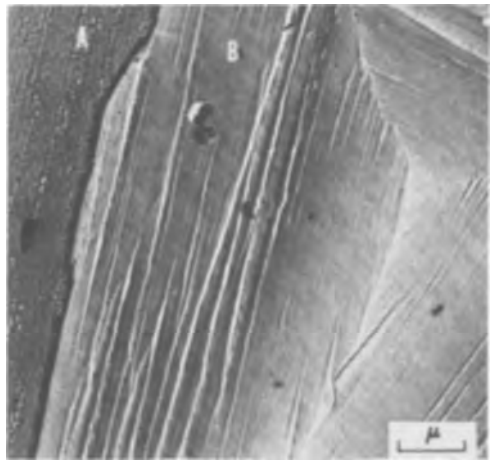

Fig. 16. Electron micrograph of platinum-shadowed replica of (A) metal at oxide-metal interface, and (B) oxide at oxide-oxygen interface after oxidation for 120 min at 350°C and a pressure of 0.01 Torr.

at the oxide-metal interface (A), and the surface of the oxide (Fe_3O_4) at the oxide-gas interface (B), are very smooth after oxidation for 5 min. In contrast, after 150 min of oxidation (Fig. 16), the surface of the metal (A) remained relatively smooth, but the surface of the oxide (B) at the oxide-gas interface became quite rough, and assumed the typical α-Fe_2O_3 "herringbone" texture. These observations suggest that the α-Fe_2O_3 platelets formed first at the oxide-oxygen interface, and grew inward toward the oxide-metal interface, since evidence of the platelets was found much earlier in the replicas of the oxide-oxygen interface than in the replicas of the oxide-metal surface. It is believed that local "masking" of the Fe_3O_4-oxygen interface, with respect to oxygen access, by the spreading α-Fe_2O_3 platelets, is sufficient to cause the observed changes in the topography of the oxide-metal interface.

Discussion

It is evident from the foregoing experimental information that the oxidation rates decreased sharply as the proportion of α-Fe_2O_3 in the oxide film increased. Wagner (23) has suggested that a low oxidation rate would result if a continuous layer of α-Fe_2O_3 existed at the outer surface of the Fe_3O_4 phase, whereas a higher rate of oxidation would result if the Fe_3O_4 phase was directly and continuously exposed to gaseous oxygen. At low oxygen pressures, the rate of formation of α-Fe_2O_3, in the surface of a previously

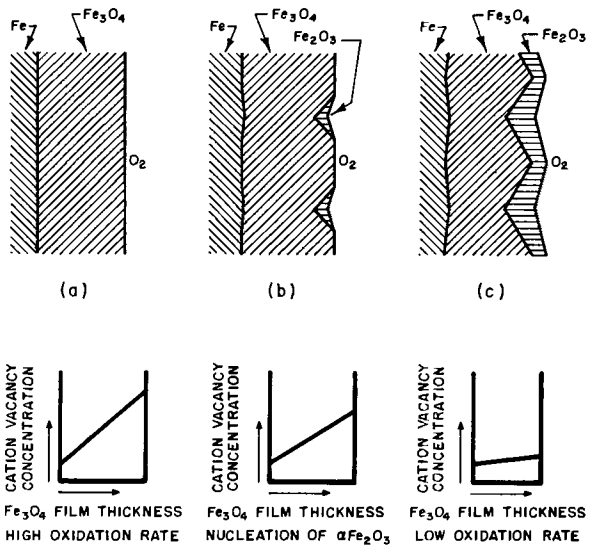

Fig. 17. Schematic diagram illustrating the effect of oxygen pressure.

existing layer of Fe_3O_4, might be low and the coverage discontinuous, whereas at high oxygen pressures, the rate of α-Fe_2O_3 formation might be high and the coverage more continuous. Two limiting cases: (*a*) a film consisting entirely of Fe_3O_4, and (*c*) a film of Fe_3O_4 covered by a film of α-Fe_2O_3 are sketched in Fig. 17, together with an intermediate case (*b*) wherein the α-Fe_2O_3 has nucleated and grown in the Fe_3O_4 film, but not to the extent that it forms a continuous outer layer.

Fe_3O_4 is a p-type, cation-deficit, semiconductor oxide (24). The following equations, based on defect equations suggested by Hauffe (24), represent the phase-boundary reactions that may occur in a layer of Fe_3O_4 in direct contact with adsorbed oxygen at the oxide-gas interface [1] and with iron at the oxide-metal interface [2]:

$$2\,O_2 \rightleftarrows Fe_3O_4 + (Fe\,\square'' + 2Fe\,\square''' + 8\,\oplus)_{\text{in } Fe_3O_4} \quad [1]$$

$$3Fe + (Fe\,\square'' + 2Fe\,\square''' + 8\,\oplus)_{\text{in } Fe_3O_4} \rightleftarrows Null_{Fe_3O_4} \quad [2]$$

where $Fe\,\square''$ and $Fe\,\square'''$ are cation vacancies in the Fe_3O_4 lattice sites normally occupied by Fe^{++} and Fe^{+++} ions respectively, and $\oplus$ are positive holes, that is, missing electrons elsewhere in the oxide lattice. The cation vacancies serve as carriers for iron ions moving outward through the oxide from the metal to the gas interface. The defect equations indicate that the cation vacancies are produced at the Fe_3O_4-O_2 interface, when oxygen is incorporated in the Fe_3O_4 crystal lattice. A change in the concentration of vacancies in the oxide lattice, produced by a change in oxygen pressure, will produce a similar change in the flux of iron ions moving outward through the oxide, and a change in the amount of iron reaching the outer surface of the oxide will produce a proportionate change in the observed oxidation rate.

According to Birchenall (25), α-Fe_2O_3 is an n-type, anion-deficit, semiconductor oxide. The following defect equations are suggested, representing the phase-boundary reactions (after a layer of α-Fe_2O_3 has formed at the outer surface of an Fe_3O_4 film) at the Fe_2O_3-O_2 interface

$$\tfrac{1}{2}\,O_2\,(g) + (O\,\square^{\cdot\cdot} + 2\,\ominus)_{Fe_2O_3} \rightleftarrows Null_{(Fe_2O_3)} \quad [3]$$

Where $O\square^{\cdot\cdot}$ is an oxygen ion vacancy and $\ominus$ is an extra lattice electron. The reactions at the Fe_2O_3-Fe_3O_4 interface are as follows

$$2Fe_3O_4 \rightleftarrows 3Fe_2O_3 + (O\,\square^{\cdot\cdot} + 2\,\ominus)_{Fe_2O_3} \quad [4]$$

$$12Fe_2O_3 \rightleftarrows 9Fe_3O_4 + (Fe\,\square'' + 2Fe\,\square''' + 8\,\oplus)_{Fe_3O_4} \quad [5]$$

The reaction at the Fe_3O_4-Fe interface is the same as given before in Eq. [2]. Thus, the boundary reactions at the α-Fe_2O_3-Fe_3O_4 interface would produce the ion and electron carriers for both types of oxide, and the external oxygen pressure should have no effect on the carrier concentration in either oxide when the Fe_3O_4 phase is covered by a continuous layer of α-Fe_2O_3.

In the temperature range in which this model is valid, a continuous layer of α-Fe_2O_3 will reduce the oxygen pressure at the outer surface of the Fe_3O_4 by many orders of magnitude to the dissociation pressure of α-Fe_2O_3 ($\sim 2 \times 10^{-34}$ Torr at 350°C). The concentration of cation vacancies will be reduced, and, in consequence, the flux of iron ions through the Fe_3O_4 layer needed to support the growth of the Fe_3O_4 layer will be reduced. After the α-Fe_2O_3 layer has become continuous, the additional weight gain of the iron specimen may be attributed mainly to the reaction of Fe_3O_4 with oxygen to produce more α-Fe_2O_3.

The proposed model for the mechanism of oxidation appears to explain the effect of oxygen pressure observed at 220°, 270°, and 350°C. Although α-Fe_2O_3 was not detected by x-ray diffraction analysis of the films formed in 150 min at 220°C and 10 or 100 Torr, this oxide phase was detected after increased reaction times under these same oxidizing conditions. Thus, an α-Fe_2O_3 layer too thin for x-ray detection, but sufficient to suppress the oxidation rate, probably was formed also at the higher oxygen pressures at 220°C.

In contrast, little or no pressure effect was observed at 450°C, and the proportions of the two oxide phases apparently did not change with increasing reaction time or with change of external oxygen pressure. Roughly equal amounts of Fe_3O_4 and α-Fe_2O_3 were found in the films formed at all pressures. Thus, it appears that the diffusion of iron outward through the Fe_3O_4 layer balances the diffusion of oxygen inward through the α-Fe_2O_3 layer, so that the process results in a dynamic equilibrium that maintains approximately equal amounts of the two oxide phases throughout the course of the oxidation at this temperature.

Conclusions

The amount of oxide formed on pure iron in a given length of time at temperatures of 220°-350°C increases as the oxygen pressure is decreased from 100 to 0.01 Torr. The oxidation kinetics are characterized by an initial, pressure-dependent period of high rate followed by a pressure-independent period of relatively low rate. The major oxide phase formed in the initial period of high oxidation rate is Fe_3O_4. As the proportion of the α-Fe_2O_3 phase in the oxide film increases, the oxidation rate decreases. The rates of nucleation and growth of the second phase, α-Fe_2O_3, appear to be pressure dependent. At high oxygen pressures, a layer of α-Fe_2O_3 quickly forms in the surface of the Fe_3O_4 film; it is believed that the presence of this layer reduces the rate of formation of cation vacancies in the Fe_3O_4 film, thereby decreasing the flux of cations through the film and lowering the oxidation rate. More time is required at low oxygen pressures for the α-Fe_2O_3 layer to form, and, consequently, the initial high rate of oxidation persists longer, and results in a thicker oxide film, than is formed at higher oxygen pressures.

Acknowledgment

The authors gratefully acknowledge the suggestions of Professor Carl Wagner in the deduction of a mechanism to explain the observed pressure effect.

Electrochemical Measurements on Zirconium and Zircaloy-2 at Elevated Temperatures

II. 200°-300°C[1]

A. L. Bacarella and A. L. Sutton

Oak Ridge National Laboratory, Oak Ridge, Tennessee

ABSTRACT

Rates of film growth in oxygenated dilute sulfuric acid have been measured on zirconium and Zircaloy-2 at temperatures from 200° to 300°C using electrochemical methods. The resulting rate-time plots were analyzed according to logarithmic and cubic kinetics. The kinetic constants obtained from these results, and those of other investigators, were correlated with respect to temperature. The calculated activation energy for the cubic rate constant was 29.7 kcal/mole. The reduction of oxygen was studied as a function of film thickness. The results showed two polarization regions, a high current region with a Tafel slope about 3-5 (2.3 RT/F) and a low current region with a Tafel slope decreasing with film thickness from 4 (2.3 RT/F) to 1.4 (2.3 RT/F). The oxygen evolution reaction was also studied at 295°C. The observed Tafel slope ranged between 0.8 to 1.0 (2.3 RT/F). The anodic process in the over-all corrosion reaction was postulated to be a field-dependent ionic transport of oxygen ions. The Tafel slope for this process increased with film thickness from 4 (2.3 RT/F) to 16 (2.3 RT/F). At 295°C, a steady-state anodic rate independent of potential was observed. This result suggests that at steady-state the film dissolution rate is equal to the rate of film formation. The weak-field approximation to the conventional anodizing equation is postulated for the film formation reaction. The film dissolution reaction is not postulated.

In recent years an increasing number of studies of redox processes on passive electrodes have been made. From these studies attempts have been made to assess the role of the passive oxide film in the kinetics of the redox processes. These studies, however, are being made on very thin films, 50-100Å. Here are reported kinetic results on films from 200 to 3000Å thick. It is hoped that the results obtained on these "thick" films and at temperatures of 200°-300°C will provide further insight into the role the passive film plays in determining the mechanism of redox processes.

The film-growth reaction involves the transport of ionic species through the film. Studies of anodic film growth have been made on valve metals (Zr, Ta, Al). These investigations, however, concern the kinetics of film growth at high field strength. Few electrochemical studies have been made concerning film growth at low field strengths.

Here, electrochemical techniques are employed to study film-growth kinetics at temperatures from 200° to 300°C. Film-growth rates based on polarization resistance measurements have been previously reported (1, 2). The polarization resistance is defined as the derivative, $(dE/dI)_{E \to E_o}$, where I is the net current flowing through the electrode at the measured potential E, and E_o is the open-circuit corrosion potential. Theoretical justification for the correlation between the polarization resistance and corrosion rate was provided by Stern and Geary (3) and Posey (4). Stern

[1] Research sponsored by the United States Atomic Energy Commission under contract with the Union Carbide Corporation.

and Weisert (1) made an extensive investigation of the literature and demonstrated the general applicability of the method. They have shown that the experimental range of the Tafel slopes, $b = dE/d\log I$, is limited, and a simple measurement of the polarization resistance, $(dE/dI)_{E\to E_o}$, provides an estimate of the corrosion rate within a factor of 2. Although the systems investigated by Stern and Weisert were two-phase corrosion systems, metal/solution, its more general applicability to systems forming a passive oxide, metal/oxide/solution, was demonstrated by Stern (6), Meyer (1), and Bacarella (2).

In the experiments reported here, current-voltage measurements were made as a function of time. The measurements were interpreted according to logarithmic polarization behavior, and the rates were determined from the polarization resistance measurements and from the extrapolation of the Tafel-lines to the open-circuit potential. The rates were calculated from the polarization resistance using Eq. [1],

$$I_{corr} = \left(\frac{dI}{dE}\right)_{E\to E_o} \times \frac{RT}{F} \times \frac{1}{(\alpha_a Z_a) + (\alpha_c Z_c)} \quad [1]$$

where I_{corr} is the corrosion rate in amp/cm^2. The quantities $\alpha_a Z_a$ and $\alpha_c Z_c$ were obtained from the Tafel slopes, $b = dE/d\log I$, for the anodic and cathodic reactions, respectively, where

$$\alpha Z = \frac{2.3\,RT}{F} \times \frac{1}{b} \quad [2]$$

Experimental

The measurements were made on Zircaloy-2 rod-type specimens (electrodes) in 0.05*M* H_2SO_4 which was saturated with 250 psi O_2 at 25°C. The solutions were prepared using C.P. H_2SO_4 and triply distilled water, two distillations of which were obtained from a two-stage all quartz commercial still.

Rate measurements as a function of time were made at 206°, 260°, and 295°C. The experiments were performed in a titanium reaction cell, Fig. 1, designed to contain approximately 175 cc of aqueous acid at 300°C and 2000 psi. The reaction cell was mounted in a vertical position and contained five convenience ports, four at the top and one at the bottom. Solution entered the cell from the bottom and exited from one of the top ports. At temperature, solution flowed through the cell at about 0.5 cc/min. The other three ports provided positions for a thermocouple well and the two electrodes, at Pt reference electrode and the Zircaloy-2 test electrode. Teflon cones were used to insulate these electrodes from the reaction cell and to provide a pressure seal. At 260°-300°C, it was necessary to air cool the Teflon cones to maintain the pressure seal. This was accomplished by providing two titanium tube extensions which were air cooled at a rate such that the temperature at the Teflon seal position was *ca.* 60°-90°C, and approximately independent of temperature changes in the reaction cell. For measurements at 295°C the Pt reference electrode was positioned entirely in the air-cooled portion of the titanium tube extension, giving a "reference" potential independent of temperature changes in the reaction cell. Side arm outlets on the titanium tube extensions provided for solution flow past the "stem" portion of the electrode. A drawing of the reaction cell, electrodes, and fittings is shown in Fig. 1 and 2.

Measurements were performed on several electrodes fabricated from different Zircaloy-2 stock, and with different surface preparations. The electrodes were machined in one piece to the shape shown in Fig. 2. For some of the initial measurements an air-formed film (360°C, 3 days) or an anodized film (180v, 1.0M Na_2SO_4, 0.05M H_2SO_4) was put on the electrode stem before exposure to the environment. The film was put on the stem to minimize the corrosion from this portion of the electrode which was at an unknown and decreasing temperature up to the air-cooled Teflon seal position. This pretreatment, however, resulted in some white oxide formation at the high-temperature region of the stem. Because of this white oxide formation subsequent measurements were made on electrodes without a pre-formed film on the stem.

The same specimen was used repeatedly, and before immersion into the cell, the oxide film formed in the previous experimental exposure was removed by polishing with No. 0 emery cloth. The polished electrode was rinsed thoroughly in distilled H_2O and then immersed in a H_2O-HNO_3-HF chemical polishing bath long enough (~2 min) further to remove several mils of metal. The electrode was then rinsed with triply

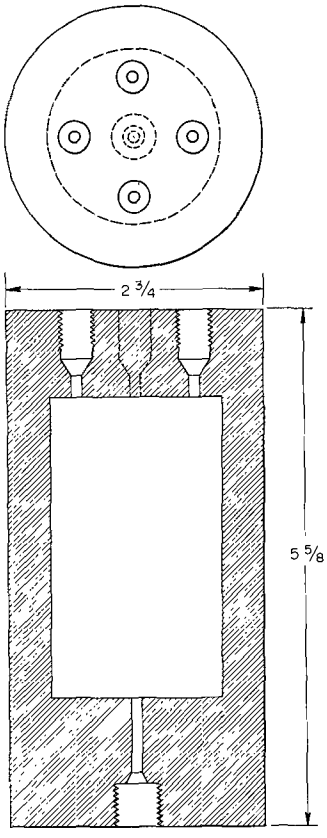

Fig. 1. Titanium reaction cell

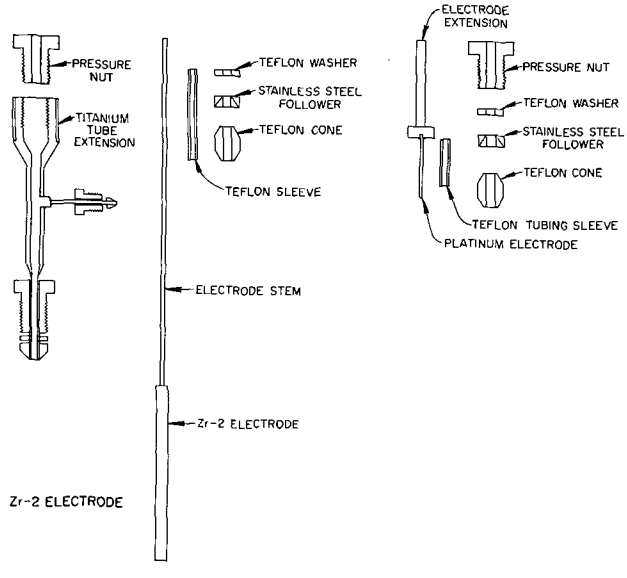

Fig. 2. Zircaloy-2 electrode and fittings

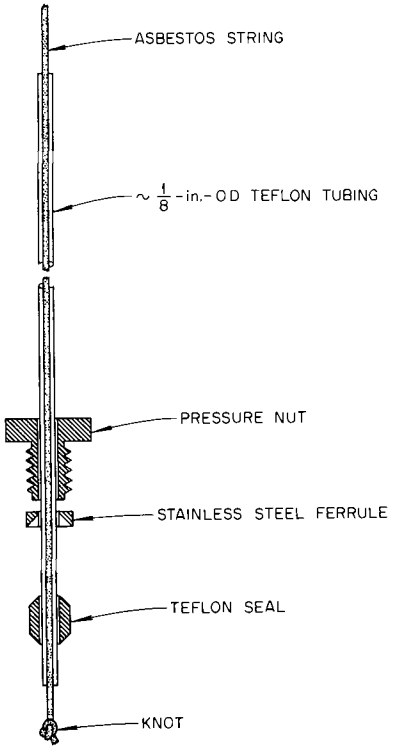

Fig. 3. Salt bridge for external reference

distilled water by rapid transfer from beaker to beaker, with a final transfer to a beaker of boiling triply distilled water for 2 min. With this surface preparation the electrode showed no areas of preferential white oxide growth. However, after long exposure at 295°C (>15,000 min) a uniform distribution of white oxide was observed to form in the high-temperature region of the electrode.

Using the apparatus and the procedures previously described (2), the solution in the reaction cell was brought to within ±5°C of operating temperature in 4-5 min and to ±1°C in 20-30 min.

Using galvanostatic and potentiostatic techniques, current-voltage measurements were made as a function of time. Rates were determined from linear polarization resistance measurements and from the extrapolation of Tafel lines to the open-circuit potential.

Voltages were measured with a L&N RIE meter, and currents were measured by recording the voltage drop across precision resistors in series in the polarizing circuit.

In some of the experiments reported here an external calomel reference electrode at 25°C and 1 atm was used. Bridging this electrode into the high temperature and pressure in the reaction cell was accomplished as shown in Fig. 3. An asbestos string was presaturated with the experimental solution and pulled tightly through Teflon "spaghetti." The asbestos string was knotted at the high-pressure and temperature end to prevent its expulsion through the Teflon spaghetti. The Teflon spaghetti and asbestos string were sealed into the cell with a Teflon cone pressure seal. The bridge entered the cell only to the air-cooled portion of the titanium tube extension since the asbestos string decomposed at high temperature.

Results

Typical current-voltage behavior, at long exposure times, for Zircaloy-2 in the oxygenated dilute sulfuric acid environment is presented in Fig. 4. Here, the measurements were made on an electrode (fabricated from plate stock) which had been exposed at 295°C and at a constant anodic potential, —0.200v *vs.* Pt/O_2 (90°C), for 28,000 min. For the last 18,000 min

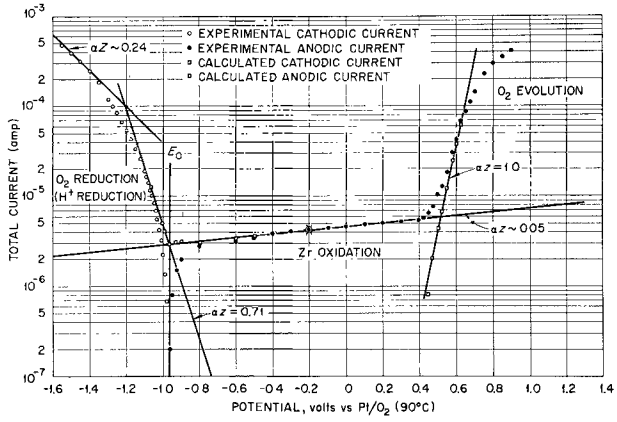

Fig. 4. Current-voltage measurements for Zircaloy-2 in O_2 saturated 0.05M H_2SO_4 295°C, after 25,000 min at —0.200v *vs.* Pt/O_2 (90°C).

at this potential the anodic rate was at a steady-state value of 4.4×10^{-6} amp or 7.3×10^{-7} amp/cm^2.

Three current-voltage regions are observed: the cathodic region from —1.600v *vs.* Pt/O_2 (90°C) to the open-circuit corrosion potential at —0.963v *vs.* Pt/O_2 (90°C), the anodic region from —0.963v to about +0.400v *vs.* Pt/O_2 (90°C), and the region of the oxygen evolution reaction at potentials above +0.400v *vs.* Pt/O_2 (90°C).

Values of the electrochemical transfer coefficient, (αZ), reported in Fig. 4, were obtained from expanded plots of the data. Other measurements, at long exposure time ($t > 2800$ min), gave values between 0.66-0.75 for the low-current cathodic ($\alpha'_c Z'_c$) and values from 0.23-0.29 for the high-current cathodic ($\alpha'_c Z'_c$). The anodic ($\alpha_a Z_a$) values ranged from 0.035-0.07 at these exposure times. The transfer coefficient for the O_2 evolution reaction ranged from 1-1.25.

Initially, the rate is changing rapidly with time, and Tafel measurements are difficult to obtain. However, from such measurements made as a function of time it was observed, for the results at 295°C, that the low-current cathodic ($\alpha'_c Z'_c$) increased from 0.25 at about 80-100 min to 0.72 at 2800 min and was then constant throughout further exposure. The value of the transfer coefficient in the high-current region of the cathodic reaction was constant at about 0.25 throughout exposure. The anodic transfer coefficient, for the oxidation of zirconium decreased from 0.17 at 100-120 min, to 0.06 at about 1000 min, and was then constant throughout further exposure.

At 268°C, ($\alpha'_c Z'_c$) increased from 0.25 to 0.60 while ($\alpha'_a Z'_a$) decreased from 0.20 to 0.10.

At 206°C, ($\alpha'_c Z'_c$) went from 0.25 to 0.45, while ($\alpha'_a Z'_a$) decreased from 0.25 to 0.10.

On the basis of these measurements, the rates at the open-circuit corrosion potential were obtained from the linear polarization resistance measurements using Eq. [1]. At 206°C, the sum of the αZ's was approximately constant at $\Sigma\alpha Z = 0.45$ throughout the experiment. At 260°C, $\Sigma\alpha Z$ was approximately 0.45 for the first 300 min, increasing linearly from 0.45 to 0.70 to 3600 min, then remaining constant at 0.70 throughout further exposure. At 295°C the sum of the αZ's was approximately constant at 0.40 for 500 min. From 500 to 2800 min a linear increase from 0.40 to 0.76 was used, and then a constant value at 0.76 throughout further exposure.

Typical rate-time data obtained from such measurements, on electrodes exposed to oxygenated 0.05M H_2SO_4 are shown in Fig. 5. Curve (a), 293°C, and curve (b), 258°C, were obtained on specimens fabricated from rod stock. Curve (c), 206°C, was obtained on a specimen fabricated from plate stock. Measurements were also made at 295°C on speci-

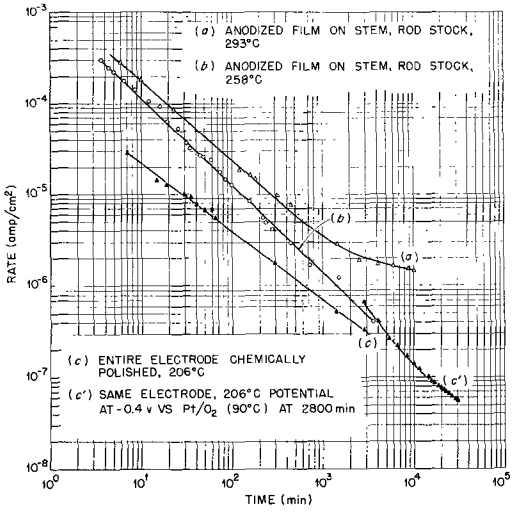

Fig. 5. Corrosion rate of chemically polished Zircaloy-2 in O_2 saturated 0.05M H_2SO_4.

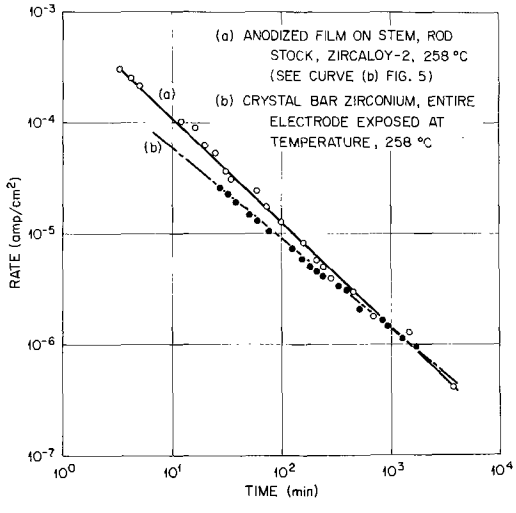

Fig. 6. Corrosion rate of zirconium and Zircaloy-2 in O_2 saturated 0.05M H_2SO_4 at 258°C.

mens fabricated from plate stock. The results are similar to those represented as curve (a).

In Fig. 6, measurements on crystal-bar zirconium at 258°C are compared with those obtained on Zircaloy-2 at 258°C [Fig. 5, curve (b)]. For the measurements on crystal-bar zirconium, the entire electrode was exposed at temperature. These results show that there is little difference between the corrosion of zirconium and Zircaloy-2, and that the "stem" portion of the Zircaloy-2 electrode does not affect the corrosion behavior.

The rate-time results shown in Fig. 5 and 6 were obtained on electrodes exposed at the open-circuit corrosion potential. The result at 293°C, represented by curve (a) in Fig. 5 shows the rate levelling off to an apparent steady-state value. At 10,280 min, the rate at the open-circuit potential, —0.900v *vs.* Pt/O_2 (60°C), is 1.3 x 10^{-6} amp/cm². The potential at this time was made anodic (700 mv) to —0.200v *vs.* Pt/O_2 (60°C), and the rate at this potential, initially ~ 3.5 x 10^{-6} amp/cm², decreased to a steady-state value of 1.1 x 10^{-6} amp/cm². Current-voltage measurements performed after anodization at this potential, Fig. 7, curve (1), showed that the rate at the open-circuit potential decreased from 1.3 x 10^{-6} to 4.8 x 10^{-7} amp/cm², and the open-circuit potential went cathodic to —0.980v *vs.* Pt/O_2 (60°C) from —0.900v *vs.* Pt/O_2 (60°C).

The potential was then made anodic an additional 500 mv to +0.300v *vs.* Pt/O_2 (60°C) and the rate

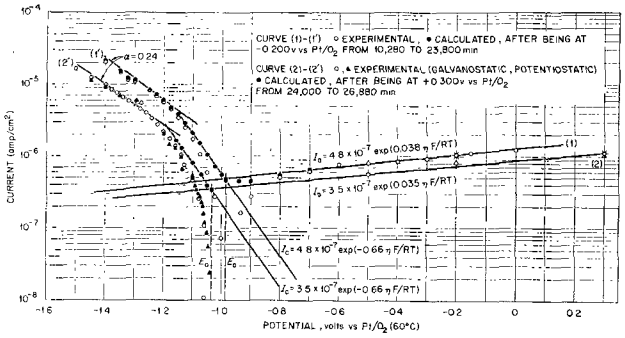

Fig. 7. Current-voltage measurements for Zircaloy-2 in O_2 saturated 0.05M H_2SO_4, 298°C for electrode (A) in Fig. 5.

again initially about 3.5 x 10^{-6} amp/cm², decreased with time to the same steady-state value, 1.1 x 10^{-6} amp/cm². Current-voltage measurements, curve (2), Fig. 7, showed the rate at the open-circuit potential decreased further to 3.5 x 10^{-7} amp/cm², and the open-circuit potential went cathodic another 55 mv to —1.035v *vs.* Pt/O_2 (60°C).

Additional evidence for a steady-state rate at this temperature was provided by the results shown in Fig. 4. Here the rate at —0.200v *vs.* Pt/O_2 (90°C) was constant at 7.3 x 10^{-7} amp/cm² for 18,000 min.

Steady-state rates were not observed for measurements at 206°and 258°C. In the experiment at 206°C, curve C, Fig. 5, the potential was made anodic at —0.400v *vs.* Pt/O_2 (90°C) at 2800 min. The anodic rate at this potential was observed to decrease continuously until the experiment was terminated at 28,000 min.

It was further observed from current-voltage measurements that both the anodic and cathodic currents were a function of film growth, Fig. 7 and 8. The anodic current decreased continually with film growth, until steady state at 295°C, while the cathodic current decreased initially for 2800 min, remained essentially constant for a further period of film growth, and then increased slightly until steady state was approached at 295°C.

From Fig. 8, the anodic reaction is apparently diffusion controlled, $\alpha Z \sim 0.0$. Other measurements made at times near to 80 min (100-120 min) have yielded Tafel-lines for the anodic reaction, with a calculated transfer coefficient about 0.17. However, at 295°C the Tafel slope increases rapidly and at 1000 min the transfer coefficient $\alpha = 0.06$, and is constant throughout further exposure.

Discussion

The reliability of the rate measurements must be demonstrated before any discussion can be attempted.

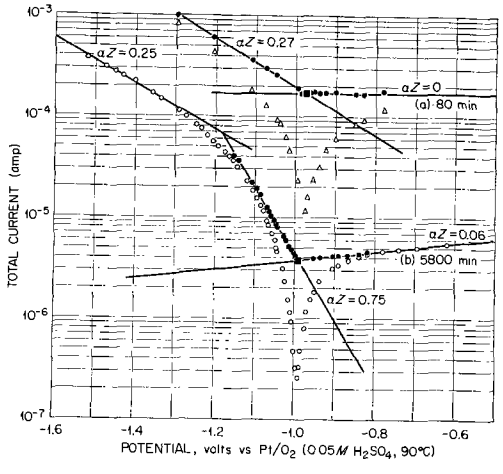

Fig. 8. Current-voltage behavior on Zircaloy-2 in O_2 saturated in 0.05M H_2SO_4 at 295°C as a function of film thickness.

Electrochemical measurements at these temperatures have not been performed by other investigators, and a comparison from the point of view of the electrochemical factors is therefore not provided.

A satisfactory basis for demonstrating the reliability of the measurements on a quantitative basis can be made by an analysis of the data according to rate laws already postulated for zirconium. The kinetic constants obtained can then be compared with those of other investigators.

Various kinetic expressions have been proposed for the corrosion of zirconium and "mechanisms" have been postulated in support of these kinetic expressions. Indeed the same data have at various times been used by different investigators to demonstrate different kinetic expressions.

The confusion demonstrates that the data are not adequate for distinguishing between cubic and logarithmic rate expression and, also, that a simple rate expression does not adequately describe the corrosion behavior over the entire period of film growth.

Here an analysis of the rate data for the initial (first 300 min) corrosion period is made according to logarithmic and cubic rate laws, and a satisfactory correlation of the data on both bases is made.

When the reported weight gain data (7) for zirconium and Zircaloy-2 are analyzed according to the empirical rate law

$$w = kt^n \qquad [3]$$

it is found that the slope of the logarithm of the weight gain *vs.* the logarithm of the time give values for the exponent n, in Eq. [3], ranging between 0.25 and 0.33. Here w is the weight gain, t is the time, and k and n are constants. A value of $n - 0.33$ represents a cubic rate law. If the derivative of Eq. [3] is taken, a relation between the rate (R) and time is obtained

$$\frac{dw}{dt} = R = nkt^{(n-1)} \qquad [4]$$

and the slope of the logarithm of the rate *vs.* the logarithm of the time give values for $(n - 1)$. With the value of n ranging between 0.25 to 0.35, the values of $(n - 1)$ range between —0.75 to —0.65. For a parabolic rate law the value of $(n - 1)$ would be —0.5.

The slopes of the log/log plots of the rate-time data reported here range between —0.67 to —1.0, with most values near —0.75. Consequently, the shape of the rate-time data, provided by the exponent $(n - 1)$ in Eq. [4], are similar to those obtained from weight gain measurements of other investigators (7). Parabolic kinetics is not observed on this basis.

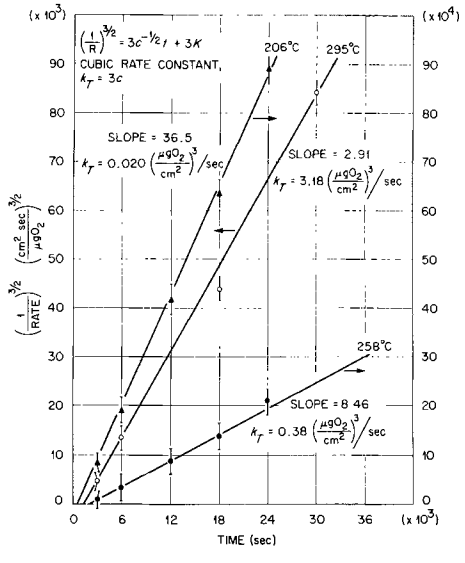

Fig. 9. Plot of $(1/rate)^{3/2}$ *vs.* time from cubic formulation of rate-time data.

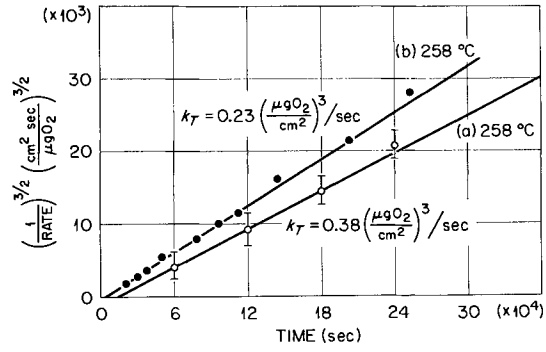

Fig. 10. $(1/rate)^{3/2}$ *vs.* time from cubic formulation of rate-time data, for zirconium and Zircaloy-2.

To obtain a quantitative comparison with other workers, the data for the first 300 min were analyzed first according to cubic kinetics, $n = 0.33$ in Eq. [3] or $(n - 1) = -0.67$ in Eq. [4].

In Fig. 9, are plotted $(1/R)^{3/2}$ *vs.* time (t) in seconds for the three temperatures here reported. The results for crystal-bar zirconium (Fig. 6) are plotted in Fig. 10. The rates, R, are expressed in weight gain units, $\mu g\ O_2/cm^2 sec$, where 1 amp/cm² = 80 $\mu g\ O_2/cm^2 sec$. It can be shown that the cubic rate constant k_T in the cubic rate law expressed as

$$w^3 = k_T t + k \qquad [5]$$

is related to the slope of the line in Fig. 9 and 10 by the relation

$$k_T = \frac{27}{(S)^2} \qquad [6]$$

where S is the slope of $(1/R)^{3/2}$ *vs.* t plot.

In Fig. 11 the calculated cubic rate constants are compared with the data of Mallet, Albrecht, and Ben-

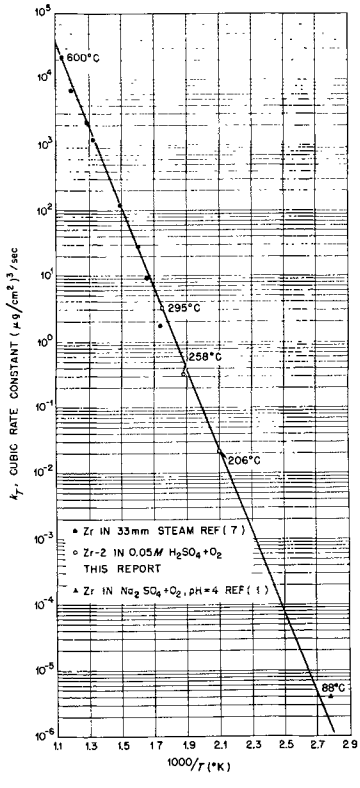

Fig. 11. Arrhenius plot of cubic rate constant for zirconium and Zircaloy-2 in steam and aqueous electrolyte.

nett (7) for crystal-bar zirconium in 33 mm steam obtained as weight gain data and with the data of Meyer (1) for crystal-bar zirconium in oxygenated Na_2SO_4, pH = 4 at 88°C, obtained using electrochemical methods. Here a correlation is provided over ten orders of magnitude in the rate constant, k_T, and over a 500°C temperature range. The calculated activation energy from these data is 29.7 kcal/mole.

This correlation provides a quantitative tie-in between the rates obtained from electrochemical measurements (88°-300°C) and those obtained as weight gain data (300°-600°C).

A further correlation with weight gain measurements is provided by the analysis of the data according to the logarithmic rate law. This correlation of the data was suggested by Jenks (8) who made an extensive analysis of the corrosion data for zirconium and Zircaloy-2 according to the logarithmic rate law.

The logarithmic law is expressed by

$$R = Ae^{-Bx} \qquad [7]$$

where R is the rate, x is the film thickness and A and B are constants. It can be shown that the logarithmic expression between the rate and film thickness (Eq. [7]) becomes the hyperbolic relation between the rate and time

$$1/R = 1/A + Bt \qquad [8]$$

where R is the rate, t is time, and A and B are the same constants appearing in Eq. [7].

In Fig. 12 are plotted the reciprocal rate *vs.* time for the data previously correlated on the cubic rate law basis. The slope of the line in Fig. 12 gives the value of B in the logarithmic rate law.

In Fig. 13 these data are compared with the data of Mallet, Albrecht, and Bennett (7) for zirconium and with the data of Cox (9) for zirconium and Zircaloy-2 in 15 psi steam at 300°C. The B values from the weight gain data are obtained from Jenks (8).

Here again quantitative agreement with weight gain data is obtained. The calculated activation energy for the parameter $1/B$ is 9.0 kcal/mole.

From similar observations, other workers (10) have postulated an initial logarithmic oxidation rate followed by a cubic rate law.

Cox (9) has postulated a double logarithmic rate expression: the initial logarithmic corrosion being con-

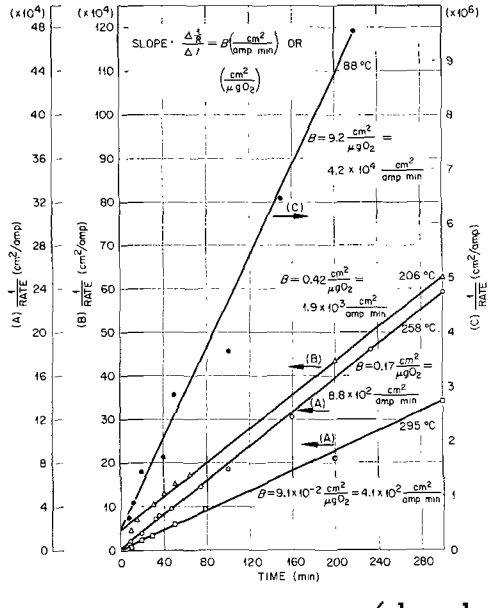

Fig. 12. Hyperbolic plot of rate-time data $\left(\frac{1}{R} = \frac{1}{A} + Bt\right)$ at several temperatures.

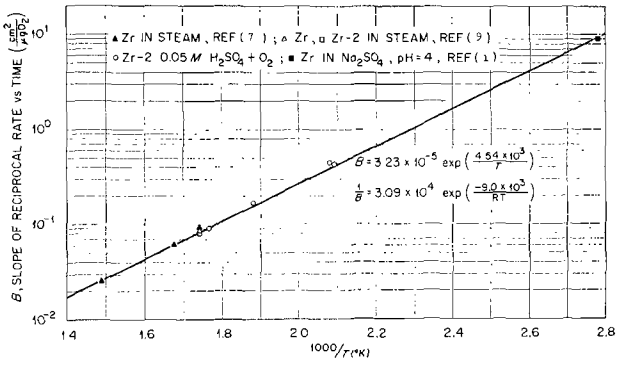

Fig. 13. Arrhenius plot of hyperbolic rate constant, B, $\left(\frac{1}{R} = \frac{1}{A} + Bt\right)$ for Zr and Zr-2 steam and aqueous electrolyte environment.

trolled by the electron flow from metal to oxide through a space-charge region in the oxide, a process suggested by Uhlig (11), with a simultaneous corrosion by easy diffusion paths, also a logarithmic rate process. This latter process is analogous to a mechanism proposed by Evans, Davies, and Agar (12).

Using electrochemical concepts, Meyer (2) has derived theoretical expressions to account for the variation in the shapes of the rate-time curves. A rate law in reasonable agreement with experiment was derived on the assumption that both ion transport (the anodic process) and the reduction of oxygen were rate determining. The assumption was made that the anodic process was controlled by a field-dependent rate-determining process within the film, analogous to the anodizing equation (13, 14), $i = A \exp(BF)$, where F is the field strength within the film and A and B are constants. The reduction current was proportional to $\exp(-\alpha_c Z_c V_f/RT)$ where V_f is the potential across the film. The resulting rate expression was roughly hyperbolic in rate-time, but did not permit an exact analytic expression.

A similar model is possible for the rate of film growth at the temperatures investigated here. The assumption that the anodic process is controlled by a field-dependent rate-determining process within the film has been more difficult to accept for the film thicknesses obtained at these temperatures. However, in studies of the anodic film growth on valve metals (Al, Zr), Charlesby (13, 14) has argued that the anodic current is an hyperbolic sine function of the field strength

$$i = A[\exp(BF) - \exp(-BF)] = 2A \sinh(BF) \qquad [9]$$

Here F is the field strength, and A and B are constants. On the basis of this equation he has shown that the particular rate law relating film thickness to time (t) will depend on the portion of the range (t) studied. In an application of this model to the thermal oxidation of zirconium, Polling and Charlesby (15) have concluded that the growth of the oxide layer is a logarithmic function of time up to temperatures of about 260°C, cubic at 300°C, and at higher temperatures tends toward a quadratic function of time. They have argued on the basis of Eq. [9] and Mott's (16) theory of oxidation, that the relation between oxide thickness and time depends on the value of the parameter Z, equal to the product of the electric field F, ion charge q, and barrier width a, divided by kT, [$Z = (qaF/kT)$]. For low temperatures when $Z > 3$ the growth should be an approximately logarithmic function of time. At higher temperatures, when Z is about equal to one, the growth should be approximately

cubic, while for lower values of Z, (at still higher temperatures) the growth is parabolic. An estimate of $(qa/kT) = 3.4 \times 10^{-6}$ cm/v was made by Charlesby (13) in a study of anodic film growth on zirconium. This value was based on $\epsilon = 20$ for the dielectric constant. In a later publication, Polling and Charlesby (17) have shown $\epsilon = 28$ on the basis of weight increase and oxygen liberated during film formation. Assuming then that the dielectric constant is about 30, (qa/kT) becomes $(30/20) \times 3.4 \times 10^{-6} = 5.1 \times 10^{-6}$ cm/v. Further, assuming qa/kT is independent of temperature, as was found for Ta (18-20), an estimate of $Z = qaV/kT\delta$, can be made. A value of $V = 2$v can be assumed for the potential drop across the film for zirconium corrosion. The film thickness δ, after 300-400 min at 250°C, is approximately 1000Å; consequently $Z \sim 5.1 \times 10^{-6} \times 2/1 \times 10^{-5} \sim 1.0$, and the film growth kinetics is cubic. In this report, the data for the first 300-400 min corrosion were analyzed according to both the logarithmic and cubic rate laws, and it is not unreasonable then to argue that the anodic process is controlled by a field-dependent rate-determining process within the film, analogous to the weak-field anodizing equation, $i = 2A \sinh Z$, where $Z = qaF/kT$. For corrosion at open circuit, however, the cathodic current as well as the anodic current can be assumed to be rate determining. The cathodic current may be represented by an expression of the form, $i_c = K_c f(C_e) \exp(-\alpha_c Z_c VF/RT)$, where K_c contains the potential independent part of the specific rate constant and $f(C_e)$ is some function of the electron concentration, C_e. The electron concentration is included in the cathodic rate expression since the cathodic current is also initially a function of film thickness and is presumably related to the trapping of electrons at anion vacancy sites. Since the Tafel slope for the anodic reaction increases rapidly with film growth, the over-all rate rapidly comes under anodic control, and to a first approximation the rate-time behavior can be interpreted primarily in terms of the anodic partial process.

Another factor which is sometimes considered in anodic film growth is the question concerning the effective force acting on an ion in the film. There is evidence (21, 22) that the effective force is the Lorentz force, $q(\epsilon + 2)F/3$, rather than the Maxwell force, qF. Here q is the charge on the ion and F is the average field, V_f/δ, where V_f is the potential across the film, and δ is the film thickness.

Meyer (23, 24) has studied reduction processes on passive zirconium in Na_2SO_4 solutions at 25° and 75°C. He has shown two Tafel regions for the oxygen reduction reaction, a low-current region with a transfer coefficient $\alpha'_c \sim 0.67$ to 0.72, $b = 1.4$ $(2.3\ RT/F)$ and a high-current region with a transfer coefficient $\alpha'_c \sim 0.25$ to 0.30, $b = 4$ $(2.3\ RT/F)$. Intermediate values of the transfer coefficient, $0.25 < \alpha'_c < 0.72$, which are observed here, are not discussed. The dual barrier model was also used to explain the unusual Tafel slopes obtained for the reduction of cupric ion on passive stainless steel in aerated 0.10M H_2SO_4 (25). Bockris and Srinivasan (26) have reported high Tafel slopes for H^+ reduction on Si and on W (contaminated with C) in 0.5M NaOH. MacDonald and Conway (27) have used Meyer's (23) theory to explain the high Tafel slopes they observed in the oxygen evolution reaction of Au. Makrides (28) employed a different mechanism to explain the high Tafel slope observed for the anodic oxidation of Fe^{+2} to Fe^{+3} in studies of the Fe^{+2}/Fe^{+3} redox kinetics on passive Ni, Fe, Fe-Cr alloys, and Ti.

A low-current region and a high-current region are also observed for the cathodic reduction of O_2 in the systems studied here, Fig. 4, 7, and 8. The high-current region is independent of film thickness, and $\alpha'_c \sim 0.23$ to 0.29, $b \sim 4(2.3\ RT/F)$. For the low-current region, however, an apparent continual increase in the transfer coefficient from $\alpha'_c = 0.26$ to 0.76 is observed. The Tafel slope decreases from $b = 4$ $(2.3\ RT/F)$ to $b = 1.3$ $(2.3\ RT/F)$.

Equations accounting for these observations can be derived and are based on a model which considers the semiconductor aspects of the film in conjunction with the dual barrier model. Here, it is assumed that with an increase in film thickness the oxide behaves more like a semiconductor, and the transfer coefficient, α_f, for electron transport through the film barrier approaches unity. The rate of charge transfer through the film barrier can be represented as

$$r_f = K_f \exp(-\alpha_f FV_f/RT) \qquad [10]$$

where r_f, if the rate, K_f, contains the potential independent part of the specific rate constant and concentrations, V_f is the potential drop across the film barrier, and α_f, the transfer coefficient, is a function of film thickness.

For the electrochemical charge transfer reaction at the oxide/solution interface, the postulated mechanism (23) is

$$O_2 + e = O_2^- \quad \text{slow} \quad 1$$

$$O_2^- + H^+ = HO_2 \quad \text{fast} \quad 2$$

$$HO_2 + e = HO_2^- \quad \text{fast} \quad 3$$

$$HO_2^- + H^+ = H_2O_2 \quad \text{fast} \quad 4$$

with step 1 the slow step. With step 4 the slow step, the rate equation is

$$r_s = Fk_4 \cdot \frac{k_3}{k_{-3}} \cdot \frac{k_2}{k_{-2}} \cdot \frac{k_1}{k_{-1}} [O_2][H^+][1-(\theta_1+\theta)] \exp\frac{-4\alpha_s FV_s}{RT} \qquad [11]$$

where r_s is the rate of the electrochemical charge transfer reaction, the k's, are the potential independent part of the specific rate constants, θ_1 and θ_2 are coverage terms for HO_2 and HO_2^-, V_s is the potential drop across the oxide/solution barrier, and α_s is the transfer coefficient. For a symmetrical barrier, $\alpha_s = 1/2$ and the apparent transfer coefficient becomes $4\alpha_s = 2$. With step 1 as the slow step the transfer coefficient is $\alpha_s = 1/2$.

In the high-current region, step 1 is rate determining. In the low-current region step 4 is rate determining. With values of the transfer coefficient (α_s, α_f) for the separate reactions, the dual barrier model predicts the measured transfer coefficient $\alpha_t = \frac{\alpha_s\alpha_f}{\alpha_s+\alpha_f}$, in terms of the measured potential $V_t = V_s + V_f$. Consequently, the measured transfer coefficient α_t increases in the low-current region from $\alpha_t = \frac{2 \cdot 1/2}{2+1/2} = 0.4$ for "thin" films, $(\alpha_f = 1/2)$, to a value $\alpha_t = \frac{2 \cdot 1}{2+1} = 0.67$ for "thick" films, $(\alpha_f = 1)$. In the high-current region, with $\alpha_s = 1/2$, and α_f again increasing with film thickness from 1/2 to 1, $\alpha_t = \frac{1/2 \cdot 1/2}{1/2+1/2} = 0.25$ for thin films and increases to $\alpha_t = \frac{1/2 \cdot 1}{1/2+1} = 0.33$ for thick films.

The oxygen evolution reaction was also studied, Fig. 4, and Tafel slopes ranging from $b = 0.8$ $(2.3\ RT/F)$ to $b = 1.0$ $(2.3\ RT/F)$ were observed. The value 4/5 $(2.3\ RT/F)$ was observed by MacDonald and Conway (27) for the O_2 evolution reaction on Au. Also at the higher current densities, a diffusion current plateau similar to the reaction on Au was observed. The measurements have not been extended to the higher current densities where the dual barrier model predicts the value $b = 4$ $(2.3\ RT/F)$ observed by MacDonald and Conway.

The observation of a steady-state rate independent of potential at 290°-300°C may be compared to observations made for the anodic film growth on iron in 1*N* H_2SO_4 at 25°C (29), and to the dissolution of zirconium in aqueous HF solutions at 25°C (30). These observations were explained by assuming a continuous formation and dissolution of film on the surface of the metal. The conventional anodizing equation is postulated for the film formation reaction in both the iron and zirconium experiments. The dissolution reaction for zirconium in the aqueous HF environment is controlled by the rate of mass transfer of undissociated HF to the surface of the film. For the dissolution reaction of iron, a purely chemical process not involving the transfer of charge across the interface was first postulated (29, 31). Vetter (32), however, postulated that the constancy of the corrosion current with potential, and its variation with *p*H could be explained if the dissolution involved the transfer of ferric ions from the oxide into solution under the action of a field at the oxide/solution interface. The field is established by the reaction, O^{2-} (oxide) + $2H^+ = H_2O$ which maintains the potential difference across the oxide interface at an equilibrium value for each *p*H.

Equilibrium between the film growth reaction and the film dissolution reaction is also postulated for zirconium at 290°-300°C. The film growth reaction involves the field-dependent ionic transport of oxygen ions (presumably via an anion vacancy mechanism) through the film. The dissolution reaction however has not been studied. Zirconium is found in solution in quantity sufficient to account for the steady-state rate. However, other mechanisms are not excluded. The appearance on nonprotective white oxide or the dissolution of oxide in the zirconium metal phase can also lead to a steady-state rate. The rate of the latter process (33) is great enough at 300°C to account for the observed steady-state rate, 5×10^{-7} to 1×10^{-6} amp/cm^2.

The Reaction of Zirconium with Carbon Dioxide and Carbon Monoxide at 850°C

R. J. Hussey[1] and W. W. Smeltzer

Department of Metallurgy and Metallurgical Engineering, McMaster University, Hamilton, Ontario, Canada

ABSTRACT

An investigation has been made of the kinetics, the chemistry, and the solid-state processes for the reaction of zirconium with carbon dioxide and carbon monoxide at 850°C. In carbon dioxide at 10 cm Hg pressure, the kinetic curve showed an initial decreasing rate, an intermediate increasing rate, and a final decreasing rate. The ratio of carbon to oxygen uptake by zirconium in carbon dioxide was dependent on time and varied from 0.19 to 0.04 over a period 1-48 hr. Carbon produced in the early stages of reaction was incorporated into the oxide and led to formation of a needle-like phase of a ternary lower oxide or a solid solution at the metal/oxide interface. Due to a high ratio of carbon to oxygen uptake in carbon monoxide, this phase developed to a distinct intermediate layer between the oxide scale and metal substrate. The kinetic curves in this gas exhibited a continuously decreasing oxidation rate; eventually breakaway occurred, possibly due to the presence of the secondary phase at the metal-oxide interface. In the range of parabolic oxidation for both carbon dioxide and carbon monoxide, the rates were similar in magnitude to that found in oxygen. Comparison of oxygen gradients demonstrated that the extent of oxygen solution in the metal was the same for oxidation in these gases.

There has been little published work on the reaction of zirconium with carbon dioxide at elevated temperatures (1-6). Some preliminary studies were made by Hayes, Roberson, and Robertson (1) at temperatures in the range 600°-1000°C. They showed the presence of both zirconium carbide and zirconium dioxide in the reaction product. A more detailed investigation was carried out by O'Driscoll, Tyzack, and Raine (2) on the oxidation of zirconium and zirconium alloys at temperatures in the range 400°-800°C. Long-term kinetic data showed that initially the rate relationship was between parabolic and cubic and subsequently it was linear, followed by breakaway. The influence of change of pressure from 1 to 8 atm on the reaction rate was shown to be slight.

More recently Debuigne and Lehr (3) have shown that zirconium oxidizes in carbon dioxide according to a parabolic rate equation up to 90 hr at 750°C. Subsequent work by Guerlet and Lehr (4) at temperatures in the range 600°-850°C indicates that the kinetics up to 25 hr obey a rate relationship intermediate between cubic and parabolic. The main reaction was believed to be dissociation of the carbon dioxide into carbon monoxide and oxygen at the gas-oxide interface and the formation of an adherent oxide film of monoclinic zirconia and concurrent solution of oxygen in the metal. The reaction leading to the formation of carbon was believed to contribute to less than 1% of the total weight gain of an oxidized specimen. Maekawa (5) also found no evidence for carbon uptake at temperatures in the range 650°-850°C.

Contrary to these findings from the latter two investigations there is evidence which demonstrates that carbon composes about 2% of the total weight gain of a specimen for oxidation in carbon dioxide in the temperature range 550°-750°C (6). Furthermore, the kinetic results indicate that there is an initial period of relatively small weight gain and decreasing rate followed by a period of rapidly increasing rate, which occurs after only 2 hr at 750°C and about 6 hr at 550°C.

In the light of the contradictory evidence in the literature, a systematic investigation has been made of the kinetics, the chemistry, and the solid-state processes occurring for the reaction of zirconium with carbon dioxide at 850°C. Since carbon monoxide is a reaction product, experiments were also carried out on the oxidation of zirconium in this gas. The results obtained are to be compared with the corresponding results for oxidation in oxygen in order that the influence of carbon, if present in the reaction product, on the various relative phenomena may be determined.

Experimental

Both the vacuum microbalance (7) and a spiral spring were used to obtain kinetic data. Carbon consumption during oxidation was determined by means of an analysis apparatus attached to the microbalance case. The analysis technique was based on the use of carbon-14 as a tracer element. A study of the solid-state processes was facilitated by using metallographic techniques, x-ray diffraction analyses, and autoradiographic techniques.

The zirconium was of the same batch as that used previously (7). Specimens were cut from both 1 and 2 mm sheet to sizes of 1.5 x 1 and 1 x 0.75 cm. Carbon dioxide, 99.99% pure, was dried by passage over phosphorus pentoxide. The carbon monoxide had a minimum purity of 99.6%; it was further purified by passage over ascarite and Linde 5A molecular sieves and finally through a trap immersed in liquid air. Radioactive carbon dioxide was prepared as described previously (8) and was dried by passage over magnesium perchlorate and phosphorus pentoxide. It was solidified at liquid air temperature and outgassed at 10^{-6} mm Hg for 6 hr prior to storage in sealed Pyrex bulbs. The activity of the gas was 0.25 μc/ml at N.T.P.

Prior to oxidation all specimens were outgassed in a vacuum of 10^{-6} mm Hg for 12 hr at room temperature and then heated in vacuum for 75 min at 850°C. Kinetic results were obtained using a microbalance of sensitivity 4.69 μg/division for short term experiments and a Ni-Span C spiral spring of sensitivity 36.0 μg/division for long term experiments. Additional weight gain data were obtained from individual specimens, which were oxidized for successively increasing times in a quartz reaction tube.

The analysis apparatus, attached to the microbalance case, enabled the gas to be sampled from the system during a kinetic experiment without interruption of oxidation. The gas was analyzed for carbon monoxide

[1] Present address: School of Metallurgy, University of New South Wales, Kensington, Australia.

($C^{14}O$) after removing carbon dioxide ($C^{14}O_2$) by freezing in liquid air. The residual gas pressure was determined by means of an end-window Geiger-Muller tube (20th Century Electronics Type EW3Hb), where the number of pulses received per second was proportional to the pressure of the gas at constant temperature (the half-life of carbon-14 is 5600 yr). The gas was returned to the balance case after analysis, which required a period of 2 hr. From a knowledge of the balance case volume and the volume of the sampling apparatus the partial pressure of the carbon monoxide was evaluated. Using this value and the total weight gain of the specimen at the moment the gas was sampled, the weight of carbon consumed by the specimen was calculated. The pressure in the balance case was not altered by more than 5% during a sampling cycle.

After oxidation the specimens were prepared for metallographic examination by abrading through 240 to 600 mesh grit SiC wet papers, polishing for 3-5 min on a 1μ diamond lap and finally for several hours on a Syntron vibratory polisher using a water slurry of 0.3μ γ-Al_2O_3 on a Selvyt cloth. Hardness profiles in the metal substrate beneath the oxide layer were determined with a Vickers microhardness indenter using the standard 124° diamond under a 20g load.

Autoradiographs, showing the presence and distribution of carbon on specimens oxidized in carbon dioxide ($C^{14}O_2$), were obtained by placing strips of Ilford Industrial G x-ray film in contact with such specimens and exposing them for periods of 1-3 weeks.

Structures of the oxidation products formed on the specimens were determined by means of x-ray reflection diffraction. Oxidized specimens were mounted on microscope slides and fitted to the stage of a Norelco diffractometer and, using CuKα radiation with a nickel filter, diffraction patterns were obtained over the range $2\theta = 30°$-$70°$.

Results

Oxidation kinetics—carbon dioxide and carbon monoxide.—Kinetic curves for oxidation in carbon dioxide at a pressure of 10 cm Hg are plotted as weight gain in mg/cm² *vs.* time in hours (Fig. 1). More detailed curves showing the early stages of reaction up to 10 hr are shown in Fig. 2. The kinetic curves given here and subsequently comprise all the data obtained. The curves may be divided into three sections. Initially there is a period lasting about 30 min during which the oxidation rate decreases. Subsequently there is a region of increasing rate until after about 10 hr the stage is again reached where the rate decreases with time up to 149 hr. Comparison of these curves with a corresponding kinetic curve for oxidation in oxygen (9) (Fig. 1) shows that initially the rate is much slower in carbon dioxide. Eventually, however, a stage is reached when the rates at a given time in both carbon dioxide and oxygen become approximately the same.

Kinetic data obtained for oxidation in carbon monoxide at 10 cm Hg pressure are plotted as weight gain in mg/cm² *vs.* time in hours (Fig. 3). The initial behavior is shown in detail in Fig. 4. At the outset the rate is more rapid than that observed for oxidation in carbon dioxide (Fig. 2). Moreover, the rate decreases until at a certain time, which varies from specimen to specimen, the rate begins to increase. Comparison again with the corresponding rate curve for oxidation in oxygen (Fig. 3) shows that the oxidation rates at a given time in these two gases are approximately of the same magnitude prior to the onset of breakaway.

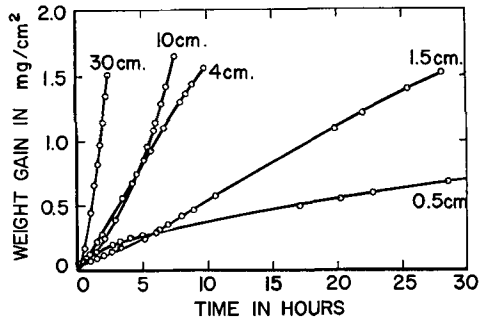

Fig. 5. Oxidation of zirconium at 850°C in carbon dioxide at various pressures.

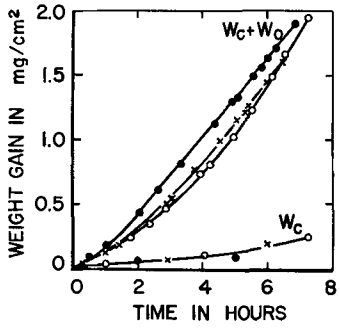

Fig. 6. Oxidation of zirconium at 850°C in carbon dioxide at 10 cm Hg pressure; $w_c + w_o$ represents total weight gain, and w_c represents weight gain due to carbon.

Influence of pressure on the oxidation kinetics.—In order to determine the effect of pressure on the oxidation rate in carbon dioxide a series of specimens were oxidized at pressures from 0.5 to 30 cm Hg. The kinetic results obtained are summarized in Fig. 5. The weight gain at a given time decreased markedly with decreasing pressure. Furthermore, there is a significant difference in rates over this pressure range during the stage of increasing rate of oxidation.

Kinetics of carbon consumption.—The rate of carbon consumption was determined by oxidizing three specimens in radioactive carbon dioxide ($C^{14}O_2$) on the microbalance at 10 cm Hg pressure. The gas was sampled periodically, and values for the amount of carbon consumed by the specimen or lost from the gas phase were obtained (Table I). These results are compared with the kinetics curves in Fig. 6. The shape of the curve for carbon uptake by the specimens was similar to that for the kinetic curves, which represent the total uptake due to carbon and oxygen consumption.

To determine whether the rate of carbon consumption decreased at longer times, an additional experiment was performed in which the amount of carbon monoxide in the gas phase was determined after a specimen had been oxidized in carbon dioxide ($C^{14}O_2$) for 48 hr. The value for the weight of carbon removed

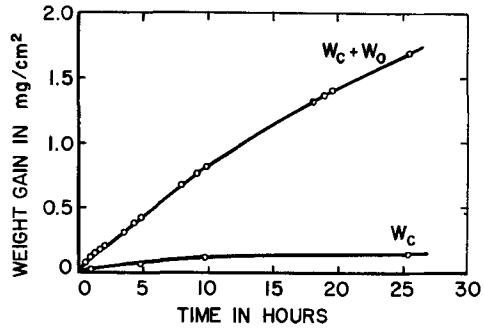

Fig. 7. Oxidation of zirconium at 850°C in carbon dioxide at 1.5 cm Hg pressure; $w_c + w_o$ represents total weight gain, and w_c represents weight gain due to carbon.

from the gas phase (Table I) shows that indeed a stage of decreasing carbon consumption is reached at this time, corresponding to that observed for the total weight gain curves. If the data are expressed as the ratio of the weight gain due to carbon (w_c) to the total weight gain ($w_c + w_o$), where w_o is the weight increase due to oxygen, the percentage of carbon formed decreased with time from 19% at 1 hr to 4% at 48 hr (Table I). The error in the values of w_c was ± 1.5%

Since there was a pronounced pressure effect on the kinetics the effect of pressure change on the rate of carbon uptake was determined. A sample was oxidized in carbon dioxide ($C^{14}O_2$) at a pressure of 1.5 cm Hg, and the gas was sampled at times from 1 to 25½ hr. The weight of carbon and the total weight gain were determined (Table I) and the corresponding curves are shown in Fig. 7. As found for the results at the higher pressure the kinetic curve in both cases is of the same form. Further apart from the initial value the ratio $(w_c/w_c + w_o)$ decreases with increasing time, and is of the same order as those values found at 10 cm Hg pressure.

Chemistry of the reaction.—In order to establish whether reaction occurred between carbon dioxide and carbon during oxidation, two experiments were devised. In the first a specimen was oxidized in 10 cm Hg pressure carbon dioxide ($C^{14}O_2$) for 12 hr in order to deposit radioactive carbon in the specimen. The radioactive gas was then pumped off and replaced by inactive carbon dioxide to the same pressure as before and oxidation allowed to proceed for a further 6 hr. If reaction took place as

$$C^{14} + C^{12}O_2 = C^{12}O + C^{14}O$$

then the carbon monoxide would be radioactive. No activity was found in the residual gas, and hence the reaction in the forward direction was negligible.

It was possible to demonstrate, however, by the second experiment that the dissociation of carbon monoxide into carbon dioxide and carbon does occur. The residual gas after oxidation of zirconium in carbon monoxide at 10 cm Hg pressure for 48 hr was sampled and analyzed for carbon dioxide. There was about 12% carbon dioxide in the gas phase. Consequently, considerable dissociation of carbon monoxide occurred during oxidation of zirconium since the formation of carbon dioxide and carbon from disproportionation of carbon monoxide at 850°C is only 0.4%.

Metallographic examination.—Several samples were oxidized for successively increasing lengths of time in carbon dioxide and in carbon monoxide at 10 cm Hg pressure to allow metallographic examination to be made at the various stages of oxidation. A mean curve is drawn through the weight gains of the various samples, as shown in Fig. 1 and 3.

During the initial stage of oxidation in carbon dioxide the specimens were covered with oxide films exhibiting interference colors. The total maximum weight gain at this stage was generally of the order of 150

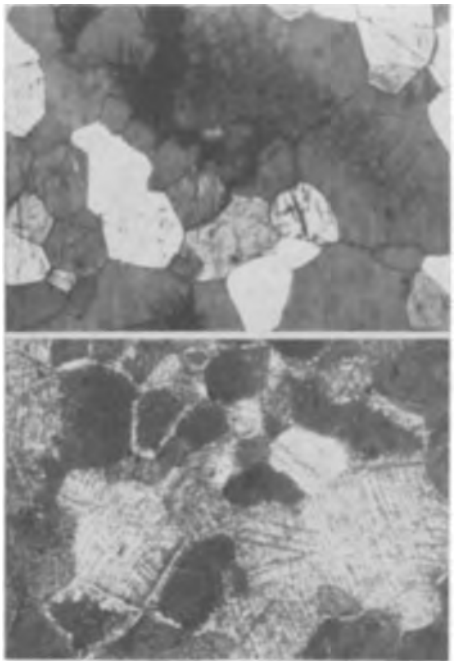

Fig. 8. Photomicrograph showing needles of an additional phase after (a) (top) 10 hr; (b) (bottom) 48 hr. Magnification approximately 160X.

$\mu g/cm^2$. Since this weight gain represents both oxide formation and oxygen solution in the metal and since at this temperature the relative amount of oxygen present as solution in the metal is likely to be large (9), the weight gain of oxygen due to oxide film formation would be much less than 150 $\mu g/cm^2$ and would correspond to a film thickness consistent with the observed interference colors. Corresponding to that portion of the curve which showed an increasing rate, areas of dark gray oxide began to appear at the edges of a specimen. As time proceeded, gray oxide also appeared on selected grains of the flat surface, and it gradually spread to cover the entire specimen.

Microscopic examination of the surfaces of specimens exposed for periods up to 2 hr in carbon dioxide showed that certain metal grains oxidized preferentially. During the stage of increasing rate of oxidation small needles of a new phase were observed on those grains covered with the thicker oxide layer. These needles appeared to nucleate at the metal grain boundaries and occasionally within the grains. Much of this phase grew across grains in directions mutually at about 60° to one another (Fig. 8a) and eventually spread across the entire grain. The number of grains on which the needles were found increased with time. Concurrently the oxide film associated with such grains thickened rapidly until only the outline of the needles became visible (Fig. 8b). Apparently the new phase nucleated and grew initially on those grains which have a preferred orientation, as indicated by a common growth direction. Adjacent grains only showed needle growth and concurrent gray oxide formation at a later stage. The needles were not of sufficient thickness to be detected on microscopic examination of sectioned specimens. Examination of those specimens oxidized over the range of pressures 0.5-30 cm Hg for periods to 25 hr revealed that the amount of new phase formed decreased as the pressure decreased until, at 1.5 and 0.5 cm Hg, needles were not detected.

In the early stages of oxidation in carbon monoxide, the specimens were covered with a gray-black glossy scale. The occurrence of cracked oxide at the specimen edges became evident after 12 hr. After oxidation for 24 and 48 hr, the oxide on the surface showed blisters of either gray or white oxide. The growth of large amounts of oxide at edges was delayed by rounding the specimen edges. As illustrated in Fig. 3, the specimen, whose edges had been rounded, showed breakaway at a later stage. Thus breakaway for the small rectangular specimens was associated with gross oxidation at edges and contributed a relatively large amount to the over-all weight gain. Larger specimens, such as those oxidized individually for 24 and 48 hr (Fig. 3), did not show a breakaway rate to any marked extent, since oxidation at edges even after 48 hr contributed only a relatively small amount to the over-all weight gain. Formation of the new phase consisting of needles was only observed during the first few minutes of oxidation, but detailed examination of their growth was obscured by the rapid growth of the scale.

Sections of specimens oxidized in carbon dioxide and in carbon monoxide after long times showed the oxide to be gray, adherent, and columnar in structure when viewed under polarized light. Scales formed in carbon dioxide were uneven due to different thicknesses of oxide on individual metal grains. The oxide layer formed on those samples oxidized in carbon monoxide, however, were generally fairly uniform. Although specimens which had been oxidized in carbon monoxide for a few hours or more did not show evidence of needles, an additional phase was found at the metal-oxide interface (Fig. 9a). This phase was more heavily concentrated at the specimen edges, where there was considerable oxide cracking (Fig. 9b). It was pale yellow in color and had a hardness of the order of 1400 DPN, which was considerably harder than the metal beneath it (maximum hardness about 1100 DPN).

Oxidized specimens showed a region of metal beneath the oxide layer, which was much harder than the pure metal. Three microhardness traverses were made on sectioned specimens, which had been oxidized for periods of 24 and 48 hr in carbon dioxide and on sectioned specimens, which had been oxidized in carbon monoxide for periods of 6 and 48 hr. As illustrated in Fig. 10, the hardness gradients, expressed as DPN (20g load) *vs.* distance from the metal-oxide interface in microns,

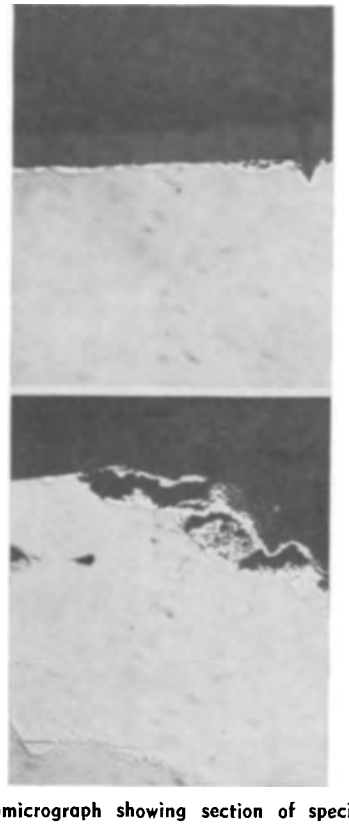

Fig. 9. Photomicrograph showing section of specimen oxidized in carbon monoxide (a) (top) surface of specimen; (b) (bottom) edge of specimen.

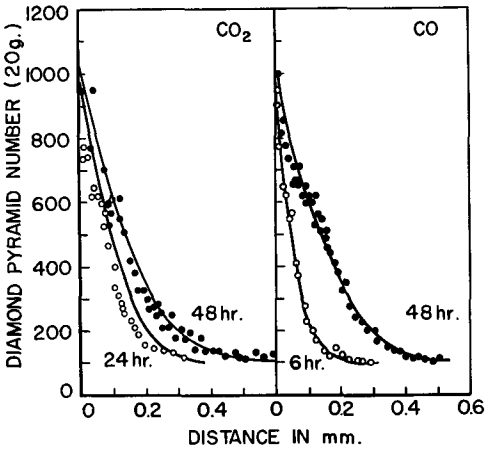

Fig. 10. Hardness gradients on specimens oxidized at 850°C at 10 cm Hg pressure. Points represent experimental determinations, and full lines represent calculated gradients.

extended to a considerable depth into the metal and the penetration distance (10) increased markedly with time.

Autoradiography.—Autoradiographs obtained from the surfaces of specimens, which had been oxidized in carbon dioxide for times from 1 to 144 hr, confirmed that there was consumption of carbon. The carbon distribution varied quite markedly as shown by the light (higher carbon concentration) and dark (lower carbon concentration) areas (Fig. 11). The carbon distribution became more uniform with long exposures, but even after 144 hr there was still a variation in concentration. Unfortunately, it was not possible to detect from the autoradiographs whether the needles had a relatively higher carbon content than the metal grains on which they were growing. Nevertheless, it was found that the areas of gray oxide were associated with a relatively higher carbon content.

Autoradiographs taken of cross sections of two specimens oxidized for 48 and 144 hr showed that the carbon consumed was confined almost entirely to the oxide and very little, if any, was present in the metal.

X-ray analyses.—Reflection x-ray diffraction patterns were obtained from two specimens, one of which had been oxidized in carbon dioxide for 22 hr at 10 cm Hg pressure, and the other which had been oxidized in carbon monoxide for 12 hr also at this pressure. Monoclinic zirconia and α-zirconium only were found to be present. There was no evidence for zirconium carbide.

Since, however, film thicknesses were such that the x-ray beam was not able to penetrate sufficiently deeply into the metal substrate, the oxide was polished back until some of the underlying metal was exposed. For the specimen oxidized in carbon dioxide the relative intensities of all the lines increased and, in particular, the metal lines. Again there was no evidence for the presence of the carbide phase. In the case of the specimen oxidized in carbon monoxide, however, besides an over-all enhancement of the diffraction lines, three extra lines were found, which were not identifiable with the metal, the oxide, or the carbide. These lines appeared at diffraction angles of $2\theta = 30°\ 50'$, $39°\ 50'$ and $48°\ 10'$. One of these lines corresponded to a very weak line ($2\theta = 48°\ 10'$) observed in the pattern for this specimen prior to polishing back the oxide. Since a new phase was observed at the metal-oxide interface after several hours (Fig. 9) it seems likely that the extra diffraction lines were associated with this phase.

In order to determine whether zirconium dioxide can take up carbon, zirconia powder was outgassed at room temperature for 12 hr and at 850°C for 75 min in a vacuum of 10^{-6} mm Hg and then heated in carbon monoxide. There was an initial rapid increase in weight, which decreased gradually until, after 120 hr, the weight gain became zero. Analysis of the gas after oxidation revealed that it contained 6% carbon dioxide. The relative increase in weight of the specimen was 0.018%. From these considerations the formula assigned to the solid solution thus formed was $ZrO_{1.993}C_{0.018}$. The zirconia powder was found to have turned gray, possibly due to either carburization by the carbon monoxide and/or nonstoichiometry by loss of oxygen. An x-ray diffraction pattern of this substance was identical to the corresponding pattern for zirconia.

Discussion

Thermodynamics.—When zirconium reacts with carbon dioxide and with carbon monoxide at 850°C several reactions are thermodynamically feasible and may occur as represented by the equations given in Table II. These reactions, however, do not account for the oxidation mechanism, because the free or combined carbon reacts with the oxide scale or the underlying zirconium-oxygen solid solution to form compounds or solid solutions for which no thermodynamic or structural data are available. For example, it has been shown that carbon combines with zirconium dioxide and that a new phase is formed beneath the oxide scale (Fig. 8 and 9).

Mechanism and chemistry—Reaction with carbon dioxide.—Oxidation led to the formation of oxide, carbon monoxide, and carbon. If the oxide grew by the inward diffusion of oxygen via anion vacancies, carbon, formed at the gas-oxide interface may be incorporated into the growing oxide layer and diffuse inward. Evidence for carbon in the oxide was shown from examination of the autoradiographs of sectioned oxidized specimens and by its absorption in the oxide on heating in carbon monoxide.

Although zirconium carbide could be formed by reactions [3] and [4], the experimental evidence demonstrated that these reactions did not occur, since zirconium carbide was not found. Thus it is concluded that

Table II. Standard free energy changes for the system zirconium-carbon dioxide

	Reaction	$\Delta G°$ (1123°K), kcal/mole
[1]	$Zr + 2CO_2 = ZrO_2 + 2CO$	−139.3
[2]	$Zr + CO_2 = ZrO_2 + C$	−133.3
[3]	$Zr + C = ZrC$	−41.6
[4]	$2Zr + CO_2 = ZrO_2 + ZrC$	−174.9
[5]	$CO_2 + C = 2CO$	−6.0
[6]	$Zr + 2CO = ZrO_2 + 2C$	−127.3
[7]	$3Zr + 2CO = ZrO_2 + 2ZrC$	−168.9

reactions [1] and [2] occur, leading to the formation of carbon monoxide and to incorporation of carbon. The reaction of carbon dioxide with the carbon formed, reaction [5], was shown not to occur.

The value of the ratio $w_c/(w_c + w_o)$ (Table I), assuming reaction [2] took place exclusively, is 0.273. From the experimental values, it was calculated that the percentage of reaction [2] occurring decreased from 62 to 11% from 1 to 48 hr, respectively, at a pressure of 10 cm Hg. Thus the extent to which this reaction occurred decreased from a relatively large proportion initially to a much smaller value at longer times.

Hayes, Roberson, and Robertson (1) have suggested that zirconium carbide is formed during oxidation and that it could be distinguished from that present in the unoxidized carbon-melted metal. Zirconium carbide in such carbon-containing zirconium is largely unattacked during oxidation in both oxygen (11) and carbon dioxide (2). The present results show, however, that the carbide could not be detected. Although Maekawa (5) and Guerlet and Lehr (4) were not able to detect carbon as a reaction product at temperatures in the range 650°-850°C, the use of the radioactive tracer carbon-14 has shown that carbon was formed during the oxidation at 850°C. Moreover, previous work (6) has proved that carbon was a product of reaction at temperatures in the range 550°-750°C.

Mechanism and chemistry—Reaction with carbon monoxide.—The main reaction products in this system are solids. In contrast to the corresponding reaction with carbon dioxide, where the ratio $w_c/(w_c + w_o)$ may vary between zero and 0.273, carbon and oxygen are formed simultaneously (reaction [6]) and the ratio is 0.429. It is assumed by comparison with the corresponding reaction mechanism for carbon dioxide that carbon is deposited initially at the gas-oxide interface and then migrates inward through the oxide scale. Reactions [3] and [7] are precluded because there was no evidence for zirconium carbide. The reverse of reaction [5] was shown to occur with the formation of carbon dioxide and concurrent deposition of carbon.

Kinetics and metallography—Carbon dioxide.—The kinetic curve obtained at 10 cm Hg pressure exhibited three distinct parts: an initial decreasing rate, an intermediate rapidly increasing rate, and a final decreasing rate. Earlier work at temperatures in the range 650°-750°C and at this pressure (6) agrees with the general shape of the reported curves. Previous results (3,4) at a pressure of 76 cm Hg show agreement to both parabolic and cubic-parabolic rate relationships, with no evidence for an increasing rate of oxidation at short times. The weight gain at a given time at 76 cm Hg pressure is greater than that found at the highest pressure of 30 cm Hg employed in this investigation. Any period of increasing oxidation rate which may have occurred at 76 cm Hg pressure was possibly obscured because of the relatively high oxidation rate or by the method of weight gain determination used.

During the initial stages, the oxidation rate was very much less than that in oxygen (Fig. 2). Possibly the oxidation rate was controlled by the dissociation rate of carbon dioxide. When the oxide film is thin migration of oxygen and carbon through it might be expected to be a relatively rapid process.

During the range of increasing oxidation rate, a needle-like phase was observed at the metal-oxide interface. On many grains these needles grew laterally at 60° to one another and appeared to have nucleated principally at grain boundaries. It is believed that the carbon concentration set up at the metal-oxide interface was sufficient for carbon to dissolve to a limited extent in the zirconium-oxygen solid solution. When this solution reached a critical concentration of carbon, the new phase was precipitated and grew in the form of needles. The required carbon content was probably quite low, since carbon is only slightly soluble in zirconium (12). Precipitates of this type were observed by Bailey (13) when zirconium foil was oxidized in the electron microscope. Bailey was of the opinion that these needles constitute a lower oxide of zirconium. It is possible, then, that in the present work, where the needles are visible in the optical microscope, they consist of a lower oxide of zirconium, stabilized by small amounts of carbon.

A specific reason cannot be advanced for the increasing rate region in the kinetic curves. The more rapid rate could be associated with the dependence of the carbon dioxide dissociation rate on surface properties of the oxide, which vary with film thickness or alternatively with the lateral growth of the needle-phase along the metal-oxide interface, causing the oxide to crack, leading to easier access of the reactants to the metal beneath. It has been shown for the iron system that the first consideration is valid (14, 15). In support of the latter consideration, Bailey (13) has suggested that growth of a lower oxide leads to cracking of the oxide film. Both of the above considerations would account for the large effect of carbon dioxide pressure over the range 0.5-30 cm Hg on the kinetics. If the chemisorption consideration accounted for the initial reaction rates, eventually diffusion of oxygen across the oxide layer would become a rate-determining step on establishment of a concentration gradient. On the other hand, this concentration gradient could be established even though the oxide was initially cracked, provided the cracks healed themselves.

The oxidation rate at a given time in carbon dioxide after about 25 hr was about the same as the corresponding rate in oxygen. When plotted in parabolic form (Fig. 12), the data show a reasonable fit to this plot and indicate that the parabolic rate constants in each case were approximately the same. Since autoradiographic results showed that carbon did not penetrate into the metal to any appreciable extent, the hardness gradients in the metal substrate were due to oxygen solution. Using the value of the diffusion constant for oxygen in α-zirconium at 850°C and the error function equation for oxygen diffusion given previously (9) the hardness profiles were calculated, assuming that hardness was proportional to oxygen concentration. These profiles represented the experimental results to a good approximation (Fig. 10). Accordingly, the oxidation mechanism may approximate to the corresponding model for oxidation in oxygen, namely, a diffusion process of oxygen in both the oxide and the metal leading to a parabolic rate of oxidation (9).

Kinetics and metallography—Carbon monoxide.—The oxidation kinetics were in the form of a continuously decreasing rate curve. No period of initial decreasing rate followed by an increasing rate was observed. However, small needles were observed on most grains during the first minute of oxidation, but were subsequently obscured by the rapidly thickening oxide film. It was possible that a period of increasing rate did

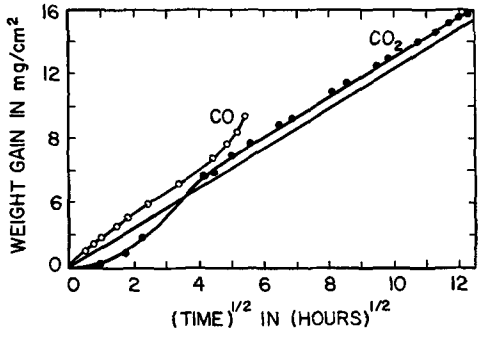

Fig. 12. Oxidation of zirconium at 850°C in carbon dioxide and carbon monoxide at 10 cm Hg pressure. Present results are compared with the corresponding curve (continuous line) for oxidation of zirconium at 850°C in oxygen at 40 cm Hg pressure.

exist, but was not detectable because of the very rapid oxidation.

During the early stages of oxidation, the ratio of carbon to oxygen from carbon monoxide is fixed at 0.429 (reaction [6]). The relatively large carbon potential would lead to a rapid carbon build-up at the metal-oxide interface and gives rise to the formation of a new phase, which was observed at this interface (Fig. 9). No evidence was found to suggest that this phase differs in structure from the needle-like phase. This second phase was not zirconium carbide and, in fact, did not correspond to any known substance. It was found to a larger extent at the edges where there was a large amount of oxide cracking and at blisters and cracks in the compact film. Possibly the presence of this phase led to eventual cracking of the oxide film, due to the stresses set up at the metal-oxide interface.

The kinetics before onset of breakaway oxidation (Fig. 12) indicate that the rate at a given time approximated to the corresponding rate found in oxygen and in carbon dioxide. On calculating the hardness gradients in the metal in the same way as for the specimens oxidized in carbon dioxide, they show good agreement with the experimental plots at 6 and 48 hr (Fig. 10). All these findings support the conclusion that oxygen dissolves in the metal during oxidation to essentially the same degree in oxygen, carbon dioxide, and carbon monoxide.

Diffusion Coefficients and Anion Vacancy Concentrations for the Zirconium-Zirconium Dioxide System

Tennyson Smith

North American Aviation Science Center, Thousand Oaks, California

ABSTRACT

Experiments have been carried out at 386°C to determine the concentration of anion vacancies at the metal-oxide interface and the diffusion coefficients for anion vacancies in zirconium dioxide films on zirconium by the "interruption kinetic technique." The conditions for which this technique is valid are discussed. The anion vacancy concentration in the oxide at the oxide-metal interface (386°C) proved to be $(7 \pm 0.7) \times 10^{-3}$ g atom/cm^3 as compared to $(2.2 \pm 2) \times 10^{-3}$ calculated from the phase diagram. Diffusion coefficients can be expressed as

$$D = 0.9 \times 10^{-3} e^{-\frac{28{,}700 \pm 600}{RT}} \quad \text{cm}^2/\text{sec}$$

Theoretical calculation of the entropy of vacancy formation and values of D_o are made assuming three models. It is concluded that electrons are trapped at anion vacancies or impurity centers, rather than act as Fermi-electrons in the conduction band.

As pointed out by Rosenburg (1), measurement of the parabolic rate constant yields values for the product DC, where D is the diffusion coefficient and C is the concentration of the diffusing defect. Independent measurements of D or C are required in order to separate D and C. These measurements are not only difficult to make but are inconclusive unless differences in sample structure and purity are demonstrably negligible. Rosenburg (1) describes a technique that will yield accurate and simultaneous determination of D and C from reaction rates alone.

Debuigne and Lehr (2) and Douglass (3) have reported values of D as a function of temperature for oxygen diffusion in pure zirconium dioxide powder. Kingery *et al.* (4) have reported values of D for oxygen diffusion in stabilized zirconia sintered pellets. Domagala and McPherson (5) have studied the equilibrium between oxygen gas-zirconium metal-zirconium dioxide. From their data one can calculate values for C at the metal-oxide interface. The diffusing defects (6), in the case of zirconium dioxide, are anion vacancies which have been created by dissolution of oxygen into the metal at the metal-oxide interface.

It is the purpose of this article, to report results for D and C, using Rosenburg's (1) interrupted anneal technique; to discuss results obtained, which did not satisfy the prescribed experimental conditions; to

compare results with those obtained by independent measurements reported by the authors mentioned above; and to compare results with theoretical values. The theoretical value of D depends on the choice of one of three models; (*a*) that the two electrons (which must be associated with each anion vacancy for electrical neutrality) are trapped at the anion vacancy; (*b*) these electrons are trapped at cation sites; or (*c*) these electrons can be considered as Fermi-electrons in the conduction band of the oxide. It has been estimated in a previous paper (7) that the concentration of electrons in the conduction band is of the order of 10^{-15} mole/cm^3, as compared to a vacancy concentration of the order of 10^{-5} mole/cm^3 for a zirconium dioxide powder. It is predicted therefore that model (c) will not be involved. We wish to distinguish between models (*a*), (*b*), and (*c*), if possible.

Experimental

Crystal bar zirconium samples about 1½ in. long by ¼ in. in diameter were machined to have hemispherical ends. They were mechanically polished on a lathe with No. 3/0 emery paper and then by 3-μ diamond dust, and were then cleaned in anhydrous ether followed by another cleaning in pure alcohol. Samples were sealed in quartz or Vycor sample holders and attached to a vacuum furnace system. The samples were first annealed at 700°C under vacuum to remove any oxide film (dissolved into sample) and then they were brought to the desired temperature. Oxidation was followed by continuously recording the oxygen pressure change in the constant volume system with a thermistor manometer, (10^{-5} to 1 Torr). The system also contained a strain gauge pressure transducer for work in the pressure range 1-1000 Torr. A constant temperature bath was built into the system to control the temperature of the thermistor and transducer to ± 0.02°C. High-purity research grade oxygen (Matheson Company) was used as-received. Maximum limits of possible impurities were listed in mole per cent as $CO_2 < 0.1$, $CO < 0.01$, $He < 0.01$, $N_2 < 0.01$, and $H_2 < 0.01$. The film thickness was calculated from the oxygen pickup and the value always checked with that obtained by comparison of the sample color with an interference-color step gauge.

Anion vacancy concentration and diffusion coefficients.—Application of Rosenburg's "interruption kinetic technique" was used to determine the diffusion coefficient D and the concentration of defects C (anion vacancies) which are involved in the oxidation of zirconium as follows.

Figure 1 shows the general situation for various defect possibilities during the oxidation of a metal.

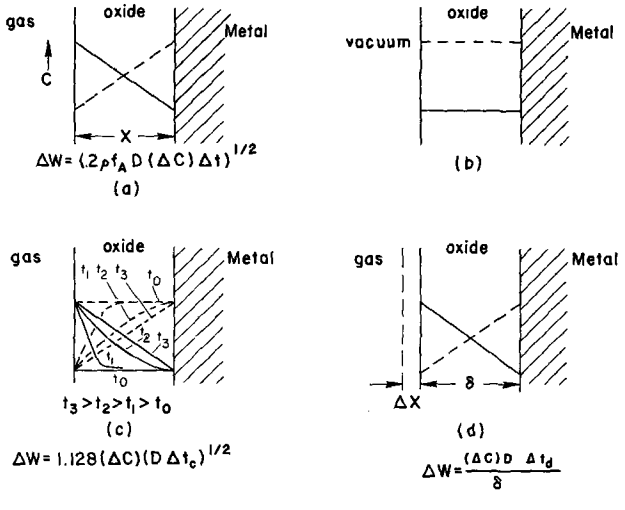

Fig. 1. Defect concentration profile: (a) during oxidation, (b) at equilibrium, after oxygen removal, (c) during semi-infinite media diffusion, (d) steady-state diffusion.

Figure 1a shows the assumed concentration profile of the diffusing defects during film growth. The solid line across the oxide in Fig. 1a represents the concentration of interstitial anions (atoms or molecules) or cation vacancies, whichever the case may be. The dashed line represents the concentration of interstitial cations (or atoms) or anion vacancies. The type of defect cannot be determined by kinetic experiments alone, but must be established by some other suitable method such as chemical analysis, marker experiments, etc. It has been found that in most cases only one type of defect is predominantly involved in any given system.

Figure 1b represents the equilibrium concentration profile after the oxidizing gas has been evacuated from the system. On admitting gas to the system again, the film acts as a semi-infinite medium for diffusion for a time, illustrated by Fig. 1c. The curves designated t_0, t_1, t_2, and t_3 represent the profile at various times between equilibrium and steady state diffusion.

Figure 1d shows the profile when steady state is reached after the interruption (film growth, Δx, is small with respect to the thickness δ). Following this, oxidation resumes as in Fig. 1a again.

