The Forming Process in Nickel Positive Electrodes

Donald Tuomi

ABSTRACT

A detailed study has been made of the phases produced and their geometric distribution during formation of Edison-type tubular positive nickel electrodes. The initial charging in lithiated KOH electrolytes converts the $Ni(OH)_2$ to a beta phase having a solid solution range for di- and tetravalent nickel. The beta crystalline structure is related to $LiNiO_2$. This phase can be further oxidized to alpha phase, a tetravalent nickelate having appreciable trivalent nickel solid solubility. Alpha phase is most readily formed during $Ni(OH)_2$ oxidation in concentrated KOH or NaOH electrolytes, but does not form in LiOH electrolytes. The addition of LiOH to the battery electrolyte contributes to alpha phase discharge and limits alpha phase reformation. The contribution of alpha phase to electrochemical capacity is limited by a low effective exchange current as compared to the beta phase.

In the production of commercial storage batteries, electrode plates are generally given a particular electrolytic processing to bring the active materials into a suitable state of electrochemical activity. This process of improving the electrical capacity of a battery is described as "forming."

The forming process produces an active material composition and spatial distribution within the electrode which can be efficiently charged and discharged. Though this may be one of the simplest steps in the manufacturing operation, it is one of the most complex processes to describe from the viewpoint of physical and chemical theory. The contributing variables include the chemical constitution of the active phases, the electrolyte composition, the ionic and electronic equipotential surface distributions, and the detailed crystalline structures generated in the electrode, as well as the spatial distribution of the active material volume changes during the forming cycles.

Several facets of this art are illustrated by data accumulated during a microscopic and x-ray diffraction examination of experimental Edison tubular positive nickel electrodes at various stages of formation. The study provides insight into the complex mechanisms contributing to the electrode behavior.

The presentation is given in an evolutionary form. After first describing the basic experimental techniques, the discussion turns to the distinct chemical phases encountered during the electrochemical processing of the nickel hydroxide. This is followed by a description of the changes encountered during the oxidation-reduction cycles. The fundamental problems to be solved in developing an accurate physical model of the electrode are considered in the discussion.

Experimental Procedures

The electrode-forming process was investigated by using experimental Edison positive tubular electrodes (1a). The ¼ in. diameter, perforated-wall, nickel-plated steel tubes were packed with alternate layers of nickel hydroxide and nickel flake. The electrodes were mounted in individual nickel-plated steel frames and placed in individual plastic test cells containing nickel plate counterelectrodes. The test cells were filled with 180 cm^3 of mixed electrolyte: 4.3*N* KOH-1.0*N* LiOH. Neither the composition or quantity of electrolyte corresponds to those used in the Edison nickel-iron alkaline cell. The individual electrodes contained 9g of nickel hydroxide, $Ni(OH)_2$. During processing, the water level in the cells was maintained so that the experimental results were characteristic of the nominal electrolyte composition.

During the normal operations, the experimental cells were connected in series to a controlled current d-c power supply. A stepping-switch voltage-monitoring system[1] was used to indicate when the discharge voltage on a cell exceeded 1v *vs.* the sheet nickel electrode. At this stage the cell would be shunted out of the circuit. This discharge voltage limit is equivalent to discharging an electrode to the sharp potential decrease at the limiting ampere hour capacity, *i.e.*, the knee of the discharge curve.

When desirable, the electrode potential was recorded as a function of time, utilizing as a reference electrode a divalent-trivalent state, well-aged (1 year or longer), Edison tubular positive mounted in a tube attached to a Luggin capillary. This reference electrode had been processed and aged in the same electrolyte composition used in the experiment. Thus the recorded potentials directly measure the deviations in the potential distribution between the experimental electrode and the relevant reference electrode state. The reference potential corresponds to the electrode existing in an equilibrium state with respect to $Ni(OH)_2$-beta phase transformation.

After electrochemical processing the electrode was removed from the electrolyte into the laboratory atmosphere. No effort usually was made to wash the active materials with water; the small amount of electrolyte in the porous structure is quickly transformed to potassium carbonate as is shown by x-ray diffraction examination. There was no significant decomposition of trivalent nickel in this process. Because of the unique layer structure of the Edison electrode the active material could be readily separated from the nickel flake simply by passing the ground mixture through a magnetic field.

The active materials at various stages were characterized by microscopic examination and by x-ray powder diffractometer patterns. The x-ray data were obtained using a G.E. XRD3 spectrogoniometer with copper K_α radiation. The powder samples were prepared by mounting the tube in a lathe and drilling equal volume concentric samples. After flake removal, the samples were used to determine the tube x-ray diffraction patterns and chemical composition as a function of the radius.

The nickel valence state in the active material was determined by reaction with standard arsenious oxide solution followed by back titration of the excess reagent with standard $KMnO_4$. The nickel, subsequently was determined gravimetrically with dimethylglyoxime and the nickel valence state was calculated Samples were not washed free of alkali since this generally caused a slight decrease in the valence state, as well as decreasing the analyzed nickel content of the sample.

Nickel Oxide Phases

In the following sections the relevant observations are summarized regarding the di-, tri-, and tetravalent nickel phases encountered during the electrochemical oxidation and reduction of Edison tubular positive electrodes. This electrode is particularly suitable for this study since the physical state of the initial phase packed into the electrode can be controlled independently and the processed material can be subject to detailed examination independent of the electronic conductor matrix.

This phase of the investigation showed that three distinct nickel phases are encountered in KOH and mixed LiOH-KOH electrolytes. The discharged state is a nickel hydroxide $Ni(OH)_2$, and the charged phases include a trivalent nickelate-beta phase and a tetravalent nickelate-alpha phase.