By solving Fick's second law, with the appropriate boundary conditions, Rosenburg reports two limiting forms of the equation relating the number of defects crossing unit area in time t. For the case of oxidation of zirconium these limiting forms can be expressed

$$W_c = 1.128\, C\, [Dt_c]^{1/2} \quad (t << \delta^2/D) \qquad [1]$$

and

$$W_d = DCt_d/\delta + \delta C/3 \quad (t > \delta^2/2D) \qquad [2]$$

where W is the gram atoms of oxygen/cm^2 of zirconium sample, C is the anion vacancy concentration (gram atom/cm^3) at the oxide-metal interface, D is the diffusion coefficient for anion vacancies, t is the time starting at reexposure to oxygen, δ is the film thickness, and subscripts refer to the period (of Fig. 1) for which the equation is valid.

We add the third limiting equation, that of film growth during period a (Fig. 1) where no interruption is made

$$W_a = (\rho f DCt_a/8)^{1/2} \qquad [3]$$

where ρ is the oxide film density, f is the weight fraction of the oxide that is oxygen. Equation [3] is derived from the parabolic growth equation

$$dW/dt = DC/\delta \qquad [4]$$

where

$$\delta = 16W/\rho f \qquad [5]$$

and 16 is the atomic weight of oxygen. As pointed out by Rosenburg, Eq. [1] and [2] are valid only if the following conditions are met: (*a*) D is independent of C; (*b*) the oxide surface is flat (roughness factor unity); (*c*) $\Delta X << \delta$; (*d*) no initial reaction (such as adsorption) contributes appreciably to W; (*e*) $t << \delta^2/D$, Eq. [1]; (*f*) $t > \delta^2/2D$, Eq. [2]. For diffusion by a vacancy mechanism condition (*a*) should be a good assumption. Condition (*b*) is difficult to ascertain accurately. Rosenburg considered his chemically polished InSb to have a roughness factor of $F = 1.3$. An estimate of the roughness factor for the zirconium samples used in this study is $F = 1.5 \pm 0.5$, from electrical capacitance measurements. Condition (*c*) is easily met, except for very thin films. Condition (*d*) is usually not met but can be corrected for. If for any reason (perhaps due to initial adsorption) the intercept of Eq. [1] is not zero, the value of the intercept, designated Z, can be treated as an additive constant. Any expression containing W must be corrected by the value Z. In order to satisfy conditions (*e*) and (*f*), order of magnitude values of D must be known in advance, or as will be shown later order of magnitude values of C must be known in advance.

The experimental data can be expressed by the following equations

$$W_c = r_c t_c^{1/2} + Z \quad (t << \delta^2/D) \qquad [6]$$

$$W_d = r_d t_d + W_o \quad (t > \delta^2/2D) \qquad [7]$$

$$W_a = r_a t_a^{1/2} \quad \text{no interruption} \qquad [8]$$

where r is the slope of a plot of W *vs.* t or $t^{1/2}$, and W_o and Z are the intercepts.

Since the values for W, r, and Z can be obtained from a single interruption experiment, we now have four equations and two unknowns. The equations for the diffusion coefficient and vacancy concentration are

$$D = [1.128\, r_d \delta / r_c]^2 \qquad [9]$$

$$D = [1.128 \times 8 r_a^2 / \rho f r_c]^2 \qquad [10]$$

$$C = 3[W_o - Z]/\delta \qquad [11]$$

$$C = [r_c/1.128]^2/r_d\delta \qquad [12]$$

$$C = [r_c/1.128 r_a]^2\, \rho f/8 \qquad [13]$$

$$C = 8[r_a r_c/1.128 r_d \delta]^2/\rho f \qquad [14]$$

Although Eq. [10], [13], and [14] are analytically correct, they are less useful than Eq. [9], [11], and [12] because very accurate values for r_a are needed (Eq. [10] and [14] are to the fourth power in r).

Results

Oxidation of zirconium at 386°C.—A sample of crystal bar zirconium was oxidized in pure oxygen at temperature (period a, Fig. 1a) until the oxide thickness was 280Å, at which point the oxygen was pumped out of the system and the sample annealed (period b, Fig. 1b).

It should be mentioned that, because of the large equilibrium constant in favor of zirconium oxidation, no vacuum system is good enough to reduce the oxygen pressure to a value that oxidation would cease. It is only because the rate-determining step becomes diffusion of oxygen in the gas phase, which at low enough pressure is slow with respect to diffusion in the solid, that equilibrium such as illustrated in Fig. 1b can be approached.

After the anneal the oxygen was re-admitted to the system and the reaction followed by recording the pressure drop with a very sensitive thermistor manometer. When normal oxidation had been re-established (periods c and d, Fig. 1c and d) and the film had thickened to 418Å, the same procedure was repeated and so on for various thicknesses up to 4850Å.

Figure 2a shows a plot of the experimental data for a film that had been annealed in vacuum for 41 hr. The question arises as to which time the slope of the curve should be taken. It is seen in Fig. 2b that between $t^{1/2} \sim 8$ and 32 the data fall close to a straight line but becomes concave up beyond $t^{1/2} \sim 32$. The slope of the line (Fig. 2b) between $t^{1/2} \sim 8$ and 32 is r_c and the intercept is Z. When oxidation approaches the condition just prior to the interruption, the slope of the line (W *vs.* $t^{1/2}$) will approach r_a. From Eq. [12] we obtain

$$r_a/r_c = (\rho f/8C)^{1/2}/1.128 \qquad [15]$$

and it is predicted that the curve (following r_c period) will be concave up if $C < 0.1\,\rho f$ and concave down if $C > 0.1\rho f$. In the case of zirconium oxidation $\rho f = 1.5$ ($\rho = 5.83$ g/cm^3, $f \approx 0.26$) and as will be shown later $C \sim 10^{-2}$ to 10^{-3} g at./cm^3 from the phase diagram, so that $r_a > r_c$ and the curve should be concave up as seen ($t^{1/2} > 32$) in Fig. 2b. From Eq. [3] and [8], [an experimental value of r_a (at 386°C) is 2.2 x 10^{-8} g at./cm^2 sec$^{1/2}$] and the order of magnitude value of $C \sim 5 \times 10^{-3}$ g/cm^3 we obtain $(\delta^2/2D) \sim 10^3$ sec. It should be noted that $t \sim 10^3$ ($t^{1/2} \sim 33$) is just where the curve in Fig. 2b begins to curve up. In order to satisfy conditions (c) and (f), it follows that r_d should be taken as the slope (Fig. 2a) at t just greater than 10^3.

The slope of the line between 1000 and 2000 sec (Fig. 2a) yields the value $r_d = 0.75 \times 10^{-10}$ g at. O/cm^2 sec, the intercept yields $W_o = 1.12 \times 10^{-7}$ g at. O/cm^2. The slope of the line between $t^{1/2} = 10$ and 32 (Fig. 2b) yields the value $r_c = 4.8 \times 10^{-9}$ g at. O/cm^2 sec$^{1/2}$ and the intercept yields $Z = 0.34 \times 10^{-7}$ g at. O/cm^2. From Eq. [9] and $\delta = 3.13 \times 10^{-5}$ cm the diffusion coefficient is calculated to be $D = 3.1 \times 10^{-13}$ cm^2/sec; from Eq. [11], $C = 0.75 \times 10^{-2}$ g at./cm^3 and from Eq. [12], $C = 0.76 \times 10^{-2}$ g at./cm^3. With the more accurate value of D we see that conditions (c), (*e*), and (*f*) have been satisfied. By taking r_d from the curve (Fig. 2a) between 2000 and 3000 sec [where condition (*c*) is less likely to be met] we obtain values of $D \sim 2.1 \times 10^{-13}$, C (Eq. [11]) $\simeq 0.98 \times 10^{-2}$ and C (Eq. [12]) $\simeq 0.93 \times 10^{-2}$. This shows that values for D and C are not extremely sensitive to condition (*c*).

Rosenburg (1) solved the diffusion equation by numerical analysis and gives a table (his Table I) which can be used to predict W *vs.* t if the correction for Z is made. The solid lines in Fig. 2 are the theoretical curves determined with the aid of Table I (1).

Figure 3 shows data for which condition (*f*) was not satisfied, *i.e.*, the time of the experiment was too short to allow $t_d > \delta^2/2D$. It is seen that, although r_c is of the right order of magnitude (3.7×10^{-9} at 380°C as compared to 4.8×10^{-9} at 386°C in Fig. 2), the

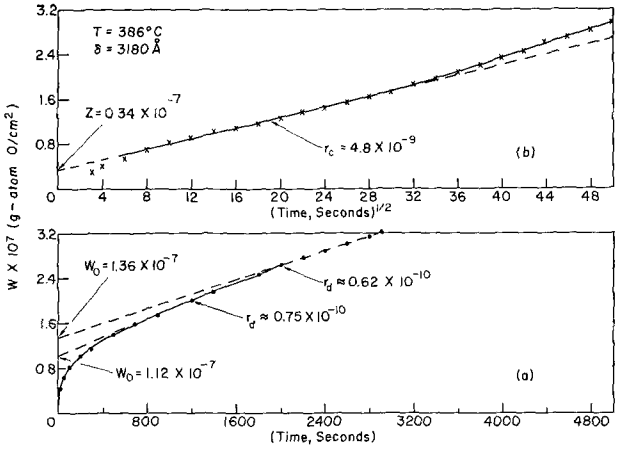

Fig. 2. Oxygen pickup by a zirconium sample after annealing the previously formed oxide layer to equilibrate the anion vacancy concentration throughout the film. The oxygen pickup is given as a function of time (a) and the square root of time (b curve).

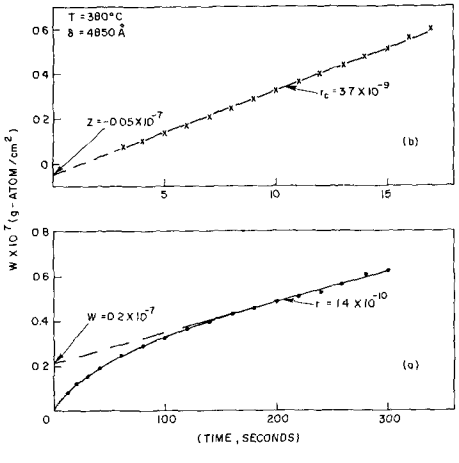

Fig. 3. Oxygen pickup by a zirconium sample after annealing the previously formed oxide layer to equilibrate the anion vacancy concentration throughout the film. The oxygen pickup is given as a function of time (a) and the square root of time (b). Apparent values for r_d and W are wrong because the condition that $t > \delta^2/2D$ was not satisfied.

Table I. Values for the diffusion coefficient and the anion vacancy concentration from kinetic data

value of r chosen as r_d is a factor of two higher. Values of D, C (Eq. [11]) and C (Eq. [12]) prove to be 53 x 10^{-13} cm^2/sec, 0.12 x 10^{-2} and 0.13 x 10^{-2} g at./cm^3, respectively. It should be noted that in spite of the fact that r_d was measured at $t \sim 300$ sec rather that $t > (\delta^2/2D \sim 3900$ sec), the experimental data are predicted with Rosenburg's Table I, e.g., the solid lines in Fig. 3 are theoretical if the values $D = 53 \times 10^{-13}$ and $C = 0.12 \times 10^{-2}$ are used. It should also be noted that C (Eq. [11]) checks with C (Eq. [12]) regardless of the value of t at which r_d is measured. It is concluded that prediction of the data [with the Table I (1)] and close correlation between C (Eq. [11]) and C (Eq. [12]) are necessary but not sufficient to establish accurate values for D and C. Care must be taken to see that all of the conditions (a-f) are satisfied.

In Table I, experimental conditions and calculated values of D, C (Eq. [11]) and C (Eq. [12]) are given. If the roughness factor is greater than unity, it is seen from Eq. [9]-[14] that values for D, calculated with the assumption that F is unity, should be multiplied by $1/F^2$. That is, any term calculated from a value of W (r_d, r_c, r_a, and δ) must be divided by F. If F is taken as 1.5 for the zirconium samples, the values of D in Table I should be multiplied by the factor 0.4. It can be seen from Eq. [9]-[14] that calculated values of C are independent of F, since F cancels in each case. The experiments represented in the top group of Table I, satisfy the conditions (a-f). The average value of D at 386°C is 3.1 x 10^{-13} cm^2/sec (if $F = 1$), an average value of C is (7.0 ± 0.7) x 10^{-3} g at./cm^3. The results for the lower group in Table I shows that high values for D result if condition (f) is not satisfied, high values of C result if condition (e) is not satisfied, and high values of C result if condition (c) is not satisfied. In the bottom group the correlation between C (Eq. [11]) and C (Eq. [12]) is within about 3%, even though the limiting conditions have not been met.

Effect of temperature.—Experiments were carried out at various temperatures without interruption. Figure 4a shows data for oxidation at 365° and 418°C. It is seen from Fig. 4b that the parabolic rate law was obeyed. Values for DC are calculated from Eq. [3] and [8] and are plotted as open circles in Fig. 6. In another experiment a sample with a 1500Å film was oxidized at various temperatures with resultant small changes in δ. It is seen from Eq. [4] that except for small curvature due to the small change in δ, that approximately straight lines should result. The slope of these lines multiplied by the average value of δ should yield values for DC. The results from Fig. 5 are plotted in Fig. 6 as solid points. The solid line is a least squares fit of the experimental points. Expressing the product $r\delta$ [where $r = (dW/dt)_\delta$] as a function of temperature we have

$$r\delta \cong DC \approx 1.5 \times 10^{-4} e^{-\frac{31{,}100 \pm 600}{RT}} \quad \text{(g at. O/cm}^2\text{-sec)} \quad [16]$$

In order to express D as a function of temperature we need C as a function of temperature.

Calculation of anion vacancy concentration from equilibrium data.—Domagala and McPherson (5) have studied the equilibrium between oxygen gas-zirconium metal-zirconium dioxide, from 500°C to above 1900°C. Oxygen forms a solid solution with zirconium up to 6.75 w/o (weight per cent) [29 a/o (atomic per cent)] at which point nonstoichiometric (oxygen deficient) zirconium dioxide precipitates. This saturation concentration (29 a/o) is constant with temperature

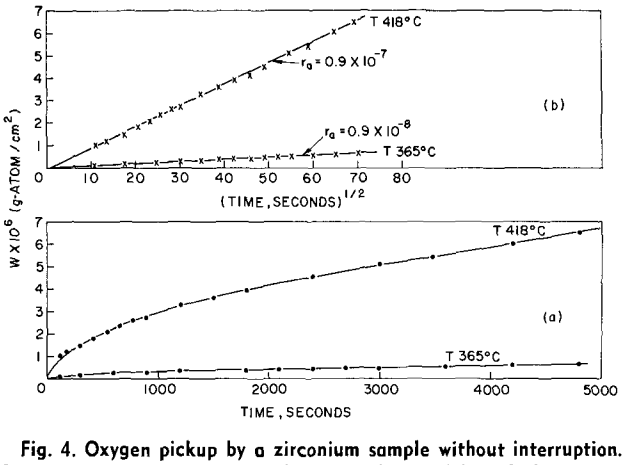

Fig. 4. Oxygen pickup by a zirconium sample without interruption. Oxygen pickup is given as a function of time (a) and the square root of time (b) at two temperatures (365° and 418°C).

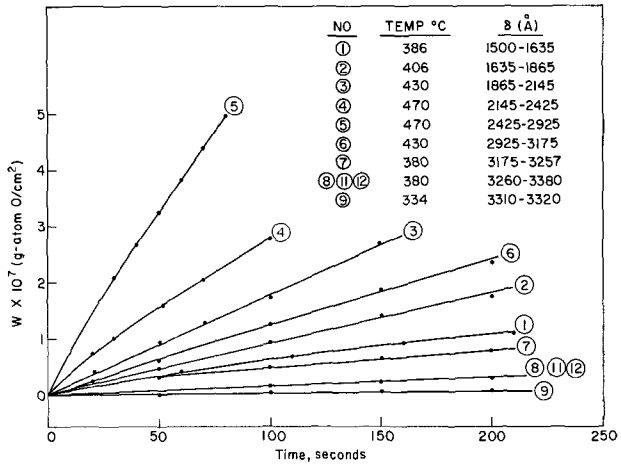

Fig. 5. Oxygen pickup by a zirconium sample at approximately constant film thickness as a function of temperature.

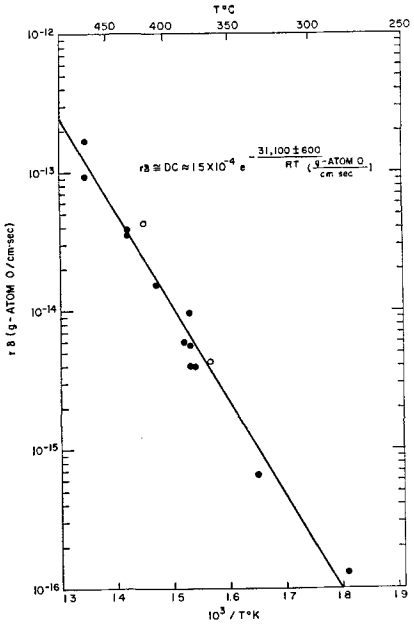

Fig. 6. An Arrhenius plot of ln $R\delta$ vs. $1/T$ for oxidation of zirconium from Fig. 5 (•). The open circles are from the curves in Fig. 4.

up to approximately 1900°C. The oxygen concentration in the zirconium dioxide is 25 w/o (65.5 a/o) at 700°C and decreases in a linear fashion to 23 w/o (63 a/o) at 1900°C. Most investigations to date have indicated that nonstoichiometric ZrO_2 has an anion deficit structure. From the above information, the concentration of oxygen ions at 700°C is

$$(25/16)/(100/5.83) = 0.091 \text{ g at. } O^{=}/cm^3$$

For stoichiometric oxide (26 w/o oxygen), the oxygen ion concentration is 0.095 g at. O/cm^3. Therefore, the anion vacancy concentration is 0.095 − 0.091 = 0.004 g at. $\square/cm^3$. A similar calculation for 1900°C yields $C(1900°C) = 0.011$ g at. $\square/cm^3$. The resulting empirical equation relating the concentration of anion vacancies and temperature is

$$C \cong 5.8 \times 10^{-6} T \qquad [17]$$

where T is in °C and C is in g at. $\square/cm^3$.

From Eq. [17] and the reported (5) experimental error of ± 0.5 w/o, at 386°C

$$C = (2.2 \pm 2) \times 10^{-3} \text{ g at. } \square/cm^3 \qquad [18]$$

as compared to

$$C = (7.0 \pm 0.7) \times 10^{-3} \text{ g at. } \square/cm^3 \qquad [19]$$

for the top group of Table I.

The above concentrations represent 2.3 and 6.7% of the oxygen ions missing, respectively, or nonstoichiometric $ZrO_{1.977}$, $ZrO_{1.926}$. At 386°C the diffusion of oxygen into zirconium metal is very slow so that the equilibrium concentration of oxygen is certainly not attained throughout the bulk metal. It is expected that the equilibrium concentration would be approached at the metal-oxide interface, but a lower than equilibrium oxygen concentration in the metal interface would tend to increase vacancy concentration as found. To test these possibilities further, experiments should be carried out on nearly oxygen saturated zirconium with oxide films about 2000Å thick.

To obtain Eq. [17] in exponential form, we make the following analysis. Consider the reaction at the ZrO_2-Zr interface to be

$$Zr_i + O^{=} \rightleftarrows \square O^{=} + 2e^{-} + O_i \qquad [20]$$

where Zr_i represents interstitial positions in the zirconium lattice, $O^{=}$ represents the oxygen ions in the ZrO_2 lattice, $\square O^{=}$ represents the anion vacancies created when oxygen ions give up two electrons e^{-}, and enter the zirconium metal as atoms, O_i, in interstitial positions. At equilibrium the chemical potential (partial molar free energy) of the species in each phase will be equal. The equilibrium constant K_v can be expressed

$$K_v = \frac{a_{\square}\, a_{e^-}{}^2\, a_{O_i}}{a_{Zr_i}\, a_{O^=}} \qquad [21]$$

where $a_{\square}$, a_{e^-}, a_{O_i}, a_{Zr_i}, and $a_{O^=}$ represent the activities of $\square$, $\square_{O^=}$, e^{-}, O_i, Zr_i, and $O^{=}$, respectively. We choose as standard states the concentration of each of the species at equilibrium at 386°C. Therefore, at 386°C, the activities are each unity and, consequently, K_v is unty. Since a_{O_i} and $a_{O^=}$ are essentially independent of temperature and since for every vacancy two electrons are promoted into the ZrO_2, $C_{e^-} = 2C$.

From Eq. [21], at any temperature

$$K_v \approx a_{\square}\, a_{e^-}{}^2 = \left[\frac{C(T)}{C(386°C)}\right]^3 \qquad [22]$$

and from Eq. [17]

$$K_v \cong \left[\frac{T}{386}\right]^3 \qquad [23]$$

Now from thermodynamics

$$\Delta\bar{F}° = \Delta\bar{H}° - T\Delta\bar{S}° = -RT\ln K_v \qquad [24]$$

where $\Delta\bar{F}°$, $\Delta\bar{H}°$, and $\Delta\bar{S}°$ are the partial molar free energy, enthalpy, and entropy changes for the reactant and products in their standard states. A plot of ln K_v *vs* $1/T$°K reveals $\Delta\bar{H}°$ to be approximately 7.1 ± 0.3 kcal/mole in the temperature range 300°-800°C. At 386°C (659K°) K_v is unity, so $\Delta\bar{F}° = 0$ and the experimental entropy change is

$$\Delta\bar{S}° = \frac{\Delta\bar{H}°}{T} \cong \frac{7100}{659} \approx 11 \pm 0.3 \text{ e.u.} \qquad [25]$$

The anion vacancy concentration can be expressed in exponential form as

$$C(T) = C(386°C)K_v^{1/3} \approx C(386°C)\, e^{\frac{\Delta\bar{S}°}{3R}}\, e^{-\frac{\Delta\bar{H}°}{3RT}} \qquad [26]$$

Equation [26] can be expressed as

$$C(T) \approx 1.4 \times 10^{-2}\, e^{-\frac{2{,}400}{RT}} \text{ g at./cm}^3 \qquad [27]$$

with $C(386°C)$ from Eq. [18] (from equilibrium studies) and

$$C(T) \approx 4.4 \times 10^{-2}\, e^{-\frac{2{,}400}{RT}} \text{ g at./cm}^3 \qquad [28]$$

with $C(386°C)$ from Eq. [19] (from oxide film studies).

The most accurate relation between D and temperature would result from the best value for the temperature coefficient and an accurate value of D at a particular temperature. It follows from Eq. [16] and [28] that the activation energy for D is (31.1 − 2.4 = 28.7) kcal/mole. If we use 28.7 kcal/mole as the best value and 3.1 x 10^{-13} cm^2/sec as an accurate value for D at 386°C we obtain the equation for D for oxide films on zirconium as a function of temperature

$$D = 0.9 \times 10^{-3}\, e^{-\frac{28{,}700 \pm 600}{RT}} \text{ cm}^2/\text{sec} \qquad [29]$$

Douglass (3) measured the diffusion coefficient of oxygen in zirconia sintered pellets. He considered the anion vacancy concentration to be constant during his experiments and obtained the equation

$$D = 5.5 \times 10^{-2} e^{-\frac{33{,}400 \pm 3{,}100}{RT}} \quad [30]$$

From the formula $ZrO_{1.994}$ (for his pellets) the constant concentration that he used, must have been equivalent to 2.8×10^{-4} g at. (vacancies)/cm^3. Douglass reported that some oxygen-saturated alpha zirconium was present in the sintered pellets. Consequently the vacancy concentration may not have been constant, but could probably best be expressed by Eq. [27]. If this is so, with Eq. [27], Eq. [30] should be written

$$D \approx (C'/C) \times 5.5 \times 10^{-2} \times e^{-\frac{33{,}400 \pm 3{,}100}{RT}} \approx 1.1 \times 10^{-3} e^{-\frac{3{,}100 \pm 3{,}100}{RT}} \quad [31]$$

where $C' = 2.8 \times 10^{-4}$.

Debuigne and Lehr (2) also report the diffusion coefficient for oxygen diffusion as a function of temperature as do Kingery *et al.* (4). From a comparison of the experimental data in Table II, it is seen that a good correlation exists between results for the oxidation of zirconium. Correlation with measurements on sintered $ZrO_{1.994}$ pellets is fair if Eq. [31] is used. A good correlation is not expected with the stabilized zirconia because of the added calcium and the different lattice structure (cubic rather than monoclinic).

Theoretical check on D.—To see if one of the models, (*a*) electrons trapped at anion vacancies, (b) electrons trapped at cation sites, or (c) Fermi-electrons in the conduction band, can be supported and the others rejected, the following analysis is made.

For vacancy diffusion in the oxide there are approximately four positions that an oxygen ion could jump into in an adjacent plane if it were vacant. Therefore, from diffusion theory

$$D \approx 4 \lambda^2 N_v P_v \quad [32]$$

where λ is the jump distance from one lattice site to another, N_v is the probability that a neighboring anion site will be vacant (just the fraction of sites that are vacant) and P_v is the probability that a jump can be made if the neighboring site is vacant.

Since $P_v = \nu e^{-\Delta F^\ddagger/RT}$, where ν is the frequency of the diffusant and $\Delta F^\ddagger$ is the activation free energy for diffusion and from Eq. [22], $N_v = \frac{C(T)}{C_{O=}} = 0.023\ K_v^{1/3}$ (where $C_{O=}$ is the total concentration of anions), then

$$D \approx (4 \lambda^2 (0.023)\ \nu \left[e^{\left(\frac{\Delta \bar{S}^\circ}{3} + \Delta S^\ddagger\right)/R} \right] e^{-\left(\frac{\Delta \bar{H}^\circ}{3} + \Delta H^\ddagger\right)/RT} \quad [33]$$

and

$$D_o \approx 0.09 \lambda^2 \nu \left[e^{\left(\frac{\Delta \bar{S}^\circ}{3} + \Delta S^\ddagger\right)/R} \right] \quad [34]$$

According to Zener (12)

$$\Delta S^\ddagger \approx \beta \frac{\Delta H^\ddagger}{T_m} \quad [35]$$

where $\Delta H^\ddagger$ is the activation enthalpy for diffusion, T_m is the melting temperature of the medium of diffusion and

$$\beta = \frac{d(\mu/\mu_o)}{d(T/T_m)} \quad [36]$$

In Eq. [36], μ and μ_o are the appropriate elastic constants at temperature T and at absolute zero, respectively. For most metals and oxides β varies between 0.35 and 0.45. By plotting Young's modulus as a function of temperature for ZrO_2 from the data of Ryschkewitsch (13) and extrapolating to 0°K, a value of β proves to be 0.4. Then since $\Delta H^\ddagger \approx 30$ kcal/mole and $T_m = 2970$°K, it follows from Eq. [35] that $\Delta S^\ddagger \approx 4$ e.u. The jump distance in the ZrO_2 lattice for oxygen ions is about 3Å. The frequency of the diffusant has been calculated in Eq. [16A] (Appendix A) to be about 3×10^{12} sec^{-1}. This frequency should also be close to that calculated with the characteristic Debye temperature.

$$\nu_{max} \approx \frac{\theta_D k}{h} = 7 \times 10^{12}\ \text{sec}^{-1} \quad [37]$$

where the Debye temperature for ZrO_2 is approximately (14) $\theta_D = 345$°K. Estimated values for the thermodynamic entropy of vacancy formation $\Delta \bar{S}^\circ$ are calculated in Appendix A for the three models. With the estimated values for the parameters in Eq. [34], we calculate the following values for D_o:

Table II, experimental	$D_o \approx 0.1 \times 10^{-2}$
$\Delta \bar{S}^\circ \sim 11$ (exp.),	$D_o \sim 1 \times 10^{-2}$
$\Delta \bar{S}^\circ \sim 14$ (model, a),	$D_o \sim 2 \times 10^{-2}$
$\Delta \bar{S}^\circ \sim 16$ (model, b),	$D_o \sim 3 \times 10^{-2}$
$\Delta \bar{S}^\circ \sim 25$ (model, c),	$D_o \sim 12 \times 10^{-2}$

Only order of magnitude values can be expected from the theoretical calculation, and it is seen that models *a* and *b* yield an order of magnitude value for D_o whereas model *c* does not. These results, along with those in Appendix A, confirm the prediction of a previous paper (7), that electrons are trapped at vacancies or impurity centers. This conclusion is in agreement with others (3, 4) (from electrical measurements).

Conclusions

Accurate values of the diffusion coefficient and concentration of the diffusing defect can be obtained with the "interruption kinetic technique." The values obtained for D and C are of the same order of magnitude as reported in the literature for oxide powders and sintered pellets, but are considered to be more accurate for oxide films on zirconium. Good correlation between calculated values for C from Eq. [11] and [12], and prediction of experimental data are not sufficient to establish that D and C values are valid. Correct values can be obtained only if all of the restricting conditions are met. It is concluded from a theoretical analysis that the electrons (associated with anion vacancies) are trapped at vacancies or cation sites rather than in the conduction band of the oxide.

The results in the paper point up the importance of measuring defect concentrations during the actual oxidation study rather than rely on measurements made during independent studies on different source material. Rate constants reported in the literature for the oxidation of metals involve the product of the diffusion coefficient and diffusing defect concentration gradient. These cannot usually be separated unless one or the other has been measured independently. There is a large probability that independent measurements will involve parameters different than those during the oxidation experiment so that absolute values of D or C may not represent the values that exist during the oxidation experiment. However, it is much more likely that coefficients of temperature and pressure, etc., would correlate well.

Manuscript received Oct. 6, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

APPENDIX A

Theoretical and Experimental Entropy of Vacancy Formation

We have considered the anion vacancy concentration at the oxide-metal interface calculated from kinetic and equilibrium studies. It is of interest next to compare theoretical values with experimental values for the entropy of the reaction at the oxide-metal interface, in terms of the three models suggested in the introduction.

The positive entropy change of Eq. [25] is associated with the increase in freedom of the electrons, interstitial oxygen atoms and anion vacancies. The entropy change for reaction [20] can be expressed in terms of the individual species:

$$\Delta\bar{S}^\circ = \bar{S}^\circ(\square O^=) + 2\bar{S}^\circ(e^-) + \bar{S}^\circ(O_i) - \bar{S}^\circ(O^=) - \bar{S}^\circ(Zr_i) \qquad [1A]$$

where $\bar{S}^\circ(\square O^=)$, $\bar{S}^\circ(e^-)$, $\bar{S}^\circ(O_i)$, $\bar{S}^\circ(O^=)$, and $\bar{S}^\circ(Zr_i)$ are the partial molar entropies of the anion vacancies electrons, interstitial oxygen atoms, anions in the ZrO_2 lattice and empty interstitial positions in the zirconium lattice, respectively. The individual entropies can be expressed in terms of their configurational and vibrational entropies as follows.

Configurational Entropy

Since α zirconium is hexagonal close packed, there are two tetrahedral and one octahedral interstices for every zirconium atom. The radius of the tetrahedral interstices are $0.225\ r_{zr} = 0.36$Å since the metallic radius (8), r_{zr}, of zirconium is 1.60Å. The radius of the octahedral interstices is approximately $0.414\ r_{zr} = 0.66$Å. Since the metallic radius r of an oxygen atom is 0.66Å, it is assumed that oxygen atoms enter only octahedral interstices. Therefore, for (29 ± 1) a/o oxygen in α zirconium, $n = 0.02$ moles/cm^3, $N = 0.071$ moles/cm^3, $n/N = 0.28$ and the configurational entropy is

$$\bar{S}^\circ_{oi}(\text{conf}) = -R \ln\left(\frac{n/N}{1 - n/N}\right) \approx 1.8 \pm 0.1 \text{ e.u.} \qquad [2A]$$

A similar argument is valid for the distribution of anion vacancies among the anion lattice positions in ZrO_2. From Domagala and McPherson's (5) equilibrium data

$$C = (2.2 \pm 2) \times 10^{-3} \text{ moles } \square/\text{cm}^3 \text{ and}$$
$$(C_{O^=}) = 0.095 \text{ moles } O^=/\text{cm}^3$$

so in this case $n/N = C/(C_{O^=}) = (2.3 \pm 2) \times 10^{-2}$ and

$$\left(\bar{S}^\circ_{\square O^=}\right)(\text{conf}) = -2 \ln\left(\frac{2.3 \times 10^{-2}}{1 - 2.3 \times 10^{-2}}\right) = 7.5 \pm 2.8 \text{ e.u.} \qquad [3A]$$

Now the electrons that leave oxygen ions are probably promoted to positions in the vicinity of zirconium ions (Zr^{+3}) in the ZrO_2. Some of the electrons can be excited into the conduction band and move freely throughout the oxide. However, if the large majority of electrons are associated with cations, the entropy of the electrons will be primarily configurational. The concentration of electrons is just twice the vacancy concentration and the cation concentration is $C_{Zr+4} = 0.0475$. Therefore, for electrons, $n/N = 0.004/0.0475 = 0.084 \pm 0.08$ and

$$\bar{S}^\circ_{e^-} = -2 \ln\left(\frac{0.084}{1 - 0.084}\right) = 4.76 \pm 4 \text{ e.u.} \qquad [4A]$$

If, however, the electrons are trapped at the vacancies, each anion vacancy has four nearest neighbor zirconium cations which can act as sites for the extra electrons. There are two electrons associated with each vacancy for electrical neutrality, so that $n/N \approx 0.5$.

Therefore,

$$\bar{S}^\circ_{e^-} \approx -2 \ln\left(\frac{0.5}{1 - 0.5}\right) = 0 \qquad [5A]$$

If the majority of the electrons were promoted into the conduction band of the oxide and acted as a Fermi-Dirac gas, an approximate equation for the entropy (9) is

$$\bar{S}^\circ_{e^-} \cong \frac{2\pi mkT}{h^2} \cdot 2\pi Nk\left(\frac{\pi V}{3N}\right)^{2/3} \qquad [6A]$$

Since

$$\frac{2\pi mkT}{h^2} \approx 10^{13}$$

and

$$\left(\frac{\pi V}{3N}\right)^{2/3} \approx 10^{-13}$$

$$\bar{S}^\circ_{e^-} \approx 2\pi R \approx 12 \text{ e.u.} \qquad [7A]$$

Vibrational Entropy

The interstitial oxygen atoms have three vibrational modes, each (assumed equal) of frequency ν_{oi}. The vibrational frequencies of the eight nearest neighbors to the interstitial oxygen atoms will be increased (from ν_{Zri} to $\nu_{Zr,oi}$) due to the presence of the oxygen atom. Therefore,

$$\bar{S}^\circ(oi) - \bar{S}^\circ(Zr_i) = 3R\left(\ln\frac{kT}{h\nu_{oi}} + 1\right) + 8R \ln\frac{\nu_{Zri}}{\nu_{Zr,oi}} \qquad [8A]$$

Removal of an oxygen anion from the oxide lattice allows the four nearest neighbor zirconium ions to relax away from the vacancy center while the next nearest neighbor anions relax toward the vacancy center.

Table IA. Comparison of theoretical values for the entropy of vacancy formation with the experimental value

Model	$\Delta S°$ e.u. Eq. [18] $C = 2.2 \pm 2$	Maximum estimated error	Eq. [19] $C = 7 \pm 0.7$	Maximum estimated error
Experimental	11	± 0.3	11	±0.3
(a) Electrons trapped at anion vacancies	15	± 8	14	±5
(b) Electrons trapped at cation sites	25	±16	16	±6
(c) Fermi-electrons in conduction band	39	$\begin{pmatrix}+96\\-23\end{pmatrix}$	25	±6

As a result

$$\bar{S}°(\square O^{=}\text{ vib}) - \bar{S}°(O^{=}\text{ vib}) = 4R \ln \frac{\nu_{Zr,O^{=}}}{\nu_{Zr,\square}} + 6R \ln \frac{\nu_{O^{=}}}{\nu_{O^{=},\square}} - 3R\left\{\ln \frac{kT}{h\nu_{O^{=}}} + 1\right\} \quad [9A]$$

where $\nu_{Zr,O^{=}}$ and $\nu_{Zr,\square}$ are the frequencies of the four nearest neighbor zirconium ions before and after the anion is removed, and $\nu_{O^{=}}$ and $\nu_{O^{=},\square}$ are the frequencies of the six next nearest neighbor anions before and after the vacancy is formed. The total vibrational entropy change for reaction [20] can be expressed

$$\Delta\bar{S}°(\text{vib}) = R \ln \left[\frac{\nu_{Zri}}{\nu_{Zr,oi}}\right]^{8} \left[\frac{\nu_{Zr,O^{=}}}{\nu_{Zr,\square}}\right]^{4} \left[\frac{\nu_{O^{=}}}{\nu_{O^{=},\square}}\right]^{6} \left[\frac{\nu_{O^{=}}}{\nu_{oi}}\right]^{3} \quad [10A]$$

Values for ν_{Zri}, $\nu_{Zr,O^{=}}$, and $\nu_{O^{=}}$ can be estimated for the normal lattice without vacancies or interstitials with the Einstein relation

$$\nu_{max} = \frac{k\theta_D}{h} \quad [11A]$$

where θ_D is the Debye temperature.

It is more difficult to estimate values for $\nu_{Zr,oi}$, $\nu_{Zr,\square}$, $\nu_{O^{=},\square}$, and ν_{oi} after defect formation.

To avoid some of the more difficult calculations, we will assume that, as shown by Huntington *et al.* (10) for interstitial copper in copper, that

$$\bar{S}°(oi) - \bar{S}°(Zr_i) \approx R \quad [12A]$$

and concentrate on Eq. [9A].

To obtain values for $\nu_{Zr,O^{=}}$ and $\nu_{O^{=}}$ for the normal ZrO_2 lattice, we will assume that at 386°C the equipartition of energy exists and that we can consider the ZrO_2 lattice as an ensemble of equivalent harmonic oscillators.

From thermodynamic literature (11) the experimental entropy of ZrO_2 at 386°C is 24 e.u. Since there are 3 g at./mole of ZrO_2 and each atom has three vibrational modes (one for each of the X, Y, and Z directions), there are $9N$ harmonic oscillators per mole of ZrO_2. It follows that

$$\bar{S}°(ZrO_2) = 9R\left(\ln \frac{kT}{h\nu} + 1\right) \approx 24 \quad [13A]$$

and that

$$(\nu_{Zr,O^{=}}) \approx (\nu_{O^{=}}) \approx 10^{13}\ \text{sec}^{-1} \quad [14A]$$

We can estimate a value for $(\nu_{O^{=},\square})$ with Zener's (12) equation

$$\nu \approx \left(\frac{\Delta H‡}{2m\lambda^2}\right)^{1/2} \quad [15A]$$

where $\Delta H‡$ is the activation energy (expressed in ergs) for diffusion, m is the mass of the diffusant, and λ is the jump distance.

The frequency calculated in Eq. [15A] is that of the vibrating particle just before passing over the barrier and this should correspond with $\nu_{O^{=},\square}$ for vacancy diffusion of oxygen in ZrO_2. Therefore, since the activation energy for oxygen diffusion in ZrO_2 is about 30 kcal/mole (see Table II) and since the jump distance is approximately 3Å

$$\nu_{O^{=},\square} \approx \left(\frac{33 \times 10^{10}}{2 \times 16}\right)^{1/2} \frac{1}{3 \times 10^{-8}} \cong 3 \times 10^{12} \quad [16A]$$

We expect a slight increase in $\nu_{Zr,O^{=}}$ as it goes to $\nu_{Zr,\square}$ [*i.e.*, $(\nu_{Zr,\square}) > (\nu_{Zr,O^{=}})$], but we will assume for the sake of simplicity that $(\nu_{Zr,\square}) \approx (\nu_{Zr,O^{=}}) \approx 10^{13}$ (see Eq. [14A]). It follows from Eq. [9A] that

$$\bar{S}°(\square, O^{=}, \text{vib}) - \bar{S}°(O^{=}_{\text{lattice}}\text{ vib}) \approx 5.2\ \text{e.u.} \quad [17A]$$

Finally, Eq. [1A] can be expressed as

$$\Delta\bar{S}° = [\bar{S}°(\square, O^{=}, \text{vib}) - \bar{S}°(O^{=}\text{ vib})] + [\bar{S}°(oi, \text{vib}) - \bar{S}°(Zr_i\text{ vib})] + \bar{S}°(\square, O^{=}, \text{conf}) + 2\bar{S}°(e^{-}\text{ conf}) + \bar{S}°(oi\text{ conf}) \quad [18A]$$

The values we have calculated for these terms are summarized as follows:

$$[\bar{S}°(\square, O^{=}, \text{vib}) - \bar{S}°(O^{=}\text{ vib})] \approx 5.2 \quad [19A]$$

$$[\bar{S}°(oi, \text{vib}) - \bar{S}°(Zr_i\text{ vib})] \approx 2 \quad [20A]$$

$$\bar{S}°(\square, O^{=}\text{ conf}) \approx 7.5 \quad [21A]$$

$$2\bar{S}°(e^{-}, \text{conf}) \approx \begin{cases}0 \text{ trapped at vacancies}\\9.6 \text{ trapped at cations}\\24 \text{ Fermi electrons}\end{cases} \quad [22A]$$

$$\bar{S}°(oi, \text{conf}) \approx 0.7 \quad [23A]$$

Table IA gives values for $\Delta\bar{S}°$ for the three models along with an estimated maximum error for each calculation. It is seen that the best correlation is obtained by assuming model (a). However, due to the large error inherent in such calculations model (b) cannot be rejected. In spite of the large error, model (c) can be rejected because values used to estimate $\Delta\bar{S}°$ would have to be off by a factor of 10^3 in order to correlate with the experimental value.

Cathode Overpotential and Surface-Active Additives in the Electrodeposition of Copper

I. Effects of Some Carboxyl and Amino Compounds

H. Schneider, A. J. Sukava, and W. J. Newby

Department of Chemistry, The University of Western Ontario, London, Ontario, Canada

ABSTRACT

Additives containing carboxyl and amino groups increase the overpotential of a copper cathode during electrolysis in an acid sulfate electrolyte, the amino group being more effective than the carboxyl. At a given additive concentration the overpotential increment apparently depends on the adsorptivity and size of the additive molecule. The adsorptivity in turn depends on the number and kind of polar functional groups, the structural relation between electron-donating atoms, and the lattice dimensions of the copper deposit. It is suggested that the behavior of a chemisorbed additive can be understood in terms of two effects, (i) the complete blockage of growth sites by chemisorption bonds and (ii) the partial blockage of adjacent sites by the physical bulk of the adsorbed molecule.

It is generally believed that the effect of addition agents on cathode overpotential (or polarization) during electrodeposition of metals arises primarily because of adsorption of the additive on the cathode surface (1-9). Possible coordination with the metal ions in solution might also have an effect (6-8, 10-14). In addition, the ability of the additive to impede metal-ion transport in the cathode film could play a more minor role (15).

This paper deals with the effects on cathode overpotential during electrodeposition of copper of a number of additives containing carboxyl and amino groups, the object being a better understanding of the correlation between cathode overpotential increments and the constitution and structure of surface-active additive molecules. The data are interpreted in accordance with the expected adsorption behavior of the compounds used.

Experimental

To facilitate comparison with published data, our experimental methods and conditions were much the same as those used in other studies (8, 16, 17). The Haring cell method was selected as the means of overpotential measurement because of simplicity and convenience. Precise control of cathode surface variables was not necessary for our purposes.

All experiments were made with 150 ml of electrolyte containing 125 g/l $CuSO_4 \cdot 5H_2O$ and 100 g/l H_2SO_4, both reagent grade. The apparent current density was 2 amp/dm^2 and the temperature was 25° (±0.5) °C. Some of the additives were Eastman's "white label" grade and others were "standardized" amino acids from the Nutritional Biochemicals Corporation. The water was distilled from alkaline permanganate in all-glass apparatus.

For each experiment the cathode was first brought to a reproducible standard state (18) by electrodeposition from standard electrolyte (which contained no additive) at 3 amp/dm^2 for about 30 min and then at 2 amp/dm^2 until a steady-state overpotential of 100 (±5) mv was attained (8, 18). The latter step usually required 1 or 2 hr.

After the standard surface was formed, the standard electrolyte was discarded and solution containing the addition agent was poured into the cell. Just as in other studies (8), a contact time of 5 min was normally allowed before closing the electrolysis circuit. This was in order that initial overpotential values in the presence of additives might be at least roughly compared and related to comparable conditions at the beginning of electrolysis.

The rapid initial changes in total overpotential during the first few seconds of electrolysis were followed in many experiments with a du Mont type 324 cathode-ray oscilloscope (C.R.O.). Thereafter more accurate measurements of the slowly changing and steady-state overpotentials were made at intervals of 5 and 15 min with a L & N K-2 potentiometer. A Nesco JY-120 recorder was used in some experiments to follow the overpotentials up to about 8 hr. For all measurements during the build-up of overpotential, the C.R.O. sweep frequency and sweep length were adjusted to give one 2-in. sweep per second.

The mechanically polished copper cathodes could be used repeatedly if they were first coated with a thin film of paraffin before the standard surface was deposited (19). The entire deposit could then be removed by peeling with a knife. The polished copper strip was attached with paraffin to the Lucite mounting block of the Haring cell and then dipped into 50% nitric acid to etch and clean the exposed surface. After rinsing and drying, the assembly was dipped into a 0.5% solution of paraffin in ether. Evaporation of the ether left the desired film on the cathode face. The standard surface was deposited over the film, followed in turn by the experimental deposit in the presence of additive. Brittle deposits were easily removed after first heating the cathode and deposit to redness and then quenching in cold water.

The paraffin film obviously prevented strong bonding between the deposit and substrate surface, but without measurable effect on overpotential values. The reason might be that submicroscopic surface protrusions provide regions of high charge density sufficient to initiate deposit nucleation without providing sufficient contact area for bond formation.

Results

A number of simple carboxyl and amino compounds were studied to determine their relative effectiveness in increasing the cathode overpotential. The purpose was to examine the effect of: (*a*) the number and kind of functional groups present in the additive molecule; (*b*) variation in the size of the hydrocarbon portion of the molecules when the functional groups are in the same structural relationship; and (c) variation in the structural relationship between the same functional groups. The compounds studied were: ethylamine, propionic acid, malonic acid, glycine, α-alanine, β-alanine, γ-aminobutyric acid, leucine, β-phenylalanine, and aspartic acid. The data for some of these cover a wide range of concentration in reasonable detail. Others are less complete. The number

of experiments varied from four with propionic acid to about forty with α-alanine.

All overpotentials in this paper are the total values. In particular, no attempt is made to consider concentration overpotential separately. Some experiments suggest that the concentration component is not significantly affected by our additives and that it is probably no greater than 10 mv under our experimental conditions. The effects of different additives can therefore be reasonably compared by reference to total overpotentials only.

Typical overpotential-time relations in Fig. 1 show that a steady state is attained in all cases after about 2 hr. The dependence of steady-state overpotentials on additive concentration is shown in Fig. 2, where the curves represent the best averages of overpotentials reproducible to within ±5 and ±10 mv at the low and high concentrations respectively. The maximum at 10 or 20 min (Fig. 1) follows an earlier maximum and minimum at about 0.01 and 0.5 sec, some values of which are shown along with the steady-state overpotentials in Table I.

The data are in general agreement with other results (4, 17). The greater the number of functional groups in the additive molecule, the greater the overpotential

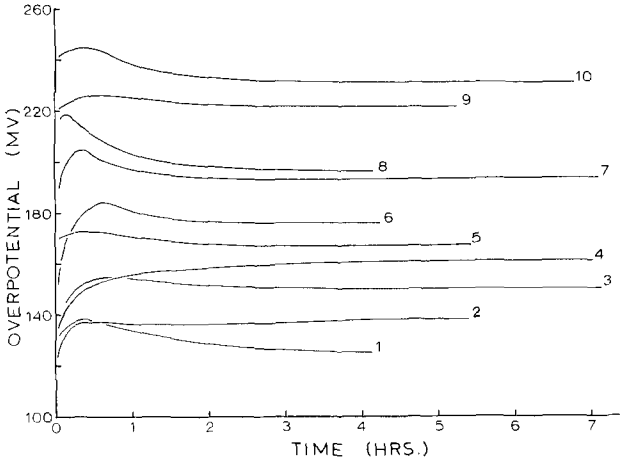

Fig. 1. Variation of total overpotential with time: curve 1, 5.0 x 10^{-3}M γ-amino butyric acid; curve 2, 4.0 x 10^{-2}M propionic acid; curve 3, 2.0 x 10^{-4}M β-alanine; curve 4, 7.5 x 10^{-5}M aspartic acid; curve 5, 1.5 x 10^{-3}M leucine; curve 6, 5.0 x 10^{-2}M ethylamine; curve 7, 5.0 x 10^{-3}M α-alanine; curve 8, 5.0 x 10^{-2}M malonic acid; curve 9, 2.8 x 10^{-3}M β-phenylalanine; curve 10, 2.0 x 10^{-2}M glycine.

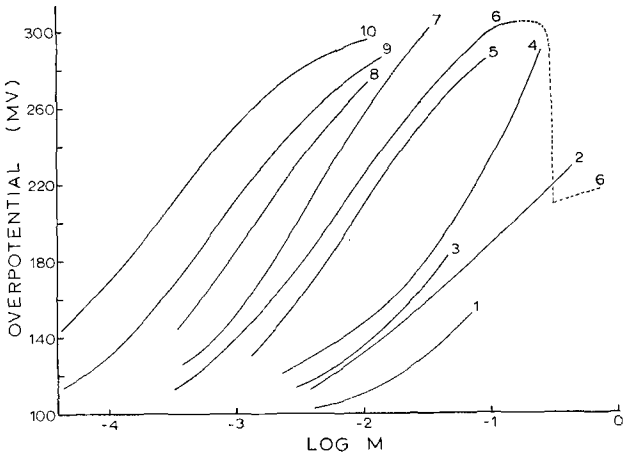

Fig. 2. Total steady-state overpotential as a function of additive concentration: curve 1, propionic acid; curve 2, ethylamine; curve 3, γ-amino butyric acid; curve 4, malonic acid; curve 5, glycine; curve 6, α-alanine; curve 7, leucine; curve 8, β-phenylalanine; curve 9, β-alanine; curve 10, aspartic acid.

Table I. Typical steady-state and initial maximum and minimum total overpotentials

Additive	Concentration, m/l	η_{max}, mv	η_{min}, mv	$\eta_{steady\ state}$, mv
β-alanine	9.0 x 10^{-4}	116	115	205
	9.6 x 10^{-3}	120	115	278
Aspartic acid	1.5 x 10^{-3}	142	135	262
	7.5 x 10^{-3}	175	171	291
Leucine	5.0 x 10^{-3}	150	147	225
	8.0 x 10^{-3}	165	158	245
β-phenylalanine	2.8 x 10^{-3}	118	113	228
Malonic acid	3.3 x 10^{-1}	(no detectable max.-min. behavior)		312
	6.6 x 10^{-1}	145	140	335
Ethylamine	1.0 x 10^{-1}	130	127	190

increment. The greater effectiveness of the amino group over the carboxyl is shown by the data for ethylamine and propionic acid, and the importance of the structural relation between functional groups is seen on comparing α-alanine, β-alanine, and γ-aminobutyric acid. In addition, when other factors are equal, the overpotential is increased by an increase in size of the hydrocarbon part of the molecule.

Apart from some experiments with α-alanine, no detailed study of the high-concentration region was attempted. The data for α-alanine at concentrations above about 3 x 10^{-1}M showed poor reproducibility, but on the average the overpotential decreased by about 90 mv when this concentration was exceeded. This is shown by the broken portion of the overpotential-log M curve in Fig. 2, where M is the molarity. The deposit surfaces showed no particular roughening that might have caused a supposed decrease in true current density to account for the overpotential drop.

Discussion

Because of the greater effectiveness of the amino group as compared with the carboxyl in increasing the overpotential (Fig. 2), it may be suggested and assumed that, since this group is undoubtedly protonated in the acid solution, deprotonation probably occurs in the adsorption with the formation of competitive chemisorption bonds by the nitrogen atom. The generally greater effectiveness of compounds containing two functional groups in probably due to greater adsorptivity resulting from two-point chemisorption bonding, in a manner suggested before for dicarboxylic acids (20). Similarly, a trifunctional molecule might be expected to adsorb by three-point bonding if the electron-donating atoms can take appropriate positions relative to copper atoms on the cathode surface. The effect of functional group multiplicity therefore depends on structural relations since changes in structure may either increase or decrease adsorptivity. The overpotential attributable to the hydrocarbon part of the molecule appears to depend only on effective size.

Effect of structure.—The data for α- and β-alanines in Fig. 2 are an example of the effect of the structural relation between the same functional groups. Both compounds appear to be stable during electrolysis, as shown by the steady states in Fig. 1, and the difference in effectiveness may therefore be attributed to different adsorptivities of the normal molecules. This difference can be understood if it is assumed that two-point nitrogen-oxygen attachment is involved at different but adjacent copper atoms.

Estimates of the range of nitrogen-oxygen internuclear distances, made with Dreiding stereomodels, show that this distance varies with bond rotation from about 2.7 to 3.6Å with α-alanine, and from about 2.1 to 4.9Å with β-alanine. Comparison of these numbers with the three shortest internuclear distances in the copper lattice, 2.55, 3.6, and 5.1Å, suggests that β-alanine is better able to form strain-free nitrogen-oxygen attachments with a copper surface since it can more easily straddle at least the two shortest copper-copper distances. Therefore, without considering bond angles or orientation (which would also be necessary

for a detailed picture of the adsorbed state), the greater effectiveness of β-alanine can be expected.

The relatively small overpotential effect of γ-aminobutyric acid requires further study. However, the fact that this compound readily undergoes ring closure to form the γ-lactam on thermal decomposition suggests the possibility that sufficient cyclization might occur in acid solution too, possibly by hydrogen bonding between the amino and carboxyl groups, to restrict its adsorption on copper mainly to one-point attachments. The weaker chemisorption could then account for the small overpotential increments.

The greater effectiveness of aspartic acid compared with β-alanine can be expected because this compound is a structural combination of α- and β-alanines with a common amino group. The variation with bond rotation of the relative positions of the amino and carboxyl groups in relation to copper atoms in the lattice suggests that aspartic acid can probably adsorb by three-point attachment, although only to a limited extent because any two-point bonding by one end might be expected to restrict the bonding capabilities of the other.

Effect of molecule size.—The data for the four α-amino acids, glycine, α-alanine, leucine, and β-phenylalanine (Fig. 2) show the increase in overpotential with increased size of the hydrocarbon part of the molecule. Because the tendency to chemisorption is undoubtedly the dominant force in adsorptivity, it can be assumed as a first approximation that the adsorptivities of all four compounds are about the same since each has the same structural arrangement of the same electron-donating groups. The overpotential attributable directly to the chemisorption bonds would be approximately the same with each compound at the same concentration, and the different overpotentials with the different compounds would be due to different size alone. This implies two distinct overpotential effects or causes, the complete blockage of some growth sites by chemisorption bonds and the partial blockage of other adjacent sites by the actual bulk of the adsorbed molecule. The bond effect would be expected to cause a simple increase in true current density, and therefore an increase in activation overpotential according to the Tafel relation, depending on the fraction of growth sites blocked by the bonds at any given time in the dynamic adsorption process. (The steady-state overpotentials in Fig. 1 mean that a dynamic equilibrium is necessarily established with respect to any additive adsorption.) The bulk or screen effect can be regarded as a superimposed hindrance against copper ion movement to adjacent growth sites, and probably as a further effect on true current density, but depending on effective molecule size.

Behavior of α-alanine at high concentration.—The drop in overpotential with α-alanine at concentrations above about 3×10^{-1}M (Fig. 2) means a reduction in the energy required for electrodeposition at the experimental rate. It seems therefore that the chemisorption of this additive undergoes a change to a weaker form under these conditions, possibly by thermal disorientation of the initial monolayer in a manner suggested by Conway and co-workers in another context (21). It might be assumed that the initial monolayer is virtually complete at about 3×10^{-1}M and that a predominant two-point chemisorption is involved with the nitrogen and oxygen atoms adjacent to the copper surface. With the disorientation arising from increased concentration, the attachment would change to one-point, possibly accommodating a greater number of molecules in the adsorbed phase. The total screen effort would be expected to increase, but the dominant bond effect could conceivably be less, with decreased overpotential the net result.

The poor reproducibility of the data above about 3×10^{-1}M was evident in that a few experiments gave overpotential values that appeared to be a continuation of the main curve (Fig. 2), while most showed the drop. This could mean that the disorientation of the monolayer is probably sensitive to minor variations in surface structure.

Manuscript received Sept. 19, 1963; revised manuscript received Feb. 1, 1965. This paper is a contribution from the Department of Chemistry, University of Western Ontario, London, Ontario, with financial assistance from the National Research Council, Ottawa.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

Cathode Overpotential and Surface-Active Additives in the Electrodeposition of Copper

II. Effects of Compounds Containing Divalent Sulfur

A. J. Sukava, H. Schneider, D. J. McKenney, and A. T. McGregor

ABSTRACT

The sulfur-containing compounds, cystine, cysteine, methionine, and dimethyldisulfide, cause greater increments in the overpotential of a copper cathode in acid sulfate electrolyte than do related compounds containing carboxyl and amino groups only. Their effectiveness is presumably due to strong chemisorption involving the sulfur atom directly. These compounds appear to undergo slow chemical change during electrolysis. At low concentrations the large cystine molecule is more effective than the smaller dimethyldisulfide, but at high concentrations this order is reversed. The large molecules in high concentration are probably subject to mutual hindrance in the adsorbed phase, while smaller molecules with the same sulfur-group content and at the same concentration are able to block growth sites more effectively by forming a higher percentage of chemisorption bonds. Steady-state overpotential increments after sufficiently prolonged electrolysis indicate that surface-active additives are not necessarily removed from the solution by electrolysis and codeposition. The mobile, dynamically adsorbed additive might give rise to excess weight because of physical enclosure of solution in interstitial spaces within the deposit. The volume percentage of such spaces probably increases the more the additive causes continual nucleation and greater polycrystallinity.

In general, sulfur-containing amino acids like cystine and methionine cause greater increments in the overpotential of a copper cathode in acid copper sulfate electrolyte than do the related nonsulfur compounds, glycine and aspartic acid (1, 2). The divalent sulfur atom evidently imparts to these molecules a special potency in their additive function. This paper presents the results of a more detailed study of the overpotential effects of some sulfur compounds, with emphasis on their possible chemisorption behavior on the copper surface.

Experimental

The experimental procedure was in all respects the same as that in part I of this series (3).

Results

The variation of overpotential with time and the effect of additive concentration on the steady-state overpotential were studied in some detail with cystine, cysteine, methionine, and dimethyldisulfide. Data with ethyl mercaptan and β-mercaptopropionic acid were limited by low solubility in the standard electrolyte. Most of the data for cystine are taken from a previous study (2, 4) and some are published here for the first time.[1] The monofunctional dimethyldisulfide was chosen partly to isolate and emphasize the additive function of the disulfide group in cystine. As before (3), comparisons are made on the basis of effects on total overpotential only.

All of these sulfur compounds increased the overpotential at all concentrations. Their effectiveness is generally much greater than that of compounds containing only carboxyl and amino groups, and to some extent they appear also to differ from the latter in their mode of action. Typical overpotential-time data in Fig. 1 and steady-state overpotential-concentration relations in Fig. 2 may be compared with the effects of nonsulfur compounds (3).

Roughly quantitative observations with the cathode-ray oscilloscope showed the same initial overpotential-time pattern with each sulfur additive. An early maximum and minimum occurred at about 0.01 and 0.5 sec (Table I), followed by a second maximum and then a slow decrease to an ultimate steady state (Fig. 1). The initial maximum-minimum difference was much more pronounced than that found with additives containing no sulfur (3). The second maximum and steady state were both attained earlier the higher the concentration.

It seemed likely that the decrease in overpotential after the second maximum, as shown best by dimethyldisulfide at low concentrations, reflects either a gradual roughening of the surface with a consequent decrease in true current density or some slow chemical change in the additive during electrolysis. To decide this point, several experiments were made in which the additive-containing electrolyte that remained at steady state after a few hours of electrolysis was re-used in another cell with a new standard cathode surface. The results showed that cystine, cysteine, and dimethyldisulfide undoubtedly undergo some change during the first electrolysis up to the time that the steady state

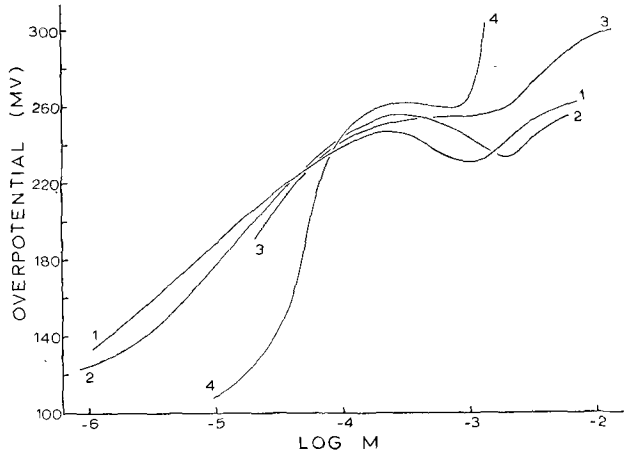

Fig. 2. Total steady-state overpotential as a function of additive concentration: curve 1, cystine; curve 2, cysteine; curve 3, methionine; curve 4, dimethyldisulfide.

is attained. This is obvious from curve 4A in Fig. 1 for a typical repeated electrolysis with dimethyldisulfide. The high second maximum was not obtained and the steady state was attained earlier at the original value. (No experiments of this kind were made with methionine.)

The steady-state overpotential-concentration curves in Fig. 2 show that the order of effectiveness of the sulfur additives is reversed at about 1 x 10^{-4}M. The smaller the molecule, the less the overpotential increment at low concentrations and the greater the increment at high concentrations. A maximum and subsequent minimum occur at roughly the same concentrations with cystine and cysteine (Fig. 2). The curve for dimethyldisulfide shows the same behavior although less well-defined, while the curve for methionine shows only general similarity.

Discussion

The variation of overpotential with time was of interest for two reasons. It has been suggested that protonation of the additive in the acid solution causes the initial maximum and minimum overpotentials because of cataphoretic surge of positively charged additive particles toward the cathode surface when the circuit is first closed (2, 5). Also, adsorption of additive on the cathode has been thought to give rise to occlusion of the additive in the growing deposit, with its supposed depletion in the solution causing a steady decrease in overpotential with time (2).

Initial maxima and minima.—The suggestion that the initial behavior shown in Table I is attributable at least in part to protonation of the additive might be readily accepted when the additive is a reasonably strong base like an amino compound. On the other hand, compounds like β-mercaptopropionic acid or dimethyldisulfide cannot be sufficiently protonated despite their Lewis-base structure and despite the high acidity of the solution at the cathode surface. When the initial overpotentials in Table I are compared with those found for nonsulfur compounds (3), and when the effect of the divalent sulfur is noted, it seems certain that the over-all behavior is governed largely by adsorption of additive on the cathode prior to electrolysis. (The free energy of this adsorption and the rate of diffusion of the additive might also be important, as might the possible dipole properties and polarizability of the additive molecules in the cathode field.) Some preliminary experiments have shown that the maximum-minimum difference with sulfur additives is increased by an increase in the period of contact between cathode and solution prior to electrolysis, but with nonsulfur carboxyl and amino compounds this variable seems to have no effect. Possibly, and in agreement with similar suggestions by others (6), such nonsulfur compounds are not appreciably adsorbed before current flow begins.

Table I. Typical steady-state and initial maximum and minimum total overpotentials

Additive	Concentration, m/l	η_{max}, mv	η_{min}, mv	$\eta_{steady\ state}$, mv
Cystine	2.08 × 10^{-5}	124	109	205
	4.16 × 10^{-5}	142	113	220
	4.16 × 10^{-4}	202	140	242
	6.24 × 10^{-4}	219	145	235
Cysteine	8.25 × 10^{-6}	115	102	176
	8.25 × 10^{-5}	141	108	237
	8.25 × 10^{-4}	182	130	243
	2.48 × 10^{-3}	204	129	235
Methionine	1.35 × 10^{-5}	110	97	190
	3.37 × 10^{-5}	132	90	212
	1.35 × 10^{-4}	222	115	245
	3.37 × 10^{-4}	248	150	255
β-mercaptopropionic acid	1 × 10^{-6}	120	109	195
Ethyl mercaptan	1 × 10^{-5} approx. (saturated)	270	165	260
	(saturated, concentration not determined)	150	116	210

	1.10 × 10^{-5}	170	120	115
	2.33 × 10^{-5}	165	115	125
	3.30 × 10^{-5}	195	107	146
	1.16 × 10^{-4}	240	130	

Steady-state overpotential and excess deposit weight.—The significance of Fig. 1 is that all our additives gave rise to an apparently true steady-state overpotential, after sufficiently prolonged electrolysis, down to the lowest effective concentrations. This is well illustrated by the curve for cysteine at 4.1 x 10^{-7}M. It is therefore certain that no appreciable reduction in the concentration of these additives occurs by any kind of bonded occlusion in the growing deposit, which means that the adsorption of additive must be sufficiently dynamic and the adsorbate phase sufficiently mobile to enable the copper lattice to grow without covering the additive molecules, except perhaps by mere entrapment of solution in interstitial spaces in the deposit.

Since electrolysis does not cause a decrease in additive concentration by codeposition, the excess deposit due to surface-active additives (7-11) might be attributed to physically entrapped solution in interstitial spaces rather than to adsorbed additive. (The excess deposit is the weight of deposit obtained in the presence of an additive in excess of that obtained in the absence of additive with the same amount of charge flow.) It may be noted that a correlation has been found between the polycrystallinity of the deposit and the excess weight (7, 8, 11); the finer the deposit, the greater the excess weight. This would mean that a greater volume percentage of interstitial spaces occurs as the deposit becomes more polycrystalline with the more extensive nucleation caused by adsorbed additive.

Chemical change.—The results of repeated electrolyses as typified by curve 4A in Fig. 1 are evidence of some chemical change during electrolysis such that the effectiveness of the additive in increasing the overpotential is reduced. This is substantiated in part by literature statements that cystine and thiourea form copper II sulfide at the cathode (12) and by similar claims for sulfur additives in the electrodeposition of nickel (13, 14). The formation of a dark anode "mud" whenever such additives are present during copper electrolysis suggests that anode effects might be an additional factor.

The marked decrease in overpotential after the second maximum leads to the conclusion that the chemical change involves a high percentage of additive when it is present in low concentration. The long-term overpotentials would then be true steady-state values caused by relatively stable reaction products or equilibrium mixtures. The equally reasonable conclusion follows that the same change must take place at high concentrations too, but that the fraction of additive undergoing change in a given period of time is less the higher the concentration. The so-called steady

states obtained with high concentrations of sulfur additives are therefore steady only because the percentage rate is small, and the overpotentials under these conditions are caused primarily by the unchanged form of the additive.

Steady-state effects.—The data in Fig. 2 show that at high concentrations the ability of sulfur additives to increase the overpotential increases with a decrease in molecule size. This can be understood if it is assumed that strong sulfur-copper chemisorption bonds are formed with a sufficiently greater contribution to overpotential than that due to the rest of the molecule. The marked difference in the ability of sulfur and nonsulfur additives to increase the overpotential can then also be explained.

It seems reasonable from the overpotential values that concentrations of sulfur additives in excess of about 1×10^{-4}M (Fig. 2) are approximately sufficient to complete the initial monolayer on the cathode surface. A given area of the surface could accommodate in this layer a greater number of the small dimethyldisulfide molecules than would be possible with cystine, since the larger nonsulfur portion of an adsorbed cystine molecule could prevent the bonding of another cystine molecule at an adjacent copper atom. The effect would be the blockage of a higher percentage of growth sites by chemisorption bonds with dimethyldisulfide than with cystine, and therefore a greater overpotential increment.

Since reaction products and unchanged sulfur additives are presumably responsible for the increments in steady-state overpotential at low and high concentrations, respectively, it would be expected that a change in the order of effectiveness might occur with change in concentration, as is shown in Fig. 2, although the complete reversal would not necessarily follow. Because of the chemical change, the data do not reliably show the relative effects of dimethyldisulfide and cystine at the lowest concentrations, with only a small fraction of the surface covered, although the larger cystine molecule can be expected to have the greater effect under such conditions, and the crossing of the overpotential-concentration curves should be found even if no chemical change occurred.

The decrease in overpotential with increase in additive concentration above about 2.5×10^{-4}M (Fig. 2) might reflect a decreased bonding effect as a result of thermal disorientation similar to that suggested previously for α-alanine (3). Since sulfur additives are evidently much more strongly adsorbed than α-alanine, it is not surprising that the maximum overpotential occurs at a much smaller concentration. The data in the region of all these maxima showed poor reproducibility, which supports the view that the cause of the maximum might be the same with both kinds of additive.

It is worth noting that the two adjacent sulfur atoms in dimethyldisulfide and cystine do not impart to these compounds a markedly greater ability to increase the overpotential than that due to the single sulfur in cysteine and methionine. The probability of sulfur-copper bonding might be greater with a disulfide, but the actual chemisorption presumably cannot involve both sulfurs simultaneously. This might be expected from the pertinent internuclear distances, 2.04Å for the sulfur-sulfur distance in the disulfide and the minimum 2.55Å between copper atoms in the lattice. With this in mind, it seems unlikely that thermal disorientation of the initial monolayer could satisfactorily account for the overpotenital drop with dimethyldisulfide at 2.5×10^{-4}M (Fig. 2), or even for the plateau if the curve is so interpreted, the reason being that dimethyldisulfide can presumably adsorb in only one regularly oriented manner by one-point attachment at one of the sulfur atoms.

A previous suggestion that cystine is probably reduced to cysteine at the cathode (2) is obviously not supported by our more detailed study. The fallacy in this view, which was based on the close similarity of the overpotential effects at low concentrations, has been noted before (15).

Structure of Electrodeposited Lead Dendrites

F. Ogburn, C. Bechtoldt, J. B. Morris,[1] and A. de Koranyi

National Bureau of Standards, Washington, D.C.

ABSTRACT

Electrodeposited lead dendrites were grown and examined by x-ray diffraction and metallographically. Their structure was essentially that of two crystals having a twist relation about a common [111] pole which was normal to the flat surface of the two-dimensional dendrites. Each dendrite contained many small voids or channels. The direction of growth was either about halfway between a <211> direction of one crystal and a neighboring <211> direction of the second crystal or halfway between <110> directions.

Electrodeposited dendrites[2] have been described and reviewed extensively by Wranglen (1). He examined dendrites of lead, tin, silver, cadmium, and copper microscopically and by x-ray diffraction and described them as single crystals. Faust and Johns (2) examined electrodeposited dendrites of lead, silver, copper, gold, and aluminum, and by metallography found at least one grain boundary in each of the dendrites growing in <211> or <110> directions, but not in dendrites growing in a <100> direction.

The lead dendrites, as shown by Wranglen, are of two main types: those that are flat and growing in a <110> direction and those that are three dimensional and growing in a <100> direction. The growth of <100> dendrites is favored by conditions of solution depletion, and they are branched at right angles. The <110> dendrites have been described as monocrystalline, branched at 60°, and growing with the plane of the dendrite parallel to a {111} plane. The lead dendrites examined by Faust and Johns were of the <110> type with "twin planes."

As part of a program of investigating the growth and character of metal crystals grown by electrodeposition, we had occasion to grow and examine some lead dendrites. We had hoped to use these as seeds for growing larger crystals, and we wished to know something about the quality of the crystals. Wranglen had considered only morphology and x-ray diffractometer measurements, and Faust and Johns had made only a very limited metallographic examination. All in all very little was known about the lead dendrites which are extremely easy to grow.

We grew numerous dendrites of lead by electrodeposition. In many respects they appeared to be the <110> dendrites of Wranglen, but were neither twinned in the usual sense nor single crystals. The apparent difference is probably attributable to the use of more powerful tools for their examination. Certainly these were not unusual growths inasmuch as they were obtained consistently and to the virtual exclusion of other types.

Growth of Dendrites

The dendrites were grown by electrodeposition in a 0.5M solution of lead acetate and 2M ammonium acetate with a lead anode and cathode. Reagent grade chemicals and distilled water were used without any purification steps.

The plating cell consisted of a 100 ml beaker filled with electrolyte and covered with a rubber stopper. The lead anode was supported at one side of the beaker through a hole in the stopper. On the other side, a glass tube 4 mm in diameter, was inserted in a hole in the stopper and positioned so that one end was in the electrolyte about a centimeter from the bottom of the beaker. The cathode was inserted in this tube so that one end was a few millimeters above the submerged end of the open tube. For some of the experiments the cathode was a long sliver of lead, and at other times it was a short cylinder of lead cast around the end of a copper wire which served to support the lead and to make an electrical connection. With this arrangement, the dendrites' growth was confined by the tube and controlled so that only one or two dendrites grew in a predetermined direction. This facilitated the measurement of growth rate and the subsequent isolation of a single dendrite for metallographic or x-ray examination. The electrolysis was carried out galvanostatically using a high resistance in series with the cell.

A scale was mounted near to and parallel to the tube so that it and the tip of the growing dendrite could be observed simultaneously through a telescope. This permitted measurement of the rate of growth or elongation of the dendrite.

The first stages of growth were usually marked by the appearance of numerous minute needles or trees. Most of these ceased to grow at a very early stage, and usually only one or two grew to lengths of more than a millimeter. This is a selective process in which the surviving dendrites are those which grow most readily and which are favorably oriented with their growth directions nearly parallel to the tube axis. As deposition was continued, the rate of advance of the tip, the growth rate, was measured. At the end of the experiment, the dendrite was recovered and examined.

A number of dendrites were grown in this manner at rates varying from 0.001 to 1 mm/min. The corresponding current densities calculated from rates of advance of the tips would be 18-18,000 ma/cm^2. The currents per unit area of tube cross section were 0.5-40 ma/cm^2.

It is of incidental interest to note here the relation between the quantity of lead in the dendrites and in the solution in the tube. The solution contained 1.3 mg of lead per millimeter length of the tube and dendrites grown at the rate of 0.3 mm/min contain an average of about 0.35 mg/mm length. Hence, dendrite growth did not depend on diffusion of lead ions from the open end of the tube. This is readily predictable without experiment, although it may not be realized by the experimenter. The deposition conditions are such that ion diffusion is more closely characterized by spherical diffusion than by linear diffusion which could not support the rapid dendritic growth. The concentration gradient for lead ions is confined to a short distance from the rapidly advancing tip.

Appearance of Dendrites

As had been observed by Wranglen (1), the dendrites were flat (Fig. 1). Their thickness ranged between 15 and 90μ. While growing, the flat surfaces were highly lustrous, but became rather dull after drying in air. Branching was close to 60° to the main stalk for some dendrites. Very often, the angles were not sufficiently well defined to measure meaningfully.

Although the dendrites were always to be described as flat, they almost always had short projections at an angle to the over-all plane of the dendrite.

[1] Present address: Howard University, Washington, D. C.

[2] As used in this paper, dendrite refers to the external form of the growth and not to its internal structure.

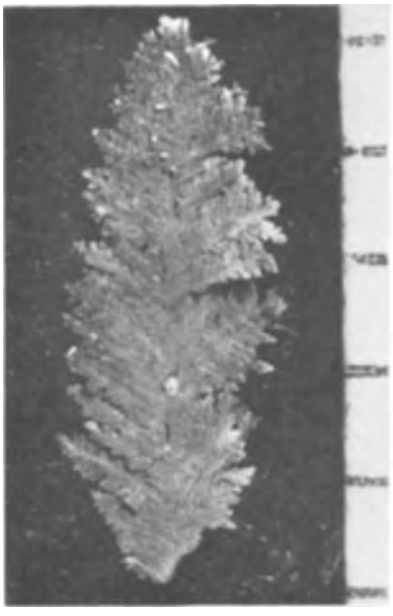

Fig. 1. Lead dendrite grown at 0.6 mm/hr; 1 div = 1 mm

These projections accounted for only a small portion of the total mass, but might account for some extra reflections of low intensity found in the diffraction patterns.

Also, a truly flat dendrite was seldom, if ever, isolated. The extreme fragility of these dendrites was such that they were difficult to handle without deformation. Some of the misalignment observed by x-ray diffraction and grain boundaries found metallographically could be and, perhaps, should be attributed to strain and deformation induced after the dendrite was formed.

X-ray Diffraction Examination

Several lead dendrites were examined by the x-ray diffraction techniques employing Laué, precession, and Weissenberg cameras. The transmission Laué patterns always indicated more than one orientation with misalignment in each. The method used by Wranglen (1) would indicate the dendrites to be single crystals.

Precession camera photographs were very informative. These were made with the axis of precession perpendicular to the flat side of the dendrite. Zero level (111) photographs of the dendrite shown in Fig. 1 show twelve pronounced {220} reflections with sixfold symmetry. The first level (111) photograph (Fig. 2) with the same setting shows two sets of pronounced {111} reflections with threefold symmetry with another double set of very weak {111} reflections displaced 60° from the primary orientations. This pattern can be accounted for if the lead is present in two primary orientations with a (111) plane common to both orientations and parallel to the plane of the dendrite with a slight amount of lead in a "twin relationship" to each of these two positions. One primary orientation is rotated 33° relative to the other and about the common [111] pole. Because of the inherent sixfold symmetry of the zero level (111) photographs, first level (111) photographs are required for determining the true angle of twist and the presence of normal twin growth, if any.

Figure 3 is a precession photograph of a dendrite with three orientations 30° and 60° apart (one pair has a twin relation). An equitorial Weissenberg photograph of the same dendrite confirms the zero level precession photograph and also clearly shows misalignment about the growth axis of the dendrite. All the diffraction methods showed considerable dispersion about the two orientations. As indicated earlier, some of this dispersion may be due to handling of the specimen.

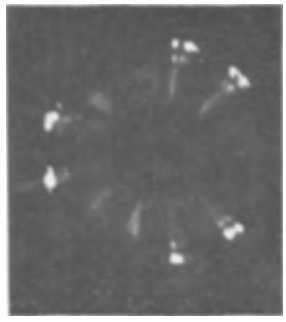

Fig. 2. First level (111) precession photograph of dendrite of Fig. 1. Pronounced (111) reflections are from material with two orientations, 33° apart. Weak (111) reflections are displaced 60° from intense reflections.

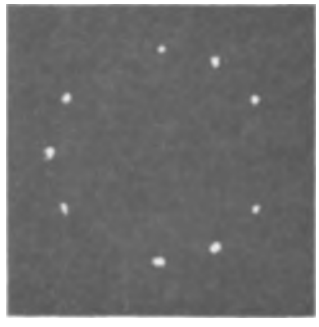

Fig. 3. First level (111) precession photograph of dendrite. (111) reflections from material with 3 different orientations, 30° and 60° apart.

The precession patterns appear to be representative of the dendrite inasmuch as patterns were made at random positions along the length and width of some of the dendrites with no significant differences observed in the appearance of the patterns. Precession patterns were also made with the plane of the dendrite parallel to the x-ray beam. While of poor quality they indicate one surface of the dendrite to be of one orientation and the opposite surface of the other orientation. Because of physical factors and the density of lead, the part of the pattern which results from reflection from the surface of the platelet is greatly enhanced over that part which depends on transmission. The two surface effects are recorded on opposite sides of the pattern (3).

Table I summarizes the angular relationship observed. The angles recorded have a precision to within about ½° insofar as they represent the angle occurring most frequently. There is, however, a spread of up to as much as ±10° from the model value.

Determination of Direction of Growth

The direction of growth of a dendrite was assumed to be parallel to the long axis of the dendrite and was measured as the angular displacement from the axis of the goniometer supporting the dendrite, after alignment for the precession photographs. This measurement could well involve an uncertainty of 2 or 3 degrees. The <110> and <112> directions were deter-

Table I. Twist angle between crystals of lead dendrites

mined from the {220} reflections of the zero level precession photographs and the {111} reflections of the first level, in terms of the angular displacement from the axis of the goniometer head. In this manner, the direction of growth was determined to be half-way, within 3° or 4°, between the $<\bar{2}11>$ directions of the two crystals (Fig. 4). The two $<\bar{2}11>$ directions were 33° apart. Also a dendrite with a twist of 27° was found to have grown in a direction half-way between two $<\bar{2}11>$ directions. Both of these dendrites, however, gave precession photographs showing weak reflections for twist angles of 60°. Another dendrite, with a twist angle of 31°, had an apparent growth direction half-way between two $<10\bar{1}>$ directions.

A fourth dendrite, with 3 orientations and twist angles of 27°, 33°, and 60°, was of interest. It grew half-way between the two $<\bar{2}11>$ directions of the two crystals 33° apart and simultaneously half-way between the two $<10\bar{1}>$ directions of the two crystals 27° apart. This simultaneous relationship is possible wherever the two twist angles total 60°.

Metallographic Examination of Cross Sections

Figure 5 is a micrograph of a portion of the cross section of a dendrite. It is immediately evident that the dendrite contains voids or channels. The dark areas are the plastic mounting material which flowed into the voids during curing.[3]

Since the voids did fill with the mounting plastic, it is evident that they were not closed off from the outside, but must have a wide opening or at least two openings. Successive polishing of the section of one dendrite revealed that any given void did not extend more than about a tenth of a millimeter along the stalk or branch.

All of the dendrites have two layers. Sometimes the voids are much less evident, and occasionally one layer is absent over a portion of the cross section. Other portions might have a third layer, as shown in

[3] Epon 815 with diethylaminpropylamine was used to mount the lead dendrites. This cures over a two-day period at room temperature. Other mounting materials tried did not fill the voids, and successful polishing and etching were not achieved.

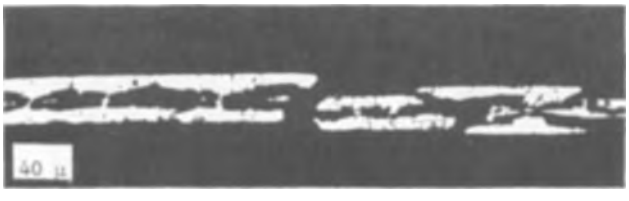

Fig. 5. Cross section micrograph of dendrite of Fig. 1, 2, and 4. Magnification approximately 200X.

Fig. 6. Cross section micrograph of lead dendrite. Magnification approximately 400X.

Fig. 6 and 5. Figure 5 shows boundaries within a layer, and we have observed cross sections with a twin boundary within a layer and parallel to the plane of the layer or dendrite.

Discussion

Pertinent to any consideration of the growth mechanism of these dendrites are the circumstances in which they were grown. The initial nuclei were numerous and oriented in many different directions, probably with many forms or combination of twin and twist boundaries and crystal imperfections. Of those present initially only those that grew the most rapidly along the axis of the restraining tube survived. This is a highly selective process, and it means that the kinds of dendrites described were faster growing, but were not the only kinds that grew. It also means that the structure favorable for the most rapid growth may not always have been the one to survive since orientation is also involved in the selection process.

The diffraction patterns and the cross-section micrographs show the dendrites to be essentially of two layers, each a layer of different orientation separated by a twist boundary. Some dendrites had 3 and/or 4 orientations with a common [111] pole. The third (and fourth) orientation always had a twin relation to one of the other orientations. The true relationship of these interfaces cannot be determined from the diffraction patterns. But is seems reasonable to think of these dendrites as having a twin and a twist boundary parallel to the plane of the dendrite. To have two twist boundaries with the twist angles totalling 60° would seem too fortuitous.

Since each dendrite observed, except for the normal twin relationship mentioned before, consisted of essentially two crystals, it seems reasonable to say that some interaction between the two crystals is responsible for rapid growth, more rapid than possible if each grew independently. It has been shown that for rapid two-dimensional growth of some dendrites with diamond, zinc blende, and closest packed cubic structure, twin lamellae are required to provide suitable re-entrant angles (4). The dendrites grown in this investigation appear to have grown by another mechanism. Such an interaction is provided by a re-entrant angle mechanism similar to that suggested by Price (5) for some cadmium crystals grown from the vapor. Figure 7 (similar to Fig. 16 of Price) shows re-entrant angles that might be formed by the two layers of the lead

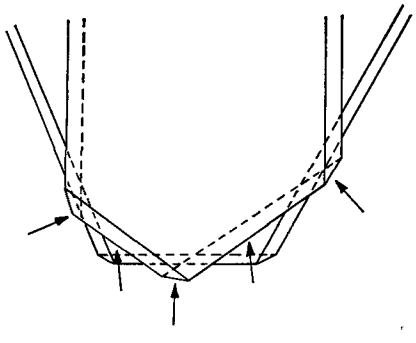

Fig. 7. Diagram showing re-entrant angles formed by overlapping crystal. Each crystal is bounded by (111) facets.

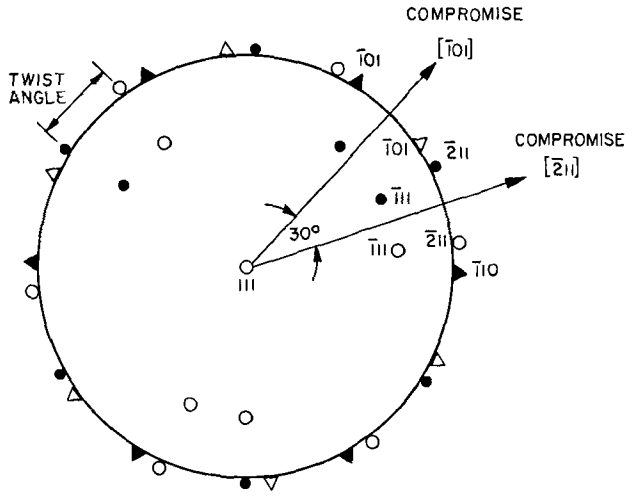

Fig. 8. Diagram showing directional orientations within plane of dendrite.

dendrites. This model assumes that all bounding surfaces are {111}.

If the two surfaces of the re-entrant angle are the same crystallographically, then one would expect no differentiation during the deposition process and, hence, the crystal boundary would not be planar and the surfaces would not remain planar. This appears to lead to complications which can be avoided by saying that the bounding surfaces, excepting the composition plane, are other than {111}; for example: {110} or {100}.

The twist angle may be determined by the relative stability associated with each possible angle. Price (5) has discussed this in terms of coincident hexagonal nets. The twist angles observed in the lead dendrites do not agree exactly with those predicted by Price on the basis of nearest neighbor considerations, but we cannot say that our results are at variance with his.

It is also possible that the twist angle is more dependent on the optimum growth directions for each crystal with the actual growth direction of the composite dendrite being a compromise. This leads to the question of what determines the growth direction and what is the growth direction.

We found growth directions that were either a compromise <$\bar{2}$11> or <$\bar{1}$01> direction. Consideration of Fig. 8 shows that although completely equivalent crystallographic directions are 120° apart for either a single or composite crystal, partially equivalent directions are 60° apart and suggest branching at 60° to the main stalk. Now if both [$\bar{1}$01] and [$\bar{2}$11] compromise directions occur we would expect branching to occur at 30° since these compromise directions are 30° apart. Since this branching angle has not been observed, it seems likely that growth occurs in only one of the two compromise directions. Now the dendrites having three or more orientations, including the material giving weak x-ray reflections, all included a twist displacement of 60°. As indicated earlier, this is a situation in which both compromise directions occur simultaneously, and either one can be controlling. Of the dendrites measured for growth direction, one gave x-ray reflections for only two orientations, and the growth direction appeared to be a compromise [$\bar{1}$01] direction.

Price (5) reported that for similar cadmium dendrites (hexagonal system) he observed the compromise direction of growth to be between two <10$\bar{1}$0> directions. This is equivalent to growth between two <$\bar{2}$11> directions for face-centered cubic systems. Our results indicate that the compromise direction of growth could also be between <$\bar{1}$01> directions.

One can conceive of mechanisms to account for growth in the compromise [$\bar{1}$01] direction, or for the compromise [$\bar{2}$11] direction. We lack, however, the knowledge to predict the growth direction.

Epitaxial Growth of ZnSe on GaAs

Alexander Baczewski

General Telephone & Electronics Laboratories Inc., Bayside, New York

ABSTRACT

Zinc selenide has been grown epitaxially on the gallium plane of gallium arsenide substrates. The overgrowth has the <111> orientation of the seed and exhibits an unambiguous Laue pattern. The vapor species was transported to the substrate in a gas stream consisting of argon, hydrogen, hydrogen chloride, and ammonium iodide. Growth rates of 5 μ/hr were usual, and thicknesses of 200μ were attained.

Recent developments in the field of injection luminescence have stimulated an interest in the preparation of single crystals of II-VI compounds and of epitaxially grown crystals using crystals of III-V compounds as a basis. This paper deals with the epitaxial growth of ZnSe on GaAs as a substrate. This combination was chosen because both compounds crystallize in the cubic zinc sulfide system and have very similar lattice spacings: GaAs 5.653 (1), ZnSe 5.667 (2). This small difference should minimize strain, particularly since intermediate layers of solid solutions of the compounds occur during deposition and further heat treat-

ment. The existence of such compounds and their continuous miscibility have been proven by the investigations of Goryunowa *et al.* (3). The high melting point of ZnSe (1515° ± 20°C) (4) and the dissociation of the vapors make it extremely difficult to prepare crystals of this material, either from the melt or from the vapor phase. Fischer (5) overcame the experimental difficulties by constructing a furnace in which a modified Bridgeman-Stockbarger growth arrangement pulls ZnSe growing epitaxially upon ZnTe under argon. In other experiments, Fischer used very high pressures of Se or Zn to prevent the dissociation of zinc selenide during zone melting.

Confronted with similar problems in the preparation of GaAs and GaP, Ing and Minden (6) adopted an open-tube synthesis system. Gallium and arsenic or phosphorus were placed in boats inside a heated quartz tube and transported toward the cooler end by reacting the metal with gaseous hydrogen chloride and by distilling the As or P at the same time. Similar methods have been described by Schaefer (7) and by Holonyak (8). The technique described in this paper makes use of the reaction of zinc selenide with hydrogen chloride at elevated temperature and the dissociation of the volatile compounds at lower temperature in an open tube system. Gallium arsenide wafers positioned in the deposition zone afford sites for epitaxial growth. The severe corrosive action of the transporter gases is reduced by the admixture of a volatile iodine compound. Nongrowth areas of the substrates are also protected by a nonreactive coating.

Experimental

Vapor transport experiments were carried out in a quartz tube (55 cm long, 44 mm ID) inside a 45-cm-long tubular furnace wound with Nichrome wire. To obtain the desired temperature profile, taps were connected with resistors. To afford another hot zone near the entrance of the furnace a heater tape was wound around the tube controlled to 200°C by a variable resistor. Another heater tape was wound around the tube between the first tape and the gas inlet. It was kept at 300°C in order to prevent back sublimation of the volatile iodide. A chromel-alumel thermocouple monitoring the temperature was enclosed in a small quartz tube attached to the reaction tube, since it had been found that a reentering tube served as a heatsink drawing all the crystal growth away from the substrate.

Another thermocouple inside the reaction tube controlled the input to the heater tapes. A rectangular quartz plate throughout the whole length of the growth tube served at one end as a support for a quartz wool plug saturated with source material. At the other end, slots were ground into the plate for holding the targets. Electronic grade zinc selenide (60-mesh) was used as the source material. The substrates were cut (0.5 x 0.5 x 0.01 cm) from undoped gallium arsenide single crystals in the (111) direction. The gallium faces were polished to half-wave flatness having a surface finish of one-quarter micron. The transport gases were prepurified hydrogen, pure argon, and hydrogen chloride (99.9% min. pure). Catalytic units removed oxygen from hydrogen and argon. Hydrogen chloride was bubbled through concentrated sulfuric acid to remove water. Teflon tubing was used for all connections. Figure 1 indicates the experimental arrangement.

A typical growth experiment was run thus: ZnSe was powdered onto a mat of quartz wool which was then rolled and enclosed in a wrapper made from woven quartz that was previously fired to remove organic substances. This arrangement ensures intimate contact between the carrier gases and source. The wrapper was fastened to the quartz plate with quartz fibers. The substrates were glued on their arsenide face with sodium silicate onto freshly cleaved and cut mica and, after a Freon spray, placed into the grooves of the quartz plate. The plate was introduced into the quartz

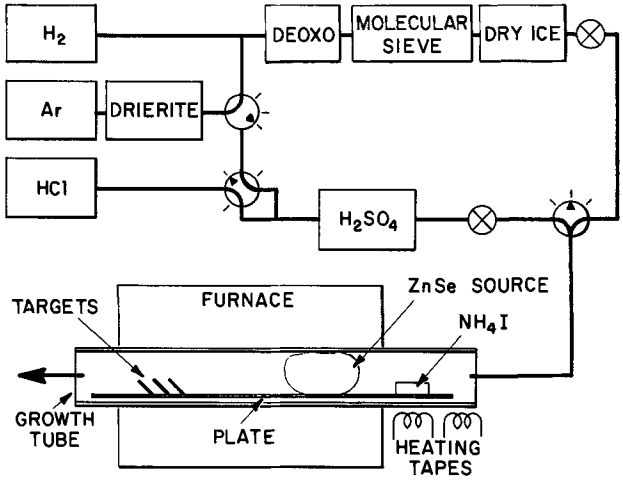

Fig. 1. Apparatus for the epitaxial deposition of zinc selenide

tube. A quartz boat containing an ammonium halide was positioned into the tube in the vicinity of the furnace. While the furnace was heated up (300°C for the first tape, 200°C for the halide, 600°-740°C for the source, 570°-610°C for the substrates) and for the following 16 hr, a flow of 20 ml hydrogen per minute and 20 ml argon per minute was maintained. Then, 1 ml hydrogen-chloride gas per minute was added to the stream. After another 24 hr, the hydrogen chloride flow was increased to 10 ml/min. Most runs were terminated after 96 hr. The assembly was cooled in a stream of hydrogen and argon.

Results

Epitaxial single crystals of ZnSe, tightly adhering to the (111) plane of GaAs, have been grown at rates from 1 to 5 μ/hr. Thicknesses of 200μ were attained. Figure 2 shows a single crystal of ZnSe removed from the GaAs substrate, and Fig. 3 shows a cross-section of a well-adhering epitaxial growth. The lower layer is the gallium arsenide substrate, the upper layer is zinc selenide. An x-ray scan proved single crystallinity. The crystals showed no visible u.v. fluorescence at room temperature and strong red fluorescence at 77°K.

Discussion

In a vapor phase transport system the probability of a reaction of the substrate with the carrier gas has to be taken in account. It is impossible to expose germanium to acidic vapors. Gallium arsenide is also severely etched under the conditions of the zinc sele-

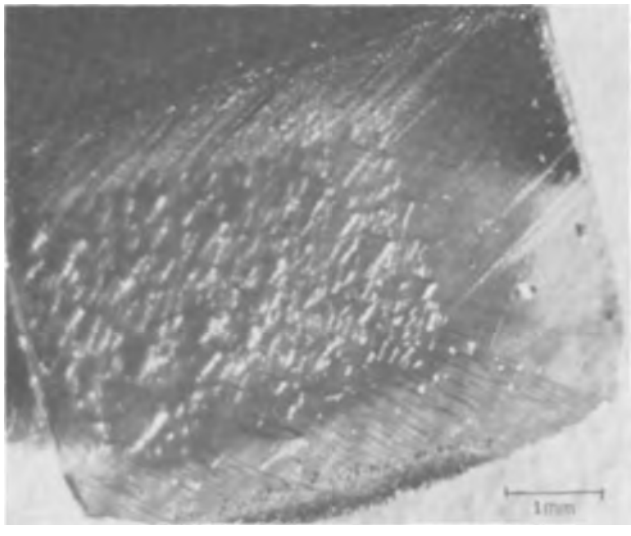

Fig. 2. Zinc selenide crystal. (111) Zinc face faces the viewer. Gallium arsenide substrate removed.

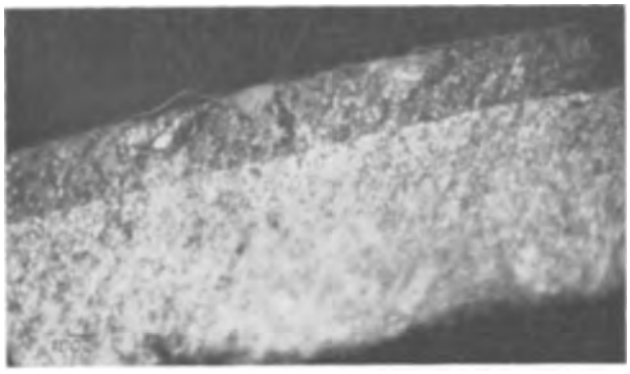

Fig. 3. Cross section of zinc selenide (dark), grown epitaxially upon (111) gallium plane of gallium arsenide substrate.

nide vapor transport in gaseous HCl. This is not to be expected because it is not soluble in concentrated aqueous hydrochloric acid unless an oxidizing agent is present. It also is only very slightly heat etched at the temperature of the substrate in the absence of hydrogen chloride. This effect may be explained by the fact that hydrogen chloride always contains small amounts of chlorine and that the chlorine content increases under the influence of heat. Experiments to enclose sacrificial amounts of GaAs in the growth tube between the source and the substrate met with no success. A simple way to remove the chlorine within the reaction tube is by a displacement reaction, *e.g.*

$$Cl_2 + 2NH_4I = 2NH_4Cl + I_2$$

Iodine as an oxidizing agent is less active than chlorine and therefore reduces the etching action of the carrier. It was introduced as volatile ammonium iodide and the above reaction occurred in the gaseous phase. Experiments proved that it prevented etching even at steeply increasing amounts of hydrogen chloride.

Very small amounts of oxygen also increase the rate of reaction of GaAs with HCl. Therefore great pains were taken to exclude it by adding catalytic deoxygenizing units to the gas purification train and by always keeping the equipment under positive pressure.

An aqueous solution of sodium silicate had been used at first for adhering the back of the substrate in order to facilitate handling and positioning. Then it had been noticed that single crystals occasionally grew although most of the substrate disappeared during the growth period. Every time the spot only remained where the adhesive had been applied. It is likely that epitaxial growth occurred in the initial stages of the experiment at the crystallite-substrate interface before the corrosive gases could etch away all of the substrate. This experience suggested the coating of all non-growth areas with a sodium silicate solution.

The initial growth of single crystals depends on the lateral mobility of growth centers which arrange themselves as a continuation of the substrate lattice. It is very important that no foreign molecules be present on the surface. Various conventional cleaning methods were tried but none was capable of rendering the surface free of contamination as ascertained by the atomizer test.[1] A method to vaporize the contaminants by the action of heat and hydrogen has been worked out. This method served also to remove and volatilize any volatile and reactive constituents of the sodium silicate adhesive. The substrates were placed into the growth tube without any special cleaning aside from a Freon spray to remove fingerprints. It was proved by the atomizer test that the substrate became wettable after 16 hr of this treatment. A similar observation has been made recently by Pizzarello (11) who increased the temperature of his substrates for a short time to improve the quality of their surfaces. He used a closed system, however, where the contaminants cannot be ultimately removed.

Gaseous hydrogen chloride reacts with ZnSe at elevated temperatures and the volatile reaction products re-form the solid in a cooler zone

$$2HCl(g) + ZnSe(s) \rightleftharpoons ZnCl_2(g) + H_2Se(g)$$

The reaction is so rapid that it has been found advantageous to dilute the hydrogen chloride with hydrogen and argon. At the temperature chosen, ZnSe has a vapor pressure of approximately 0.05 mm (9), a fact which demonstrates the advantages of vapor transport over sublimation methods. The dissociation of H_2Se at that temperature which might cause deposition of selenium upon the substrate is almost negligible and is further reduced by the presence of hydrogen.

Crystals grown at a faster rate displayed more irregularities than the ones grown at slower rates. Those grown at a 1 ml/min flow of hydrogen chloride had smooth surfaces (Fig. 2), whereas those grown at a 11.5 ml/min flow showed regular arrays of (111)-oriented pyramids (Fig. 4). Similar surface defects have been observed by Newman and Goldsmith (12) in their investigation of the vapor growth of gallium

Fig. 4. Zinc selenide deposited upon (111) gallium face of gallium arsenide at high flow rates.

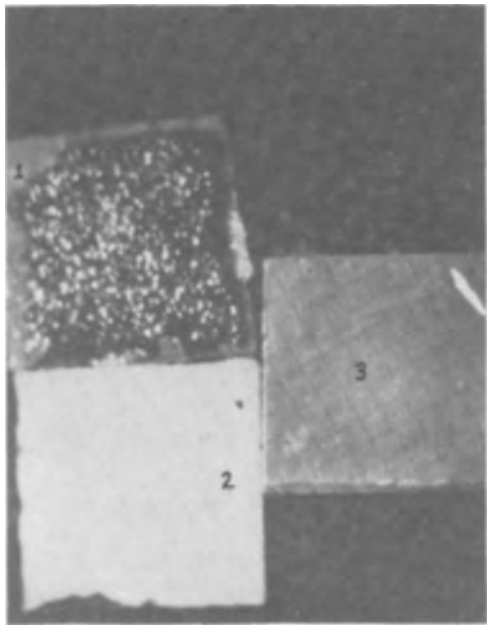

Fig. 5. Substrates plus overgrowths upon (111) gallium plane that has been exposed at different temperatures (see text).

[1] A fine mist of water is sprayed under standard conditions against the sample. If the surface is clean a continuous film of water is obtained. This test is capable of detecting 8×10^{-8}g of water shedding contaminant per square centimeter. Freshly cleaved mica serves as a standard for cleanliness (10).

arsenide. The reactive deposition of zinc selenide in a gas stream occurs over a wide temperature range in contradistinction to the equilibrium conditions in a closed system (8). Crystallization has been observed in a zone ranging from 620° to 520°C. The habit, however, changes as a function of temperature, the optimum for single crystal growth lying above 585°C. Figure 5 shows three substrates that had been exposed to different temperatures. Number one (591°C) shows a clear epitaxial layer, number two (568°C) has a multicrystalline deposit which appears white on the photograph and number three (538°C) had a multicrystalline layer which spalled off when the sample was removed from the tube. It therefore shows the shiny surface of gallium arsenide.

X-Ray Diffraction Topographs of Imperfections in Gallium Arsenide by Anomalous Transmission of X-Rays

E. D. Jungbluth

General Telephone & Electronics Laboratories, Incorporated, Bayside, New York

ABSTRACT

Imperfections in single crystals of GaAs grown by the Czochralski and horizontal gradient freeze method have been observed by the anomalous transmission of x-rays. Slip occurs equally on the three octahedral (111) planes in the Czochralski pulled ingot. Radial slip predominates in crystals grown by the gradient freeze technique. The variation in the distribution of dislocations in crystals grown by both techniques is observed and compared. Large inclusions of tin and tin arsenide have been detected in heavily doped GaAs. The formation of SiO diffusion masks on single crystal GaAs causes large strains when the sample is heat-treated under diffusion conditions.

The interest in gallium arsenide as the subject of research in the semiconductor industry has been heightened in the last two years by the emergence of the injection laser. One of the parameters influencing the electrical performance of a semiconductor material is the occurrence of structural imperfections. The prominent role that dislocations play in affecting electrical characteristics has been the subject of several papers which include the influence of dislocations on the electrical conductivity in metals (1), microplasma phenomena in silicon p-n junctions (2,3), and the distribution of dislocations in relation to voltage distribution and photoconductive response in gallium arsenide (4).

The observation of dislocations in gallium arsenide has heretofore been limited, for the most part, to the identification of etch pit sites, on major crystallographic planes, with emergent dislocations (5-7). The limitations of analyzing dislocation networks by means of surface topography is obvious. Moreover, the high dislocation densities present in commercially available GaAs complicate the use of x-ray diffraction microscopy. In respect to the control of dislocation densities the state of the art in gallium arsenide crystal growth is in its infancy compared with growth of silicon or germanium crystals.

X-ray diffraction microscopy can be used to produce topographs which effectively map the geometrical distributions of a variety of crystalline imperfections. The extinction-contrast technique has been applied successfully to materials exhibiting low x-ray absorption (8, 9). Thus, images of dislocations, segregation, precipitation and stacking-fault phenomena have been observed in silicon. For materials with high x-ray absorption, a complementary technique utilizes the Borrmann effect to record imperfections (10-12). Both techniques have the advantage over etching in being nondestructive. This paper reports on the direct observation of imperfections in single crystals of gallium arsenide by use of the Borrmann effect, *i.e.*, the anomalous transmission of x-rays.

Experimental Techniques

The technique employed in this study is based on the parallel-beam method of Barth-Hosemann (13). A standard copper x-ray diffraction tube, operated at 20 kv and 20 ma, was utilized. The images were recorded on 50μ Ilford nuclear plates with about a 12-hr exposure. Only the diffracted image is presented in subsequent figures, which are photographic negatives, *i.e.*, the diffraction contrast is reversed relative to the nuclear plates.

The crystals, which are grown by both Czochralski and horizontal gradient freeze methods, were oriented optically and sectioned in 1-mm-thick wafers. Sections were cut normal to the growth axis, along (111) planes, parallel to the growth axis along (112) planes, and at 19°21′ to the growth axis along one of the octahedral (111) planes. In the boat-grown samples, which were not seeded, the axis of the (111) plane that lies

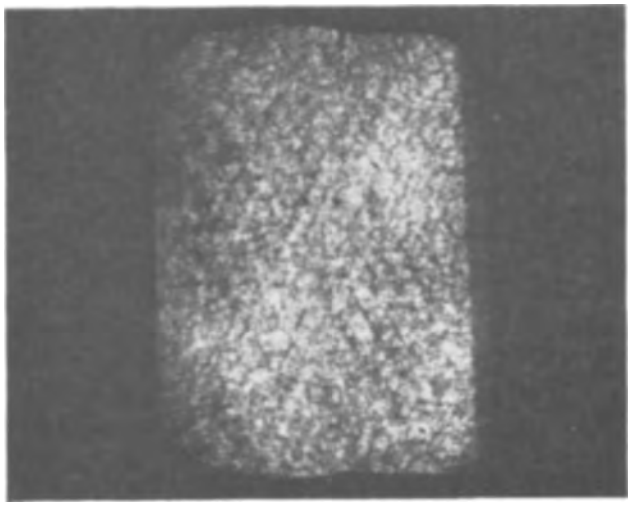

Fig. 1. Radial distribution of dislocations in GaAs; {220} reflection. Czochralski growth technique.

closest to the long dimension of the crucible is arbitrarily considered to be the growth axis. The wafers were chemically polished in a 1:2:3 solution of $HF:HNO_3:H_2O$ to remove surface damage.

Results

Distribution of dislocations.—It is well known that the dislocation densities vary both across the diameter and along the length of Czochralski-grown semiconductor crystals. Orders of magnitude variation have been observed in both cases. Figure 1 is an x-ray topograph of one of our GaAs wafers oriented normal to the growth axis and sectioned from an ingot grown by the Czochralski method. The variation of the diffraction contrast across the slice is indicative of variation in the dislocation density. The darker areas correspond to imperfect regions. An order of magnitude difference in dislocation density is estimated from the center to the edge of the crystal and was confirmed by etch pit techniques to vary from 10^4 to 10^5 dislocations/cm^2. Individual dislocations are difficult to resolve at this dislocation density due to the strong interaction of strain fields surrounding each dislocation. The threefold symmetry of the dislocation patterns, which is evident in the original topograph, suggests slip in the octahedral (111) planes.

The variation of the dislocation density along the length of the crystal is obvious in Fig. 2. This section was oriented along a (112) plane. Thermal stresses that arise due to temperature fluctuations complicate the growth of defect-free material. Slip mechanisms

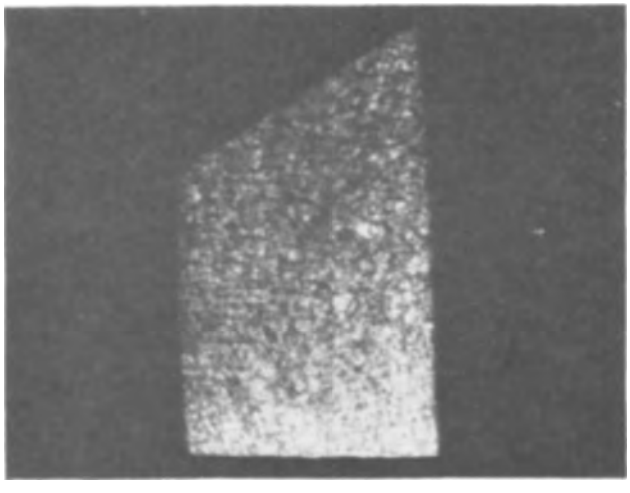

Fig. 2. Axial distribution of dislocations in GaAs; {220} reflection. Czochralski growth technique.

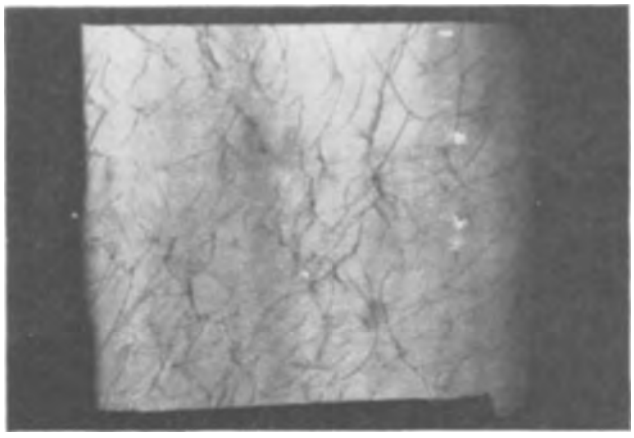

Fig. 3. Low-dislocation-density GaAs; {220} reflection. Horizontal gradient freeze technique.

during the growth process are influenced by thermal stresses, which could be responsible for the observed variation in dislocation density. Compounding this problem is the motion of the melt through the temperature zone in the Czochralski technique. The radial and axial thermal variations associated with this growth method tend to vary the localized stresses and consequently slip is easily induced.

The horizontal gradient freeze method circumvents some of the problems associated with the Czochralski method. The melt itself remains stationary, while solidification occurs due to a movement of the temperature gradient along the ingot. Hence, it is only necessary to control the temperature profile, since the melt itself is not moving. Therefore, crystals may be grown with a rather low defect structure.

Figure 3 is a typical example of the high perfection available in GaAs crystals grown by the gradient freeze method. This crystal is n-type, resistivity 0.13 ohm-cm, and has an etch pit density of about 200 per cm^2. The section is oriented along a <111> direction closest to the long dimension of the boat. The distribution of dislocations appears random, and no preferred concentration of dislocations was observed. Although the dislocations in most cases were curvilinear, a tendency to align near the <110> directions was observed. Most of the dislocations appear with the same resolution along their entire length. This indicates that the dislocations lie in the plane of the wafer and suggests that slip is principally in a radial direction. The mechanical constraint imposed on growth by the confining walls of the crucible boat apparently imposes less difficulties in the way of the growth of good crystals than do the thermal gradients of the Czochralski technique.

Figure 4 is a {220} reflection of a section of gallium arsenide grown by the gradient freeze method. This

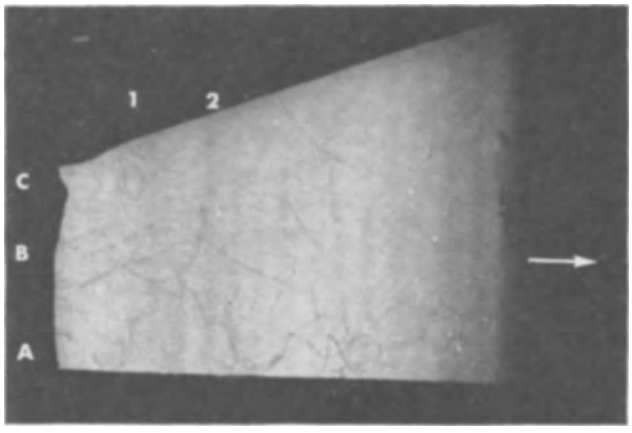

Fig. 4. {220} reflection of a GaAs wafer; A side facing beam; the direction of the diffraction vector is indicated.

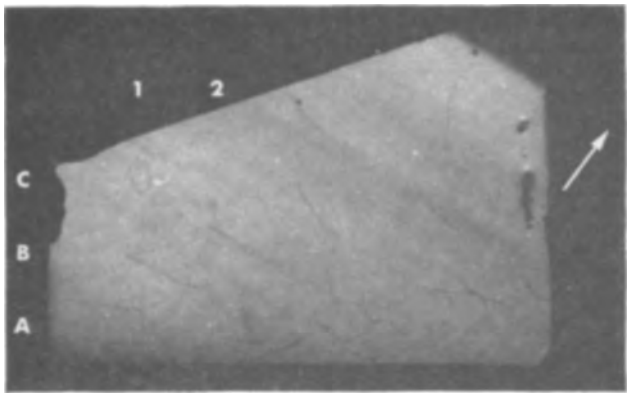

Fig. 5. {202} reflection of the same wafer as Fig. 4; A side facing beam.

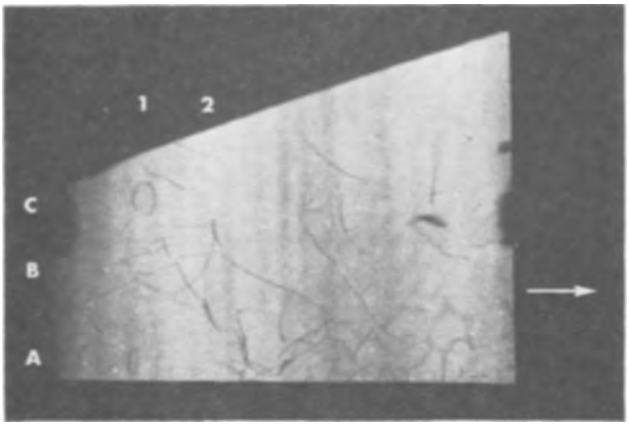

Fig. 6. {220} reflection of same wafer as Fig. 4; B side facing beam.

section is oriented along an octahedral (111) plane, A face toward the beam side. This crystal was zinc doped to a concentration of about 1.7 x 10^{18} at./cm^3. The dislocation group at B-1 appears well resolved, but runs from the A to B surface of the crystal. Vestiges of other dislocations are seen, but with decreased contrast and resolution due to the unfavorable contrast conditions in this reflection. In the {202} reflection of Fig. 5, the same dislocation group, B-1, has a minimum of contrast. The directions of the diffraction vectors are indicated in the micrographs. The dislocation group B-1 must therefore have a strong Burgers vector component in the <220> direction and have a strong component lying in the {202} planes. If the crystal is remounted, so that the B side faces the beam, then several new dislocations appear for the same {220} reflection as in Fig. 4. The ring dislocation at C-1 is observable in both Fig. 4 and 6, while a new ring at A-1 becomes visible in Fig. 6. In addition, an improved sharpness of several of the dislocations is apparent in Fig. 6. This is a consequence of the spreading of the beam within the crystal lattice and could lead to misinterpretations involving the perfection of any given wafer (14). This is interpreted to mean that the ring dislocation at A-1 lies closer to the A surface of the crystal. The ring at C-1 must lie approximately midway between the A and B surfaces since it is visible in both reflections. By considering the geometry of the wafer, it has been determined that the dislocation ring at A-1 must lie approximately 300μ from the A surface. There was no evidence for segregation or precipitation in crystals grown by the gradient freeze method and doped with zinc to the order of 10^{18} at./cm^3.

Impurity traces.—The anomalous transmission x-ray method has been used for impurity trace analysis for arsenic in germanium and oxygen in silicon (15). The electron probe is being used extensively to trace the chemical species of inclusions in a variety of host matrices. Lublin has identified the formation of tin and

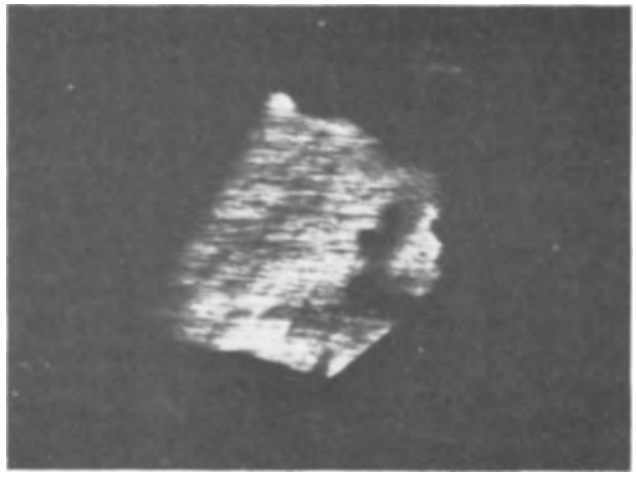

Fig. 7. X-ray topograph of heavily tin doped GaAs; precipitation of tin complexes appear as large dark spots.

tin arsenide inclusions, of sizes up to 200μ, in heavily doped GaAs using the electron probe (16). Figure 7 is an x-ray topograph of a section of Czochralski grown GaAs doped with tin to an average concentration of 10^{18} at./cm^3. The large dark spots are not reflection dependent, indicating the presence of an insoluble foreign species. The largest spot was in the order of 200μ size and is attributed to the presence of a precipitated species of tin. Probe analysis revealed an inhomogeneous concentration of impurity varying from 10^{18} to 10^{20} at./cm^3. The precipitates consisted of two phases, pure tin and tin arsenide. The formation of large precipitates due to doping beyond the solubility limits could actively participate in the degradation of the electrical characteristics of active devices.

Selective masking effects.—Silicon monoxide is known to be an effective mask against the diffusion of zinc and cadmium in GaAs (17). The creation of densely dislocated regions under SiO masks on germanium occurs as the substrate approaches plastic deformation temperature (18). In order to ascertain the effect of SiO masks on the perfection of GaAs substrates, samples were prepared in the following way. Circular masks (5 mm diameter) of SiO were deposited on substrates similar to that of Fig. 3. The deposits were 840Å thick and bonded to the substrate at 500°C. The sample was subsequently zinc diffused at 1100°C for 3 min. Figure 8 is a topograph of the resulting dislocation pattern. High x-ray absorption, indicative of severely disturbed lattices, occurs in the region under the mask. In the surrounding regions, which are unmasked, dense dislocation networks may be resolved. The dislocation networks in the unmasked portion are due to the in-diffusant of high concentrations of substitutional zinc (19). Heat-treatment of similar samples, but unmasked, at elevated temperatures did

Fig. 8. Zinc diffusion through a circular SiO mask.

not generate any additional imperfections. No change in the topograph was observed after SiO deposition but prior to diffusion. The strain associated with the oxide mask extends 300μ below the surface of the mask. The difference in the x-ray absorption between masked and unmasked areas must be due to inherent stresses set up by the dissimilar thermal expansion coefficients which activate slip systems at elevated temperatures.

ABSTRACT

The oxidation of $MoSi_2$, Mo_5Si_3, and Mo_3Si has been studied at temperatures of 1300°-2000°K, and at oxygen partial pressures of 2-20 Torr. Below 1970°K, at oxygen pressures around 10 Torr, measurements of the rate of total oxygen consumption *vs.* time show an initial period of high linear rate, an intermediate region where the rate declines sharply with time, and a final plateau region of virtually zero oxidation rate. For each of the silicides, the total oxygen consumed prior to the attainment of the plateau decreases with temperature, and under given experimental conditions is largest for Mo_3Si, less by a factor of about six for Mo_5Si_3, and less by another factor of six for $MoSi_2$. The oxidized samples display a smooth glassy outer oxide layer that bridges across the tops of the cracks in the alloys and an inner oxidized zone, consisting of several irregular phases. Electron microprobe analysis and x-ray photomicrographs of the oxidized specimens show that the outer protective oxide is pure SiO_2, within the limits of detectability, *i.e.*, the outer oxide contains less than 0.1% Mo. The inner oxide layer contains SiO_2, molybdenum rich phases, including the terminal solid solution phase, and the original alloy phase. Evidence is presented that suggests that the oxide layers grow by inward diffusion of oxygen to the oxide/alloy interface where preferential oxidation of silicon occurs. The excellent oxidation resistance of the molybdenum silicides derives from the formation of this continuous layer of pure silica. Above 1970°K, at oxygen pressures above 10 Torr, an increased oxidation rate is observed due to formation of SiO(g) at the alloy/oxide interface, which causes rupture of the protective oxide. Below 1970°K, at oxygen pressures near 2 Torr, the rate of oxidation of $MoSi_2$ is linear at all times since the oxygen partial pressure is insufficient to maintain a protective SiO_2 layer on the alloy surface.

The remarkable oxidation resistance of molybdenum disilicide at temperatures between 1200° and 1970°K has been recognized for many years and has been ascribed to the formation of a self-healing coating of high silica content glass (1-11). Oxidation resistance measurements have generally been limited to net weight change after a specified period in oxygen or air, and apart from the initial survey of Kieffer and Cerwenka (2), work has concentrated on $MoSi_2$ to the virtual exclusion of the lower silicides Mo_5Si_3 and Mo_3Si.

Quantitative weight change data on the oxidation of $MoSi_2$ is fragmentary and contradictory. At 1270°K (1) the net weight change was reported to be negative for the first 25 min in oxygen and positive for the next 40 min. At 1380°K (4) small net weight losses were observed in 75 and 150 hr. Between 1470° and 1770°K net weight gains were found in two laboratories (1-5), but the values reported after 300 hr at 1470°K differ by a factor of ten. Also at 1470°K, a single publication (1) includes two weight change *vs.* time curves that differ by orders of magnitude in both rate of oxidation and absolute value of the weight change in a 1-hr period. At 1840°K, Long (5) measured net weight losses of 4×10^{-4} g/cm^2 in periods of 100 and 135 hr. From the available experimental evi-

dence it has been deduced that the products of oxidation of $MoSi_2$ must be $Mo_5Si_3 + SiO_2$ and/or a ternary Mo-Si-O glass (9). It has also been suggested (9) that in the early stages of oxidation of Mo_5Si_3, evolution of $MoO_3(g)$ predominates over Mo_5Si_3 or ternary oxide formation and that the composition of the oxidation product layer is thus shifted toward higher silica content.

The present study was undertaken to obtain a systematic comparison of the oxidation behavior of the three silicides, Mo_3Si, Mo_5Si_3, and $MoSi_2$, above 1000°C at oxygen partial pressures below 20 Torr. Continuous measurements of total oxygen consumption rate *vs.* time, as well as metallographic and electron probe analysis of the oxide films, are reported. The total oxygen consumed was measured rather than the more usual net weight change, since during the oxidation of molybdenum silicides, net weight change is compounded of a weight gain due to the formation of $SiO_2(c)$ and a weight loss due to vaporization of molybdenum oxides. Total oxygen consumption is a direct sum of the amounts of oxygen in all of the product oxides, volatile and nonvolatile, and hence is more directly related to alloy oxidation rates. Metallographic and electron probe microanalyses of the oxide films show that the protective oxide on the molybdenum silicides is pure SiO_2 containing less than 0.1% of molybdenum. In addition, for all of the silicides, an enhancement of the molybdenum content of the alloy at the alloy/oxide interface is observed. It is suggested that $SiO_2(c)$ and gaseous molybdenum trioxide are produced simultaneously in the initial stages of silicide oxidation, that the silica flows laterally to cover the alloy surface, and the reaction continues at an exceedingly slow rate by the preferential oxidation of silicon at the alloy/oxide interface. On this basis, the observation of a net weight gain or weight loss should be very sensitive to precise experimental conditions.

Experimental Method

Samples in the form of ingots about 10 cm long and 0.7 cm in diameter were synthesized from du Pont semiconductor grade silicon and General Electric high-purity molybdenum powder by cold pressing, low-temperature sintering, and zone melting of the sintered compact with a moving induction coil (12). Products were analyzed for crystal structure, stoichiometry, and purity by standard electron probe, x-ray, chemical, and spectrographic analytical methods. Synthesis of each silicide resulted in polycrystalline material within 1% of stoichiometric composition. Due to vaporization of silicon, all samples were on the molybdenum-rich side of stoichiometry, the Mo_3Si contained a small amount of second-phase terminal solid solution; Mo_5Si_3 samples were single phase; $MoSi_2$ samples contained a small amount of second phase material Mo_5Si_3. In all cases the volume percentage of second phase detected was less than 1%. Impurities included C, Al, O, and B in the ppm range.

The experimental procedure for determination of the oxidation rate has been described in detail in Part I of this series (13). A thermal conductivity cell of the type employed in vapor phase chromatography was used to compare the oxygen concentration in a helium stream before and after removal of some of the oxygen by reaction with the heated samples. In the present experiment samples approximately 0.3 cm long were cut from the zone melted bars described above, polished through diamond dust, and cleaned with acetone and distilled water. The samples were then mounted by three-point contact with Al_2O_3 support rods and degassed at 2100°K in helium prior to oxidation. Samples prepared in this manner were enclosed in a Pyrex and quartz flow system, and heated inductively; the rate of total oxygen consumption was monitored continuously with the thermal conductivity cell. All of the oxidation measurements were made in atmospheres of helium and oxygen flowing at about 95 cc/min with a total pressure of 760 Torr. A linear gas velocity of approximately 3 cm/sec was maintained in the neighborhood of the samples.

Oxidized samples were sectioned, mounted, and polished for optical examination and electron probe microanalysis. Standard static and scanning electron probe microanalysis techniques were used to determine concentrations near the oxidized surface and to provide backscattered electron and x-ray micrographs of the oxidized samples. The instrument (Cambridge Instrument Company, Ltd.) incorporated an incident electron beam and 20° x-ray take-off angle. An electron accelerating voltage of 15-40 kv and an electron beam current of 0.5 to 1 x 10^{-7} amp were used; the electron beam diameter was approximately 1μ. The molybdenum content was determined by analysis of the MoKα and MoLα characteristic x-rays; the silicon content was determined by analysis of the SiKα characteristic x-rays.

The data obtained were corrected for x-ray absorption effects using the data of Green (14) and absorption coefficients from a recently published compilation (15). Fluorescence effects are of negligible importance in this particular system (16-17) when the SiKα and MoLα characteristic x-rays are employed. No correction for electron deceleration effects was included since such a correction would be limited by incomplete quantitative data on the electron behavior in the alloys and the elemental standards (17); however, this effect is not expected to alter the results substantially.

Experimental Results

Oxidation behavior.—The majority of the oxidation experiments were conducted between 1300° and 1970°K in atmospheres maintaining an oxygen partial pressure of near 10 Torr. For such low oxygen partial pressures, the thermal conductivity technique measures rates of total oxygen consumption, dQ/dt, directly and continuously. The curves of total oxygen consumption, Q, *vs.* time for Mo_3Si, Mo_5Si_3, and $MoSi_2$ were obtained by integration of the experimental rate curves from time zero to selected times and are shown in Fig. 1. In general, the data show an initial period of rapid linear oxidation, a short intermediate period when the rate of oxidation diminishes with time, and a final region in which the oxidation rate is exceedingly slow.

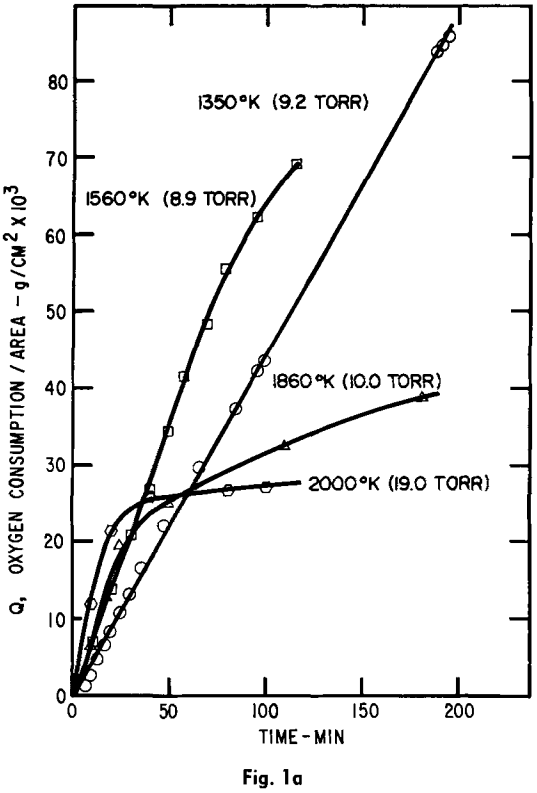

Fig. 1a

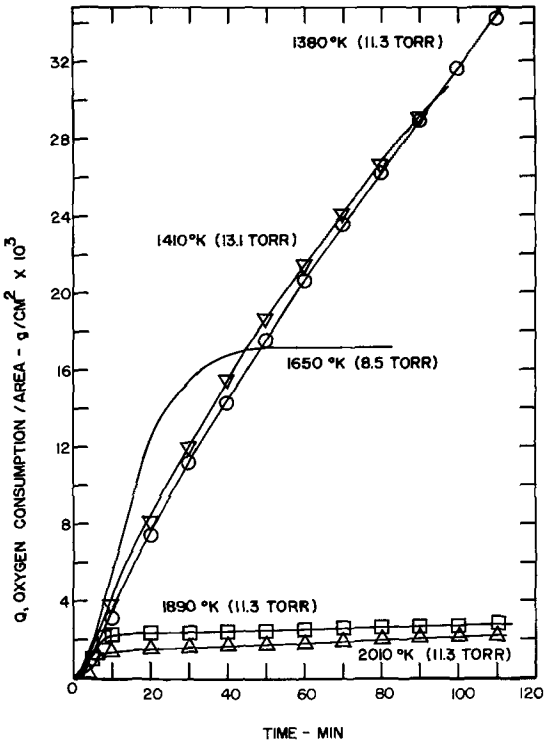

Fig. 1b

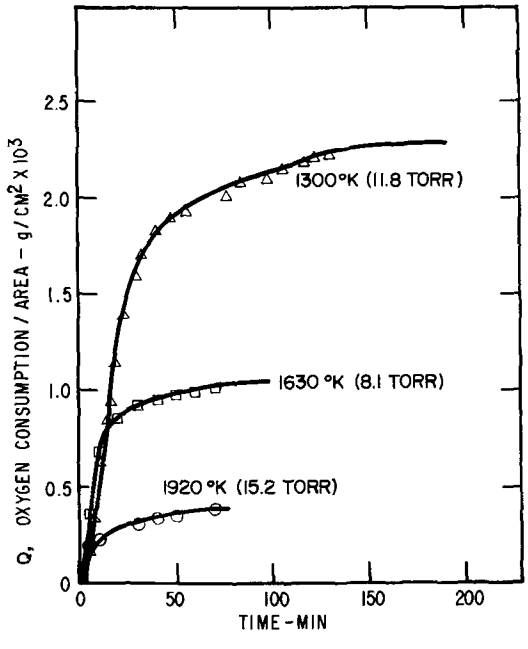

Fig. 1. Oxygen consumption *vs.* time curves: a, Mo_3Si; b, Mo_5Si_3; c, $MoSi_2$.

Mo_3Si oxidized at 1350°K displays no final plateau region, although the rate of oxidation as measured by the thermal conductivity curve was observed to decrease slowly with time. At 1560°K, a distinct decrease in oxygen consumption rate is seen after about 80 min; at 1860°K the decrease in rate occurs earlier, and at 1960°K, a definite plateau region is observed (Fig. 1a). For Mo_5Si_3, a limiting rate is not seen over the period of observation at 1380° or 1410°K, but a plateau region is prominent at the higher temperatures (Fig. 1b). In the case of $MoSi_2$, the final oxidation rates are very slow in every experiment (Fig. 1c).

The oxidation rates observed, once a limiting rate has been reached, are of the same order for all of the molybdenum silicides. However, the total depth of alloy oxidized prior to the plateau region is greatest for Mo_3Si, less by a factor of about six for Mo_5Si_3, and less by another factor of six for $MoSi_2$. For all three silicides, the asymptotic value of net oxygen consumption, Q_o, decreases with increasing temperature between 1300° and 2000°K. This decrease is not necessarily in contradiction to the customary increase in the rates of chemical reactions with temperature, since at least two steps are required for the attainment of a limiting oxidation rate. Both volatile molybdenum trioxide and condensed $SiO_2(c)$ are formed in the early stages of oxidation. The rate-limiting step leading to the plateau might be the lateral flow of SiO_2 to form a continuous boundary layer. The higher the temperature, the earlier the rate-limiting process takes over, thus leading to lower values of total oxygen consumption with temperature.

The total oxygen consumption Q, *vs.* time, t, plots can be fitted approximately by two parameter equations of the form $Q = Q_o\,[1 - \exp(-\alpha t)]$, as suggested earlier by Jaenicke (10) where Q_o and α depend on temperature, pressure, and surface composition. However, Q, the total oxygen consumed, is a composite quantity representing the sum of the amount of oxygen in each of the product oxides. Since at least two oxides are formed during the course of oxidation of molybdenum silicides, such curve fittings tend to obscure the complexity of the basic oxidation mechanism, and will not be employed here.

Above 1970°K, there is a change in the mechanism of oxidation of $MoSi_2$ that results in an irregular final region of the oxidation curves. For example, a portion of a typical recorder tracing for the oxidation of $MoSi_2$ at a temperature of 2000°K and an oxygen partial pressure of 9 Torr is shown in Fig. 2. The ordinate is proportional to rate of total oxygen consumption, the abscissa is proportional to time. The initial behavior is similar to that at lower temperatures, a period of high oxidation rate that diminishes with time to a low value. The plateau region is interrupted, however, by short periods of increased oxygen consumption, which are associated with small protrusions of SiO(c) found in the oxide film on cooling and identified by x-ray diffraction analysis. Figure 3 shows the total oxygen consumption *vs.* time curve constructed by integration of the experimental rate curve, part of which is reproduced in Fig. 2. The small irregularities apparent in the rate curve are not seen in the integrated plot. However, in both figures it is clear that the oxidation rate drops rapidly to a low value, rises sharply, and then drops once more, as the protective oxide film is ruptured by evolution of SiO(g) and then heals. As the experiment continues, repetitions of this process occur. At similar temperatures and oxygen partial pressures, Mo_3Si and Mo_5Si_3 do not display this behavior (Fig. 1a and 1b), probably, as discussed below, because of the lower activity of silicon in the alloys.

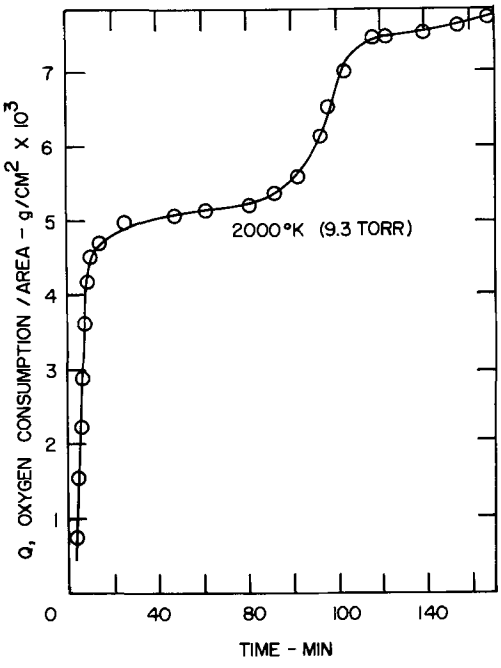

Fig. 3. Oxygen consumption vs. time curve for $MoSi_2$ under conditions leading to film rupture.

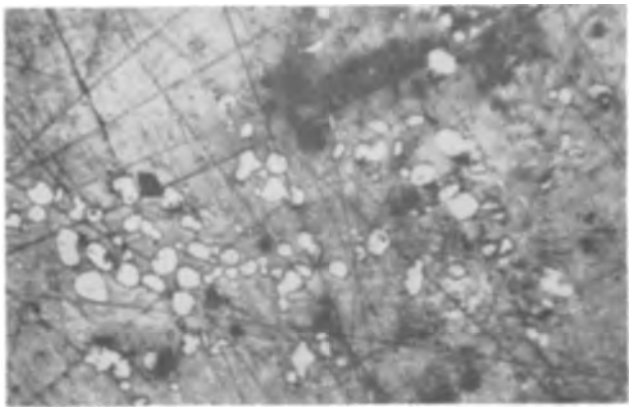

Fig. 4. Photomicrograph of Mo_3Si surface prior to oxidation. Magnification 60X.

At temperatures below 1970°K and oxygen partial pressures near 2 Torr the oxidation of $MoSi_2$ is linear, and no decrease in the oxidation rate occurs even when the total oxygen consumption exceeds the high-pressure asymptotic value for the given temperature. In one experiment conducted at 1950°K and oxygen partial pressure of 1.6 Torr, linear oxidation was allowed to proceed for an hour, after which the oxygen partial pressure was raised to 13 Torr. The oxidation rate decreased immediately, and the customary final plateau region described above was observed.

Oxide film examination.—Specimens oxidized in the temperature range 1300°-1970°K as described above were subjected to optical examination and electron probe microanalysis. Figure 4 is a photomicrograph of a typical sample of Mo_3Si prior to oxidation. The distribution of round second-phase inclusions of the α-solid solution of silicon in molybdenum is to be noted. Figure 5 shows a cross section of a similar sample after oxidation at 1860°K at an oxygen partial pressure of 10 Torr. A smooth gray outer oxide and a partially oxidized inner layer can be seen. It is also observed that the α solution phases available in the original material are enveloped by oxide, indicating significant diffusion of oxygen into the bulk silicide. Thus the terminal solid solution served as an inert marker as it was not oxidized. Another area of this

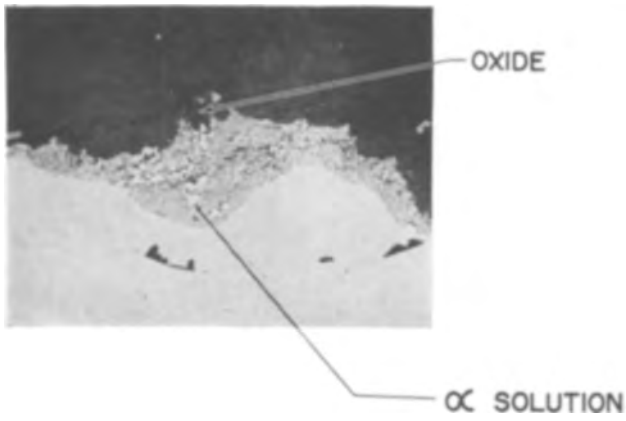

Fig. 5. Photomicrograph of a cross section of Mo_3Si after oxidation at 1860°K and 10 Torr. Magnification approximately 90X.

oxidized specimen is shown in Fig. 6. Figure 6a is an optical micrograph of the oxide film; Fig. 6b is a back-scattered electron micrograph of the same field of view. In such a micrograph, areas of higher density appear light due to the larger electron backscattering coefficient of these areas. It is observed that the outer oxide is less dense than the original silicide and that the inner oxide consists of phases which are more and less dense than the silicide. Figures 6c and 6d are SiKα and MoLα x-ray micrographs of the same field of view. In Fig. 6c, areas of high molybdenum content are dark and areas of high silicon content are light; in Fig. 6d the situation is reversed. Thus, the outer layer is a region of high silica concentration; the in-

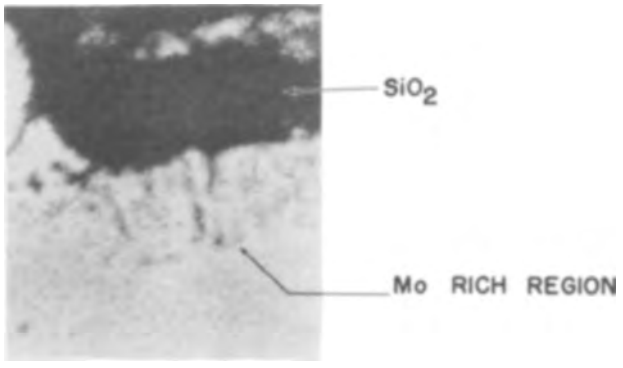

Fig. 6d. X-ray micrograph taken with MoLα radiation

ner oxide layer consists of areas of high molybdenum content and areas of high silicon content. In addition, a narrow region of high molybdenum content separates the unoxidized silicide from the oxidized layers.

Quantitative analyses of the various oxide products were achieved by a series of static beam analyses. The results, presented in Table I, show that the outer oxide is SiO_2 containing less than 0.1% molybdenum. To confirm this observation, oxidized samples were annealed overnight at 1370°K in an argon atmosphere; it was observed by x-ray diffraction techniques that the outer oxide layer was transformed to β-crystobalite. Due to the irregularity of the inner oxide region, exact chemical analyses of the phases were not possible; however, the silicon-rich areas contained less than 2% molybdenum, and the molybdenum-rich areas were at least 95% molybdenum. It appears therefore that the inner oxide consists of SiO_2 and terminal solid solution molybdenum phases. The narrow region of high molybdenum content observed between the unoxidized silicide and the oxide layers contained from 96 to 100% molybdenum and is the terminal solid solution molybdenum phase.

A cross section of an Mo_5Si_3 pellet after oxidation at 1890°K in an atmosphere with an oxygen partial pressure of 5 Torr is presented in Fig. 7. Again a smooth gray outer oxide and an inner partially oxidized region was observed. It is noted that the oxide bridges across the top of cracks that intersect the surface to the same depth as in the surrounding alloy. This is an example of the self-healing tendency of the oxide which contributes to the low oxidation rates of all the molybdenum silicides. Electron probe microanalyses of the oxidation products show that the same type of reactions occur in both the Mo_5Si_3 and Mo_3Si specimens. The outer oxide is SiO_2; the inner oxide region consists of SiO_2 and molybdenum-rich phases, including terminal solid solution molybdenum phases. Mass balance is preserved by the existence of a molybdenum gradient across the alloy/oxide interface.

The oxide developed on $MoSi_2$ specimens was too thin to allow electron probe microanalysis to be performed; however, it is probable that the oxidation products are similar to those observed on the lower silicides.

of the component elements. Preferential oxidation of one constituent may occur for thermodynamic or kinetic reasons. The free energies of formation of $MoO_3(g)$ and $SiO_2(c)$ at 1500°K are −95 (18) and −154 (19) kcal/mole, respectively. Thus, although molybdenum is somewhat more noble than silicon, both oxides are sufficiently stable so that neither can be excluded on thermodynamic grounds. $MoO_2(c)$ with a free energy of formation of −77 kcal/mole (20) at 1500°K and $SiO(g)$ with $\Delta F_{f,1500} = -52$ kcal/mole (19) are also thermodynamically possible products.

The work reported above established that the outer solid oxide layer formed on the molybdenum silicides is pure SiO_2, containing not more than 0.1% molybdenum. In addition, at the end of every oxidation experiment, $MoO_3(c)$ was found condensed on the cool walls of the reaction chamber. It is therefore suggested that the principal products of oxidation of molybdenum silicides in the 1300°-2000°K range at oxygen pressures around 10 Torr are a volatile molybdenum oxide and $SiO_2(c)$. While extrapolation of mass spectrometric data on the products of oxidation of molybdenum at low oxygen pressures (21) suggests that under the conditions of the present experiments the vapor might be expected to contain $MoO_3(g)$, $(MoO_3)_2(g)$, and $(MoO_3)_3(g)$, the precise vapor composition is not important to the subsequent discussion, and for simplicity, the molybdenum species will be assumed to be $MoO_3(g)$.

Oxidation behavior.—The specific oxidation behavior observed in these tests is determined by kinetic considerations. On the basis of the data presented, it is possible to outline the phenomena involved in the oxidation of the molybdenum silicides. Let us first consider the behavior of specimens oxidized below 1970°K at high oxygen partial pressures. In the initial period of rapid linear oxidation rate, we postulate that $MoO_3(g)$ and $SiO_2(c)$ are formed simultaneously in proportion to the concentrations of molybdenum and silicon in the alloy surface. $MoO_3(g)$ should evaporate as rapidly as it forms, while $SiO_2(c)$ should nucleate and grow on the silicide surface. The growth of $SiO_2(c)$ will decrease the surface area directly available for reaction with the atmosphere and therefore the rate of oxygen consumption will diminish with time. At the temperatures of the present experiments, the SiO_2 will flow and eventually form a continuous protective layer. Subsequently, the rate of oxidation will be determined by diffusion through this barrier and will be negligible. As temperature is increased, flow of the SiO_2 occurs more rapidly; the resultant decrease in the exposed silicide surface area limits the total oxygen consumption.

Once a continuous layer of silica has formed, subsequent oxidation can continue only by diffusion of reactive components through the film barrier. It is clear from the very low final rates of total oxygen consumption observed and from the electron probe results that vaporization of MoO_3 cannot continue once a protective film of $SiO_2(c)$ has formed. If $MoO_3(g)$ evolved at the $SiO_2(c)$-alloy interface below 1970°K, it would rupture the silica film, and irregularities would be seen in the oxygen consumption rate curves as the protective film was broken and healed. Such periodic increases in oxidation rate were not observed at these temperatures. At the $SiO_2(c)$-gas interface, $MoO_3(g)$ could only form if molybdenum migrated from the alloy through the silica film. In this case molybdenum should have been detected in the outer oxide film. No molybdenum was detected in the oxide; in addition, the alloy immediately adjacent to the oxide layer was distinctly enriched in molybdenum compared to the bulk alloy.

In fact, the metallographic results indicate that the oxide layer grows at least in part by inward diffusion of oxygen. The electron probe results show that silicon is oxidized preferentially at the oxide-terminal solid solution interface, and that successive layers of increasing molybdenum content are produced between the bulk alloy and the oxide. The stability of a high molybdenum content phase between the bulk alloy and the oxide suggests that the oxygen activity at the alloy-oxide interface is very low. It is therefore likely that inward diffusion of oxygen through silica and outward diffusion of silicon through the alloy and molybdenum-rich phases occur to a significant extent during the final stage oxidation.

The process occurring in the plateau region of the curves in Fig. 1-3 is postulated to be oxidation of silicon at the silicide/oxide phase boundary. The rate-controlling step in this region might be either the rate of diffusion of oxygen through $SiO_2(c)$, diffusion of silicon through the terminal solid solution, or the chemical reaction at the phase boundary.

It is difficult to determine the exact rate-controlling process. The activation energy for permeation of oxygen through vitreous silica at 1200°-1350°K is about 20 kcal/mole, and the diffusing species is thought to be molecular oxygen (22). High-temperature oxidation experiments on silicon metal (23, 24) suggest an activation energy which is even higher, about 40 kcal/mole, and relates to motion of oxygen ions (25). The rate of oxidation of the molybdenum silicides in the final region is so low that it is difficult to determine an activation energy with any accuracy or to decide whether the reaction is linear or parabolic. Nevertheless, the activation energy does appear to be less than 20 kcal, and reactions at the silicide/oxide phase boundary and/or diffusion of the silicon through the terminal solution must be considered as possible rate-controlling steps.

Applying data of Norton on the migration of oxygen through silica to the present experiments, one may calculate the oxygen partial pressure at the terminal solid solution/oxide interface. At an ambient oxygen pressure of 12 Torr the effective oxygen pressure at the terminal solid solution/oxide interface, for a silica film thickness of 1 mm, would be less than 10^{-12} Torr at 1300°K and 10^{-10} Torr at 2000°K. Since the limiting film thickness for all of the molybdenum silicides is greater than 10^{-3} mm, the oxygen pressure at the interface is less than 10^{-7} Torr in every case. At this pressure, by extrapolation of the data of Berkowitz *et al.* (26), the rate of oxidation of molybdenum should be less than 10^{-10} g/cm²-min of oxygen at all temperatures. Silicon will thus be oxidized preferentially, but its low concentration at the interface under steady-state conditions will contribute to the low oxidation rates observed in the final plateau region.

On the basis of the above discussion it is possible to understand why some workers have observed net weight losses and others have observed net weight gains in the high-temperature oxidation of $MoSi_2$. The stoichiometric oxidation of a molybdenum silicide of formula $MoSi_x$ to $MoO_3(g)$ and $xSiO_2(c)$ would result in a net weight loss unless x were greater than three. Once a continuous film of $SiO_2(c)$ has formed, and possibly even before, silicon is oxidized preferentially and loss of molybdenum from the alloy ceases; hence a net weight gain becomes possible. The oxidation of the molybdenum-rich alloys, Mo_5Si_3 and Mo_3Si, always results in net weight losses. The oxidation of $MoSi_2$ can result in net weight losses or weight gains, depending on the molybdenum concentration at the surface, the surface topography, and the precise conditions of temperature, pressure, and flow.

Above 1970°K, at high oxygen pressures, the rate of oxidation of $MoSi_2$ was observed to increase markedly. Samples quenched from the high temperature were covered with brown protrusions, identified by x-ray as $SiO(c)$. The breakdown of the protective silica film has been ascribed (6) to the formation of $SiO(g)$ at the alloy-oxide interface by the reaction

$$Si(alloy) + SiO_2(c) = 2SiO(g) \qquad [1]$$

For silicon at unit activity, the equilibrium pressures of $SiO(g)$ calculated for reaction [1] are 3.6×10^{-1} Torr at 1500°K and close to 1 atm at 2000°K (19). At

the higher temperature, the pressure is sufficient to rupture the protective oxide film. The decreased silicon activity of the lower silicides, Mo_5Si_3 and Mo_3Si, should result in lower equilibrium SiO(g) pressures and hence in a silica film stable to higher temperatures. This was found by Fitzer (10) and in the present investigation.

At 1950°K at a low oxygen partial pressure, 1.6 Torr, oxidation was found to be linear, and a solid oxide failed to form on the surface of $MoSi_2$. This behavior may be explained by a mechanism first proposed by Wagner (26) in connection with the oxidation of pure silicon. The oxygen partial pressure may be considerably less at the solid surface than in the bulk gas due to a slow rate of diffusion across a boundary layer of gaseous SiO(g) formed via reaction [1]. Hence, the oxygen pressure at the surface may be insufficient to maintain a layer of SiO_2(c). The activity of silicon over the two-phase system $MoSi_2$-Mo_5Si_3 at 1960°K is about 0.1. The Wagner theory predicts that, under the experimental conditions described, an oxygen partial pressure of 20 Torr in the bulk gas is required for formation of SiO_2(c). Experimentally, a silica film was formed on an $MoSi_2$ surface at an oxygen pressure of 13 Torr but failed to form at 1.6 Torr, in excellent agreement with the theory.

Summary

Continuous measurements of total oxygen consumption *vs.* time were made for Mo_3Si, Mo_5Si_3, and $MoSi_2$ in the range 1300°-2000°K at oxygen pressures around 10 Torr. The results for all of the silicides investigated in this temperature and pressure range show an initial region of rapid linear oxidation, an intermediate region of declining oxygen consumption rate, and a final region of small oxidation rate.

In the initial period, SiO_2(c) nucleates and grows at silicide surface sites and MoO_3(g) evaporates as rapidly as it forms.

In the intermediate region of declining oxidation rate, the reactive surface area is decreasing due to the growth of SiO_2(c).

The final region is attained when a continuous layer of SiO_2 has formed on the alloy surface by growth and lateral flow. In the final region, silicon is oxidized preferentially at the alloy/oxide interface at a slow rate, which is controlled either by diffusion of the reactive components or by a phase boundary reaction.

The resultant outer oxide layer is pure SiO_2(c) containing less than 0.1% of molybdenum; mass balance near the surface of the silicides is preserved by the establishment of layers of increasing molybdenum content between the bulk alloy and the outer oxide.

Above 1970°K, at oxygen partial pressures of 10 Torr, an increased oxidation rate of $MoSi_2$ is encountered due to the formation of SiO(g) at the oxide alloy interface which causes rupture of the protective oxide.

Below 1970°K, at oxygen partial pressures near 2 Torr, the rate of oxidation of $MoSi_2$ is linear at all times since the oxygen partial pressure is insufficient to maintain a protective SiO_2 layer on the alloy.

Finally, it is important to note a significant difference between the oxidation of bulk molybdenum silicides and the oxidation of silicide coatings on molybdenum (27). The coatings are not in thermodynamic equilibrium with the metal, and silicon can diffuse away from the coating into the substrate, with a deleterious effect on coating performance (28).

Prevention of Oxidation in a Glow Discharge Environment with Sputtered Permalloy Films as an Example

Eric Kay

IBM San Jose Research Laboratory, San Jose, California

ABSTRACT

Problems associated with the elimination of significant amounts of oxygen inclusions in sputtered thin films grown in a plasma environment are discussed. In particular data are presented to show that a plasma environment can easily be produced in which the concentration of ground state, excited and ionic oxygen containing species is sufficiently low so that no discernible effects on the magnetic properties of sputtered Permalloy films due to antiferromagnetic inclusions can be detected. Experimental evidence is also given to show that neither the energy of bombarding ion species at the cathode nor the inevitable electron bombardment of the substrate need influence the inducement of a truly uniaxial anisotropy into the NiFe film provided independent temperature control of the film during its growth can be achieved. A comparison between d.c. and asymmetric a.c. as well as substrate biasing with respect to the plasma is made with particular reference to the substrate environment.

The presence of very small concentrations of oxygen in the environment in which a thin film grows has in the past more often than not been considered detrimental to the attainment of well controlled physical properties of the resultant film. This has been largely due to the fact that the theoretical significance of such small concentrations of oxygen incorporated, often in a structurally undefined way, in the thin film is difficult to ascertain.

More recently well controlled small partial pressures of oxygen in the film growth environment have been used to advantage. Herrick (1) has shown that intentional burial of oxygen gas in the film condensate during growth, estimated at 10^{19} atoms/cc, can greatly retard or even arrest the grain boundary motion in semiconducting CuI films. Recent examples (2, 3) of technological significance in the production of microcircuits might be the significant extension of sheet resistance per square while maintaining reasonably low temperature coefficients in refractory metal films by trapping small amounts of oxygen during film growth.

In studies of magnetic thin films very little has been reported on such deliberate introduction of very small concentrations of reactive species in the system during film growth. The significance of inadvertently incorporated impurity sites has, however, been the subject of numerous publications. Several authors have attempted to correlate the "inevitable" presence of small amounts of oxides in NiFe films to their magnetic behavior (4-8). In particular the explanation of magnetic properties of thin sputtered and evaporated Permalloy films as reported by Francombe (9) and Prosen (10) respectively invoke the presence of significant amounts of oxides as determined by electron diffraction. It is the purpose of this paper to show that oxidation of sputtered Permalloy films grown in a d-c glow discharge environment need not be a significant problem at any stage during film growth. Data will be presented indicating that neither the usual ultrahigh vacuum bakeout techniques nor deliberate high energy ion bombardment of the growing film during deposition, as first suggested by Frerichs' (11) asymmetric a-c sputtering technique for "oxygen free" film growth, are necessary to obtain uniaxial sputtered NiFe films with low coercivity, H_c, and magnetic anisotropy field, H_K. It will also be shown that such magnetic properties can be obtained independent of the cathode fall potential used in the discharge provided independent control of the substrate temperature is maintained.

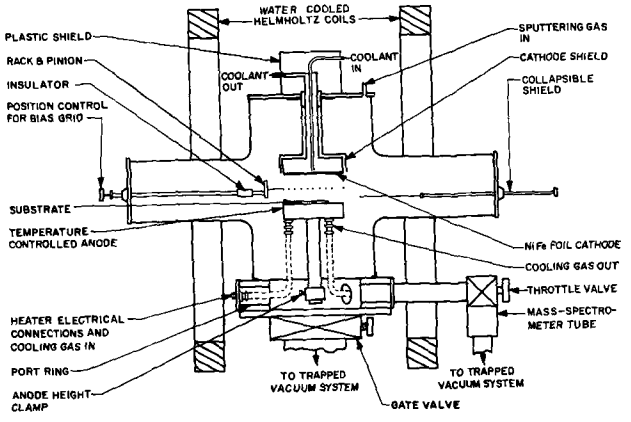

Fig. 1. Schematic of a d-c glow discharge apparatus

Experimental

The configuration of the glow discharge sputtering apparatus is shown schematically in Fig. 1. Ultrahigh vacuum facilities requiring time consuming high temperature bakeout procedures were deliberately excluded from our apparatus. Instead, a method of film preparation as described in detail in our earlier publication (12) involving inert gas ion bombardment of the entire apparatus, including the substrate surface, just before the NiFe deposition and continuous precleaned inert gas flushing was used as a means of reducing contaminants in the system. This precleaning approach was based on findings of atomically clean crystal surfaces obtained by ion bombardment in much more idealized systems (13), as well as promising results reported on glass by several authors (14-17) in a glow discharge system. An ultimate pressure of 1 x 10^{-7} Torr was routinely attained. Our mass spectrometer data were obtained using a Diatron 20 spectrometer tube which continuously monitored the effluent gases leaving the discharge chamber. The Diatron was operated at a 10^{-5} Torr level while the discharge chamber during sputtering was at a pressure in the 10^{-1} to 10^{-2} Torr region. The gas analysis runs were obtained with all the effluent gases going through the 2 in. mass spectrometer pumping system. The actual film preparation runs were made with all the gas going through the 4 in. pumping station right below the discharge chamber.

Most of the significant structural, chemical, and magnetic property changes occur during the first 2000Å

of film growth; which, therefore, was the thickness range in which most of our film measurements were made. Metal and glass substrate preparation and temperature control as well as standard magnetic property evaluation and actual discharge procedures were described in detail earlier (12).

The oxide content of the sputtered films was cross checked by several standard methods as follows. Reflection electron diffraction to distinguish film surface[1] oxidation from film bulk oxidation; high resolution surface replication using Pt-C replicas to allow correlation of the reflection diffraction data with the surface topography. High resolution transmission electron diffraction to check for film bulk oxide formation in excess of approximately 1% and transmission microscopy to observe the effect of possible oxidation on crystal shape, size, and continuity of the NiFe films.

A gravimetric microchemical method of film analysis was used for films which could not be stripped off the metal or glass substrates for subsequent transmission electron diffraction. A large body of experimental data indicated that an accurate total weight of the film can be more reliably and certainly more conveniently determined by the use of a Rodder quartz ultramicrobalance, than by an indirect method of film thickness and density measurement. The capacity of the microbalance is 200 mg. The sensitivity is 0.06 μg and the accuracy is ± 0.5 μg.

The accurately weighed films were dissolved in dilute HNO_3 and analyzed in solution by well-established spectrophotometric methods using o-phenanthroline for iron and 8-dimethylglyoxime for nickel. By comparing the amounts determined independently in this way with the total weight of the original sample, quantitative estimates of the purity of NiFe films could be made. The accuracy of this spectrophotometric method of analysis for Fe deteriorates when the sample weight is less than approximately 150 μg of which only 30 μg is Fe in an 80:20 NiFe sample. To check recovery for very thin films larger substrate areas and consequently larger film weights must be used.

In some cases the effect of positive ion bombardment of the growing NiFe film during deposition on subsequent magnetic properties of these sputtered films was examined. The positive ion bombardment to the exclusion of negative ion or electron bombardment was accomplished by inserting a bias grid as shown in Fig. 1. This grid was grounded and the entire substrate assembly biased negative with respect to the grid. Good temperature control during these film ion bombardment runs was possible only because the substrates were in excellent thermal contact with the entire temperature controlled anode assembly.

Results and Discussion

It has been well recognized that oxidation during film synthesis can occur in several stages. The first and most difficult to ascertain can be caused by the presence of oxidizing agents, such as adsorbed or dissolved gases on or near the surface of the substrate. The second stage can occur from bombardment of the film during deposition by oxidizing species, and the third stage could be oxidation of the film surface after deposition. All three of these oxidation possibilities have been invoked by several authors to account for deviations from the predicted behavior of pure NiFe films. These oxidation sources will be examined here, particularly as they pertain to a glow discharge environment as encountered in this work.

Oxidation at the substrate-film interface.—Substrate surface oxidation would be expected to reflect itself particularly during the very early stages of film growth. Our sputtered films less than 100Å thick which were occasionally successfully stripped off our glass substrates showed no evidence of oxide formation using high resolution electron diffraction as a criterion. This is in sharp contrast to Prosen *et al.* (10) results for their thermally evaporated "normal" NiFe films deposited onto glass substrates in a 10^{-6} Torr environment. They report finding an initial layer of about 100Å thickness consisting of αFe_2O_3 and $NiFe_2O_4$ as determined by electron diffraction. Their substrates were precleaned by ion bombardment (no details given). Also contrary to Prosen's findings our films could always be dissolved completely in 0.3M HNO_3 as determined visually as well as by ultramicrobalance weighings of the resultant substrate and comparing it with its original weight. Spin wave pinning experiments as described by Kooi *et al.* (18) are being considered as an additional analytical approach to establish the presence or absence of antiferromagnetic inclusions, *e.g.*, oxides at the substrate-film interface.

It should be remembered that during the initial stages of film deposition, in the argon d-c discharge environment, the dielectric glass substrate is immersed in the negative glow, and its surface will, therefore, float at a negative potential with respect to the plasma as soon as the substrate shielding arrangement is removed. Therefore, besides the deliberate high energy ion bombardment of the substrate before film deposition in which the anode table is temporarily made the cathode of the system, the film is again inevitably subject to low energy ion bombardment (2-3 ev) due to the negative space charge build-up at the dielectric glass surface as soon as it is exposed to the plasma to initiate film deposition. Judging from purity of our $<$100Å NiFe films, this low energy inert gas ion bombardment may remove weakly bonded contaminants throughout film growth. It certainly cannot be responsible for sputtering in the usual sense. Threshold energies for detectable momentum transfer sputtering are of the order of 20 ev.

Unquestionably the mechanism involved in this substrate cleaning procedure is quite different to the many more or less sophisticated chemical procedures described in the literature. The effective removal of surface contaminants on glass by chemical means is particularly complex because the chemistry involved is not clearly understood. The existence of dissolved gases, such as H_2O, CO_2, and O_2, has been reported by many authors. In addition, several authors (19) have postulated the existence of a silica gel layer of several thousand angstroms on the surface of glass. Some of the commonly used chemical "cleaning" reagents can be absorbed by this gel, and evidence exists (20) that the cationic components of glass can diffuse into this gel from below and react with the absorbed chemicals to form a surface, the composition of which is complex.

Low energy ion bombardment of the substrate in glow discharge environment must undoubtedly be included in any mechanism describing the well-established general observation that the substrate to metal film bond is much stronger for sputtered films than for similar films condensed onto glass substrates in a high vacuum environment. This stronger bond need not necessarily be accounted for by assuming an oxide layer at the interface, as has been suggested several times in the literaure.

Oxidation during film growth.—All our high resolution transmission electron diffraction patterns for thick films up to 1500Å could be accounted for entirely by fcc NiFe alloy as demonstrated by a typical example in Fig. 2a.

Since, in contrast to evaporated films, it is usually difficult to strip sputtered NiFe films off glass substrates, it was often unavoidable to get transmission diffraction data off carbon coated copper electron microscope grids which were placed next to the glass substrates. This is a commonly used practice and is sometimes justifiable from the point of view of crystal structure studies where an amorphous C film substrate can be assumed to be similar to an amorphous glass surface. However, it is well to remember the limitations of this practice when problems of oxidation are of interest. First, it is very difficult to say to what

[1] "Film surface" does not refer to a monolayer, since such can only be selectively analyzed by low energy electron diffraction techniques and not by "reflection" diffraction, as used here

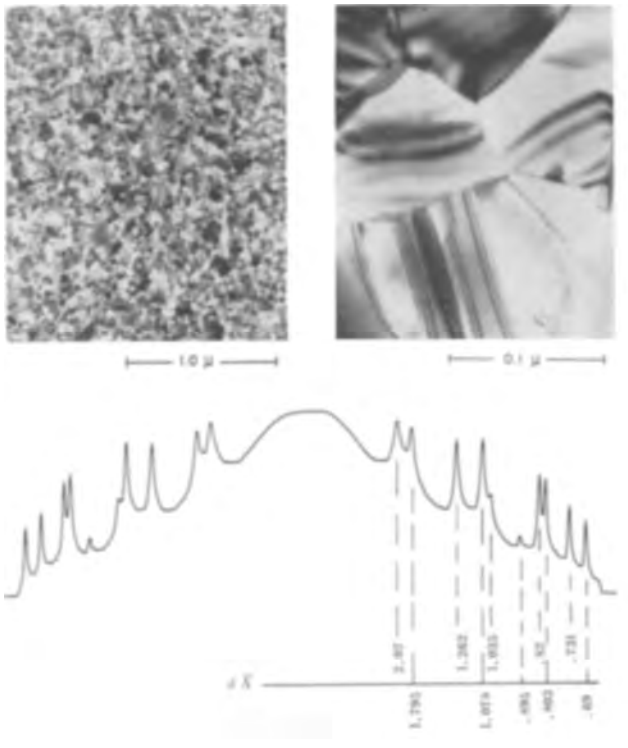

Fig. 2a. Typical transmission electron micrographs of a 700Å sputtered NiFe film made in a precleaned system showing continuous platelet structure at two magnifications, and a densitometer trace of the electron diffraction pattern of this film.

degree the surface temperature of a carbon film on a conducting Cu grid approximates the surface temperature of a dielectric, such as glass, when these are placed on an anode assembly immersed in a plasma. Second, the surface contaminants of glass cannot be assumed to be the same as those on a carbon film. Within these limitations, however, the transmission diffraction data from sputtered NiFe films on C should be indicative of the degree of oxidation or lack thereof during stage two; *i.e.*, oxidation due to reaction with oxidizing species in the plasma during film growth.

Since no oxide patterns developed in our films to film thicknesses up to 1500Å, we find our results again in conflict with diffraction results by Prosen who finds a stratified oxide composition throughout his thick films if prior to film deposition in a 10^{-6} Torr environment the glass substrate were exposed to a 10^{-3} Torr O_2 environment. Furthermore, on our thick films all of the film weight as determined with the ultramicrobalance was accounted for spectrophotometrically as Ni and Fe to within $\pm 1\%$, except in those cases in which the precleaning procedure was deliberately excluded. In these latter cases the electron diffraction data clearly showed oxide structure and the "gravimetric" Ni and Fe analysis showed less than 100% recovery of the original film weight. The electron micrographs of such films were discontinuous with large holes clearly visible as shown in Fig. 2b. As anticipated the coercivity in such films increased and the saturation magnetization decreased. No systematic magnetic study of partially oxidized NiFe films was made, since the aim in this work was to avoid oxidation.

Oxidation after film deposition.—Reflection electron diffraction patterns of many of the films examined during this study showed a complete absence of any oxide patterns. In view of the independently studied surface morphology of these films, these reflection diffraction patterns are interpreted as indicating that if surface oxides were formed either during examination of the film in the Kerr magnetic optic apparatus or during subsequent examination in the electron microscope then such oxides could only have been present as one or two monolayers or as amorphous oxides. If the latter were the case then the magnetic and microchemical data indicate less than 1% of amorphous surface oxide. Also, the lack of incoherent scattering contributing to the background of the reflection diffraction patterns suggests the absence of significant amounts of amorphous oxide (see Fig. 2c).

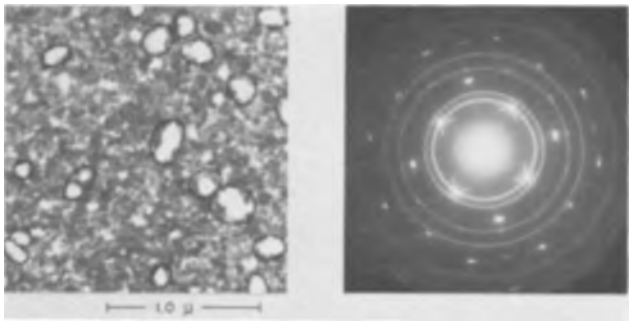

Fig. 2b. Transmission electron micrograph and electron diffraction pattern of 700Å sputtered NiFe film made in a "dirty" system. Circled areas are holes in the film.

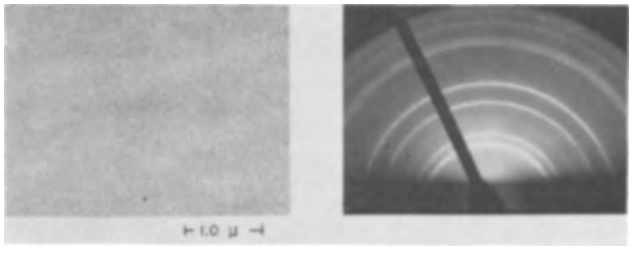

Fig. 2c. Pt-C replica and reflection electron diffraction pattern of a 700Å NiFe film made in a carefully cleaned system.

The absence of oxide structure together with the magnetic stability for many months indicates that surface oxidation was insignificant with respect to magnetic properties. As expected, every NiFe film which showed no evidence of any oxide formation also had exactly similar saturation magnetization values. Verification of this can be seen from the equal heights of the typical B.H. loops of films shown in Fig. 3, all three of which were of identical thickness.

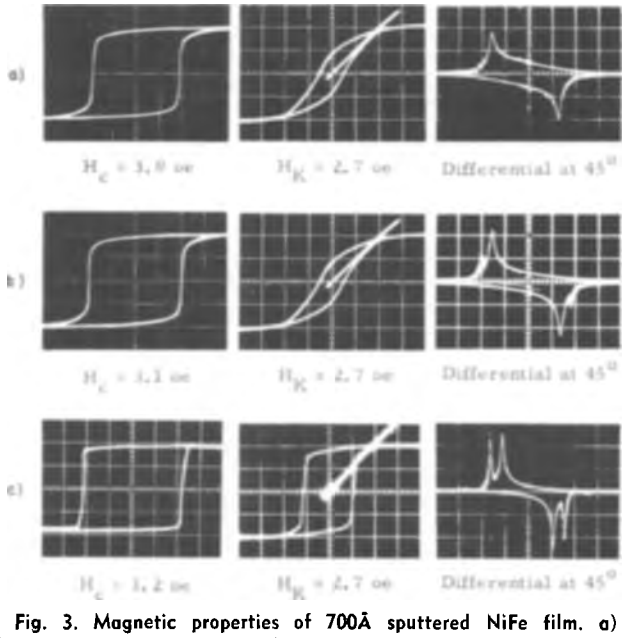

Fig. 3. Magnetic properties of 700Å sputtered NiFe film. a) Substrate at ground potential, cathode potential at —2000v. b) Substrate at —100v with respect to plasma, cathode potential at —2000v. c) Substrate at ground potential, cathode potential at —3500v.

From the results discussed so far it would appear that significant amounts of oxidizing species were not present in our glow discharge system during film growth. Monitoring the partial pressures of gas species as they leave the discharge chamber was used as a diagnostic technique to determine what types of gases were being created or removed from the vapor phase during consecutive stages of film preparation. It must be pointed out that this is not to be interpreted as an analysis of the actual species which exist in the plasma in the immediate vicinity of the growing film. It is well-known that a variety of relatively long-lived electronically excited, free radical and ionic species exist in various regions of the d-c discharge which would not show up as such in the exit gas of the discharge system. Knewstubb and Tickner (21) have recently shown that in an argon discharge in which water was estimated to be present at a partial pressure of 10^{-6} Torr, H_3O^+ is the only oxygen containing positive ion species that can readily be detected by mass spectrometry in the negative glow region. It is pertinent to note that the concentration of this particular molecule ion, like others, drops very sharply at different distances from the cathode, depending on the presence of small amounts of other impurity gases such as H_2. The mass spectrometric analysis by Lunt and Gregg ((22) on a 3 x 10^{-2} Torr oxygen d-c discharge further illustrates the point that different species exist in well-defined regions of the discharge. They found no negative ions in the negative glow region, yet 50% of the negative current carriers in the positive column were O^- ions. Our films are grown on substrates held in the negative glow region.

Mass spectrometric data presented in Table I clearly show that the amount of hydrogen leaving our discharge chamber increased by almost two orders of magnitude as soon as the discharge was initiated. Since the water signal only decreased by a factor of less than two, it is clear that the water decomposition in the discharge cannot account for the hydrogen increase. The decomposition of hydrocarbon in the discharge was considered a more likely mechanism whereby H_2 is produced because of the fact that methane fragments increased significantly as soon as the discharge was turned off. After lengthly pumping the CH_4 peaks fell to their original low value. These observations are tentatively interpreted as indicating that as soon as the discharge is turned on, low amu hydrocarbons are produced, some of which are further decomposed to H_2 and some are gettered by the walls and the film deposit. As soon as the discharge is turned off, the production of H_2 ceases and the gettered hydrocarbons are desorbed and show up as CH_4 in the exit gas. The 32 peak was barely detectable and remained essentially unchanged throughout. The mass spectrometer ion currents listed in Table I are uncorrected for relative ionization efficiency and pumping effects, etc., and can, therefore, be used only to determine the relative increase or decrease of the partial pressure of a given mass number during the various stages of film preparation.

Table I. Residual gas composition before and during sputtering in a dynamic flow system. All effluent gases through Diatron at 1 x 10^{-5} Torr. Sputtering chamber at 10^{-1} Torr argon.

amu	Diatron collector current, picoamps: Before sputtering	During sputtering	Directly after sputtering	Species
2	0.17	15.6	7.8	H_2
12	0.01	<0.01	0.03	C
13	0.01	<0.01	0.07	CH
14	0.15	0.03	0.18	N, CH_2
15	0.25	0.15	1.14	CH_3
16	0.09	0.14	1.29	CH_4, NH_2
17	0.42	0.18	0.23	OH, NH_3
18	1.8	1.1	1.0	H_2O
28	1.8	0.31	0.57	CO, N_2, C_2H_4
32	0.12	0.09	0.09	O_2
44	0.39	0.12	0.15	Organics

The degree to which the presence of H_2 and CH_4 during film deposition was responsible for the lack of discernible amounts of Fe-Ni-oxide must remain conjectural.

Effect of cathode fall potential and substrate biasing on magnetic properties of NiFe *films.*—It has been reported earlier that (23) low coercivity (<4 oe) sputtered NiFe films having a well-defined uniaxial anisotropy could not be prepared at ion energies ~ <3000 ev bombarding the NiFe cathode. Such was also our experience at the beginning of this study. Isotropic films with H_c values in excess of 10 oe were common on glass substrates. A more pronounced deviation from the zero magnetostriction composition leaving the cathode than that observed at 3500v (12) was considered a distinct possibility during the early stages of sputtering, which could account for the high H_c films. However, x-ray fluorescence analysis of NiFe films which were made at a cathode potential of 2000 ev in this laboratory showed no significant variation in the NiFe ratio throughout film growth and was equal to 4.0.

Two possibilities remained that had not previously been resolved which could account for high coercivity films. First, that in a 2000 ev cathode potential run electron bombardment of the substrate placed on the grounded anode does not raise its temperature sufficiently to get into the critical temperature region shown (12) necessary to obtain low wall motion threshold energies. Second, that although the physical location of the substrate with respect to the cathode was the same for these 2000 ev runs as for that previously reported at 3500 ev, the electron temperature profile along the discharge is significantly displaced at this lower energy. This could result in larger concentrations of reactive ionized oxygen containing species being formed in the immediate vicinity of the substrate where the film is growing, thereby increasing the possibility of introducing a more significant amount of antiferromagnetic inclusions in our films than was the case at 3500 ev. Two sets of runs were made to distinguish between temperature and increased ion concentration effects.

Any direct correlation between coercivity, H_c, at a given thickness and film temperature can only be ascertained unequivocally if the film temperature remains constant throughout the film growth. Large temperature profiles during film growth reflect themselves crystallographically especially in particle size and defect structure as demonstrated earlier (12). This in turn is related in different ways to the domain wall energy as one goes from thin films to thicker films, as discussed by Middelhoek (24) and can be expected to reflect itself in the H_c values.

With the use of a special substrate temperature control system to be described elsewhere, the substrate temperature was maintained within ± 1°C throughout film deposition. The temperature chosen was 350°C which was shown in our previous publication to be ideal for uniaxial anisotropy sputtered NiFe films. One set of experiments was run with cathode fall potential at 2000 ev and with the metal substrates held at ground potential and at a temperature of 350° ± 1°C. The resultant films had a well-defined uniaxial anisotropy and had low coercivity values. Typical magnetic data is shown in Fig. 3a. As can be seen these films were inverted, *i.e.*, $H_c > H_K$, and were similar to those prepared at 3500 ev, Fig. 3c.

All the high coercivity, isotropic NiFe films on glass which we obtained at the beginning of this study at cathode potentials of 2000 ev undoubtedly resulted from low substrate temperatures during film growth. Since independent temperature control of the substrate was not available at that time large temperature profiles from room temperature to several hundreds of degrees during a 100 sec run was the inevitable situation as originally described by Francombe *et al.* (9), who obtained magnetically isotropic films at low cathode potentials. From their data it is evident that at

2000 ev the temperature of glass substrates barely reached 200°C which is apparently inadequate (12) to induce a uniaxial anisotropy into these films.

In a second set of runs the effect of deliberate positive ion bombardment and rejection of negative ions from the film during deposition was examined. This was accomplished by biasing the entire anode assembly including the metal substrate 100v negative with respect to the grounded ring structure or grid which was introduced into the negative glow region above the "anode" assembly. We have shown previously (25) that this type of configuration rejects from the substrate most of the electrons and any negative ions which may be present. However, part of the positive ions which diffuse through the negative glow region will be continually accelerated into the substrate across this 100v gradient. The rest will drift toward the Crookes dark space and be accelerated into the cathode. A certain degree of analogy to Frerich's asymmetric a-c sputtering technique is obvious. The temperature of the substrate was again controlled throughout deposition at 350° ± 1°C. The structural and magnetic properties of the films prepared in this manner were essentially identical to those in the unbiased configuration (see Fig. 3b). We interpret this to show that the rejection of electrons and negative ions (if present) and bombardment by 100 ev positive ions on the growing NiFe film played no discernible role in determining magnetic properties in our system.

These data, therefore, suggest that low coercivity, H_c, and low anisotropy field, H_K, films having low dispersion of the easy axis direction of magnetization can be made in a d-c discharge at any voltage provided the critical substrate temperature is maintained throughout film growth and the oxidizing species in the discharge environment are minimized by appropriate precleaning procedures.

Manuscript received Jan. 27, 1964; revised manuscript received Jan. 4, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

Trace-Ion Diffusion in Molten Alkali Carbonates

P. L. Spedding and R. Mills

Diffusion Research Unit, Research School of Physical Sciences, Australian National University, Canberra, Australian Capital Territory

ABSTRACT

Tracer-diffusion coefficients have been measured for Na^+ and $CO_3^=$ ions in the pure Na_2CO_3 melt and of Na^+, K^+, and $CO_3^=$ ions in a eutectic mixture of lithium, sodium, and potassium carbonates. The open-ended capillary method was used for these measurements. In the Na_2CO_3 melt, agreement with the Nernst-Einstein equation is found at 910°C, but at 1050° there is a discrepancy of 22%. The experimental activation energies for diffusion of the ions in both the pure Na_2CO_3 melt and the eutectic mixture are the same within ±1 kcal.

In recent years the alkali carbonate melts have been studied extensively with regard to many of their physical and transport properties by Janz and coworkers (1-3). However, diffusion measurements in these systems are either scant or lacking. We have therefore instituted a program of tracer-diffusion studies and initially investigated two kinds of systems, the pure sodium carbonate melt and an eutectic mixture of sodium, potassium, and lithium carbonates.

The sodium carbonate system was chosen because tracer-diffusion measurements, in conjunction with existing conductivity data, allow both testing of the Nernst-Einstein equation and the calculation of friction coefficients. In addition, diffusion measurements previously reported in this system by Djordjevic and Hills (4) appear to be anomalous. The eutectic mixture of alkali carbonates was studied both from interest in the fundamental structure of eutectics and from its importance as an electrolyte in high-temperature fuel cells. With regard to this latter factor, it is possible that transport data of this type will be useful in evaluating sources of energy loss in actual fuel cell systems.

Experimental

Apparatus.—The apparatus, which is illustrated in Fig. 1, consisted of a furnace and its ancillary shields, enclosing a diffusion cell. The furnace, A, was capable

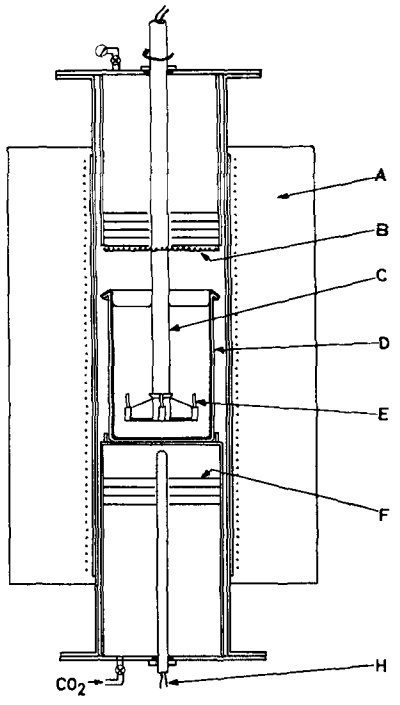

Fig. 1. Cross-sectional view of the furnace and capillary diffusion apparatus: A, furnace; B, auxiliary heater; C, hollow capillary holder containing measuring thermocouple; D, salt bath contained in a 80% Au-20% Pd lined stainless steel pot; E, capillaries; F, heat shields; H, sensing thermocouple for saturable reactor control.

of operation up to 1000°C and a saturable reactor-type control maintained the temperature of the diffusion zone in the furnace to within ± 0.3° at the 700°C point. The measuring thermocouple was calibrated to ± 0.2° up to 500°C with a platinum resistance thermometer, and also with the primary and secondary fixed points for S, Ag, Au and Zn and Al. Originally the furnace relied on the heat shields, F, to maintain the temperature vertically through the furnace, but it was found that at the higher temperatures this was not sufficient to prevent a negative temperature gradient being set up through the diffusion zone. This resulted in convectional currents in the capillaries, and to overcome this effect an auxiliary heater, B, was provided which enabled any desirable temperature gradient to be applied. The furnace was normally operated so that a positive gradient was just measurable. It was also found to be necessary to cool the saturable reactor core by means of a small fan to prevent slow temperature drifts particularly in the lower temperature range.

The diffusion cell consisted of a large bath of salt, D, into which the holder containing the diffusion tubes, E, could be lowered. The holder assembly, C, was capable of rotation so that the speed at the capillary mouth could be varied up to 325 mm/sec. In addition the holder could also be given vertical travel at a rate depending on its speed of rotation. At maximum rotation speed the vertical movement was 2 cm/hr. This provision was made to ensure that there was no build-up of radioactive material in the path of travel of the capillary mouth. Subsequently, tests showed this to be unnecessary so, for the majority of determinations, the holder was rotated in the one horizontal plane. In order to test for immersion effects, provision was made to open and close the capillary mouth by means of a sliding mechanism.

All metal components of the apparatus contacting the molten carbonate were made from palau: an 80% wt. gold-20% wt. palladium alloy. This alloy has been reported to be resistant to carbonate attack (1). Actual measurements at 1000°C for 94 hr have shown this alloy to be essentially unaffected by carbonate, despite the development of a blue-gray surface discoloration at between 350°-660°C.

The alloy diffusion tubes had thick walls both to provide sufficient mechanical strength to allow them to be handled by tongs without damage and also to impart sufficient thermal inertia to allow them to be transferred to the main furnace without solidification of the melt. The actual length of the capillaries (nominally 3.5 cm) was measured on a travelling microscope at 20°C and corrected to the temperature of the particular determination by using accurate thermal expansion data for the alloy (5).

Materials.—Analytical reagent grade lithium, sodium, and potassium carbonates were used for the salt bath and as a dilutant for the labelled material. The carbonates for the bath were dried at 120°C to constant weight before use whereas those for radioactive material dilution were melted under a carbon dioxide atmosphere and stored in a desiccator until use. The long-lived radioactive sodium carbonates were obtained from the Radiochemical Centre, Amersham, England; one being labelled with Na^{22} and the other with C^{14}. The short-lived Na^{24} and K^{42} carbonates were obtained from the Australian Atomic Energy Commision, Lucas Heights, New South Wales.

Procedure.—The diffusion tubes were filled in a small auxiliary furnace using a manually operated filling capillary and were then quickly transferred to the tube holder in the main furnace. The filling temperature was about 100°-200°C above the melting point of salt. The tubes were almost completely immersed and equilibrated for 3 hr under a positive carbon dioxide pressure. The temperature gradient was carefully controlled at the start of diffusion to ensure that the tube temperature was the same as the environment into which it was lowered. If the slide was used, it was run onto the top of the tube just before immersion and slowly removed immediately afterwards to give the start of the diffusion run. Normally, a medium-sized drop of radioactive salt on the top of the tubes was sufficient to minimize immersion effects at the start of diffusion. At the end of a diffusion run the temperature of the furnace was dropped to within 100°C of the melting point before removing the tubes from their holder for analysis.

The radioactive salt was removed from the diffusion tubes into aqueous solution by vibratory drilling. For Na^{22} diffusion the resulting solution was made up by weight in a counting vial and counted by standard techniques using a Franklin linear amplifier and a RIDL scaler. The C^{14} was counted with the same apparatus using standard liquid scintillation procedures. The scintillator solution used consisted of 1-4 dioxane as solvent and the following solutes: 50 g/l of naphthalene, 4 g/l of 2-5 diphenyloxazole and 0.1 g/l of 1-4-di-2-(5-phenyloxazole)-benzene. A 10 ml aliquot of this dioxane-scintillator solution was admitted to the counting bottle together with a 5 ml aliquot of the radioactive solution which had been made up to 25 ml in a volumetric flask.

The general design of the apparatus was initially tested by determining the diffusion coefficient of Na^{22} in 0.3M NaCl solution at 25°C. This work established first that there was no measurable difference between the use of a large drop of solution on the top of the diffusion tube or the use of the slide to minimize immersion effects. Second, it showed that there was need for tube-holder rotation, but that no measurable difference existed between rotation in the one horizontal plane or in a changing horizontal plane. The extension of these aqueous experimental conditions to molten salts is discussed later.

Auxiliary Measurements

Comparison with previous work.—As a check on the apparatus and procedure, the tracer-diffusion coefficient of Na^{22} in $NaNO_3$ was measured and compared with the values of Dworkin *et al.* (6). This system has

Table I. Diffusion of Na^{22} in $NaNO_3$ melt

also been used for checking by Angell and Tomlinson (7). As shown in Table I, our agreement with the above workers is good.

End effects.—Errors in diffusion measurements due to end-effects associated with the open-ended capillary method, have been the subject of much enquiry and discussion. Two sources of error are involved and are usually termed the "immersion effect" and the "Δl" effect. The nature of these effects has been described in detail by, among others, Mills and Kennedy (8), Wang (9), Berne and Berggren (10), and Angell and Tomlinson (7). It is fairly well established that the immersion error is negligible if a large drop of active solution remains on the capillary face just prior to immersion and if reasonably long times of diffusion are used. As these conditions pertained to this study, this type of error needs no further discussion. In aqueous solutions the Δl effect can be made negligible as a source of error. Mills (11) has shown that if a flow of liquid of controlled velocity (in the range 1-3 mm/sec) was passed over the capillary faces in his apparatus then the measured diffusion coefficients coincided with those accurately determined with the diaphragm cell. It was concluded from this that the effect must be minimized under these conditions. In molten salts, there are no independent data against which a flow rate can be tested to give the magnitude of the Δl effect. In consequence, two indirect approaches to the treatment of the problem can be distinguished.