Divalent nickel phase.—The divalent nickel hydroxide, $Ni(OH)_2$, is generally accepted as the discharged state for the nickel electrode. The phase, however, has a variable crystalline structure dependent on the preparative procedure. The phase can vary from a highly crystalline material to a turbostratic structure layer lattice, as in the thin films studied by Wynne-Jones, to a practically amorphous freshly precipitated hydrous material as illustrated in Fig. 1. Corresponding to variations in the nickel hydroxide crystallinity changes may occur in the chemical composition (1b).

For this study the starting material is a stoichiometric nickel hydroxide prepared by spraying $NiSO_4$ solution into tanks containing a hot NaOH solution. The precipitated nickel hydroxide is collected and dried. After the impurities of sodium hydroxide, carbonate, and sulfate are removed by leaching with hot water, the nickel hydroxide is dried again. The major constituent is a well crystallized $Ni(OH)_2$, as shown by the x-ray diffraction pattern in Fig. 2. The crystallite size is in the 1000Å range as shown by diffraction line half-breadth measurements at half-maximum intensity. There is no marked difference in the crystallite "a" or "c" direction dimensions. It is not an amorphous phase, and the diffraction lines are characteristic of the $Ni(OH)_2$ structure. The compound can be classed as an electrical insulator. To a very large extent the crystallite size of the discharged state $Ni(OH)_2$ was controlled

by the initial crystallite size. The oxidation-reduction cycle conditions did not produce rapid reconstructive transformations of the $Ni(OH)_2$ lattice during beta-$Ni(OH)_2$ cycling. This does not imply, however, that the $Ni(OH)_2$ discharge state represents an ideal precisely stoichiometric material. Rather, the solid phase should represent some solid solution bound for the electrolytic system under examination.

Trivalent nickel phase.—The electrochemical oxidation of nickel hydroxide in an alkaline electrolyte based on KOH as the major component produces a trivalent nickel-containing phase which has a unique diffraction pattern. Glemser and Einerhand (2) introduced the designation β-NiOOH ($Ni_2O_3 \cdot H_2O$) for this oxidation product. Considering the structural and chemical properties outlined below, a more appropriate name for the trivalent nickel oxide is "beta" phase, without assigning a particular chemical formula.

If the well-crystallized nickel hydroxide is electrochemically oxidized to the trivalent state in 2M NaOH, or 2M KOH, or 5M LiOH at room temperature for 96 hr at 0.25 amp, the product obtained is characterized by the x-ray diffraction pattern shown in Fig. 3. The in-

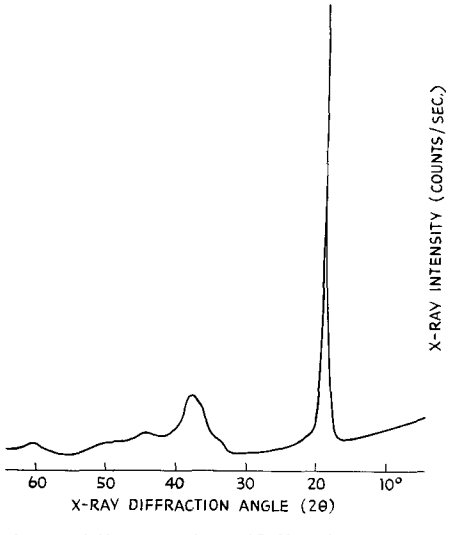

Fig. 3. X-ray diffraction data (CuK_α) for the first oxidation product obtained during crystalline $Ni(OH)_2$ electrochemical oxidation in 2M KOH or NaOH or 5M LiOH at room temperature.

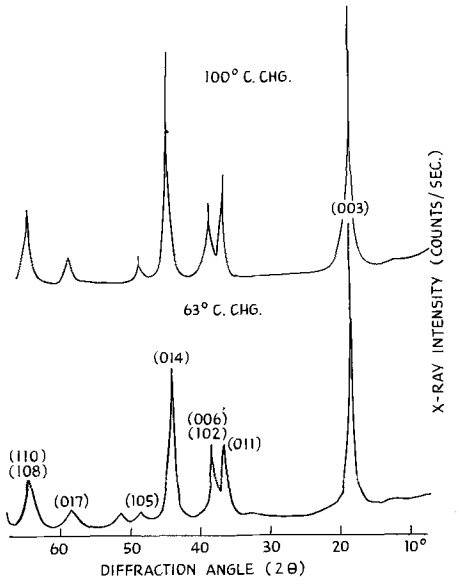

Fig. 4. X-ray diffraction data (CuK_α) for the oxidation product formed during the electrochemical oxidation of crystalline $Ni(OH)_2$ in 5M LiOH at 63° and 100°C.

tense diffraction line at 19° is practically coincident with the $Ni(OH)_2$ (001) plane reflection. This coincidence has led to the description of the $Ni(OH)_2$ oxidation as involving a simple removal of protons from the lattice corresponding to a continuous series of solid solutions from the di- to the trivalent states (3). The reaction within this framework would not be viewed as a conventional two-phase transformation process. It should be emphasized that the x-ray diffraction pattern of beta phase did not change significantly if the oxidation product was first examined wet as formed or after air drying without washing to remove the electrolyte. The nickel valence state in beta phase varied from 2.90 to 3.08.

Insight into a structural description of beta was provided through a study of the electrochemical oxidation of the $Ni(OH)_2$ in hot 5M Li(OH) electrolytes. At 63° and 100°C the oxidation product from crystalline $Ni(OH)_2$ is a well-crystallized trivalent nickel compound as shown in Fig. 4. This diffraction pattern can be related to the $LiNiO_2$ crystalline structure (4) as shown in Table I, rather than to $Ni(OH)_2$. The degree of ordering in the beta phase structure or the crystallite domain size is dependent on the electrochemical oxidation conditions, *i.e.*, electrolyte composition, temperature, and the cycling conditions including current density, cycle number, open-circuit times, and cycle depth.

Chemical analyses of the beta phase from the LiOH electrolyte showed a Li/Ni mole ratio of 0.40 for the low-temperature material unwashed compared to 0.72 for the more crystalline high-temperature material. The corresponding nickel valence states were 3.07 and 2.97. Thus, during the LiOH anodic oxidation of the nickel hydroxide significant amounts of electrolyte cation diffuse into the crystalline solid in apparent opposition to the applied electric field.

The chemical analyses of beta phase indicated that a unique chemical stoichiometry could not be assigned. Applying the electrical neutrality boundary condition on the chemical analyses for nickel, alkali, and carbonate ions indicated that virtually an anhydrous oxide phase was involved. Washing as-formed beta phase with water resulted in an extraction of alkali ions and a decided reduction in the total nickel content, *i.e.*, an increase in the water content. The phase has zeolitic exchange characteristics.

The x-ray diffraction peaks for beta phase can be assigned indices on the basis of the $LiNiO_2$ crystalline structure as shown in Fig. 5. Chemically beta phase is more appropriately described as a trivalent nickelate rather than as a trivalent nickel oxide. This beta phase is a low electrical resistivity, 1 ohm-cm or less, n-type semiconductor as indicated by thermoelectric power measurements, rather than the low electrical resistance p-type phase encountered in the lithium doped nickel oxides (5). Thermal decomposition results in the conversion of the n-type compound to a p-type phase. It should be recognized that the lithium-doped p-type NiO solid solutions have only a superficial electrochemical activity.

A rather direct comparison of the beta phase to the trivalent nickel products obtained by various oxidation procedures is given by the x-ray diffraction patterns summarized in Fig. 6. The logarithmic x-ray intensity data were obtained under conditions comparable to Fig. 1, whereas the linear x-ray intensity data are scaled to the same base used for the other patterns. The trivalent oxides prepared by chemical procedures are essentially amorphous. The Haissinsky thin film-anodic deposition oxide is identical to the material extensively studied by Wynne-Jones and associates (6). This oxide phase clearly is distinctly different from the beta phase oxide obtained during anodization of a well crystallized

$Ni(OH)_2$. The general diffraction characteristics are consistent with the observations reported by Briggs and Wynne-Jones (7).

In summary the trivalent nickel crystalline structures depend markedly on the preparative techniques and on the starting material characteristics. For a given set of conditions reproducible products are obtained. For the electrochemical oxidation of crystalline $Ni(OH)_2$ a characteristic trivalent nickel material x-ray diffraction pattern is obtained. The material is best described as a trivalent nickelate conveniently designated as beta phase.

Tetravalent nickel.—At the T. A. Edison Research Laboratory in 1956, D. M. Meter and C. Y. Li discovered that prolonged oxidation of the trivalent beta phase in porous plaques resulted in the appearance of a new phase characterized by an intense x-ray powder diffraction line at 7.08Å (12.5° 2θ) replacing the intense beta phase line at 4.7Å. In previous survey studies on tubular, positive electrodes this 7.08Å line (the lowest diffraction angle line) had been designated as a measure of the concentration of an alpha phase. It now became obvious that the new phase, alpha, forming as an oxidation product from trivalent beta must involve tetravalent nickel. Further experimentation demonstrated that crystalline nickel hydroxide is readily oxidized at room temperature to alpha if very concentrated KOH or NaOH electrolytes are used.

The alpha phase is characterized by the x-ray diffraction pattern shown in Fig. 7. This pattern is characteristic of the products formed in greater than 4M KOH and NaOH. At lower alkali concentrations the overvoltage relationships with respect to oxygen evolution limit the extent of alpha formation.

Chemical analyses were performed on alpha phase prepared under various conditions. In the first study a set of tubes packed with crystalline $Ni(OH)_2$ was charged for 17 days at 125 ma [19 Faradays/mole $Ni(OH)_2$] in three different electrolytes. The products were washed free of nickel flake using the forming electrolyte, rinsed quickly with water, and dried in a desiccator. The observed valence states were as follows:

Electrolyte	Nickel valence
45% KOH	3.34
45% KOH saturated with LiOH	3.36
4.3*N* KOH plus 1.0*N* LiOH	3.22

The three products had practically identical x-ray diffraction patterns.

A second group of electrodes was charged for 160 hr at 125 ma in 45% KOH, 7.4 Faradays/mole $Ni(OH)_2$. The oxidized product had a very distinct gray metallic luster, a graphite appearance. This new phase had a much greater volume than the original $Ni(OH)_2$ or beta phase, thereby causing either electrode distortion or an ejection of the material through the tube perforations into the electrolyte. The valence state of the nickel varied with the material processing as follows: (*a*) the ejected gray metallic luster paste wet with 45% KOH, a 3.34 valence; (*b*) the tube product washed rapidly with water by decantation while magnetically separating the nickel from the liquor, followed by drying at room temperature, a 3.44 valence; (*c*) centrifugal separation of a dispersion of alpha in 45% KOH, followed by room temperature drying, a 3.48 valence. The initial alpha phase obtained immediately after removing the electrode from the circuit reacted very vigorously with alcohol; but the samples dried for analysis reacted comparatively slowly. Furthermore, the initial gray metallic luster had been replaced by a distinctly black appearance. Consequently, it appears certain that the valence of 3.48 is appreciably less than is possible for alpha at the end of electrolysis. On the other hand, the valence state of alpha could be reduced to practically 3.0 without producing significant changes in the x-ray diffraction pattern for alpha phase.