In one approach, an attempt is made to select flow conditions (usually by rotation of the capillaries in the melt) under which the Δl effect will be minimal. A flow rate approximately in the region 1-3 mm/sec as specified by Mills (11) for aqueous solution has been used by some investigators (6, 7). It will be realized of course that this flow rate will give conditions which will vary with such parameters as the capillary dimensions and the fluid viscosity so that the Reynold's number is the more basic consideration. Fortunately in many of the above cases, the geometry of the system and the physical properties of the molten salts have given Reynold's numbers overlapping the range used by Mills (11). The approach can be criticized in the respect that conditions applicable to aqueous solutions do not necessarily apply to molten salts even with identical Reynold's numbers. Experimental control of temperature and flow are much less rigorous in the latter case. However, the absence of end errors greater than the over-all experimental error has been verified by using capillaries of differing lengths or by using different diffusion times (6, 7). The two errors are comparable (±1-3%) so that studies where the Δl effect is not recognizable serve to put an upper limit on its magnitude.

The alternative approach adopted by Bockris and co-workers (12, 13) has been to find a plateau in the rotation rate *vs.* diffusion coefficient curve (usually at higher Reynold's numbers than those used above), employ a flow in this region and then estimate the Δl produced and correct for it. In these studies, the effect has been related to physical parameters by an empirical equation established for aqueous dye solutions. Use of this formula in molten salts is criticizable for the same reasons as the approach above. A more serious criticism is that rather large corrections of unknow accuracy may be involved, of the order of 10-20%, which affect the accuracy of the corrected experimental values correspondingly.

In this study we have adopted the first approach and used low flow rates of 1-3 mm/sec. (Reynold's numbers 5-16). This procedure will give, in our opinion, in the final analysis, the more accurate diffusion coefficients. As a first test of the apparatus, studies were carried out in aqueous solution using a dye system. Flow rates below Re=5 allowed a definite build-up of material at the tube mouth while rates above Re=16 disturbed the solution at the trailing edge of the capillary mouth within the observed boundary layer. Further studies were carried out using Na^{22} trace-ion diffusion in an aqueous 0.3M NaCl solution as the calibrating system. It was found that within the above flow conditions the measured coefficients were on an average within 0.6% of the diaphragm cell values (11). As the flow rate was increased beyond this range the measured coefficients increased steadily. Trace-ion diffusion of Na^{22} in the molten carbonate eutectic at 685°C showed that the coefficients varied in a more pronounced way with flow rate. The measured diffusion coefficients rose sharply by 7% from nonstirred to stirred conditions (Re=5-16) and then continued to rise slowly with increasing flow rate until at Re = 140, it increased by a further 5.3%. Measurements in the chosen flow rate range (Re=5-16) with tubes of different lengths gave the same diffusion coefficients within the usual experimental errors. It seems apparent therefore that under these flow conditions the Δl effect will be minimal.

Diffusion coefficients were determined also for sodium ion in the eutectic at several different temperatures using tubes of different diameter. Tubes with diameters of 1.0 mm or below gave virtually identical results and were therefore used for all determinations.

Isotope effects.—The qualifying assumption is made when determining diffusion coefficients using isotope tracers that there is no observable isotope effect. This was checked by determining diffusion coefficients in the carbonate eutectic during the same run, using Na^{22} and Na^{24} tracers (Table II).

There is obviously no difference observable above experimental error among the diffusion coefficients. The Na^{22} (calculated) figures are taken from the equations in the main body of the results.

Expansion coefficient.—Practically no data exist for the thermal expansion of the 80% gold-20% palladium alloy. Values were therefore determined up to 1000°C using standard techniques (5) (Table III).

Dissociation pressures.—In order to ensure that the composition of the carbonate melts remained constant they were maintained under carbon dioxide at a pressure well in excess of their respective dissociation pressures. The actual dissociation pressures were determined using a static method and in the case of sodium

carbonate they were in reasonable agreement with previous workers who used this method (14, 15) (Table IV).

Results

Tables V and VI list data for tracer-diffusion of various ions in the two melts investigated. The constants in the equations were calculated by the method of least squares (16). Figure 2 illustrates how the diffusion rates of the ions compare in the pure melt and in the eutectic.

Discussion

Examination of Figure 2 shows that in both media the smaller the individual ion the higher its diffusion rate. It may also be noted that the effect of the eutectic is to slow down the $CO_3^=$ ion but speed up the Na^+ ion.

Trace-ion diffusion data for the pure Na_2CO_3 system together with the values of Djordjevic and Hills (4) are reported in Table V. There are large discrepancies between the two sets of values. However, the fact that

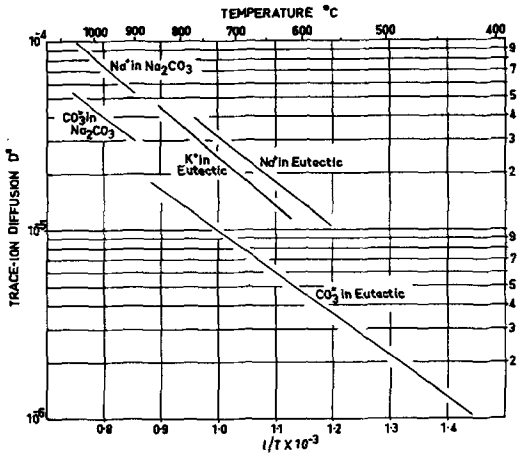

Fig. 2. Tracer diffusion coefficients of Na^+ and $CO_3^=$ in pure Na_2CO_3 and of Na^+, K^+, and $CO_3^=$ in the ternary eutectic plotted against the reciprocal of the absolute temperature.

in our study the diffusion rate of the small cation is greater than that of the large anion, as well as a much better correlation with the Nernst-Einstein equation would lead to the assumption that the open-ended capillary values are more correct.

The Nernst-Einstein equation for Na_2CO_3 is of the form

$$\mu_{Na_2CO_3} = (2F^2/RT)(D^*_{Na^+} + D^*_{CO_3^=}) \quad [1]$$

where μ is the molar conductance. This equation can be used to calculate values of μ at various temperatures, and these can then be compared with the experimental values from conductance studies. We have used the data of Janz and Lorenz (1), and the temperature variation of the observed and calculated molar conductances are shown in Fig. 3. Previous investigators have found that values of μ calculated from tracer-diffusion data are generally greater (10-40%) than those obtained from conductance studies. It has also been found that the deviation becomes smaller as the temperature decreases. In our study the deviation at 1050°C is +22% and with decrease in temperature it reaches zero at 910°C and −2% at about 900°C. The reality of the negative deviation at 900°C is questionable as the compounding of errors by the addition of the diffusion coefficients, would give a maximum total error of several per cent in the calculated values. It is tempting to attribute this negative deviation, if real, to the Bardeen-Herring correlation factor (17) which has been applied to the corresponding calculation in ionic solids. However, the application of

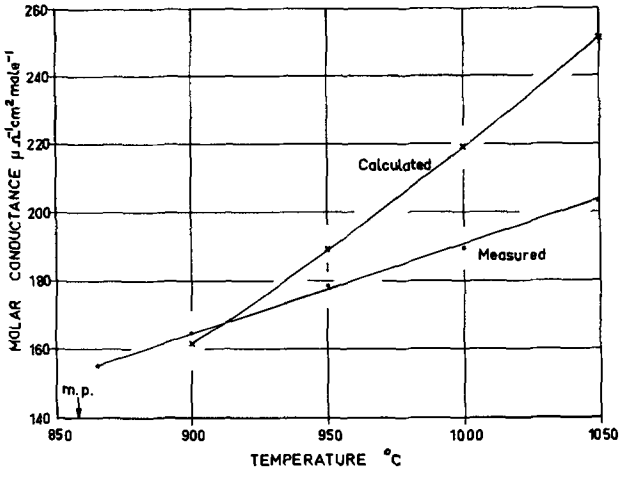

Fig. 3. Molar conductance of Na_2CO_3 as measured by Janz and Lorenz (1) and as calculated from the Nernst-Einstein equation using the measured tracer diffusion coefficients.

such a concept about 42° above the melting point is very arguable.

An explanation advanced for the positive deviation of conductances calculated from tracer-diffusion data is the presence of ion pairs or neutral molecules in the melt. Janz and Lorenz (3) have recently summarized evidence for the existence of ion pairs of the form $[M^+CO_3^=]^-$ in alkali carbonate melts. If such ion pairs move as a kinetic unit, they could act as a vehicle for the movement of the tracer species but because of the masking of charge, contribute little to conductance. However, Janz and Lorenz (1) suggest that rotation of such ion pairs as in a Grotthus-type mechanism may be the rate-determining process in conduction. We would expect that such a mechanism should be equally effective in promoting tracer-diffusion. The temperature dependence of the deviation from the Nernst-Einstein equation could then be explained by postulating that at lower temperatures the rotational mechanism of transport is predominant. As conduction and tracer-diffusion are equally affected the Nernst-Einstein equation is obeyed. With increasing temperature, the translational mode becomes more important, favoring tracer-diffusion so giving the observed positive deviation.

An alternative method of treating conductance and diffusion data is to calculate the friction coefficients for interaction among the various species. The basic formulations for this type of description have been given by Klemm (18) and Laity (19).

In Table VII, we give a summary of these friction coefficients at four temperatures and for comparison the values for $NaNO_3$ as calculated from the data of Van Artsdalen *et al.* (20) by Djordjevic and Hills (4). A fairly close correspondence at the lower temperatures between the values for $NaNO_3$ and Na_2CO_3 is evident. Plots of $d \ln r/d\ 1/T$ are found to be linear as has been similarly found for $NaNO_3$ by Laity (19). However, it seems that little information can be gleaned from this approach at the present stage.

A more informative approach is to compare the experimental activation energies for the various transport processes both in the pure Na_2CO_3 melt and the carbonate eutectic mixture. These are shown in Table VIII.

Examination of Table VIII shows that the experimental activation energy for viscous flow in pure Na_2CO_3 ($E_{vis} = 25.7$) is much larger than that for conductance ($E_\Lambda = 4.23$). Such a difference is usual for molten salts although this case is one of the most marked examples. The qualitative explanation which is normally offered to explain these differences is that in conduction, the current is carried mainly by the small ions, (Na^+ in the case of Na_2CO_3), which can migrate through the lattice without appreciable disturbance and thus have an associated low activation energy. In viscous flow on the other hand the observed high activation energy is attributed to the necessity to displace the large anions relative to one another. However, the activation energy for tracer-diffusion for the $CO_3^=$ ion ($E_{D^*CO_3^=} = 12.2$) is much lower than E_{vis}, and yet in the diffusion process these large anions must again be displaced. The first salient fact that we must seek to explain therefore is the high value of E_{vis} for pure Na_2CO_3.

It is suggested that the high value of E_{vis} is due to an additional factor which affects viscous flow to a much greater degree than the other transport processes. Most models of molten salts assume that their chief structural characteristic is the existence of interpenetrating anion and cation lattices which do not have the long-range order of the crystalline state, yet are sufficiently real to the extent that each ion has, on the average, more nearest neighbors of opposite than of its own charge. When a velocity gradient is imposed on an ionic liquid the associated shearing force has to distort this lattice, and there will therefore be a restoring force opposing flow. There will therefore be an electrostatic increment added to the viscosity and in this respect the effect is distantly analogous to the Falkenhagen effect in dilute electrolytes. The effect would also be greater for multiply charged ions. In the eutectic however, where E_{vis} is only 10.7 kcal/mole, the presence of three ions of widely different size would distort the lattice considerably so that the required shearing force is much less. The much lower values of the activation energies for conduction and diffusion can then be attributed to the ability of the ions to migrate through the lattice without appreciable disturbance.

A second point of considerable interest in Table VIII is that the activation energies for diffusion of anions and cations both in the pure Na_2CO_3 and in the eutectic are all very similar. This is in accord with nearly all other tracer-diffusion measurements in molten salts. One conclusion that can be drawn from this practical equivalence is that some sort of cooperative act is involved in the diffusion process. The coupled-vacancy concept suggested by Borucka, Bockris, and Kitchener (21) is one possibility. The predominant diffusing species for Na_2CO_3 could then be the $[Na^+CO_3^=]^-$ ion pair whose existence was postulated by Janz and Lorenz (3) and which has already been invoked above to explain deviations from the Nernst-Einstein equation. On this model, the low value for E_Λ could then be explained in terms of a predominant contribution to conductance of the migration of free Na^+ ions.

Although the explanations offered above give an approximate qualitative accord with the observed data, there are obvious points of criticism. For example, the movement of free Na^+ ions would also contribute to tracer diffusion, and one might therefore expect the over-all activation energy, for diffusion of Na^+ ions to be less than that for $CO_3^=$ ions. In fact $E_{D^*Na^+}$ is slightly higher than $E_{D^*CO_3^=}$. It should also be emphasized that these experimental activation energies in Table VIII which are obtained from plots of experimental data are not necessarily equivalent to the theoretical activation energies, such as for instance given by Eyring's rate process theory, and caution must be used in interpreting the smaller trends among them.

Attention has also been drawn to the fact that the equivalence of cation and anion experimental activation energies in tracer diffusion is in accord with the theory of Cohen and Turnbull (22). The basic concept of this theory as far as diffusion is concerned is that

molecular transport occurs by the movement of molecules into voids, with a size greater than some critical value, formed by the redistribution of free volume. Although originally intended for simple molecular liquids, it has been found to be applicable also to molten salts. The equation of interest in this context is

$$D^* = ga^*u \exp \frac{(-\gamma v^*)}{(\bar{v}_m \alpha T)} \quad [2]$$

where g is a geometric factor, a^* the approximate ionic diameter, u the gas kinetic energy, γ a numerical factor to correct for overlap of free volume, v^* the critical void volume, $\bar{v}_m$ the mean molecular volume, and α the coefficient of thermal expansion. It is readily seen that

$$\frac{E_{D^*}}{R} = \frac{\gamma v^*}{\alpha \bar{v}_m} \quad [3]$$

Lunden (23) has stated that $\gamma v^*/\alpha \bar{v}_m$ is fairly close to unity for both anion and cation for all halides and nitrates which are nearly completely ionized. It is probable that similar considerations apply to the alkali-metal carbonates.

Acknowledgment

Grateful acknowledgment is made to the Reserve Bank of Australia for a grant for fuel cell research, part of which has been used to finance the above study.

Manuscript received Dec. 7, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

The Coverage of Platinized Platinum Electrodes with Simple Organic Species

P. R. Johnson[1] and A. T. Kuhn

Chemistry Department, University of Pennsylvania, Philadelphia, Pennsylvania

ABSTRACT

The adsorption of formic acid, formaldehyde and the "reduced CO_2" species on platinized platinum electrodes was studied. A simultaneous determination of the number of coulombs and the number of chemical equivalents involved in the reduced CO_2 species, showed it to be a two-electron reduction product. Analysis of the solution failed to reveal any desorbed products.

Of the many possible methods available for the measurement of adsorbed species (1) on the surface of an electrode, one first described by Pavela (2), was used in this work. Although this method (which is described below) has certain inherent limitations and involves certain assumptions, it is simple to use where it is applicable.

In this method, the electrode at open circuit is immersed in the electrolyte containing the adsorbing species. After a period of time, it is withdrawn, rinsed with distilled water, and replaced in another cell containing a similar electrolyte. Galvanostatic transient measurements may then be made without any danger of readsorption from the bulk of the solution during the measurement period. The limitations of the method are mainly that it can be used to measure adsorption only at the open-circuit potential. Several objections to the method are listed by Breiter (3). The results of this author (4), however, indicate that at higher adsorbent concentrations certainly, results obtained by Pavela are in excellent agreement with those obtained by galvanostatic or potentiostatic transient methods. A further objection to the method, which does not appear to have been previously made, is the possibility of oxidation of the adsorbed material, either directly by the oxygen in the air, or by a simultaneous anodic and cathodic process, in which the oxygen is electrochemically reduced. In spite of all these objections, the work of Breiter cited above, and certain of the measurements described below, indicate that the method is a valid one.

The purpose of the work was threefold. First, it was felt that only by a simultaneous correlation of coulombs and chemical equivalents of CO_2, could the reduced CO_2 species recently described by Giner (1), be better characterized. Second, working with formic acid, it was hoped to confirm a recent result of Breiter (4), in which he shows formic acid adsorption to be both one and two site in nature. Last it was felt

[1] Present address: O. M. B. Werke, Trottheim-Weser, Germany.

that some knowledge of formaldehyde coverage might be useful.

The only recent references in the literature concerning the reduction of CO_2 are due to Van Ryssselberghe (5) and Jordan (6). However, both of these workers used mercury electrodes and very high cathodic overpotentials. That the former of these two authors reported almost quantitative formation of formic acid from CO_2 under these conditions may or may not be relevant to the experiments described here, which were all done on platinum electrodes at potentials close to zero on the N.H.E. scale. Cohen and Jahn (7), however, reported (in a very early work) traces of formic acid with a large number of different electrodes including platinum.

Experimental Technique

The cell used in this work was a conventional three compartment cell, with the counterelectrode separated from the working electrode compartment by a fine glass frit. The reference electrode was the "dynamic hydrogen" electrode, recently described by Giner (8). All quoted potentials are in the same solution. The supporting electrolyte was $2N$ H_2SO_4, and all measurements were made at 25° ± 1°C except when otherwise stated. The working electrode consisted of two superimposed circular disks of platinized platinum gauze, 55 mm in diameter. The potential scans were made with a Wenking potentiostat, at the rate of 90 mv/min. Current was recorded on an Esterline Angus recorder.

Results

The first set of experiments was designed to test the validity of Pavela's method. The reduced CO_2 was formed on the electrode in the manner described by Giner (1), by holding the electrode potentiostatically at 0.0v for 15 min while passing CO_2 through solution. After formation, the species was anodically oxidized with the potential sweep, both with and without transfer and washing of the electrode. During the oxidation, a stream of prepurified nitrogen was passed through the electrolyte. In both cases, an oxidation peak was observed at 650 mv. The number of coulombs under the peak was measured, having first subtracted the small but measurable current recorded in a blank run where no reduced CO_2 was formed. The area under the peak was found to be 8.57 coulombs, ±0.4 coulombs, irrespective of whether the electrode had been washed and transferred or not. The appearance and shape of the peak were identical in both cases. It was felt that these results constituted a test of the method, and that its further use was justified.

Reduced CO_2 species.—The procedure used here was to alternate two types of experiments. In the first case, having formed the reduced CO_2 in the manner previously described, the electrode was transferred and

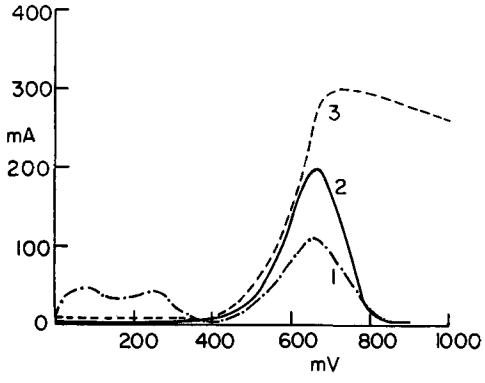

Fig. 1. Current-voltage scans following transference and rinsing of the electrode. Curve 1, Reduced CO_2; curve 2, formic acid 1M; curve 3, formaldehyde 1M; scan rate 90 mv/min; $2N$ H_2SO_4.

washed and placed in a cell containing $2N$ H_2SO_4. The 90 mv/min potential scan was then applied, the current being recorded. In the second case, having formed the reduced CO_2 species, the electrode was transferred to a cell containing 50 ml of $50N$ NaOH. It was found simpler, in this case, to perform a galvanostatic oxidation, and an anodic current of 100 ma was passed for 3 min. At the end of this time, the electrode was removed and washed, with the washings decanted back into the cell. The contents of the cell were then titrated with $0.137N$ H_2SO_4, using first phenolphthalein and then methyl red as indicators. The difference between the two titres gives the amount of carbonate present in solution. A set of dummy runs was made, identical to the above in all respects, except that the reduced CO_2 was not formed in the first place. These experiments enabled a small correction to be made for losses in washing, aerial carbon dioxide etc. Results are shown in Table I and in Fig. 1.

Coverage with formic acid.—A 1M solution of formic acid was used in $2N$ H_2SO_4. The electrode was transferred with washing as previously described, and the potential scan was applied. Results again are shown in Table I and in Fig. 1.

Coverage with formaldehyde.—A 40% aqueous solution of formaldehyde, free from added preservative was used and diluted down to give a 1M solution in $2N$ H_2SO_4. The current-voltage curves obtained after washing and transfer, using the potential scan, were very different from those previously encountered. In the first place, the maximum current was, initially at least, some two times larger than those in the previous experiments with formic acid, etc. Second, contrary to the good reproducibility of these experiments, the currents in the formaldehyde experiments were irreproducible by a factor of 100%. Third, the current-voltage curve did not show a peak but rather a plateau, beginning at 650 mv and extending beyond 1.00v into the oxide region (see Fig. 1). The last difference was observed after the electrode had stood for several hours in distilled water. A white flocculence was observed on and close to the surface of the electrode, which was assumed to be a formaldehyde polymer. No further quantitative experiments were attempted.

From Table I, it may be seen that the number of chemical equivalents of reduced CO_2 formed (from the titration) are

$$(0.45 - 0.15) \times 10^{-3} \times 1.37 \times 10^{-1} = 4.11 \times 10^{-5}$$

From the potential scan measurements, the number of equivalents is $8.57/nF$, where F is the Faraday, n the number of electrons involved in the reduction. This term is thus 4.44×10^{-5}, if $n = 2$ is assumed, which agrees with the titration value within the limits of experimental error.

Analysis of cell solutions.—Experiments were made to see whether any of the reduced CO_2 might desorb

from the electrode into solution, and there be identifiable. In the apparatus described above, three runs were made, each one of 24-hr duration. During this time, CO_2 was slowly bubbled into solution, while the electrode was potentiostatically held at 0.0v. Two of these runs were made at 25°C, while the third was made at 80°C, since the work of Giner (1) shows that the reduction process is faster at this temperature. All three solutions, plus a control solution to check the presence of possible impurities, were tested as follows.

The chromotropic acid test for formaldehyde and formic acid was applied, first on a portion of each solution, then after the solution had been shaken with magnesium shavings, to reduce formic acid to formaldehyde. These tests were all negative, although the sensitivity of the test, using known dilute formic acid solutions, was better than 1 ppm of formic acid. The Schiff test for aldehydes gave negative results. The final test was for carbon monoxide, where (in a separate 24-hr run at 25°C) the carbon dioxide was not bubbled through the cell, but the cell was presaturated with CO_2 and sealed. This was to avoid expulsion of any CO formed by the CO_2 stream. The cell was then purged with pure nitrogen, the effluent gas being passed through a commercial CO detection kit with a threshold sensitivity of 50 ppm. No coloration was observed. This experiment was repeated, using the same electrode and solution, after one week, since the results of Gilman (see the Discussion section) indicate that the desorption of CO is an extremely slow process. Again no coloration was reported. The conclusion was reached that none of the substances tested for was present in detectable amounts.

Discussion

Reduced CO_2

If the foregoing results are accepted, it must be assumed that two electrons are involved in the reduction of each carbon dioxide molecule. This at once eliminates a large number of species and leaves such compounds as C=O, HCOOH as virtually the only simple molecules corresponding to CO_2, twice reduced. Two other possibilities cannot be ruled out. The first of these is the compound OHC-COOH, glyoxal. This is the only other compound both reasonably simple and also complying with the stoichiometric requirements outlined above. It has further interest, being speculatively mentioned as a possible "blocking species" or "poison product," in a recent paper on the electro-oxidation of formic acid by Brummer and Makrides (9). The second alternative is that the species being investigated here, the reduced CO_2, is incapable of existing in free solution, just as the hydrogen atom can exist only in the adsorbed state, and not in solution. This last possibility would mean that the reduced CO_2 could never be identified by conventional chemical means, since it would either not desorb, or else, in so doing, would react either with a similar molecule or with water to form a stabler species. So the final choice lies between these alternatives.

As described in the Results section, no formic acid was found in solution, nor any formaldehyde, nor (by the Schiff test) any aldehyde. Furthermore, we know, from the work of Breiter (4) both the shape of the formic acid adsorption isotherm, and we have some idea of the time required for equilibrium to take place. Thus, from Fig. 6 in this work (4), we see that a θ value similar to the one observed for reduced CO_2 in this work would correspond to a high and easily detectable concentration of formic acid in the bulk solution.

The blank Schiff test would seem to preclude the glyoxal compound unless, like CO, it is a compound only slightly desorbed. Further evidence against this compound is seen in Table II where its coverage is compared with other species.

Table II. Compared coverages

Species	Work	Q_H/Q_x
Reduced CO_2	Giner (1)*	0.7:1
Reduced CO_2	This work	0.7:1
Carbon monoxide (1 atm)	Gilman (10)	0.7:1
Formic acid 1M	Breiter (4)	0.8:1
Formic acid 1M	This work	0.9:1
Glyoxal	Brummer and Makrides (9)	1:1 (approx.)

* Value not quoted directly, obtained from published data by curve weighing.

A meaningful way of comparing coverages, especially when collating values of different authors and different species, is to express the coulombic equivalent of the coverage as a function of the hydrogen coverage for the same electrode Q_H. Table II sets out to do this. It is thus seen that the coverage of the electrode with reduced CO_2 matches the figure quoted by Gilman for 1 atm of CO. The desorption of CO may also be seen from the work of Gilman. He found a CO coverage of 0.5 mC/cm^2 on the electrode, in the presence of 1 atm of the gas. When he waited for approximately 15 min and swept the solution with argon during this time, he found a CO coverage of 0.42 mC/cm^2. From these figures, we may say that carbon monoxide does not, to all intents and purposes, desorb, for if the desorption found by Gilman is expressed as a current, it comes to the order of 1.0×10^{-7} amp/cm^2, which is the order of magnitude of impurity currents found in even the most scrupulously clean experiments. It is thus not possible to say whether the CO was desorbed or electrooxidized. In either case, this result suffices to show why, if the reduced CO_2 is in fact carbon monoxide, its detection in solution is so difficult. Furthermore, the very "poisoning" nature of carbon monoxide ensures that once the electrode is so covered, little further reaction can proceed.

Formic Acid Results

The results of the formic acid coverage experiments with platinized platinum, obtained by a method different from that of Breiter for bright platinum and supporting his results, confirm the inhomogeneity of formic acid adsorption, showing both one and two site adsorption to be possible.

There must be a considerable difference in the electrochemical behavior of these two types, and consideration of the two site adsorbed formic acid as the "blocking species" is in many ways more attractive than the invocation of such species as glyoxal which have been neither observed nor suspected as intermediates in the electrooxidation of formic acid.

Breiter has shown (11) that the adsorption of 10% of oxygen on an electrode surface inhibits the electroorganic oxidation reaction by almost an order of magnitude. In the same way, the current decay at constant potential reported by so many observers, in potential regions where oxygen adsorption is not considered possible, is also of similar magnitude. In both cases, it is possible that certain "preferred sites" are lost, either by oxygen or formic acid coverage. Equally it is known that severe oxidation or reduction will replace these sites in circulation until they are removed once more.

Formaldehyde Results

The anomalous and irreproducible behavior of this compound, together with the observation of a white flocculent and insoluble polymer, is less surprising when the polymerisability of the substance is taken into account.

Similar behavior has been observed in the anodic oxidation of cyclohexadiene (12) which coated the electrode with a glassy polymer. The implications of the present work seem to be that reactions in which formaldehyde is an intermediate or starting product

may be poisoned by a polymer which was observed in these experiments on account of a higher formaldehyde concentration than that used by most other workers, in the presence of a large platinized platinum electrode.

Conclusions

The main conclusions arising from this work are as follows. First, the reduced CO_2 is a doubly reduced species. Second, from negative tests and from a comparison of coverages, this species is most probably carbon monoxide. Third, a polymer formation is reported for the first time in the electrooxidation of formaldehyde. Last, the inhomogeneous adsorption of formic acid is confirmed.

Manuscript received May 13, 1964; revised manuscript received Oct. 26, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

Oxygen Overvoltage Measurements on Bright Platinum in Acid Solutions

I. Bright Platinum

James P. Hoare

Research Laboratories, General Motors Corporation, Warren, Michigan

ABSTRACT

Overvoltage measurements were made on bright platinum in sulfuric acid solutions both for the anodic evolution and the cathodic reduction of oxygen. It has been found that the experimental data are compatible with a kinetic equation of the type

$$i = i_o' \frac{A'}{A} \left[e^{-z'\alpha'(E - E'_o)F/RT} - e^{z'(1-\alpha')(E - E'_o)F/RT} \right] - i_o'' \frac{A''}{A} \left[e^{z''(1-\alpha'')(E - E''_o)F/RT} - e^{-z''\alpha''(E - E''_o)F/RT} \right]$$

which was derived from a consideration of a polyelectrode model. By using the proper boundary conditions, this equation reduces to more familiar forms in certain regions. The Tafel slopes were found to be 0.122 for anodic and 0.095 for cathodic overvoltage. The i_o is 1.3×10^{-9} amp/cm^2. At the rest potential of 1.06v, a value of 0.32 μa/cm^2 was calculated for the corrosion current density, i_m, using the derived rate equation. This value agrees well with those estimated in the literature. It is suggested that the rate-determining step for anodic evolution of oxygen is

$$(H_2O)_{ads} \rightarrow (OH)_{ads} + H^+ + e$$

and for cathodic reduction

$$(O_2)_{ads} + e \rightarrow (O_2^-)_{ads}$$

The reversible oxygen potential can be observed only on a completely covered surface, and the over-all electrochemical process is

$$O_2 + 4H^+ + 4e \rightleftharpoons 2H_2O$$

in either direction. Peroxide is formed as an intermediate in the reduction of oxygen, but at the steady state concentration of 10^{-5} M this does not disturb the over-all kinetics.

From a series of investigations of the nature of the rest potentials observed on noble metal electrodes in oxygen saturated acid solutions (1, 2), it has been suggested that the metal-oxygen systems are not simple ones but involve more than one electrochemical process occurring on the same metal surface. Such systems are referred to as polyelectrodes (3) and the rest potentials are mixed potentials (4). In order to understand the mechanism of the oxygen electrode, the system must be polarized. In the literature, most attention has been paid to the evolution of oxygen (5), whereas less work seems to have been done on the reduction of oxygen (6). A contributing factor may be the fact that peroxide builds up as a complicating intermediate in the reduction of oxygen. In either case, anodic or cathodic overvoltage, steady potentials were not generally obtained at low current densities (7); only at the higher current densities could steady potential values be obtained. A satisfactory interpretation of these observations may be made in terms of a polyelectrode. It is the purpose of this work to interpret some overvoltage measurements on the noble metals from such a view point. This report will record the investigation of the Pt/O_2 electrode.

Experimental

The measurements were made on small beads (0.04-0.05 in. in diam) melted at the end of Pt wires (99.99% pure). All purification techniques were the same as before (1). Tight-fitting clear Teflon spaghetti was

slipped over the Pt wire leads and pressed up against the Pt bead so that only the bead was exposed to the solution. Polyethylene was not used in the test compartment of the cell, since it was feared that the presence of peroxide, produced in the reduction of oxygen, might attack the polyethylene and contaminate the electrode surface just as was cautioned in the use of concentrated HNO_3 (2). A dual Teflon cell (1) was used and an α-Pd-H reference electrode (8) was mounted in the left-hand compartment. Three test beads as checks were mounted in the right-hand compartment.

Because the i_o for the oxygen reaction on Pt in acid solutions is quite low, about 10^{-9} amp/cm^2 (9, 10), overvoltage measurements must be made at very low current densities (μa/cm^2). This may be done in two ways; (*a*) by using very large electrodes such as those of Watanabe and Devenathan (11) with an ordinary current supply, or (*b*) by using small electrodes with very large resistors in series with the current supply. The second method was chosen because the large electrodes in the first method require large cells and great quantities of solution to be cleaned, and hence, increase enormously the chances for contamination of the system with impurities. The series resistance box was made up of 10-, 50-, and 100- megohm resistors, having a total resistance of 670 megohms. In addition to this, a very large resistor was made by drawing a pencil line on a strip of Mylar with contacts at various points along the strip. The current was determined by measuring the potential drop across a standard resistor with a General Radio Electrometer, Model 1230A. By means of a switch, this meter could be removed from the circuit when the cell potentials were measured. The potential drop between the test electrode and the reference electrode was measured with a second General Radio Electrometer in series with a standard cell to buck the measured potential so that a low scale could be used on the meter. In this way, the potential could be read within $\pm$0.5 mv. An electronic current interrupter (12) was used to determine the solution iR drop between the test and reference electrodes. It was found that, up to a current density of 1 ma/cm^2, the iR correction was less than a millivolt.

The partial pressure of oxygen, P_{O_2}, was varied by diluting the oxygen flow with nitrogen. A rough determination of the P_{O_2} was obtained from the rotameter readings and the final one from a Beckman Oxygen Analyzer. All experiments were carried out at a temperature of 25° $\pm$ 1°C in 2*N* H_2SO_4 solutions. To minimize contributions to the potential by concentration polarization, the system was stirred with gas flows of at least 350 cc/min. At this rate of stirring, there was not any dependence of the potential on stirring rate over the complete range of current density values studied.

In general, the following procedure was used in determining the current-potential curves after the Pt/O_2 electrode had come to a steady rest potential. In some experiments (Fig. 1) in which the region in the neighborhood of the rest potential was to be investigated, the electrode was polarized at the lowest current densities first. In others, (Fig. 2 and 3) the system was polarized either anodically or cathodically at the highest current density to be investigated until the potential became steady (when the change in potential with time was less than 1 mv over an interval of 10 min). Then, the current density was lowered stepwise to the lowest current density to be investigated, after which it was raised again stepwise. The steady potential (potential change was less than 0.5 mv over an interval of 120 sec) was recorded at each current step, and the plotted curves represent the data obtained from at least three, and in some cases from as many as six or seven, complete cycles of decreasing and increasing current density. As seen in the next section, there is usually a transition region between the data at low current densities and that at the higher ones in which steady potential measurements could not be obtained. To get reproducible results, the data in Fig. 1 must be obtained before that in either Fig. 2 or 3. Oxygen overvoltage, defined as

$$\eta = E_{O_2} - E_{rev}$$

where η is the overvoltage and E_{O_2} is the potential of the oxygen electrode at a given current density, i, was determined by using a value of 1229 mv (13) for the reversible oxygen potential, E_{rev}.

Results

A plot of the potential against the apparent current density at very low current densities is given in Fig. 1. The complete oxygen overvoltage curves as a function of the logarithm of the apparent current density are given in Fig. 2 for the cathodic reduction of oxygen and in Fig. 3 for the anodic evolution of oxygen on bright platinum. In Fig. 4, the overvoltage data are plotted such that the i_o's for the two overvoltage curves can be determined. Finally, Fig. 5 is the plot of the overvoltage as a function of the partial pressure.

In general, it may be seen from Fig. 2 that the cathodic overvoltage curve consists of three parts. If the Pt/O_2 electrode is polarized from the steady state rest potential at current densities no greater than about 1 μa/cm^2, a linear potential-current curve is obtained in which the points may be reproduced within $\pm$0.5 mv. Beyond this point, the curve becomes logarithmic and, provided a current density of about 100 μa/cm^2 is not exceeded, a reproducible curve with a slope of about 0.070 is obtained. At high current densities (in the neighborhood of 1 ma/cm^2) a limiting current is reached, and the system is polarized to the discharge of H^+ ions. After polarizing the system at high current densities, the potential follows the upper

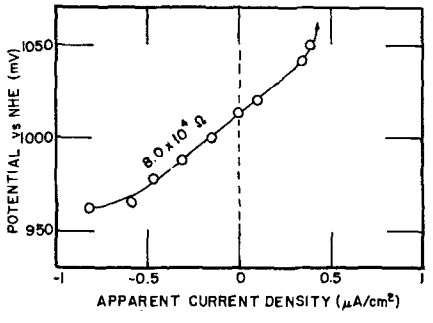

Fig. 1. Polarization data for bright Pt at low current densities in the vicinity of $E = E_{rev}$.

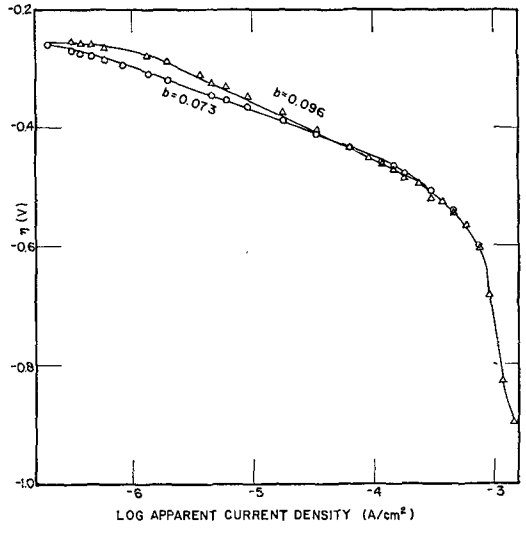

Fig. 2. Oxygen cathodic overvoltage curves on a bright platinum bead. Circles represent data of first cycle of polarization and triangles that averaged over four additional cycles.

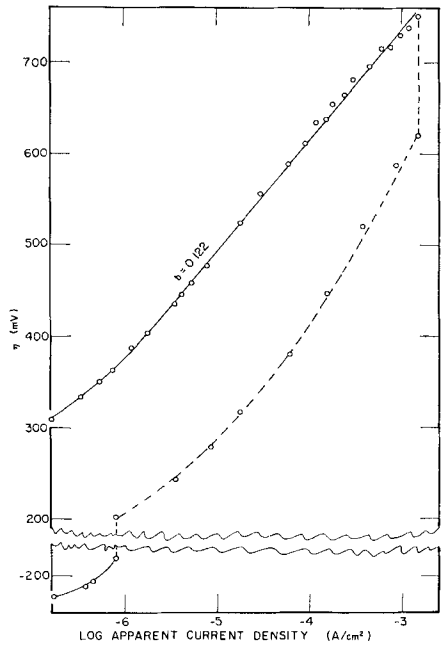

Fig. 3. Oxygen anodic overvoltage curves on a bright platinum bead. The dashed line represents non-steady state points obtained for increasing anodic currents from the rest potential, E_m. At the highest current, the system was permitted to drift to a steady state condition represented by the vertical dashed line. The solid line is the average of three cycles of anodic polarization and represents steady state points.

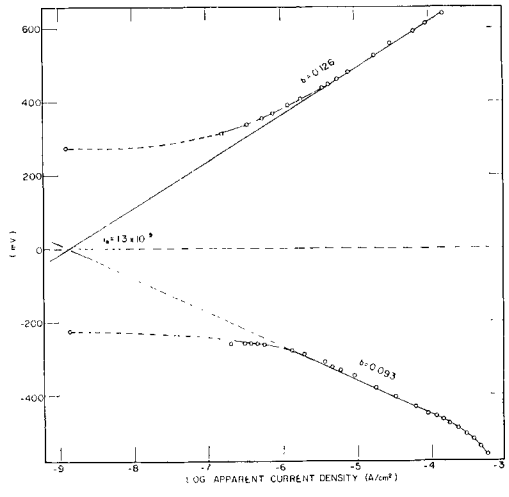

Fig. 4. Plot of the anodic and cathodic overvoltage for bright platinum. The extrapolated Tafel slopes cross at zero overvoltage or a potential of 1.229v.

curve in Fig. 2 when the current is decreased (the slope changes from 0.073 to 0.096). If the Pt/O_2 electrode is polarized initially at the highest current density studied until a steady state is reached, after which the overvoltage curve is obtained, a logarithmic curve with a slope of 0.095 ± 0.003 (from 10 observations) is found (upper curve of Fig. 2). The points in Fig. 2 were averaged from four cycles of decreasing and increasing current density over the whole range with a deviation from the mean within ±6 mv.

At very low anodic current densities, a linear, $E - i$, curve is obtained with the same slope as the cathodic curve which passes through the rest potential as shown in Fig. 1. The slope is 6.0 ± 2.0 x 10^4 ohms (10 observations). At higher current densities the points are no longer time-invariant and drift to more noble values, as shown by the dotted line in Fig. 3. As the current was increased, the points on the dashed curve were not steady. Finally, at the highest current density, the

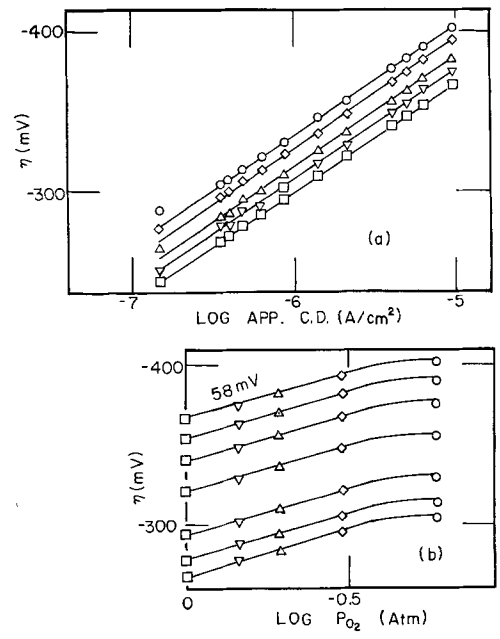

Fig. 5. (a) Plot of oxygen overvoltage as a function of the partial pressure of oxygen, P_{O_2} · P_{O_2} = 1, □; 0.688, ▽; 0.518, △; 0.331, ◇; 0.167, ○. (b) Plot of oxygen overvoltage against the log of P_{O_2}. A slope of 58 mv indicated a one-electron rate-determining step.

system was maintained under these conditions until the potential did become steady (as indicated by the dotted line). Now, the anodic overvoltage curve was obtained as shown by the full line in Fig. 3. The points are averaged from three cycles of polarization, and the deviation from the mean was within ± 5 mv. The slope of this curve is 0.122 ± 0.006 (4 observations).

In Fig. 4 are given the anodic and cathodic overvoltage curves taken on the same bead with the cathodic curve taken first and the anodic second. In both cases, the electrode was polarized at the highest current density studied until the potential became steady, after which the overvoltage curve was determined. The points are the average of three cycles of polarization. It may be seen that the slopes of these lines intersect at zero overvoltage; the i_0 is 1.3 x 10^{-9} amp/cm².

A plot of the overvoltage for different values of P_{O_2} is shown in Fig. 5a where the points are the average of three or four cycles of polarization over the indicated current density range. The deviation from the mean was within ±2 mv. Points taken from these curves were used to plot the overvoltage as a function of log P_{O_2} in Fig. 5b at the given current densities. The slope of these lines is 58 mv. There appears to be some flattening of the curves at the low values of P_{O_2}.

Discussion

The general electrode kinetic equation may be written as

$$i = \vec{k}C_r e^{-z\alpha EF/RT} - \overleftarrow{k}C_o e^{z(1-\alpha)FE/RT} \qquad [1]$$

where i is the current density, $\vec{k}$ and $\overleftarrow{k}$ are the specific rate constants for the forward and back reactions, C_r and C_o are the concentrations of the reductant and the oxidant in the bulk of the solution, z is the number of electrons exchanged in the rate-determining step, α is the symmetry factor which gives the fraction of the total electrode potential which drives the forward reaction (often its value is close to 1/2), E is the potential, F the Faraday, and R and T have their usual significance. At the equilibrium potential, E_o, the rates of the forward and back reactions are equal,

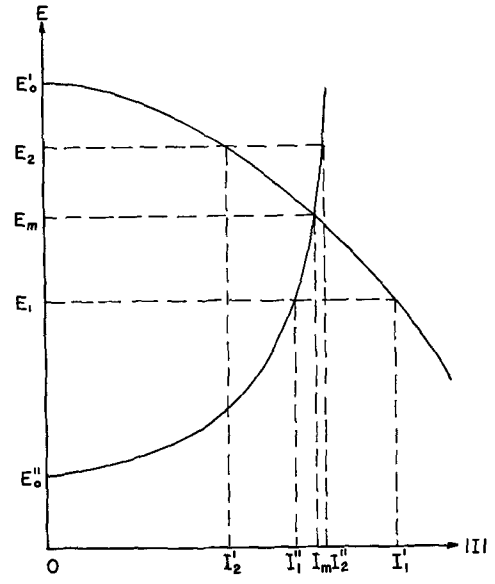

Fig. 6. Schematic diagram of the local cell polarization curves of the two half-reactions of the polyelectrode system, Pt/Pt-O/O_2. Potential vs. NHE is plotted along the ordinate while the absolute value of the local cell current is plotted along the abscissa. At $E = E_m$, $I_m = I' = I''$; at all other potentials, $I = I' - I''$. See text for details.

and so the anodic and cathodic current densities are equal

$$i_o = i_c = i_a = \vec{k}C_r e^{-z\alpha FE_o/RT} = \overleftarrow{k}C_o e^{z(1-\alpha)FE_o/RT} \quad [2]$$

It may be shown (14) that the rate equation in the cathodic direction may be written as

$$i_c = i_o\,[e^{-z\alpha\eta F/RT} - e^{z(1-\alpha)\eta F/RT}] \quad [3]$$

and in the anodic direction

$$i_a = i_o\,[e^{z(1-\alpha)\eta F/RT} - e^{-z\alpha\eta F/RT}] \quad [4]$$

where η, the overvoltage is defined as $\eta = E - E_o$.

These are the kinetic equations for activation overvoltage at a simple electrode. In the case of a polyelectrode, the system is not at equilibrium but at a steady state, since a local cell current, I, is always flowing. There are two electrode reactions and two i_o's. Since the mixed potential, E_m, is between the equilibrium potentials, E'_o and E''_o of the two reactions, the system with the more noble E_o, E'_o, will be cathodically polarized, while the other, E''_o will be anodically polarized. The equations are

$$[i' = i'_o\,e^{-z'\alpha'(E-E'_o)F/RT} - e^{z'(1-\alpha')(E-E'_o)F/RT}] \quad [5]$$

and

$$[i'' = i''_o\,e^{z''(1-\alpha'')(E-E''_o)F/RT} - e^{-z''\alpha''(E-E''_o)F/RT}] \quad [6]$$

At the mixed potential, E_m, as shown in the diagram in Fig. 6, the local cell current, I, is related to the currents of the two component reactions, I' and I'', by

$$I = I' = I'' \quad [7]$$

In Fig. 6 E'_o is 1229 mv for the O_2/H_2O reaction, $O_2 + 4H^+ + 4e \rightleftharpoons 2H_2O$, and E''_o is 880 mv for the Pt/Pt-O reaction. Pt-O $+ 2H^+ + 2e \rightleftharpoons$ Pt $+ H_2O$. It has been suggested (1), from a study of rest potentials, that the shapes of the polarization curves are similar to those shown in Fig. 6. When the system is polarized away from E_m, the observed current is $I = I' - I''$. From [5] and [6] the kinetic equation becomes $i = i'A'/A - i''A''/A$, or

$$i = i'_o\frac{A'}{A}\,[e^{-z'\alpha'(E-E'_o)F/RT} - e^{z'(1-\alpha')(E-E'_o)F/RT}]$$

$$-i''_o\frac{A''}{A}\,[e^{z''(1-\alpha'')(E-E''_o)F/RT} - e^{-z''\alpha''(E-E''_o)F/RT}] \quad [8]$$

Here, A' is that part of the surface area on which the O_2/H_2O reaction takes place, A'' is that on which the Pt/Pt-O reaction takes place, and $A = A' + A''$. For the condition that

$$RT/F < |(E - E'_o)| \text{ and } |(E - E''_o)| \quad [9]$$

Eq. [8] reduces to the following, since the second term in each bracket drops out.

$$i = i'_o\frac{A'}{A}e^{-z'\alpha'(E-E'_o)F/RT} - i''_o\frac{A''}{A}e^{z''(1-\alpha'')(E-E''_o)F/RT} \quad [10]$$

If the system at an open-circuit potential of $E = E_m$ is galvanostatically cathodized, a given current, I, is maintained and, since the electrode surface is an equipotential surface, the potential will shift from E_m to E, where

$$I_1 = I'_1 - I''_1 = i'_1A' - i''_1A'' = i_1A \quad [11]$$

in a similar fashion, one obtains the following if the system is anodically polarized to E_2

$$I_2 = I'_2 - I''_2 = i'_2A' - i''_2A'' = i_2A \quad [12]$$

At $E = E_m$, $I_m = I' = I''$, or

$$i'_oA'e^{-z'\alpha'(E_m-E'_o)F/RT} = i''_oA''e^{z''(1-\alpha'')(E_m-E''_o)F/RT} = I_m \quad [13]$$

Let the polarization at the very low current densities be defined as

$$p = E - E_m \quad [14]$$

Eliminating E between Eq. [10] and [14] and using the definition of I_m from Eq. [13], one obtains

$$i = \frac{I_m}{A}\,(e^{-z'\alpha'pF/RT} - e^{z''(1-\alpha'')pF/RT}) \quad [15]$$

For very low current densities, the exponentials may be expanded in a series and only the first two terms are kept. This gives

$$i = \frac{I_m}{A}\{1 - z'\alpha'pF/RT - [1 + z''(1-\alpha'')pF/RT]\}$$

$$i = \frac{I_m}{A}\frac{pF}{RT}\,[-z'\alpha' - z''(1-\alpha'')] \quad [16]$$

This shows that the polarization is a linear function of the current density in this region as demonstrated in Fig. 1. The quantity, p, may be positive or negative and the slope, $di/dp = \dfrac{I_mF}{ART}\,[-z'\alpha' - z''(1-\alpha'')]$. Assuming that $\alpha' = \alpha'' = \frac{1}{2}$, and that $z' = z'' = 1$, since it is generally believed that only one electron is transferred at a time

$$I_m = -(di/dp)\frac{ART}{F} \quad [17]$$

Taking $-di/dp = 1.25 \times 10^{-5}$ mhos (see Fig. 1), $I_m/A = 3.2 \times 10^{-7}$ amp/cm^2, the local cell current density, i_m, at $E = E_m$. This value agrees quite well with the value (0.2 μa/cm^2) found by Vetter and Berndt (15) for i_m on bright Pt in 1N H_2SO_4 solution.

In general, A' and A'' are functions of the potential. In the case where the surface is covered by a layer of adsorbed oxygen (anodic polarization at high current densities), the Pt/Pt-O reaction is virtually eliminated and $A' \rightarrow A$. Here, the A-term drops out and reproducible, steady potential data are obtained. Similarly, at high cathodic polarization, only the reduction

of oxygen contributes to the current and again, $A' \rightarrow A$. In the region of E_m steady values of the potential are obtained because the values of the change in potential, $E - E_m$, were very small, and the nature of the surface did not change appreciably. However, in the transition region between these extreme cases A' and A'' varied, and as noted above, drifting potentials and hysteresis phenomena were observed.

As the electrode is polarized in the cathodic direction, further away from $E = E_m$, Eq. [16] no longer holds, i is no longer a linear function of the potential, and Eq. [10] must be used to describe the system. From Fig. 6, it is assumed that $i'_o >> i''_o$, because the Pt/Pt-O reaction is more easily polarized than the O_2/H_2O reaction. Then, the second term of Eq. [10] drops out; also, $A' \rightarrow A$. Since now the system is determined by the cathodic reduction of oxygen, the overvoltage is described by the equation

$$\eta_c = \frac{RT}{z\alpha F} \ln i_o - \frac{RT}{z\alpha F} \ln i_c \qquad [18]$$

as demonstrated by the data presented in Fig. 2. Here the system is no longer a polyelectrode system, but a simple one with only one i_o. At a current density of about 10^{-3} amp/cm^2, a limiting current sets in, and the system is polarized to the discharge of hydrogen ions. Figure 2 shows that the reduction of oxygen is the rate-controlling process, since the polarization curve is continuous over the entire range of current densities up to the limiting current density. This is not true for the anodic polarization curve, as shown in Fig. 3.

As one polarizes the system anodically from $E = E_m$, Eq. [16] no longer holds and Eq. [10] must be considered. In this case, as E becomes more noble, it approaches E'_o, and the condition $RT/F < |(E - E'_o)|$ no longer holds. The exponential in the first bracket becomes very small and, consequently, $i'' > i'$. Now the current is determined by the Pt/Pt-O reaction, which is at a limiting current condition, as seen in Fig. 6. Therefore, for a given constant anodic current, the potential drifts with time as observed experimentally until a new system is reached. This situation is described by the dashed curve in Fig. 3. It is suggested that the new system, for which steady state polarization data are obtained, is the anodic evolution of oxygen on a complete layer of adsorbed oxygen about a monolayer thick. The potential drift is produced under anodic polarization conditions by the slow formation of a monolayer of oxide which according to Lingane (16) contains a large amount of PtO_2. Once this layer is formed, which does not build up much beyond a monolayer thick (17), steady-state measurements may be made. In this case, the O_2/H_2O reaction contributes virtually all the anodic current since oxide formation virtually ceases, and Eq. [8] transforms to Eq. [4]. In this region, the overvoltage is described by the relationship

$$\eta_a = -\frac{RT}{z(1-\alpha)F} \ln i_o + \frac{RT}{z(1-\alpha)F} \ln i_a \qquad [19]$$

Again, the system is no longer a polyelectrode, and a single i_o may be assigned to the system. Since the surface of the electrode, now, is quite different from that when the potential was E_m, the system does not return to $E = E_m$ on open circuit but to a point about 270 mv more noble than the reversible potential of 1229 mv, as shown in Fig. 4. This was also observed by Bockris and Huq (9). With time, such a potential drifts to less noble values, indicating that a complete layer of adsorbed oxygen is unstable in acid solutions as found before (2).

From Fig. 4, it is seen that the extrapolated slopes of the cathodic and the anodic overvoltage curves cross at the reversible potential of 1229 mv. Similar observations were made by Hoar (10) and by Bockris and Huq (9). These data indicate that the O_2/H_2O reaction does proceed on a Pt/O_2 electrode and that the reversible potential could be observed if the surface could be maintained inert and electronically conducting. This, in effect, occurs on the Pt surface at high cathodic current densities and on the conducting monolayer of adsorbed oxygen on Pt at high anodic current densities. In general, these conditions are not met on open circuit. It has been shown that, if the Pt surface is passivated by treatment with concentrated nitric acid (2), a conducting, chemically inert layer is formed. In this case, the reversible potential of 1229 mv was observed on open circuit.

The difference in the values of the slopes of the anodic and cathodic curves most likely represents the difference in the paths over which the anodic and cathodic processes take place. In the absence of a peroxide stabilized system [H_2O_2 added to the electrolyte in such systems as those investigated by Yeager (18) and Berl (19)] the evolved oxygen comes from adsorbed water. Kaganovich and co-workers (20) have shown that the anion participates in the reaction at very high current densities and very high concentrations. However, in the present case, the water molecule is probably oriented with the oxygen next to the chemically inert, conducting layer of adsorbed oxygen on the electrode surface. An electron is transferred to the electrode to form an adsorbed OH group, and a hydrated H^+ ion migrates into the solution. When two OH groups are adsorbed on neighboring sites, an activated complex composed of two adsorbed OH groups is formed. With the transfer of two more electrons, this complex falls apart to give an adsorbed O_2 molecule, (which can then desorb) and two hydrated H^+ ions. Peroxide need not be involved because an O-O bond is not broken but formed. Rozental and Veselovski (21), using O^{18} techniques, have shown that the adsorbed oxygen layer, Pt-O, does not participate in the electrode reaction but only serves as the surface on which the reaction proceeds. Breiter (22) has come to similar conclusions.

For the case of the reduction of oxygen, however, the O-O bond must be broken. In all cases, after polarization, peroxide can be detected. There is some evidence (23) that with continued polarization the H_2O_2 concentration builds up to a steady state value. The data in Fig. 2 support this, since after the first one or two cycles of cathodic polarization a reproducible overvoltage curve is obtained. From the tests made with $TiSO_4$ reagent (24), this steady-state concentration of H_2O_2 is between 10^{-6} and 10^{-5}M for Pt/O_2 electrodes. What determines the value of this steady-state concentration is the ability of the electrode surface to decompose the H_2O_2 formed. Bockris (9) found that concentrations of H_2O_2 less than 10^{-4}M do not interfere with the cathodic Tafel slope. This concept seems to be supported by the data in Fig. 4.

From the data presented in Fig. 5, it may be seen that the rate-determining step in the reduction of oxygen must depend on the partial pressure of oxygen and must be a one-electron step (59 mv per decade of the log P_{O_2}). Suppose that molecular oxygen is adsorbed on the Pt-O layer, then the rate-determining step could be the discharge of one electron to form O_2^-. The second electron could be transferred more rapidly to form $O_2^=$ which would combine with two hydrated H^+ ions to form the relatively stable intermediate H_2O_2. This intermediate builds up to a steady-state concentration ($\sim 10^{-5}$M) because of the catalytic decomposition of the H_2O_2 to H_2O and O_2. The resulting O_2 can undergo the transfer of two more electrons so that effectively a 4-electron process has taken place. The decomposition of H_2O_2 may occur chemically or electrochemically as proposed by Gerischer (25), but such processes do not contribute current to the external circuit since the electrochemical decomposition proceeds through a local cell mechanism in which the local cell current is lost to the external circuit.

Although it is not advisable to use the Tafel slope alone as a diagnostic criterion for the electrode kinetics of such a complicated electrode process as the oxygen electrode, the slopes of the anodic and cathodic curves,

0.122 and 0.095, respectively, are close to the value of $2RT/F$ which Bockris (26) finds for a slow-discharge-of-an-electron step. Therefore, for the anodic evolution of oxygen on an adsorbed layer of Pt-O, the rate-determining step may be

$$(H_2O)_{ads} \rightarrow (OH)_{ads} + H^+ + e \qquad [20]$$

For the cathodic reduction of oxygen on platinum, it may be

$$(O_2)_{ads} + e \rightarrow (O_2^-)_{ads} \qquad [21]$$

In both cases, the over-all reaction involves the transfer of four electrons so that the over-all reaction is

$$O_2 + 4H^+ + 4e \rightleftharpoons 2H_2O$$

as suggested by the data in Fig. 4.

The data in Fig. 4, also, provide a value of the stoichiometric number equal to $3 < \nu < 4$, which appears to be inconsistent with the proposed mechanisms. In the anodic evolution of oxygen, ν should be 2 since two OH radicals must be formed from two molecules of water. Also, a value of 2 would be expected in the reduction of oxygen since the transfer of an electron to $(O_2)_{ads}$ occurs a second time from the O_2 liberated by the decomposition of the peroxide formed in the first steps. However, as pointed out by Parsons (27), ν cannot be determined from the slopes of the anodic and cathodic overvoltage curves if the activated complex in the rate-determining steps for the anodic and cathodic processes is not the same. It is quite likely that such is the case from a consideration of the reactions given by Eq. [20] and [21]. This could provide an explanation for the anomalous values of ν obtained from the data in Fig. 4.

From the analysis of the Pt/O_2 electrode presented here, it is important to realize that reproducible steady state data can only be obtained when there is some hope of characterizing the nature of the surface on which the electrode process is taking place. If this is not done, drifting potentials and hysteresis effects are observed as demonstrated in the transition region between the data obtained at low and at high current densities.

Oxygen Overvoltage Measurements on Bright Platinum in Acid Solutions

II. Bright Platinum in H_2O_2 Stabilized Acid Solutions

James P. Hoare

Research Laboratories, General Motors Corporation, Warren, Michigan

ABSTRACT

Oxygen overvoltage measurements were made on a Pt/O_2 electrode in H_2O_2-stabilized acid solutions. The concentration of H_2O_2 was 0.1M. It was found that the rest potential did not reach the reversible O_2/H_2O_2 potential (682 mv), and was independent of the H_2O_2 concentration and of the partial pressure of oxygen. These findings are explained in terms of a polyelectrode model in which the rest potential is a mixed potential composed of the half reactions

$$H_2O_2 \rightarrow O_2 + 2H^+ + 2e$$

and

$$H_2O_2 + 2H^+ + 2e \rightarrow 2H_2O.$$

From the polarization data, it is concluded that the mixed potential and the electrode kinetics are controlled by the reaction

$$O_2 + 2H^+ + 2e \rightleftharpoons H_2O_2$$

The system acts as though it were a reversible O_2/H_2O_2 electrode with an E_o of 810 mv. A value of 1.13×10^{-3} mho is calculated for the rate of the electrode reaction. The rate-determining step both in the anodic and the cathodic directions involves the discharge of the first electron.

In general, it is found that the presence of H_2O_2 may be detected in any system in which the reduction of oxygen takes place. Berl (1) found that oxygen is reversible to the HO_2^- ion in alkaline electrolytes at inert electrodes, and Yeager and co-workers (2) obtained reproducible results from their work on oxygen electrodes in alkaline solution when the system was "stabilized" by adding H_2O_2 to the system. For very dilute concentrations of peroxide in acid solutions, it was found (3) that the rest potential was shifted to less noble values with increasing H_2O_2 concentrations. For larger concentrations of H_2O_2, however, the rest potential did not reach the reversible value of 682 mv (4) quoted for the O_2/H_2O_2 reaction but became independent of the H_2O_2 concentration and dependent on the *p*H, as observed by Bockris and Oldfield (5) and by Gerischer (6). Apparently H_2O_2 is always present in the reduction of oxygen because the O-O bond is so strong that a stable peroxide intermediate is formed. Tracer experiments carried out by Yeager and coworkers (7) in alkaline H_2O_2 solutions indicate that the O-O bond is never broken.

The present report is concerned with oxygen overvoltage experiments carried out on Pt electrodes in acid solutions to which peroxide had been added.

Experimental

The cell, electrode, solution preparations, and experimental techniques are the same as those described before (3, 8). In most cases, the electrode was allowed to come to a steady state in oxygen saturated 2*N* H_2SO_4 solution. Then, the required amount of H_2O_2 was added to the solution with a hypodermic syringe after which polarization measurements were made. All potentials are referred to the normal hydrogen electrode (NHE). The solutions were stirred with purified oxygen at a rate of about 275 cc/min at which rate all observed potentials were independent of stirring. The work was carried out at a temperature of 25° ± 1°C.

Results

A plot of the polarization curves at low current densities obtained on Pt, Au, and Rh electrodes in O_2-saturated 2*N* H_2SO_4 solution which is 0.1M in H_2O_2 is presented in Fig. 1. The cathodic overvoltage curve, Fig. 2, and the anodic overvoltage curve, Fig. 3 [determined from the rest potential value rather than from the reversible oxygen potential (4) of 1229 mv], were obtained on bright Pt on O_2-saturated 2*N* H_2SO_4 which is also 0.1M in H_2O_2. Figure 4 gives the partial pressure of oxygen (P_{O_2}) data.

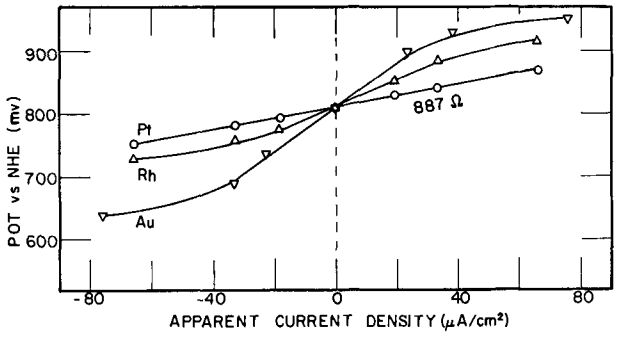

Fig. 1. Polarization of Au, Rh, and Pt electrodes at low current densities in 0.1M H_2O_2 acid solution (2*N* H_2SO_4). All electrodes have the same rest potential (810 mv) but different rates of reaction ($-di/d\eta$).

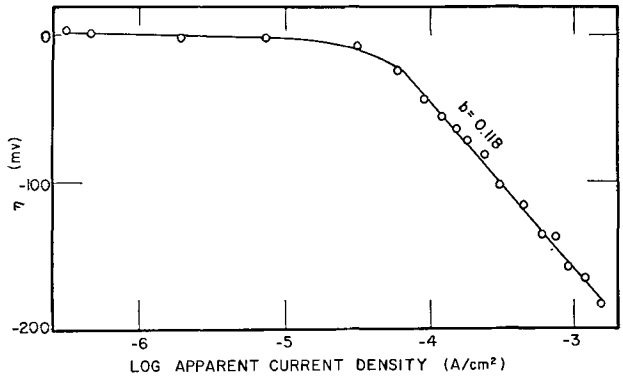

Fig. 2. Overvoltage measurements for the cathodic reduction of oxygen on bright Pt in 0.1M H_2O_2 acid solution (2*N* H_2SO_4). The overvoltage was determined from the rest potential instead of 1229 mv.

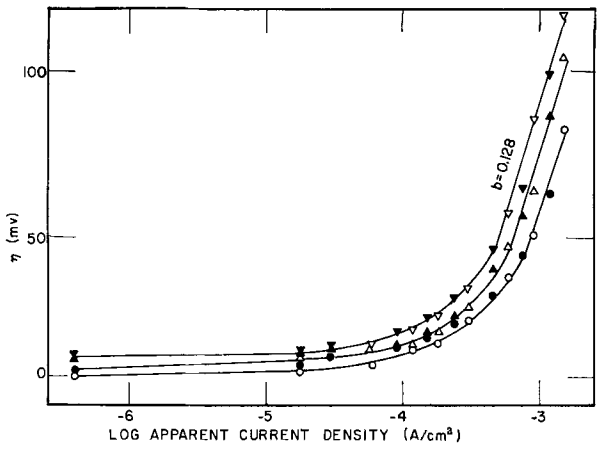

Fig. 3. Overvoltage measurements for the anodic evolution of oxygen on bright Pt in 0.1M H_2O_2 acid solution (2N H_2SO_4). The overvoltage was determined from the rest potential. Open symbols represent data for increasing polarization and filled symbols that for decreasing values. Three cycles of polarization are presented, the polarization increasing with each cycle. The slope of 0.128 does not change.

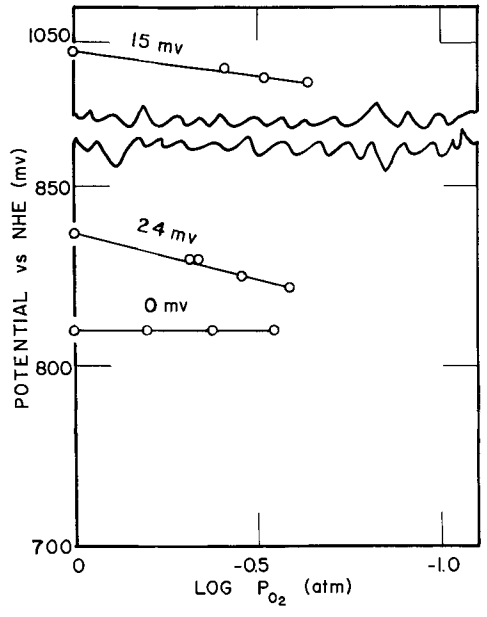

Fig. 4. A plot of the rest potential as a function of the partial pressure of oxygen for bright Pt in acid solutions containing different amounts of H_2O_2. The top curve contains no H_2O_2; the middle, 4 x 10^{-6}M H_2O_2; the bottom, 0.1M H_2O_2.

When H_2O_2 was added to the system, the rest potential fell rapidly to less noble values, and, as seen in Fig. 1, the steady rest potential was the same on the three different metals. However, the rate of the electrochemical reaction is different for each metal as shown by the different slopes. The points in Fig. 1 represent the average value of at least three complete cycles of polarization through the rest potential; the deviation from the mean was within ±2 mv.

It was found that the polarization of a platinum electrode in H_2O_2 stabilized acid solution was very low, as shown in Fig. 2 and 3. With cathodic polarization a reproducible curve was obtained after one or two cycles of polarization. The reproducible curve on which the points represent the average values of at least three cycles of polarization is presented in Fig. 2. These points could be reproduced within ±6 mv. A Tafel slope of 0.118 was obtained. In contrast, the anodic curves were not reproducible from one cycle to another but drifted progressively to larger overvoltage values at the higher current densities. A constant slope of 0.128 was observed.

The fact that the rest potential at high H_2O_2 concentrations is independent of the P_{O_2} has also been observed by other investigators (5, 6, 9). In addition, the overvoltage is independent of P_{O_2} in acid solutions of about 0.1M H_2O_2. The top curve in Fig. 4 is a Pt/O_2 electrode in H_2O_2-free solution; the middle curve, in a solution 4 x 10^{-6}M in H_2O_2; the bottom curve, in a solution 0.1M in H_2O_2.

Discussion

As H_2O_2 is added to a system in which a Pt/O_2 electrode is at rest in O_2-saturated acid solution, the rest potential is shifted to less noble values, and the slope of a plot of the potential as a function of the P_{O_2} deviates from a value of 15 mv towards one of 30 mv (see Fig. 4). Yet, as the H_2O_2 concentration increases, the potential becomes independent of the H_2O_2 concentration and does not reach the reversible potential of 682 mv (4) for the O_2/H_2O_2 reaction

$$O_2 + 2H^+ + 2e \rightleftharpoons H_2O_2, \qquad E_o = 682\,\text{mv} \qquad [1]$$

Since the rest potential also becomes independent of P_{O_2} at this point, it must be a mixed potential (10) because the Nernst equation is not obeyed. Giner (9) also came to this conclusion. The observed rest potential in strong H_2O_2 solutions is 810 ± 5 mv [in good agreement with the value obtained by Bockris (5) at pH = 0] and is independent of the electrode material in striking contrast to the systems in which peroxide is absent (11). This behavior indicates that the mixed potential does not involve a metal/metal oxide reaction.

The data in Fig. 4 show the influence of a 2-electron, potential-determining reaction. Therefore, in all probability one of the half-reactions determining the mixed potential is the O_2/H_2O_2 reaction, Eq. [1]. The other half-reaction could either be the O_2/H_2O reaction

$$O_2 + 4H^+ + 4e \rightleftharpoons 2H_2O, \qquad E_o = 1229\,\text{mv} \qquad [2]$$

or the H_2O_2/H_2O reaction

$$H_2O_2 + 2H^+ + 2e \rightleftharpoons 2H_2O, \qquad E_o = 1770\,\text{mv} \qquad [3]$$

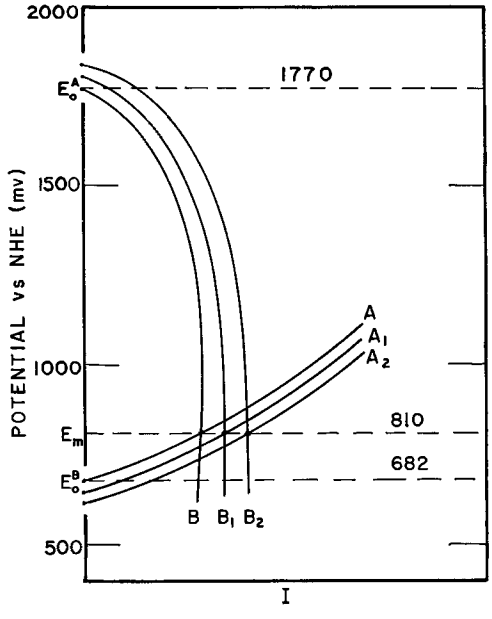

Fig. 5. Schematic diagram of the local cell polarization curves for a Pt electrode in 0.1M H_2O_2 acid solution (2N H_2SO_4). The A-curves represent the reaction $O_2 + 2H^+ + 2e \rightleftharpoons H_2O_2$; the B-curves, $H_2O_2 + 2H^+ + 2e \rightleftharpoons 2H_2O$. The curves A to A_2 and B to B_2 sketch the change in shape for increasing P_{O_2}. Since the mixed potential, E_m, is the same for each pair of curves, the observed rest potential is independent of P_{O_2}.

In the presence of high concentrations of H_2O_2, Eq. [3] is favored as the other half-reaction. For low H_2O_2 concentrations, the potential is probably determined by a complicated interaction of all three of the above reactions plus, no doubt, a metal/metal oxide reaction. This conclusion is supported by the lack of a simple relationship between potential and P_{O2} in this region in solutions with varying concentrations of H_2O_2 as observed here and by Giner (9).

Figure 5 is a sketch of the mixed potential diagram for a Pt/O_2, H_2O_2 electrode for high concentrations of H_2O_2. The A-curves are those for the O_2/H_2O_2 reaction for increasing concentrations of H_2O_2; and the B-curves, for the H_2O_2/H_2O reaction. Since the rest potential is so much closer to the E_o of the O_2/H_2O_2 reaction than the E_o of the H_2O_2/H_2O reaction, the H_2O_2/H_2O reaction must be strongly polarized down to the O_2/H_2O_2 reaction by the local cell action, as shown in the diagram. Because the O-O bond is so strong, the rate of the H_2O_2/H_2O reaction, as well as the i_o, should be small. Such a picture agrees with Yeager's findings (7) that the O-O bond is not broken easily.

The local cell is set up such that Eq. [3] is driven in the cathodic direction while Eq. [1] is driven in the anodic direction. Both reactions depend on the peroxide concentration, but $E^A{}_o$ is inversely dependent whereas $E^B{}_o$ is directly dependent on it. As a result, the corresponding pairs of curves cross at the same potenital producing the observed effect that the rest potential, E_m, is independent of the H_2O_2 concentration.

In the presence of H_2O_2, there will be competition between O_2 and H_2O_2 molecules for available adsorption sites on the electrode surface. For large concentrations of H_2O_2, the competition may become so strong that the surface is mostly covered with adsorbed peroxide and very sparsely covered with adsorbed oxygen. For ordinary values of P_{O2} the surface is saturated with adsorbed oxygen because, here, an oxygen saturated surface is only sparsely covered with oxygen. If this were the case, the potential would not respond to changes in P_{O2}, as observed experimentally.

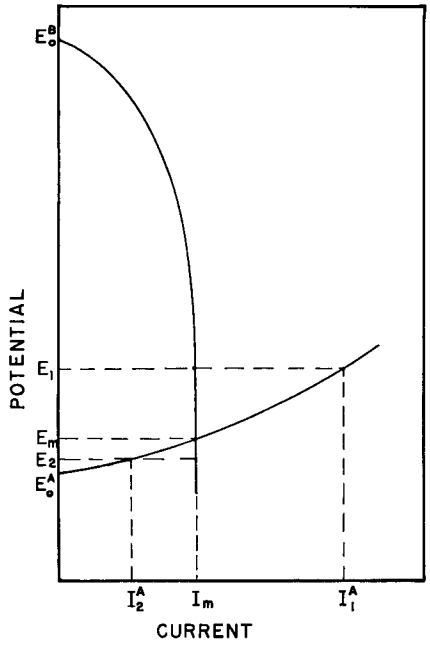

Fig. 6. Schematic diagram of the polarization of the local cell set up at a Pt electrode in 0.1M H_2O_2 acid solution (2N H_2SO_4). At the mixed potential, E_m, the H_2O_2/H_2O reaction is in a virtual limiting current condition. Changes in the local cell current, $I = I^A - I^B$, produced by anodic (E_1) or cathodic (E_2) polarization, are made up chiefly by I^A since $I^B \sim I_m$, the local cell current at open circuit. The kinetics, then, are controlled by the O_2/H_2O_2 reaction.

When the system is polarized galvanostatically, the potential is shifted to a point where the demanded current, I, equals the difference between the partial currents, I^A and I^B, as shown in Fig. 6. It may be seen that virtually all of the anodic current is contributed by the O_2/H_2O_2 reaction because the H_2O_2/H_2O reaction is in a condition of a virtual limiting current at $E = E_m$, that is, $I^B = I_m$. In like manner, the cathodic current, I_2, is controlled by $I^A{}_2$. This explains the linear curve in Fig. 1 which passes through the rest potential without a change of slope. As far as the polarization data are concerned, the system behaves like a reversible O_2/H_2O_2 electrode with an E_o of 810 mv. This is why the overvoltage data presented in Fig. 2 and 3 were determined from the rest potential value rather than from 1229 mv. When the system is polarized to potentials less noble than $E^A{}_o$ in Fig. 6 (682 mv), the reduction of oxygen according to Eq. [1] controls the electrode kinetics, since the H_2O_2/H_2O reaction (Eq. [3]) is in a limiting current density region. In this case, the system behaves like a single electrode system with only one i_o important to the kinetics. Consequently, the overvoltage curve, Fig. 2, obeys a Tafel relationship. Similarly, the curves in Fig. 3 have Tafel regions.

From the slope of the curve in Fig. 1, the rate (12) of the O_2/H_2O_2 reaction of Pt ($-di/d\eta$) is 1.13 x 10^{-3} mho. The i_o obtained from Fig. 2 is 3.98 x 10^{-5} amp/cm^2. If the overvoltage is calculated from 1229 mv, the i_o is 7.76 x 10^{-9} amp/cm^2. It is not possible to determine an i_o from Fig. 3 because the value changes with each cycle of polarization. For such a complicated system as the oxygen electrode, it may be better to use the linear slope of the E-i curve, $-di/d\eta$, at very low current densities (see Fig. 1), rather than i_o, for comparison of the catalytic activity of various electrode surfaces. This is suggested because the choice of values for $-di/d\eta$ is less than those for i_o. Using the equation for the corrosion current density, i_m, derived before (8),

$$i_m = -(di/dp)\left(\frac{RT}{F}\right)$$

one obtains a value of 2.9 x 10^{-5} amp/cm^2 for i_m. Because of the direction of the local cell action, H_2O_2 is consumed. This relatively large corrosion current explains the high rate of the catalytic decomposition of H_2O_2 as compared to the homogeneous decomposition reaction (6).

The overvoltage curves in Fig. 2 and 3, together with the data in Fig. 1, indicate that the anodic and cathodic reactions are the reverse of one another. Reproducible curves are obtained in the cathodic reduction of oxygen because peroxide is produced and a steady-state concentration of H_2O_2 can be maintained. In the anodic evolution of oxygen, however, the H_2O_2 is consumed and the overvoltage increases with each cycle of polarization. The anodic slope of 0.128 suggests that an electron discharge step is rate-controlling, probably the first electron discharge step

$$(H_2O_2)_{ads} \rightarrow (HO_2^-)_{ads} + H^+ + e \qquad [4]$$

A slope of 0.118 for the cathodic reduction of oxygen suggests that the rate-determining step for the reduction of oxygen at a Pt/O_2, H_2O_2 electrode may also be an electron discharge step

$$(O_2)_{ads} + e \rightarrow (O_2^-)_{ads} \qquad [5]$$

even though the overvoltage is independent of P_{O2}. This may be so because the surface is saturated with adsorbed oxygen.

It may be seen, then, that the concept of a polyelectrode (14) successfully explains the behavior of the rest potential of a Pt/O_2, H_2O_2 electrode in strong solutions of H_2O_2. The overvoltage curves indicate that the anodic and cathodic reactions are the reverse of one another, since the reaction

$$O_2 + 2H^+ + 2e \rightleftharpoons H_2O_2$$

controls both the mixed potential and the electrode kinetics. Such a scheme is in agreement with Yeager's finding that the O-O bond is very difficult to break and that a peroxide stabilized Pt/O_2 electrode is a good reversible oxygen electrode.

Manuscript received Nov. 6, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

Determination of the Composition of Complexes and Their Instability Constant by Calorimetry

I. The Cuprocyanide Complexes

Abner Brenner

National Bureau of Standards, Washington, D. C.

ABSTRACT

The calorimetric method for determining the chemical formula and the instability constant of a complex ion involves the determination of the partial molal heat effects resulting from the separate addition of increments of each of the constituents of the complex to a complete range of mixtures of the constituents. The general mathematical derivations necessary for the utilization of the method have been developed, and the complex copper cyanides have been used as an example. The instability constants for the $Cu(CN)_3^{--}$ and the $Cu(CN)_4^{---}$ ions were found to be 1.0×10^{-5} and 2.3×10^{-3}, respectively.

The determination of the composition of complexes and of their instability constants is an important aspect of chemistry. With the resurgence of inorganic chemistry during the past two decades, these subjects have taken on an increased interest. Treatises (1) dealing with the methods of determining the composition of complexes and tabulation (2) of the instability constants of over a thousand complexes have appeared recently.

The composition of stable complexes offers no problem, because the compounds can be isolated and analyzed, or their composition can be established by a titration, as for example, the composition of the argentocyanide ion by the titration of a silver salt with cyanide ion. However, complexes which have relatively large instability constants, for example 10^{-3}, may dissociate too much to be determined in that manner, and special procedures must be used. One of the most used methods is Job's method of continuous variation (3) which involves preparation of a complete series of mixtures of the two constituents of the complex, each mixture having the same number of moles; for example, 0.9 mole of A with 0.1 mole of B, and 0.8 mole of A with 0.2 mole of B, 0.7 mole of A with 0.3 mole of B, etc. Job showed that certain properties of the series of solutions, for example the absorption of light or the heat of reaction, were a maximum or minimum at the stoichiometric composition. Another general method of establishing the composition of complexes is thermometric titration.

After the chemical formula of a complex ion has been established, the instability constant may be determined by a variety of means. For example, known concentrations of the two reactants are brought together in a system, and the concentration of the complex which is formed is determined by spectrophotometry. The necessary information is then at hand for using the mass action expression for calculating the instability constant.

The calorimetric method, which is reported in this paper, for determining the chemical formula and the instability constant of a complex ion involves the determination of the partial molal heat effects resulting from the separate addition of increments of each of the constituents of the complex to a complete range of mixtures of the constituents. The general mathematical derivations necessary for the utilization of the method have been developed, and the complex copper cyanides have been used as an example. The method is of general applicability. It has not been reported previously in the literature.

In the following treatment, concentrations are used instead of activities. This is permissible, since the early work on the law of mass action has shown that many systems yield a reasonably satisfactory constant, if concentrations are used in the mass action expression. In this presentation the instability constant is used instead of the stability constant. Since the former is a small number for the cases considered here, some of the derivations are simplified by showing that some terms containing the constant can be neglected owing to its smallness.

Principle of the Calorimetric Method Illustrated by the Cuprocyanide Complexes. Qualitative Discussion

Consider the formation of a complex compound, A_mB_n, from the two reactants A and B. The calorimetric method consists in measuring the heat evolved by the reaction of a small increment (for example 1g) of one of the reactants (A or B) with a mixture of a large amount (for example several hundred grams) of A and B. The heat effect, Δh, is a function of the composition of the reaction mixture, that is, of the ratio

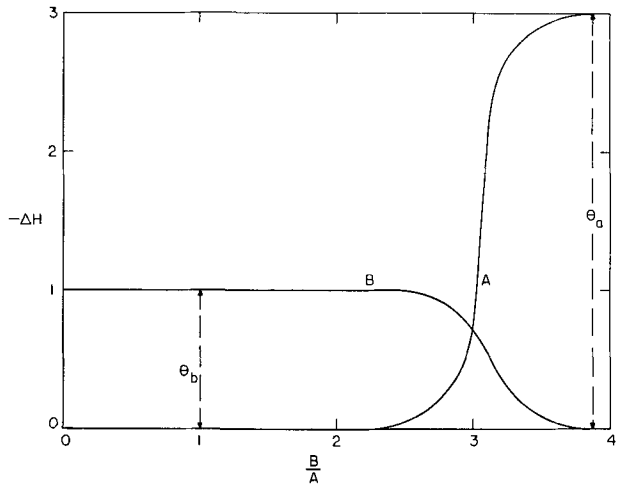

Fig. 1. Schematic representation of the partial molal heat effects occurring with a system of two components, A and B, which produce only one complex, AB_3. Curves A and B represent the heat effects obtained on adding increments of A and B, respectively, to mixtures initially containing A and B in various proportions. Note that the two curves cross at the stoichiometric composition. θ_a and θ_b are the maximum partial molal heat effects representing complete conversion of the increment to complex.

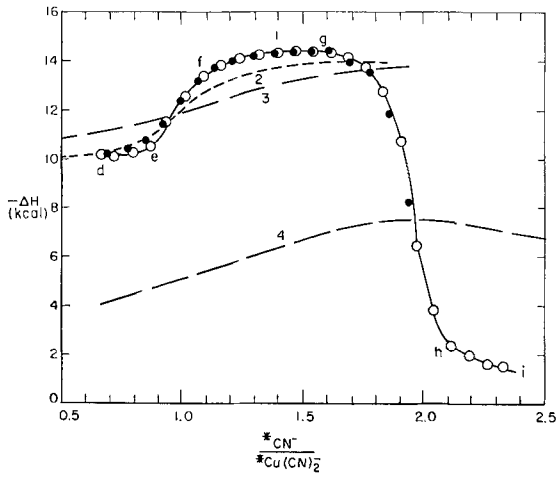

Fig. 2. Curve 1. Experimental data representing the addition of increments of solid sodium cyanide to a system initially consisting of a solution of the cuprocyanide ion, $Cu(CN)_2^-$. The open and solid circles represent the data of duplicate experiments.

The mass action equations are:

$$\text{I.}\ \frac{[Cu(CN)_2^-]\,[CN^-]}{[Cu(CN_3^{--})]} = k_1$$

$$\text{II.}\ \frac{[Cu(CN)_3^{--}]\,[CN^-]}{[Cu(CN)_4^{---}]} = k_2$$

Reactions I and II both occur in the region d-e-f and mainly reaction II in the region g-h-i. Curves 2 and 3 represent the determination of the constant k_1 by the graphical method for the region d-e-f-g. Curves 2 and 3 represent assumed values of k_1 of 10^{-5} and 10^{-4}, respectively, with $k_2 = 10^{-3}$. Curve 4 represents the integral heat effects that would have been obtained by Job's method, if various proportions of $Cu(CN)_2^-$ and CN^- were mixed, the sum of the two constituents always being 1 mole. On the abscissa, $*Cu(CN)_2^-$ represents the initial number of moles of $Cu(CN)_2^-$, that is, the number of moles of copper in the system. $*CN^-$ represents moles of cyanide initially added to the $*Cu(CN)_2^-$ solution.

of B to A. The heat effects are reported as a partial molal quantity, ΔH, where $\Delta H = \Delta h/dM$, and dM represents the fraction of a mole of increment added to the reaction mixture. The value of ΔH will vary from zero to some maximum value. The latter value is obtained by adding an increment of one salt to a large quantity of the other salt in the unadulterated state, as this results in virtually complete reaction of the increment. The experimentally determined ΔH can be better envisioned as the heat obtained by adding one mole of a reactant to an infinite amount of the mixture.

Figure 1 shows a diagrammatic representation of the partial molal heat effects accompanying the formation of a single complex from increments of A or B. The partial molal heat effect is plotted against the composition of the mixture. Two curves are shown, as increments of either A or B can be added to the reaction mixture. Curve B for increments of reactant B shows that, on adding the latter to mixtures rich in A, a constant value of ΔH is obtained initially. This is because virtually the whole increment of B reacts. This value of ΔH representing complete reaction of the increment is given the symbol θ. Near the stoichiometric point, the value of ΔH rapidly decreases and then becomes virtually zero, because virtually all of the A in the mixture is already combined and the effect of more B in shifting the equilibrium farther toward a more complete reaction is small. A similar train of events, represented by curve A, takes place on adding increments of A to reaction mixtures comprising the range of composition from pure B to pure A. It will be noted that curves A and B cross at the stoichiometric point. In this example the sharpness of the curve serves to indicate the stoichiometric composition of the complex, but this indication cannot be depended on in general.

The calorimetric method will be referred to in this publication as the method of increments.

The data for the cuprocyanide system, shown in Fig. 2, were obtained by adding increments of solid sodium cyanide, about 1g, to a solution containing 0.6 moles of copper as cyanide, the initial composition of the solution approximated the composition corresponding to the $Cu(CN)_2^-$ ion. An ordinary Dewar vessel calorimeter was used in a thermostatted oil bath.

Temperatures were measured with a platinum resistance thermometer. Much of the equipment was the same as that used by Sherfey and Brenner (4) in their studies of electrochemical calorimetry. The interpretation of the data is as follows. The addition of sodium cyanide to the initial system which contained $Cu(CN)_2^-$ resulted in the formation of $Cu(CN)_3^{--}$ ion. The partial molal heat was constant and (equal to 10 kcal/mole CN^-) during this reaction, as the curve shows a plateau extending from d to e. When this reaction was about completed, the heat effect rapidly changed to a larger value, representing the formation of the $Cu(CN)_4^{---}$ ion. During the formation of this latter ion from the $Cu(CN)_3^{--}$ ion the partial molal heat effect was sensibly constant, as shown by the plateau extending from f to g. The large decrease in heat effect between g and h represents virtually the disappearance of $Cu(CN)_3^{--}$, hence, the heat effect falls toward that of the heat of solution of sodium cyanide ($\Delta H = 0.26$ kcal/mole), but does not attain it.

Since solid sodium cyanide was used, the heat effect also involved the heat of solution of this salt, and this heat effect should be subtracted from the heat of reaction of an increment. This necessity could have been avoided by adding the increments in the form of a solution. Since the heat of solution of the sodium cyanide (a cooling effect) was only 0.26 kcal cal, which was about the size of the experimental error involved in the determinations of the partial molal heat effects, no corrections were made.

If copper cyanide were added in increments to a solution initially consisting only of sodium cyanide solution, a similar curve with two plateaus would be obtained, representing first the formation of the $Cu(CN)_4^{---}$ ion and next the formation of $Cu(CN)_3^{--}$.

The sharp breaks in the curve corresponding to a ratio of $\frac{*CN^-}{*Cu(CN)_2^-}$ of 1 and 2 shows unambiguously

the composition of the two complexes which have been formed. Here $*Cu(CN)_2^-$ represents the initial composition of the solution, hence, also the copper concentration; and $*CN^-$ represents the cyanide ion added subsequently as increments. Since the slope of such curves may not always be sharp enough to indicate the composition of a complex, a general method for determining the composition from the maximum partial molal heats of reaction, θ, is given in a later section.

The following treatment of the method of increments is divided into several sections. The treatment of a system of reactants which form only one complex is considered first. Under this heading there are two general subjects: (A) the determination of the composition of the complex from the maximum partial molal heat effects, θ, and (B) the determination of the instability constant from calorimetric data such as shown in Fig. 2. Item (B) has two parts, representing the use of two different methods of reporting concentrations. For aqueous solutions molar concentrations are most convenient, but for fused salt systems, mole fraction is more convenient; hence, the derivations for a system of a single complex were done for both types of concentration. The treatment of systems forming two or more complexes comes after the simple system as with the latter there are two general parts A and B. The treatment of the calculation of instability constants for systems of two or more complexes is more involved than for a system of a single complex and the obtaining of explicit algebraic formulas for the constants may not be possible. For that reason, a graphical method which is of a general applicability is also given.

Method of Increments Applied to System of One Complex

Determination of composition of complex.—Before the method of increments can be applied to the determination of the instability constant, the composition of the complex must be established. This is easily accomplished for a system of reactants, A and B, which form only one complex, A_mB_n. Two calorimetric measurements are required:

1. The maximum partial molal heat effect, θ_a, is obtained by the addition of an increment of A to unadulterated B. Since there is a large excess of B, A is virtually completely converted into the complex

$$mA + nB \rightarrow A_mB_n \qquad [1]$$

The heat of this reaction forming a mole of A_mB_n is $m\theta_a$.

2. Similarly, an increment of B is added to a large excess of A to yield the maximum partial molal heat effect, θ_b. The heat of this reaction forming a mole of A_mB_n is $n\theta_b$.

Since $m\theta_a$ must equal $n\theta_b$

$$m/n = \theta_a/\theta_b \qquad [2]$$

Since m and n must be integers, the ratio θ_a/θ_b establishes the composition of the complex.

Determination of the instability constant.—Instability constant based on molar concentrations.—General derivation.—The first step in determining the instability constant is to set up the mass action expression for the formation of the complex. In this section the expression will be based on molar concentrations. The general expression for the formation of the complex represented by Eq. [1] is

$$\frac{(C_y)^m\,(C_x)^n}{C_a} = k \qquad [3]$$

where C_y is the concentration of constituent A, C_x is the concentration of constituent B, and C_a is the concentration of the complex in a mixture which is in equilibrium, and k is the instability constant.

For purposes of calculation, the expression is rewritten in terms of the initial amounts of A and B used in preparing a mixture. These amounts are expressed as concentrations in moles per liter and will be represented by y and x, respectively, and the concentration of the complex by $\bar{a}$. The concentrations of A and B after $\bar{a}$ has been formed will be, respectively, $y - m\bar{a}$ and $x - n\bar{a}$, and the mass action expression is

$$(y - m\bar{a})^m \cdot (x - n\bar{a})^n = k\bar{a} \qquad [4]$$

The following derivation deals with increments of B which are added to various mixtures of A and B, prepared from a fixed amount of A. To determine k in Eq. [4], the concentration of $\bar{a}$ must be derived from the calorimetric data. This is done by first finding an algebraic expression for $\bar{a}$ in terms of the partial derivatives, $\bar{a}'$ and $\bar{a}''$, of $\bar{a}$ with respect to x. Later it is shown how the values of $\bar{a}'$ and $\bar{a}''$ are readily obtained from partial molal heat effects, ΔH.

The derivation is clearer if the physical meaning of $\bar{a}'$ is made evident. Instead of considering it as the ratio of two differentials, consider it as the fraction of a mole of complex, A_mB_n, formed by adding 1 mole of B to an infinite amount of reaction mixture of A and B of various compositions. For example, in Eq. [4], if n were 1, then the maximum amount of complex which could be formed from 1 mole of B (in an infinite amount of mixture) would be 1 mole. If the mixture already contained more than the stoichiometric ratio of B, the amount of complex formed from the additional amount would be small. Thus, in this example, $\bar{a}'$ is a number which expresses the fraction of reaction of the increment and varies between unity and zero. If the value of n in Eq. [4] were 2, then the value of $\bar{a}'$ would vary between the limits of zero and 0.5. In general, $\bar{a}'$ is a fraction varying between the values of zero and $1/n$ and represents the number of moles of complex formed by adding one mole of reactant to an infinite amount of mixture.

Differentiation of $\bar{a}$ in Eq. [4] with respect to x gives

$$m(y - m\bar{a})^{m-1} \cdot (-m\bar{a}')\,(x - n\bar{a})^n + n(y - m\bar{a})^m(1 - n\bar{a}')\,(x - n\bar{a})^{n-1} = k\bar{a}' \qquad [5]$$

Dividing Eq. [5] by Eq. [4] gives

$$\frac{-\bar{a}'m^2}{y - m\bar{a}} + \frac{n(1 - n\bar{a}')}{x - n\bar{a}} = \frac{\bar{a}'}{\bar{a}} \qquad [6]$$

A further simplification is introduced if the value of $\bar{a}'$ is calculated only for the stoichiometric point, that is, where $x/y = n/m$. This relation is best introduced into the equation by using a new variable, z, such that

$$x = nz,\ y = mz \qquad [7]$$

Equation [6] then becomes

$$\frac{-m\bar{a}'}{z - \bar{a}} + \frac{1 - n\bar{a}'}{z - \bar{a}} = \frac{\bar{a}'}{\bar{a}} \qquad [8]$$

Solving Eq. [8] for $\bar{a}$

$$\bar{a} = \frac{\bar{a}'z}{\bar{a}'(1 - m - n) + 1} \qquad [9]$$

when $x/y = n/m$

If the partial differentiation of $\bar{a}$ in Eq. [4] had been made with respect to y instead with respect to x, the final equation would have been the same as Eq. [9], except that $\bar{a}'$ would be with respect to y. Since at the stoichiometric point, $\bar{a}$ would have the same value for both equations, this means that

$$\frac{\partial\bar{a}}{\partial x} = \frac{\partial\bar{a}}{\partial y} \qquad [10]$$

when $(x/y) = (n/m)$.

Physically, this relation means that curves A and B of Fig. 1 must cross at the stoichiometric point, because as shown later, the partial derivatives are proportional to ΔH, the ordinate of the curve.

The intersection of the two curves would be a very precise method of obtaining the composition of the complex, if the partial molal heat effects for both $\bar{a}$ and b could be obtained experimentally.

An expression for the instability constant k is obtained by substituting in the original mass action expression of Eq. [4] the values of x, y, $z - \bar{a}$, and $\bar{a}$, as given in Eq. [7]-[9]. At the stoichiometric point Eq. [4] has the form

$$m^m n^n (z - \bar{a})^{m+n} = \bar{a}k \qquad [11a]$$

and

$$k = \left[\frac{z(1 - \bar{a}'m - \bar{a}'n)}{\bar{a}' - \bar{a}'m - \bar{a}'n + 1}\right]^{m+n} \cdot \frac{m^n \cdot n^n(\bar{a}' - \bar{a}'m - \bar{a}'n + 1)}{\bar{a}'z} \qquad [11b]$$

for values of the variables at the stoichiometric point.

Experience with this equation showed that it was not suitable for calculating k because the expression in the parenthesis, $(1 - \bar{a}'m - \bar{a}'n)$ is a small number, if k is small, and it appeared that $\bar{a}'$ could not be calculated (see following section) with sufficient accuracy from the experimental data to give the parenthesis a meaningful value. For example, if m and n were both unity, $\bar{a}'$ would be very nearly 0.5, and the value of the parenthesis would be nearly zero. If the data were not precise, its value might even appear to be negative, which is obviously erroneous.

It was felt intuitively, that there should be a relation between the instability constant and the steepness of the curves, A or B (Fig. 1), where they passed through the stoichiometric point, and this suggested that the differentiation be carried a step further. The following treatment shows that the introduction of the second derivative, $\bar{a}''$, makes the calculation of k practicable.

Equation [6], which does not explicitly involve k, is chosen for partial differentiation of $\bar{a}$ and $\bar{a}'$ with respect to x.

$$\frac{(y - m\bar{a})(-m^2\bar{a}'') + m^2\bar{a}'(-m\bar{a}')}{(y - m\bar{a})^2} + \frac{(x - n\bar{a})(-n^2\bar{a}'') - n(1 - n\bar{a}')^2}{(x - n\bar{a})^2} = \frac{\bar{a}\bar{a}'' - (\bar{a}')^2}{\bar{a}^2} \qquad [12]$$

For the stoichiometric point where $x = nz$ and $y = mz$, the equation simplifies to

$$\frac{m\bar{a}''}{(z - \bar{a})} + \frac{m(\bar{a}')^2}{(z - \bar{a})^2} + \frac{n\bar{a}''}{(z - \bar{a})} + \frac{(1 - n\bar{a}')^2}{n(z - \bar{a})^2} = \frac{-\bar{a}''}{\bar{a}} + \left(\frac{\bar{a}'}{\bar{a}}\right)^2 \qquad [13]$$

This equation is simplified by use of Eq. [8] and [9] and leads to an expression for $z - \bar{a}$

$$z - \bar{a} = \frac{\bar{a}'}{\bar{a}''n} \cdot [\bar{a}'n(m + n - 1)(\bar{a}'m + \bar{a}'n - 2) + n - 1] \qquad [14]$$

On substituting in the mass action expression of Eq. [4] or Eq. [11a] for x, y, and for $z - \bar{a}$ as given by Eq. [14] and $\bar{a}$ as given by Eq. [9], a general expression for k is obtained for values of the variables at the stoichiometric point:

$$k = \left[\frac{\bar{a}'}{\bar{a}''n}\right]^{m+n} \cdot \frac{m^m n^n(\bar{a}' - \bar{a}'m - \bar{a}'n + 1)[\bar{a}'n(m + n - 1)(\bar{a}'m + \bar{a}'n - 2) + n - 1]^{m+n}}{\bar{a}'z} \qquad [15]$$

In Eq. [15] $\bar{a}'$ and $\bar{a}''$ represent partial derivatives with respect to x. To obtain the equation which is valid for adding increments of y to a reaction mixture, interchange m and n and let $\bar{a}'$ and $\bar{a}''$ be the partial derivatives with respect to y.

Equation [15] appears to be more cumbersome than it is in reality. For example, if m and n were both unity, the equation would be

$$k = \frac{4[\bar{a}'(1 - \bar{a}')]^3}{(\bar{a}'')^2 z} \qquad [16]$$

when $(x/y) = (n/m)$.

It will be noted that this equation does not contain small differences between large numbers. The value of $1 - \bar{a}'$ involves no difficulty since the value of $\bar{a}'$ is close to 0.5.

Before illustrating the use of Eq. [16] with the cuprocyanide system, it is necessary to show the relation between the partial derivatives, $\bar{a}'$ and $\bar{a}''$, in the equation and the experimentally determined partial molal heat effects.

Relation between partial molal heat effects and the partial differentials.—The following discussion shows that the partial differential, $\bar{a}'$ is proportional to the partial molal heat effect, ΔH. Figure 1 shows that the partial molal heat effect corresponding to the complete reaction of an increment of B is θ_b. Where ΔH has a value less than θ_b, this indicates that only a fraction of the increment has reacted. More specifically, the fraction of the increment that has reacted and been converted to the complex is equal to $\Delta H/\theta_b$. The discussion at the beginning of this section showed that the moles of complex, A_mB_n, formed from the complete reaction of a mole of B added to an infinite system was $1/n$. In the case of incomplete reaction of an increment, the moles of complex formed would be $(1/n)(\Delta H/\theta_b)$. This expression is the same as $\bar{a}'$, which was shown (at the beginning of the previous section) to represent the number of moles of complex formed by adding one mole of reactant to an infinite amount of mixture of A and B.

$$\bar{a}' = \Delta H/n\theta_b \qquad [17]$$

Here $\bar{a}'$ refers to partial differentiation with respect to x, which latter represents the reactant B.

Differentiation of Eq. [17] with respect to x gives an expression for $\bar{a}''$

$$\bar{a}'' = \frac{1}{n\theta_b}\frac{\partial(\Delta H)}{\partial x} \qquad [18]$$

Thus, $\bar{a}''$ is proportional to the slope, $\partial(\Delta H)/\partial x$, of the curves, such as shown in Fig. 1, if the abscissa reads directly in terms of the variable x. However, the value of the partial molal heat effect, ΔH, is usually plotted against the composition, $f(x,y)$, of the mixture of A and B, for example against the ratio x/y or the ratio $x/(x + y)$, so that the stoichiometric compositions can be more readily seen from the figure. The slope of the curve is $\partial(\Delta H)/\partial f(x, y)$. The derivative of ΔH with respect to x is then obtained by the following relation

$$\frac{\partial(\Delta H)}{\partial x} = \frac{\partial(\Delta H)}{\partial f(x, y)} \cdot \frac{\partial f(x, y)}{\partial x} \qquad [19]$$

If the abscissa represents the ratio x/y, Eq. [19] becomes

$$\frac{\partial(\Delta H)}{\partial x} = \frac{1}{y}(\text{Slope}) \qquad [20]$$

If the abscissa represents the mole fraction $x/(x+y)$, Eq. [19] becomes

$$\frac{\partial(\Delta H)}{\partial x} = \frac{y}{(x+y)^2}\,(\text{Slope}) \qquad [21]$$

Example of the cuprocyanide system.—As an example of the method of increments, the value of k is calculated for the formation of the complex cuprocyanide ion, $Cu(CN)_4^{---}$ from $Cu(CN)_3^{--}$. In this system two complexes can be obtained from the $Cu(CN)_2^-$ ion as already discussed.

$$Cu(CN)_2^- + CN^- \rightleftarrows Cu(CN)_3^{--} \qquad [22]$$

$$Cu(CN)_3^{--} + CN^- \rightleftarrows Cu(CN)_4^{---} \qquad [23]$$

At the first slope, e-f, shown in Fig. 2, the $Cu(CN)_2^-$ ion is being converted into both $Cu(CN)_3^{--}$ and some $Cu(CN)_4^{---}$ ion, and the considerations of the preceding derivation do not apply without modification. However, at the slope, g-h, only an insignificant concentration of the $Cu(CN)_2^-$ can be present, as indicated by the constancy of the heat effect in the neighborhood of g, hence, the reaction involves only the formation of a single complex, $Cu(CN)_4^{---}$ according to Eq. [23].

The mass action expression for Eq. [23] is

$$\frac{(y-\bar{a})(x-\bar{a})}{\bar{a}} = k \qquad [24]$$

where x and y represent, respectively, the initial concentrations expressed in moles per liter, of CN^- and $Cu(CN)_3^{--}$; and $\bar{a}$ represents the concentration of $Cu(CN)_4^{---}$. The value of the instability constant, k, is given by Eq. [16]. The curve gives $\bar{a}' = 0.5$ (according to Eq. [17]) at the stoichiometric point where $x/y = 1$ $\left(\text{or}\ \frac{*CN^-}{*Cu(CN)_2^-} = 1\right)$. The slope of the curve in the figure at the stoichiometric point is $\frac{\partial \Delta H}{\partial(x/y)}$, and equals −56,500. The concentration of copper as complex was 0.6M. The value of $\bar{a}''$ is obtained from Eq. [18] and [20]

$$\bar{a}'' = \frac{1}{n\theta_b}\cdot\frac{1}{y}\,(\text{Slope}) = \frac{1}{14{,}000}\cdot\frac{1}{0.6}\,(-56{,}500) = -6.7$$

Substitution in Eq. [16] of $\bar{a}'' = -6.7$, $\bar{a}' = 0.5$, and $z = my = 0.6$ gives

$$k = 0.0023 \qquad [25]$$

Derivation of expressions for calculating k when the mass action expression is written in terms of mole fractions.—For fused salt systems, concentrations expressed in terms of mole fractions are easier to use than molarities, since mole fractions depend only on the weight of each component, whereas molarities require also a knowledge of the densities of the mixtures, data for which are not, in general, available. It will be assumed that the mass action law will yield a constant with concentrations expressed as mole fractions, although this constant will not necessarily be numerically equal to that obtained with molar concentrations.

For the purpose of the mathematical derivation, the mass action law is expressed in this section in terms of mole fractions. However, for experimental purposes and for the subsequent calculation, it is more convenient to express the magnitude of the initial additions, x and y, to the mixture and of the increments directly in terms of moles. Thus, the derivatives of the product, $\bar{a}$, with respect to x or y will also be in terms of moles. The reaction to be discussed is

$$rA + sB \rightleftarrows ArBs \qquad [26]$$

Let y and x in this discussion represent the moles of reactants, A and B, initially used to make up the mixture and let $\bar{a}$ represent the moles of product, ArBs, formed. The moles of A and B present at equilibrium are $y - r\bar{a}$ and $x - s\bar{a}$, respectively. The total number of moles, f, present in the reaction mixture is: $(x - s\bar{a}) + (y - r\bar{a}) + \bar{a} = y + x + \bar{a}(1 - r - s) = f$. The mass action law expressed in mole fractions is

$$\frac{\left[\frac{y-r\bar{a}}{f}\right]^r\left[\frac{x-s\bar{a}}{f}\right]^s}{\frac{\bar{a}}{f}} = k \qquad [27]$$

For greater ease in calculating the partial derivative of $\bar{a}$ with respect to x, the equation is rearranged to a more convenient form

$$\left[\frac{y+x+\bar{a}(1-r-s)}{y-r\bar{a}}\right]^{r-1}\left[\frac{y+x+\bar{a}(1-r-s)}{x-s\bar{a}}\right]^s = \frac{y}{k\bar{a}} - \frac{r}{k} \qquad [28]$$

$$\left[1+\frac{x+\bar{a}-s\bar{a}}{y-r\bar{a}}\right]^{r-1}\left[1+\frac{y+\bar{a}-r\bar{a}}{x-s\bar{a}}\right]^s = \frac{y}{k\bar{a}} - \frac{r}{k} \qquad [29]$$

Differentiation of Eq. [29] and rearrangement of terms gives

$$\left\{\left[\frac{y+x+\bar{a}(1-r-s)}{(y-\bar{a}r)^{r-1}(x-\bar{a}s)^s}\right]^{r+s-2}\right\}\left[\frac{s(\bar{a}'x-\bar{a}'rx-y-\bar{a}'ys-\bar{a}+\bar{a}r)}{x-\bar{a}s} + \frac{(r-1)(y+\bar{a}'y-\bar{a}'ys-\bar{a}r+\bar{a}'rx)}{y-\bar{a}r}\right] = \frac{-y\bar{a}'}{k\bar{a}^2} \qquad [30]$$

The first term of Eq. [30] on the left, indicated by the braces, can be replaced by substituting from Eq. [28], to give an equation which does not contain k

$$\frac{y-\bar{a}r}{y+x+\bar{a}(1-r-s)}\cdot\left[\frac{s(\bar{a}'x-\bar{a}'rx-y-\bar{a}'ys-\bar{a}+\bar{a}r)}{x-\bar{a}s} + \frac{(r-1)(y+\bar{a}'y-\bar{a}'ys-\bar{a}r+\bar{a}'rx)}{y-\bar{a}r}\right] = \frac{-y\bar{a}'}{\bar{a}} \qquad [31]$$

The next step is to find the value of this expression at the stoichiometric point where $x/y = s/r$, and this is done most conveniently by introducing the variable, z, such that $x = sz$ and $y = rz$.

On making this substitution in Eq. [31], the following simple expression is obtained for the relation between $\bar{a}$ and $\bar{a}'$

$$\bar{a} = z\bar{a}'(r+s) \qquad [32]$$

If the differentiation of $\bar{a}$ had been done with respect to y instead of x, the same Eq. [32] would have been obtained except that a' would be the derivative of $\bar{a}$ with respect to y. This equality indicates that the two partial derivatives are equal and that the two curves such as shown in Fig. 1 must cross at the stoichiometric composition. This was the same result as that obtained in the derivation based on molar concentrations.

An expression for k now can be obtained by substituting the expression for $\bar{a}$, as given in Eq. [32], into the original mass action expression, Eq. [27]

$$\frac{r^r \cdot s^s (1 - \bar{a}'r - \bar{a}'s)^{r+s}}{(r+s)\bar{a}'[(r+s)(1 + \bar{a}' - \bar{a}'r - \bar{a}'s)]^{r+s-1}} = k \quad [33]$$

This equation is not recommended for calculation of k for the same reason as that given in the previous discussion dealing with molar concentrations; namely, the factor $(1 - \bar{a}'r - \bar{a}'s)$ represents a small difference and cannot be determined accurately. Therefore, as in the prior discussion in an earlier section, it is necessary to obtain an equation for k based on the second derivative of $\bar{a}$.

In order to differentiate the cumbersome expression in Eq. [31], it was rewritten in the following form

$$(r-1)(y + \bar{a}'y - \bar{a}'ys - \bar{a}r + \bar{a}'rx) + \frac{s(y - \bar{a}r)(\bar{a}'x - \bar{a}'rx - y + \bar{a}'ys - \bar{a} + \bar{a}r)}{x - \bar{a}s} = \frac{-y\bar{a}'(y+x)}{\bar{a}} - y\bar{a}'(1 - r - s) \quad [32]$$

Differentiation of Eq. [32] gives

$$(r-1)(\bar{a}''y - \bar{a}''ys + \bar{a}''rx) + \frac{s(y - \bar{a}r)(\bar{a}''x - \bar{a}''rx + \bar{a}''ys)}{x - \bar{a}s} + s(\bar{a}'x - \bar{a}'rx - y + \bar{a}'ys - \bar{a} + \bar{a}r)\left[\frac{(x - \bar{a}s)(-\bar{a}'r) - (y - \bar{a}r)(1 - \bar{a}'s)}{(x - \bar{a}s)^2}\right] = \frac{-y\bar{a}'}{\bar{a}} + y(y+x)\cdot\left[\frac{-\bar{a}\bar{a}'' + (\bar{a}')^2}{\bar{a}^2}\right] - y\bar{a}''(1 - r - s) \quad [33]$$

The value of Eq. [33] is computed for the stoichiometric point by substituting $x = sz$, $y = rz$, and substituting for $\bar{a}$ and $\bar{a}'$ as necessary and, also using Eq. [32]. Equation [33] then simplifies to

$$z - \bar{a} = \frac{\bar{a}'_x r(\bar{a}'_x r + \bar{a}'_x s - \bar{a}'_x - 1)}{\bar{a}''_x s} \quad [34]$$

If the differentiations had been done with respect to y, the equation would be the same except for the interchanging of r and s

$$z - \bar{a} = \frac{\bar{a}'_y s(\bar{a}'_y r + \bar{a}'_y s - \bar{a}'_y - 1)}{\bar{a}''_y r} \quad [35]$$

The terms $\bar{a}''_x$ and $\bar{a}''_y$ refer to differentiation with respect to x and y, respectively.

Division of Eq. [34] by Eq. [35] leads to the result

$$\frac{\bar{a}''_x}{\bar{a}''_y} = \frac{r^2}{s^2} \quad [36]$$

This shows that the slopes of the curves for increments of x and y at the stoichiometric point are inversely proportional to the square of the coefficients of B and A in the chemical reaction.

An expression for k is obtained for values of the variables at the stoichiometric point by substituting Eq. [34] into the original expression Eq. [27] and letting $x = sz$ and $y = rz$.

$$k = (-1)^{1-s-r} \cdot \left[\frac{\bar{a}'r}{\bar{a}''_x z(r+s)}\right]^{r+s} \cdot \left(\frac{r}{s}\right)^r \cdot \frac{(\bar{a}'r + \bar{a}'s - \bar{a}' - 1)}{\bar{a}'} \quad [37]$$

If r and s were both unity, the equation for k would simplify to

$$k = \left[\frac{\bar{a}'}{2\bar{a}''z}\right]^2\left[\frac{\bar{a}' - 1}{\bar{a}'}\right] \quad [38]$$

Thus far, no utilization has been made of Eq. [37] for fused salt systems. However, an investigation of the complexes present in a mixture of molten potassium chloride and cadmium chloride is in progress in our laboratory and is well toward completion. This system will be interpreted by the use of Eq. [37].

Derivation of the Composition of Complexes and of the Instability Constant for Reactants Forming Two or More Complexes

The discussion of the previous section showed that, for two reactants which form only one complex, the composition of the complex and the instability constant can be easily obtained by the method of increments. The investigation of a system of two reactants which form two or more complexes is no more difficult to deal with experimentally than a system of a single complex, except that similar data must be collected for each of the complexes. The calculations, however, are considerably more involved because two complexes may be formed simultaneously. The partial molar heat effect, ΔH, would then be a composite of two different heats of reaction.

Determination of the composition of the complexes.— The first subject to consider is the determination of the stoichiometric composition of the complexes from the maximum partial molal heat effects. In the case of the copper cyanide system, as already mentioned, the breaks in the curve are sharp enough to indicate the composition of both complexes, but this is not a general method, as such steep slopes in the curves do not occur unless the instability constants are small, for example 10^{-3}.

Figure 3 represents a schematic diagram of a system of three complexes. The horizontal portions of the curves are evidence of the existence of a different complex on each side of the plateau. As increments of B are added to mixtures starting with pure A and progressing through all ranges of composition to pure B, the initial complex formed contains the highest ratio of A to B and the subsequent complexes contain a successively lower ratio of A to B. Similarly, if increments of A were added to mixtures which were initially high in B and then proceeded through all ranges of composition to pure A, the initial complex would contain the highest proportion of B to A. However, the same series of complexes must be formed whether the increments are made with A or B. These qualitative ideas assist in understanding the sets of equations used for deriving the composition of the complexes from the partial molal heat effects.

To illustrate the method, the composition of complexes will be derived for the particular situation in which three complexes are successively formed from A and B. The partial molal heat quantities of interest in this derivation are the maximum partial molal heat effects, θ, corresponding to the plateaus as shown in Fig. 3.

On adding increments of constituent B to a complete series of mixtures three maximum partial molal heat effects, θ_1, θ_2, and θ_3, would be obtained experimentally, if there were three complexes.

$$rA + sB \rightleftarrows A_rB_s\,;\ \Delta R_1 = s\theta_1 \quad [39]$$

$$tA_rB_s + (rv - st)\,B \rightleftarrows rA_tB_v\,;\ \Delta R_2 = (rv - st)\,\theta_2 \quad [40]$$

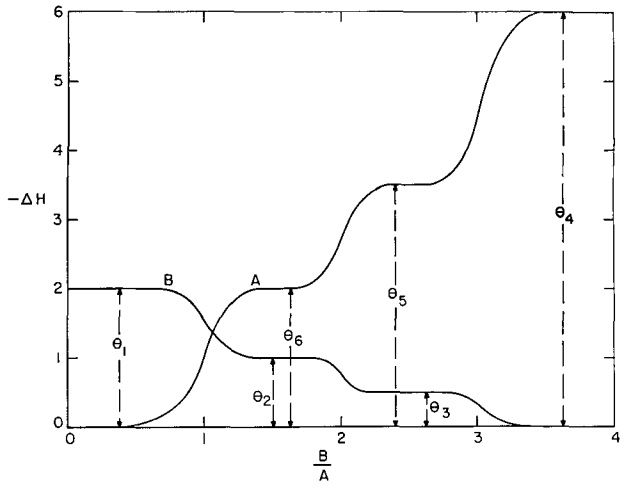

Fig. 3. Schematic representation of the partial molal heat effects for a system of two components which produce three complexes, AB, AB_2, and AB_3.

$$mA_tB_v + (nt - mv)\,B \rightleftarrows tA_mB_n\,;\,\Delta R_3 = (nt - mv)\,\theta_3 \quad [41]$$

ΔR refers to the heat effect for the equation as written, that is, for the formation of 1 mole of product in Eq. [39], r moles of product in Eq. [40], and t moles of product in Eq. [41].

However, for calculating the composition of the complexes, the equations for the reactions must be in the simple form of Eq. [39], that is, show the heat effect for the formation of the complex directly from A and B. Hence, Eq. [40] and [41] for the formation of A_tB_v and A_mB_n must be modified.

The equation for the direct formation of A_tB_v is obtained by multiplying Eq. [39] by t, adding to Eq. [40] and dividing by r. The final result is

$$tA + vB \rightarrow A_tB_v\,;\,\Delta R_{2a} = \frac{st(\theta_1 - \theta_2) + rv\theta_2}{r} \quad [40A]$$

Similarly, the equation for the direct formation of complex A_mB_n from A and B is obtained by multiplying Eq. [40A] by m and adding to Eq. [41] to give the following equation:

$mA + nB \rightarrow A_mB_n\,;\,\Delta R_{3a} =$

$$\frac{mrv(\theta_2 - \theta_3) + mst(\theta_1 - \theta_2) + nrt\theta_3}{rt} \quad [41A]$$

To permit the calculation of the coefficients, m and n, r and s, t and v, three additional equations, similar to Eq. [39], [40A], and [41A] must now be obtained for the addition of increments of A to a range of mixtures starting with pure B

$$mA + nB \rightleftarrows A_mB_n\,;\,\Delta R_4 = m\theta_4 \quad [42]$$

$$vA_mB_n + (nt - mv)\,A \rightleftarrows nA_tB_v\,;\,\Delta R_5 = (nt - mv)\,\theta_5 \quad [43]$$

$$sA_tB_v + (rv - st)\,A \rightarrow vA_rB_s\,;\,\Delta R_6 = (rv - st)\,\theta_6 \quad [44]$$

Since the coefficients are small integers, the ratios of m/n, t/v, and r/s are adequate to determine them. To determine the ratio, r/s, Eq. [44] is multiplied by r/s and added to Eq. [40], giving the result

$$\frac{r(rv - st)}{s}A + (rv - st)B \rightleftarrows \frac{(rv - st)}{s}A_rB_s$$

$$\Delta R_{2,6} = (rv - st)\,\theta_2 + \frac{r(rv - st)\,\theta_6}{s} \quad [45]$$

Simplifying, the equation becomes

$$rA + sB \rightleftarrows A_rB_s\,;\,\Delta R_{6a} = s\theta_2 + r\theta_6 \quad [46]$$

To obtain the ratio, s/r, the heat effect, ΔR_{6a}, of Eq. [46] is equated to the heat effect, ΔR_1, of Eq. [39]

$$s\theta_1 = s\theta_2 + r\theta_6 \quad [47]$$

This equation leads to the result that

$$s/r = \theta_6/(\theta_1 - \theta_2) \quad [48]$$

To obtain the ratio, t/v, multiply Eq. [43] by t/v and add to Eq. [41], giving the result

$$\frac{t(nt - mv)}{v}A + (nt - mv)B \rightleftarrows \frac{(nt - mv)}{v}A_tB_v$$

$$\Delta R_{3,5} = (nt - mv)\,\theta_3 + \frac{t(nt - mv)}{v}\theta_5 \quad [49]$$

Simplifying, this gives

$$tA + vB \rightleftarrows A_tB_v\,;\,\Delta R_{5a} = v\theta_3 + t\theta_5 \quad [50]$$

Equate the heat effect, ΔR_{5a}, of Eq. [50] to the heat effect R_{2a} of Eq. [40A]

$$v\theta_3 + t\theta_5 = \frac{st(\theta_1 - \theta_2) + rv\theta_2}{r} \quad [51]$$

This equation is solved by making a substitution for for s/r given in Eq. [48], to give the result

$$t/v = (\theta_2 - \theta_3)/(\theta_5 - \theta_6) \quad [52]$$

To obtain the ratio, n/m, equate the heat effect, ΔR_{3a}, of Eq. [41A] to the heat effect, ΔR_4, of Eq. [42].

$$m_{\theta 4} = \frac{mrv(\theta_2 - \theta_3) + mst(\theta_1 - \theta_2) + nrt\theta_3}{rt} \quad [53]$$

This equation is solved by making a substitution for s from Eq. [48] and a substitution for v, using Eq. [52], to yield the following result

$$n/m = \frac{(\theta_4 - \theta_5)}{\theta_3} \quad [54]$$

Equations [48], [52], and [54] give the compositions of the three complexes in terms of the maximum partial molal heat effects, θ, which latter are determined experimentally under conditions that result in essentially complete reaction of the increment. If more than three complexes are formed, the procedure which has been illustrated can be extended. If only two complexes, A_rB_s and A_tB_v, were formed, the two equations for the addition of increments of B would be the same as Eq. [39] and [40]. The equations for the addition of increments of reactant A would be similar to those of Eq. [42] and [43]

$$tA + vB \rightleftarrows A_tB_v\,;\,\Delta R_3 = t\theta_3$$

$$sA_tB_v + (rv - st)\,A \rightleftarrows vA_rB_s\,;\,\Delta R_4 = (rv - st)\,\theta_4 \quad [55]$$

The formula for determining their composition would be

$$\frac{s}{r} = \frac{\theta_4}{\theta_1 - \theta_2} \text{ and } \frac{v}{t} = \frac{\theta_3 - \theta_4}{\theta_2} \quad [56]$$

Calculation of instability constants when two complexes are formed.—Derivation for a system with one and two ligands added.—The instability constant was derived in an earlier section for equilibria involving only one complex, and a formula was applied to the copper cyanide system, shown in Fig. 2, for the reaction of $Cu(CN)_3^{--}$ with CN^- to form $Cu(CN)_4^{---}$. The equations could not be similarly applied to the sloping portion of the curve, e-f, because two equilibria were involved. Along the slope the addition of CN^- to a mixture containing $Cu(CN)_2^-$ ion resulted in the formation of both $Cu(CN)_3^{--}$ ion and $Cu(CN)_4^{---}$ ion.

To determine the instability constant for the formation of $Cu(CN)_3^{--}$, the constant for the formation of $Cu(CN)_4^{---}$ must also be taken into consideration.

The method of calculating the instability constant for the equilibria involving the $Cu(CN)_3^{--}$ ion is done in the following sections in two ways. The first method is an analytic one involving the derivation of a formula for calculating k. The formula is applicable only to a system of reactions in which one complex is derived from the other by addition of only one additional ligand. The other method of calculation is a graphical one and the procedure can be applied generally. For pedagogic purposes the specific calculation of the instability constant of the cuprocyanide system

$$Cu(CN)_2^- + CN^- \rightleftarrows Cu(CN)_3^{--} \qquad [22]$$

will be carried through first. The extension to a general procedure will then appear simpler.

Two reactions take place simultaneously when increments of cyanide ion are added to mixtures consisting of $Cu(CN)_2^-$ and $Cu(CN)_3^{--}$. Depending on the composition of the mixture, $Cu(CN)_3^{--}$ and $Cu(CN)_4^{---}$, both can be formed, or only $Cu(CN)_4^{---}$ at the expense of both $Cu(CN)_2^-$ and $Cu(CN)_3^{--}$. The mass action expressions are

$$\frac{[Cu(CN)_2^-][CN^-]}{[Cu(CN)_3^{--}]} = k_1 \qquad [57]$$

$$\frac{[Cu(CN)_3^{--}][CN^-]}{[Cu(CN)_4^{---}]} = k_2 \qquad [58]$$

The ratio of k_2 to k_1 will be used in the following derivations. The value of k_2 was calculated earlier; see Eq. [25].

$$\frac{k_2}{k_1} = K \qquad [59]$$

K is a number larger than unity, when the instability constant, k_1, for the formation of the first complex is smaller than that for the succeeding complexes.

In terms of concentrations, Eq. [57] and [58] are written as follows

$$(y - \bar{a} - b)(x - \bar{a} - 2b) = \bar{a}k_1 \qquad [60]$$

$$\bar{a}(x - \bar{a} - 2b) = bk_2 \qquad [61]$$

where y = moles of $Cu(CN)_2^-$ initially used, expressed as mole/liter; x = moles of CN^-, initially added to the $Cu(CN)_2^-$, and expressed as moles/liter; $\bar{a}$ = molar concentration of $Cu(CN)_3^{--}$ formed; b = molar concentration of $Cu(CN)_4^{---}$ formed. Note that the formation of 1 mole of $Cu(CN)_3^{--}$ removes only one mole of $Cu(CN)_2^-$ and one mole of CN^-, whereas the formation of one mole of $Cu(CN)_4^{---}$ removes two moles of CN^-.

Equations [60] and [61] involve three unknowns, $\bar{a}$, b, and k_1 (k_2 is known); and at least one more equation is required for calculating them.

Two additional equations are derived from the first and second derivatives of $\bar{a}$ or b with respect to x.

Divide Eq. [60] by Eq. [61] to give Eq. [62], which does not contain x

$$(y - \bar{a} - b) = \frac{\bar{a}^2}{bK} \qquad [62]$$

Equation [62] is differentiated with respect to x, considering both $\bar{a}$ and b as dependent variables

$$-\bar{a}' - b' = \frac{bK(2\bar{a}\bar{a}') - \bar{a}^2 b'K}{b^2K^2} \qquad [63]$$

This equation is simplified using Eq. [62] and the approximate relation

$$-\bar{a}' = 2b' - 1 \qquad [63A]$$

to give an equation involving b'

$$b' = \frac{2\bar{a} + bK}{\bar{a}(4 - K) + Ky} \qquad [64]$$

Equation [63A] is obtained by differentiating Eq. [61]

$$1 - \bar{a}' - 2b' = k_2\left[\frac{\bar{a}b' - b\bar{a}'}{\bar{a}^2}\right] \qquad [65]$$

Since the instability constant, k_2, is a small number, for example 0.002, $1 - \bar{a}' - 2b'$ can be considered as equal to zero. This involves no appreciable error, since $\bar{a}'$ and b' cannot be determined from the experimental data with this precision.

The use of the approximation gives equations which do not fit the part of the reaction indicated by the portion of the curve g-h-i in Fig. 2. An equation for b' which does not involve the approximation and, hence, is valid for all of curve 1, was derived, but no use is made of it in this treatise.

$$b' = \frac{\bar{a}^2(2\bar{a} + bK)}{(\bar{a}k_2 + 2\bar{a}^2)(2\bar{a} + bK) - K(y - \bar{a} - 2b)(bk_2 - \bar{a}^2)} \qquad [64A]$$

With Eq. [64], three simultaneous equations are available for solving for the three unknowns. In addition an equation for b'' is obtained by differentiating Eq. [64]. After making the differentiation, the expression for b'' is simplified by use of Eq. [63A] and [64]

$$b'' = \frac{2b'(b' - 1)(4 - K) + 2}{\bar{a}(4 - K) + Ky} \qquad [66]$$

The expression in the numerator of Eq. [66] occurs frequently, hence, it will be represented by the symbol, α. Equation [66] then becomes

$$b'' = \frac{\alpha}{\bar{a}(4 - K) + Ky} \quad \text{with} \quad \alpha = 2b'(b' - 1)(4 - K) + 2 \qquad [67]$$

Equations [60], [61], [64], and [66] or [67] comprise a system of four simultaneous equations in three unknowns. These equations will next be solved for K, the ratio of k_2 to k_1. The plan of attack is to use Eq. [64] as the basis for substitutions. Values of $\bar{a}$ and b are obtained as functions of K so that the substituted equations contain only one variable, K.

The variable, b, can be obtained as a function of $\bar{a}$ and K by solving Eq. [62]

$$b = \frac{K(y - \bar{a}) \pm \sqrt{K^2(y - \bar{a})^2 - 4\bar{a}^2K}}{2K} \qquad [68]$$

The value of b from Eq. [68] is substituted into Eq. [64] and the equation is simplified to give the following

$$2b' - 1 = \frac{\sqrt{K^2(y - \bar{a})^2 - 4\bar{a}^2K}}{\bar{a}(4 - K) + Ky} \qquad [69]$$

Note that this equation contains two unknowns: K and $\bar{a}$. The value of $\bar{a}$ in terms of K is determined from Eq. [67] and substituted into Eq. [69], as follows.

First note that the denominator of Eq. [69] is readily obtained from Eq. [67]

$$\bar{a}(4 - K) + Ky = \frac{\alpha}{b''} \qquad [70]$$

Equation [70] also leads at once to an equation for $\bar{a}$ which contains only the unknown, K

$$\bar{a} = \frac{\alpha - b''Ky}{b''(4 - K)} \qquad [71]$$

Also, for substituting into Eq. [69], the value of $y - \bar{a}$ is readily obtained from Eq. [71]:

$$y - \bar{a} = \frac{4b''y - \alpha}{b''(4 - K)} \qquad [72]$$

Substitution of the values from Eq. [70], [71], and [72] into Eq. [69] gives after some simplification

$$2b'-1=\frac{\sqrt{K^2(4b''y-\alpha)^2-4K(\alpha-b''Ky)^2}}{\alpha(4-K)} \quad [73]$$

Further simplification yields

$$(2b'-1)\alpha=\sqrt{\frac{K(4b''^2y^2K-\alpha^2)}{4-K}},$$

$$\alpha=2b'(b'-1)(4-K)+2 \quad [74]$$

The value of b' is not restricted by Eq. [74], and we can select the point on the curve where $b'=0.5$. However, the value of b'' must also be taken for this same point. With $b'=0.5$, Eq. [74] takes the following simple form

$$K=16(b''y)^2 \quad [75]$$

The following discussion shows the method of evaluating b' and b'' from calorimetric data for a reaction involving the formation of two complexes. The method is similar to that given earlier for a single complex.

Relations between partial molal heat effects and the partial derivatives.—In a reaction involving the formation of two complexes by adding increments, dx, of the ligand B, part of the increment goes to form one complex and part goes to form some of the higher complex. It is assumed that a significant amount of a third complex is not simultaneously formed; hence, only the situation involving two complexes needs to be treated.

The following equations for the formation of the complexes are not given in the most general form, such as those of Eq. [39] and [40], but they are more suitable for pedagogic purposes.

$$mA+nB\rightleftarrows A_mB_n; \qquad \Delta R_1=n\theta_1 \quad [76]$$

$$A_mB_n+rB\rightleftarrows A_mB_{n+r} \text{ or } A_mB_s,\ s=n+r;\ \Delta R_2=r\theta_2 \quad [77]$$

According to the discussion in an earlier section and Eq. [17], the value of ΔH for the reaction of Eq. [76] is

$$\Delta H_1=n\theta_1\bar{a}' \quad [78]$$

where $\bar{a}'=\partial A_mB_n/\partial x$

The value of ΔH_2 for the formation of complex A_mB_s consists of two terms. The complex is considered as being formed from A and B through the intermediary of the formation of A_mB_n. The value of ΔH_2 is, therefore

$$\Delta H_2=b'(n\theta_1+r\theta_2),\ b'=\partial A_mB_s/\partial x \quad [79]$$

The total partial molal heat effect is the sum of Eq. [78] and [79].

$$\Delta H=\Delta H_1+\Delta H_2=\bar{a}'n\theta_1+b'(n\theta_1+r\theta_2)$$

In a later section, a relation is shown between $\bar{a}'$ and b' (Eq. [95]) according to which, $\bar{a}'=(1-sb')/n$

On substituting for $\bar{a}'$ in Eq. [80], the final result for the relation between the partial molal heat effect, ΔH, and b' is

$$\Delta H=\theta_1+rb'(\theta_2-\theta_1) \quad [81]$$

The value of b'' can be obtained by differentiating Eq. [81] and using the slope of the curve in the same manner as described earlier for a single complex.

Numerical calculation for the cuprocyanide system.—The equations for the cuprocyanide system were given by Eq. [22] and [23], and they correspond to Eq. [76] and [77] with $m=n=r=1$.

Since $\theta_1=10{,}000$ cal and $\theta_2=14{,}000$ cal, the value of ΔH corresponding to $b'=0.5$ is readily obtained from Eq. [81].

$$\Delta H=10{,}000+4{,}000\ b'=12{,}000 \quad [82]$$

This value of ΔH is at the midpoint of the slope.

The value of b'' is next obtained by differentiating Eq. [81].

$$\frac{\partial\Delta H}{\partial x}=rb''(\theta_2-\theta_1) \text{ or}$$

$$b''=\frac{1}{4000}\cdot\frac{\partial\Delta H}{\partial x}=\frac{1}{4000}\cdot\frac{1}{y}\text{ (Slope)} \quad [83]$$

The slope of the curve at the midpoint is 15,600 and $y=0.6$. Hence, $b''=\frac{1}{4000}\cdot\frac{1}{0.6}(15{,}600)=6.5$

Substituting this value for b'' in Eq. [75] gives

$$K=16(b''y)^2=16(6.5\times0.6)^2=243 \quad [84]$$

$$k_1=k_2/K=0.0023/243=9.5\times10^{-6} \quad [85]$$

Calculation of the instability constant by graphical means when two complexes are formed.—The algebraic solution of a set of simultaneous equations such as those presented by Eq. [60] and [61] of the previous section becomes too difficult when the concentrations are raised to a power, and a graphical method of solution is more convenient. The procedure is actually a kind of curve fitting. The instability constant, considered as a parameter, is given a series of values, and for each value a curve is calculated, representing ΔH as a function of the initial composition of the mixtures. By successive calculations a curve can be found that fits the experimental one as closely as desired. The equations for a general case are derived, but the example of the copper cyanide complexes is used to illustrate the numerical procedure.

Let the reaction of the ligand B with A be as represented in Eq. [76] and [77]. As in the previous derivations, y and x represent the concentrations of A and B expressed as molar concentrations. The following are the mass action equations

$$(y-m\bar{a}-mb)^m\ (x-n\bar{a}-sb)^n=\bar{a}k_1 \quad [86]$$

$$\bar{a}(x-n\bar{a}-sb)^r=bk_2 \quad [87]$$

In this discussion, k_2 is assumed to be known, since it can be obtained as described in the section on Relation between partial molal heat effects without the interference of the reaction of Eq. [86].

To obtain an equation not containing x, each side of Eq. [86] is multiplied by itself r times and each side of Eq. [87] is multiplied by itself n times.

$$[y-m(\bar{a}+b)]^{mr}(x-n\bar{a}-sb)^{nr}=(\bar{a}k_1)^r \quad [88]$$

$$\bar{a}^n(x-n\bar{a}-sb)^{nr}=(bk_2)^n \quad [89]$$

$$\text{Let, } (k_1)^r/(k_2)^n=1/K \quad [90]$$

Divide Eq. [88] by Eq. [89] to eliminate the expression containing x

$$\frac{[y-m(\bar{a}+b)]^{mr}}{\bar{a}^n}=\frac{(\bar{a}k_1)^r}{(bk_2)^n}=\frac{\bar{a}^r}{Kb^n} \quad [91]$$

$$Kb^n[y-m(\bar{a}+b)]^{mr}=\bar{a}^s,\ n+r=s \quad [92]$$

Differentiation with respect to x and substituting $[y-m(\bar{a}+b)]=Z$

$$nb^{n-1}b'KZ^{mr}-Km^2b^nb'rZ^{mr-1}-Km^2\bar{a}'b^nrZ^{mr-1}=\bar{s}\bar{a}'\bar{a}^{s-1} \quad [93]$$

A relation between b' and $\bar{a}'$ is obtained by differentiating Eq. [87] with respect to x

$$r(x-n\bar{a}-sb)^{r-1}(1-n\bar{a}'-sb')=k_2\frac{d(b/\bar{a})}{dx} \quad [94]$$

Since k_2 is small and the parenthesis $(x-n\bar{a}-sb)$, which represents unreacted x, is also small, then

$1 - n\bar{a}' - sb'$ can be set equal to zero. This approximation is legitimate, since the error made by this approximation in calculating the heat of reaction would not be as large as that involved in the experimental calorimetric determination, which is probably several per cent.

$$1 - n\bar{a}' - sb' = 0 \text{ or } \bar{a}' = \frac{(1 - sb')}{n} \qquad [95]$$

On substituting the expression for $\bar{a}'$ from Eq. [95] and $\bar{a}^s$ from Eq. [92] into Eq. [93] and simplifying, an expression for b' is obtained

$$\frac{1}{b'} = \frac{\bar{a}n(nZ - m^2br)}{b(sZ + m^2\bar{a}r)} + s \qquad [96]$$

The procedure of calculating a series of curves is as follows. Take a value of y which will be held constant for the whole series of curves. The variation of the composition of the solution is obtained by letting x vary. Assume a value of k_1 for a given curve. The value of k_2 is assumed known. Give b a series of values and calculate the corresponding values of $\bar{a}$ from Eq. [92] which does not contain x. Calculate the values of x from Eq. [89], using the values of $\bar{a}$ and b which have been determined. The moles per liter of the initial additions used to form the solution are now known. The value of b' is obtained from Eq. [96]. The last step is to calculate the value of the heat of reaction, ΔH, from the series of values of b' and plot a curve of ΔH *vs.* the ratio of x to y.

Examples of the graphical method applied to the copper cyanide system are given in Table I and graphed as curves 2 and 3 in Fig. 2. For the sake of simplicity, k_2 was taken as equal to 10^{-3}. The value of y (initial concentrations of $Cu(CN)_2^-$) was taken as 0.6M and considered as a constant. For given values of b, the value of $\bar{a}$ was calculated from the following equation which was obtained from Eq. [90] to [92] with $m = n = r = 1$ and $s = 2$: $\bar{a} = \frac{1}{2}[-bK + \sqrt{bK(bK - 4b + 4y)}]$. The values of x were obtained from Eq. [89] using it in the form: $x = bk_2/\bar{a} + \bar{a} + 2b$. The value of b' was calculated next, using Eq. [64]:

Table I. Illustration of the graphical method for addition of increments of CN^- to a cuprocyanide solution. Computation of curves showing the relation between partial molal heat effect, ΔH, and the $*CN^-/*Cu(CN)_2^-$ ratio of the bath

k_1^β	K^β	x	$\frac{x}{y}$	$\bar{a}$	b^β	$\bar{a}'$	b'	ΔH, kcal

10^{-4}	10	0.431	0.71	0.331	0.05	0.42	0.29	11.15
10^{-4}	10	0.567	0.94	0.3663	0.10	0.09	0.46	11.85
10^{-4}	10	0.743	1.24	0.343	0.20	−0.36	0.68	12.7
10^{-4}	10	0.876	1.46	0.275	0.3	−0.62	0.81	13.2
10^{-4}	10	1.16	1.94	0.05	0.55	−0.96	0.98	13.9

Data which are known: Initial $*Cu(CN)_2^-$ concentration of the bath (represented by y) was 0.6M. Instability constant, k_2, for reaction: $Cu(CN)_4^{---} \rightleftarrows Cu(CN)_3^{--} + CN^-$ was taken to be 1.0×10^{-3}, and the heat of reaction $\Delta H = -14{,}000$ cal. k_1 is the instability constant for the reaction: $Cu(CN)_3^{--} \rightleftarrows Cu(CN)_2^- + CN^-$ with the heat of reaction $\Delta H = -10{,}000$ cal.

The columns marked with β indicate values of the variables which have been assumed for purposes of calculation. The data in the other columns represent values calculated as indicated in the text.

For definition of the other variables, see text: $K = k_2/k_1$; x = initial concentration of CN^- (moles/l) used in the solution; $\bar{a}$ = concentration $Cu(CN)_3^{--}$, moles/l; b = concentration $Cu(CN)_4^{---}$, moles/l; $\bar{a}' = \frac{\partial \bar{a}}{\partial x}$; $b' = \frac{\partial b}{\partial x}$.

$$b' = \frac{2\bar{a} + bK}{4\bar{a} + K(y - \bar{a})}$$, which can be derived from Eq. [96] with the help of Eq. [92] and the relation: $Z = y - m(\bar{a} + b)$. Finally, the values of ΔH were calculated from Eq. [81] which had the form: $\Delta H = 10{,}000 + 4{,}000\ b'$. Curve 2 with the assumed value of 10^{-5} for k_1 comes closer to the experimental curve than curve 3 with $k_2 = 10^{-4}$. No attempt was made to make a closer approximation with the graphical method as the purpose here was primarily for demonstration.

Discussion

The calorimetric method for determining the composition of complexes and their instability constants is more general than any of the other methods because heat is always involved in a reaction. The method can be applied to aqueous solutions, fused salt systems, and even to gaseous systems. Not enough experience has been obtained with it to know its limitations and precision.

In comparison with Job's method of continuous variation, which is much used for determining the composition of complexes, it has a wider applicability because it can be used for systems in which more than one complex is formed. Job's method cannot in general be applied to systems which form more than one complex. This was recognized by Job himself (3b). Nevertheless, Vosburgh and Cooper (5) showed that under some circumstances information on the existence and even the composition of more than one complex in a solution could be obtained by measurements of light absorption, using light of various wavelengths. However, Job's method used in conjunction with calorimetric measurements would not show the existence of more than one complex. For example, application of Job's method to the copper cyanide system would lead to only one maximum. This is illustrated by curve 4 in Fig. 2 which shows the results that would have been obtained by Job's method. These data were obtained by calculation from the data of the method of increments.

The calorimetric method bears a resemblance to thermometric titrations. There are some differences in the experimental procedures, but the main difference is in the analysis of the data. In both methods successive increments of one of the reactants are added to the reaction mixture. However, the thermometric method is actually an integral method, because the datum which is plotted is the extent of the temperature rise that has occurred since the initiation of the experiment with the addition of the first increment. In the calorimetric method, a difference of temperature is measured, and the ideal is to keep the system at almost constant temperature by adding a small increment; furthermore, the system must be allowed to return to its initial temperature before another increment is added. The variation of the heat effects are opposite in the thermometric and calorimetric methods. Consider the addition of increments of a strong acid reactant to a system consisting initially only of a strong alkali, until neutralization is accomplished. In the thermometric method, the plot of temperature against additions would show a steeply rising curve until the neutralization point were reached, beyond which the curve would be constant. In the calorimetric method, the curve of partial molal heat effect against composition would be horizontal until the neutralization point was reached, beyond which point, the curve would sharply fall to zero.

The following values of 25°C of the instability constants of the complex cyanide ions were obtained with the method of increments

$$\frac{[Cu(CN)_2^-][CN^-]}{[Cu(CN)_3^{--}]} = k_1 = 1.0 \times 10^{-5}$$

$$\frac{[Cu(CN)_3^{--}][CN^-]}{[Cu(CN)_4^{---}]} = 2.3 \times 10^{-3}$$

Penneman and Jones (6) obtained similar values, $k_1 = 1.5 \times 10^{-5}$ and $k_2 = 5.7 \times 10^{-3}$, for 25°C by observing the infrared absorption spectra of the compounds in order to establish their concentration in solution. Rothbaum (7) obtained the following values for 20°C by measurement of the electrode potentials of copper in cyanide solutions

$$k_1 = 1 \times 10^{-5} \text{ to } 5 \times 10^{-5} \qquad k_2 = 5 \times 10^{-2}$$

Of these methods, the measurement of electrode potentials is the least satisfactory, as there is doubt that the potential is reversible and that it actually represents the assumed reaction. The method of Penneman and Jones required that various complex compounds be prepared so that their absorption spectra could be obtained. The detection of the $Cu(CN)_2^-$ ion was not feasible because of its low relative absorption coefficient, and the concentration of this ion and also of the cyanide ion had to be obtained by difference. In comparison, the method of increments did not require the isolation of any of the complexes.

Acknowledgment

The author wishes to acknowledge the assistance of J. M. Sherfey who did the laboratory work on the calorimetric measurements of the cuprocyanide system, and the interest and support of Fielding Ogburn in the calculations. The author also wishes to thank the Division of Research, Chemistry Branch, Atomic Energy Commission, for their continuing support of the project on electrochemical calorimetry of which project this research is a byproduct.

The Utilization of Thermogalvanic Cells for Studying the Freezing of Electrolytic Solutions and Ion Migration in Ice

Minas Ensanian

Physical Chemistry Group, Bell Aerosystems Company, Buffalo, New York

ABSTRACT

Ion transport during the freezing of electrolytic solutions to dry ice temperatures has been followed by means of a thermogalvanic cell. The low-temperature limit of an operating cell depends primarily on ion size and polarizability. Unexplained low-temperature changes in electrode polarity as well as spontaneous outbursts of energy have been observed. The technique offers a method for studying the ion-rejection process at an advancing ice-liquid interface as well as ion migration through ice.

With respect to the demineralization of saline water by the freezing method it is known that an ion-rejection process (1, 2) is in operation at the advancing solid/liquid interface. Although a number of studies have appeared in related areas such as the electrical conductivity of ice, etc. (3-20) the literature with respect to this problem is severely limited and the mechanisms and phenomenon poorly understood.

This communication summarizes an exploratory examination of beryllium, aluminum, iron, copper, magnesium, zinc, tin, and lead thermogalvanic cells in which the electrolyte surrounding one of the electrodes is gradually frozen. The principle objective was to ascertain the feasibility of using a thermocell as a tool for the investigation of ion migration during the freezing of electrolytic solutions and subsequently in the resulting doped ice.

In spite of difficulties that are inherent in the study of any nonequilibrium system the experimental results, although preliminary, are nevertheless of such a nature as to strongly demonstrate the potential of the thermocell approach.

Experimental Procedure

The thermogalvanic cells consisted simply of a very large Pyrex U-tube which contained about 400 ml of electrolyte and at whose ends were two identical electrodes partially immersed in the electrolyte. The metal electrodes approximately (1/64 x 1/2 x 3 in.) were made from available sheet materials and cleaned by standard procedures. In one case the electrode was placed against a thin tipped glass tube containing a chromel-alumel thermocouple and positioned in the center of the arm with a minimum distance slightly more than ¼ in. from the glass wall.

The other electrode which remained at ambient temperature was attached in a similar manner to a mercury thermometer. Temperature measurements were made at the tips of the electrodes which were 34 in. apart.

All emf's were measured by L&N null and thermocouple potentiometers and precautions were taken to insure against metallic thermocouple effects.

The cold arm of the U-tube was surrounded by a polyethylene jacket which extended about ½ in. above and 2½ in. below the level of the electrode and which was kept firmly packed with powdered dry ice. The electrolytes were 0.1M solutions of reagent grade beryllium, aluminum, iron(ic), copper(ic), magnesium and zinc sulfates except for tin(ous) chloride and lead nitrate. In the case of the tin salt a well mixed 400 ml suspension of an equivalent amount of material was

used although a large part of the suspension settled at the bottom of the U-tube, no such settling was observed with the nonacidified iron salt which appeared to be in solution. No acids were added to these solutions which along with the electrodes were newly made for each experiment.

An experiment would commence on packing the jacket (about 30 min after insertion of the electrodes) with about 2500g of powdered dry ice. Due to factors such as dry ice evaporation and recrystallization repacking was necessary during the course of an experiment, and since it was important to standardize the freezing rate the problem was minimized by a slow continuous packing and it was found that the vibrational effects in so doing had no effect on the potentials. Minor temperature variations as a result of this purely mechanical (packing) factor are not serious unless they occur at what may be termed "cut-off" (T_o) or "transition temperatures" (T_t) and although difficult to reproduce may be defined as follows. (T_o) denotes that temperature at which the output potential and current become zero, *i.e.*, the thermocell is no longer operative so long as the cold electrode is at that temperature or lower. The latter term (T_t) refers to that temperature at which a polarity change is observed, *i.e.*, when both the potential and current drop to zero and then rise again; however, in so doing the polarity of the cold and hot electrodes of the cell have changed with respect to their original connections with the positive and negative posts of the potentiometer.

Experimental Results

Some experimental results are shown, and in Tables I and II the values represent the average of three experiments.

During a 4-hr period the ambient temperatures (T_2) never varied more than ±2°C. The polarity for the cold and hot arms of the cell refers to the positive and negative terminals of the potentiometer prior to any low temperature transitions where such occurred. At times, as the electrodes were placed in the solution, one or two polarity changes would occur, and although the solutions were not made acidic, these were probably due to invisible gas films or local cell effects on the metal surfaces, since experiments conducted, *e.g.*, with magnesium in very weak acid solutions, displayed polarity changes (as a result of some gas evolution) which were almost oscillatory in nature while the temperature differential maintained between the electrodes was negligible.

However, the polarity would immediately stabilize after the jacket was packed with dry ice. For the systems studied the average time to freeze was 19 min and the average freezing temperature was 7°C.

At temperatures below —30°C both beryllium and tin were found to be quite sensitive to minor temperature variations (± 2°C). Tin exhibits numerous outbursts of energy if the freezing operation is interrupted, *i.e.*, if the temperature is held constant for several minutes then followed by a 1° or 2° rise. Plots of output voltage *vs.* temperature for both metals under these circumstances are almost periodic with pronounced dampening in the beryllium curve.

For example, if the emf of the tin thermocell at —34°C is 90 mv, then temperature stabilization will produce a rapid decay and reduce the voltage to zero. When this is followed by a slight rise in temperature several minutes later, the emf suddenly exceeds 0.1v and again decays to zero on temperature stabilization. This has been tested at lower temperatures and confirmed in view of profound experimental difficulties associated with temperature control. However, if freezing proceeds uninterrupted (continuous packing of the dry ice is necessary) the cell voltage is reasonably stabilized approximately up to the apparent cut-off temperature.

Under the experimental conditions described here great difficulty was encountered in attempting to cool the tin cell below —70°C, and it is quite possible that the system will continue to operate at considerably lower temperatures; the same may be true of beryllium.

Another interesting factor is that when a system is "thermally shocked," *i.e.* by a sudden removal of the dry ice when the thermocell is at a low temperature (see Shock Temperature in Table III), the established zero potential state or the absence of any voltage may persist from 2-25 min, after which the voltage suddenly switches back on. Although there is no strong evidence as yet, there seems an indication that except perhaps for iron and tin (whose duration is short) the duration of the zero potential state is remarkedly uniform, *viz.*, around 15 min. However, a longer period is generally required to attain the voltages and respective temperatures shown in Table III. As a result of thermal shocking one of two things may occur, *viz.*, the high voltage may persist through the phase transition or it may begin to decay within 10° or 20° of the freezing point and finally cut-off near 0°C followed by a polarity change, although producing negligible voltage.

In this respect the iron thermocell has on several occasions exhibited an extraordinary behavior in that,

Table I. Observed polarity, cut-off, and transition temperatures for the systems studied

Electrode system	Radii of ion, A	(T_o) °C	(T_t) °C	Polarity Cold elect.	Polarity Hot elect.	Function of the cold electrode
Beryllium (2+)	0.34	−70	−38 −60	+	−	Cathode
Aluminum (3+)	0.57	−63		+	−	Cathode
Iron (3+) (2+)	0.67 0.83	−60	−41 −60	+	−	Cathode
Copper (2+)	0.70	−45	−33 −45	−	+	Anode
Magnesium (2+)	0.78	−22		−	+	Anode
Zinc (2+)	0.83	−9		−	+	Anode
Tin (2+)	1.12	−70		−	+	Anode
Lead (2+)	1.20	−29	−7	−	+	Anode

Ionic radii are taken from Goldschmidt (21). Ambient temperatures were generally 25°C. Be, Fe, and Cu systems displayed two low-temperature polarity transitions.

Table II. Magnitudes of potentials before and after freezing

Electrode system	Maximum observed potential before freezing, mv	Temp, °C	Highest observed potential after freezing, mv	Temp, °C
Be	100	12	100	12
Al	275	9.5	375	−12
Fe	7	12	50	−28
Cu	9	7.5	21	−27
Mg	40	9	40	9
Zn	9	12	13	6.3
Sn	9	8.5	90	−34
Pb	2	9	27	−23

Table III. Thermal shock temperatures and potentials

Electrode system	Shock temp, °C	Voltage, mv	Temp, °C
Be	−69	>100	−10
Al	−78	500	−8.5
Fe	−74	100	−7
Cu	−37	13	−8
Mg	−30	60	0
Zn	−30	14	0.5
Sn	−70	14	−8.8
Pb	−50	14	−1.2

under conditions of thermal shock (which induces defects within the crystal lattice and thus facilitates diffusion), the polarity transition has occurred almost at the same temperature as when the heating rate was considerably slower, *i.e.*, during the initial cooling. During thermal-shock experiments no unusual colorations were noticed in ice in the region of the electrode at the time the dry ice was removed, except for a dark blue color of short duration in an isolated case with copper; however, the possibility exists. Likewise it was not possible to determine the effects of the cracking (noise resulting from expansion) on the potential in the absence of an automatic recording device.

Discussion

Neglecting for the moment any chemical factors associated with the phenomena of impurity accommodation within the ice lattice, one may expect some correlation between (T_o) and the ionic radii as is shown in Table I. The behavior of beryllium and tin are to be expected in view of beryllium's small size and tin's very high polarizability.

The relatively low cut-off temperature for lead (as compared with magnesium and zinc) is also a reflection of polarization phenomena.

On the assumption that cation-migration through ice is somehow related to the ionic-potential (after Cartledge) (22) then (T_o) should decrease in the same order as the electrode metals are listed, with beryllium having the lowest cut-off temperature and lead the highest. This would be true if migration depended solely on the ability of the cation to polarize the susceptible O^{2-} ion and might help to explain the rather close proximity of beryllium, aluminum, and iron in Table I.

One may draw an analogy between ice and quartz on the assumption that ice has a quartz-like structure, *i.e.*, by substituting the oxygen atoms for the silicon in quartz although the hydrogens do not bond the oxygens in the same rigid manner. The comparative role of ionic potential for rigid and nonrigid oxygen bonding may be shown by comparing this work with that of Gibson and Vogel (23) who found that Li^+ moves much more easily through crystalline quartz than do Na^+ and Cu^+, while Mg^{2+}, although smaller than Na^+, scarcely moves at all.

The fact that the cells are operative at low temperature would seem to indicate the existence of discrete water molecules (24) in the ice.

Again on the basis of ionic potential in this investigation, copper, magnesium, and zinc fall into the proper order.

When negligible current is drawn the total voltage (E_t) produced by a thermogalvanic cell is given by (dE/dt) (T_2-T_1) and therefore, the output should increase with an increase in the temperature differential. However, on the assumption that the freezing process will interfere with ion migration and the formation of ice (via the ion-rejection mechanism) will deplete ion concentration, one would expect a potential drop (during the freezing cycle) just prior to solidification, but this is not always the case. In fact, the stability of the voltage during the phase transition (liquid to solid) is at times remarkable and particularly in the case of beryllium and tin the experimental voltages are greater at the freezing point than the theoretical based on the above expression. The magnitudes of the potentials before and after freezing are shown in Table II.

With respect to hysteresis (reversibility of emf, temperature plots) the reproducibility of a transition temperature (polarity change) ordinarily could only be expected (during a warm-up period) if the heating and freezing rates were equal in view of the residual entropy of ice, since the crystal can exist in any one of a large number of configurations, each corresponding to certain orientations of the water molecules.

In view of the scarcity of data truly characteristic of the systems studied, the results are too complicated for a ready interpretation of the mechanism of the observed low-temperature polarity transitions.

A polarity transition denotes a change in the sign of the current transporting species (analogous to the sign of the Hall constant of a semiconductor) and the phenomena may be a reflection of elastic relaxation in the crystalline material resulting in a molecular reorientation and therefore, in spite of steric factors (ionic radii) the possibility of "anionic conduction" exists.

Quartz and lead iodide, for example, display anisotropy in their conductivity, and in the latter the anisotropy is several powers of ten at low temperatures and is temperature dependent.

If the observed transitions are due to processes at the electrode surface or are interfacial in nature, then they might be associated with the bursting of surface films or some type of semiconductor phenomena at the interface (metal/doped ice) irrespective of the multiplicity of the low temperature polarity transitions, *e.g.*, at −38° and −60°C for beryllium.

In an isolated incident a copper thermocell, after being at (T_o) for about 5 min displayed an outburst of energy exceeding by a factor of 10 any previously recorded voltage with this system in this investigation.

The origin of the factor responsible for the observed transitions may possibly be ascertained by the symmetry of voltage-temperature plots in the transition region, *i.e.*, whether the curves are parabolic. This would entail refined automatic recording equipment as well as means for greater temperature control.

The iron and copper curves in the transition region, although plotted from limited and preliminary data, appear to exhibit symmetry, and on this basis one may conclude that the phenomena resides within the ice.

Numerous questions however remain to be answered, *viz.*, the effects of degassing the electrolyte and the use of an inert gas atmosphere, characterization of the metals and their surfaces, changes as a result of varying the anion of the salt, pH, the effects of variations in the length of the ice below the electrode and thermal gradients and concentration gradients.

With respect to these considerations and the fact that the experimental work was carried out under conditions where temperature regulation and the measurement of potential and temperature was done manually, the experimental error may be considerable. Nevertheless, in terms of the desired objective, the value of the approach has been demonstrated. It is possible that, if the freezing and heating rates are extended to periods of several days or longer and with a fair degree of temperature control, one may reasonably expect data that will lead not only to a better understanding of the phenomena involved during the freezing of electrolytic solutions, but perhaps to the nature of the ion rejection as well. There is no reason to believe that with some ingenuity, perhaps entailing a high-pressure electrode, even hydrogen ion migration through ice cannot be investigated by this technique.

Returning to the problem of the desalination of sea water by the freezing process, if the observed outbursts of energy reside in the bulk of the ice, then with regard to the large-scale demineralization of salt water, the remote possibility arises of recovering some of the spent energy by taking advantage of the thermoelectric properties of ice. After all, thunderstorm electricity (25) is somehow associated with the freezing of water droplets, thermal gradients, and charge separation.

Conclusion

1. These experiments indicate that the thermocell approach can be developed into a method for studying the freezing of electrolytes and ion migration in ice.

2. Thermogalvanic action in dilute electrolytes has been shown to persist near dry ice temperatures, ion size and polarizability being important.
3. Although the evidence is limited it appears that low-temperature polarity transitions are a bulk rather than a surface phenomena.
4. Outbursts of energy at low temperatures may be indicative of cooperative relaxation processes in ice.
5. The observed increase in ion migration as the result of a slight temperature rise in the doped ice seems reconcilable with the known fact that water from aged arctic ice is potable, the older ice having experienced two or more warm-up periods.
6. Future refinements of this work must consider the nature of the electrode surface with regard to nucleation and growth of ice crystals.

Acknowledgment

The author is grateful to Robert T. Foley for his introduction to the subject of thermogalvanic potentials. This study has proceeded only because of his complete cooperation and that of Robert E. Salomon and William Rogers, Jr. Suggestions from Alfonso R. Gennaro and André J. de Bethune are gratefully acknowledged. The author is indebted to C. Roland Eddy for an interesting discussion concerning the origin and nature of the observed polarity changes and to the Leeds & Northrup Company for the loan of a potentiometer, and lastly, Charles Counts for assistance in the laboratory.

The initial phase of this work was done at Melpar, Incorporated, and Temple University.

Manuscript received June 2, 1964; revised manuscript received Nov. 23, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

Technical Notes

Improved Techniques for Acid Polishing and Forming Etch Pits at Dislocations on the (100) Face of Copper Crystals

Lawrence D. Dyer

Research Laboratories, General Motors Corporation, Warren, Michigan

The purpose of this note is to report two useful improvements in the methods of surface preparation and characterization of copper single crystals. The first is an addition of phosphoric acid to the cupric chloride polishing solution of Young (1). This improvement gives a surface sufficiently smooth to reduce the electropolishing time to as little as ½ min. The second is an electrochemical technique for forming excellent dislocation etch pits on the (100) face. The etching is carried out in the same phosphoric acid solution in which the crystal is electropolished, thereby avoiding the possibility of contamination in transferring the crystal from one vessel to another.

Sample Preparation

The test samples were single crystals of copper in the shape of bars ½ x ¾ x 2½ in. cemented to ⅛ in. thick glass slides with a commercial cyanoacrylate resin. They contained 1.5 to 3 x 10^4 dislocation sites/cm^2 on their (100) working surfaces (2). Prior to electropolishing, the orientation of the (100) planes of each crystal was determined to within 0.01° relative to the actual surface of the sample (3). Then each crystal was polished to this (100) orientation in an acid polishing machine (4), and the final smoothing was done electrolytically in a bath of 60% orthophosphoric acid.

Acid Polishing Improvement

During the initial polishing, it was sometimes necessary to remove a wedge of material up to 0.10 in. thick in order to obtain a surface of the desired orientation. To accomplish this in a reasonable time, concentrated hydrochloric acid saturated with $CuCl_2 \cdot 2H_2O$ was used. At this stage the surfaces of the crystals were rather rough and would require 20-40 min elec-

tropolishing to reach a usable smoothness. It was found empirically that a particularly smooth surface could be obtained in all subsequent acid polishing of a given sample by using an acid polishing solution of 70 g/liter $CuCl_2 \cdot 2H_2O$ in a 2:1 mixture of concentrated hydrochloric acid and 85% orthophosphoric acid. This solution removes material about 1/3 as fast as the concentrated solution. Either solution is continually depleted in cupric ion concentration as polishing proceeds, but the proper cupric ion concentration may be restored by additions of 30% H_2O_2 (5). After acid polishing with the solution that is more dilute in copper, the surface of the crystal in the electropolishing bath becomes bright very quickly and is usable at 30 sec elapsed time. However, we usually continue the electropolishing for a total of 3 min to allow additional smoothing to occur. The reduction in electropolishing time from the former 30 min to the present 3 min is particularly important when it is desired to reduce the rounding of edges and the amount of removed material.

Formation of (100) Etch Pits

The advantages of electrochemical methods for forming etch pits at dislocations have been described by Bertocci, Hulett, and Jenkins (6), who reported success with such a method for the (111) face of copper using acid chloride-bromide solutions. Some dislocation etch pits were also observed for (100) and (110) surfaces, but the occurrence of random faceting with the chloride-bromide solutions made interpretation difficult. In the process of trying to make these solutions work better on the (100) face, the present electrochemical method was discovered. It was noticed that in certain circumstances dislocation etch pits appeared even in the phosphoric acid electropolishing bath before subjecting them to the acid chloride-bromide electrochemical etch. A necessary condition was that the phosphoric acid polishing bath be quite low in copper concentration. While etching at a single voltage gave satisfactory etch pits, the background roughness was always unacceptable. However, it was discovered that a proper sequence of two voltages and etching times eliminated the objectionable background roughness while producing satisfactory etch pits. This method is reminiscent of the transient electroetching technique originally used by Young (7) for revealing dislocations in impure copper crystals. Optimum combinations of voltages and times were established at $v_1 = 0.3$-0.5v, t_1, 50-60 sec, and $v_2 = 1.0$-1.3v, $t_2 = 30$-45 sec depending on the size of pits desired. This set of voltages and times depends slightly on the concentration of cupric ion in the phosphoric acid polishing bath and on the rate of stirring, if any. The method fails to work entirely when the bath becomes more concentrated than 0.05M in cupric ion, in agreement with the work of Bertocci, Hulett, and Jenkins (6) on the (111) face in acid chloride-bromide solutions. The pits are similar to those observed on LiF by Gilman (8), fresh dislocations appearing as small, shallow but sharp pyramids. Aged dislocations appear as large deep pyramids. Flat-bottomed pits of both kinds appear and can probably be interpreted as dislocations that have moved or no longer have a component perpendicular to the (100) surface (9). Since the crystal is not transferred from the electropolishing bath to a separate etching solution in this method, it has the advantage of avoiding the possibility of picking up a film of contaminant from the atmosphere or from the surface of either solution. With this method, some background etching occurs and some nondislocation etch pits form around large pits, but these can be distinguished from those at fresh dislocations; the former are extremely shallow compared with the other types, and the latter are arranged in flow patterns downstream from the large pits. The new method gave pits that were smaller and more uniform than those obtained with the ferric chloride etch so that the newer method has a greater resolution of fine details. Etch pit counts on several crystals by the two methods gave the same results.

In practice it has been possible to start with a solution of 0.01M copper in 60% orthophosphoric acid and to use it for extended periods for both dislocation etching and electrolytic polishing. When the solution becomes about 0.04M in copper, it may be reduced to 0.01M by replacing ¾ of it with 60% orthophosphoric acid.

Manuscript received Jan. 7, 1965.

Note on Single Crystalline Calcium-Aluminate, $Ca_{12}Al_{14}O_{33}$

L. H. Brixner

Pigments Department, Experimental Station, E. I. du Pont de Nemours & Company, Wilmington, Delaware

In the CaO/Al_2O_3 phase diagram shown by Lea (1) the compound $6CaO \cdot 7Al_2O_3$ is listed as the one with the lowest melting point, about 1450°C. This is a temperature at which the Czochralski crystal growing technique should be particularly suitable if the composition melts congruently and has no disruptive phase changes between the melting point and room temperature. The fact that, according to Swanson (2), $Ca_{12}Al_{14}O_{33}$ is cubic should also make it an interesting novel host crystal for lasers if indeed good-sized single crystals could be grown.

We set out, therefore, to study the growth characteristics of this compound as well as the fluorescent emission of some rare earth ions incorporated in $Ca_{12}Al_{14}O_{33}$. Valence compensation can be achieved according to $Ca^{+2}{}_{12-2x}Ln^{+3}{}_xNa^{+1}{}_xAl_{14}O_{33}$. The fact that Cr^{+3} might also substitute for Al^{+3}, as in $Ca_{12}{}^{+2}Al_{14-x}{}^{+3}Cr_x{}^{+3}O_{33}$ makes this host especially interesting, particularly in view of the fact that Kiss (3) has just demonstrated a cross pumped laser using an yttrium aluminum garnet crystal doubly doped with Cr^{+3} and Al^{+3}. However, both garnets, $Ln_3Al_5O_{12}$, and simple rare earth aluminates of the type $LnAlO_3$ melt considerably higher than $Ca_{12}Al_{14}O_{33}$ and generally require the Verneuil technique for the preparation of large crystals.

Single crystal growing experiments with $Ca_{12}Al_{14}O_{33}$ were carried out with a 25 kw Westinghouse radio-frequency generator (450 kc/sec) as a power source. An automatic radio-frequency voltage controller regulating to 2.5% was used in conjunction with the generator. The melt was contained in a pure Ir crucible

of 40-mil wall thickness. The melting point as observed with an optical pyrometer was 1470°C, which is probably 20°-30°C low. The vapor pressure at the melting point is low and crystals up to 4 or 5 in. in length and ½ in. in diameter were readily pulled at speeds from ½ to 1 in. an hour. At slow rotation rates of about 10-60 rpm, the cross section of the crystals had essentially triangular symmetry, whereas at high rotation speeds it was almost round.

Crystals were invariably slightly orange or greenish in color, and to date we have not been able to grow completely colorless crystals, although Linde's best grade of Al_2O_3 and Baker and Adams Special Reagent grade $CaCO_3$ were used as starting materials. Since the Al_2O_3 is of a quality which produces colorless sapphire, we suspect that the source of impurities is associated with the $CaCO_3$, and further purification of this chemical seems necessary. Since the growth rates so far employed for the preparation of the single crystals have been fairly rapid (½-1 in./hr) an alternate explanation for the coloration would be defects generated to minimize any produced strain.

Laue back reflection photographs confirmed the single crystal nature of the pulled rods and the lattice parameter of 11.984Å derived from an x-ray powder diagram is in good agreement with the data given in (2). X-ray fluorescence analysis gave 48.63% CaO, 51.30% Al_2O_3 (calc. 48.53% CaO; 51.47% Al_2O_3). Semiquantitative spectrographic analysis showed Si (300 ppm), Ba (20 ppm), Fe (100 ppm), and V (50 ppm) in detectable quantities. Of these, Fe or V particularly could have been the source of the coloration of the crystals.

The thermal conductivity of single crystalline $Ca_{12}Al_{14}O_{33}$ was measured by an absolute technique and found to be 28.6 mw/cm-deg in the growth axis direction. The hardness, measured with a Reichert microhardness tester, was 6.9 on Mohs scale. Fluorescent emission (excited with 2537Å uv radiation) as a function of activator concentration was determined for the $Ca_{12-2x}Tb_xNa_xAl_{14}O_{33}$ and $Ca_{12-2x}Eu_xNa_xAl_{14}O_{33}$ systems. The typical green Tb^{+3} emission occurred in three lines centered around 485, 538, and 573 mμ, with the 538 mμ line being the most intense. Optimum quantum yields were observed at $x = 3$, which corresponds to 28.2 w/o (weight per cent) Tb, an exceptionally high optimum activator concentration for Tb. The europium emission centered around 590 mμ and 610 mμ with the shorter emission being more intense. Optimum emission occurred with the composition $Eu_3Na_3Ca_6Al_{14}O_{33}$, which contains 27.2% Eu.

More work with these systems seems indicated, particularly in view of the close structural and compositional relationship between the garnets such as $Y_3Al_5O_{12}$ ($a_o = 12.01$Å) and $Ca_{12}Al_{14}O_{33}$ ($Ca_4Al_{3.66}O_{11}$) with an a_o of 11.98Å.

Acknowledgment

The assistance of Mr. F. Walls in growing the single crystals is greatly appreciated.

Chromium Fluorescence in the $LaAlO_3$-$LaGaO_3$ System

R. Mazelsky and R. Ohlmann

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

A careful structural examination has been made of the rare earth perovskite-type compounds, ABO_3, where the oxidation state of the A and B ions are three. Of particular interest in this paper are $LaAlO_3$ and $LaGaO_3$. Geller (1, 2) has examined these compounds and has found that, at room temperature, they are rhombohedral and orthorhombic, respectively. It has been reported (3-5) that $LaAlO_3$ is a suitable matrix for examining the fluorescent properties of the rare earth and transition metal ions, such as neodymium and chromium since they can be incorporated substitutionally over a large concentration range. In this paper the fluorescence of chromium ions in $LaAlO_3$, $LaGaO_3$, and in solid solutions of the two is reported with emphasis on the variation of fluorescence as the Al/Ga ratio is changed.

The compounds were prepared from 99.99% Lindsay La_2O_3 and Linde optical grade Al_2O_3. The Ga_2O_3 was prepared from 99.9999% gallium metal purchased as the oxide from Alcoa. The materials were prepared from the powders by firing intimate mixtures at 1400°-1500°C. In all cases, within the limits of the sensitivity of x-rav powder diffraction, the materials were single phase. Lattice parameters were calculated from the high-angle reflections and were uncorrected for absorption. The fluorescence spectra were obtained using a one-meter Jarrell-Ash Company spectrometer, the samples being excited by an AH-6 mercury lamp with a $CuSO_4$ solution filter. All optical measurements were made on samples in which 0.5% of the B site ions were replaced by chromium.

The variation of the cube root of the volume with composition is shown on the upper curve of Fig. 1. There is a linear dependence until the composition reaches approximately 80% $LaGaO_3$ at which point there is an anomalous expansion. The lower section of Fig. 1 shows the fluorescence maxima splitting and line shape of the R-lines as a function of composition. There is a regular increase of the energy of the fluoresence peak as the concentration of gallium increases. $LaGaO_3$ and $LaAlO_3$ show twin fluoresence peaks at 77°K, but the splitting is not clearly resolved in the solid solutions due to the much broader line widths occurring than those in the "pure" compounds. This is in agreement with results reported by Tolstoy and Shun-Fu (6) who reported on the Al_2O_3-Ga_2O_3 system doped with chromium.

Chromium activated $CeAlO_3$ was also prepared. The powder photograph was conveniently indexed as orthorhombic, $a = b = 3.762$Å, $c = 3.794$Å. This would calculate to a volume intermediate between $LaAlO_3$ and $PrAlO_3$ as expected. Only weak chromium fluorescence was observed, which is perhaps due to quenching by the trivalent cerium.

In both $LaAlO_3$ and $LaGaO_3$ there is little question that chromium shows a strong preference for the B (Al or Ga) site. This is both because of the relative sizes of the ions (La/Al or Ga≈2) and the coordination number of 12 for lanthanum as opposed to 6 for aluminum and gallium. In both materials the chromium would be in a slightly distorted oxygen octahedron. In $LaAlO_3$ the lattice symmetry is rhombohedral while

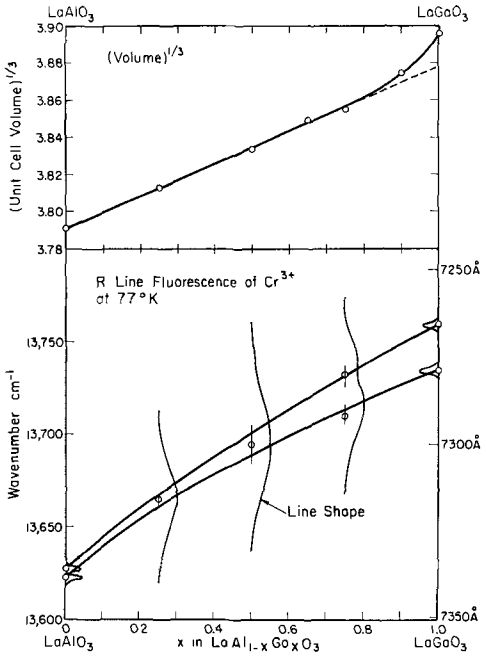

Fig. 1. Upper curve, (unit cell volume)$^{1/3}$ for various solid solutions of $LaAlO_3$ — $LaGaO_3$. Lower curve, fluorescence in the R-lines of Cr^{+3} in $LaAlO_3$ — $LaGaO_3$ solutions at 77°K.

in $LaGaO_3$ the symmetry is orthorhombic although in both cases there are relatively small deviations from the cubic lattice (1, 2). The lattice parameters shown in Fig. 1 show a smooth variation with composition. In the series there is a transformation from the rhombohedral to the orthorhombic lattice as $LaGaO_3$ is added to $LaAlO_3$, but it is not easily detectable from powder x-ray analysis. However, there should be only small changes in the oxygen ion environment around the chromium throughout the series.

As $LaGaO_3$ is added to $LaAlO_3$ the volume of the unit cell increases. This is consistent with the ionic radii reported by Geller (7) for Al^{+3} (0.558Å), Ga^{+3} (0.613Å). The ionic radius for Cr^{+3} in the perovskite lattice is calculated by Geller to be 0.608Å. This would indicate that chromium is somewhat "squeezed" in $LaAlO_3$ and in an appropriately sized site in $LaGaO_3$. The net effect would be for the Cr^{+3} - O^{-2} distance to increase as the solid solution ranges from $LaAlO_3$ to $LaGaO_3$.

The R-line from Cr^{3+} in octahedral surroundings is due to transitions between the ^2E excited state and the $^4A_2$ ground state (8). The splitting of the R-line arises from a trigonal distortion of the symmetry combined with the spin-orbit coupling in $LaAlO_3$. The R-line may be split by the orthorhombic distortion in $LaGaO_3$, but it is likely the spin-orbit interaction also is important in this crystal. To first order, the energy difference between ^2E and $^4A_2$ does not depend on the crystalline field but only on the exchange energy caused by the electrostatic electron repulsion. However, this energy, which is measured by fitting Racah parameters B and C to experimentally determined energy levels, is always calculated to be lower for Cr^{3+} in crystals than for free ions because of the neglect of the interactions with the ligand orbitals and higher energy states (9). There is also a 30% variation in these parameters between various hosts (10). The approximations present in existing theories prevent a meaningful theoretical correlation between the 9% increase in the ^2E - $^2A_2$ energy difference and the 2.6% increase in the lattice parameter from $LaAlO_3$ to $LaGaO_3$. In fact, for Cr^{3+} in the garnet structure, the energy of this transition decreases in going from $Y_3Al_5O_{12}$ to $Y_3Ga_5O_{12}$ (9), just the opposite of what was found in the present case.

The 24 cm^{-1} splitting of the R-lines in $LaGaO_3$ compared to 5.4 cm^{-1} in $LaAlO_3$ may be qualitatively understood as due to the greater distortion of the Cr^{3+} site from octahedral symmetry in $LaGaO_3$ compared to $LaAlO_3$ (1, 2), although in both cases the distortion is small. The broad line widths of the fluorescence observed from the solid solutions is likely to be an inhomogeneous broadening arising from the individual Cr^{3+} ions being in somewhat different surroundings from each other. This suggests that the Al and Ga distribute themselves at random in the various B sites. The line shape may be expected to be Gaussian, but the presence of a pair of lines made this difficult to verify.

Growth Rate and Defect Structure of Gel-Grown Crystals

H. K. Henisch, J. I. Hanoka, and J. Dennis

Materials Research Laboratory, Pennsylvania State University, University Park, Pennsylvania

In the course of previous work (1), it was shown that large and well-ordered crystals of a variety of materials, suitable for solid-state experimentation, can be grown at or near room temperature in gels. The method is specially valuable for crystals which by virtue of their low dissociation temperatures or low solubilities cannot be grown from the melt, from the vapor, or directly from solution.

From observations of the growth process, it was tentatively concluded that there exists in the immediate neighborhood of the crystal surface a supersaturation which remains constant during growth. A direct test of this hypothesis would involve microanalytic procedures which, in the prevailing circumstances, would be very difficult to apply. It is, however, possible to devise an indirect test by reference to theories of crystal growth (2-4) which concern themselves specifically with stagnant solutions. In particular, Frank (3) has developed equations which give a description of diffusion-controlled growth rates for several different idealized geometries. In the ordinary way, stagnancy in solutions is hard to achieve, but in a gel system it is

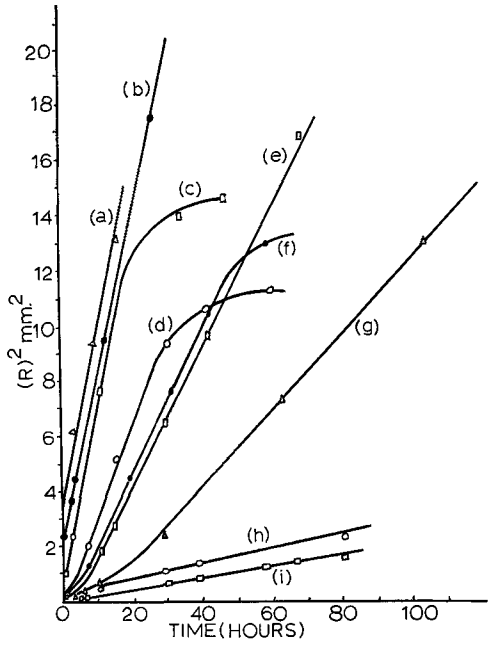

Fig. 1. Time-size relations of gel-grown crystals: (a), (c), sodium tartrate; (b), (e), (g), calcium tartrate; (d), (f), strontium tartrate; (h), (i), sodium oxalate.

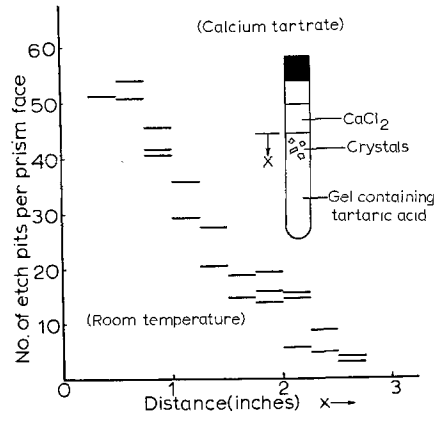

Fig. 2. Etch pit counts as a function of distance from diffusion interface. Etch pit numbers averaged over four nearly equal faces; each line represents measurements on one crystal.

completely assured. Such systems therefore provide new opportunities for applications of the theory, all the more since the essential correctness of the model has already been confirmed by means of multiple-beam interferometry (5).

The growth rates calculated by Frank involve the "reduced radius" s which, for a spherical system, is defined as $rD^{-1/2}\,t^{-1/2}$, where r is the radius of the crystal, D the diffusivity, and t the time. A constant value of s implies a constant solute concentration at the crystal surface, and vice versa. It is a simple matter to check whether s is indeed constant during growth, and results of this kind are given below. Since the starting time is not known, it is the relationship between r^2 and t which must be tested for linearity.

Two limitations must be borne in mind: one arising from the initial transient period during which steady-state concentrations are established, and one arising from exhaustion of the available solute. Both factors must give rise to nonlinearity. The duration of the first is not easy to calculate, but the second can be estimated without difficulty from the original reagent concentrations in the gel and from the distance between the crystal under observation and its nearest neighbor. In addition, there may be smaller difficulties due to departures from the simple geometry envisaged by Frank, although various linear projections used for R in Fig. 1 gave consistent results.

Using the techniques already described (1), several types of crystals have been grown, some in systems which involve only simple crystallization in the presence of the gel and some which involve a chemical reaction resulting in the formation of the solute. Linear r^2 *vs.* t relationships have been observed in both cases, suggesting that the chemical reaction as such was not the rate-determining process in crystal growth. Results are shown in Fig. 1. In each case, departures from linearity set in during the later stages of growth at times which could reasonably be associated with the onset of interaction between the diffusion regions surrounding neighboring crystals. The appearance of distinct linear regions may be taken as a confirmation of the constant surface supersaturation hypothesis.

It has already been reported (1) that the color of calcium tartrate crystals growing in waterglass depends on the illumination during growth. These color changes were traced to varying iron contamination, iron being a common impurity in waterglass. The same effects can be reproduced in sodium metasilicate gels by making a small amount of iron available. Since effective segregation coefficients generally depend on the speed of crystal growth, it was of interest to examine whether irradiation of the growing crystals changes the growth rate as well as the iron content. No growth rate changes were detected. The mechanism whereby light inhibits the inclusion of iron impurity thus remains unclear. The observations do, however, support the conclusion that we are dealing with systems in which the growth rate is controlled by the diffusion process in the gel and not by the detailed mechanism of crystal growth.

In systems which depend on the diffusion of one reagent through a gel charged with another, the average crystal growth rate is greatest near the top of the diffusion column where the concentration gradients are high, and small near the bottom where the gradients are likewise small. Corresponding to this distribution of growth rates, there is also a distribution in the number of etch pits on any crystal face, as shown in Fig. 2. If the occurrence of etch pits is accepted, in the most general terms, as a measure of disorder, then Fig. 2 and the arguments above suggest strongly that the growth rate itself determines the number of defects built into the crystal, even in the absence of foreign impurities. Such a process had already been envisaged by Jagodzinski (6) and Washburn (7) and is, presumably, linked with the low surface mobility of molecules at the growth temperature. The average etch pit densities observed on gel-grown crystals of the kind listed in Fig. 1 are comparable with those found on good germanium crystals, *i.e.*, 10^3 to 10^4 pits/cm^2. Occasionally, crystals are found which have lower etch pit densities by an order of magnitude.

It is plausible to suppose that the constant surface supersaturation maintained in the gel system is responsible for the high degree of order. The surface diffusion coefficients are expected to increase (8) with increasing temperature, leading to greater perfection and thus to fewer etch pits. A small but significant effect of this kind has been observed on calcium tartrate over the practical range of growth temperatures (20°-65°C).

The Viscosity of Some Molten Lead Compounds

C. B. Oliver

Central Research Laboratories, The General Electric Company Limited, Wembley, England

Although melts in the lead fluoride-lead oxide system are commonly used as solvents for growing crystals of refractory oxides by the fluxed-melt method [e.g., White (1)], very few physical data have been published for these liquids. As part of an investigation into fluxed-melt growth processes, a fairly rapid survey of the viscosities of melts in the lead-fluoride-lead oxide system was made using a rotating crucible viscometer. This work was not designed to yield viscosity values of high absolute accuracy, but to determine quickly the relative magnitudes of viscosities of different compositions.

Apparatus

The method is essentially that of Margules (2) and Lillie (3), in which a crucible containing the liquid is rotated at constant speed, and the viscous torque on a bob suspended in the liquid is measured.

The crucible was of platinum to reduce chemical attack by the liquids and was 50 mm deep and 50 mm in diameter. It was supported inside a Kanthal electric furnace (maximum operating temperature 1250°C) by an alumina tube which could be rotated about a vertical axis at several speeds between 2 and 20 rpm, selected by a gear-box.

The liquids used evaporated fairly rapidly, changing the liquid depth appreciably in a few hours. The platinum bob was therefore in the form of a disk 2 mm thick and 40 mm in diameter, which was totally immersed and suspended by a platinum rod 2 mm in diameter. The viscous drag on the rod was relatively small so that small variations in liquid depth had a negligible effect on the total viscous torque.

The platinum rod projected above the furnace and was suspended by a steel wire 7 ft in length. The crucible was rotated in each direction alternately, and the difference between the equilibrium positions of the bob was measured with an optical lever 2 meters long. At equilibrium the torque exerted on the bob by the rotating liquid was balanced by the elastic torque of the suspension, and the deflection of the optical lever from the rest position provided a measure of the viscosity.

Vertical adjustment of the disk position to within about 0.05 mm was effected with a micrometer screw. This was used in setting up, and also to measure the liquid depth, the point at which the disk touched the crucible bottom or the liquid surface being determined visually with a mirror.

A Pt-Pt/13%Rh thermocouple was dipped into the liquid to measure its temperature to within ±3°C between each viscosity measurement. Reproducible curves of viscosity against temperature were obtained by making measurements while the liquid temperature slowly changed through about 100°C, thus avoiding the need for elaborate temperature control. The rotation of the crucible provided adequate stirring. About five minutes was required for each viscosity measurement, during which time the temperature change was negligible. Observations were made during periods of up to 30 hr in some cases. The depth of the liquid was measured and samples taken for chemical analysis at frequent intervals.