The chemical composition of alpha phase formed in a 45% KOH electrolyte was as follows: 50% Ni, 17% K, and 33% O, OH. Assuming all the nickel is present in the tetravalent form, the formula $K_{0.5}Ni_{1.0}O_{2.0}(OH)_{0.5}$ or $(KOH)_{0.5}NiO_2$ satisfies the electrical neutrality requirement corresponding to 16.5% K^+, 49.4% Ni^{+4}, 27% O^{-2}, and 7.1% OH^-.

For the 45% KOH electrolyte the K/Ni mole ratio for alpha phase was 0.412; but in the mixed electrolyte 4.3*N* KOH with 1.0*N* LiOH the K/Ni mole ratio was 0.237 and the Li/Ni ratio 0.0915. The quantities involved do not correspond to simple mole ratios.

The x-ray diffraction data for the alpha phase can be related to the results reported by Glemser and Einerhand (8) for γ-NiOOH as shown in Table II. The γ-NiOOH was obtained by reacting $NaNiO_2$ or $KNiO_2$ with water or by reacting their β-NiOOH with Na_2O_2. This γ-NiOOH phase could be readily oxidized to a +3.48 valence by hypobromite.

Alpha phase is readily formed only during prolonged anodization of $Ni(OH)_2$ in concentrated alkali containing K or Na cations, and only if the nickel has been oxidized through beta phase. The material is more appropriately described as a tetravalent nickelate within which trivalent nickel has appreciable solid solubility. An empirical formula describing this condition is

$$M_2 Ni^{+3}{}_{2(1-y)} Ni^{+4}{}_y O^{-2}{}_{4-y}$$

where M is a monovalent cation including H^+ or H_3O^+ along with the large atomic radius K^+ and Na^+ ions and y varies from 0.5 to an upper limit of 1.0. The phase designation "alpha" is preferable to the γ-NiOOH notation since it does not convey prejudices regarding the detailed chemical composition. This is analogous to the γ, δ, etc., notation applied to the MnO_2 electrochemically active materials. The alpha phase, as noted by Glemser and Einerhand, has a laminar structure.

Electrode Formation

Now consider the phenomena encountered during the formation of an Edison tubular positive electrode. This electrode can be visualized as a sandwiching of nickel flake and nickel hydroxide layers in a perforated tube. The nickel flake forms the electronic contact from the nickel hydroxide to the tube walls while the perforations in the tube walls provide ionic access between the porous bed-granular nickel hydroxide and the electrolyte.

First consider the direct observation of the initial charge process, then the effect of cycling on the microstructure and the x-ray diffraction effects, and finally, the electrochemical properties of the formed electrode.

Direct microscopic observation.—The initial study of the forming process involved the direct microscopic observation of the nickel hydroxide oxidation. The tube wall was carefully ground from a section of the tube exposing the edges of several layers. After mounting in a sample holder frame the electrode was immersed in the electrolyte. A binocular microscope was used to observe the changes produced during cycling.

The exposed surface of $Ni(OH)_2$ lamellae presented a distinct gray-green granular structure, having both a variable grain size and density distributed between nickel flake layers. The particles ranged from loose open-pore aggregations to dense green microporous grains, showing conchoidal fracture characteristics.

During electrode oxidation at the half normal rate, 125 ma/tube a series of changes was visible. The average behavior corresponded to the oxidation front (formation of black oxide) migrating from the metal contact surfaces into the hydroxide layer. The migration rate was fastest at the periphery near the nickel plated tube contact to the nickel flake and slowest in the center of the exposed layer.

During a 48 hr charge period in the lithiated electrolyte the green layer progressively changed to a distinctly black oxide beta phase which was gradually converted to a distinct gray metallic luster nickelate phase, alpha. Probing the oxidized surface with a needle showed that the brittle divalent nickel hydroxide phase had been transformed into a deformable, more or less plastic layer.

Several unusual phenomena were observed during the oxidation. The more dense, translucent green $Ni(OH)_2$ particles were the most difficult to oxidize. However, numerous isolated dense particles, even several located the maximum distance from the electronic current tap, were immediately oxidized to the black phase. Other grains showed a distinct transitional behavior, suggesting an initial rapid surface oxidation, followed by a slower bulk process.

The easily oxidized grains probably contained excess alkali incompletely removed during normal production processing. The excess alkali would decrease the local electrochemical potential required for the oxidation reaction. In the more slowly oxidized grains several parameters appeared to be rate-controlling. The very low porosity grain structures had a limited electrolyte accessibility. In the extremely porous, high-surface area structures secondary adsorption exchange processes within the porous bed or local reactions of alkali with adsorbed materials could slightly shift the electrochemical potential distribution. Finally, some grains did not appear to have good electronic contact with the substrate. This did not appear to be a major limiting variable, perhaps because the oxidized phases are good electronic conductors and only a small area contact is sufficient to provide adequate electronic conductivity.

Oxygen evolution during charging appeared to occur from the alpha phase surface. This gas evolution on a peripheral phase automatically serves to limit the extent of oxidation in the interior of the layer. During open-circuit stand, gas evolution was predominantly from interior void structure. The electrochemical couple contributing to oxygen evolution depended on internal local cell action. Within the close packed porous bed structure gas bubble formation was restricted by capillarity; the surface tension forces contributed to increased gas solubility as well as to controlling the gas bubble flow path out of the porous bed through the coarsest pore structure.

Metallographic and x-ray diffraction studies.—The extensive confounding of variables evident in the first observation of the formation led to a detailed metallographic and x-ray diffraction study of formation. The initial survey studies showed that the x-ray diffraction patterns of "air dried" active materials were not significantly different from freshly formed products.

For this second study a number of tubular electrodes were processed to various stages of formation under controlled charge and discharge conditions. Samples were periodically removed for detailed metallographic examination and for x-ray diffraction characterization.

The metallographic structures originally photographed in color by B. Bastian are illustrated by black and white prints in Fig. 8. The photographs span the central radial cross section from the tube center to the periphery (= ⅛ in.). The nickel flake is distributed in an approximate layer configuration.

Within the unformed tube, Fig. 8a, the nickel hydroxide shows the two extreme forms: (*a*) translucent green dense grains and (*b*) white or very pale green low-density grains. All gradations between these extremes can be found. More or less gray-black grains result from the crushing of dark blue-gray to black particles observed in the pure $Ni(OH)_2$. These grains apparently had a trace of surface thermal decomposition to NiO during drying.

After 4 hr charge at 125 ma, 1/12 the first cycle input or 0.2 Faraday/mole Ni, the structure appeared as

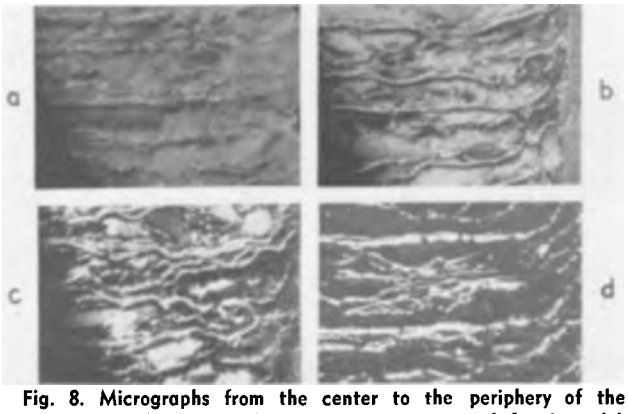

Fig. 8. Micrographs from the center to the periphery of the tubular electrode (right edge) at various stages of forming: (a) initial $Ni(OH)_2$ layer; (b) after 4 hr charge at 125 ma; (c) after 8 hr; and (d) after 48 hr.

shown in Fig. 8b. The black oxidized phase observed earlier formed at metal-electronic contact and migrated into the active material. The reaction is not restricted to the periphery of the tube only, but extends to the center of the electrode. As noted earlier, some interior grains quickly oxidized to the dark black form. In several regions the stereo-microscopic examination indicated that a thin superficial oxide penetrated into a porous grain, but that the electrochemical oxidation did not proceed rapidly into the crystallite interior. At this early stage the x-ray diffraction data indicated a progressive transformation of nickel hydroxide to beta phase from the periphery to the center of the electrode. This, obviously, was a statistical average behavior.

After 8 hr charge the uncharged $Ni(OH)_2$ distribution corresponded to Fig. 8c. Dense as well as porous green grains were present in both oxidized and unoxidized forms. The migration of the phase transformation front into the layers was apparent throughout the tube.

After 24 hr charge at 125 ma, 1.1 Faradays/mole Ni, the green $Ni(OH)_2$ had disappeared as shown in Fig. 8d. The granular characteristics of the layer were no longer evident, but probing with a needle revealed the presence of particulate structure in the layer. At this stage x-ray diffraction data as a function of tube radius showed that only slightly more than half the $Ni(OH)_2$ had been oxidized to beta phase. Thus, a surface oxidation had proceeded rapidly to a diffusion-length depth in the crystallites contacting the electrolyte. The absence of significant $Ni(OH)_2$ line broadening implied that below a certain size oxidation proceeded rapidly. As the reaction progressed the individual small crystallites were removed, a small fraction at a time, so no net broadening of x-ray diffraction lines was readily discernible.

The 24 hr charge was midway through the first charge cycle. At this time the peripheral region x-ray diffraction patterns showed that alpha phase was beginning to form from the beta phase though a considerable fraction of unoxidized $Ni(OH)_2$ was distributed throughout the tube.

Extending the charge to 48 hr at 125 ma, 2.2 Faradays/mole Ni, does not significantly alter the microscopic structure. The general shading of the black active material becomes more metallic. However, as shown by the x-ray diffraction data in Fig. 9, substantial conversion of beta to alpha phase was occurring in the peripheral half while appreciable $Ni(OH)_2$ was still present within this region of the electrode. The increase in active material volume during alpha phase formation should effectively reduce the local current density on the central volume of active material. Although a distinct grain structure still was present, the more highly charged material appeared to be more plastic during sample processing.

During the first discharge cycle the electrode delivered 0.6 Faraday/mole Ni. The active material changed to a

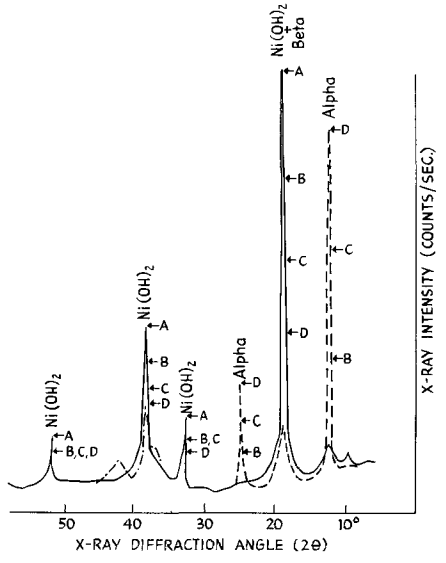

Fig. 9. X-ray diffraction data for concentric volumes of active material after first formation cycle 48 hr charge at 125 ma: (A) center quarter; (B) second quarter; (C) third quarter; and (D) peripheral quarter.

distinctly granular solid, losing its metallic luster. Both beta and $Ni(OH)_2$ appeared to be more or less hard crystalline solids. The x-ray diffraction data showed that at the normal rate only a portion of the alpha phase was discharged. The green nickel hydroxide was not recovered as a discharge product, rather the material was distinctly black in the discharged state. Re-oxidation again formed the more plastic lighter luster active material.