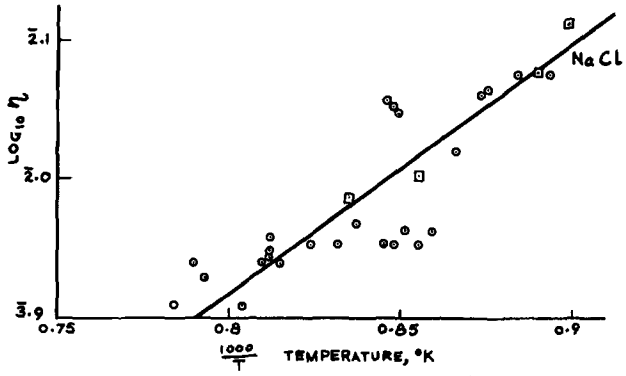

Fig. 1. Graph of log η against the reciprocal of the absolute temperature for sodium chloride. (Ω = 13 and 18.6 rpm, d = 3.7 cm.) ○, This work; □, Lorenz (1912).

The apparatus was partially enclosed and ventilated to remove harmful vapors.

Calibration

The viscometer was calibrated with water at 19°C, at which temperature the viscosity of water is 0.01030 poise (4).

The lower surface of the disk was held 10 mm above the crucible bottom throughout this work. At this height the deflection was found to be insensitive to small variations in the disk position.

The relation between viscosity and the apparatus variables was found to be

$$\eta = \frac{k\theta}{\Omega f(d)} \qquad [1]$$

where η is the viscosity in poise; k = 0.2 and was a constant for the apparatus; θ is the deflection of the optical lever from its rest position, in cm; Ω is the rotation speed of the crucible in rpm; and $f(d) = 5.56\ (d - 1.2)^{1/2} + 15$, where d is the liquid depth in cm.

The height of liquid above the top surface of the disk was $(d - 1.2)$ cm, and the expression for $f(d)$ implied that the viscous torque exerted on the disk by the liquid around and below it is independent of the height of liquid above the disk, as might be expected.

Equation [1] was found to be valid for speeds below 20 rpm; above that speed inertial effects became significant. All the variables were measured with an accuracy of ± 1% or better, but the accuracy of k, the

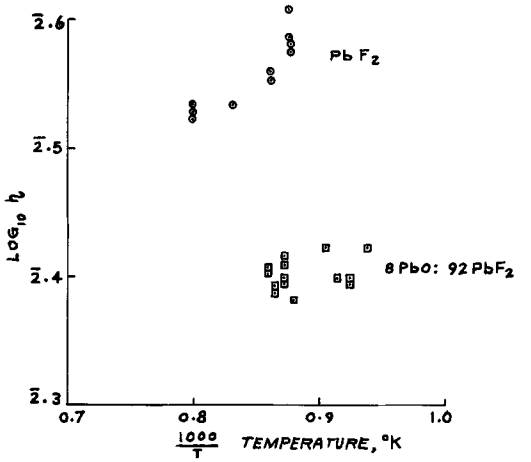

Fig. 2. Graph of log η against $1/T$ for: ○, lead fluoride (Ω = 9.3 rpm, d = 3.5 cm); □, 8 mole % lead oxide —92% lead fluoride mixture (Ω = 4.65 rpm, d = 2.4 cm).

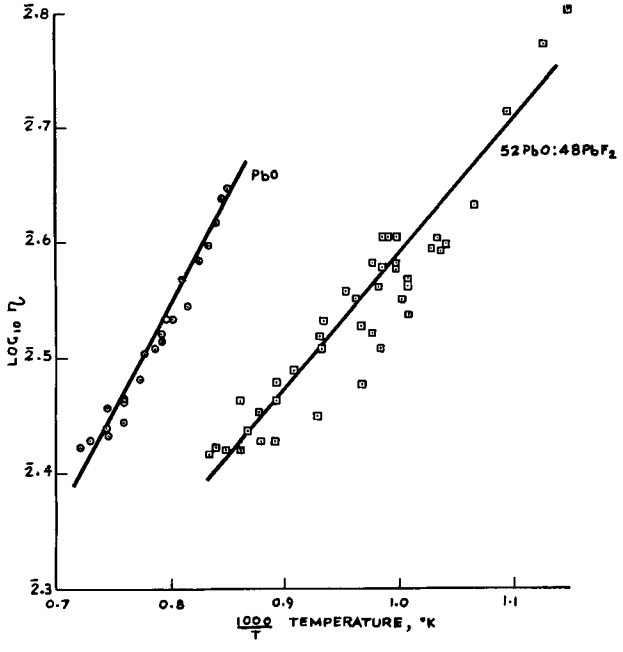

Fig. 3. Graph of log η against $1/T$ for: ○, lead oxide (Ω = 4.65 rpm, d = 2.4 cm); □, 52 mole % lead oxide —48% lead fluoride mixture (Ω = 4.65 rpm, d = 1.5 and 2.5 cm).

calibration constant, was only about ± 10%. No correction was made for thermal expansion at the working temperature, as the experimental accuracy did not warrant it.

The calibration was checked, using sodium chloride. The logarithm of viscosity is shown as a function of the reciprocal of the absolute temperature in Fig. 1, and it can be seen that the results are consistent with those of Lorenz (5). The activation energy for viscous flow was calculated from the slope of the graph according to the usual equation (6, 7).

$$\eta = A \exp (E/RT) \qquad [2]$$

where η is the viscosity in poise; T is the absolute temperature; E is the activation energy for viscous flow; R = 1.99 cal/°C, is the gas constant per mole; and A is a constant for a given liquid over a small temperature range. The values of E and A for NaCl, given in Table I, are somewhat inconsistent with values given by Murgulescu and Zuca (8) for other alkali halides (E = 4 to 7 kcal/mole and A = 0.0005 to 0.0012

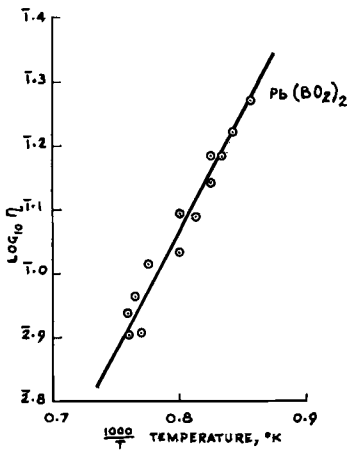

Fig. 4. Graph of log η against $1/T$ for lead borate (Ω = 2.3 rpm, d = 2.9 cm).

poise) but the agreement is sufficiently close to confirm the validity of Eq. [1].

Results

Figures 2, 3, and 4 show log η as a function of the reciprocal of the absolute temperature for four compositions in the PbF_2-PbO system and also for lead borate. The speed of rotation of the crucible and mean depth of the liquid are also given in each case.

The lead fluoride was an extra pure grade from British Drug Houses Ltd., with total impurities of less than 0.1%. All other reagents were of Analar grade.

Results for lead fluoride and the 8 mole % lead oxide-lead fluoride mixture are of low accuracy, because only the observations made at low temperatures and during the first 5 hr after melting were reproducible. At higher temperatures or after longer periods the composition of the melt changed due to the reaction of the lead fluoride with atmospheric water vapor to produce lead oxide. Results are only presented for melts for which chemical analysis of samples showed less than 1% change from the normal composition. Values of E and A for these compositions were not derived, but it is clear from Fig. 2 that the viscosity of the 8 mole % lead oxide mixture is lower than that for pure lead fluoride at the same temperature.

Results for lead oxide and the 52 mole % lead oxide-lead fluoride mixture, shown in Fig. 3, are more reliable and the accuracy of the values of E and A in Table I is about ± 20%. It will be seen that at a given temperature the viscosities of the mixture are appreciably lower than those of the individual components.

The effects of modifying the viscosity of lead oxide by adding other materials were briefly investigated. The results for lead borate are shown in Fig. 4. The accuracy is again estimated at ± 20%. The results show that the addition of a large amount of boric oxide increases the viscosity of lead oxide, as was anticipated from the high viscosity of boric oxide itself.

It was not possible to determine the effect on viscosity of the addition of sodium chloride to lead oxide because the liquids were immiscible and the platinum was rapidly attacked at the interface between the two liquids.

Purification and Crystal Growth of Gold

Paul H. Schmidt

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

A prerequisite for electronic band structure studies of a metal is a high resistance ratio, a measure of the electronic quality and "purity" of a metal. Past attempts to purify gold to achieve a high resistance ratio have been relatively unsuccessful. At best, resistance ratios, $R_{300°K}/R_{4.2°K}$, approaching 400 have been recorded on zone refined and vacuum melted gold. This note describes a technique which has been developed for producing single crystals of gold on which resistance ratios to 6040 have been measured.

During manufacture and previous crystal growing and purification operations the container material primarily used has been graphite. However, according to Hansen (1), carbon is soluble in gold up to 0.3 wt % (2). It is therefore logical to suspect carbon as one of the primary elements associated with the low resistance ratios of high-purity (metallic) gold. Studies were therefore initiated to investigate the variation of resistance ratios with crystals grown in different container materials and gases.

Crystal Growth

The Bridgman method of crystal growth was selected for crystal fabrication. Single crystals of gold were grown in graphite, single crystal sapphire, and boron nitride crucibles.[1] Crystals grown in graphite crucibles were lowered through the furnace in a sealed and evacuated (5×10^{-6} Torr) fused silica container. Sapphire and boron nitride crucibles were lowered through the furnace in flowing dry oxygen in a sintered alumina sleeve, Fig. 1. All containers were prefired at a temperature several hundred degrees higher than the working temperature to vaporize impurities which might otherwise contaminate the gold. The temperature of the furnace in the hot zone was maintained at 1150° ± 1°C, approximately 100°C above the metal's melting point, to insure complete melting and prevent stray nuclei formation. The drop rate in all cases was 0.5 in./hr across a 20°-30°C/0.1 in. temperature gradient. Crystals up to 3½ in. long and ⅝ in. diameter have been made by this method and were limited in size only by the dimensions of the containers. The usual growth direction of these Bridgman grown crystals, as confirmed by optical and x-ray methods, was parallel to a <211> direction. It was observed that very careful handling and support of these crystals was required to avoid plastic deformation and strain. Crystals were easily removed from the graphite containers. Crystals grown in boron nitride containers were also easily removed although some sticking occurred due to the boric oxide binder. Crystals were easily removed however by either peeling off the crucible or immersing it in hot water for 15 to 30 min. Sapphire containers were very difficult to remove and had to be broken away from the crystal. Most sticking was observed at the tail end (end freezing last) of the crystal.

[1] Graphite crucibles were made from high-purity AUC grade graphite supplied by the National Carbon Company. Sapphire crucibles were supplied by Linde Air Products. Boron nitride crucibles were supplied by High Temperature Materials, Inc.

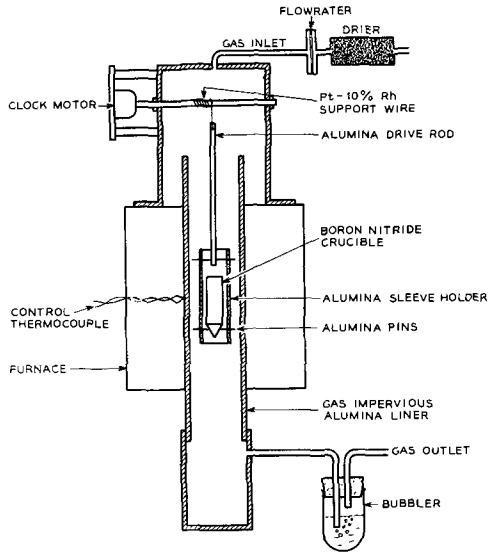

Fig. 1. Crystal growth apparatus

Table I

Container	Atmosphere	Supplier	Raw material resistance ratio	Melted material resistance ratio	Remarks
Graphite	Vac. 1×10^{-5} Torr	Sigmund Cohen Co. 99.999% rod	366	tip 230 tail 596	Crystal easily removed
Graphite	Vac. 1×10^{-5} Torr	American Smelting and Refining Co. 99.999% rod	69	~100	Crystal easily removed
Sapphire	Flowing dry oxygen	Sigmund Cohen Co. 99.999% rod	366	4000	Gold wet container in spots —difficult to extract
Boron nitride	Flowing dry oxygen	Sigmund Cohen Co. 99.999% powder	366	6040	Easily removed by peeling off container
Boron nitride & B_2O_3 cover flux	Air	Sigmund Cohen Co. 99.999% rod	366	686	Easily removed by peeling off container
Electron beam float zone	~1×10^{-6} Torr vacuum	Johnson Mathey 99.999% powder	—	28	Difficult to carry zone ⅛" diameter
Radio frequency float zone	~1×10^{-6} Torr vacuum	Sigmund Cohen Co. 99.999% rod	366	—	Could not carry zone due to low surface tension of gold

Some small diameter crystals of gold were also made by float zone refining techniques. The low surface tension of gold however, made application of these techniques unattractive for future crystal growth and purification, Table I.

Results and Conclusions

The above experiments revealed that crystals grown in sapphire or boron nitride crucibles in the presence of oxygen displayed higher resistance ratios than crystals grown in graphite containers in vacuum, Table I.

The mechanism believed to be responsible for purification is

$$\text{Au} + \text{carbon Impurity in raw material} \xrightarrow[1150°\text{C}]{\text{Oxygen atm}} \text{Au} + \text{CO/CO}_2$$

A carbon-oxygen reaction and the formation of carbon monoxide/carbon dioxide gas is presented as the mechanism for purification. Removal of carbon monoxide/carbon dioxide from the system is effected with the flowing oxygen carrier. Some improvement in resistance ratio was also observed along the boule axis and can be easily justified by segregation due to the mechanism of normal freezing.

It appears therefore that single crystals of gold of high electronic quality and purity can be grown by the Bridgman method. Use of boron nitride containers in the presence of an oxygen atmosphere was the prerequisite for successful purification. Although boron nitride was found to be a very satisfactory container material, it was not unique. It further appears that this method would be applicable to several other metals. However, slight modification of the procedure outlined for gold might be required. These modifications would include the use of different atmospheres, cooling of the melt in vacuum, and subsequent vacuum degassing. The crystals grown for this study are presently being used for electronic band structure studies and therefore sampling for analysis is impossible at this time.

The Calcium Chloride-Calcium Oxide Fused Salt Electrolytic System: Solubilities, Metal Contents, and Freezing Points

W. D. Threadgill

Department of Engineering, School of Engineering, Vanderbilt University, Nashville, Tennessee

During an investigation (1) of the production of metallic calcium by electrolysis of calcium oxide dissolved in molten calcium chloride in a modified moving cathode type cell, related investigations of solubility of the oxide, freezing points, and metal content of the electrolyte were made. Electrolytes of calcium chloride and calcium oxide-calcium chloride mixtures were used.

Raw materials used were A.C.S. analytical reagent grade, anhydrous calcium chloride and calcium oxide, N. F. IX, lumps. The calcium chloride was used as received. The oxide was kept at a temperature of 980°C for a period of 7 hr before use to decompose any carbonate that might be present.

Freezing temperature as a function of composition is shown in Fig. 1. The solid line portion of the graph represents the data for fourteen mixtures in which a definite plateau was observed on the cooling curve as an indication of the freezing point. The dashed line represents the data obtained for twelve mixtures in which no definite plateau occurred in the cooling curve, but the slope of the curve changed at the temperature taken as the freezing point.

Three mixtures exhibited a second freezing point at 593°, two at 596°, one at 602°C. This suggests the possibility of an eutectic mixture with a freezing point in the range 593°-602°C. Furthermore, a mixture with a calcium oxide concentration of 16.9% by weight exhibited only one freezing point, 593°C, suggesting that this is possibly the composition of the eutectic. Concentrations greater than 18.8% by weight were not used because at this high concentration the melt was very viscous, and it was questionable whether the oxide that was not dissolved would settle out or remain in suspension.

The anhydrous calcium chloride, which had an oxide concentration of 0.1% due to hydrolysis, exhibited a freezing temperature of 766°C. Extrapolation of the freezing point curve to zero oxide concentration gives a freezing temperature of 768°C for the calcium chloride used.

According to data contained in the International Critical Tables (2), from the work of Sackur (3), for calcium chloride freezing at 765°C addition of 5.72% oxide reduced the freezing temperature to 742°C. A mixture containing 10.23% calcium oxide was reported to have a freezing point of 727°C. Frary (4) found the freezing point of a mixture containing 6.24% oxide and 3.38% carbonate to be 705°C and noted that additional oxide gave partial freezing at about 770°C. The freezing temperature of the chloride he used was 766°C. The melting point of pure calcium chloride is reported as 773.9° and 744°C (5-7).

Early experimenters (8, 9) who worked with fused salt electrolytes noted a black coloration after elec-

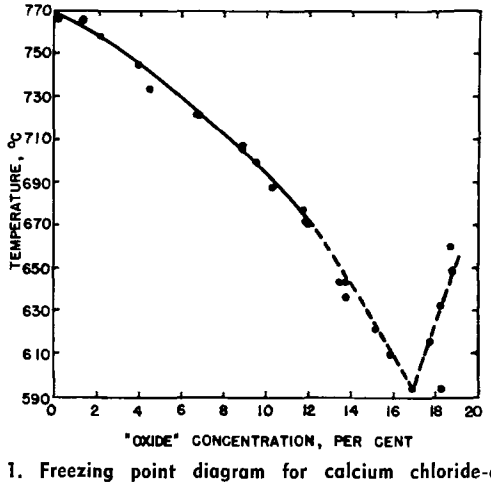

Fig. 1. Freezing point diagram for calcium chloride-calcium oxide system.

trolyzing for some time. It is the consensus of opinion of most investigators that the metal is suspended in the melt as fine particles and that no subsalt of calcium is formed, although calcium subchloride has been prepared by Guntz and Bassett (10) and Wohler and Rodewald (11) at temperatures of 1000°C or above.

In order to determine the metal content of the electrolyte, samples were obtained at intervals during electrolysis and analyzed for metallic calcium by a volumetric procedure based on measurement of the volume of hydrogen gas evolved by the reaction of calcium metal with water. Particular attention was given to the sampling procedure so that the sample would not be obtained in regions of strong convection currents since this would probably give a high metal content.

At 816°C the metal content (weight per cent) of the chloride electrolyte varied from 0.02 to 0.04% with the average for seven different determinations being 0.03%. This electrolyte had not previously been subjected to electrolysis. In comparison, Kunitomi (12) found 0.14% metal at this temperature. At 795°C, the metal content varied from 0.02 to 0.05% with the average for six different determinations being 0.03%. In comparison, Kunitomi (12) found 0.1% metal at this temperature.

At 816°C, the metal content of a calcium chloride-calcium oxide electrolyte containing 0.7% by weight oxide averaged 0.02% for five different determinations. At 830°C and an oxide concentration of 1% by weight, the metal content of the mixed electrolyte varied from 0.02 to 0.03% with the average of six different determinations being 0.02%. In comparison, Kunitomi (12) found 0.16% metal in a chloride electrolyte at this temperature.

The over-all average of thirteen different determinations with the electrolyte of calcium chloride alone was 0.03%. The over-all average of eleven different determinations with the chloride-oxide electrolyte was 0.02%.

In all cases, the metal content of the electrolyte during this investigation was markedly below that found by Kunitomi (12). A probable explanation of this discrepancy lies in difference in operating and sampling techniques. Kunitomi (12) used a much higher current density, 516 amp/in.^{2}, than was used in this case, approximately 300 amp/in.^{2}. This increase in current density possibly resulted in much stronger convection currents in his apparatus even though he was using approximately twice the quantity of electrolyte used here. These stronger currents would cause a higher degree of bath agitation and tend to sweep more metal away from the cathode. Samples taken from regions in which these currents were present would be expected to contain a higher concentration of metal than the less agitated regions.

Lorenz (9) stated that is was possible to lower the "metallic fog" content of the electrolyte by adding other substances which had an inhibiting action on its formation; however, no specific substances were mentioned. In this investigation, calcium oxide exhibited this inhibitory effect since the current used in each case was the same and operating conditions and techniques were maintained identical as nearly as possible.

Ageing Effects in Thin Anodic Oxide Films on Au in $HClO_4$

S. B. Brummer

Tyco Laboratories, Inc., Waltham, Massachusetts

In a previous paper (1) it was shown that the properties of thin oxide films on Au depend strongly on the potential, E_a, at which they are formed. Thus, as the potential is increased the amount of oxide on the electrode increases, being a monolayer at about 1.45v *vs.* H_2/H^+ in the same solution. In addition, the reduction of a potentiostatically preformed oxide becomes more difficult at higher potentials of formation, although the reduction is still quantitative (2). In this paper, some experiments are reported which indicate that the properties of the anodically formed films are sensitive also to the time for which they are formed, τ_a. In effect, the oxide is growing slowly even at long times of formation and becomes harder to reduce. Ageing effects of this kind are well known for thick oxide films (3), but very little is known about the ageing of very thin films. Frumkin (4) reports such effects for anodically formed films on Pt; however, there appears to have been no quantitative investigation of this phenomenon.

Experimental Procedure

Oxides were formed at each potential by means of a Wenking fast rise potentiostat. To measure the extent of oxidation, Q_a, the oxides were usually reduced galvanostatically at ~300 μa/cm^2. Switching of the counterelectrode from the potentiostatic to the galvanostatic circuit was achieved with a Hg-wetted relay. The potential-time transient was followed on an oscilloscope via a high impedance voltage follower (Philbrick P2 amplifier used as electrometer). The method of determining from the oscilloscope traces the amount of oxide and the potential of reduction of the oxide has been described previously (1). Usually, a large part of the oxide is reduced at a constant potential. However, at short times of formation and/or at low potentials of formation and/or with large reduction currents, the oxide reduction curve (chronopotentiogram) shows a sloping portion rather than a flat plateau. In these cases, the first potential at which the oxide starts to be reduced was used in assessing the reduction potential of the oxide at the given current density. This is illustrated in Fig. 1. For reduction experiments with linear potential sweeps, an Exact Electronics function generator (Model 250) was used to generate the potential ramp, and the potential across a decade resistance box (General Radio Company, 0.05%) was recorded with an oscilloscope. In some

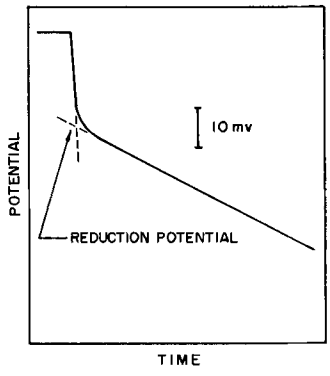

Fig. 1. Estimation of the reduction potential from chronopotentiograms when the oxide reduction takes place over a range of potentials.

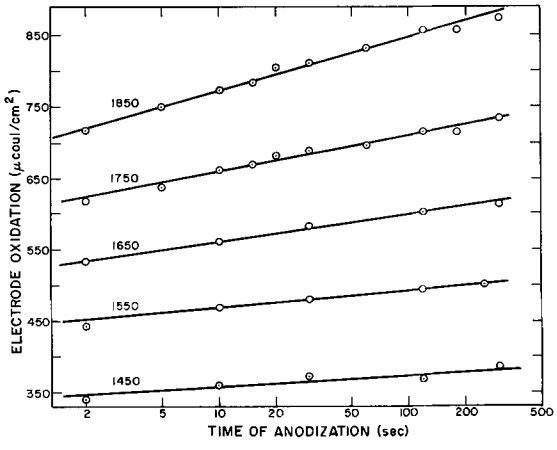

Fig. 2. Growth of oxide at various potentials (mv vs. R.H.E.) as a function of time.

cases, two plug-in units were used in the oscilloscope, allowing an X-Y presentation.

In other respects, the methods and procedures are as previously described (1). It is to be emphasized that the counterelectrode should also be of Au; if Pt is used, the working electrode is contaminated with what appears to be about a monolayer of Pt. Experiments were carried out in 1*N* $HClO_4$ at room temperature (23° ± 2°C). A hydrogen reference electrode was used, and potentials are reported against Pt, H_2/H^+ in the test solution.

Results and Discussion

Growth of the oxide.—Figure 2 shows some results during the latter stages of the oxide growth for the extent of the electrode oxidation as a function of time at each potential. Growth of the oxide appears to follow a semi-logarithmic relationship, *i.e.*,

$$Q_a = a + b \log \tau_a \qquad [1]$$

where a and b are constants. At the shortest anodization times used here, 2 sec, most of the oxide has already formed. Thus, at 1.85v, the oxide is already at 82% of its 5-min value after 2 sec of formation and, at 1.45v, it is 88% of its 5-min value. However, it appears from information available in the literature for the growth of thin oxide films on Pt (5, 6), particularly from the data of Gilman (6), we may have considerable confidence in the applicability of Eq. [1] to the earlier stages of the oxide growth. If these oxides are considered as adsorbed layers rather than as distinct compounds (7), then Eq. [1] would follow from the application of the Temkin adsorption isotherm, sometimes known as Elovich kinetics (8). We may estimate a monolayer of oxide as 400 (1) or 450 (9), or 650 (9) μcoul/cm², but whichever of these is the most

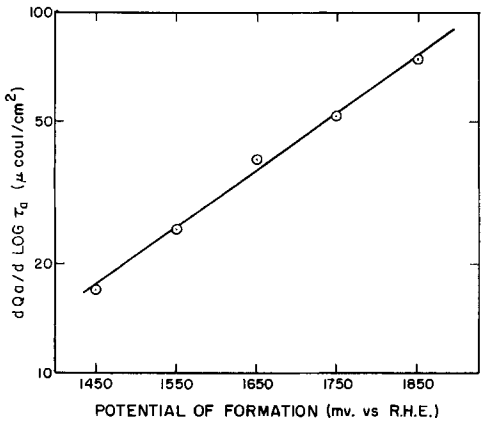

Fig. 3. Semi-logarithmic expression of the growth-rate constant *b* as a function of potential.

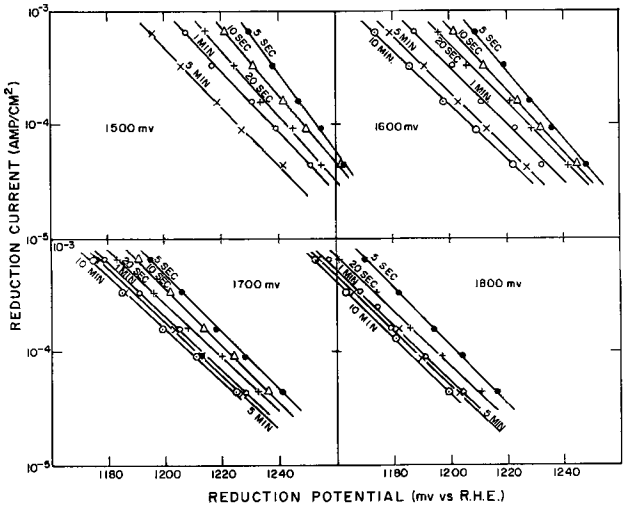

Fig. 4. Current-potential curves for the reduction of oxides, as a function of time and potential of formation.

reasonable, the present data extend from less than a monolayer to considerably above a monolayer. Despite this, there is a smooth variation of the parameter b of Eq. [1] with E_a (Fig. 3).

As expected, the growth rate of the oxide is higher, in absolute terms, at the higher potentials of formation, and also, as indicated above, the fractional growth (2 sec to 5 min) is more at the higher potentials. Although the growth rate is relatively slow even at the highest potentials (Fig. 2), the equating previously (1) of the 5-min value of Q_a with its infinite time value does involve small errors in the Q_a values presented, as does the procedure used by Laitinen and Chao (10). For example, at 1.85v the 5-min values should perhaps be about 8% less than the 1-hr value of Q_a. However, it is unlikely that the oxide thickens indefinitely, for as has been observed at the higher potentials (1, 2), the oxide has a finite rate of dissolution; hence the error in selecting the 5-min values of Q_a would be less than this. In fact very little difference was found between the 5-min and 20-min values of Q_a (1).

Reduction of the oxide.—The reduction kinetics of the oxide are shown in Fig. 4 as a function of E_a and τ_a. It is seen that at a given potential of formation the oxide becomes progressively harder to reduce with longer times of formation. At any potential of formation, the general effect is a shift of the Tafel line for the reduction of the oxide (slope 39-41 mv) to lower potentials. At the shorter times of formation, however, the slope tends to be less than the usual value, par-

ticularly at the lower potentials. As has been noted, reduction potentials in this region are the least reliable as the chronopotentiogram has the least satisfactory plateau.

The time variation of the oxide reduction kinetics is more pronounced at the lower potentials of formation. The oxides stabilize much more rapidly at their ultimate (5 or 10 min) properties at higher potentials of formation; this is despite the fact that the oxide, at the higher potentials, is much "thicker" (if "thickness" is the relevant term for $\sim 0.8 \leq$ layer thickness ≤ 2 layers) and, thus, presumably, any transport processes through the film would be more difficult. On the other hand, the higher field resulting from the higher potential would help to counteract this for ion migration processes through the film. So, although there is both relatively and absolutely a much larger change in the quantity of oxide formed during the range of τ_a, 2 sec to 5 min, at the higher potentials of formation, the properties of the oxide change much more, during this time, at the lower potentials of formation.

Use of triangular potential sweeps for oxide reduction.—It is clear from the data presented here that triangular sweeps are to be employed for studies of oxide reduction only with extreme caution. In the method of Will and Knorr (11), the oxide is formed over a range of potentials, and not only is this likely to lead to an inhomogeneous oxide *per se* (1), but also the oxide has only a fraction of a second to "age." Consequently, we would not expect the results obtained on the cathodic sweep of the triangles to be quantitatively significant. This is apparent from the curves shown in Fig. 5. These represent the current potential curves for the reduction of oxide formed under various conditions. Curve A is the current-potential curve for the reduction of oxide formed for 5 min (*i.e.*, $\simeq$ infinite time) at 1500 mv. A full description of such curves will be given later. Curves B and C represent the reduction of oxide formed during the anodic part of a 0.14 v/sec triangular wave. In B, the triangle was terminated at 1500 mv, in C at ~1600 mv. As expected, A and B are not comparable, relatively little oxide being formed in B. C was chosen such that $Q_A = Q_C$. We note that the oxide in C is more easily reduced and, also, is reduced over a wider range of potential (*i.e.*, the peak is shorter and squatter). A comparison of B and C indicates that a considerable part of Q_C is formed between 1500 and 1600 mv, *i.e.*, at a higher potential than the top potential of A. From the previous work (1) it would, therefore, be supposed that the oxide in C would be harder to reduce than that in A. Thus, the main reason why curve C indicates an oxide which is misleadingly easy to reduce is because the oxide has not had enough time to "age." The broadness of the peak in C would indicate that the oxide is unusually inhomogeneous compared with A. The reduction curves obtained after various times of formation at a fixed potential (Fig. 6) do not indicate that unaged oxide is usually more inhomogeneous than the aged material; for example, the width of the reduction peak at the current corresponding to half the maximum current is the same for each time of formation, about 80 mv in this instance. Thus the inhomogeneity of the oxide in C, which is too large to be associated solely with the formation of oxide over a range of potential *per se* (1), must result mainly from the "freezing-in" of oxide configurations formed at short times at the lower potentials. These configurations will not have "aged" out in the short time before the cathodic sweep. In order to avoid such errors, say to keep the reduction potential at a given current to less than 5 mv with respect to the 5 min values, we would have to allow at least 2 min at 1600 (cf. Fig. 4). This involves extremely slow sweep rates and clearly indicates that the method of Will and Knorr (11) is not suitable to study such reactions quantitatively.

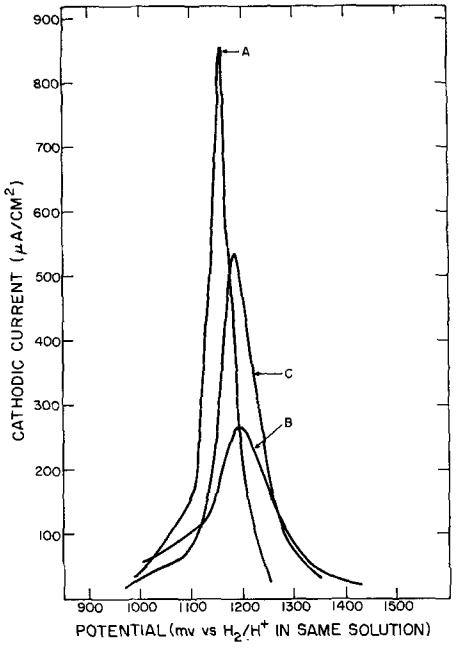

Fig. 5. Current-potential curves for the reduction of oxides, made with linear potential sweeps of 0.14 v/sec. Curve A, oxide reduced after 5 min at 1500 mv; curve B, oxide formed and reduced during triangular potential sweep, reversed at 1500 mv; curve C, triangular sweep reversed at ~ 1600 mv, such that $Q_A = Q_C$.

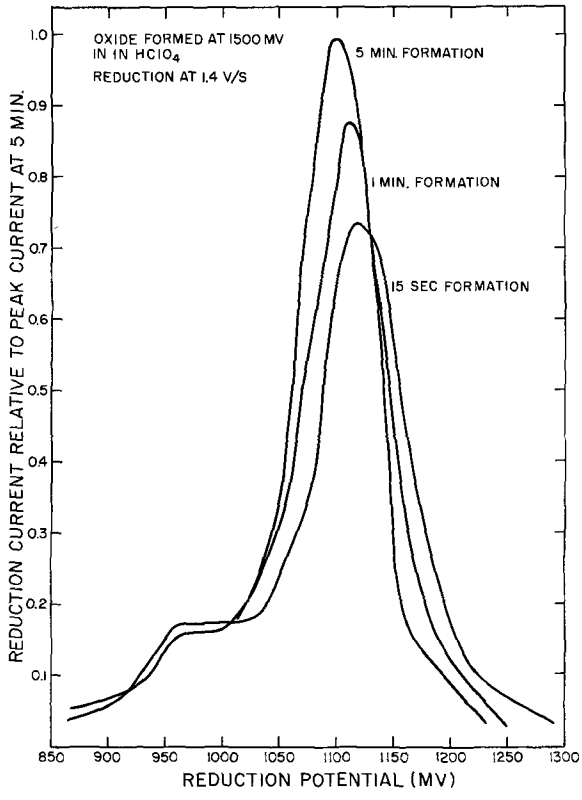

Fig. 6. Current-potential curves for the reduction of oxides, made with linear potential sweeps of 1.4 v/sec, as a function of time of formation at 1500 mv.

Summary

1. The properties of anodic oxide films on Au in 1*N* $HClO_4$ have been studied as a function of time (2 sec to 5 min) and of potential of formation (1450 to 1850 mv *vs.* Pt, H_2/H^+ in the same solution).

2. Over the range observed (10-20% of the total oxide), the oxide grows slowly with time, apparently according to Elovich kinetics, although the constants are potential-dependent.

3. Oxides formed at longer times at a given potential are harder to reduce.
4. This "ageing" effect is greatest at the lower potentials of formation, despite the greater thickness of the oxide at the higher potentials and despite the larger change in the amount of oxide at the higher potentials.
5. Because of these ageing effects, the triangular sweep method of Will and Knorr is not suitable to study these films.

The Kinetics of the Stannous/Stannic Redox Reaction at Carbon Electrodes

H. Lerner and L. G. Austin

Department of Fuel Technology, College of Mineral Industries, The Pennsylvania State University, University Park, Pennsylvania

As part of an experimental study to determine the effects of a porous diffusion electrode on the over-all kinetics of an electrochemical reaction (1,2), it was desired to employ a redox couple having a relatively low exchange current and a fairly simple reaction mechanism. A study of the literature (3) showed that the Sn^{2+}/Sn^{4+} redox couple in HCl might meet these requirements. Vetter (4) concluded, as a result of some steady-state cathodic polarization measurements at mercury and platinum electrodes, that this redox couple reacted fairly irreversibly according to the mechanism

$$Sn^{2+} \rightleftarrows Sn^{3+} + e^- \quad \text{Step r}$$
$$Sn^{3+} \rightleftarrows Sn^{4+} + e^- \quad \text{Step o}$$
$$\overline{Sn^{2+} \rightleftarrows Sn^{4+} + 2e^- \quad \text{Over-all reaction}} \qquad [1]$$

The rate equation for this mechanism is given by (4, 5),

$$i = 2i_{o,r}e^{\alpha_r F\eta/RT}\frac{[(1 - i/i_{L,R}) - (1 + i/i_{L,O})e^{-2F\eta/RT}]}{[1 + (i_{o,r}/i_{o,o})e^{-(1-\alpha_r+\alpha_o)F\eta/RT}]} \qquad [2]$$

where $i_{o,r}$, $i_{o,o}$, α_r, α_o are the exchange currents and transfer coefficients for steps r and o, respectively, $i_{L,R}$ and $i_{L,O}$ the limiting currents for Sn^{2+} and Sn^{4+}, respectively, and F, η, R, T, and i have their usual significance. Equation [2] was derived on the assumption that the concentration of Sn^{3+} would be very small so that any mass transport effects involving this species could be neglected. The terms involving i_L reflect the use of the Nernst diffusion layer theory to account for mass transport effects involving Sn^{2+} and Sn^{4+}. When $i_{o,r}/i_{o,o} >> 1$ and $i_{o,r}/i_L << 1$ three distinct irreversible regions of the mechanism can be obtained during steady-state measurements of voltage *vs.* current. The regions are:

1. *Step o rate controlling*

$$[e^{-2F\eta/RT} << 1 << (i_{o,r}/i_{o,o})e^{-(1-\alpha_o+\alpha_r)F\eta/RT}, i/i_L << 1]$$
$$i = 2i_{o,o}e^{(1+\alpha_o)F\eta/RT} \qquad [3]$$

For example, if $i_{o,r}/i_{o,o}$ is about 10^3 and $\alpha_r \simeq \alpha_o$, this Tafel region would extend from η equal to about 30 mv to about 120 mv.

2. *Step r rate controlling*

$$[(i_{o,r}/i_{o,o})e^{-(1-\alpha_o+\alpha_r)F\eta/RT} << 1 \text{ and } i/i_L << 1]$$
$$i = 2i_{o,r}e^{\alpha_r F\eta/RT} \qquad [4]$$

For the figures given before, this Tafel region starts at η about 240 mv and the upper limit will occur at about $i = 0.1\ i_L$.

3. *Step r and mass transport rate controlling*

$$[(i_{o,r}/i_{o,o})e^{-(1-\alpha_o+\alpha_r)F\eta/RT} << 1 \text{ and } i/i_L \text{ tending to one}].$$
$$i = 2i_{o,r}e^{\alpha_r F\eta/RT}(1 - i/i_L) \qquad [5]$$

The lower limit of η will be the same as for Eq. [4] while η becomes large as $i \rightarrow i_L$.

The only anodic polarization measurements reported by Vetter used Hg electrodes, but since Hg could be expected to react at the anodic potentials required for the oxidation of Sn^{2+}, this work is suspect (although it agreed with the results of cathodic polarization measurements). In the study reported here, pyrolytic carbon electrodes were used to establish with greater certainty the mechanism and form of the anodic rate equation for the Sn^{2+}/Sn^{4+} couple at a solid electrode. The results obtained from the steady-state and galvanostatic measurements discussed below supported the mechanism of Eq. [2].

Experimental

The water used throughout the experimental work was prepared by deionizing tap water with an Ilco research model ion-exchange column, stirring it for 48 hr with a spectrographic grade of graphite powder (SP-1, National Carbon Company), filtering, and distilling. The purpose of the graphite treatment was to reduce the amount of adsorbable organic impurities in the water. The specific resistance of the water was greater than 10^6 ohms. Hydrochloric acid was pre-

pared by distilling the concentrated reagent grade material (Fisher) after it had been diluted to approximately the constant boiling mixture concentration (~6.1M). The distillate, which was a middle cut, was then diluted to 4M. The HCl was considered acceptable for use when its polarographic current was equal to, or less than 0.2 μa ($m^{2/3}t^{1/6} \sim 2.5$) at —0.72v *vs.* a SCE. Two methods were used to prepare the 4*N* HCl solution of the Sn^{2+}/Sn^{4+} couple. The first consisted of dissolving reagent grade (Fisher) $SnCl_7 \cdot 2H_2O$ and $SnCl_4 \cdot 5H_2O$ in 4*N* HCl, stirring the solution with graphite for two days and filtering. In the second method, 4*N* HCl was stirred with graphite for two days, filtered and electrolyzed at a Hg cathode with the evolution of hydrogen ($i \sim 0.5$ ma/cm^2). Nitrogen (passed through a purification train containing an HCl solution of VCl_2, a charcoal trap in a dry ice-acetone bath and suitable saturators) was used to stir the HCl. After three days of electrolysis some of the HCl was removed from the electrolysis cell (with the current still flowing) and placed in the test cell. Reagent grade tin (Fisher) was then added to the HCl and dissolved by heating. The resulting $SnCl_2$ solution was then stirred in the presence of air to obtain an approximately equimolar solution of $SnCl_2$ and $SnCl_4$. The concentrations of the redox couple were determined by a potentiometric method, with the $SnCl_4$ being determined following its reduction to $SnCl_2$ with a lead reductor. No significant difference was found in results obtained from the solutions prepared by the two methods.

The test cell was a 250 ml glass beaker which had been cleaned with hot chromic acid solution and preconditioned with 4*N* HCl for at least a week. The cell cover was made of Lucite and contained holes for the pyrolytic carbon electrode (area = 0.25 cm^2), the platinum counter electrode (area = 12.8 cm^2), the salt bridge of the saturated calomel reference electrode and a nitrogen inlet tube. The carbon test electrode was made from a piece of pyrolytic graphite (~½ x ½ x 3 in.) which had been machined into a cylinder with the long dimension parallel to the basal plane. One end of this cylinder (edge plane) was machined perpendicular to the axis, and a piece of Alphex shrinkable tubing (FIT-275) was used to mask off the sides. This tubing, made of irradiated polyolefin, shrinks to a predetermined size on heating. This gave a tight, leak-proof fit. The cell was maintained at 25.0° ± 0.03°C in a water bath, and the solution was stirred with a magnetic stirrer.

The circuit for the steady-state measurements was of conventional design, providing an input impedance of about 10^{11} ohms for the voltage measurements and an accuracy and reproducibility of better than 1%. The galvanostatic measurements utilized a regulated voltage supply (Harrison, #800A-2), a relatively large series resistor and a mercury relay (Western Electric, #275-B). With appropriate circuitry (6) it was possible to obtain a constant current pulse of variable duration with a rise time of less than 5 μsec. The voltage-time traces were recorded using an oscilloscope and a Polaroid camera.

All of the measurements were performed following deaeration of the system overnight. In the steady-state measurements a small amount of negative hysteresis was obtained at the lower current densities. It was found, however, that, if the system was brought to $i/i_L \simeq 0.7$ prior to a measurement, completely reproducible results were obtained over the entire polarization curve. A galvanostatic technique was used to correct for IR effects in the steady-state measurements of η.

Results and Discussion

Figure 1 shows the steady-state values of polarization *vs.* log current for the oxidation of a solution of 0.104M $SnCl_2$ and 0.081M $SnCl_4$ in 4M HCl at the pyrolytic carbon electrode. The polarization (η) was obtained from the relationship, η = measured voltage-

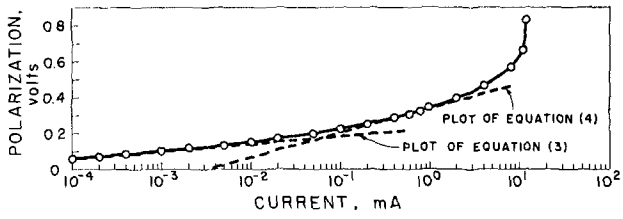

Fig. 1. Experimental plot of polarization vs. log current for steady-state oxidation of 0.104M $SnCl_2$ and 0.081M $SnCl_4$ in 4*N* HCl at pyrolytic carbon electrode (area = 0.25 cm^2). Solid line, experimental results; dashed line, extrapolations of results according to Eq. [3] and [4].

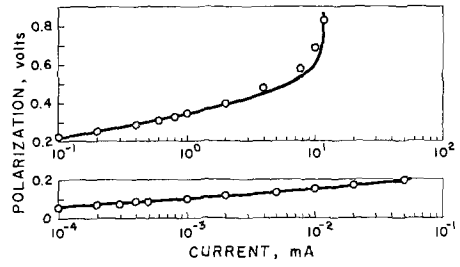

Fig. 2. Fit of experimental results of Fig. 1 to Eq. [2]

open circuit voltage, where the open-circuit voltage (—0.127v *vs.* SCE) was taken as the reversible voltage. [This open-circuit voltage was extremely reproducible over long periods of time, independent of any measurement sequence and insensitive to changes in stirring rates. The value given by Vetter (4) is 0.16v *vs.* NHE for 1M HCl, but the potential of this couple is dependent on the HCl concentration, decreasing as the concentration of HCl increases (7). In addition a liquid junction potential of about 30 mv (8) existed between the saturated KCl solution of the reference electrode and the 4M HCl solution containing the redox couple. The corrected open-circuit potential for the Sn^{2+}/Sn^{4+} couple was therefore about 0.15v *vs.* NHE, in reasonable agreement with Vetter's value.] Figure 1 also contains plots of the experimental data according to Eq. [3] and [4], from which the kinetic constants were obtained. These plots gave good straight lines with the values, $\alpha_o = 0.41$, $i_{o,o} = 8.0 \times 10^{-6}$ ma/cm^2, $\alpha_r = 0.43$ and $i_{o,r} = 7.0 \times 10^{-3}$ ma/cm^2.

Figure 2 shows the fit of the experimental data of Fig. 1 to Eq. [2]. Equation [2] was plotted using a value of $i_L = 11.5$ ma and the values of the kinetic constants that were obtained from Fig. 1. Excellent agreement was obtained over the first four decades of current, but in the final decade where the value of current approaches the limiting current, the agreement was not as good and some deviation of the experimental results from Eq. [2] can be observed. A similar deviation was obtained with a different concentration of the redox couple at the pyrolytic carbon electrode (which showed it was not due to a variation of the activity coefficient with concentration), and also for several porous carbon electrodes. To account for this deviation a number of possibilities were considered.

The possibilities of impurities in the system or errors in the measurements were rejected because: (i) the deviation was very reproducible and was found in all of the systems studied; (ii) the voltage and current measuring sections of the apparatus were carefully calibrated prior to all of the measurements; (iii) no hysteresis effects were observed in this current region; and (iv) impurity effects usually occur only in the low current region, whereas, this deviation occurred at relatively large currents. The results were reproducible when the position and shape of the counter electrode were changed, which showed that the effect was not due to nonuniformity of current distribution. Another possibility was that there existed some chemical step in the mechanism which preceded the electron transfer

Table I. Consistency of $i\tau^{1/2}$ as a function of i for $Sn^{2+} \rightarrow Sn^{4+} + 2e^-$ at a pyrolytic carbon electrode*

1.44	45.3	6.73	9.68
2.39	15.6	3.95	9.44
4.80	4.07	2.02	9.70
5.80	2.86	1.69	9.80
7.48	1.74	1.32	9.87
13.4	0.55	0.74	9.92

* 0.0675M $SnCl_2$ and 0.0945M $SnCl_4$ in 4*N* HCl; area of electrode = 0.25 cm^2.

steps (*e.g.*, dissociation of $SnCl_4^{2-}$ to Sn^{2+}). If this chemical step were slow enough to control the rate of the reaction partially at higher currents, the current would be less than that predicted by Eq. [2]. This possibility was investigated with the galvanostatic technique by measuring $i\tau^{1/2}$ as a function of i for the oxidation of Sn^{2+}, see Table I.

It is clear that $i\tau^{1/2}$ is constant within the limits of experimental error, and therefore (9) a slow preceding chemical step is not present.

Since the deviation occurred only in the region where the rate of mass transport of Sn^{2+} to the electrode was partially controlling the rate of the reaction, it was considered that the deviation was probably due to a breakdown of the simple Nernst diffusion layer theory. It is well known that this theory is at best only a good approximation (10). One reasonable explanation for the breakdown of this theory for the system used in this study is the density change which would be expected to occur in the diffusion layer region as a result of the buildup in concentration of $SnCl_4$ as $i \rightarrow i_L$ [(dens. of $SnCl_4$)/(dens. of $SnCl_2$) > 1 for equimolar concentrations]. This would lead to a corresponding increase in the mass transport coefficient and give rise to the observed deviation between Eq. [2] and the experimental results.

Figure 3 compares the experimental data of Fig. 1 with experimental results obtained for a lower concentration of the redox couple (0.0120M $SnCl_2$ and 0.0088M $SnCl_4$ in 4*N* HCl). The ratio of the limiting currents for the two concentrations of $SnCl_2$ is 9.2 which is approximately the same as the ratio of their concentrations, 8.7. At any given current in the regions of Eq. [3] and [4] the approximately tenfold change in concentration of the redox couple results in a change in η of approximately 0.040 and 0.10v, respectively. This is in fairly good agreement with the expected values (assuming first-order kinetics) of $\Delta\eta = 0.040$v and $\Delta\eta = 0.12$v, respectively.

Summary and Conclusions

From the results of steady-state and galvanostatic measurements on the edge-atom plane of a pyrolytic carbon electrode, and from previous results reported in the literature for Hg and Pt electrodes, it appears that the mechanism for the redox reaction $Sn^{2+} \rightleftarrows Sn^{4+} + 2e^-$ consists of two consecutive one-electron transfer steps (reaction [1]), where the intermediate Sn^{3+} has a very small concentration. The second step in the anodic process has the lower exchange current, and at low currents it is rate controlling. At sufficiently large currents the first step becomes rate controlling and the rate equation assumes a simple Tafel form with a slope of 2.3 $RT/\alpha_T F$. The values of the kinetic parameters on the edge-atom plane of pyrolitic graphite were $i_{o,r} = 7.0 \times 10^{-3}$ ma/cm^2, $i_{o,o} = 8.0 \times 10^{-6}$ ma/cm^2, $\alpha_r = 0.43$ and $\alpha_o = 0.41$, based on the open-circuit potential of —0.122v *vs.* a SCE. The double layer capacity of the edge plane was 127 $\mu Fd/cm^2$, so that the geometric exchange current densities given above are probably about 6 or 7 times larger than the values for a smooth surface.

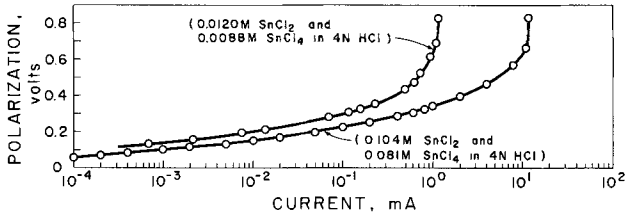

Fig. 3. Comparison of experimental polarization *vs.* log current results for two different concentrations of the $SnCl_2/SnCl_4$ couple.

On the Potential/pH Diagrams of the $Cu\text{-}NH_3\text{-}H_2O$ and $Zn\text{-}NH_3\text{-}H_2O$ Systems

H. E. Johnson[1] and J. Leja

Department of Mining and Metallurgy, University of Alberta, Edmonton, Alberta, Canada

One of the most promising developments in the study of the stress corrosion cracking of alpha brass in aqueous ammonia environments has been Mattsson's (1) correlation of the pH dependence of cracking with certain features of the potential/pH diagrams for the $Cu\text{-}NH_3\text{-}H_2O$ and $Zn\text{-}NH_3\text{-}H_2O$ systems. These diagrams were based on the thermodynamic data published by Latimer (2) in 1952. In the course of extending the stress corrosion studies to define more precisely the effect of various copper ammine complexes (3), it

[1] Present address: Esso Production Research Company, Houston, Texas.

appeared that the diagrams proposed by Mattsson might be improved by the inclusion of intermediate copper-ammine and zinc-ammine complexes (containing less than four ammonia ligands per coordinating metal ion), and by re-locating the regions of stability of the solid phases CuO, Cu_2O, and $Zn(OH)_2$. Since both Mattsson (1) and Hoar (4) have correlated the Cu_2O region with the tarnish formation on alpha brass undergoing stress corrosion cracking, it is important that the corrected potential/pH diagrams be considered in any further investigation of this type.

Construction of Diagrams

The principles of construction of potential/pH diagrams are well known (5) but it is useful to reiterate the two main conventions (5a) that are observed in setting up the equations from which the graphs are constructed. Considering the general reaction

$$aA + bB + cH_2O + mH^+ + ne^- = 0 \qquad [I]$$

Convention I. For reactions without oxidation ($n = 0$), the coefficients a and m are taken as positive. The substance A is then the more basic of the compounds involved, and therefore appears to the right of substance B in the diagram.

Convention II. For reactions with oxidation ($n \neq 0$), a and n are taken as being positive, so that substance A is the more highly oxidized of the compounds involved, and thus appears above substance B in the diagram.

The data used in the construction of the corrected diagrams are given in Table I: they do not differ significantly from those used by Mattsson (1).

Figures 1a, 2a, and 3a are taken from Mattsson's (1) work (the line numbers refer to his equations); the diagrams have been re-drawn to the same scale as the corrected diagrams which are presented in Fig. 1b, 2b, and 3b. The line numbers in the "b" diagrams refer to the following chemical reactions and the corresponding potential/pH equations:

$$Cu^{++} + e^- = Cu^+$$
$$E = 0.153 + 0.0591 \log [Cu^{++}]/[Cu^+] \qquad [1]$$

$$E = -0.156 - 0.089\, pH - 0.089 \log [NH_4^+] + 0.0295 \log [Zn(NH_3)_3^{++}] \quad [23]$$

$$Zn(NH_3)_4^{++} + 4H^+ + 2e^- = Zn + 4NH_4^+$$
$$E = 0.055 - 0.118\, pH - 0.118 \log [NH_4^+] + 0.0295 \log [Zn(NH_3)_4^{++}] \quad [24]$$

The lines represented by Eq. [1]-[24] were plotted in Fig. 1b, 2b, and 3b by substituting the following concentrations in the appropriate equations: 0.05M total dissolved copper, 0.001M total dissolved zinc, and 1.0M total dissolved ammonia (NH_3 plus NH_4^+). The copper and ammonia concentrations correspond to the approximate composition of solutions used in stress corrosion cracking tests (1, 3, 4) on alpha brass (copper added as copper sulfate; ammonia added as ammonium hydroxide and/or ammonium sulfate). The zinc concentration was determined analytically in the course of (or at the conclusion of) such tests; Mattsson's Zn-NH_3-H_2O diagram (Fig. 3a) is based on a zinc concentration of 0.01M, whereas Fig. 3b was calculated for 0.001M Zn, which is more representative of the actual zinc concentration (3).

Discussion

A comparison of the diagrams shows the following important differences:

(a) Fig. 1a has been modified as shown in Fig. 1b to indicate the stepwise addition of NH_3 ligands (our Eq. [4], [5], [6], [7], [12], and [13]); Mattsson's diagram is not incorrect in this respect, but does not clearly show the regions where intermediate complexes are formed. These regions are very important in the stress corrosion cracking of brass, since rapid cracking times have been correlated (3) with the presence of copper-ammine complexes containing an average of 1.5-3.0 NH_3 ligands per copper ion originally present in test solutions.

(b) In Fig. 2a, Mattsson shows a region of stability for the solid phase $Cu(SO_4)_{0.25}(OH)_{1.5}$, which precipitated from his test solutions during storage. We have not observed a similar aging phenomenon if CO_2 dissolved in distilled water was removed by boiling or purging with N_2 and consequently have not included this substance in Fig. 2b.

(c) Fig. 2a shows a stability region for Cu_2O which appears to be incorrectly located. Mattsson's equation No. (15) was written as

$$0.5Cu_2O + 2NH_4^+ = Cu(NH_3)_2^+ + H^+ + 0.5H_2O \quad [II]$$

which may be re-written as

$$2Cu(NH_3)_2^+ + 2H^+ + H_2O = Cu_2O + 4NH_4^+ \quad [III]$$

to give a negative free energy change of −23.2 kcal/mole Cu_2O. The reaction can also be written as

$$Cu_2O + 4NH_3 + 2H^+ = 2Cu(NH_3)_2^+ + H_2O \quad [IV]$$

with a free energy change of −27.4 kcal/mole Cu_2O (which is our Eq. [17]). Equations [III] and [IV] appear contradictory since, according to Convention I, Cu_2O is more basic than $Cu(NH_3)_2^+$ and should appear to the right of $Cu(NH_3)_2^+$ if Eq. [IV] is considered, and vice versa, $Cu(NH_3)_2^+$ is more basic than Cu_2O if Eq. [III] (or [II]) is considered. Obviously, one of these two reactions is inapplicable. Reaction [IV] can be justified as taking precedence over reac-

tion [III] because its free energy change is greater than that for reaction [III]. Further, careful tests (10) with pure copper in ammoniacal solutions of pH 6-8 have established no formation of Cu_2O tarnish in the Cu_2O region indicated in Mattsson's diagram, Fig. 2a. Therefore, we have concluded that reaction [IV] is the correct one, and represented the Cu_2O stability region to the right of $Cu(NH_3)_2^+$ region, as in Fig. 2b.

(d) For reasons analogous to those discussed above, the region for the stability of CuO in Fig. 2a appears also incorrectly placed. Mattsson's re-written equation No. (11)

$$Cu(NH_3)_4^{++} + 2H^+ + H_2O = CuO + 4NH_4^+; \Delta G^\circ = -22.4 \text{ kcal/mole CuO}$$

was compared by us with its paradoxical counterpart

$$CuO + 4NH_3 + 2H^+ = Cu(NH_3)_4^{++} + H_2O; \Delta G^\circ = -28.2 \text{ kcal/mole CuO}$$

which is represented by line 16 in Fig. 2b, after concluding that it is the more favored one.

Halpern (8) has published a diagram of the Cu-NH_3-H_2O system in which the CuO region is located far to the right as we have shown in Fig. 2b; his diagram is calculated for dissolved copper concentrations of 10^{-6} M, so the absolute positions of the lines differ from those in Fig. 2b, but the relative positions of the CuO and $Cu(NH_3)_4^{++}$ regions are in accordance with our considerations.

(e) Finally, in Fig. 3a, the region of stability of $Zn(OH)_2$ appears to be incorrectly predicted, again for the same reasons as discussed before. Mattsson's equation No. (19) written as

$$Zn(OH)_2 + 4NH_4^+ = Zn(NH_3)_4^{++} + 2H^+ + 2H_2O$$

(which has a free energy change of +21.74 kcal/mole) was compared with the reaction

$$Zn(OH)_2 + 4NH_3 + 2H^+ = Zn(NH_3)_4^{++} + 2H_2O; (\Delta G^\circ = -28.82 \text{ kcal})$$

which is not shown in Fig. 3b because the line separating the $Zn(OH)_2$ and $Zn(NH_3)_4^{++}$ regions occurs at a pH of 13.

(f) The stepwise formation of the zinc-ammine complexes is not ignored in Fig. 3b, but the uptake of the first three NH_3 ligands occurs over such a narrow pH range that the separate regions could not be shown on the pH scale used. For this reason, only line 21 is included in the diagram.

(g) Because of the different assumptions regarding the dissolved zinc content of test solutions, the absolute positions of lines separating solid and dissolved substances are lower in Fig. 3b than in 3a. This does not affect the relative positions of the various stability regions.[3]

The blue-black tarnish which develops in brass exposed to copper-ammonia solutions in the pH range 6.0-8.0 was tentatively identified as Cu_2O by Mattsson (1) (on the basis of microscopic examination) and by Forty and Humble (9) on the basis of ring patterns obtained during electron diffraction of tarnish flakes (that had been damaged by mishandling or by heating and curling in the electron beam). Johnson and Leja (3) confirmed this identification by means of x-ray diffraction patterns obtained on tarnished brass strips and on tarnish powder scraped from the brass, and by polarographic analysis of tarnish powder. Since Mattsson's potential/pH diagram for the heterogeneous system Cu-NH_3-H_2O system (Fig. 2a) shows a stability region for Cu_2O over the pH range 4-7.5, it is natural that both Mattsson (1) and Hoar (2) correlated the tarnish appearance with the potential/pH diagram. However, there are two important points that have been overlooked in making this correlation:

(i) The potential/pH diagrams in Fig. 2 are calculated for pure copper, and it has been shown (10) that the solutions of pH 6-8 which rapidly tarnish brass do not produce a tarnish on pure copper (as predicted by Fig. 2a).

(ii) The tarnish penetrates the brass substrate and does not loosely deposit on the surface (9, 10) from the bulk solution. This indicates that the Cu_2O tarnish is produced and stabilized by localized reactions at the brass/solution interface. Since the equation for the line separating the stability regions of $Cu(NH_3)_2^+$ and Cu_2O (Eq. [17], Fig. 2b) is

$$pH = 10.03 - \log \frac{[Cu(NH_3)_2^+]}{[NH_3]^2} \qquad [V]$$

the stability of Cu_2O in a brass-cupric ion-ammonia system at a pH as low as 6, for example, can be explained if the ratio in the log term of Eq. [V] is greater than 10^4. It has been shown (3) that there is no drastic increase in the pH at the brass/solution interface (as compared to the pH in the bulk solution) therefore the above condition for Cu_2O stability at low pH must be realized by the preferential formation of $Cu(NH_3)_2^+$ as a result of the reaction

$$2Cu(NH_3)_2^{++} + Zn = 2Cu(NH_3)_2^+ + Zn^{++}$$

[3] According to Dr. Pourbaix, a potential/pH equilibrium diagram for the system Zn-NH_3-H_2O was prepared about 10 years ago by F. Jolai (Paris), no reference of publication is available.

Brief Communications

Hexavalent Fluorides of Tantalum and Niobium

G. W. Mellors and S. Senderoff

Development Department, Parma Research Laboratory, Union Carbide Corporation, Parma, Ohio

It has been found that hexavalent compounds of tantalum and niobium can be prepared by the electrolysis of solutions of the pentavalent tantalum and niobium fluorides dissolved in molten alkali fluorides with any suitable conducting cathode and an inert anode such as graphite. It is known that similar electrolysis of molten chlorides, mixed chlorides and fluorides, and mixed fluorides and oxides does not produce these higher valence tantalum and niobium compounds, but instead produces chlorine or oxygen at the anode. Only in the case of an essentially pure fluoride system does one observe that no gas is produced at the anode, but that instead, the higher valence tantalum or niobium fluoride is formed. It is noteworthy that copious fluorine evolution occurs at the anode when the molten alkali fluoride mixture alone is electrolyzed with a graphite anode. On addition of a few per cent of either K_2TaF_7 or K_2NbF_7 gas evolution instantly ceases, and formation of the hexavalent compounds takes place.

For example, a solution used for plating tantalum (1) containing 14.2 w/o (weight per cent) K_2TaF_7 dissolved in Flinak[1] was electrolyzed in an argon atmosphere with a graphite anode and copper cathode at 770°C and anode and cathode current densities of 100 ma/cm² for 21 hr to convert 71% of the contained tantalum to the hexavalent state. This was confirmed by titrating the oxidized form with a known weight of tantalum metal according to the reaction

$$5Ta^{6+} + Ta^0 \rightarrow 6\,Ta^{5+}$$

Nb^{5+} was oxidized to Nb^{6+} in a similar system in which K_2NbF_7 replaced the K_2TaF_7. The completeness of the conversion, however, could not be established in this case because niobium metal reacts with Nb^{5+} as well as with Nb^{6+} so the titration is ambiguous. In the tantalum case it is known that tantalum metal does not react with Ta^{5+} in these systems under the given conditions.

Identification of the valency state.—The valence state of the compounds was established by means of chronopotentiometry using a Ni/NiF_2, Flinak|| reference electrode as described elsewhere (2). Figure 1 shows the anodic chronopotentiograms for the oxidation of K_2TaF_7 dissolved in Flinak and for the solvent alone. It is clear that the solvent and graphite electrode are clean anodically below 0.7v and the plateau in Fig. 1 which starts near 0.2v results from the oxidation of the added Ta^{5+}. The average $E_{1/4}$ for this oxidation obtained from 10 chronopotentiograms is 0.19 ± 0.01v noble to the Ni/NiF_2, Flinak|| reference electrode. Figure 2 shows the anodic-cathodic chronopotentiogram on the K_2TaF_7 solution and the $\tau_{cathode}/\tau_{anode}$ is seen to be 0.33. This indicates that the product of the anodic reaction is a soluble compound (3). The difference of nearly 0.1v in potential of the cathodic and anodic steps indicates a little irreversibility even after correction for the IR drop.

Figure 3 shows a plot of the potential-time characteristics of a typical chronopotentiogram such as that in Fig. 1. For a reversible oxidation to yield a soluble product this plot should be a straight line with a slope of 2.3 $RT/n\mathbf{F}$ where n is the number of electrons involved in the oxidation. The data shown by the circles

[1] Flinak is the eutectic mixture of KF, NaF, and LiF.

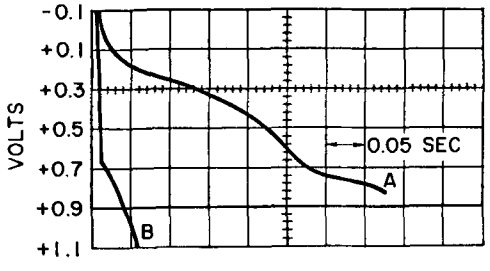

Fig. 1. Anodic chronopotentiograms. A, solution of K_2TaF_7 in Flinak; current density, 0.0139 amp/cm²; concentration, 3.6 x 10^{-5} mole/cm³; temperature, 750°C; anode, graphite. B, Flinak solvent only; current density, 0.015 amp/cm²; temperature, 750°C; anode, graphite.

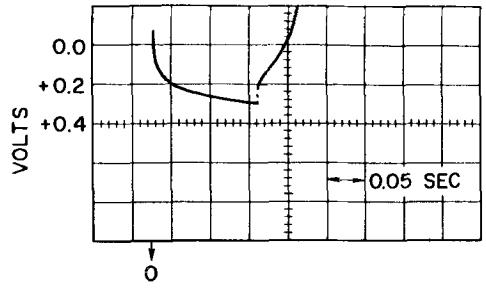

Fig. 2. Anodic-cathodic chronopotentiogram of K_2TaF_7 in Flinak; anodic cycle on left, cathodic on right; current density, 0.015 amp/cm²; temperature, 750°C; concentration, 3.6 x 10^{-5} mole/cm³; electrode, graphite.

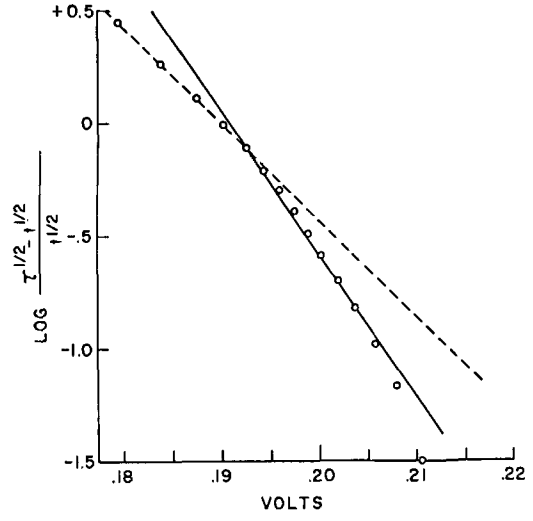

Fig. 3. Electron number for oxidation of K_2TaF_7 in Flinak from E vs. $f(t)$ plot.

do not give a straight line, and alternative plots for irreversible reactions or insoluble products (3) depart much further from straight lines. If one draws the solid line through the data points for times longer than $\tau_{1/4}$ (ordinate = 0) the slope yields a value of 1.0 for n. If one draws the dotted line through the other extreme using only the initial points for $t < \tau_{1/4}$ the slope of the line still gives a value of n of only 1.4. One may reasonably conclude from this that the oxidation is a one-electron oxidation and the small departure observed in the initial part of the curve results from some interaction between the graphite electrode and the pentavalent tantalum in the electrolyte. This may account for the small degree of irreversibility indicated in Fig. 2. Finally, the value of $i\tau^{1/2}$ for the oxidation at two concentrations of K_2TaF_7 gives a diffusion coefficient for $[TaF_7]^{-2}$ of 1.5 x 10^{-5} at 750°C if one takes n as 1.0 in the equation

$$\frac{i\tau^{1/2}}{c} = \frac{1}{2}\pi^{1/2} n\mathbf{F}D^{1/2} \quad (4)$$

This diffusion coefficient is identical to that found for the heptafluotantalate ion from the chronopotentiometry of its 3-electron reduction (2).

Similar chronopotentiograms and their analysis for the oxidation of fluoniobate show that it is also a one-electron oxidation, slightly irreversible, with the hexavalent niobium fluoride completely soluble in the Flinak at 770°C. The $E_{1/4}$ value for the oxidation is 0.25v noble to the nickel reference electrode.

It is realized that until these compounds are isolated and their structure determined by spectroscopy or other means, they cannot be unambiguously characterized as hexavalent metal fluorides. However, these data show unambiguously that a new oxidation state has been produced by a one-electron oxidation of heptafluotantalate ion in a fluoride medium, and that the ion being oxidized has the same diffusion coefficient as $[TaF_7]^=$. It might be suggested that the formation of a F_2^- ion (analogous to peroxy compounds) and its coordination with the $[TaF_7]^=$ could be consistent with the data. While this cannot be disproved at this time, it seems unlikely that such a compound would be thermally stable at the temperature of these experiments or that $2F^- \rightarrow F_2^- + e$ would occur at only 0.2v noble to nickel when the estimated potential for $F^- \rightarrow 1/2\ F_2^0 + e$ is 2.7v *vs.* the same Ni/Ni^{2+}, Flinak|| reference half-cell.

Properties of the hexavalent niobium and tantalum fluorides.—The compounds are indefinitely stable in molten Flinak between 700° and about 850°C. On cooling they decompose with the evolution of fluorine to form the pentavalent compounds, but it is possible that by rapid quenching the hexavalent material might be preserved at lower temperatures. They are strong oxidizing agents as shown by their $E_{1/4}$ potentials which are more than 1v noble to the $E_{1/4}$ potentials for the reduction of the pentavalent tantalum and niobium compounds (2). They rapidly dissolve their respective metals as well as the refractory lower fluorides such as TaF_2 which are insoluble in molten Flinak solution.

Acknowledgment

The authors are indebted to W. J. Reinhart, who made the chronopotentiometric measurements, R. L. Zupancic, who operated the electrolysis cells, and Professor H. A. Laitinen for his valuable discussion and criticism.

This work is the subject of patent applications filed in the United States and elsewhere and further studies on the electrochemistry and chemistry of these compounds are continuing.

Manuscript received Jan. 22, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

Anodic Oxide Films on Vanadium

R. G. Keil and R. E. Salomon

Department of Chemistry, Temple University, Philadelphia, Pennsylvania

The growth of anodic oxide films on aluminum, tantalum, zirconium, and hafnium has been investigated by a number of workers (1). Films exhibiting sharp interference colors which are characteristic of thickness can be prepared by anodization in a variety of aqueous electrolytes. Attempts to extend these studies to other metals, such as vanadium, are complicated by the appreciable solubility of the oxidation product in aqueous media. If such films could be grown, however, a direct quantitative chemical analysis of them would be quite feasible.

Young (2) suggests the use of partly nonaqueous electrolytes as media for the growth of water soluble anodic oxide films. Anhydrous organic solvents dissolve only small quantities of salt and cannot be made highly conductive. Furthermore, these solutions when used as anodization media often lead to unusual oxidation states (2).

It has been found that the anodic oxidation of vanadium in anhydrous acetic acid that has been saturated with $Na_2B_4O_7 \cdot 10H_2O$ leads to films which exhibit well-defined interference colors characteristic of formation voltage and thickness. The growth of these films is rather sensitive to the water-borate ratio although the total borate present is not of major significance.

Samples of vanadium in rod form, 99.4% pure, were wet polished with aluminum oxide powders, etched in 6.7*N* nitric acid, and then washed with glacial acetic acid. The specimens were placed in a thermostated anodization cell containing a Ag/AgAc reference electrode and a platinum foil cathode. Provisions for purging and stirring the solution with dry nitrogen were made. Electrolyte was added to the cell and the electrode was anodized at constant voltage for periods of from 10 to 15 min. The current was followed by means of a recorder.

After anodization the films were washed in glacial acetic acid and allowed to dissolve into distilled water. The resulting solution was analyzed quantitatively for vanadium by a colorimetric method (3).

Film growth could be inferred by the observation of the changing interference colors. The current, which initially appeared to be limited by the electrolyte resistance, decreased monotonically and approached a limiting value of the order of 0.50 ma/cm^2 in a few minutes. The interference colors were found to be characteristic of formation voltages for potentials up to 25v whereas breakdown occurred above this point. The solution obtained by dissolving a known area of the film in distilled water was found to contain pen-

Table I. Relation between formation voltage, film color, and amount of vanadium (V)

Formation voltage, v	Film color	Total vanadium (V) moles $cm^{-2} \times 10^7$
7.0	Light yellow	
9.0	Yellow	1.00
11.0	Dark yellow	1.08
12.0	Reddish yellow	
13.0	Purple	1.15
15.0	Blue	1.23
22.0	Green	

tavalent vanadium in an amount that was linearly related to the formation voltage. Results are shown in Table I.

Blank runs showed that correction of the data due to dissolution of the bare metal in distilled water were unnecessary. Several other electrolytes such as anhydrous acetic acid saturated with sodium metaborate, absolute methanol saturated with $NaNO_3$, $NaNO_2$, $Na_2B_4O_7 \cdot 10H_2O$, Na_2CO_3, $Na_2C_2O_4$, H_3BO_3, and acetic acid saturated with Na_2SO_4 and small amounts of water were tried and found to be unsatisfactory.

The results suggest that small quantities of water are necessary and that this water should be tied up by hydration to reduce the solubility of the oxide film. Specular reflectance measurements on the thicker oxides permit tentative identification of the film as nonstoichiometric V_2O_5 (4).

Correction

In the paper by Willem van Hees "A Bacterial Methane Fuel Cell" which was published in the March 1965 issue of the Journal, the last reaction in column 2, page 260, should read

$$E = E_o' - RT/2f \ln ([AH_2]/[A])$$
$$= E_o' - 0.03 \log 10^c = E_o' - 0.03c$$

Discussion Section

This Discussion Section includes discussion of papers appearing in the JOURNAL of The Electrochemical Society, Vol. 110, No. 8 (August 1963) and Vol. 111, No. 5, 7, 8, 9, 11, and 12 (May-December 1964). Discussion not available for this issue will appear in the Discussion Section of the December 1965 JOURNAL.

A Technique for the Evaluation of Hydrogen Embrittlement Characteristics of Electroplating Baths

M. A. V. Devanathan, Z. Stachurski, and W. Beck
(pp. 886-690, Vol. 110, No. 8)

M. A. V. Devanathan,[1] Z. Stachurski, and W. Beck[2] (Additional comments by the authors of the paper): The paper which Dr. Dubpernell discusses is one of a series of three papers[3-5] devoted to interrelated problems. Investigated in the three papers were: diffusion of hydrogen through palladium,[3] iron and steel,[4,5] the mechanism of hydrogen evolution on iron,[4] and hydrogen embrittlement of steel during electroplating.[5] The answer to most of Dubpernell's questions can be found in the cited papers. The principle of the method used in all three papers has already been discussed in a reply by Dr. Beck.

The method was based on certain assumptions. These are:

1. Adsorption of atomic hydrogen takes place on the test membrane while hydrogen is evolved on the "cathodic side" of the membrane.
2. Atomic hydrogen diffuses to the other side of the membrane, the potential of which is maintained anodic with respect to hydrogen.
3. Ionization of hydrogen on the "anodic side" of the membrane is a source of current which is monitored and called permeation current.
4. The rate of diffusion of atomic hydrogen through the membrane under the given conditions is proportional to the hydrogen coverage on the cathodic side.

The validity of the above assumptions was carefully checked by us.[3,4] The questions asked by Dubpernell indicate that it is necessary to describe again briefly how this was done.

The authors' first experiments were run on palladium membranes. It was found that the variation of the permeation currents with time corresponds to that predicted by diffusion theory. The diffusion coefficient was found to be independent of the thickness of the membrane and corresponded to extrapolated values of gas penetration at elevated temperatures. The anodic side of the membrane never became passive in experiments with electrolytically evolved hydrogen. The reason is that its potential was negative *vs.* reversible potential of α-Pd in alkaline solution and was positive *vs.* reversible potential of hydrogen in the same solution. Only in the one case when we filled one cathodic compartment with H_2 instead of electrolyte did the anodic side become completely passivated. The penetration current in this particular case was initially about 100 times larger than during any experiment with electrolytic evolution of hydrogen conducted by us. This large penetration current fell irreversibly to nearly zero. Passivation was in this case probably associated with the formation of β-Pd.

In the authors' work on hydrogen evolution on iron[4] they always covered the anodic side of the iron membrane with a very thin layer of palladium. This "protected" it against anodic passivation and did not impede hydrogen penetration. They also found that annealing of Armco iron prior to experiments led to reproducible results. Without annealing, no steady-state penetration could be obtained and blistering was frequent.

On palladium-coated annealed iron membranes the variation of penetration with time also was as predicted by diffusion theory. The diffusion time lag was proportioned to the square of the thickness of the membrane; the diffusion coefficient was reasonably independent of membrane thickness. The reciprocal of the permeation rate increased linearly with the membrane thickness. The diffusion coefficient again was found to be in agreement with one extrapolated from high-temperature permeation measurements. The mechanism of hydrogen evolution from acids was found (from changes in coverage of atomic hydrogen) to be slow discharge, in accordance with Frumkin. This seems to be sufficient evidence that what was measured was really hydrogen penetration and not any "side reaction" as postulated by Dubpernell.

The third phase of the experiment[5] was the application of the above method to the problem of hydrogen embrittlement of steel during electroplating. The principal point of this work was that the electroplated coating was the controlling factor with respect to the quantity of hydrogen, penetrating the steel. This is due to the very low permeation rate of hydrogen through coatings (mainly Cd). The entire discussion of Dubpernell of "damage due to excessive pretreatment" is therefore pointless. Steel served merely as the support for the coatings. The amount of hydrogen which penetrated during the formation of a coating could be measured by the method described. This was then compared with the extent of embrittlement of another sample of steel which was plated from the same type of bath and tested mechanically in independent experiment. The correlation was presented.[5]

As a last point of the discussion, Dubpernell insists that it is molecular rather than atomic hydrogen which diffuses through the membrane. With respect to palladium, it was long ago found by means of paramagnetic susceptibility measurements that dissolved hydrogen gives electrons to the d-band of palladium.[6] It is therefore entirely ionic. A similar situation seems to prevail with iron. Bryan and Dodge[7] determined the diffusion coefficient of hydrogen for penetration from the gaseous phase. Extrapolation of their values for footnote 3 to room temperature gives values in close agreement with our data.[8] The particles diffusing must be therefore the same at room temperature and at elevated temperature.

Furthermore, the work by Sieverts *et al.*[9] has shown that the diffusing species is not molecular hydrogen. He found that the solubility of gaseous hydrogen in iron was proportional to the square root of the pressure of H_2. He concluded that H_2 dissociates and dissolves in α-Fe in the form of atoms.

There is moreover no difference between penetration through polycrystalline iron and through monocrystals.

[9] A. Sieverts, W. Krumbhaar, and E. Juresch, *Z. Phys. Chem.*, 77, 591 (1911).

For penetration from the gas phase this was checked by Smithels and Ransley[10] and for electrolytically evolved hydrogen by McBreen.[8] Shwed and Sharpenko[11] have shown that introduction of hydrogen in iron reduces its work function. The explanation is that hydrogen is in the ionized or partially ionized state.

The above facts seem to the authors' to establish an adequate basis for their experimental method.

G. Dubpernell[12]: The additional comments from Stachurski are of interest but fail to be convincing. It is still felt that the proposed method is not a measure of either hydrogen diffusion or hydrogen embrittlement. A few inaccuracies appear to warrant further comment.

Stachurski states that the anodic side of the membrane never became passive (with but one exception). However, the publication in question states that "Whenever the permeation currents were large the anodic side of the palladium showed a tendency to passivate with formation of visible oxide films," and refers further on to ". . . the formation of visible oxide films on the anodic side of the membrane. . . ." These statements were taken to indicate a not infrequent formation of visible oxide films on palladium.

Reference is made to the coating of the anodic side of iron membranes with a very thin layer of palladium, but the thickness of these layers is not given. It is stated that these layers ". . . did not impede hydrogen penetration," but this is not considered to be true. Rather thin membranes of sound palladium metal have been found to be impermeable to hydrogen; they are then considered to be "poisoned," or in need of "cleaning" or "activation," but it is felt by the writer that solid palladium does not normally permit hydrogen diffusion at room temperature and that the adsorption of hydrogen which occurs should be classed as some type of compound formation between hydrogen and palladium, rather than diffusion.

Stachurski states that without annealing no steady-state penetration of the Armco iron membranes could be obtained. How would he explain the lack of diffusion without annealing?

Stachurski is not correct when he says that Dubpernell insists that it is molecular rather than atomic hydrogen which diffuses through the membrane. It is felt that sound, solid, undamaged membranes do not permit any diffusion whatsoever at room temperature, whether they be of palladium or iron. It is only when the electrolyte is able to penetrate a pore or capillary in the metal that the current enters and may cause hydrogen or oxygen evolution within the metal or on the back side of a membrane, according to whether it is charged cathodically or anodically.

The statement of Mott and Jones in 1936 appears to relate to compound formation between hydrogen and palladium and is not believed to have any bearing on the question of diffusion.

Bryan and Dodge studied the diffusion of hydrogen through iron at 126°-693°C, using hydrogen pressurers of 0.033-300 atm. In agreement with many other investigations they showed that hydrogen is insoluble in iron at room temperature. Stachurski should accordingly not try to apply any of their data to room temperature measurements.

The reference to Sieverts is also to high-temperature work which likewise shows that hydrogen is insoluble in iron at room temperature, and does not seem to contain any discussion of the possible dissociation of hydrogen in iron at high temperatures. Several other papers by Sieverts[13,14] do discuss this point, but Sieverts considers it of doubtful validity, since the solubility of sulfur dioxide in copper also varies as the square root of the pressure and yet the sulfur dioxide is not dissociated.

Smithels and Ransley also worked at high temperatures (100°-1600°C); while they did fail to find any difference between polycrystalline iron and a single crystal, they also showed that hydrogen is insoluble in iron at room temperature.

The thesis by McBreen has not yet been published and is unavailable for comment. Likewise the paper by Shwed and Sharpenko is not available to the writer.

The work of at least nine or ten other investigators has also shown the apparent insolubility of hydrogen in iron at room temperature. An excellent summary is given by Blake, Jordon, and Pumphrey.[15] It is this very lack of solubility of hydrogen in iron at room temperature which is probably one of the causes of hydrogen embrittlement. Solubility of even part of the hydrogen in the iron would probably be quite helpful or even eliminate embrittlement. Hewitt[16] concludes that ". . . hydrogen in solid low alloy steel remains in interstitial solution only above about 130°C. Below this temperature it seems to precipitate rapidly into traps associated with dislocations. . . ."

It may be of interest that Martin and Rummel in a mass spectral study[17] were unable to detect any monatomic hydrogen diffusing in the inside of a palladium tube 0.003 in. thick. Even above the ionization potential of hydrogen they only obtained large yields of both masses 2 and 3.

In summary, the proposed method for the determination of hydrogen permeation and for the evaluation of hydrogen embrittlement, seems of doubtful validity.

The Reaction at the Iron Alkaline Electrode

A. J. Salkind, C. J. Venuto, and S. U. Falk (pp. 493-495, Vol. 111, No. 5)

P. B. Mee[18]: Salkind, Venuto, and Falk found that in the discharged condition, the iron active material contained αFe, Fe $(OH)_2$, and Fe_3O_4, although Fe_3O_4 was found only when the material had been previously washed in a reducing solution. They also reported the presence in their x-ray diffraction patterns of a minor peak at 2.22Å which appeared whenever strong patterns of αFe were observed. Salkind *et al.* did not however provide any hypothesis as to the origin of this peak.

Such a peak has also been observed in this Laboratory during the examination of iron active material, and has been attributed to the presence of $\alpha Fe_2O_3 \cdot H_2O$, which is stoichiometrically equivalent to 2FeOOH. The material used in this Laboratory's examination was prepared by conventional Edison-type processes and was supplied by Alkaline Batteries Ltd., Redditch, England. One specimen was examined in the as-prepared powdered condition and the second after forming in the following manner. Thirteen grams of as-prepared iron active powder were compressed into a conventional pocket, fully charged using four positive tube electrodes at 600 ma for 15 hr, and then discharged at the same current until the cell voltage had fallen to 1v. (Four positive tube electrodes were used to ensure that discharge was under negative electrode control.) The cycle was repeated three times, and after the final discharge, the cell was short circuited for half an hour. The pocket was finally washed in distilled water and allowed to dry before examination.

			2.09 (15)				
2.03 (100)						2.03	2.03
			2.01 (20)				

In Table I the x-ray reflections observed from the iron negative active materials are recorded in comparison with ASTM standard data, showing that, in agreement with Salkind *et al.*, the as-prepared material consisted of αFe and Fe_3O_4. The as-formed and discharged material in the present experiment contained αFe, $\alpha Fe_2O_3 \cdot H_2O$, and Fe_3O_4.

During our analysis considerable x-ray line broadening was evident, as shown by the traces of Fig. 1;

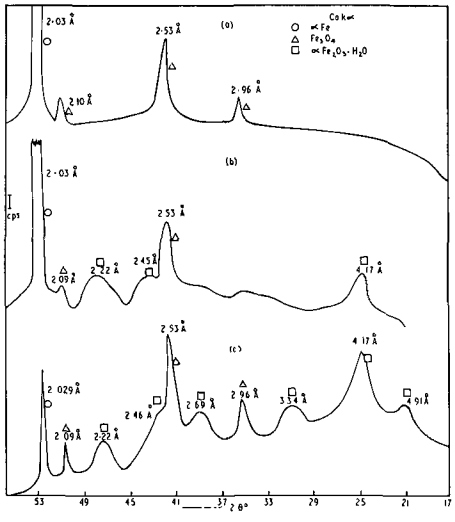

Fig. 1. X-ray diffraction traces from (a) as-prepared material, (b) as-formed material, and (c) as-formed material after dissolution of α Fe in $FeCl_3$ solution.

the lines varied widely in sharpness indicating a possible platelike particle shape. Assuming the line broadening to be due entirely to crystallite size effects, analysis of the x-ray patterns indicates that the mean crystallite sizes of αFe and Fe_3O_4 in the as-prepared material were > 1500 and 600-700Å, respectively. Similarly it was found in the as-formed and discharged material that $D_{\alpha Fe} > 1500$Å, $D_{Fe_3O_4} \sim 200/300$Å, and $D_{\alpha Fe_2O_3 \cdot H_2O}$ (110) $\sim$ 65Å in the orthorhombic lattice.

Examination in a type EM6 electron microscope indicated that the as-prepared material consisted of particle agglomerates and very thin flakes of Fe_3O_4, whereas the as-formed material had an irregular particle shape and wide particle size range, 500 → 25000Å, with the majority in the range 500 → 7000Å. Electron diffraction patterns were consistent with the presence of $\alpha Fe_2O_3 \cdot H_2O$. Marked shape anisotropy would, of course, lead to deviation from the theoretical relative intensities of the lines in the x-ray diffraction pattern and might thus explain why only one of the lines of $\alpha Fe_2O_3 \cdot H_2O$, *i.e.*, at 2.22Å, was observed by Salkind *et al.* A further possibility would arise however if insufficient filtration had been used in that the line could then be the Kβ reflection of α Fe (110).

A. J. Salkind, C. J. Venuto, and S. U. Falk: We are very interested in the work of Mr. Mee in examining the oxide states of iron and we are pleased to observe that he has substantiated much of the data which we reported.

In his discussion he mentioned two possibilities for the existence of the reflection at 2.22Å which appears in our work and which we did not identify at that time. The first is the possibility of $\alpha Fe_2O_3 \cdot H_2O$ and the second a line due to stray radiation caused by the insufficient filtration of the Cr x-ray beam.

From the data presented by Mr. Mee it appears that he does have $\alpha Fe_2O_3 \cdot H_2O$ in the material prepared in his experiments. We believe his latter suggestion however, is the cause of the 2.22Å reflection in our experiments for the following reasons:

1. We never obtained the 2.22Å peak unless the αFe was very intense.
2. We obtained it in the pattern for Armco iron indicating it is not necessarily a battery reaction product.
3. This could not be $\alpha Fe_2O_3 \cdot H_2O$ because all other lines were identified as αFe and or Fe_3O_4 *vs.* $Fe(OH)_2$ in our patterns. None of the other $\alpha Fe_2O_3 \cdot H_2O$ lines were recorded.
4. We believe that the 2.22Å peak is probably due to CrKβ radiation reflected from the (110) plane of αFe. 2θ angle calculated on the basis using CrKβ = 2.08479 and a d-value for the (110) plane of α-Fe gave an angle 61.9°. This compares favorably with the 2θ of 62° where the 2.22Å line was recorded on our charts.

Since our original work we have x-rayed the high αFe samples with chromium radiation and increased Vanadium filtration and also with copper radiation using a monochromator. In both instances the 2.22Å peak was eliminated.

We do not doubt that Mr. Mee is correct in that he produced $Fe_2O_3 \cdot H_2O$ under his particular experimental conditions. We suggest that this is being caused by the reaction of air oxygen with his iron active material.

A Kinetic Study of The System Si-$SiCl_4$

R. R. Monchamp, W. J. McAleer, and P. I. Pollak
(pp. 879-881, Vol. 111, No. 7)

S. E. Craig, Jr.[19]: In their article on the etch rates of silicon by $SiCl_4$, Monchamp, McAleer, and Pollak follow established tradition by noting that mass transport is, or may be, important and then completely

[19] Arizona State University, Tempe, Ariz.

omitting mass transport considerations from their analysis. Apparently the authors join many researchers in the epitaxial field who believe that "true kinetic" analyses are somehow more noble or more general than analyses which involve mass transport considerations. Certainly mass transport solutions are general. Once developed for a particular geometry, they apply to reactors of that geometry for any reaction whether the reaction is mass transfer controlled or not. On the other hand, the true kinetic and equilibrium relationships apply to particular reactions regardless of reactor type. In any practical case, the equilibrium and kinetics of the reactions couple with the transport phenomena in the reactor to produce the observed overall kinetics. Any analysis must therefore give adequate consideration to all three of these phenomena.

This general lack of attention to mass transport considerations is somewhat surprising since in most of the operational epitaxial reactors, mass transport is of major importance, while in many, it is the rate controlling phenomenon. Monchamp's work may be a classic example of how attempts to circumvent mass transport considerations can lead to erroneous conclusions.

The sealed reactor used by Monchamp would have very slow mass transfer; hence, we would not be surprised to find the kinetics limited by the rate of gas phase transport. Monchamp concluded that mass transport was not important because he measured an apparent activation energy of 49,100 cal/mole. A large activation energy usually indicates a reaction where mass transport is unimportant, but this is not always the case as shown below.

Since the reactor contains $SiCl_4$ in great excess, the kinetics could not be limited by the rate of transport of $SiCl_4$ to the surface, but the kinetics could be limited by the rate at which $SiCl_2$ is transported from the surface. This can be expressed in terms of a mass transport coefficient, k_p, and the partial pressure difference between the surface, p_{SiCl_2}, and the bulk gas phase, $p^o_{SiCl_2}$

$$r = k_p\,(p_{SiCl_2} - p^o_{SiCl_2}) \qquad [1]$$

Equation [1] applies whether the reaction is mass transport controlled or not. When "true kinetic" data are being sought, this equation is used to calculate the true partial pressure at the interface. If the equilibrium constant is small, the partial pressure of $SiCl_2$ in the bulk gas will be essentially zero while the partial pressure of $SiCl_4$ at the interface will be essentially the total measured pressure, p_{SiCl_4}. If the reaction rate is mass transport controlled, equilibrium will exist at the interface. Under these conditions, as Monchamp points out

$$K = \frac{(p_{SiCl_2})^2}{p_{SiCl_4}} \qquad [2]$$

From a combination of [1] and [2], the exact equivalent of Monchamp's Eq. [8] is obtained

$$r = k_p\,K^{1/2}\,P_{SiCl_4}{}^{1/2} \qquad [3]$$

If k_p is independent of pressure, then the 0.49 power rate dependence on P_{SiCl_4} is fully explained. In open tube, flow reactors mass transport coefficients based on partial pressure driving forces are inversely proportional to the total pressure. However, in the reactor design reported, the mass transport is mainly dependent on the rate of natural convection caused by the difference in density of the gases at the hot zone and cold zone. Since the densities of the gases are directly proportional to the total pressure, it is not unlikely that the net result is a k_p independent of pressure. Experimental verification of this point is needed.

When we take natural logarithm of Eq. [3], and differentiate the result with respect to the reciprocal of the absolute temperature at constant pressure we obtain

$$\frac{d(\ln R)}{d(1/T)} = \frac{d(\ln k_p)}{d(1/T)} + \frac{1}{2}\frac{d(\ln K)}{d(1/T)} \qquad [4]$$

or

$$-\frac{\Delta E_o}{R} = -\frac{\Delta E_m}{R} - \frac{1}{2}\frac{\Delta H^o}{R} \qquad [4a]$$

The left side of Eq. [4] is the slope of the straight line in Fig. 3 of Monchamp's paper and is equal to minus the apparent over-all activation energy, ΔE_o, divided by the ideal gas constant, R. The first term on the left of Eq. [4] is minus the apparent activation energy for mass transport, ΔE_m, divided by R. From thermodynamics, the last term in Eq. [4] is minus one-half of the standard enthalpy of reaction, ΔH^o, divided by R.