After several additional forming cycles in the lithiated electrolyte the nickel hydroxide was fully oxidized to beta phase. Simultaneously, the amount of peripheral alpha phase steadily decreased, both after charge and discharge. In the charged state the active material had a very high electronic conductivity in the range of 1 ohm-cm^{-1}. By contrast, the discharged phase was an electrical insulator, containing a large number of defect sites having strong optical absorption in the visible spectrum.

After the forming process was completed in the lithiated electrolyte the electrode no longer contained a significant alpha phase component. The charged phase was beta. The electrode similarly cycled in a 5M KOH electrolyte contained an appreciable amount of alpha which was cycled during charge and discharge, as well as remaining as a distinct phase not readily discharged at the operational current densities.

Electrochemical behavior. — The electrochemical processing of the electrode in lithiated electrolytes results in a series of structural changes in the active material which are not directly evident in the electrochemical ampere-hour capacity measurements.

The electrochemical capacity data on the electrodes are summarized in Table III. From the capacity measurements alone no indications are obtained of the complex changes occurring within the electrode during cycling. Generally, an exceptionally large initial cycle

Table III. Electrochemical capacity during electrode processing through a set of forming cycles in 4.3*N* KOH 1.0*N* LiOH electrolyte

Cycle No.	Cycle condition	Amp-hr capacity
1	48 hr 125 ma	1.70
2	8 hr 250 ma, 15 hr 125 ma	1.68
3	8 hr 250 ma, 15 hr 125 ma	1.69
4	15 hr 250 ma	1.63
5	7 hr 250 ma	1.33
6	7 hr 250 ma	1.33

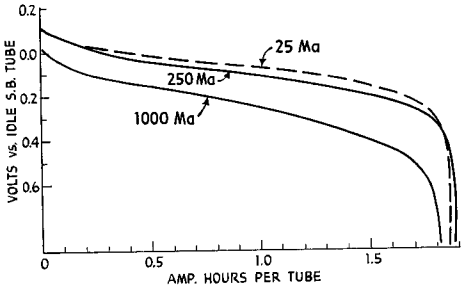

Fig. 10. Discharge potential vs. electrochemical capacity at 0.1, 1.0, and 4.0 normal discharge rates (25, 250, 1000 ma) after a 7 hr charge at 1½ normal rate (375 ma) for a tubular electrode fully formed in 4.3*N* KOH-1.0*N* LiOH electrolyte. Dotted curve obtained by subtracting initial polarization term from 100 ma curve.

capacity was associated with extensive alpha phase formation during charge along with a relatively efficient discharge.

An electrode formed in a pure KOH electrolyte did not show any drastic difference in capacity as compared to forming a lithiated electrolytes. However, on continued cycling the capacity tended to decrease as the amount of "floating" alpha phase increased. In a lithiated electrolyte the capacity remained stable or increased slightly as the efficiency of cycling beta phase improved and the last traces of alpha were eliminated. The electrode valence state during formation varied from slightly greater than 3.0 in the periphery to 2.5 to 2.7 in the center; but, after formation, the charged valence state was close to 3.0 throughout.

A fully formed electrode operating under equilibrated structure conditions in the 4.3*N* KOH-1.0*N* LiOH electrolyte shows a surprisingly small rate sensitivity of electrochemical capacity as illustrated by the potential-capacity curves in Fig. 10. This capacity at saturation charge corresponded to 0.71 Faraday/mole Ni output compared to normal rate condition delivering 0.5 Faraday/mole Ni. After correcting for the nickel valence state variation in the discharged electrode, this capacity corresponds closely to a 1.0 valence change in the active cycling material. Thus, the capacity of a cycling lithiated electrode after forming is complete corresponds to an oxidation reduction reaction between a trivalent and a divalent nickelate state. Extensive overcharge of the electrode formed in a lithiated electrolyte does not produce alpha phase. On the other hand, at the relatively low operational lithium concentrations the active material does not behave as a characteristic lithium nickelate in the charged state.

Discussion

The nickel hydroxide positive electrode is, inherently, a complex physical-chemical system. As yet, sufficient progress has not been made on the fundamental electrochemical theory to give a framework of logical simplicity within which to organize observations. On the other hand, only through attempts at data organization does there finally begin to evolve a description for the detailed structure presented within the functioning general electrochemical corrosion systems involving solid phases. The differences encountered between passive and active electrochemical systems are matters of degree, rather than differences involving fundamentally different conceptual frameworks.

With this in mind, now consider systematically various aspects of the functioning electrode. The over-all objective is to describe the three-dimensional system: electrolyte, phase I, phase II, and electronic contact. The discussion is conveniently divided into four areas: (*a*) the tetravalent oxide phase, (*b*) the nickel hydroxide phase transformation, (*c*) the gross electrochemical oxidation reduction process, and (*d*) the detailed kinetics problem.

Tetravalent nickel.—As noted by Falk (3) various formulas have been suggested for the charged materials in the nickel electrode. Generally speaking, excess electrochemical capacity beyond the trivalent state has been associated with a solid solution of tetravalent nickel in the trivalent oxide (9) although some have considered the excess capacity to be associated with adsorbed oxygen (10). General agreement that a distinct tetravalent nickel phase is not encountered in anodic oxidations has existed.

In this investigation a tetravalent nickel oxidation product, alpha phase, was obtained from a crystalline $Ni(OH)_2$ under particular experimental conditions. The alpha phase was readily formed during overcharge of the electrode in concentrated KOH or NaOH electrolytes. The degree of crystallinity of the alpha phase was determined by the crystallinity of the $Ni(OH)_2$. The ease of alpha phase formation increased with increasing alkali concentration and decreasing temperature. A further qualification was present, namely, that the system oxygen overvoltage had to be sufficiently high for an adequate driving voltage to be generated across the solid-electrolyte interface, space charge region to drive the oxidation reaction forward.