For open tube flow type reactors, ΔE_m is generally quite small and ranges from 0 to about 5 kcal/mole. However, for the reactor used by Monchamp, the mass transport depends on the natural convective currents which depend on the temperature difference between the cold zone and the hot zone. Hence, for this case we would estimate an abnormally high ΔE_m of from 5 to 10 kcal/mole. Again, this requires experimental verification.

There is considerable uncertainty in the standard enthalpy of reaction in the range of temperatures used by Monchamp. From the available literature,[20-25] $\Delta H^o_{1383°K}$ is calculated to be between 66.12 and 81.64 kcal/mole.

From Eq. [4a] and the above data, the apparent activation energy of the reaction would be between 38.12 and 50.82 kcal/mole for reaction kinetics which are fully mass transfer controlled. These values are in satisfactory agreement with Monchamp's reported value of 49.10 kcal/mole.

Since Monchamp's measured activation energy is apparently the sum of equilibrium and mass transport effects, it cannot be considered a true activation energy in the sense of Eyring[26]. Thus it is meaningless for Monchamp to speculate on the kinetics of reaction being controlled by the rate of desorption. All of the observed phenomena could be fully explained by simple mass transport and equilibrium.

Whether the data reported by Monchamp really represent true kinetic data or not can only be resolved by a critical experiment. Had he used a flow-type reactor, the experiment would have consisted of varying the total flow rate while keeping the feed gas composition, temperature, and pressure constant. If this does cause a change in reaction rate, mass transport is important and must be considered. Such a simple test cannot be used on Monchamp's closed system. However, he could vary the reactor diameter to produce a change in the mass transfer coefficient. A more critical test would be deliberately to increase the rate of natural convection by installing a cold gas return line as shown in Fig. 1. If this had an effect on the rate of deposition, mass transport would definitely be an important consideration in this reaction.

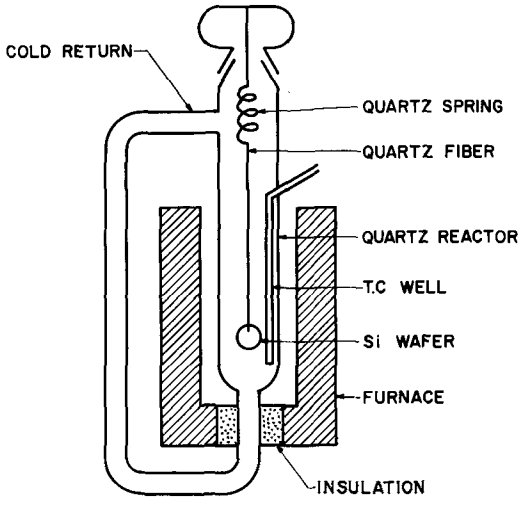

Fig. 1. Suggested modification of Monchamp's reactor to test for the significance of mass transport.

R. R. Monchamp[27], W. J. McAleer[28], and P. I. Pollak[29]: We have enjoyed reading Professor Craig's comments and, in general, are in full agreement with his concern for the part that is played by mass transport phenomena in gas systems. However, some of his comments lead us to believe that perhaps he had misunderstood several of our statements and, of course, he could not know the details of some of the negative type results we had obtained. In addition to technical reasons stated in our paper, we purposely did not want to work in a dynamic flow system since we knew that Dr. Thomas, with whom we had correspondence at that time, was examining such a system. His work has now been published.[30] Having been major commercial producers of epitaxial silicon, we were quite aware of the fact that the system under investigation was not an operational epitaxial reactor. We purposely designed it in this manner to simplify the experimentation.

We don't agree with Professor Craig that our conclusions are necessarily erroneous, since we took what we considered adequate precautions to assure ourselves that we were operating in a kinetic regime which was mass transport independent. The general agreement of the experimental findings of Alstrup and Thomas with our published results bears witness to this fact. Based on their results, in which a dynamic flow system was used, Alstrup and Thomas also arrived at a surface adsorption or desorption mechanism as the rate-controlling step rather than a mass transport controlled phenomena, as suggested by Professor Craig. Apart from this, we are very happy with Professor Craig's analysis and agree that many more experiments could have been carried out to satisfy his criticism. This is usually true for all research publications in the literature, and we would be stunned indeed if no improvement over our work would be possible. Unfortunately, we are no longer in a position to examine some of the questions raised by Professor Craig, and we suggest that he carry out the ultimate experimental and theoretical analysis of this system instead.

Aside from its technical significance, if our paper has accomplished nothing but to generate an interest and increased activity in the study of the $SiCl_4$-Si-H_2 kinetics, then we feel quite successful. We might further point out that this etching reaction was to be a starting point in a study of the entire $SiCl_4$, $SiCl_{4-x}H_x$, H_2, Si system. Judging from the confliction of opinions and interpretations of data for this first step, it is apparent that there is room for many more investigations and that it will be some time before the kinetics of the entire system are resolved.

Oxidation of Aluminum by Carbon Dioxide in the Presence of Cryolitic Electrolyte

S. Gjerstad and B. J. Welch (pp. 976-980, Vol. 111, No. 8)

W. B. Frank[31]: Gjerstad and Welch have presented convincing evidence that the rate-determining step in the oxidation of aluminum by carbon dioxide in the system cryolitic melt-molten aluminum is the "transfer of the dissolved metal or reacting species, from the melt-metal interface to, or near the melt-gas interface." There also appears to be evidence in their paper and elsewhere that the reacting species is predominantly dissolved sodium rather than aluminum or aluminum monofluoride.

Sodium has been identified in the vapors above the fused cryolite-aluminum system.[32] The sodium pressure is a function of melt composition,[33] increasing with sodium fluoride content and decreasing in acid (aluminum fluoride rich) melts. The appreciable solubility of sodium in sodium halide fusions has been reported by Bredig.[34]

Aluminum monofluoride pressures resulting from the aluminum-melt reaction have also been measured spectroscopically[33] and found to be much lower than those of sodium near the cryolite composition. Only in highly acid bath does the aluminum monofluoride pressure approach that of sodium.

Aluminum monofluoride and sodium can be thought of as being generated independently by aluminum-melt reactions. The sodium producing reaction can be written

$$Al + 6NaF\left\{\begin{matrix}\text{melt}\\\text{species}\end{matrix}\right\} \rightleftarrows Na_3AlF_6\left\{\begin{matrix}\text{melt}\\\text{species}\end{matrix}\right\} + 3Na \qquad [1]$$

The appreciable activity of sodium fluoride in cryolite-base melts results from the partial dissociation[35-37] of cryolite. The free energy change for the above reaction is +7 kcal at 980°C. Thus, this reaction is more favored thermodynamically than reaction (B) of Gjerstad and Welch.

The free energy change for the aluminum monofluoride producing reaction

$$2Al + Na_3AlF_6\left\{\begin{matrix}\text{melt}\\\text{species}\end{matrix}\right\} \rightleftarrows 3NaF\left\{\begin{matrix}\text{melt}\\\text{species}\end{matrix}\right\} + 3AlF \qquad [2]$$

is +50 kcal at 980°C The relative values for the free energy changes of reactions [1] and [2] and the melt activities resulting from the partial dissociation of cryolite are qualitatively consistent with the spectroscopically observed pressures of Na and AlF.

The decreased reactivity of the liquid Cu-Al alloy from that of pure aluminum appears to substantiate sodium as the major species oxidized by carbon dioxide. The ratio of the reactivities of the 50 mole % Al alloy to that of pure aluminum was observed by

Gjerstad and Welch as 0.58. On the basis of the electrochemical measurements of Grube and Hantelmann[38] the aluminum activity in a 50 a/o (atomic per cent) Al-Cu alloy at 980°C is indicated to be 0.28. From reaction [1] it is seen that the sodium activity is proportional to the cube root of the aluminum activity of the metal phase. Thus if sodium is the dominant oxidizable species, the ratio of reactivities should be $(0.28)^{1/3}$ or 0.66, in reasonable agreement with the observed ratio of Gjerstad and Welch of 0.58.

The increased reduction of CO_2 to CO by the NaF-AlF_3 melt-aluminum system with increased sodium fluoride content reported by Thonstad[39] is also consistent with the concept of sodium as the dominant species oxidizable by CO_2.

It is interesting to note that the diffusion rate of dissolved metal in the melt appears to be anomalously high, based on the measured rate of reaction and estimates of the solubility of either sodium or aluminum. The observed reaction rate of 7.8×10^{-6} moles $CO_2/cm^2/min$ at 980°C is equivalent to 2.6×10^{-7} g atoms $Na/cm^2/sec$ or 8.7×10^{-8} g atoms $Al/cm^2/sec$. These figures are in good agreement with Thonstad's[39] reported "total reactivity" for aluminum. Assuming the aluminum concentrations to be zero at the melt-gas interface and the saturation solubility of 0.1 w/o (weight per cent)[40] at the melt-metal interface, a diffusion coefficient of 2×10^{-3} cm^2/sec is calculated from Fick's law of diffusion. An even higher diffusion coefficient is calculated for sodium on the basis of an estimate of sodium solubility. Diffusion coefficients for ionic species in fused salts are generally in the range of 10^{-5} to 10^{-4} cm^2/sec.[41] No measurements of diffusion coefficients of metals dissolved in molten salts are reported in the literature.

S. Gjerstad and B. J. Welch: We agree with Dr. Frank that the experimental data published since this paper went to press[42-44] tend to support the sodium alternative as the more probable mechanism. In our discussion we were not concerned with the origin of the solvated species, but mechanism of its oxidation. The calculations of Frank indeed give added support to the sodium alternative, and if the more recent aluminum activity determined by Wilder[45] (0.265) is used, the agreement becomes even better. Angell and Tomlinson[46] have measured diffusion coefficients of Cd dissolved in $CdCl_2$ and obtained values of the same order of magnitude as those reported for ionic species in fused salts. Since Nanis and Bockris[47] have shown that the magnitude of diffusion coefficients in fused salts is dependent only on the melting temperature and the absolute temperature, the calculated values of diffusion based on measured Al solubilities are unreasonably high. This would therefore tend to support further the sodium alternative. In our opinion the question that is to be resolved is what is the nature of the solvated species—free sodium, or Na_2^+ as suggested by Thonstad.[44]

Use of Index of Refraction Liquid for the Measurement of the Refractive Index of Thin Transparent Films on Silicon

A. E. Lewis (pp. 1007-1009, Vol. 111, No. 8)

R. H. Muller[48]: It is interesting to see that the time-honored immersion method for the determinaiton of refractive indices has found a new application for transparent solid films. One of the limitations of the method described is due to the necessity of a well-observable light interference such as saturated interference colors in the film before immersion. This requires, as stated by the author A. E. Lewis, equal reflectivities of the air-oxide and oxide-metal interfaces at normal incidence. An extension of the present technique, using particular angles of incidence[49] and polarized light should alleviate this situation.

As reported earlier,[50] "optimum" angles of incidence $\phi||$ and $\phi\perp$ exist for light polarized parallel and normal to the plane of incidence,[51] respectively, under which the amplitudes of the reflections from the air-film and film-metal interfaces are equal. This results in easily observable interference phenomna, even under conditions where the difference in reflectivity precludes any observation at normal incidence. Typical values of these optimum angles of incidence have been computed for silicon covered by transparent dielectric films of the reported refractive index of the oxide and adjacent values. The results are given in Table I together with those for two other base-metals. Numerical values used for the complex refractive index of the metals $n_2(1 - i\kappa_2)$ are also listed in Table I.

Table I. Optimum angles of incidence ϕ for light interference in transparent dielectric films on metal surfaces

Film refractive index n_1			1.30		1.45		1.60	
Angle of incidence			$\phi\|\|$	$\phi\perp$	$\phi\|\|$	$\phi\perp$	$\phi\|\|$	$\phi\perp$
Metal	Optical constants n_2	κ_2						
Si	4.05	0.01	76°	68°	76°	63°	76°	57°
Ni	1.75	1.95	84°	71°	84°	65°	84°	59°
W	3.46	0.94	82°	70°	82°	63°	82°	57°

In the modification of the immersion technique, suggested here, the reflection coefficient[52] of the film-liquid interface is a much steeper function of the refractive index difference between the two phases than under normal incidence (Fig. 1). Thus, the sensitivity of the method is improved in addition to making observation of the film interference easier. The use of polarization normal to the plane of incidence will in general be preferable to that parallel to the plane of incidence because the observations are possible at a lower angle of incidence which is often more convenient. As shown in Fig. 1, for an angle of incidence of 75°, which represents an average of the desirable values listed in Table I, the polarization normal to the plane of incidence also is associated with a somewhat better sensitivity.

It must be borne in mind that the immersion method presupposes a sharp boundary between homogeneous dielectrics. It is therefore strictly valid only for non-absorbing films. Computations for the reflection on absorbing media carried out according to Koenig[53] in-

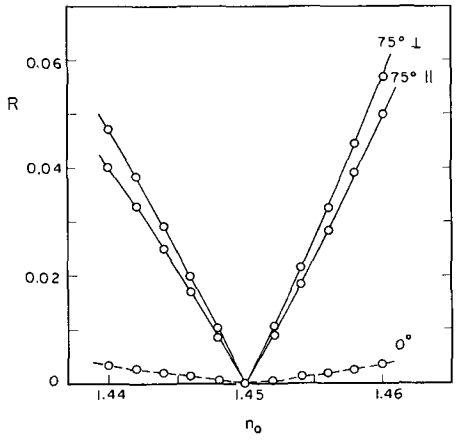

Fig. 1. Reflection coefficients R for dielectric medium (n_1 = 1.45) in contact with another dielectric of variable refractive index n_0. Angles of incidence 75° and 0°, polarization parallel (||) and normal ($\perp$) to the plane of incidence.

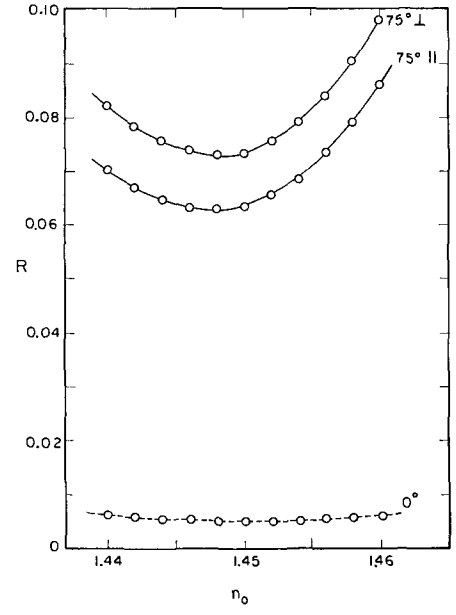

Fig. 2. Reflection coefficients of a slightly absorbing medium (n_1 = 1.45, κ_1 = 0.01) in contact with a dielectric of variable refractive index n_0. Angles of incidence 75° and 0°, polarization parallel and normal to the plane of incidence.

dicate that even for very slightly absorbing films (absorption index $\kappa_2 < 0.05$), the minimum in reflectance at the liquid-film interface, which occurs instead of the zero reflectance for a dielectric, gives only an approximate value of the real part of the complex film refractive index (Fig. 2).

A. E. Lewis: An increase in the intensity of the interference color obtained from a thin film is obtained by increasing the angle of incidence as shown by Muller[54] for a thin nonabsorbing film on a reflecting substrate in air. An examination of Fresnel's laws of reflection shows that this is expected because of the refraction occurring at the air-film interface. The angle of incidence increases faster than the angle of refraction as the angle of incidence is increased. The reflectance of the air-film interface therefore increases faster than the reflectance of the substrate. As the reflectance of the air-film interface increases relative to that of the substrate, the two reflectances become more equal and the intensity of the interference color increases.

This condition does not apply to the measurement of the index of refraction of a film using liquids. In this

[54] R. H. Muller, *J. Opt. Soc. Amer.*, 54, 419 (1964).

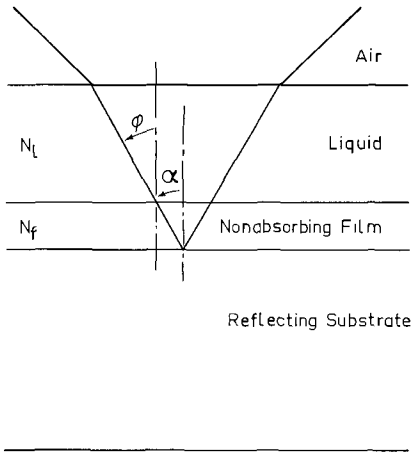

Fig. 1. Refraction of light in liquid covered film where $n_l \approx n_f$

method a "thick" liquid is applied to the film as shown in Fig. 1. Because the refractive index of the film and the liquid are almost equal, *i.e.*, $\Delta n = 0.005$, the angle of refraction (α) is only slightly different from the angle of incidence (ϕ), and although the reflectance of both the film and the substrate increase with increasing angle of incidence, there is no observable differential increase of the film reflectance relative to the substrate.

The conclusion that no increase in the sensitivity of the method is obtained by varying the angle of incidence in either polarized or nonpolarized light has been confirmed by observations made as a result of this discussion.

There is no statement in the paper that observable interference colors require equal reflectances of the air-film and film-substrate interfaces at normal incidence. The only requirement is that the reflectances must yield an observable interference color. This condition is fulfilled for very unequal reflectances and for angles of incidence other than zero. The technique found most suitable is to observe a film-step immersed in a liquid without a microscope or other optical aid. Immersed steps can be seen by this technique that can not be seen under a microscope.

As stated by Muller and also in the paper the method is applicable to nonabsorbing films. Films not strictly nonabsorbing such as SiO (index of refraction as high as 2.1) have, however, been measured without difficulty using this method. Such films are brown and obviously absorbing even in thicknesses less than a micron.

A High Performance Propane Fuel Cell Operating in the Temperature Range of 150-200°C

W. T. Grubb and C. J. Michalske (pp. 1015-1019, Vol. 111, No. 9)

G. H. J. Broers[55]: The authors, on page 1018 (Discussion and Results), mention four factors that may affect the steady state rate of oxidation: (i) mass transport of fuel or water to the electrocatalyst sites. (ii) . . . . . adsorption . . . . . (iii) . . . . . surface reactions . . . . (iv) rate of mass transport of CO_2 away from the reaction sites.

Then it is concluded that (i) and (iv) will not be rate determining, since the observed polarization curves are well removed from the limiting current region.

In my opinion this conclusion does not hold with regard to (iv). Considering reaction

$$C_3H_8 + 6H_2O = 3CO_2 + 20\,H^+ + 20\,e^- \qquad [1]$$

the theoretical influence of CO_2 mass transport on the Nernst potential E of the anode is of the form

$$\Delta E(CO_2) = (3RT/20\,F)\ln(1 + i/i_o) \qquad [a]$$

[55] Central Technical Institute, T.N.O., 198 Hoogte Kadijk, Amsterdam, Netherlands.

where R, T, and F have their usual significance, i is the current density and i_o is a constant; i_o is associated with the effective diffusion layer thickness δ, the effective diffusion constant D and the concentration c_o of CO_2 at the reaction sites when $i = 0$:

$$i_o = 20\ FDc_o/3\delta \qquad [b]$$

The + sign in [a] is typical for mass transport of reaction products: away from the reaction sites. Generally this mode of transport does not yield limiting currents (unless the electrode becomes blocked completely by the product), but will give rise to a pseudo Tafel behavior whenever $i >> i_o$.

In that case the linear plot of ΔE *vs.* i according to [a], yields a polarization curve of a shape similar to that of "activation controlled processes," that is, similar to the curves shown in, *e.g.*, Fig. 6 on page 1018.

Since very little will be known about δ, D, and c_o under the experimental conditions, an *a priori* neglection of mass transport effects of type (iv) might not be justified.

Of course, Grubb and Michalske's discussion on the factors (ii) and (iii) need not be ruled out by the present argument on (iv).

W. T. Grubb and C. J. Michalske: It is agreed that CO_2 mass transport could affect the rate under Broers' conditions without showing a limiting current behavior. Experimental evidence to show whether Broers' conditions apply to the present case is lacking. There is evidence that the performance of saturated hydrocarbon anodes in phosphoric acid at 150°C is a rather strong function of the structure of the fuel molecule.[56] We therefore favor the hypothesis that the fuel molecule is involved in one or more rate-determining steps and that mass transport of CO_2 away from the anode is not rate determining under the conditions of our experiments.

Mechanical Stresses during the Oxidation of Copper and Their Influence on Oxidation Kinetics. III

W. Jaenicke, S. Leistikow, and A. Stadler
(pp. 1031-1037, Vol. 111, No. 9)

U. R. Evans[57]: The authors have used the derivation of the logarithmic equation put forward by Davies, Agar, and myself in 1954 in interpreting their results. They are right in saying "one has to be cautious stating and interpreting oxidation laws;" but their observations on stress in the film certainly do seem to confirm the interpretation of the laws which we then put forward to explain our results on iron.

I appreciate also their reference to my "indirect evidence" of stresses in films published in this JOURNAL in 1947. In the same year I reported some much more direct evidence, but my paper,[58] presented at a symposium, escaped general notice. Those who have access to the symposium report may care to study my photographs (especially Fig. 3, 4, 7, 8, and 10), which are probably more convincing than any verbal description. For those who have no access, I attempt a summary.

Rectangles of nickel foil were heated along one edge to give wedge-shaped films producing interference colors. cemented to glass by means of petroleum jelly (vaseline), after which the nickel was removed anodically, leaving the films clinging to the glass, but now showing complementary colors. Had the films been stress-free they would have remained flat, but in fact the thicker parts of the films developed wrinkles, showing that while attached to the metal they must have been unnaturally compressed, although only after the removal of the nickel, were they free to assume a relatively unconstrained state by wrinkling, thus relieving the compressional stresses. Very instructive was one case (Fig. 10), where an island of metallic nickel had escaped anodic attack, and the film remained anchored to it, so that the wrinkles somewhat recalled the ridges of a mountain radiating from a central peak.

While the thicker films suffered wrinkling, an indication of fairly uniform stress, the thinner films curled up into tight rolls, indicating a stress gradient; one area was photographed by reflected light (Fig. 7) and by transmitted light (Fig. 8), and it is seen that the roll includes about 2½ convolutions, showing that the stress on this thin film must have been much higher at one face than the other.

The thinnest films of all failed in some cases either to wrinkle or curl, but remained flat. This was not because there was no stress, but because, when the thickness is sufficiently small, the decrease of strain energy accompanying curling or wrinkling will be less than the energy needed to deform the vaseline or to detach the film. When the vaseline was weakened by warming, these very thin films broke into contorted shapes.

The thicknesses at which these different phenomena passed into one another depended on the mechanical pretreatment of the nickel, but the following generalization was based on the study of over 100 tranfers:

"In the thick region, the film is strongly wrinkled . . . . The wrinkles usually come closer together as the films become thinner . . . Below a certain thickness (probably about 1000Å on nickel abraded with 2/0 emery), slits or holes appear in the film; at the edge of the gaps, the films tend to curl . . . At still lower thicknesses (about 500Å) the whole film is broken up into fragments . . . . which become smaller and more numerous as the thin region is approached, and then tend to curl up into rolls. Films too thin to give colors often curl into such tight rolls that the greater part of the vaseline surface is left bare. The tendency to curl increases as the thickness diminishes . . . The number of convolutions seen within the rolls increases as the film becomes thinner, showing that the stress gradient must increase as thickness diminishes. Observation is assisted if lines are drawn on the surface (before heating with heat-resistant pastel, or after heating with a lead pencil); the lines are clearly visible after transfer . . . The cause of the wrinkles in the thick film is found in the fact that the nickel oxide occupies, at its natural density, 1.6 times the volume of nickel destroyed in producing it . . . Wrinkling cannot be explained by differential thermal expansion, since the coefficient of expansion of nickel is too low, even if that of the oxide is neglected; moreover, similar wrinkling has been observed in the films formed on iron without heating by anodic treatment in sulphuric acid.[59]"

The explanation offered in 1947 for the stress (based essentially on the Pilling-Bedworth mechanism) is only valid for a film formed by movement of oxygen inward, not of metal outward. It is today generally believed that on nickel there are two layers, one produced by oxygen moving inward and the other by nickel moving outward. At first sight, this would seem to account for the curling, since the inner part only would be in compressional stress. Unfortunately, the curling is observed to take place in the wrong direction, and it must frankly be confessed that, although the observations provide convincing proof of stress in the films, they leave the origin of that stress still in doubt. The curling may represent a stress gradient produced in the metal by abrasion or other treatment and inherited by the oxide.

W. Jaenicke, S. Leistikow, and A. Stadler: We are glad, that in the foregoing remark Dr. Evans has again brought the attention to his ingeneous experiments of

[56] W. T. Grubb and C. J. Michalske, Proc. 18th Annual Power Sources Conference, Atlantic City, p. 17.

[57] 19, Manor Court, Grange Road, Cambridge, England.

[58] U. R. Evans, "Influence of Residual Stress on Chemical Behavior:" Symposium on Internal Stresses in Metals and Alloys, Organized by the Institute of Metals in London, 1947. Report published 1948, p. 291.

[59] U. R. Evans, *Nature*, 126, 130 (1930).

1947. They demonstrate, that on Ni similar effects happen as on Cu, in spite of the much higher reaction temperatures, which could cause plasticity of the oxide, as we have found at 500°C with copper. Evans has dissolved the metal to make visible the stress gradients within the oxide, while in some of our experiments the layer was reduced and by this way a dilatational stress within the metal could be measured. It is difficult however to understand the wrinkling of the thicker films if this is due only to stress relieving of strained homogeneous films because one has to consider new compressions at the concave parts and dilatations at the convex parts of the NiO.

We are pleased that also in Dr. Evans' opinion a simple volume effect like the Pilling-Bedworth rule does not cause permanent stresses in the interior of oxide layers if they grow by metal-ion transport. We wish to go farther and we believe, that this rule is of no importance also if the place of reaction is an inner phase boundary as long as the metal surface is flat. Such surfaces of course are seldom maintained during the reaction, especially if polycrystalline material or alloys are oxidized.

The Oxidation of Pyrolytic Graphite at Temperatures of 1400°-1800°F and at Air Velocities of 25-100 cm/sec.

M. Levy and P. Wong (pp. 1088-1091, Vol. 111, No. 9)

D. E. Rosner[60] and H. D. Allendorf[61]: The recent paper of Levy and Wong raises several interesting questions concerning the true high-temperature kinetics of pyrolytic graphite oxidation and the effects of diffusional limitations on the apparent kinetics of such highly exothermic heterogeneous chemical reactions. We wish to call attention here to aspects of practical and/or theoretical interest, some of which are currently under investigation at this laboratory.

Departures from Arrhenius behavior.—As noted by Levy and Wong, the fact that they, as well as many other investigators, have observed the transition from chemical to diffusion control to occur at surface temperatures in the 1100°-1200°K range is a reflection of the similarity of the reaction systems employed, especially as regards grade of carbon, specimen size, pressure level, and flow rate. However, in many aerospace applications (*e.g.*, leading edges for lifting Earth reentry vehicles [62] transport conditions are such that the transition is delayed to much higher surface temperatures (above 1400°K). The true specific reactivity of pyrolytic graphite at elevated surface temperatures is therefore of particular interest.

While it is tempting to make a simple straight line extrapolation (of kinetic regime data) on the Arrhenius plane, such a procedure would be unrealistic for the following reason.[63] If one casts the kinetic data of Levy and Wong in the form of a dimensionless reaction probability, ϵ, (*e.g.*, the probability that a carbon atom will be removed per O_2 strike) one finds that, in the kinetic region investigated, ϵ has a locally Arrhenius temperature dependence $\epsilon_0 \exp(-E/RT)$ with a pre-exponential term ϵ_0 that greatly exceeds unity. Since ϵ (as defined above) cannot exceed 2 (if each O_2 strike leads to the formation and desorption of 2 CO molecules) it is obvious that the Arrhenius temperature dependence (*i.e.*, constant activation energy) cannot be maintained at indefinitely high surface temperatures. Indeed, the kinetic data of Levy and Wong reveal that a leveling off of the true specific reactivity must occur somewhere below about 2400°K (a surface temperature well below the sublimation threshold). Maxima in the high-temperature oxidation probability of graphite in O_2 have been reported in the past[64] and have recently been observed at about 1600°K by the discussors in preliminary work with both diatomic and atomic oxygen.[63] As a corollary to these remarks, it is clear that an observed reduction in apparent activation energy is not a sufficient condition for invoking external diffusional limitations to explain experimental observations. One must (as Levy and Wong have done) investigate other effects, such as the dependence of reaction rate on flow rate, to rule out true kinetic departures from simple Arrhenius behavior.

Kinetics of the attack of graphite by atomic oxygen[63].—In the aerospace environment cited above[62,65,66] oxygen atoms are formed behind shock waves by thermal dissociation of O_2. Moreover, it is unlikely that there will be adequate time for homogeneous oxygen atom recombination in the cooler regions of the gas flow adjacent to the solid surfaces.[65,66] Consequently, the true kinetics of the attack of high-temperature pyrolytic graphite by atomic oxygen is a subject of current importance and one for which apparently no experimental data exist. Indeed, it remains to be seen whether pyrolytic graphite will display significantly improved oxidation resistance over ordinary commercial graphite in such an environment. Our preliminary experiments on the attack of commercial graphite (Speer Company, Grade 580) by atomic oxygen[63] in the surface temperature range 1100°-2000°K reveal that O-atom strikes are considerably more effective (a factor between 6 and 80 times) than O_2 in removing carbon atoms from the lattice. We hope to extend this work to other forms of graphite using experimental techniques similar to those employed in footnotes 63, 67.

Diffusional effects for exothermic surface reactions[68].—In discussing the transition from chemical to transport control one usually expects a monotonic dependence of reaction rate parameters (apparent activation energy, reaction order, *etc.*). However, it should be pointed out that for strongly exothermic, temperature sensitive surface reactions (such as graphite oxidation) this transition can display rather intriguing (certainly not monotonous!) behavior.[68] For example, in the intermediate regime the observed activation energy, reaction order, and sensitivity to flow velocity changes need not lie between the limits set by reaction rate and diffusion control. (Specifically, the apparent activation energy can exceed the true activation energy and the reaction rate can, locally, decrease with an increase in flow velocity.[69]) For a reaction of a prescribed kinetic order, in a system in which radiative heat transfer is negligible, these "overshoots" are largely determined by the magnitude of the product[68]

$$\alpha \equiv r_D \cdot \frac{Y_{O_2,\infty} Q}{\bar{c}_p T_\infty} \cdot \frac{E}{RT_\infty}$$

where r_D is the recovery factor for chemical energy, dependent on the ratio of the Fick coefficient for O_2 diffusion through the gas mixture to the mean thermal diffusivity of the mixture (r_D is a number of order unity); $Y_{O_2,\infty}$ is the oxygen mass fraction in the oxidiz-

[69] There is a suggestion of such behavior in the 1400° and 1500°F data reported in Fig. 3 of the paper, although additional points in the velocity range 25-50 cm/sec would be required to verify this.

ing gas; Q, the heat of oxidation (combustion) per unit mass of oxygen; $\bar{c}_p$, the mean specific heat of gas mixture; T_∞, the temperature of oxidizer stream; E, the true activation energy of the surface reaction; and R, the universal gas constant.

For graphite oxidation in air under the conditions investigated by Levy and Wong, even assuming CO(g) to be the dominant reaction product (which underestimates Q), this parameter appears to be large enough to produce significant effects on the nature of the transition from reaction rate-to-diffusion control. We would therefore like to ask if the authors of the paper have observed any evidence of this type. If not, perhaps radiative heat transfer in the furnace environment suppresses this interesting class of transition phenomena. This may also explain their observation that the graphite surface temperature never exceeded the furnace temperature by more than 20°K, whereas simple theory[68] would have predicted a temperature excess ΔT_{max}, given by

$$\Delta T_{max} = r_D Y_{O_2,\infty} Q/\bar{c}_p$$

(which amounts to more than 100°K in the present system).

Finally, Levy and Wong made reference to the concept of resistance additivity in discussing the transition from chemical to diffusion control. While this concept has been of undeniable qualitative value, we would like to emphasize that it should not be quantitatively applied to situations in which the interfacial mass flux $\dot{m}''$ associated with the oxidation process has a significant effect on the local boundary layer profiles.[70,68] This point, which has also been considered by Welsh and Chung,[72] is specifically illustrated in Fig. 1 for the case of graphite ablation in air at a forward

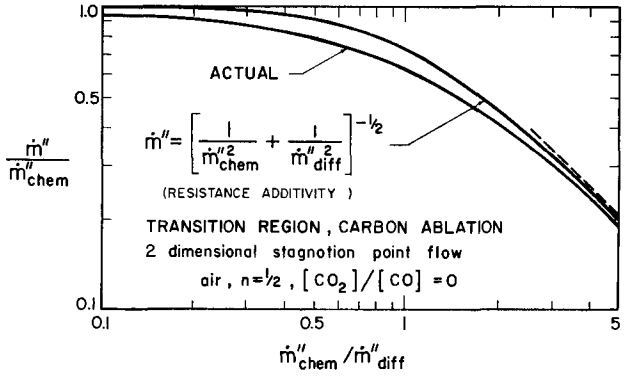

Fig. 1 Failure of the method of resistance additivity for the ablation of graphite in air.

stagnation point. In making these illustrative predictions we have assumed that the true reaction order is ½ and CO(g) is the dominant reaction product. At surface temperature levels such that primary CO_2 is formed in appreciable amounts the shape of the transition is also expected to exhibit a marked dependence on the relation between the primary CO/CO_2 ratio and local O_2 partial pressure.[72]

This discussion is based on work carried out under Air Force (Office of Scientific Research, Propulsion Div.) support, Contracts AF 49 (638) 1138 and AF 49 (638)-1195.

[70] This is especially true for the oxidation of tungsten or molybdenum in non-vitiated air at surface temperatures such that the metal oxides are volatile. [71]

M. Levy and P. Wong: We wish to thank Dr. D. E. Rosner and H. D. Allendorf for their interesting discussion.

We acknowledge the importance of the reaction of pyrolytic graphite with atomic oxygen but not at the temperature (1033°-1255°K) and low air velocities considered in our paper. Equilibrium constants for the reaction $\frac{1}{2}\ O_2(g) \rightleftarrows O(g)$ indicate that the dissociation of oxygen molecules becomes appreciable above 1473°K.

Regarding conditions where the apparent activation energy can exceed the true activation energy and the reaction rate can, locally, decrease with an increase in flow velocity, we have not observed this phenomenon in the transition region.

The Transmission of Electrolytically Deposited Hydrogen Through a Palladium Membrane Electrode

G. W. Castellan, R. A. La Pietra, and P. L. Damour

(pp. 1273-1283, Vol. 111, No. 11)

G. Dubpernell[73]: The difficulty with the work presented in these papers is that it is predicated on the assumption that electrolytically evolved hydrogen can diffuse through a palladium diaphragm freely and easily at room temperature. If the investigator assumed that hydrogen cannot diffuse through solid palladium at room temperature, he would have little difficulty in proving his point, as this is believed to be the case actually, even though not the widely accepted view. It is felt that adsorption of hydrogen and compound formation between hydrogen and palladium should not be regarded as synonymous with diffusion through a membrane.

It is postulated that the observed effects are due to porosity of the membranes and to the direct evolution of hydrogen on the back of the membrane through the pores. Little effort seems to have been made to check for such porosity of the membranes, even though a simple means has been suggested.[74]

Thus La Pietra and Castellan found it necessary to "clean" their palladium membranes by a 12 hr anodic treatment in 2*N* H_2SO_4 at 69.5 ma/cm^2, although they do not state what was present to require such prolonged anodic cleaning. They ". . . were plagued by the lack of reproducibility . . ." which could not be eliminated by anodic activation of the entrance side of the foil between each series of measurements. In his dissertation[75] La Pietra notes that even with the prolonged anodic cleaning about one in every four experiments gave anomalous results in that the percentage transmission of hydrogen was very much lower, and it was decided to reject all such runs. He also actually noted the appearance of "leaks" in some of his palladium diaphragms, and when he tried to test for leaks with acid indicator paper on the back of the diaphragm, found that this cut the transmission of hydrogen by more than half, and such a procedure had to be discontinued. It is also worthy of note that the results with the thinnest foil, 0.001 in. thick, were extremely erratic and consequently were not reported.

It appears likely that the prolonged anodic treatment in 2*N* H_2SO_4 could corrode holes through the palladium diaphragms. Palladium is not as resistant to corrosion as many of the other platinum metals and is known to corrode under these conditions.[76]

It would appear to have been in order to determine the weight loss or change in thickness of the palladium diaphragms, but they do not seem to have been examined after the tests.

[76] M. Pourbaix, "Atlas D'Equilibres Electrochimiques á 25°C," p. 361, Gauthier—Villars and Cie, Paris (1963).

Damour and Castellan anodized their palladium membranes at 100 ma for 30 min. It appears from Damour's dissertation[77] that the exposed area on each membrane was 1 cm in diameter, so the current density of anodization would have been about 127 ma/cm^2. In this work the preliminary cleaning of the membrane by flaming in a gas flame (Meker burner) as used by La Pietra was questioned, and a hydrogen-oxygen gas flame was used instead. Nevertheless, "poisoning" of the surface of the palladium was appreciable, and many times no gas would diffuse through the foils.

It seems evident that much more is involved here than a simple diffusion of hydrogen through palladium, and that a re-evaluation and a new approach would be in order. It is felt that much can be learned from a more painstaking study of thin, undamaged membranes handled with extreme care, and that if such membranes fail to permit any diffusion, they should not be regarded as poisoned, or in need of surface activation or cleaning.

G. W. Castellan, R. A. La Pietra, and P. L. Damour: The principal purpose of the prolonged anodic treatment of the cell system was not so much to clean the electrodes as to purify the electrolytic solution. The 12 hr electrolysis in Part II was replaced in Part III with a 30 min anodization to activate the electrode but in Part III the sulfuric acid solution was pre-electrolyzed for 12 hr in a flask outside the system.

We did not check the membranes specifically for porosity after using them. However, we attribute our inability to obtain satisfactory results with the thinnest (0.001 in.) membrane to the development of punctures in the membrane. If the pores are produced by anodic corrosion we think that our experiments would not have been as reproducible as they were.

On the general question of whether hydrogen diffuses through the bulk of the metal or through pores, we do not thing that the experiments in the set of papers in question here provide evidence on either side of this question. We have assumed in the interpretation that the hydrogen diffuses through the bulk of the metal. Other experiments, notably those in which the resistance of palladium is measured as a function of hydrogen content,[78,79] indicate strongly to our minds that hydrogen does diffuse through bulk palladium at room temperature.

As far as the question of compound formation is concerned, again the experiments in question here do not yield evidence on either side. And, at least within this limited scope we think one can take either side as a legitimate point of view.

We agree that the system deserves further examination using a number of different approaches. The situation with regard to "poisoning" is particularly unsatisfactory.

The Density and Surface Tension of Molten Fluorides, II. The System NaF-LiF-ZrF_4

G. Mellors and S. Senderoff (pp. 1355-1357, Vol. 111, No. 12)

H. M. Scholberg[80]: The authors have shown break points at low concentrations of ZrF_4 in the mixed fluoride solvents used for Fig. 4 and 5, which are not justified because of the following reasons. Gibbs equation suggests that the curves of Fig. 4 and 5 should be concave downward; otherwise, if it were drawn as a series of straight lines, as the authors have done, the force-area curve that would be obtained would be a step curve. Certainly, within the precision indicated by the authors, there appears to be no reason for discarding a smooth force-area curve in favor of a stepped curve. The break at high concentration shown in Fig. 5 is probably real as it has its counterpart in similar curves of organic surface active substances in water, where the break point is usually interpreted as the point of micelle formation.

A calculation of the surface excess at high concentration using Fig. 4 gives the value 3.90 x 10^{14} molecules/cm^2. This compares rather well with the value of 8.15 x 10^{14} calculated by means of the perfect gas law for surfaces. In view of the high pressures involved it is reasonable to expect that this sort of agreement would indicate that activity would not change the situation significantly.

It is possible, as I have shown in an article[81] to correlate surface tension and viscosity data to determine molecular structure parameters for solutions. I believe that it would be extremely interesting to apply that method to this problem.

G. W. Mellors and S. Senderoff: We do not accept the contention that the breaks at low concentration in Fig. 4 and 5 are less justified than the break at higher concentrations in Fig. 5, since there is no evidence for formation of solid phases at the temperatures studied at any concentration. If, however, micelle formation is equivalent to what we have called "clustering" or "ordering" in the liquid state, this may occur at both high and low concentrations.

There is no basis for the statement that the Gibbs equation curves must, *a priori*, result in curves concave downward. In fact, one cannot predict theoretically what shape curves will be obtained in a system such as this in which the identity of the solute species changes with composition as a result of interaction with the solvent. It will be noted in Fig. 5 that the Gibbs plots (lower curves) are concave downward at low concentration and concave upward at high concentration. This fact is strong evidence that the solvent species has changed from one complex ion $[ZrF_7]^{=}$ to another $[ZrF_5]^{-1}$.

M. A. Bredig[82]: Proof for the existence of complexes in molten salt mixtures is generally hard to come by. Thus, one is not readily persuaded that in Fig. 4 and 5 proposed "sharp breaks" actually exist as evidence for the occurrence of complex ions ZrF_7^{-3} and ZrF_5^{-} and for "clustering" or "ordering" corresponding to compositions Na_3ZrF_7 and K_3ZrF_7. The scattering of the experimental points, most pronounced in the top (enthalpy) curve in Fig. 4, seems much too large to justify drawing straight-line segments such as those shown in these figures. A gradual curvature over the whole range is actually indicated such as the authors present in Fig. 3 by the one smooth curve with which Fig. 4 showing the same data are not consistent. Furthermore, it is very improbable that clustering to a composition Na_3ZrF_7 (or K_3ZrF_7) would occur at 800°C, well above the melting point: Segregation of Na and Li does not take place even in the far more sensitive solid state at as low a temperature as the ternary eutectic (590°) where not pure Na_3ZrF_7 as stated by the authors but the solid solution phase $(Na, Li)_3ZrF_7$ forms, very rich in lithium (approximating just the Na:Li ratio 2:3 that was present in the measurements; cf. "Phase Diagrams of Nuclear Reactor Materials," R. E. Thoma, Editor, Oak Ridge National Laboratory, November 20, 1959, ORNL-2548, Table and Fig. 3.37, page 60/61; in press, *J. Chem. Eng. Data*, July 1965).

G. W. Mellors and S. Senderoff: We do not agree that the data shown in Fig. 4 and 5 would be correctly represented by smooth curves.

There is no inconsistency between Fig. 3 and 4. The logarithmic plot of Fig. 4, by magnifying the low con-

centration portion, makes the inflections in this region clearly evident. In the linear plot of Fig. 3 these inflections are less clearly defined, but departures of points from the curve may be observed near 10 and 25 mole% ZrF_4.

Our statement that "Na_3ZrF_7 ($\sim$ 11.7 mole % ZrF_4) is a solid phase found in equilibrium with the melt at the 604° eutectic temperature" is correct according to ORNL-2548 cited by MAB which is also our ref. (3). There is no special significance to the 590° eutectic cited by MAB since, in fact, the solvent composition we used falls between that of these two eutectic mixtures.

Plasma Anodized Aluminum Oxide Films

G. J. Tibol and R. W. Hull (pp. 1368-1372, Vol. 111, No. 12)

W. A. Pliskin[83]: The authors stated, "For very thick films, the method of Pliskin and Conrad,[84] using three wavelengths, provides an extension of this simple nondestructive method into the micron range." The original published paper[84] on the Vamfo technique (which is the name we had given this method) showed that it can be used for the measurements of film thicknesses from several hundred angstroms to several microns. The thicknesses of films thicker than a micron can be measured with use of only one interference filter. Also, the thicknesses of films in the range of 800Å to a micron and of known refractive index can be measured accurately using only one filter if the order of approximate thickness is already known or determined as described in Section b, p. 47, of ref. 84. The three or more filter technique described on p. 46 of ref. 84 is intended for those cases where both the approximate film thickness is not known and the thickness is less than 1μ. It is only one of several Vamfo variations described in that paper. The variation which we have used most commonly for thickness measurements is based on Eq. [2] (see p. 44 and end of Section b on p. 47 of ref. 84) with $d = N\lambda/2\mu \cos r$.

G. J. Tibol and R. W. Hull[85]: Pliskin describes in Ref. 84 several variations of a technique he calls "Vamfo" in which monochromatic interference fringes are observed as the sample is tilted, so that the film thickness follows the equation he states above. The thickness d is determined only when the refractive index μ is known. If μ is unknown, an additional measurement must be made. In Pliskin and Conrad's paper it is shown that a step measurement at normal incidence may be used as the second measurement.

When examining capacitor dielectric films, Tibol and Hull have found capacitance to be a very useful second measurement. The rapid change of dielectric constant with deviations from full film density magnifies the precision of the film thickness determination. We considered it to be significant that the thickness and dielectric constant determinations could be made on the actual samples to be electrically measured without any prior assumption of film structure.

Call for Papers for Cleveland Meeting, May 1966

Papers are being solicited for the Spring Meeting of the Society, to be held at the Sheraton-Cleveland Hotel in Cleveland, Ohio, May 1, 2, 3, 4, and 5, 1966. Technical sessions probably will be scheduled on: Electric Insulation, Electronics (including Luminescence and Semiconductors), Electrothermics & Metallurgy, Industrial Electrolytic, and Theoretical Electrochemistry.

To be considered for this meeting, **triplicate copies of the usual 75-word abstract, as well as of an extended abstract of 500-1000 words** (see notice on page 121C of the May issue), must be received at The Electrochemical Society, 30 East 42 St., New York, N. Y., 10017, *not later than December 15, 1965. Please indicate on 75-word abstract for which Division's symposium the paper is to be scheduled, and underline the name of the author who will present the paper.* No paper will be placed on the program unless one of the authors, or a qualified person designated by the authors, has agreed to present it in person. Clearance for presentation of a paper at the meeting should be obtained before the abstract is submitted. An author who wishes his paper considered for publication in the JOURNAL or ELECTROCHEMICAL TECHNOLOGY should send triplicate copies of the manuscript to the Managing Editor of the appropriate publication 30 East 42 St., New York, N. Y., 10017. Concerning papers to be published in the JOURNAL, see notice on per page charge on page 133C of this issue.

Presentation of a paper at a technical meeting of the Society does not guarantee publication in the JOURNAL or ELECTROCHEMICAL TECHNOLOGY. However, all papers so presented become the property of The Electrochemical Society, and may not be published elsewhere, either in whole or in part, unless permission for release is requested of and granted by the Editor. Papers already published elsewhere, or submitted for publication elsewhere, are not acceptable for oral presentation except on invitation by a Divisional program Chairman.

Design of Primary and Secondary Cells

II. An Equation Describing Battery Discharge

C. M. Shepherd

U. S. Naval Research Laboratory, Washington, D. C.

ABSTRACT

A discussion is given of the derivation and application of an equation which gives an excellent description of a wide variety of cell and battery discharges. This equation gives the cell potential during discharge as a function of discharge time, current density, and certain other factors. It makes possible a complete description of cell discharge characteristics, using a minimum of experimental data and at the same time pinpointing experimental errors. It can also be used to describe cell charges, capacities, power evolution, and to predict capacities. A description is given of a simple numerical method for fitting this equation to a particular set of battery discharge curves. A graphical method is described for comparing characteristics of various types of cells.

This paper is one of a series whose ultimate goal is to determine procedures for designing batteries having optimum properties such as minimum weight or minimum volume. In particular, the derivation and application of an equation describing cell discharge will be discussed. The equation can be used to locate variations in the discharge data due to experimental error, uncontrolled variables, etc., thus minimizing the amount of experimental data needed and cutting the costs of evaluation. A complete set of discharge curves can be described by a single equation, making it possible to present in less space a more detailed description of cell characteristics than has been customary in many battery papers.

Derivation and Determination of the Discharge Equation

The mathematical analysis given here is based on the assumption that the following conditions are applicable: (*A*). The anode and/or cathode have porous active materials. (*B*). The electrolyte resistance is constant throughout discharge. (*C*). The cell is discharged at a constant current. (*D*). The polarization is a linear function of the active material current density.

When ionic discharge is the slow or rate determining process, the relationship between steady-state current density and activation overpotential at an electrode in a constant concentration electrolyte is usually written as

$$i = i_o e^{\alpha\eta ZF/RT} - i_o e^{-(1-\alpha)\eta ZF/RT} \qquad [1]$$

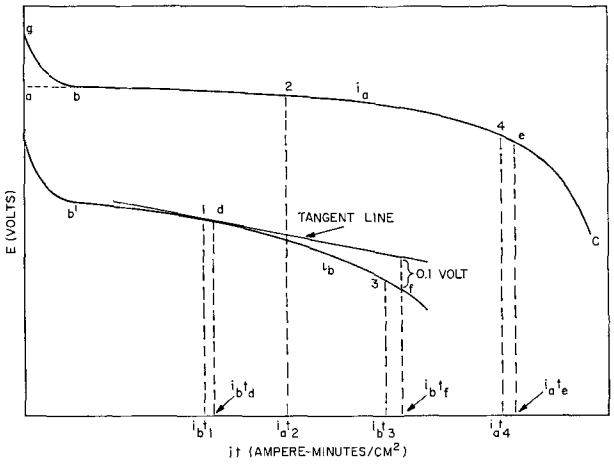

Fig. 1. Typical discharge curves used in equation fitting

where i is the apparent current density in amperes per square centimeter, i_o is the apparent exchange current density in amperes per square centimeter, α is the transfer coefficient ($0 \leq \alpha \leq 1$), Z is the number of electrons transferred in the rate-determining step, F is the Faraday, R is the gas constant, and T is the temperature in °K. The steady-state activation overpotential, η, is positive for the deposition of cations.

When the exponential terms are expanded as a series, powers greater than one can be neglected if η is sufficiently small and Eq. [1] becomes

$$\eta = \left(\frac{RT}{ZFi_o}\right) i \qquad [2]$$

thus establishing a linear relationship between η and i which is fairly accurate up to the values of η equal to approximately 0.03v. If Eq. [1] is applicable to a cell, the variation of η with change in i can be fitted by a straight line within approximately 0.02-0.04v up to values of η equal to about 0.2-0.4v. A potential drop of this magnitude would cover the major portion of the polarization that occurs during most battery discharges.

In Fig. 1, two solid curves, i_a and i_b, are shown which represent typical battery discharges. The potential in volts is plotted as a function of (it), the quantity of electricity that has been obtained from the battery at time t. It is assumed in the derivation that follows that the polarization is linear to the right of point b and b'. If all factors except polarization are ignored, then E_c, the cathode potential during discharge, is defined as

$$E_c = E_{sc} - K_c i_{am} \qquad [3]$$

where E_{sc} is a constant potential, K_c is the cathode coefficient of polarization per unit active material current density, and i_{am} is the active material current density. The successful use of Eq. [3] as a fundamental equation in the derivation that follows does not necessarily imply that the theoretical factors associated with Eq. [1] apply to most battery discharges even though both equations are linear.

In the case of a porous electrode the active material current density i_{am} is defined as being inversely proportional to the amount of unused active material and is also equal to i at the beginning of the discharge. Consequently

$$i_{am} = \left(\frac{Q_c}{Q_c - it}\right) i \qquad [4]$$

where t is the time at any point during the discharge and Q_c is the amount of available cathode active material expressed in units such as ampere hours per unit area.

When Eq. [4] is substituted in Eq. [3]

$$E_c = E_{sc} - K_c\left(\frac{Q_c}{Q_c - it}\right)i \qquad [5]$$

Similarly

$$E_a = E_{sa} - K_a\left(\frac{Q_a}{Q_a - it}\right)i \qquad [6]$$

where the subscripts a and c denote the anode and cathode values for the constants, respectively. A sign convention is used here which makes the value of the potential terms positive.

If Q_a is approximately equal to Q_c, as it generally is in a well designed cell, Eq. [5] and [6] can be summed to give

$$E = E_s - K\left(\frac{Q}{Q - it}\right)i \qquad [7]$$

where $E = E_a + E_c$ is the potential of the cell (neglecting the internal resistance) at any time t during the discharge; $E_s = E_{sa} + E_{sc}$ is a constant potential; $K = K_a + K_c$ is the polarization coefficient in ohm cm^2; and $Q = Q_a = Q_c$ is the available amount of active material in coulombs or similar units per unit area.

If Q_a is appreciably larger than Q_c, then the numerical increase in the value of the last term in Eq. [6] will be small compared to the numerical increase in the value of the last term of Eq. [5] as (it) approaches Q_c in value. Consequently, the second term of Eq. [6] can be considered to be approximately constant and the sum of Eq. [5] and [6] will still have approximately the form shown in Eq. [7]. Under these conditions the approximate values of K, Q and E_s will be $K = K_c$, $Q = Q_c$, and $E_s = E_{sa} + E_{sc} - K_a i$. If Q_c is appreciably larger than Q_a, then the approximate values of K, Q, and E_s will be $K = K_a$, $Q = Q_a$, and $E_s = E_{sa} + E_{sc} - K_c i$. Thus Q is determined by the amount of available active material on the controlling electrode which is the one that fails first. A similar argument will show that the same type of equation will be approximately true when several cells are connected in series to form a battery.

When the potential drop due to internal resistance is considered, Eq. [7] becomes

$$E = E_s - K\left(\frac{Q}{Q - it}\right)i - Ni \qquad [8]$$

where N, the internal resistance per unit area, is measured in ohm cm^2 or other suitable units.

When Eq. [8] is evaluated mathematically, a set of curves is obtained, one of which, plotted in Fig. 1, is a dotted line from a to b and a solid line from b to c. The initial drop in potential at the beginning of a cell discharge is not included in Eq. [8]. Consequently another term must be added to correct for the difference between the dotted line potential calculated from Eq. [8] and the solid line gb that represents the actual discharge potential. It has been found that the expression $A\exp(-BQ^{-1}it)$, where A and B are empirical constants, gives an excellent estimate of the initial potential drop in virtually every case. When this term is added to Eq. [8], the final equation

$$E = E_s - K\left(\frac{Q}{Q - it}\right)i - Ni + A\exp(-BQ^{-1}it) \qquad [9]$$

is obtained. In a number of cases the initial drop in potential was too rapid to be included in the observed experimental data and consequently, the value of $A\exp(-BQ^{-1}it)$, being negligible, could be ignored.

That portion of the discharge curve that lies to the right of point b in Fig. 1 could be predicted from Eq. [9] if the numerical values of E_s, K, Q, and N were known, providing the basic assumptions were true. However, the labor involved in determining these values would be so large that it probably would be easier, and certainly more accurate, to determine discharge curves experimentally. However, Eq. [9] can be fitted numerically to experimental discharge data, thus determining empirical values of E_s, K, Q, N, A, and B. Such a numerical equation gives an accurate description of the cell or battery discharge and can be used to describe energy evolution, cell capacity, and can be used in predicting cell capacities. Despite its successful applications, it must be considered to be an empirical equation since the numerical values of K, Q, and N that are determined in this manner will vary considerably at times from their true values as defined in the basic assumptions.

There are a number of methods that can be used to determine the numerical values of E_s, K, Q, N, A, and B in Eq. [9] from experimental discharge data, most of which are unsuitable. The least squares solution is particularly involved and time-consuming. The following approach is easily applied, rapid, reasonably accurate and is used in fitting Eq. [9] to discharge curves obtained at a number of current densities. In Fig. 1, four points, labeled 1, 2, 3, and 4 have been selected on two discharge curves which were obtained at the moderately low current density, i_a, and the moderately high current density, i_b. The values of E and (it) at points 1, 2, 3, and 4 are E_1, E_2, E_3, and E_4 and i_bt_1, i_at_2, i_bt_3, and i_at_4, respectively. These four points are chosen to the right of the initial potential drop. Thus the value of $A\exp(-BQ^{-1}it)$ is negligible and the potential at point 2 is found from Eq. [9] to be approximately

$$E_2 = E_s - K\left(\frac{Q}{Q - i_at_2}\right)i_a - Ni_a \qquad [10]$$

Similarly

$$E_4 = E_s - K\left(\frac{Q}{Q - i_at_4}\right)i_a - Ni_a \qquad [11]$$

Subtracting Eq. [11] from Eq. [10] gives

$$E_2 - E_4 = Ki_a\left(\frac{Q(i_at_4 - i_at_2)}{(Q - i_at_1)(Q - i_at_2)}\right) \qquad [12]$$

The equation for $E_1 - E_3$ is obtained in a similar manner and is divided into Eq. [12] to give

$$\frac{E_2 - E_4}{E_1 - E_3} = \frac{i_a}{i_b}\,\frac{(i_at_4 - i_at_2)}{(i_bt_3 - i_bt_1)}\,\frac{(Q - i_bt_3)(Q - i_bt_1)}{(Q - i_at_4)(Q - i_at_2)} \qquad [13]$$

When numerical values of E, i, and (it) are taken from the discharge data in Fig. 1 and substituted in Eq. [13], a quadratic equation in Q is obtained which is solved to give a numerical value of Q. This value of Q is substituted in Eq. [12] and solved to obtain a numerical value of K. When these values of Q and K are substituted in Eq. [10] and a similar equation for E_1, two simultaneous equations are obtained which may be solved to give numerical values for E_s and N. When these values of E_s, N, K, and Q are substituted in Eq. [9], E is obtained as a specific function of (it). The calculation of Q by use of Eq. [13] can generally be simplified by choosing point 2 in a manner such that i_at_2 equals either i_bt_3 or i_bt_1.

The two discharge curves, i_a and i_b, that are chosen as a basis for these calculations should be representative of the complete set of discharge curves and should show no obvious visual discrepancies that would indicate variations not present in the other curves. They are selected in the following manner. If (it) is held constant, Eq. [9] shows that the potential E to the right of point b in Fig. 1 may be stated as a linear function of the current density, i, in the form

$$E = E_s - B_1 i \qquad [14]$$

where B_1 is a constant equal to $K\left(\frac{Q}{Q - it}\right) + \mathrm{N}$

A fairly good fit to Eq. [14] is shown in Fig. 2 where E has been plotted as a function of i for five values of

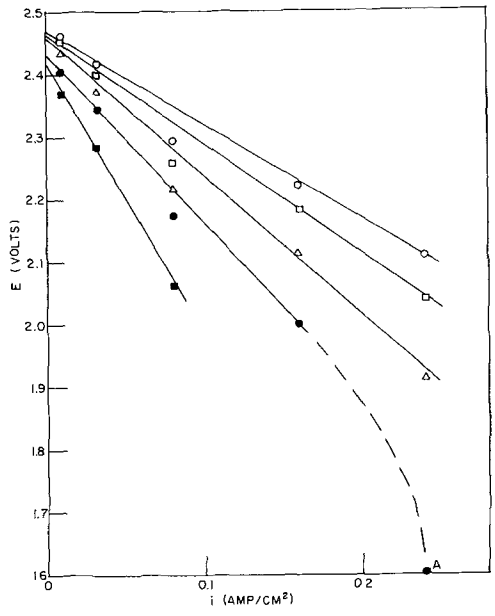

Fig. 2. Potential during cell discharge *vs.* current density for constant values of (*it*). The *it* values in amp-hr/cm²: ○, 0.00266; □, 0.00532; △, 0.00798; ●, 0.01063; ■, 0.01329.

(*it*) using the discharge data for the lead-zinc cell shown in Fig. 4g. The potentials, E at the current density, $i = 0.0798$ amp/cm², were considerably lower than the straight lines drawn through the corresponding values of (*it*), thus showing that this particular discharge was out of agreement with the remainder of the data. Variations this large were not observed as a rule. The remaining four values of i gave good straight line fits in Fig. 2. Either of the two low values of i could be used for i_a and either of the two high values could be used for i_b. As a rule a plot of E *vs.* i for each of two values of (*it*) will be sufficient to select satisfactory values of i_a and i_b. Points such as A which were taken past the knee of the discharge curve should not be used in making up these charts of E *vs* i. Very low values and very high values of i are avoided if feasible in selecting i_a and i_b since these extreme values have a tendency to be less accurate. With a little experience, i_a and i_b often can be selected on the basis of judgment without drawing up a chart such as that shown in Fig. 2.

If Eq. [9] is a perfect fit for the discharge data, then the plot of E *vs.* i as illustrated in Fig. 2 would consist of straight lines intersecting on the E axis at $E = E_s$. If the plot of E *vs.* i gives lines that do not intersect on the E axis or if they are curves, then Eq. [9] does not describe the discharge data perfectly. However, Eq. [9] is so adaptable that it can describe such cases with good accuracy and it has not been necessary to reject any data on this account. Discharge data were not accepted for study here whenever they were so erratic and full of error that a plot of E *vs.* i did not give some semblance of a smooth curve. It was found that all of the data that were acceptable on this basis could be fitted by Eq. [9]. Virtually all of the room temperature discharge data taken from the literature were found to be acceptable. At low temperatures the available data were more erratic and less acceptable.

The points 1, 2, 3, and 4 used to calculate the numerical values of the parameters K, Q, and N are selected in the manner illustrated in Fig. 1. A tangent is drawn to the high current density discharge curve at point d and point f is selected to be 0.1v below the tangent line. Point d is determined by eye by laying a transparent plastic straight edge tangent to the curve and adjusting the point of tangency until $i_b t_d$ equals 0.5 $i_b t_f$. This method is rapid and sufficiently accurate. Point e is located in a manner similar to f. The value of E for point 3 is approximately 0.03v

Table I. Values of ΔE in volts

	(*i t*)						
i	2	5	10	20	30	50	65
2	0.116	0.106	0.091	0.068	0.045	0.019	0.007
10	0.133	0.118	0.088	0.057	0.037	0.013	0.002
20	0.145	0.123	0.087	0.050	0.032	0.008	0.000
40	0.144	0.120	0.084	0.048	0.027	0.006	0.000

80	0.140	0.115	0.086	0.056	0.031	0.003	0.001
100	0.143	0.123	0.085	0.049	0.026	0.009	0.003
120	0.153	0.118	0.085	0.049	0.025	0.010	0.000
Avg.	0.139	0.118	0.087	0.054	0.032	0.0095	0.0018

greater than it is for point f. The value of E for point 4 is approximately 0.02v greater than it is for point e. Point 1 is chosen so $i_b t_1$ equals approximately 0.5 $i_b t_3$. If $i_b t_f / i_a t_e$ is less than 0.7, point 2 is chosen directly above point 3 so that $i_a t_2$ will equal $i_b t_3$. If $i_b t_f / i_a t_e$ is greater than 0.7, point 2 is chosen directly above point 1 so that $i_a t_2$ will equal $i_b t_1$. This procedure gives an approximate location of the points which supply the numerical data to substitute in Eq. [12] and [13], and make possible the calculation of numerical values of K, Q, N, and E_s which can be substituted in Eq. [9] along with values of A and B to give a fairly good numerical description of the discharge data. Values of E *vs.* (*it*) for different discharge rates can be calculated from this numerical equation and compared to the actual discharge data. If the agreement is not good enough, it can be improved by the method of successive approximations. A new calculation can be made using slightly different locations for one or more of the four points on the two discharge curves, i_a and i_b. If the calculated points were too far away from the measured results in the area to the left of some point such as 4, it could be corrected by selecting a new location for point 4 which would be slightly to the left of the old location and calculating a new numerical equation. The points calculated by this new equation to the right of point 4 would be a little farther away from the actual discharge data as a rough rule than those calculated from the first equation. A fairly good fit should be obtained with the first calculated equation. If it is at all possible, a very good fit will have been obtained by the third calculation. Each calculation should take less than one hour of time.

The calculations thus far are sufficient to give a numerical evaluation of Eq. [8], which is plotted in Fig. 1 as a dotted line from a to b and a solid line from b to c. The difference in potential, ΔE, between this calculated dotted line of Eq. [9] and the true discharge potential shown by the solid line gb in Fig. 1 is approximated by the term $A \exp(-BQ^{-1}it)$ in Eq. [10]. In Table I values of ΔE *vs. it* are given for each discharge curve of the Edison cell shown in Fig. 4a. The average values of ΔE *vs.* (*it*) in Table I are plotted on semi log paper in Fig. 3 and fitted by a straight line

whose equation is $\Delta E = A\exp(-BQ^{-1}it)$. The intercept on the ordinate gives the numerical value of A. The numerical value of B/Q can be calculated from the slope or from a single point taken on the straight line. In nearly all cells the value of ΔE is much less at high values of it/Q than in the example shown in Fig. 3 where $\Delta E = 0.006$v at it equals 50 or it/Q equals 0.433. In most cells ΔE would be less than 0.006v at a value of it/Q equal to 0.10 and would be close to zero in value at it/Q equals 0.15. If points 1 and 2 were chosen in Fig. 4a at $it = 50$ then a correction of $\Delta E = 0.006$v should be subtracted from the values of E_1 and E_2 to be used in calculating the constants in Eq. [9]. This value of ΔE could not be estimated accurately until after the first calculation had been made.

Discussion of the Equation and its Applications

Experimental discharge data for a number of different types of batteries have been plotted as solid lines in Fig. 4 (1, 2, 3, 4, 5). The potential E is shown for various current densities, i, as a function of (it) which is expressed in ampere hours per square centimeter or ampere hours per cell where the area is not known. Equation [9] has been fitted numerically to each set of discharge data thus obtaining a different numerical equation for each chart in Fig. 4. The numerical values of the constants for each of these equations are shown in Table II and are dependent on the unit of time, t, and also on the unit of area used in defining the current density. Since the area is unknown in most cases, the area of the entire cell is

taken as the unit area and the current density is defined as the amperes per cell and is equal in value to the total discharge current. The points in Fig. 4 are calculated from these equations. It can be seen that the calculated points give good fits in every case to the solid lines that represent the actual discharge data. Thus the information in Table II is sufficient to give an excellent description of the discharge data in Fig. 4 at a considerable savings in space. Equation [9] was applied to a wide variety of discharge data from various types of physically constructed batteries for each of the common battery systems. The examples selected for Fig. 4 were in each case the one which covered the widest range of current densities. Equation [9] was also fitted successfully to discharge data from the following systems: PbO_2-Cd-H_2SO_4, HgO-In-KOH, air cell-air-Zn-KOH, AgCl-Zn-NaCl, PbO_2-Pb-$HClO_4$, CuO-Zn-NaOH, NiOOH-Zn-KOH, Cl_2-Zn-$ZnCl_2$, PbO_2-Sn-$HClO_4$, PbO_2-Pb-HBF_4, HgO-Zn-KOH. No individual curves were omitted in any case. The poorest fit obtained in all the cases studied was with the dry cell data which is shown in Fig. 4e. Most of the data was taken from the literature and was selected to cover as wide a range of current densities as possible. Unfortunately, the amount of low temperature discharge data was limited and some of it had to be rejected as erratic when tested by the method illustrated in Fig. 3.

In Fig. 4b and 4c the discharge took place in two steps and it was found that a separate equation could be fit to each step. The first step in each case is indicated by the subscript 1 on the figure number in Table II. For example, the equation for the silver cell in Fig. 4b would be

$$E = 1.8310 - 0.005138\left(\frac{37.06}{37.06 - it}\right) i + 0.00388\, i + 0.020 \exp(-0.60\, it)$$

or

$$E = 1.5567 - 0.0004\left(\frac{112}{112 - it}\right) i - 0.00067\, i$$

whichever is higher in value.

Whenever the calculated values of E_s, K, Q, and N are the true or defined values and are not affected by the choice of the four points, Eq. [9] fits that particular discharge data theoretically. Whenever the calculated values of E_s, K, Q and N are not the true or defined values and are affected by the choice of points 1 to 4, Eq. [9] is fitting that particular discharge data empirically. In this latter case, there are a number of specific combinations of numerical values of E_s, K, Q and N which will give good fits to a particular set of discharge curves. Among these combinations E_s and Q will be fairly constant while K and N may vary somewhat, N becoming smaller as K becomes larger. For example, two individuals fitting Eq. [9] to a particular set of discharge curves might get two different equations, each of which fit the data quite well even though they had appreciably different values for K and N.

As a very rough rule, a closer approach to a theoretical fit is generally found in the presence of one or more of the following conditions: the discharge data covers a narrow range of current densities, the potential drop due to polarization is low, the electrolyte does not change in composition during discharge, the slope of the discharge curves before the knee is relatively small, the ratio $(it)/Q$ is fairly large and covers a relatively narrow range of values of (it), and the calculated value of N is not negative. Most of these conditions can be observed in Fig. 4a.

In any case, Eq. [9] is so adaptable that wide variations in its constants, particularly K and N, enable it to be fitted with good accuracy to a very wide range of discharge data. A large increase in the numerical value of K will be accompanied by such a large decrease in the value of N that N will often be negative in value as can be seen in Table II. Since N is the internal resistance in the original derivation and theoretically cannot be negative in value, it is obvious that Eq. [9] must be considered to be empirical in most of its curve fitting applications and there is no reason to believe that it should have to describe fully the discharge of every type of battery.

In Fig. 2 the measured potential is low for the points at i equals 0.0798 amp/cm². In Fig. 4g the measured potential at this current density is appreciably lower than the calculated potential thus indicating the very strong likelihood of an error in this data. When there are only three discharge curves and two of them are correct, it is not possible to tell by this method which one of the three is in error without collecting more data. A fourth discharge made at a different current density will, if correct, determine which of the other three curves contains the error.

An examination of all of the data fitted by Eq. [9] shows that the differences between the calculated and the measured results are often larger at the highest current densities than they are at intermediate current densities. This larger variation can be attributed to the high relative dispersion of the data; the fact that the highly simplified calculation methods given here tend to give the poorest fit at high current densities; and the fact that the poorest fit is often obtained at the extreme limits when fitting equations to measured data. There is also a tendency for a very few of the calculated curves at the lowest current density to have less slope and a smaller capacity than the observed data. This condition is most noticeable in Fig. 4g and seems to be most generally associated with batteries whose electrolytes change appreciably in concentration during discharge. As a rough empirical approximation, it is assumed that the drop in potential in a battery is directly proportional to the change in electrolyte concentration during discharge, assuming all other factors are neglected. Equation (9) can then be written as

$$E = E_s - K\left(\frac{Q}{Q - it}\right) i - Ni + A \exp(-BQ^{-1}it) - Cit \quad [15]$$

where C is a constant.

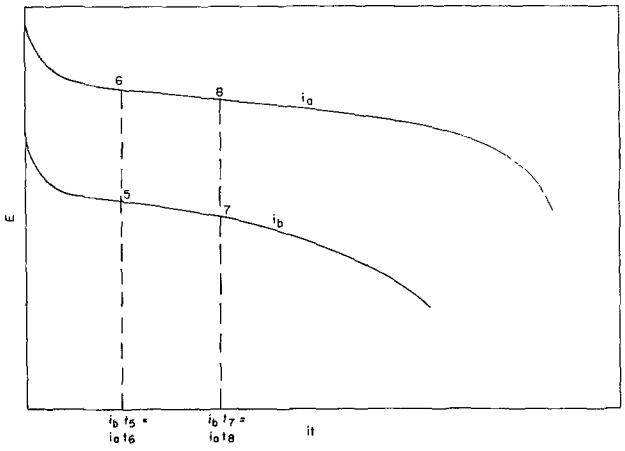

Fig. 5. Typical discharge curves to be used in numerical calculation of C.

To determine the numerical value of C select four points as shown in Fig. 5 which are far enough past the initial potential drop for the exponential term to be negligible. From Eq. [15]

$$E_5 = E_s - Ki_b\left(\frac{Q}{Q - i_b t_5}\right) - Ni_b - Ci_b t_5 \quad [16]$$

and

$$E_7 = E_s - Ki_b\left(\frac{Q}{Q - i_b t_7}\right) - Ni_b - Ci_b t_7 \quad [17]$$

Subtracting Eq. [17] from Eq. [16] gives

$$E_5 - E_7 = Ki_b\left[\left(\frac{Q}{Q - i_b t_7}\right) - \left(\frac{Q}{Q - ibt_5}\right)\right] + C(i_b t_7 - i_b t_5) \quad [18]$$

Similarly

$$E_6 - E_8 = Ki_a\left[\left(\frac{Q}{Q - i_b t_7}\right) - \left(\frac{Q}{Q - ibt_5}\right)\right] + C(i_b t_7 - i_b t_5) \quad [19]$$

From Eq. [18] and Eq. [19]

$$C = \frac{i_b(E_6 - E_8) - i_a(E_5 - E_7)}{(i_b - i_a)(i_b t_7 - i_b t_5)} \quad [20]$$

Numerical values of C are calculated from Eq. [20] and substituted in Eq. [15].

Let $E' = E + Cit$.

Then $E_1' = E_1 + Ci_b t_1$, $E_2' = E_2 + Ci_a t_2$, $E_3' = E_3 + Ci_b t_3$, and $E_4' = E_4 + Ci_a t_4$. If E_1', E_2', E_3', and E_4' are substituted for E_1, E_2, E_3, E_4, respectively, in Eq. [10] to [13], they can be used to calculate numerical values of Q, K, N, and E_s in the manner previously described.

Numerical values of Eq. [15] were determined in this manner for the lead-zinc cell shown in Fig. 4g and found to be

$$E = 2.4775 - 0.9237\left(\frac{0.0181}{0.0181 - it}\right)i - 0.4295\,i - 4.25\,it$$

Calculated points from this equation are shown in Fig. 6 to give a better fit to the experimental data than was obtained by the use of Eq. [9].

If the basic assumptions are assumed to be true during the charge of a cell, then the following equation would hold for the potential during charge

$$E = E_s + K\left(\frac{Q}{Q - it}\right)i + Ni - A\exp(-BQ^{-1}it) \quad [21]$$

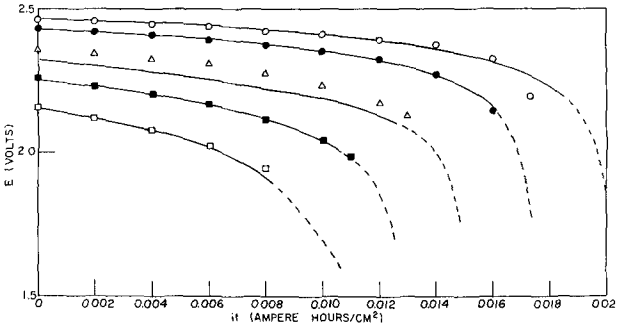

Fig. 6. Comparison of points calculated from the discharge equation with solid lines representing actual discharges at various current densities. PbO_2-Zn-H_2SO_4 reserve cell. Calculated points, amp/cm²: ○, 0.00957; ●, 0.0319; △, 0.0798; ■, 0.1595; □, 0.2393.

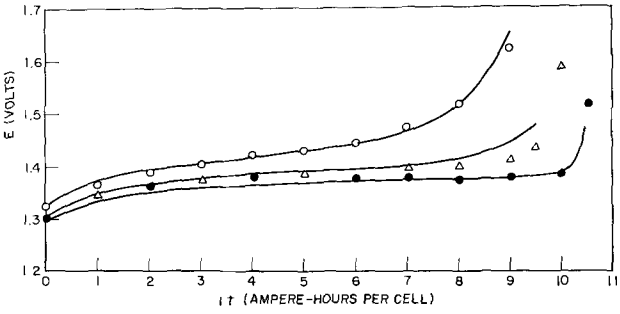

Fig. 7. Comparison of the charge data of a Ni-Cd cell with the calculated results for various current densities. Nickel cadmium cell, Ni-OOH-Cd-KOH. Calculated points, amp/cell: ○, 16.0; △, 2.5; ●, 0.16.

Equation [21] can be obtained from Eq. [9] by reversing the signs of the last three terms. Equation [21] has been fitted to the charge of a Ni-Cd cell in Fig. 7. The solid lines represent the actual data and the points are calculated from the equation

$$E = 1.379 + 0.0024\left(\frac{1}{1 - 0.095\,it}\right)i - 0.00116\,i - 0.08\exp(-0.693\,it)$$

The use of Eq. [21] in describing the charging of a cell has been tested on a very limited amount of data. Consequently, it is not yet certain to what extent it can be successfully applied.

The total energy W_t that has been evolved from the beginning of the discharge up to time t is defined by the equation

$$W_t = \int_o^t i\,E\,dt$$

Substituting Eq. [8]

$$W_t = \int_o^t\left[E_s i - K\left(\frac{Q}{Q - it}\right)i^2 - Ni^2 + Ai\exp(-BQ^{-1}it)\right]dt \quad [22]$$

$$W_t = [E_s\,it + KQi\ln(Q - it) - Ni^2t - AQ/B\exp(-BQ^{-1}it)]_o^t \quad [23]$$

$$W_t = E_s it - KQi\ln(1 - it/Q)^{-1} - Ni^2t + AQ/B(1 - \exp(-BQ^{-1}it)) \quad [24]$$

The constants from an equation describing the discharge of a Ni-Cd cell at 27°C were substituted in Eq. [24] and the total energy evolved at time t was found to be

$$W_t = 1.25\,it - 0.0238\,i\ln(1 - 1.05\,it)^{-1} - 0.006\,i^2t + 0.0248\,[1 - \exp(-3.83\,it)] \quad [25]$$

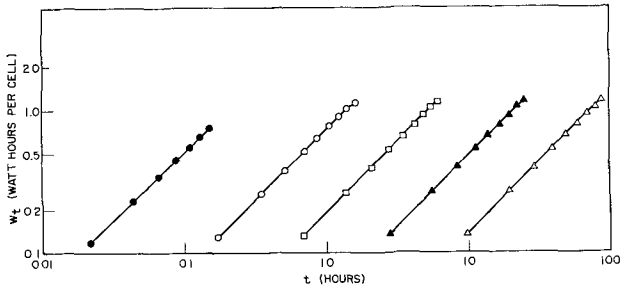

Fig. 8. Comparison of the energy evolved during the discharge of a Ni-Cd cell with the calculated results for various current densities. Sealed nickel cadmium cell, NiOOH-Cd-KOH, 27°C. Calculated points, amp/cell: •, 4.5; ○, 0.56; □, 0.14; ▲, 0.035; △, 0.010.

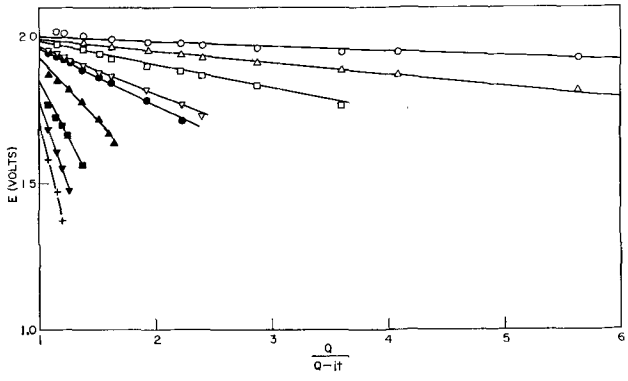

Fig. 9. Discharge curves showing the potential as a function of $Q/Q\text{-}it$ for various current densities. Lead acid cell, PbO_2-Pb-H_2SO_4. Current density, amp/cell: ○, 0.8; △, 2; □, 4; ▽, 8; •, 10; ▲, 20; ■, 40; ▼, 60; +, 80.

In Fig. 8, W_t in watt hours per cell for a Ni-Cd battery has been plotted as a function of t in hours for various values of the cell current in amperes. The solid lines are obtained from calculations based on numerical integration of the actual discharge data. The points are calculated from Eq. [24]. The agreement between the calculated and the measured results in such cases depends entirely upon how well Eq. [9] can be fitted to the original discharge data.

Once the discharge is past the initial potential drop, the exponential term becomes negligible and Eq. [9] can be written as

$$E = E_s - Ni - \left(\frac{Q}{Q - it}\right)Ki \qquad [26]$$

which shows the potential E to be a linear function of $Q/(Q - it)$ with slope $-Ki$ for any given current density, i. Actual discharge potentials were taken from the lead acid battery discharge data in Fig. 4d and plotted in Fig. 9 against $Q/(Q - it)$ for each of nine current densities. Straight lines gave good fits to these plotted points. The average value of the K's, determined from the slopes of each of these nine lines was 0.0195 as compared to the calculated value of 0.0189 given in Table II.

In Fig. 9 the values of E for $Q/(Q - it)$ equals one can be seen from Eq. [26] to be

$$E = E_s - (N + K)i \qquad [27]$$

which shows E here to be a linear function of i with slope, $-(N + K)$, and intercept, E_s. Values of E for $Q/(Q - it)$ equals one were taken from Fig. 9 and plotted in Fig. 10 to give a straight line. The numerical values of E_s and N determined from this straight line were 1.998 and −0.0155 as compared to the calculated values of 2.003 and −0.0150 given in Table II. The values of E_s, K, and N determined by the two methods are virtually identical and show that the graphical

method of Fig. 9 and 10 can be used in fitting Eq. [9] to discharge data whenever the value of Q is known. If the basic assumption holds true, then Q can be calculated from the amount of active material on the controlling electrode and the graphical method is applicable. In the more empirical applications, such as the lead acid battery just shown, the calculated value of Q will be somewhat less than the value determined from the amount of active material and the graphical method would not be accurate. Almost all of the available discharge data gave no information on the amount of active materials and consequently the feasibility of using this graphical method for fitting Eq. [9] to discharge data has not yet been determined.

Presentation of Discharge Data

A study of Eq. [9] suggests the possibility of plotting battery discharge data against dimensionless quantities in a manner that would make possible more direct comparisons between various types of cells. In Fig. 11 the potential during discharge is plotted as a function of it/Q where it/Q is the fraction of active material used up at time, t. Discharge data are shown here at the 1-hr and the 11-hr rate for four common types of cells. The value of it/Q at the end of the discharge is the efficiency of utilization of the active material. In each case, the discharge was assumed

to be ended when E equalled $E_s - Ki - Ni - 0.25$v. Thus in Fig. 1, curve i_a, the end voltage would be 0.25v below the voltage at point a. A drop of more than 0.25v would have precluded the use of much of the available data. In Fig. 4 the discharge curves are shown as dotted lines wherever they extended past this assumed end point.

Here in Fig. 11 is a method of comparing at equal discharge times such factors as efficiencies, potentials, variations of potentials with time, potential drops due to internal resistance, etc., for various types of constructions of cells. The two curves at A1 represent two different sizes and constructions of lead acid cells. Although the difference in discharge characteristics is small between these two cells, it could, in many cases, be quite large and could be readily demonstrated on a chart of this type. Other things being equal, the cell size is not important here, since each cell is being discharged at a particular value of Q/i that is held constant with change in cell size, which is equivalent to saying n times the current would be drawn from a cell n times as large. The values of Q/i given in Fig. 11 represent the time each cell would have taken to discharge 100% of the active material on the controlling electrode at the particular current density, i. The discharge characteristics of the four cells in Fig. 11 could have been compared by plotting E *vs.* it/Q at a constant value of Q/i such as 10 hr, thus giving a slightly different graph. A number of other variations can be made of this chart. The vertical axis could be the ratio of the discharge potential to the theoretical potential. In this case the area under the curve would be the theoretical watt hour efficiency. If the vertical axis were the ratio of the discharge potential to the average charge voltage, E_c, the area under the curve would be the watt hour efficiency defined by the ratio of the output in watt hours to the input in watt hours. The equation for this latter curve can be obtained by dividing E_c into Eq. [9] to give

$$\left(\frac{E}{E_c}\right) = \left(\frac{E_s}{E_c}\right) - \left(\frac{K}{E_c} i\right)\left[\frac{1}{1 - (it/Q)}\right] - \left(\frac{N}{E_c} i\right) + \left(\frac{A}{E_c}\right)[\exp(-BQ^{-1})(it)] \quad [28]$$

where each quantity in brackets or parentheses is dimensionless. In Fig. 11 the values of it/Q were taken from Table II and are empirical to a certain extent. If Q had been calculated from the actual amounts of active material on the controlling electrode, its value would have been slightly larger and the discharge curves in Fig. 11 would be changed slightly. Values of (it) per unit weight of active material or per unit cell weight, or watt hour efficiencies could have been used in place of it/Q for the abscissa in Fig. 11. The important thing in each of these cases is that the use of some form of dimensionless quantity, or factor closely related thereto, as either or both of the coordinates enables a quantitative, visual study and comparison to be made of the characteristics of certain types of equivalent discharges, either for different types of cell systems, or different constructions of the same cell system, or both. As shown in Eq. [28], the equation for each of these cases can be obtained easily from Eq. [9].

Manuscript received Feb. 4, 1965. This paper was presented at the Boston Meeting, Sept. 16-20, 1962.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

The Electrode Potential of the Semiconductor CuS in Solutions of Copper Ions and Sulfide Ions

P. Ruetschi[1] and R. F. Amlie

The Carl F. Norberg Research Center, The Electric Storage Battery Company, Yardley, Pennsylvania

ABSTRACT

The electrode potential of cupric sulfide was measured in aqueous acidic solutions of cuprous chloride and cupric chloride, as well as in alkaline solutions of sulfur and sulfide ions. The redox couples Cu^{++}/Cu^{+} and S/S^{--} exhibit high reversibility on this electrode material. Nonstoichiometric excess sulfur in CuS behaves energetically like free elemental sulfur. The reason for the voltage increase observed when elemental sulfur is added to a cuprous chloride electrode is explained by the mechanism that the electrode reaction changes from $e^{+}CuCl \rightleftarrows Cu + Cl^{-}$ to a redox mechanism, $e + CuCl_2 \rightarrow CuCl + Cl^{-}$ at the $CuS^{=}$ solution interface, whereby cupric chloride is generated by the chemical reaction $2CuCl + S \rightleftarrows CuCl_2 + CuS$. The principle of coupling a chemical reaction with an electrochemical reaction in a closed cycle is shown to be of considerable advantage for the construction of certain types of battery electrodes.

As a result of the discovery that electrodes of cuprous chloride in magnesium chloride electrolyte show an increased electrode potential when the cuprous chloride is intimately mixed with elemental sulfur (1), an investigation was undertaken to elucidate the mechanism responsible for this phenomenon. It had been observed previously that cuprous chloride and sulfur mixtures, when suspended in a chloride electrolyte, reacted to form cupric sulfide. This reaction does not take place with mixtures of the dry materials in the absence of aqueous electrolytes, even when heated to the melting point of sulfur, but it proceeds when these mixtures are immersed in acidic aqueous magnesium chloride solutions according to

$$2\,CuCl + S \rightarrow CuS + CuCl_2 \text{ (dissolved)} \qquad [1]$$

The precipitation of CuS was confirmed experimentally by x-ray analysis, and the formation of $CuCl_2$ in solution by colorimetry. As early as 1889 Vortmann and Padberg (2) described this reaction qualitatively.

In view of reaction [1], it was considered desirable to determine the effect of cupric ion concentration on the potential of a cupric sulfide electrode. The present investigation also includes a study of the cupric sulfide electrode in solutions containing both cupric and cuprous ions, and further in solutions containing sulfide ions.

Electrochemical Properties of Metal Sulfides

An investigation of metal sulfide electrodes in aqueous solutions was carried out by Wrabetz, in collaboration with Noddack and Herbst (3-5). According to Wrabetz *et al.* the electrochemical behavior of heavy metal sulfide electrodes in aqueous solutions is influenced by the presence of nonstoichiometric excess sulfur in these materials. The sulfide electrodes differ from a normal electrode system of the first or second kind in that only a minute Faradaic current can flow without a complete exhaustion of the available excess sulfur and a corresponding alteration in the composition of the electrode surface. It was observed that many metal sulfide electrodes, in contact with solutions containing the corresponding cations, establish a reversible potential. It was also found that the metallic sulfides, in aqueous solutions containing the respective cation, have their own electrochemical potential series which is more noble than that of the respective parent metals. Many of the metal sulfides, studied in solutions containing different concentrations of the cation, showed the electrode potentials to be determined by the solute activity in accordance with the Nernst relationship. Only one measurement with a cupric sulfide electrode was described in the work of Wrabetz, and its potential was approximately 0.24v positive to that of copper in the cell system $Pt/CuS/CuSO_4$ (0.1m)/Cu. The potentials were unstable due to high resistance between the loose cupric sulfide powder and the platinum wire used for making contact.

Wrabetz *et al.* (3) were the first workers to systematically study the electrochemistry of metal sulfide electrodes in aqueous solutions; prior investigations lack quantitative data and are thus of limited value. However, a study by Trumpler (6) is pertinent since he measured the potentials of a series of metallic sulfide semiconductors in solutions containing the respective cations. He also studied metal sulfide electrodes in solutions containing sulfide ions and dissolved sulfur (*i.e.*, polysulfide ions), and came to the conclusion that sulfide electrodes exhibited the same potentials as an inert metallic electrode such as platinum.

Cupric sulfide is usually obtained as a lustrous, blue-black salt which is insoluble in water and cold dilute strong acids, although it dissolves readily in hot, moderately dilute nitric acid. Copper(II) sulfide is converted to Cu_2S at elevated temperature in the presence of air, and at lower temperatures in a hydrogen atmosphere. It is slowly oxidized by moist air. Copper(II) sulfide is a semiconductor showing an exceptionally high electronic conductivity, having a specific resistance in the order of 10^{-4} ohm-cm. Badecker (7) reports 1.25×10^{-4} ohm-cm and Fischbeck and Dorner (8) give 4×10^{-5} ohm-cm, which may be compared with 1.7×10^{-6} ohm-cm for copper metal. Cupric sulfide is reported as crystallizing in both the hexagonal and monoclinic systems (9). Remy describes the crystal structure as hexagonal with the lattice constants $a_o = 3.972$Å, $c_o = 16.344$Å.

Experimental

The electrochemical study of copper (II) sulfide in chloride solutions of copper ions, sulfide ions, or polysulfides was carried out by measuring electrode potentials both under equilibrium conditions and during current flow. The experiments were performed in Pyrex glass cells, one of which together with the electric circuit, is depicted in Fig. 1. All electrode potential measurements with chloride electrolytes were made by means of saturated calomel reference electrodes (0.241v *vs.* NHE), with the liquid junction established in the interconnecting capillary tube. In addition to the reference electrode capillary, the cell of Fig. 1 was also provided with a connection to the counter elec-

[1] Present address: LeClanche, S.A., Yverdon, Switzerland.

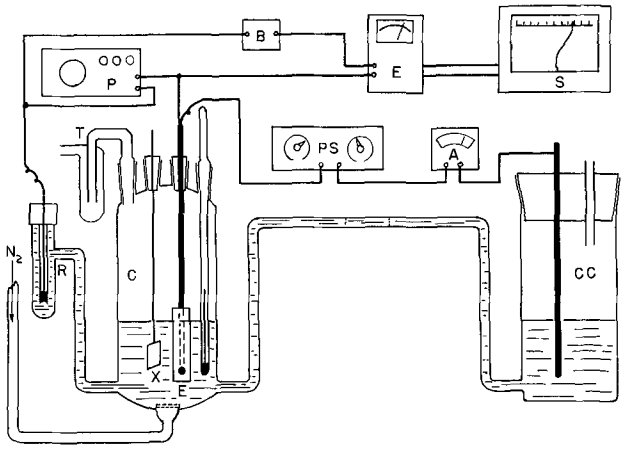

Fig. 1. Schematic of apparatus. C, Pyrex test cell: auxiliary Pt electrode; E, sample electrode; R, reference electrode; CC, counter electrode cell; P, potentiometer; B, bias box; E, electrometer-amplifier; S, strip chart recorder; PS, power supply; A, ammeter.

trode compartment and with a gas inlet. Effective purging of dissolved oxygen was realized by the continuous introduction of a finely divided stream of prepurified nitrogen gas ($O_2 < 8$ ppm) introduced through a fritted-glass disk. The nitrogen was purified by passing it through a heated column of copper turnings. The counter electrode was a 0.6 cm diameter graphite rod in a separate compartment, which was connected to the test cell by an electrolyte bridge approximately 25 cm in length. A porous filter paper plug was inserted into the electrolyte bridge to reduce convection between compartments. The top section of the test cell was provided with four standard taper joints which held the sample electrode, the platinized platinum electrode, a gas exit bubble trap, and a thermometer. All experimental data were taken at 25°C.

Potentials were measured by means of both a Rubicon portable potentiometer (±0.0002v) and a General Radio type 1230-A DC Electrometer-Amplifier used to drive a Honeywell recorder. A bias box was included in the electrometer input to avoid switching of the electrometer polarity during discharge. A multirange constant current supply provided well regulated currents over the desired range.

Cupric sulfide electrode samples were retained in a 0.63 cm diameter cavity, drilled into a rectangular epoxy block as shown in Fig. 2. The epoxy block encapsulated a graphite rod of spectrographic purity, 0.63 cm in diameter, to provide contact with the electrode material in the cavity. The cupric sulfide was compacted into the cavity at pressures in the order of 3000 psi (150 lb total force) which was usually sufficient for cohesive compaction and could not be greatly exceeded due to the limited mechanical strength of the cast epoxy. Loosening of the pellet was only observed after prolonged immersion in acidic electrolytes, and this difficulty was eliminated by the addition of a few per cent of powdered Teflon to the CuS powder prior to compaction. Fisher Certified Reagent CuS used in this study was further purified by allowing it to remain in contact with a large quantity of 4% HNO_3 for 24 hr with intermittent shaking to achieve good dispersion. The acid solution acquired a faint blue color during this treatment due to the removal of copper. The sample was filtered, washed with distilled water, and dried at 100°C in air. Electrode potentials were measured during periods up to 3 days to insure that the stable equilibrium values had been obtained.