Although alpha phase has been undoubtedly encountered in many investigations, its existence as a distinct component was not readily recognized for several reasons. The phase is characterized by a significantly greater molar volume than the lower oxide phases; consequently, formation of the phase at the periphery of an electrode can restrict the oxidation of the interior phase. This can occur through a restriction of the ionic conduction into the interior as well as by the evolution of oxygen on the surface of alpha. A further complicating factor is the low effective exchange current for alpha phase. At the normal current densities it is not readily discharged to the divalent state. The presence of low oxygen overvoltage impurities in the systems can prevent alpha phase formation. Finally, the detailed crystalline form and prior processing of the active material may have provided a form which is not oxidizable to the tetravalent state.

The broad spectrum of solid-state structures encountered in the oxidation of nickel to the high valence states (ranging from amorphous to well-crystallized structure depending on the initial material) strongly implies that solution-precipitation processes are not significant factors in the reaction. The phase transformation cannot be viewed as simple proton migrations out of the $Ni(OH)_2$ lattice to form solid solutions, since the alkali cation is an essential component of the oxidized phase. The transport of large ionic radius cations into the crystal lattice during charge implies the presence of large ionic radius lattice imperfections comparable to K^+, OH^-, H_3O^+, and H_2O groups contributing to solid-state diffusional processes.

The metallic luster encountered in the most highly oxidized alpha phase implies a rather high density of conduction electrons in the n-type material. A detailed study of the electronic properties of the phase would be of intrinsic interest in the description of the electronic energy states of the nickel ion. A detailed charge and mass balance experiment involving the oxidation of green crystalline $Ni(OH)_2$ to the alpha phase form is needed to define clearly the chemical composition and nickel valence state limitations in the compound.

Trivalent nickel phase transformation.—Another area of confusion in the nickel electrode description is the form of the phase transformation in nickel hydroxide oxidation to the trivalent beta phase. Both Salkind (11) and Falk (3) consider the x-ray diffraction patterns in which some $Ni(OH)_2$ lines disappear and others appear as implying a solid solution phase transformation between $Ni(OH)_2$ and beta phase. On the other hand, Foerster (9) in 1907 considered the oxidation to proceed with the formation of a new phase, a solid solution of tetravalent nickel in a trivalent oxide. Briggs and Wynne-Jones (7) have shown that thin film nickel electrodes involve two distinct phases, a dis-

charged state, $Ni(OH)_2$, and a charged state designated NiOOH.

More recently, Conway and Gileadi (12) have found that a reversible potential is only obtained over a limited range of porous plaque oxidation in a KOH electrolyte, namely, 20-50% of the total charge capacity. They assumed that the potential was determined by a surface phase of constant composition superimposed on a bulk phase of varying degree of oxidation, but not potential determining. The possibility that the potential was characteristic of a two-phase system was considered unlikely because the transformation was viewed as a variation in the extent of solid solution oxidation. Furthermore, the kinetic data on electrode charging implied the existence of a surface phase intermediate in bulk phase charging.

The electrode potential dependence on the alkali and water activity can be used to determine a single electrode reaction equation (13). Unfortunately, such data have not been obtained for a broad range of experimental conditions. These data, however, have led to equations involving from 0.42 to 2.28 moles of water per mole of nickel oxidized. Generally, the alkali concentration dependence has been viewed as a KOH adsorption on the active material and not as an essential component of a crystalline solid.

Through the study of beta phase formation in different electrolytes at high temperature it was shown that in LiOH electrolytes a distinct crystalline phase could be obtained. This phase had the characteristic x-ray diffraction pattern of lithium nickelate. Thus, the observed coincidence of beta and nickel hydroxide x-ray diffraction patterns reflects a coincidence of $LiNiO_2$ and $Ni(OH)_2$ diffraction lines rather than showing a solid solution of trivalent nickel in the nickel hydroxide crystal lattice. The beta phase x-ray diffraction lines assigned by Glemser and Einerhand (8) as (001), (100), and (110) of β-NiOOH are, respectively, transformed to the (003), (006), (102) (011), and (110) (108) reflections in the $LiNiO_2$ structure.

The oxidation of nickel hydroxide produces a new phase, beta. The phase contains cations characteristic of the electrolyte, but not in stoichiometric quantities. Chemical analysis of beta phase produced under a variety of conditions showed a nickel valence range from 2.6 to 3.1. The phase was readily obtained as a single product during $Ni(OH)_2$ anodization in dilute KOH or LiOH electrolytes. The beta phase formed in NaOH electrolytes gave modified x-ray diffraction patterns suggestive of several distinct phases between the divalent and tetravalent states.

The observed variability of the beta valence state, as well as the limited range of charge state characterized by the reversible potential, can be partially explained by recourse to the observations made by Goodenough and associates (14). The chemical composition of lithium nickelate was shown to vary as

$$Li_x Ni^{+2}{}_{1-x} Ni^{+3}{}_x O$$

over a solid solution range $O < x \leq 0.3$ as cubic NiO, for $0.3 < x \leq 0.388$ as a hexagonal oxide, but for $0.388 < x \leq 0.5$ as rhombohedral $LiNiO_2$. Thus, the beta phase nickel valence state data can be made self-consistent if the compound involves a solid solution range for divalent nickel in a trivalent phase, as well as a tetravalent nickel in the trivalent nickelate.

This description of beta phase properties would explain partially the variability of the electrode potential characteristics during charge and discharge, as well as the anomalously large pseudocapacitance. When the active material exists in the solid solution state the electrode potential reflects the variation in the Ni^{+2} and Ni^{+4} ion activity in the Ni^{+3} lattice. The solid solution range will depend on the detailed conditions determining the solid solution free energy function, *i.e.*, the imperfections controlling the detailed trivalent phase crystalline structure.