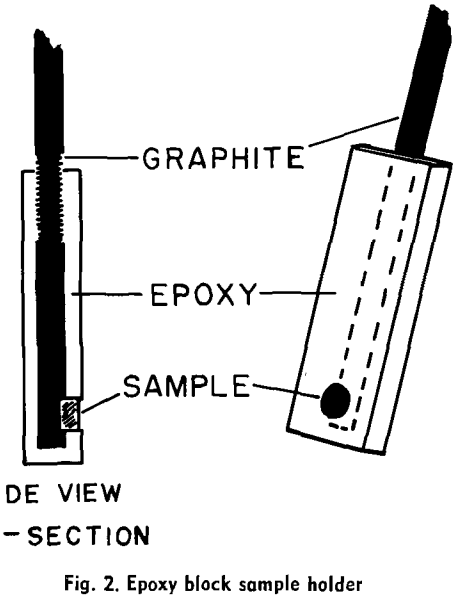

Fig. 2. Epoxy block sample holder

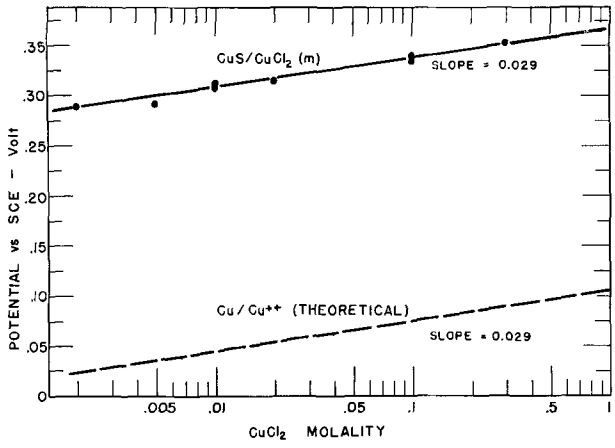

Fig. 3. Cupric sulfide potential as a function of $CuCl_2$ concentration. 1.0M HCl, 2M total (Cl^-). Theoretical Cu/Cu^{++} couple plot assumes $\gamma Cu^{++} = 1$.

Results and Discussion

Effect of $CuCl_2$ *concentration on the* CuS *electrode potential.*—The dependence of the cupric sulfide potential (*vs.* saturated calomel) on the concentration of cupric chloride is shown in Fig. 3. In addition to the molal $CuCl_2$ concentration indicated, the solutions were 1*M* in HCl, with an addition of KCl adjusted to give a total chloride concentration of 2*M*. The *p*H values of the solutions were maintained essentially constant by this procedure, and the extent of complexing of cupric chloride ions was maintained constant (10). The cupric chloride concentration was varied by more than two orders of magnitude while the ionic strength changed only from 2.0 to 2.3. Under these conditions the mean activity coefficient of cupric chloride can be expected to remain nearly constant throughout the series of measurements. The results show that the CuS electrode in a $CuCl_2$ electrolyte obeys the theoretically expected relationship for a divalent ion. The electrode responds to the Cu^{++} activity in a reversible manner, and the potential-log concentration plot of Fig. 3 has a slope 0.029 which is in agreement with that predicted by the Nernst relationship

$$E = E_{o(CuS/CuCl_2)} + (2.3\,RT/2F) \log [CuCl_2] \quad [2]$$

at 25°C. The theoretical behavior for the Cu/Cu^{++} electrode couple is also included in this graph for comparison, in order to illustrate that the sulfide electrode is about 0.260v more positive. This potential increase of the sulfide electrode can be explained by the supposition that the nonstoichiometric cupric sulfide, containing excess sulfur in the crystal lattice, can promote the following potential determining reaction

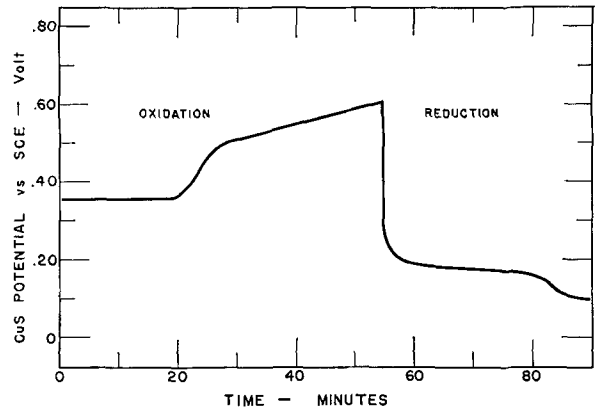

Fig. 4. Chronopotentiometric curve of CuS polarization during charge (oxidation) and discharge. 5 ma (16 ma/cm^2); 0.1*M* $CuCl_2$, 1.0*M* HCl, 2*M* total (Cl^-).

$$2e^- + Cu^{++} + S_{(CuS)} \rightleftarrows CuS \qquad [3]$$

or

$$2e^- + Cu^{++} + \square_{(CuS)} \rightleftarrows CuS \qquad [4]$$

where $S_{(CuS)}$ represents excess sulfur and $\square_{(CuS)}$ is a copper ion deficiency in the CuS lattice. Subtracting from [3] or [4] the equation

$$2e^- + Cu^{++} \rightleftarrows Cu$$

one obtains

$$S_{(CuS)} + Cu \rightleftarrows CuS \qquad [5]$$

or

$$\square_{(CuS)} + Cu \rightleftarrows CuS \qquad [6]$$

The free energies of Eq. [5] and [6] determine the voltage difference between the CuS/Cu^{++} electrode and the Cu/Cu^{++} electrode. The experimental value of 0.26v, corresponding to a free energy increase of $\Delta G = -nFE = -11.9$ kcal, is very close to the free energy of formation of CuS from elemental copper and sulfur, namely −11.7 kcal (11). The excess sulfur in CuS is therefore shown to be essentially "free" sulfur.

Cupric sulfide can phenomenologically be considered as a "dilute copper metal," analogous to a metal amalgam. The "dissolved" Cu^{++} ions in CuS are able to equilibrate with Cu^{++} ions in solution and are able to support limited forward and backward electrochemical reactions. It is evident that deposition of Cu^{++} ions into the sulfide can only proceed as long as there is excess sulfur (or deficiency of copper) in the CuS structure. Dissolution of copper can proceed until the surface is so rich in sulfur that conductivity is impaired and strong polarization begins.

Polarization curves at constant current charge and discharge are illustrated in Fig. 4. The CuS/Cu^{++} couple is relatively easily polarized with slight current flow. No metallic copper is formed during cathodic polarization since (Cu^{++}) ions are discharged into the CuS crystal where they combine with excess sulfur or cation vacancies. During anodic polarization Cu^{++} ions are dissolved out of the CuS lattice, leaving excess sulfur or cation vacancies. On continued cathodic polarization, as the excess sulfur is depleted (or the Cu^{++} vacancies filled), the CuS electrode potential becomes polarized to more negative potentials and the reduction of cupric ions to cuprous ions becomes the predominant reaction. The corresponding reduction step is clearly indicated in Fig. 4.

The CuS *electrode in solutions of* Cu^+ *and* Cu^{++} *ions.*—A study was made on the behavior of the CuS electrode in solutions containing both Cu^+ and Cu^{++} ions. Figure 5 shows a plot of the potential (measured *vs.* a saturated calomel electrode) against the molal ratio of cupric chloride to cuprous chloride. The cupric chloride concentration was maintained at 0.1*M*, whereas the cuprous chloride concentration was varied between 0.003 and 0.30 moles per 1000g of water. These solutions also contained 1*M* HCl to maintain a constant pH and the requisite quantity of KCl to bring the total chloride concentration of the solutions up to 2*M* (12-15).

Cuprous chloride powder, dried at 100°C in an inert atmosphere, was added to the cell electrolyte after removal of dissolved oxygen, and a constant stream of purified nitrogen was maintained to prevent contact of the solution with air. Both the cupric sulfide electrode and a platinized platinum electrode reached the same stable potential after equilibration in a given solution. The results of the experiments shown in Fig. 5 demonstrate that the CuS electrode functions as the inert part of the redox electrode

$$e^- + Cu^{++} \rightarrow Cu^+ \qquad [7]$$

with

$$E = E_{o(CuCl_2/CuCl)} + (2.3\,RT/F)\log([CuCl_2]/[CuCl])$$

Anodic and cathodic polarization measurements showed that this redox reaction exhibited excellent reversibility at the solid CuS surface. High current densities could be supported in the forward and reverse directions with only small potential changes. To cite one example, in a solution 0.10*M* in both cuprous and cupric chloride, with an apparent current density of 3.2 ma/cm^2, the potential decreased 15 mv during reduction and increased 15 mv during oxidation, after 20 min. The corresponding polarizations for platinized Pt were about 380 mv and 60 mv, respectively. The reversibility of the redox reaction at the CuS electrodes was therefore better than that at the platinized platinum electrode. From Fig. 5 it is seen that the CuS electrode potential in solutions containing both monovalent and divalent copper ions is more negative than in solutions of cupric ions only, and that the potential is dominated by redox reaction [7]. The same potentials were realized with a platinized platinum electrode as with a CuS electrode which substantiates that the measured potentials were reversible redox values.

This important result provides a clear explanation of the mechanism of a cuprous chloride electrode, containing sulfur, in a water-activated battery (1). Wetting of the electrode initiates the reaction between cuprous chloride and sulfur, producing CuS and $CuCl_2$ according to reaction [1]. The cupric ions generated in this manner are reduced in a subsequent electrochemical step, according to Eq. [7], which has been shown to be very fast. The excellent reversibility of this redox reaction makes possible a relatively high discharge current and also dictates that the redox couple will determine the electrode potential. The reaction of cuprous ions with sulfur replenishes the cupric ion concentration and maintains the Cu^{++}/Cu^+ ratio essentially constant. In this manner, cuprous chloride and sulfur are consumed to form cupric sulfide and chloride ions as the end-products of the discharge reaction. CuS has been identified as the end-product in discharged electrodes by x-ray diffraction analysis. This mechanism explains how elemental sulfur appears to be readily reducible with little polarization, and how the high positive voltage level is attained. The $Cu/CuCl/Cl^-$ potential in 2*M* chloride solution at pH 0 is about −0.10v against the saturated calomel reference electrode. The $Cu^{++}/(Cu^+)$ redox potential, as measured by the CuS electrode at very low (Cu^+) concentrations, is in the vicinity of 0.35v (*vs.* SCE), as may be seen from Fig. 5. It is evident that a potential increase of about 0.45v can therefore be attained. This increase has actually been realized during activation and discharge of cuprous chloride-magnesium batteries by the addition of sulfur to the cuprous chloride active material (1). It is thus evident that the addition of sulfur can provide a substantial benefit by increasing the energy output of this battery system.

From a thermodynamic standpoint, the maximum available voltage increase is given by the difference in free enthalpy between the reactions

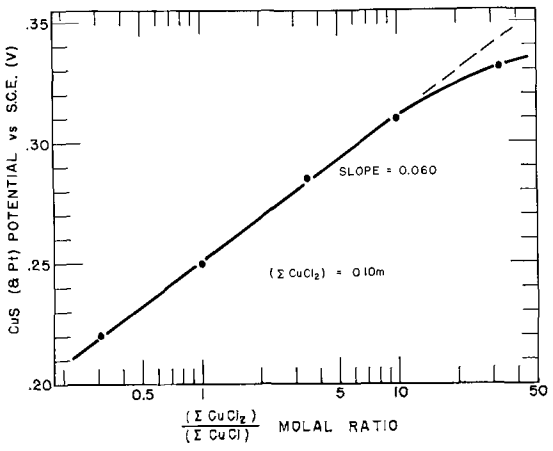

Fig. 5. Cupric sulfide (and platinized Pt) potential as a function of the $CuCl_2/CuCl$ molal ratio. 0.1M $CuCl_2$, 1.0M HCl, 2M total (Cl^-).

$$e^- + CuCl \rightleftarrows Cu^+ Cl^- \qquad [8]$$

and

$$e^- + CuCl + S \rightleftarrows CuS + Cl^- \qquad [9]$$

From the difference in free enthalpy one obtains $\Delta E = -\Delta G/nF = 11.7/23.06 = 0.506$v.

Experimental results given in reference (1) indicate that this theoretical upper limit can be approached rather closely. This would mean that the reaction of sulfur according to Eq. [1] proceeds to nearly the saturation concentration of $CuCl_2$ in solution, such as to render the free energy of reaction [1] equal to zero. According to Latimer, reaction [1] has a positive free energy of 2.7 kcal if all the reactants and products are in the crystalline state and does thus not proceed spontaneously. However, for dissolved $CuCl_2$ at 1M concentration the free energy is −2.5 kcal. Thus, the equilibrium cupric chloride concentration for reaction [1] is close to the saturation value of about 5.8M.

The potential of CuS was also briefly investigated in solutions containing only cuprous chloride, but no cupric chloride. Oxygen was removed carefully from these solutions to avoid oxidation and metallic, oxide-free copper powder was stirred into the solution to remove any cupric ions present by the reaction $Cu^{++} + Cu \rightarrow 2\ Cu^+$. The electrode potentials were erratic and not reproducible. This is apparently due to a lack of an exchange between cupric ions in solution and in the solid. The hypothetical reaction $e^- + Cu^+ + S_{(CuS)} \rightleftarrows CuS$ does not seem to proceed because the excess free sulfur $S_{(CuS)}$ reacts preferably with CuCl according to reaction [1], producing cupric ions which become potential determining according to reaction [7].

There is however one additional reaction which deserves attention in this connection. If an electrode of CuS is immersed in a solution of CuCl which is free of $CuCl_2$, the potential remains considerably higher than that of copper in a solution of CuCl. Solutions free of $CuCl_2$ are conveniently prepared by removal of oxygen and reacting the CuCl solutions with clean metallic copper powder. The reaction

$$Cu + CuCl_2 \rightarrow 2\ CuCl$$

removes all traces of divalent copper.

The electrode potential of CuS in CuCl solution is maintained at nearly the same level even after applying small currents in the cathodic direction. It was established experimentally that the following reaction proceeds

$$e^- + CuCl + CuS \rightarrow Cu_2S + Cl^- \qquad [10]$$

The product Cu_2S was identified by x-ray analysis. Up to one third of the capacity of CuS could be utilized in this manner. In a 0.3M solution of CuCl (1M HCl + 1M KCl) the open circuit voltage of the electrode was +0.156v *vs.* Hg_2Cl_2, which is 0.271v above the potential of the Cu/CuCl couple. Theoretically, one calculates for the couple $CuS/Cu_2S/CuCl/Cl^-/CuCl/Cu$ a voltage of 0.385v.

Reaction [10] therefore constitutes a further reserve capacity of electrodes containing cuprous chloride and sulfur. After exhaustion of the sulfur according to reaction [1] and formation of CuS, the cuprous chloride can further react according to Eq. [10], at a slightly reduced voltage level.

Response of the CuS electrode to sulfide ions.— Sodium sulfide solutions varying in concentration between 0.001 and 0.5M were prepared with 0.5M sodium chloride as the supporting electrolyte, and the potential of the CuS electrode measured in these solutions, using a saturated calomel reference electrode. The *p*H values increased with increasing Na_2S concentration, attaining 13.1 in the 0.5M Na_2S + 0.5M NaCl solution. Sodium sulfide is extensively hydrolyzed in these solutions

$$Na_2S + H_2O \rightleftarrows NaHS + NaOH$$

with

$$HS^- \rightleftarrows H^+ + S^{--};\ K = 10^{-14}$$

From this one calculates for the concentration of $[HS^-]$

$$[HS^-] \rightleftarrows [H^+]\ [S_t^{--}]/([H^+] + 10^{-14}) \qquad [11]$$

where S_t^{--} is the total concentration of divalent sulfur present ($S^{--} + HS^-$). The electrode potentials of CuS in sulfide ion solutions are shown in Fig. 6. At very low sulfide ion concentrations the potential rises to a positive and constant value which must represent an adsorption potential by chloride ions.

The potential decreases sharply as the Na_2S concentration is increased above 0.003M and follows subsequently a straight line on the logarithmic plot, with a slope of about 30 mv.

If the reaction at the sulfide electrode is written in the form

$$2e^- + S_{(CuS)} + H_2O \rightleftarrows HS^- + OH^- \qquad [12]$$

and at the mercurous chloride reference electrode as

$$2e^- + HgCl_2 \rightleftarrows 2Hg + 2Cl^- \qquad [13]$$

the over-all reaction becomes

$$S_{(CuS)} + 2Hg + 2Cl^- + H_2O \rightleftarrows Hg_2Cl_2 + HS^- + OH^- \qquad [14]$$

where $S_{(CuS)}$ is the excess sulfur in CuS. One would then expect the following potential dependence

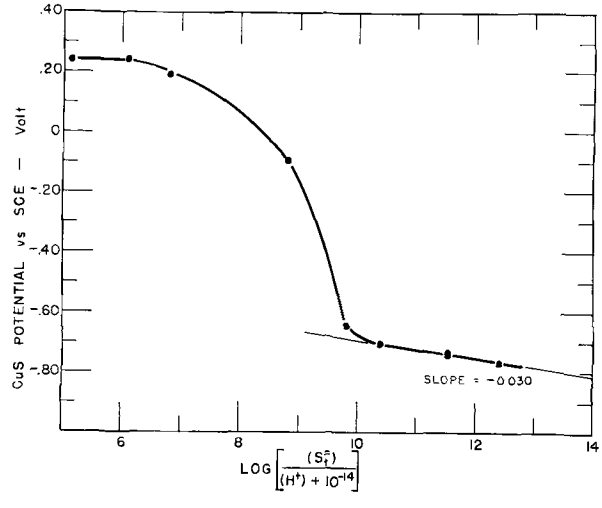

Fig. 6. Cupric sulfide potential as a function of log $[(S_t^{--})/(H^+ + 10^{-14})]$ where (S_t^{--}) = total Na_2S concentration. 0.5M NaCl.

$$E = E_{o(CuS/S_t^{--})} - (2.3\,RT/2F)\log \{[S_t^{--}]/([H^+] + 10^{-14})\} \quad [15]$$

since (Cl^-) concentration was maintained constant. This would predict a slope of —0.029v, when the potential is plotted against the logarithmic term. The experimental results of Fig. 6 agree well with this prediction.

The deviation between the experimental and theoretical slope is due to a dissolution of sulfur and the presence of polysulfides in the more concentrated sulfide solutions, as shown below in greater detail.

The standard potential of the couple

$$2e^- + S \rightleftarrows S^{--}$$

at pH 14 is —0.72v *vs.* calomel according to Latimer.

This value checks well with the experimentally measured value extrapolated with the help of reference (15), from the data of Fig. 6, to a concentration of 1*M* at pH 14, which is another indication that the excess sulfur in CuS is essentially "free."

It has been pointed out that sulfur readily dissolves in alkaline solutions. Hickling (16) has studied the behavior of solutions containing both dissolved sulfur and sodium sulfide, on inert electrodes. He found that the dissolved sulfur species were able to support a reversible redox potential and high currents in the forward and backward direction. Also Gerischer (17) reports that the electrochemical oxidation of sulfide to sulfur can proceed with high efficiencies. It was of interest to measure the redox couple

$$2e^- + S_{(dissolved)} + H_2O \rightleftarrows HS^- + OH^- \quad [16]$$

on CuS electrodes.

Solutions containing sulfur and sulfide in varying concentrations were prepared, and the voltage of CuS in these solutions measured against a calomel reference electrode. The potentials showed extreme reversibility and were established with ease. Forward and backward electrochemical reactions could be maintained with very small polarization. It was discovered that on CuS the redox couple was even more reversible than on platinized platinum.

According to Eq. [16] one obtains for the potential

$$E = E_{o(S/SH^-)} - (2.3\,RT/2F)\log [[S_t^{--}]/\{[S]([H^+] + 10^{-14})\}] \quad [17]$$

Figure 7 confirms this behavior; the slope checks excellently with the theoretical value. These results are in agreement with the data reported by Hickling and, moreover show that Eq. [17] can be applied to solutions of different pH values.

Conclusions

1. Cuprous chloride reacts with sulfur in acidic aqueous chloride solution to produce cupric sulfide and dissolved cupric chloride; the latter reaches an equilibrium concentration close to saturation.

2. The increase in voltage observed when sulfur is added to a cuprous chloride electrode in acidic magnesium chloride solution is caused by the fact that the electrode mechanism changes from

$$e^- + CuCl \rightarrow Cu + Cl^-$$

to

$$e^- + CuCl_2 \rightarrow CuCl + Cl^-$$

where the cupric chloride is generated by chemical reaction between cuprous chloride and sulfur:

$$2CuCl + S \rightarrow CuCl_2 + CuS$$

If the cupric chloride reaches the equilibrium concentration, the total free energy of formation of CuS (11.7 kcal) can be utilized as electrical energy and the over-all process can be written in the form

$$e^- + CuCl + S \rightarrow CuS + Cl^-$$

resulting in a theoretical voltage increase of 0.506v. Further capacity could be delivered by the electrode through the reaction

$$e^- + CuCl + CuS \rightarrow Cu_2S + Cl^-$$

with a theoretical electrode potential increase of 0.38v.

3. The discovery of this phenomenon is of practical importance to the technology of cuprous chloride-magnesium batteries.

4. Potential measurements of CuS in solutions containing either cupric ions or sulfide ions indicate that the nonstoichiometric excess sulfur in CuS acts essentially as "free" sulfur.

5. In solutions containing both dissolved sulfur and sulfides, CuS exhibits the characteristics of a very reversible redox electrode

$$2e^- + S \text{ (dissolved)} \rightarrow S^{--}$$

$$S^{--} + H^+ \rightleftarrows HS^-$$

6. While Wrabetz (3) showed that nonstoichiometric micro-quantities of excess sulfur in metal sulfides are responsible for the high electrode potential of these materials in solutions of their cations, the present investigation showed that similar over-all effects can be achieved with stoichiometric macro-quantities of elemental free sulfur, mechanically admixed with cuprous chloride to form the electrodes, whereby the sulfur regenerates continuously the higher oxidation state of the electrode couple from the lower oxidation state and large current outputs at an increased voltage become possible.

7. The utilization of a purely chemical step in the production of electrical energy according to the scheme

$$\begin{array}{ccccccc} A & + & B & \xrightarrow{\text{chemical reaction}} & C & + & D \\ \uparrow & & & & & & \\ \text{electrochemical reaction} & & & & & & \end{array}$$

may have considerable merit in the construction of various types of battery electrodes.

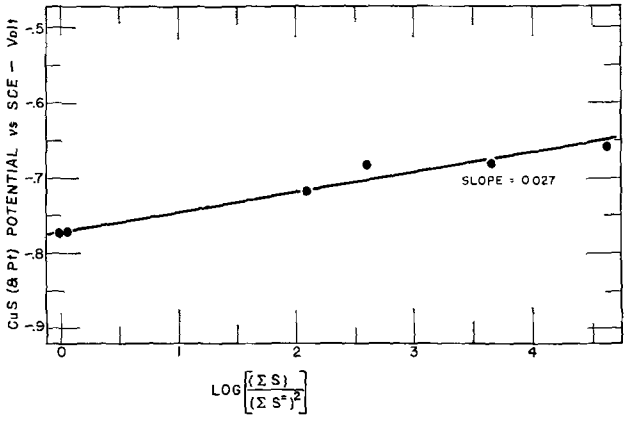

Fig. 7. Cupric sulfide (and platinized Pt) potential as a function of log $(\Sigma S)/(\Sigma S^=)^2$ Total sulfide concentration, $(\Sigma S^=)$, corrected hydrolysis by $[H^+]\ [S^=]/[HS^-] = 10^{-14}$; 0.5*M* NaCl.

ABSTRACT

The corrosion behavior of AISI 304 and 410 steels as well as 23.5 Cr-21.5 Ni steels in superheated steam at temperatures between 400° and 600°C was found to be influenced markedly by preliminary surface treatments: electrolytic polishing, mechanical polishing, milling, lathe-turning, grinding. The treatments accompanied by cold-working reduced the corrosion rate, the effect being retained for long times (at least 2000 hr for AISI 304 steel at 450°C). This enhanced corrosion resistance is attributed to the presence of cold-worked surface layers which were detected by measurement of x-ray line broadening. Electron microprobe analyses of the oxide layers and of the underlying metal showed that the oxide is enriched and the metal depleted in chromium and manganese. These elements thus seem to diffuse through the cold-worked layer toward the oxide. In water, at 300°C and below, the phenomena are more complex and not yet fully understood.

The corrosion of stainless steels in water and steam at high temperature has been studied extensively in recent years in connection with nuclear reactor construction (1). One of the factors liable to modify the corrosion rate is the initial surface treatment of the metal. The studies carried out previously, however, scarcely enable the importance of this corrosion factor to be evaluated and, above all, to be understood.

Fowler, Douglas, and Zyzes (2) consider that the initial surface treatment does not have an important effect on the corrosion of stainless steels in pressurized water between 250° and 320°C. On the other hand, Friend (3) thinks that roughness is disadvantageous, and Roebuck, Breden, and Greenberg (4) recommend actual machine finishing or pickling in order to obtain good corrosion resistance under these conditions. Nevertheless, they consider that the favorable effect of these treatments diminishes greatly during long-term tests. Videm and Aas (5) show that the surface treatment of stainless steels has considerable influence on their behavior in water at high temperature, but do not give details of the favorable treatments. Tolstaya *et al.* (6) show that electrolytic polishing decreases the corrosion rate by a factor of 2, while Rockwell and Cohen (7) put the factor at about 10. On the other hand, Ruther and Greenberg (8) found that electrolytic polishing had a disastrous influence on the behavior of stainless steels in steam at 650°C. Stiefel (9) indicates that a finely machined surface behaves much better in steam at 650°C than a nonmachined surface, but does not specify the type of machining.

In order to try to evaluate and understand the role played by the surface treatment, we endeavored to distinguish the three characteristics of the surface of a metal, as defined by Jacquet (10):

1. Microgeometric characteristics (roughness).
2. Chemical characteristics. Pollution and, particularly, the presence of an oxide film are the most important.
3. Physical or structural characteristics. Disturbances in the metallic lattice, either at the microscopic, submicroscopic, or atomic levels, caused by the surface treatments. Hardness changes and internal stresses in the surface layers are possible consequences of these structural disturbances.

One of the aims of this study was to see which of these characteristics could have an influence on the corrosion of stainless steels in water and steam over a fairly wide temperature range.

Preliminary Experiments and Objectives

The first part of the study, published elsewhere (11), concerned AISI 304 stainless steel. The curves in Fig. 1 reproduce the results obtained in autoclaves in pressurized water at 300°C and in steam at 400°C and 200 atm pressure with specimens which have been subjected to various mechanical surface treatments or to

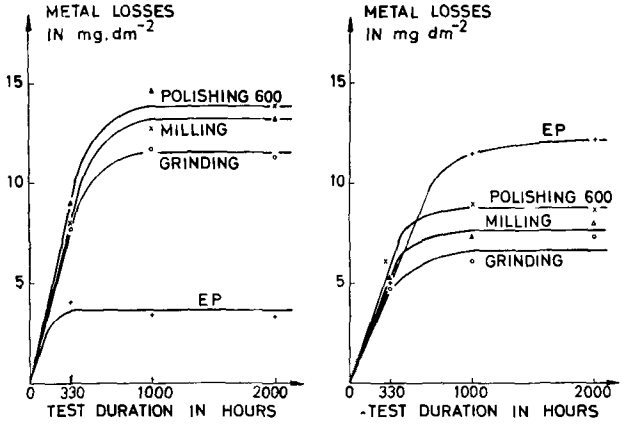

Fig. 1. Corrosion of AISI 304 in autoclaves: (a) (left), water at 300°C; (b) (right), steam at 400°C, 200 kg/cm².

electrolytic polishing. Details of these treatments are given in the experimental section of this paper. The values reported are averages over many tests, each involving a large number of specimens which made it possible to study statistically the significance of the results. It was found that electrolytic polishing appreciably improved the corrosion behavior in water at 300°C as compared with the three mechanically treated states. In steam at 400°C, the mechanically treated samples behaved better than in water at 300°C and became better than the electrolytically polished specimens.

The preliminary studies suggested that the following areas should be investigated: (*a*) to discern if the differences observed in water at 300°C and in steam at 400°C were due to a change in the physical state of the water or to the rise in temperature; (*b*) to cover a wider temperature range; (c) to investigate whether the surface treatment affected only the initial phase of oxidation or whether this effect persisted to longer times. The very slight corrosion of stainless steels under these conditions did not make it possible to study by autoclave tests the corrosion rate after 1000 hr with sufficient accuracy; (*d*) to ascertain whether other stainless steels behave similarly; (*e*) to discern what surface state characteristic is responsible for the observed effects.

Experimental

Specimen preparation.—The material used for this investigation was mainly AISI 304 stainless steel. Some additional tests were made using AISI 410 steel and also with a steel containing 23.5% Cr and 21.5% Ni.

Prior to the corrosion tests, the surface of the specimens was treated in a standardized manner. Three different mechanical treatments were used: (i) mechanical polishing through 600 grit paper, (ii) machine grinding with carborundum (grain size 80), and (iii) milling. A fourth type of treatment was electrolytical polishing in a perchloric-acetic acid bath. These treatments were followed by a chemical conditioning of the resulting surfaces. The standard method was immersion for 2 min in boiling water. Occasionally, conditioning techniques were tried in order to check if this step in the preparation of the specimens might alter the corrosion behavior. Alternate treatments were as follows: (*a*) exposure during 8 days in an air-conditioned room at 20°C and 50% humidity; (*b*) immersion for 2 min in nitric acid of density 1.33 at 20°C; (*c*) pickling during 25 min in a bath composed of 10% HNO_3, 3% HF, and 87% H_2O at 30°C (a layer of 6μ was dissolved by this treatment). Some of the mechanically treated specimens were heated under H_2, A, or in vacuum at 1050°C followed by quenching. The specimens were then chemically conditioned by the standard method (2 min in boiling water).

The surface of the treated specimens was examined by various methods: the roughness of the surface was measured with a profilograph Talysurf model 3 (Taylor-Hobson); the results are expressed in terms of the "central line average," henceforth designated as C.L.A. which is defined as the mean absolute deviation of the profile from the center line. Results of these measurements are given in Table I.

The oxide films formed on stainless steel in various media were compared by coulometric reduction in

Table I. Effect of surface treatment on roughness values of AISI 304 steels

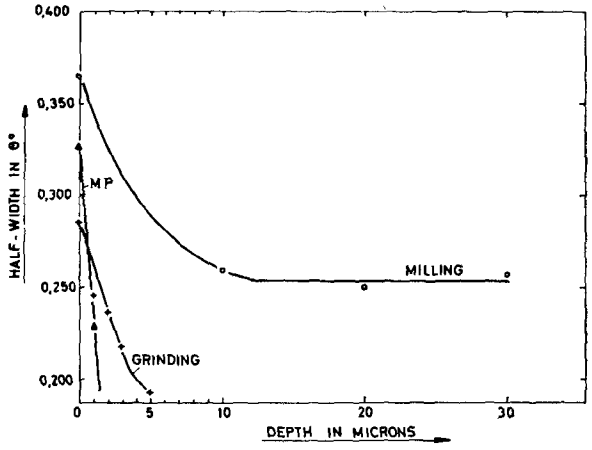

Fig. 2. Measure of the surface cold work of AISI 304 using the half-width of the (111) austenite line. Depth for which the ray profile is similar to that of the electrolytic polished state; grinding, 5-6μ; mechanical polishing, 1-2μ.

sulfuric acid. This method, as described previously (12), makes it possible to evaluate the number of coulombs required to reduce the passivation oxides of stainless steels as well as the exchange current, expressing slow oxidation in sulfuric acid (13). This last value may therefore indicate the protection conferred by the oxide independently of its thickness. The exchange current values obtained with these different chemical treatments vary greatly (13).

In order to evaluate the thickness of the layers affected by the various mechanical treatments, the broadening of the (111) austenite line in the x-ray diffraction pattern of the specimen was measured. For this purpose, the method for the study of surface layers by grazing emergence of the diffracted beam, described by Legrand (14), was adapted to an asymmetrically mounted focusing camera. The Kα line of copper, obtained from a bent quartz crystal monochrometer was used. Figure 2 shows the variation in the half-peak width of the (111) line measured on the photometric recordings. It can be seen that the depths of the cold-worked layer depend greatly on the mechanical treatment. The method reveals no further surface cold-work for specimens polished through 600 grit paper, after 2μ have been dissolved, whereas 6μ are to be removed from ground specimens, and milled specimens are still thoroughly cold-worked at a depth of 30μ.

Autoclave tests.—This technique has been described previously (15). The water used in all of the experiments was extremely pure (resistivity reading 20 Mohm-cm and oxygen content below 15 x 10^{-6} g/liter).

Measurement of the diffused hydrogen.—When a metal is oxidized in oxygen-free water, hydrogen is produced. If the specimen under study is in the shape of a small capsule containing water or steam, the hydrogen formed diffuses through the walls. Bloom *et al.* (16) have shown that it is possible to plot the corrosion-*vs.*-time curve by measurement of the quantity of evolved hydrogen. A longitudinal section through the capsules used is shown in Fig. 3. They are small cylinders of 20 mm diameter and 38 mm length. After annealing, all inside surfaces are subjected to the specified treatments. Bottom and top are then sealed by electron beam welding. The required quantity of water is added through the filling tube which is then pinched off and sealed by spot welding. The sealed capsules are placed in a gas collecting rig, a flow sheet of which is shown in Fig. 4. The rig is made of Pyrex glass and can hold ten capsules which are placed in ten gas collecting chambers heated individually by electric furnaces. The gas accumulated in each collecting chamber is periodically swept into a gas chromatograph for measurement. Because of the high precision

of hydrogen determination by gas chromatography, this method makes it possible to measure accurately the low corrosion rate of AISI 304 steel at 300°C after 1000 hr. This was not possible with autoclave measurements.

Results and Discussion

The corrosion was evaluated after reduction of the oxide layer in a stream of pure hydrogen at 800°C. It was always assumed that the metal to oxygen ratio was that of magnetite. However, for high corrosion rates, i.e., for electrolytically polished specimens at temperatures above 450°C, the results are given by simple measurement of the weight gain, as reduction in hydrogen and descaling have proved unsatisfactory. The values obtained are thus slightly below the real total corrosion values since the metal lost as detached scale in the autoclave is not taken into account.

In order to examine the oxide layers microscopically, polished cross sections were prepared after protecting the oxide by a layer of cobalt deposited electrolytically.

Variations in composition of the oxide and the underlying metal were determined with the electron microprobe. Specimens oxidized in steam for 1000 hr were used for these measurements.

Table II shows the total corrosion values from 1000-hr experiments in autoclaves at different temperatures in pressurized water and superheated steam for the electropolished and mechanically treated states. As the three mechanically treated states give very close corrosion values, the corrosion results for the milled and the electropolished specimens only are indicated. The corrosion rate at 500°C is sufficiently high for the autoclave measurements to indicate the oxidation

* For the calculation of the corrosion rates, the metal to oxygen ratio was assumed to be that of magnetite.

kinetics, even after 1000 hr (Fig. 5). This is not so at 300°C.

The corrosion rates of AISI 304 steel measured by hydrogen diffusion are shown in Table III.

These results show that:

1. The adverse influence of a mechanical surface treatment noted for AISI 304 in water at 300°C did not occur in superheated steam at the same temperature. In saturated steam, however, the results were similar to those obtained in water. Below the critical temperature, the physical state of water must thus be considered as an essential factor of the behavior. Between 250° and 350°C, the corrosion in superheated steam was independent of the surface state and was generally lower than in water.

The fact that the corrosion of electropolished specimens in water was higher at 200° than at 250°C and 300°C is due to the larger quantity of metal in solution in the water at 200°C. It is probable that the transformation of more soluble ferrous hydroxide into magnetite is slower at 200° than at 300°C (1, 17).

2. The curves in Fig. 6 summarize the results of AISI 304 corrosion after 1000 hr in superheated steam at various temperatures. The corrosion in this medium, which was independent of the surface state up to 350°C, was dependent on this factor above 400°C. A mechanical surface treatment improved the behavior of the specimens above that temperature; this improvement increased with temperature. At 600°C, the total corrosion rate of electropolished specimens in 1000 hr was more than 50 times greater than that of mechanically treated specimens.

3. The hydrogen diffusion data (Fig. 7 and 8) and also the 500°C autoclave curves (Fig. 5) clearly demonstrate that the effect of the surface treatment is not a short-term effect; under the conditions employed in our experiments, the oxidation kinetics in steam from 400°C upwards and for exposure times up to 2000 hr

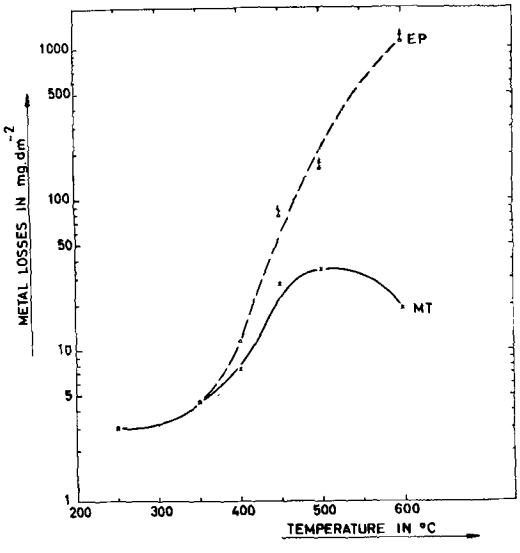

Fig. 6. Total corrosion of AISI 304 in 1000 hr in superheated steam (autoclaves).

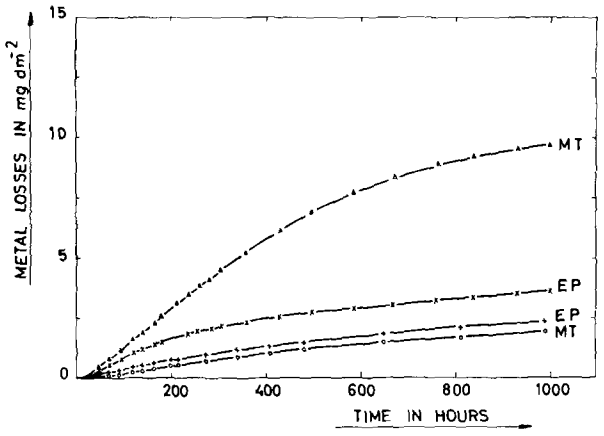

Fig. 7. Total corrosion of AISI 304 at 300°C measured by hydrogen evolution. △, X, Water 300°C; +, ○, superheated steam at 300°C.

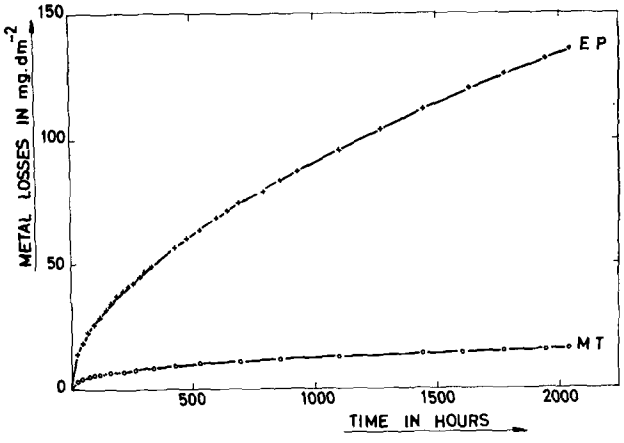

Fig. 8. Total corrosion of AISI 304 in superheated steam at 450°, 70 kg/cm², measured by hydrogen evolution.

are considerably altered by mechanical treatment. The favorable effect of electrolytic polishing on corrosion in water at 300°C was retained after 1000 hr.

4. The favorable effect of a mechanical surface treatment on corrosion in steam at high temperature is the same for AISI 410 and 23.5 Cr-21.5 Ni steels as for AISI 304 steel. On the other hand, electrolytic polishing imparts no noticeable improvement on these steels in water at 300°C.

5. The various roughness values obtained by the different mechanical treatments do not alter appreciably the corrosion behavior of AISI 304 steels in water and steam. Furthermore, the different methods of chemical conditioning of the surface did not bring about noticeable effects. The pickling of a previously electropolished specimen also did not change the corrosion behavior of the surface in water and steam at high temperature. It is thus impossible to relate the behavior of electrolytically polished specimens in this medium to the presence of an oxide film formed during polishing as was the case in the corrosion of iron-chromium alloys oxidized in oxygen (18).

The influence of cold-work on the corrosion behavior was shown by the specimens which had been pickled in the nitric-hydrofluoric acid bath after the four surface treatments. Only the milled specimen which had been cold-worked to a depth greater than 6μ, maintained a low corrosion rate at 500°C after pickling, whereas the three other surface treatments produced corrosion rates similar to that of the electropolished specimen. All the specimens which were quenched from 1050°C behaved similarly in steam at 500°C to the electropolished specimens.

Fig. 9. Section of an AISI 304 sample marked with a diamond point and oxidized for 1000 hr in steam at 500°C.

Figure 9 shows a section of an electropolished specimen of AISI 304 steel on which a mark was scribed with a diamond point under constant load. The specimen was oxidized during 1000 hr in steam at 500°C. It can be seen that the oxide layer on the area cold-worked by the diamond point is distinctly thinner than on the remainder of the surface. These results show that the improvement in the behavior in steam at high temperature observed after mechanical treatment is due to the presence of a cold-worked layer several microns thick.

The electron microprobe analysis of cross sections of mechanically treated specimens was not possible because after 1000 hr at 500°C in steam the oxide films are too thin (0.4μ). However, surface analysis of a specimen was carried out, the depth of penetration of the beam being about 3μ. The results obtained were therefore only qualitative, but a very marked enrichment of the oxide layer in chromium and in manganese was observed. This is shown in Table IV.

The microscopic study of oxides formed on electropolished specimens has shown that they consist of two layers separated by the initial surface of the metal. The outside layer is highly crystallized magnetite, free of chromium and nickel, whereas the inside layer probably resulted from an internal oxidation of chromium in a nickel-rich austenite matrix (19). The chromium content of the metal under the oxide layer is given in Table V.

It may be ascertained that no chromium concentration gradient is formed in the metal of the electropolished sample, whereas with the mechanically treated samples a depletion of the chromium content is found in the neighborhood of the oxide, which itself is rich in chromium. It is therefore probable that the diffusion rate of the chromium is higher in the layer affected by the mechanical treatments because of the increased number of dislocations in the crystal lattice.

The film initially formed on the cold-worked surfaces would be greatly enriched in chromium as a result of this diffusion and might thus afford a greater degree of protection against later oxidation of the iron. A similar mechanism has been suggested by Poulignier *et al.* (20) to explain the favorable effect of superficial cold-work on the oxidization of Cr-Ni-Co-Mo alloys in air.

Table IV. Electron microprobe analysis of a milled specimen of AISI 304 steel oxidized for 1000 hr in steam at 500°C

Analyzed layer	Concentrations in %				
	Fe	Cr	Ni	Mn	Si
Original metal	69	18	11	1.5	0.9
Oxide	59.6	23.6	10	6.2	0.6

Table V. Chromium content of the metal under the oxide layer of AISI 304 steel specimens oxidized for 1000 hr at 500°C

Thickness of the metal consumed by corrosion	Milled 0.4μ	Ground 0.4μ	Electropolished Approx. 2μ
Depth under oxide layer, μ	Chromium contents in %		
2	17.3	17.3	18.0
5	17.4	17.6	18.0
10	17.7	17.9	18.0
20	17.7	18.1	18.0
30	18.1	18.1	18.0
200	18.1	18.1	18.0

Conclusions

The corrosion rate of stainless steel in superheated steam at high temperature is greatly affected by the initial surface treatment of the metal. The essential factor was found to be cold-work which reduces considerably the corrosion rates. Definition of the surface state in terms of its roughness is totally inadequate. Pickling or electrolytic polishing are also insufficient to define a surface state, because the cold-worked surface layers may not have totally disappeared.

In water at 300°C and below, more complex phenomena seem to be involved in which the physical state of the water, the temperature, and the surface state of the metal as well as its composition contribute in a manner which is not yet fully understood. The investigation of these mechanisms is more difficult because of the low corrosion values obtained.

It should be possible to make use in nuclear power plants of the considerable improvement in corrosion behavior in superheated steam produced by suitable surface treatments.

Acknowledgment

This work was supported by the Commission of the European Atomic Energy Community. The authors thank for the permission to publish this paper. Thanks also due to Mr. Hochmann, Director of Research of the Company "Ateliers et Forges de la Loire," for his kindness to permit the electron microprobe analyses to be carried out in his laboratories.

Manuscript received Oct. 2, 1964. This paper was presented at the Washington Meeting, Oct. 11-15, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

The Migration of Metal and Oxygen during Anodic Film Formation

J. A. Davies, B. Domeij, J. P. S. Pringle, and F. Brown

Research Chemistry Branch, Chalk River Nuclear Laboratories,

Atomic Energy of Canada Limited, Chalk River, Ontario, Canada

ABSTRACT

Beta-ray spectroscopy and radiotracer techniques have been used to study the transport of metal and oxygen during anodic oxidation. Both species are mobile during oxide film growth on Al, Nb, Ta, and W, but in Zr and Hf only oxygen transport is observed. Radiotracer measurements showed that the amount of metal dissolving in the electrolyte was usually less than 1% of the total oxidized, but that for Al it could be as high as 40%, depending on the current density and electrolyte used.

Although the anodic oxidation of metals has been studied extensively in recent years, the nature of the mobile species within the growing oxide film has not been clearly established. Experimental evidence has been presented in Al, for example, to suggest that anodic oxidation proceeds by metal ion migration (1, 2), by oxygen ion migration (3), or by a combination of both processes (4, 5).

To resolve such discrepancies, a "transport number" experiment is required in which a thin surface layer is tagged with a completely immobile marker atom, whose position is then followed during the subsequent anodic oxidation. If the metal ions alone are mobile, new oxide will be formed at the oxide/electrolyte interface on top of the tagged layer, and so the marker will become buried. On the other hand, if oxygen ions are the only mobile species, the new oxide forms at the metal/oxide interface underneath the tagged layer, and so the marker remains close to the outer surface throughout the oxidation.

The ideal marker atoms for such a transport experiment should be (i) uncharged, so that they do not migrate under the influence of the applied electric field; (ii) large in size, so that they do not diffuse significantly within the oxide lattice; (iii) present in trace amount, so that the macroscopic properties of the tagged oxide remain unaltered; and (iv) such that their depth beneath the surface can be determined *in situ*, without damaging or destroying the oxide layer. Previous investigations (1, 6) have not fulfilled these criteria.

Radioactive isotopes of the heavier inert gases should approximate the ideal marker closely. Of all the possible atomic markers, the inert gases are the most likely to remain uncharged within the oxide lattice. The heavier gases are much bigger than either metal or oxygen ions and, if radioactive, can be used in trace amounts. Furthermore, the radioisotopes Xe^{125} and Rn^{222} decay with the emission of monoenergetic conversion electrons and α particles respectively, and so their depth beneath the surface of a solid can be measured *in situ* by means of high precision nuclear spectroscopy (7, 8).

Our earlier experiments on the anodic oxidation of Al and Ta in aqueous solution (3) showed that the Xe^{125} markers in anodic Al_2O_3 remained very close to the outer surface. We also noted that an appreciable amount of aluminum went into solution during anodizing, which suggested that aluminum ions might be mobile but were not building oxide at the outer surface. Subsequent experiments (4,5) showed that the final location of the marker atoms within the aluminum oxide layer depended markedly on the current density used and also on the nature of the electrolyte. At higher current density we observed an appreciable burying, which shows that metal transport is responsible, at least in part, for oxide growth. We have now found that the amount of aluminum going into solution during anodizing also varies with the current density; obviously, this loss must be considered in assessing the relative importance of cation mobility in the growing oxide.

Consequently, it was decided to carry out a more detailed radiochemical investigation of the anodizing behavior of Al and Ta. Two types of experiments have been used: (i) transport number experiments using Xe^{125} marker atoms as in the previous work (3, 5); and (ii) experiments with neutron-activated metals in order to determine the amount of metal ion dissolving during the anodic oxidation. The effect of current density was studied in both sets of experiments, and for Al the nature of the electrolyte was varied. In addition, the anodic behavior of zirconium, niobium, hafnium, and tungsten was studied.

Experimental Procedure

Xe^{125} *depth measurements.*—In these experiments, trace amounts of Xe^{125} were incorporated in a thin anodic oxide layer on the surface of a metal foil. After measuring the mean depth of the Xe^{125} atoms, the foil was anodized further to produce a thick oxide film, and the mean depth of the Xe^{125} atoms was again determined. The difference in the Xe^{125} depths, divided by the thickness increment of the oxide, gave the fraction of the anodic oxide formed outside the Xe^{125} layer.

A previous paper from this laboratory (9) has described the use of an isotope separator for injecting Xe^{125} into solid targets. The Xe^{125} ions strike one tenth of the area of the target, 3.5 x 1.0 cm, as a line 3.5 cm long and 0.1 cm wide; the total number of Xe^{125} was always less than $10^{12}/cm^2$, and so the atomic concentration of Xe^{125} in the tagged layer did not exceed 20 ppm. A relatively low injection energy, either 3 or 5 kev, was used to keep the depth of the tagged layer small. The Xe^{125} could have been injected directly into the oxide layer, and a very narrow Xe^{125} depth distribution would have resulted (10). Because of the possibility that radiation damage to the oxide might affect its anodizing behavior, we preferred to put the Xe^{125} into the metal, and then anodize to convert the surrounding metal to oxide. As the distribution of embedded Xe is known for Al (9) and W (11), it is possible to calculate the anodizing voltage required to oxidize just this depth, and suitable voltages for the other metals could be inferred. This procedure does not eliminate the possibility that radiation damage in the metal may affect the anodic oxidation, but it has previously been shown that this is negligible for Al (12).

With the Xe^{125} atoms in a very thin layer of oxide, the target was inserted into the source chamber of the Chalk River $\pi\sqrt{2}$ β-spectrometer and the shapes of the

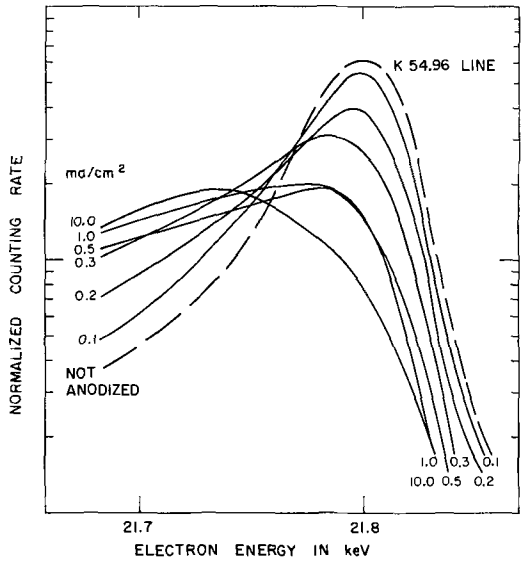

Fig. 1. The K54.96 conversion electron spectra from Xe^{125} atoms in anodic Al_2O_3; 3 kev Xe^{125} in Al subsequently anodized to 125v. The effect of current density is shown.

21.79 and 155.2 kev electron peaks, arising from K conversion of the 54.96 and 188.4 kev nuclear transitions, respectively, were measured. The target was then removed, anodized under the desired conditions, replaced in the spectrometer, and the peaks remeasured. Further anodizing and peak measurements were carried out as needed. The depth of the Xe^{125} layer after anodizing was found from the conversion electron spectra by comparing the observed attenuation of the 21.79 kev peak with that produced by absorbers of known thickness (7). The 155.2 kev peak is not significantly attenuated by the absorber thicknesses involved in the present work; it was measured to provide a normalizing factor for eliminating variations in source strength, geometrical efficiency, etc., in the spectrometer. Sample K54.96 spectra are shown in Fig. 1 for the anodization of Al in aqueous citrate.

A detailed description of this β-spectroscopic method for measuring small penetration depths has been given elsewhere (7). In the article, the method had been calibrated against known thicknesses of Al and Au absorbers; it was necessary for the present purpose to extend these calibrations to anodic oxides. Accordingly, anodized Al and W targets were bombarded with monoenergetic Xe^{125} ions of 1, 40, and 160 kev energy, and the Xe^{125} conversion electron spectra measured. The mean penetration depth, $\bar{R}$, of Xe^{125} in anodic Al_2O_3 and WO_3 is known accurately as a function of incident energy from the work of Domeij *et al.* (10), and the targets were anodized sufficiently (70v for W, 125v for Al) to ensure that essentially all the Xe^{125} was stopped in the oxide layer. Comparison of $\bar{R}$ against the normalized K54.96 peak height, N, in Fig 2 shows that N decreases exponentially with $\bar{R}$ as observed previously for Al and Au. Strictly, the mean "exponential" depth, $\bar{x}$, defined in the previous article (7) should be used for comparison with N, but the discrepancy between $\bar{R}$ and $\bar{x}$ is small provided that the thickness of the Xe^{125} layer is also small, as is the case in these oxides.

Xenon penetration depths are not known experimentally for the other anodic oxides; it was assumed that the electron stopping powers of HfO_2 and Ta_2O_5 were the same as that of WO_3. To provide a calibration for ZrO_2 and Nb_2O_5, the mean penetration depths of 80 kev Xe^{125} ions in these oxides were calculated from the theory of Lindhard (13) and used with the experimentally observed K54.96 peak height to construct the calibration shown in Fig. 2. These theoretical pene-

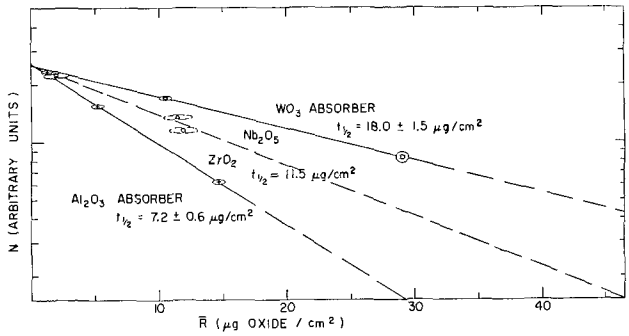

Fig. 2. Calibration of N, the normalized counting rate at the natural peak position of the K54.96 line, against the mean depth, $\bar{R}$, of the Xe^{125} atoms in anodic oxides.

tration depths, 11.9 $\mu g/cm^2$ for ZrO_2 and 11.5 $\mu g/cm^2$ for Nb_2O_5 are estimated to have an error of about 10%; it was assumed that the calibration for these two oxides was the same.

Dissolution of metal during anodizing.—A neutron activation technique was used to measure the extremely small amounts of metal ion that dissolve during anodic oxidation. Metal targets identical to those used above were irradiated in the NRX reactor at a flux of 2 x 10^{13} n cm^2/sec until a specific activity of ~10 mc/g was attained. No suitable radioisotope of Nb is produced by neutron activation, and the short half life of Al^{28} makes it necessary to start with a much higher specific activity (approximately 1000 mc/g) in order to have sufficient time to carry out the anodic oxidation. The irradiated targets were anodized at constant current to various voltages, and the amount of metal dissolved was determined by comparing with a standard. The latter was prepared by dissolving a known weight of the irradiated metal in an identical volume of etching solution.

Target preparation.—The targets were high-purity metal foils of dimensions 3.5 x 1.0 x 0.02 cm. Apart from W, all targets were polished either chemically or electrochemically in order to remove the mechanically damaged surface region using the following reagents:

(*a*) For Nb and Ta: chemically polished with a 5:2:2 mixture of concentrated H_2SO_4:HNO_3:HF acids.
(*b*) For Zr and Hf: chemically polished in a 45:4:51 mixture of concentrated HNO_3:concentrated HF:H_2O.
(*c*) For Al: electrochemically polished in perchloric acid-acetic anhydride.
(*d*) For W: not polished; the same material was used as in ref. (11).

Immediately prior to use, targets of Al and W were given a final pre-anodizing treatment, which consisted of the successive formation and dissolution of several anodic oxide layers approximately 1000Å thick. Unfortunately, no suitable reagent for dissolving the anodic oxides of Zr, Nb, Hf, and Ta without attacking the underlying metal is known to us, and so this pre-anodizing treatment could not be applied.

Anodizing procedure.—The anodic oxidations were all carried out at constant current, using the following electrolytic solutions:

(*a*) For Nb and Ta: 0.1M Na_2SO_4 in water.
(*b*) For Zr, Hf, and W: 0.4M KNO_3 + 0.04M HNO_3 in water.
(*c*) For Al: (i) Vermilyea's solution A (6), *i.e.*, sodium tetraborate (50 g/l) in 95% ethylene glycol—5% water; (ii) ammonium dihydrogen citrate (30 g/l) in water. The electrolyte temperature was always 25°C.

Results

Mobility of metal and oxygen.—Before discussing the behavior of individual metals, it is necessary to establish the significance of the experimental results. For

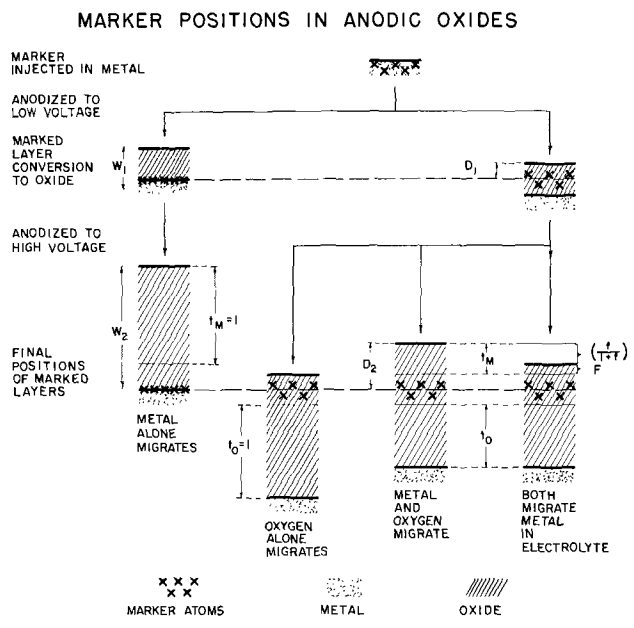

Fig. 3. Effect of metal and oxygen migration on the final position of an inert marker in an oxide film.

this purpose, the oxide is assumed to grow on a plane surface, to be of effectively uniform thickness at all times, and to be free of flaws; it is also assumed that the marker is present in negligible concentration and is truly immobile. There are then three possibilities for oxide growth; either the metal alone moves, or the oxygen alone, or they both move. The effect of metal and oxygen mobility on the final marker position is illustrated in Fig. 3.

If metal ion migration is solely responsible for film growth, the fresh oxide layers will be formed at the oxide/electrolyte interface on top of the marked layer. The situation is complicated, however, by the fact that the metal layers consumed during the oxidation must be replaced by oxide if the film is to remain in contact with the metal. Since the oxygen is, by definition, immobile, the oxide film must adjust itself to the metal surface by some process of plastic flow deformation; under these circumstances, the marker atoms will be trapped at the oxide/metal interface. Such markers would, therefore, appear buried by the full depth of the oxide film, but no practical example of this has yet been found.

If the oxide grows entirely by the inward movement of oxygen ions, migrating either directly through the oxide or by a series of replacement events, then the fresh oxide layers will be formed at the metal/oxide interface underneath the marked layer. The latter will, therefore, remain close to the oxide/electrolyte interface, and no burying of the marker will be observed.

If both metal and oxygen move, the marker atoms will be found somewhere in the middle of the film, the exact position depending on the relative mobilities of the metal and oxygen. Since all the metal ions migrating across the marked layer give rise to oxide above it, and all the oxygen ions migrating inward to oxide below, it is evident that the final position of the marked layer within the oxide can be used as a measure of the ionic transport fractions of metal and oxygen. Denoting these fractions by t_m and t_o, such that $t_m + t_o = 1$, it follows that t_m is equal to F, the fractional burying of the marked layer.

So far, it has been assumed that fresh oxide is formed only at the surfaces of the existing oxide. This is where it must occur if either the metal or the oxygen is the sole mobile species. If, however, both are mobile, the possibility arises that fresh oxide can be formed at points within the existing oxide, as suggested by Cheseldine (14). Growth of new oxide within the existing oxide does not appear to occur under the conditions of the present experiments, for if it did the Xe^{125} distribution would tend to broaden; the experiments with Rn^{222} show that no significant broadening takes place (4).

For the practical determination of t_m, account must be taken of the finite depth of the Xe^{125} markers in the initial oxide film. Accordingly, differential experiments were carried out in which the Xe^{125} depth, D_1, was measured in the low voltage oxide of thickness W_1. After anodizing to high voltage to produce an oxide film of thickness W_2, the depth, D_2, of the Xe^{125} was again measured. The fraction F was then obtained from

$$F = \frac{D_2 - D_1}{W_2 - W_1}$$

The cationic transport fraction, t_m, is equal to F only if no metal dissolves in the electrolyte; if metal does dissolve, say a fraction, f, of that giving rise to oxide, then

$$t_m = \frac{F + f}{1 + f}$$

Niobium, tantalum, and tungsten (*Fig.* 4).—After bombardment with Xe^{125}, samples of these three metals were anodized to low voltage in order to incorporate the Xe^{125} in the oxide layer, and then reanodized to a much higher voltage. No Xe^{125} was lost from any of these oxides during the oxidation process, and only trace amounts of metal were found in the electrolyte; less than 0.1% for Ta, and less than 0.5% for W. No information could be obtained for Nb as no suitable radioisotope was available. Oxide thicknesses were extracted from the appropriate information in Young's book (15). The increase in the Xe^{125} depth divided by the increase in the total oxide thickness gave the fractional burying, F, of the Xe^{125}; with such a small loss of metal to the solution, F approximates the cationic transport fraction t_m very closely.

As can be seen from Table I, t_m is close to 0.30 for all three metals, and so the oxygen mobility is about twice that of the metal. The error in each determination is probably about ± 0.03, due to uncertainties in the Xe^{125} depth; variations in the individual errors quoted for the latter are due to differing counting rates in the samples measured. The Xe^{125} depths in Nb_2O_5 are less reliable because of the larger uncertainty in the calibration; Ta_2O_5 has been assumed to have the same

calibration as WO_3. No value for the Xe^{125} depth in Nb anodized at 10 ma/cm² to 10v was measured, and so a value of 5 μg/cm² was chosen. In the light of these errors, no significant variation of t_m with current density or oxide thickness is observed in these metals.

Zirconium and hafnium (Fig. 5).—As can be seen from Table II, the fractional burying, F, of the Xe^{125} in these metals was very small at all the current densities used. Substantial amounts of Xe^{125} were lost during the anodizing process, together with a small loss of metal; we have no data for Hf, but about 0.6% of the Zr appeared in the electrolyte. As is well known, the anodizing behavior of these two metals is much more variable than that of the metals already discussed; there is a marked tendency to evolve oxygen, with resulting lower current efficiency for the formation of oxide. Accordingly, the oxide thicknesses were calculated from a fixed rate of 20 Å/v (15), using a density of 5.5 g/cm³ for ZrO_2 and 9.7 g/cm³ for HfO_2 (16); the errors in these thicknesses could easily reach 25%.

The amount of metal appearing in solution corresponds to approximately 1.0 μg/cm² of oxide, and this loss is nearly sufficient to account for the magnitude of the Xe losses. If the Xe^{125} tagged layers nearest the surface are removed, the depth distribution of the remaining Xe^{125} will change in such a way that the measured mean depth increases. This effect could account for at least part of the apparent burying; certainly t_m is not greater than 0.05. Accordingly, the thickening of the anodic oxide in these metals must proceed almost entirely by oxygen migration.

Aluminum.—In solution A.—The results obtained on anodizing Al to 125v in solution A (50 g/l sodium tetraborate in 95% ethylene glycol, 5% water) are given in Table III. The Xe^{125} is completely retained in the oxide at all current densities and occurs at the same depths, 31 μg/cm², within the experimental error of 3 μg/cm². Some 2% of the metal appears in the electrolyte, the amount decreasing with increasing current density. The mean value of t_m calculated from these results is 0.58 ± 0.04; the error in the individual results is greater than this at 0.06, arising largely from uncertainty in the Xe depth.

In these experiments with Al, the preliminary anodization to low voltage was omitted, and t_m was calculated by a different method. The mean range, $\overline{R}$, of 3 kev Xe^{125} projectiles in polycrystalline Al foil is known to be 2.9 μg/cm² (9), which corresponds to 5.5 μg/cm² of Al_2O_3. This value was then substituted for D_1 and W_1 in the formula already given for F. Oxide thicknesses were calculated from the weight gains recorded by Bernard and Cook (17) at constant current in an ammonium pentaborate/glycol electrolyte; reasonable agreement with a constant voltage calibration made in solution A is observed.

In ammonium citrate (Fig. 1).—The results obtained on anodizing Al to 125v in 3% aqueous ammonium citrate are shown in Table IV, and are substantially different from those obtained in solution A. In order to relate t_m to the observed Xe^{125} depth in the oxide, two other factors must be taken into account; the first is the dissolution of the Al in the electrolyte, and the second is the loss of Xe^{125}.

Although the amount of Al appearing in the electrolyte decreases with increasing current density as in solution A, the fraction f is nearly twenty times as great at the same current density. It was observed that this dissolution occurs only during anodizing; if the oxide is immersed in the electrolyte without an applied field for a time comparable to the anodizing time, the dissolution is negligible. Similarly, if the applied voltage (100v) was less than that used to form the oxide (125v), no dissolution occurred either. These results confirm Hoar and Mott's hypothesis (18) that the dissolution of the Al is field assisted.

The Xe^{125} is all retained in the oxide except at very low current densities, where for 0.2 ma/cm², the loss of 8% is insufficient to affect the mean Xe^{125} depth very much. The 69.5% loss at 0.1 ma/cm², however is in a very different category, because the observed Xe^{125} depth is then a measure of the Xe^{125} remaining, which may have a very different depth distribution from the original. Two extreme possibilities can be considered. The Xe^{125} layer can be removed completely from 69.5% of the surface, the remaining 30.5% being untouched and thus retaining its original depth distribution. Under these circumstances, the measured depth corresponds to that measured at other current densities, although the significance of the resultant t_m is open to question. Alternatively, the Xe^{125} layer may

be removed uniformly across the surface, leaving 30.5% of the Xe^{125} behind at all points. In polycrystalline Al, 30.5% of the 3 kev Xe^{125} projectiles penetrate more than 2.8 μg/cm², which corresponds to 5.3 μg/cm² of Al_2O_3. The net burial of the Xe^{125} atoms is then 5.5-5.3 μg/cm² or 0.2 μg/cm², not 5.2 μg/cm² as observed. Both values have been used in the calculations for Table I to give the possible range for t_m.

The oxide film thickness was calculated from data available in the literature, as no experimental calibrations were available for the constant current conditions used here. For aqueous borate electrolytes, Young (15) has given an equation relating the current density to the field strength across the oxide, from which angstrom per volt increments can be obtained for any current density. Young, however, measured his oxide thicknesses by a method which included the charge to form the films as a parameter and apparently assumed 100% current efficiency for oxide formation. This is not so; as with aqueous citrate, substantial amounts of Al pass into the borate electrolyte. If Young's values are corrected for the loss of Al to solution, they become very similar to those obtained by Bernard and Cook (17) in ammonium pentaborate/glycol; the latter have therefore been used to compute the oxide thicknesses in aqueous citrate as well as in solution A.

Calculations of Table IV show that in aqueous citrate, t_m does vary with current density, from about 0.37 at 0.1 ma/cm² to 0.72 at 10 ma/cm². The experimental error in each value is about 10%, arising both from uncertainty in the Xe^{125} depth and in the fraction of Al going into solution; errors in the total oxide thickness have relatively little effect, except at high current density. The value of 0.72 recorded at 10 ma/cm² may not therefore be significantly greater than 0.58, but the variation of t_m with current density in aqueous citrate definitely is significant.

Although there does not appear to be any chemical difference between the oxides formed in aqueous and nonaqueous electrolytes (15, 17), it has long been known that Al tends to give duplex films in the former. The outer layer, that next to the electrolyte, has a low resistance to the passage of ionic current and is porous (19), whereas the inner "barrier" layer is continuous and has a high resistance. It is questionable whether the films produced here contain pores, as pore formation has only been observed, for neutral electrolytes like ammonium citrate, on prolonged anodizing at about 0.01 ma/cm² (19, 20), which is one tenth of the lowest current density used here. The agreement between the oxide thicknesses formed in aqueous and nonaqueous electrolytes is additional evidence against the presence of a porous layer. Nevertheless, these citrate films do show similarities to porous films, particularly as regards the solution of Al in the electrolyte.

No direct measure of the Al dissolving in the electrolyte appears to have been made under conditions in which the anodic films are known to be porous, but values of f can be calculated from data on the amount of Al remaining in the oxide (21, 22). Thus on anodizing in 15% H_2SO_4 at 21.1°C for 30 min, the fraction f ranges from 0.57 at 13 ma/cm² to 0.44 for 78 ma/cm². This variation is qualitatively similar to that observed in the citrate electrolyte, but the f values are somewhat greater. It seems possible, therefore, that the variation in t_m is related to the onset of porous oxide formation.

Discussion

The differing results reported in the literature for oxygen and metal mobility in these oxides stem from incomplete interpretation of the experimental data. This arises first from a belief that either the metal or the oxygen can move, but not both (2), and second from a tacit assumption that the foreign atoms used as

markers are themselves immobile. To illustrate, the work of Lewis and Plumb (1) will be discussed.

These workers anodized aluminum at 50v in 3% ammonium tartrate and then briefly at 52v in radioactive 0.1% $H_2S^{35}O_4$ electrolyte; analysis of the oxide by slow dissolution in 5% H_3PO_4-2% CrO_3 at 50°C showed that almost all the radioactivity was removed in the first 4 min. The reverse experiment, 15v in the $S^{35}O_4^{--}$ electrolyte first followed by 50v in tartrate, was also performed, whereupon the bulk of the radioactivity dissolved between the eighth and fourteenth minutes in the stripping solution. Lewis and Plumb concluded that the oxide applied first was removed last and, hence, that fresh oxide was being formed at the oxide-electrolyte interface. However, these workers had apparently no means of knowing when their oxide was completely dissolved, and consequently, in the reverse experiment, they had no means of knowing whether any oxide was being formed underneath the radioactive layer due to oxygen migration. Furthermore their interpretation rests on the assumption that the $S^{35}O_4^{--}$ is a truly immobile marker. Were the sulfate ion mobile, it would, from its charge, tend to move in toward the metal-oxide interface, and these experiments could then be interpreted solely on the basis of oxygen migration.

Similar experiments have been performed with tantalum, using the film formed in concentrated sulfuric acid as the marker layer. Such films dissolve much more rapidly in HF than do films formed in dilute aqueous electrolytes, and this property has been used to analyze the duplex films. Vermilyea (6) anodized first in dilute aqueous sulfate, and then in concentrated sulfuric acid, and found that the faster dissolving layer was on the outside of the final oxide film. Like Lewis and Plumb, he concluded that metal was the mobile species. Franklin, as reported by Young (15), carried out the reverse experiment, using concentrated sulfuric acid first and dilute acid second, and found that the faster dissolving layer was in the middle of the final oxide. Very recently, Cheseldine (14) has repeated this last experiment almost exactly, forming his marker layer in formic acid rather than concentrated sulfuric. His observations were the same as Franklin's, and he concluded that both the metal and the oxygen were mobile. His value for t_m, 0.48, is however rather larger than that reported here.

It is quite clear that in these experiments on Ta, the marked layer has different properties from the rest of the oxide, and the same may be true of the $S^{35}O_4^{--}$ experiments on Al. In an effort to avoid the complications of chemically different layers, Amsel and Samuel (2) have used O^{18} as the tracer during the anodization of Al, and determined its position in the final oxide by means of nuclear spectroscopy. The introduction of a marker that is part of the oxidation system in principle increases the information that may be obtained from the experiment, for the final depth distribution of the O^{18} is a function not only of the oxygen mobility, but of the method by which it moves. Difficulty in determining the O^{18} distribution with sufficient accuracy, however, limits the information that can be obtained by this nuclear method.

Amsel and Samuel found that a thin O^{18} layer put on first remained essentially in contact with the metal/oxide interface during subsequent anodization to high voltage in an O^{16} electrolyte. They therefore concluded that either the oxygen was immobile, or that it moved in single jumps from one lattice plane to the next, so that the order of the oxygen atoms in the oxide was conserved. The mixing of the O^{16}/O^{18} layers predicted on the basis of the second assumption was not observed, but even with 100% oxygen transport, it would only have been three times the experimental limit of detection. Amsel and Samuel's results are not therefore in conflict with the present observation of about equal metal and oxygen transport in Al.

The results obtained from previous experiments are not therefore in conflict with those reported here, provided that the usual assumption is made; that the Xe^{125} markers are immobile. The Xe^{125} could move in these oxides for one of two reasons; it could diffuse, or it could move under the influence of the applied field because it has a net charge. Since no experimental evidence can be presented on the second point, it will be assumed, for the purposes of the present paper, that the Xe is not charged.

The absence of Xe^{125} diffusion in these oxides is well established. Except for injection energies below 5 kev, all the Xe^{125} striking the surface of anodic Al_2O_3 and WO_3 remains in the oxide (10). This behavior exactly parallels that of the corresponding metals, where the low sticking factor at low bombardment energies was ascribed to failure of the ions to penetrate to a sufficient depth in their initial impact (12). Furthermore, experiments in this laboratory by Kelly have shown that on heating anodic Al_2O_3, no Xe^{125} is released below 600°C, even when the Xe^{125} is injected directly into the oxide at such low energy, 1 kev, that it must be very close to the surface. And finally, the range and the range straggling of injected Xe^{125} ions in anodic Al_2O_3 and WO_3 agrees well with that expected from the theory (13) of Lindhard *et al.* on the range of energetic particles in amorphous solids.

Although the Xe^{125} does not diffuse appreciably in the static oxide, there remains the possibility that it could diffuse in the growing oxide. If so, the distribution of the Xe^{125} markers in the oxide should broaden. The β-ray spectrometry method used here provides no information on the depth distribution of the Xe^{125}, but in a similar experiment using the closely related isotope Rn^{222}, it was shown, by α-particle spectrometry, that no appreciable broadening of the distribution occurs (4).

Magnetic Properties and Corrosion Behavior of Thin Electroless Co-P Deposits

J. S. Judge, J. R. Morrison, D. E. Speliotis, and G. Bate

Systems Development Division, International Business Machines Corporation, Poughkeepsie, New York

ABSTRACT

Thin magnetic films of Co-P were prepared in two somewhat different electroless cobalt solutions. The magnetic properties and the corrosion behavior of these films as a function of thickness was studied. The films exhibited high coercivities with a maximum of about 1000 oe at a thickness of 600Å. The magnetic moment of these films was found to decrease on exposure to high humidity and moderate temperatures (40°-70°C); this was used as a means of studying the extent of corrosion. The extent of corrosion was found to vary as the 2/3 power of the thickness of the film.

Advances in information storage have created an increasing demand on the capacity of the storage media. For very high density applications, the thinness of the recording surface is of the utmost importance. A thin recording medium not only facilitates the writing of sharper transition regions by the recording transducer, but is also better able to resist demagnetization. Metallic surfaces of chemically deposited Co-P have been investigated as recording media (1, 2). However, the thickness region below 4000Å, which is of far greater importance for high density recording, has not been investigated. It is primarily this region that is the subject of our study.

Two thickness series, produced in somewhat different solutions, were examined. The structural and magnetic properties of these deposits were investigated. Furthermore, the magnetic moment of the deposits was found to decrease on exposure to relatively mild conditions of humidity and temperature. This phenomenon was utilized to study the corrosion behavior of the deposits.

Preparation

The films were deposited on Mylar substrates which were presensitized with the usual $SnCl_2$-$PdCl_2$ treatments (3). Prior to this, the Mylar substrate had been rendered hydrophilic by a two-step process involving immersion first into a hot chromic-sulfuric acid solution, and then into a hot sodium hydroxide solution.

Two somewhat different electroless cobalt solutions were used, a sulfate and a chloride solution. The composition and conditions of the plating solutions were:

Sulfate		Chloride	
$CoSO_4$	0.11M	$CoCl_2$	0.13M
NaH_2PO_2	0.19M		
$(NH_4)_2SO_4$	0.50M	$NH_4H_2PO_2$	0.18M
Na_3(citrate)	0.12M	$(NH_4)_2H$(citrate)	0.155M

Temp.: 80°C; pH: 8.7 at 50°C (pH adjusted with NH_4OH); no agitation.

Thickness, Composition, and Structure

Figure 1 shows the dependence of the weight of the deposit on plating time for the two solutions. From the slope of these curves, the plating rates were measured to be 1.35 $\mu g/cm^2$/sec for the deposits from the sulfate solution, and 1.12 $\mu g/cm^2$/sec for the deposits from the chloride solution. These weights were determined by x-ray fluorescence measurements.

The weight of phosphorus deposited was also determined in this way. The dependence of the weight of phosphorus deposited on the total weight of the deposits is shown for the deposits from both solutions in Fig. 2. It can be seen from this plot that there is no apparent change in per cent phosphorus (within the precision of the data) over this thickness range. The average phosphorus content obtained from the slope of the plots of Fig. 2 is 5.8 ± 0.35% and 5.0 ± 0.2% for the deposits from the sulfate and chloride solutions, respectively.

Assuming a density similar to bulk cobalt of 8.9 g/cm^3, these films cover a thickness range from 200 to 5000Å.

The structure of the films was examined by x-ray diffraction, and was found to be hcp, with crystallite

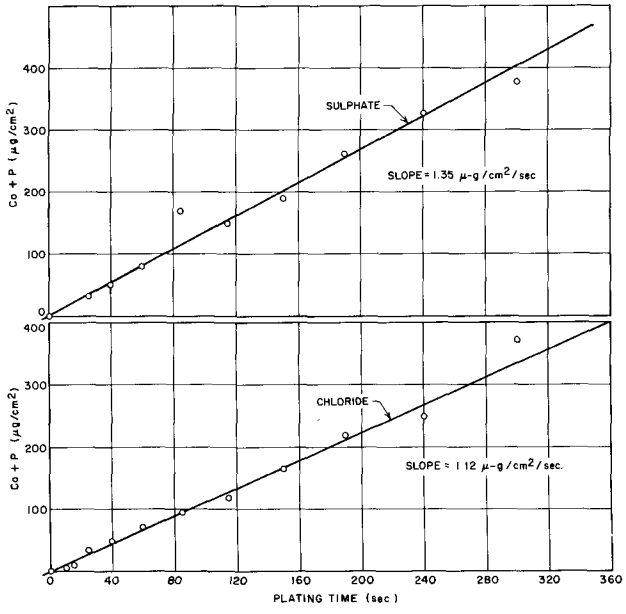

Fig. 1. Weight of deposits vs. plating time.

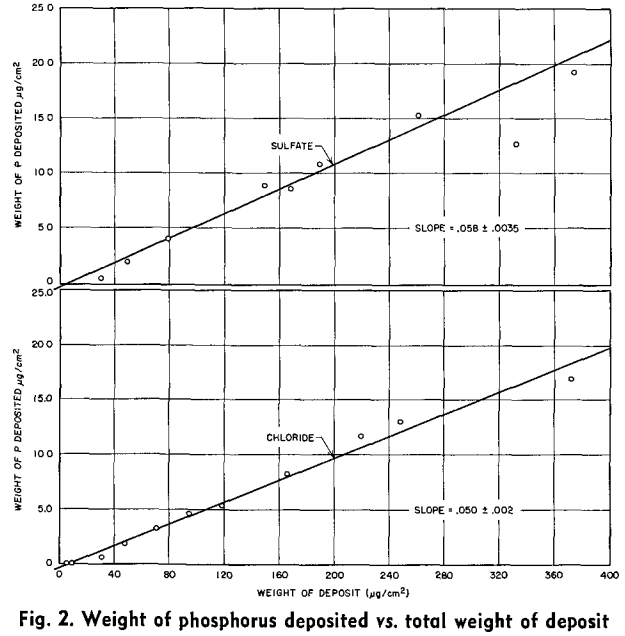

Fig. 2. Weight of phosphorus deposited vs. total weight of deposit

size ranging from 200 to 700Å. This technique gave no evidence of the whereabouts of the phosphorus.

The films had a residual compressive stress of ~20,000 psi. This stress was estimated from the curvature of a sample with plating on only one side (4).

Magnetic Properties

Magnetic measurements were performed using a vibrating sample magnetometer and a very sensitive torsion balance magnetometer (5). The variation of coercivity with thickness is shown in Fig. 3; both curves rise quickly from zero to a maximum coercivity at a thickness of 600-700Å, and then decrease more gradually, tending to a constant coercivity of approximately 400 oe at very large thicknesses. Referring to Fig. 3, we distinguish three different regions of the dependence of coercivity on thickness. Region a (less than 200Å) is dominated by a large number of superparamagnetic regions, resulting in coercivities increasing rapidly with increasing particle size. Region b (300-1000Å) is characterized mostly by a single domain region with very high coercivity. It is interesting to note that this thickness range corresponds to the size of the crystallites. Finally, region c (>1000Å) corresponds to the growth of multidomain regions. Further support to this interpretation can be derived from Fig. 4, where the ratio of remanent to saturation moments is plotted as a function of the thickness of the deposit. In region a, one would expect very low squareness due to the presence of superparamagnetic regions. Region b is characteristic of individual single domain regions with increasing interactions. Finally, region c, with relatively high squareness, is characteristic of strongly coupled and multidomain areas.

The magnetic moment density of the deposits was found to be 111 emu/g for samples prepared in the sulfate bath, and 116 emu/g for samples prepared in the chloride bath, and independent of the thickness of the deposit. The calculated magnetic moment densities, assuming the phosphorus to exist in the films as the nonferromagnetic Co_2P, were 120 emu/g and 125 emu/g for the films from the sulfate and chloride baths, respectively. The discrepancy between the measured and calculated values of the magnetic moment of the deposits may be attributed to the presence of some cobalt oxide or an amorphous cobalt phase (6).

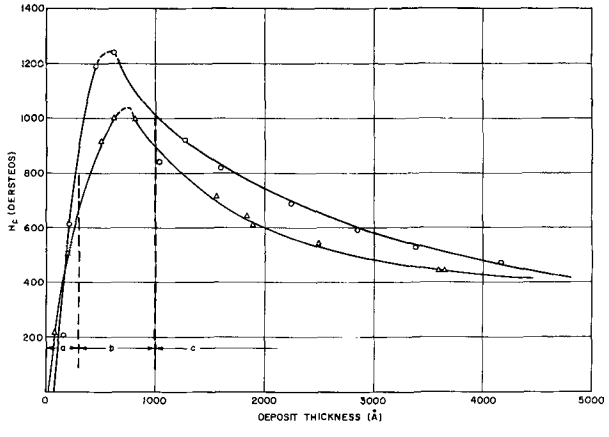

Fig. 3. Coercivity *vs.* thickness; △, chloride; ○, sulfate

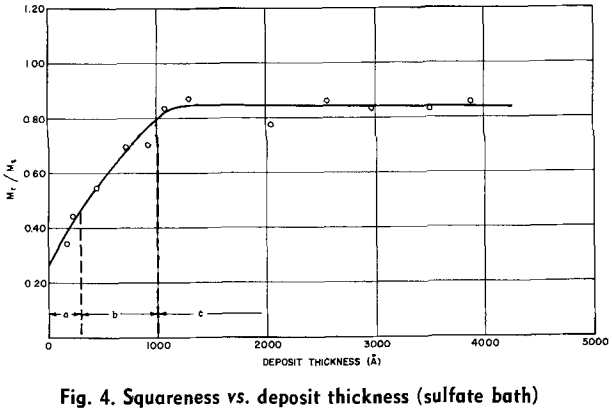

Fig. 4. Squareness *vs.* deposit thickness (sulfate bath)

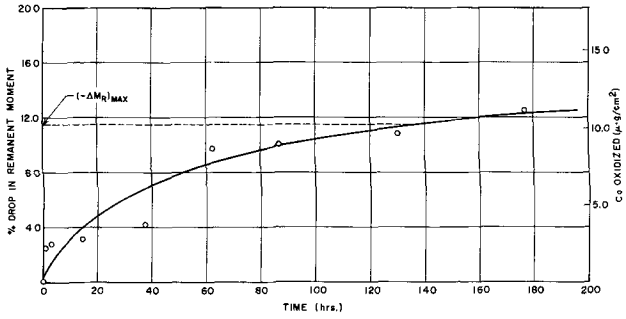

Fig. 5. Per cent decrease in remanence with time due to corrosion

Corrosion Behavior

The corrosion behavior of these deposits was followed by periodically measuring their magnetic moments as they were exposed to high humidity and temperature. Apparently, because of the thinness of these films, and their consequently high surface to volume ratio, relatively large percentage changes in their magnetic moments occurred

A torsion balance magnetometer (5) was used in these studies This instrument had the necessary sensitivity for measurements of small changes in remanent moment. Sensitive measurements of saturation moments were too time consuming to obtain and since there was no apparent change in squareness with corrosion and since the greater sensitivity of the torsion balance was necessary, all the corrosion data are based on changes in remanent moments

The sample used was a disk of 1 cm diameter. These disks were placed in a constant temperature-humidity cabinet and periodically removed for measurements of M_r.

Ten samples plated in an identical manner to a nominal thickness of 1000Å were subjected to this test at 43.5° ± 1.5°C and 80 ± 5% relative humidity. A typical curve of per cent drop in remanent moment *vs.* time is shown in Fig. 5.

The remanent moment, M_r, is related to the amount of ferromagnetic (unoxidized cobalt) by the following relationship

$$M_r = Sq.\ M_s$$

where M_s is the saturation moment of the sample and $Sq.$ the squareness of the sample.

$$M_s = \sigma_s\left(\frac{W}{A}\right)A = \sigma_s\, XA$$

where W is the weight of unoxidized cobalt, A the

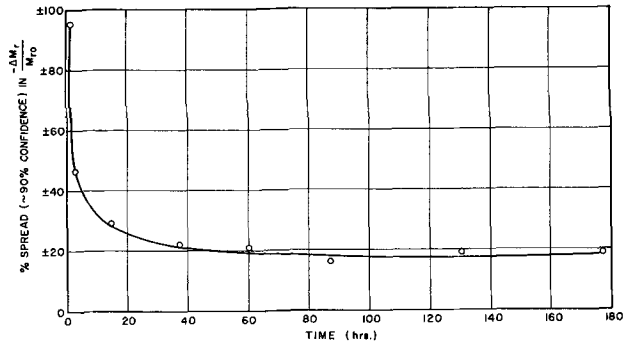

Fig. 6. Per cent deviation from the average change in ten samples

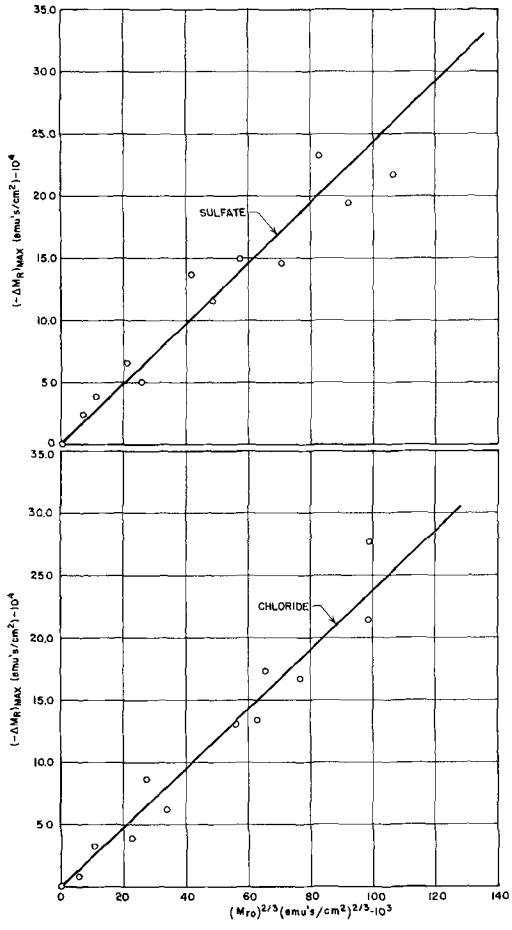

Fig. 7. Dependence of extent of corrosion on initial moment

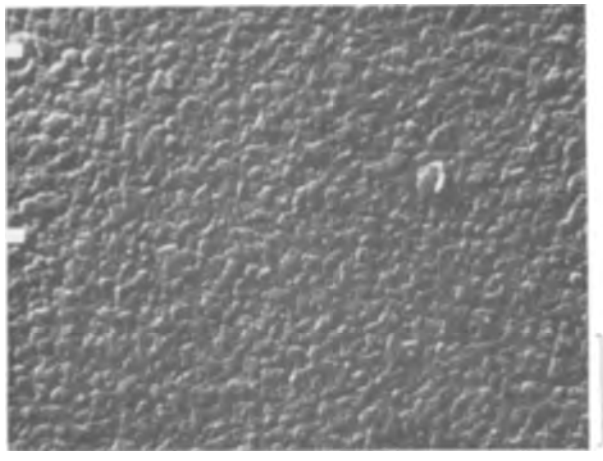

Fig. 8. Electron micrograph of electroless cobalt on Mylar

area of the sample, $X = W/A$, σ_s the saturation moment per gram

$$M_r = Sq.\ \sigma_s XA$$

$$\text{or the fraction of cobalt oxidized} = \frac{-\Delta X}{X_o} = -\Delta M_r/M_{ro}$$

then $-\Delta X = -\Delta M_r X_o/M_{ro}$ = weight per unit area of cobalt oxidized. The weight per unit area of oxidized cobalt for the 1000Å film has been indicated on the right hand ordinate of Fig. 5.

The reproducibility was evaluated by plotting the per cent spread (90% confidence level) in the value of the percentage corrosion as a function of time. This is plotted in Fig. 6; it shows that "identical" samples level out to within ±20% of the same final value of

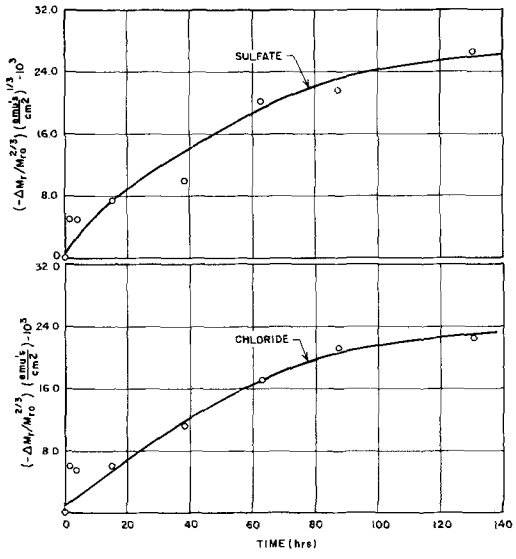

Fig. 9. Corrosion *vs.* time; temperature, 43.5°C; relative humidity, 80%.

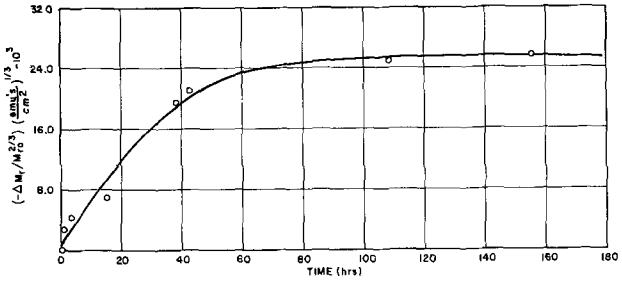

Fig. 10. Corrosion *vs.* time; temperature, 65°C relative humidity, 80%.

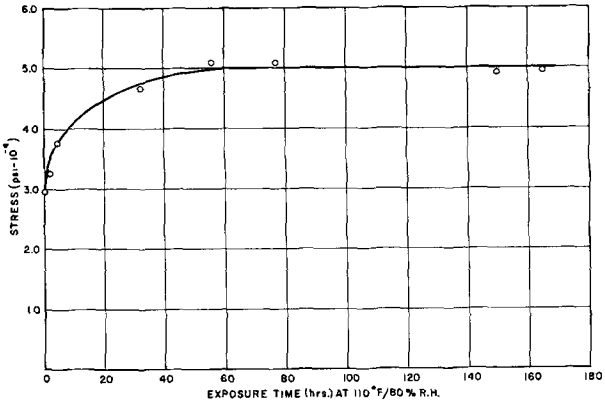

Fig. 11. Deposit stress *vs.* corrosion time

corrosion. The necessity of considering the average behavior of a number of samples is apparent.

When the two thickness series previously described were subjected to these conditions (43.5°C, 80% R.H.), it was found that the change in remanent moment increased with increasing thickness. This effect is particularly apparent, considering only the maximum drop in remanent moment after sufficiently long exposure (*i.e.*, a value at times greater than 100 hr; for these purposes $(-\Delta M_r)_{Max}$ is $-\Delta M_r$ after 140 hr exposure, see Fig. 5). The dependence of $(-\Delta M_r)_{Max}$ on sample thickness was found to best fit an $M_{ro}^{2/3}$ dependence. This dependence is shown in Fig. 7 for samples from both solutions. This dependence would result if the film were composed of hemispherical clumps

the surface area of which increased as the 2/3 power of their thickness. Electron micrographs of similar samples lend support to this interpretation (see Fig. 8).