For the electrochemical oxidation process a series of half-cell reactions can be written. The simplest case to consider is the oxidation of $Ni(OH)_2$ to a lithium nickelate solid solution saturated with divalent nickel, namely:

$$1.577\ Ni(OH)_2 + 1.0\ Li^+ + 2\ OH^- \rightarrow 2.577\ Li_{0.388}\ Ni^{+2}{}_{0.224}\ Ni^{+3}{}_{0.388}\ O + 2.577\ H_2O + 1.0\ e$$

or

$$1.577\ Ni(OH)_2 + 1.0\ Li^+ + 2\ OH^- \rightarrow LiNi^{+2}{}_{0.5773}\ Ni^{+3}{}_{1.00}\ O_{2.577} + 2.577\ H_2O + 1.0\ e$$

If a portion of the lithium sites are occupied by protons, then the oxidation reaction would correspond to an equation of the form

$$1.577\ Ni(OH)_2 + (1.0 - Y)Li^+ + (2 - Y)OH^- \rightarrow Li^+{}_{1-Y}\ H^+{}_Y\ Ni^{+2}{}_{0.577}\ Ni_{1.0}\ O_{2.5773} + (2.577 - Y)H_2O + 1.0\ e$$

Depending on the extent of H^+ substitution of Li^+, from 1.577 to 0.577 moles of H_2O may be formed per Faraday. The solid solution in equilibrium with the $Ni(OH)_2$ may be oxidized to a trivalent state as a single phase system according to the reaction

$$0.224\ Li^+ + 0.448\ OH^- + Li_{0.388}\ Ni^{+2}{}_{0.224}\ Ni^{+3}{}_{0.388}\ O \rightarrow 1.224\ Li_{0.5}\ Ni_{0.5}\ O + 0.224\ H_2O + 0.224\ e$$

For the lithium nickelate oxidation to an average valence of 3.1 the reaction could be written as

$$0.0984\ Li^+ + 0.1968\ OH^- + Li_{0.5}\ Ni_{0.5}\ O \rightarrow 1.098\ Li_{0.545}\ Ni^{+3}{}_{0.41}\ Ni^{+4}{}_{0.045}\ O + 0.0984\ H_2O + 0.0984\ e$$

As before, the substitution of protons for the lithium ion would diminish the net water evolved in the reaction.

The determination of the electrochemical reactions will require complex experimentation. The system mass balance should be determined as a function of the oxidation state. This requires an initial electrode impregnated or packed with a well-defined $Ni(OH)_2$ initial phase. The electrodes subsequently should be oxidized and reduced under controlled potential conditions in various composition alkaline electrolytes, using a combination of gas coulometry and electrolyte chemical analysis to establish the mass transport conditions.

The available data indicate that there are two distinct types of electrochemical oxidation-reduction reactions proceeding in the nickel positive electrode. One process is the transformation of phase A into phase B, the second, the oxidation-reduction of a component present in a solid solution single phase material.

Additive effects.—A long-standing puzzle has been the precise role of the lithium in the mixed KOH-LiOH electrolytes, which confers an increased capacity and a long life to the positive electrode (15). The increase in electrode potential observed with a lithiated electrolyte has been interpreted as an increase in the oxygen overvoltage permitting charge to higher nickel oxidation states (16). This hypothesis was substantiated by oxygen overvoltage measurements on nickel plates (17). From the electrode formation studies clearly a complex collection of phenomena accompany lithium addition to the electrolyte.

During formation in a mixed electrolyte both potassium and lithium ions move into the active material during charge and out during discharge. In a pure LiOH electrolyte the oxidation process only produces beta phase; no alpha phase is formed even under drastic overcharge conditions. In the mixed electrolyte alpha phase is initially formed, but during cycling it is discharged and disappears as a system component. On the other hand, in a pure KOH electrolyte the peripheral alpha phase contributes to the electrochemical capacity if the discharge rate local current density is sufficiently small. But if the current density is too

large, the alpha phase does not cycle and functions as an inert phase decreasing the effective amount of active material. Extensive overcharge of fully formed electrode in the lithiated KOH electrolyte does not result in alpha phase formation. Thus, the electrode capacity is increased by restricting the cycling to a beta phase with a negligible tetravalent phase contribution. The effective cycle life capacity is increased through the elimination of the floating alpha phase formation process.

The mixed electrolyte imposes further restrictions on the beta phase. With repeated sorption-desorption of K^+ and Li^+ during cycling, the beta phase is restricted to a unique degree of long range order (or disorder) typified by a unique x-ray diffraction pattern rather than gradually recrystallizing through a reconstructive phase transformation to the ordered lithium nickelate solid solution lattice. This minimizes the solid solubility range of divalent nickel with respect to the trivalent state. The nickel hydroxide is oxidized more or less directly to a trivalent state rather than to a lower level divalent nickel in solid solution in a trivalent $LiNiO_2$-type crystalline lattice.

The increased capacity attainable in the lithiated electrolyte can be attributed to the elimination of the rate-sensitive, low density alpha phase, which is not efficiently cycled at normal current densities. The elimination of alpha also permits ready oxidation of $Ni(OH)_2$ throughout the compacted layers. This is accompanied by an apparent increase in the oxygen overvoltage.

The effects are not to be directly attributed to growth of insulating barrier layers of one form or another, limiting electronic conduction processes as suggested by Tichenor (5). The increase in capacity through bismuth hydroxide addition to the $Ni(OH)_2$, as noted by Tichenor, is dependent on the formation during overcharge of an alpha phase which can be discharged efficiently at the operational current densities and is formed even in lithiated electrolytes. Thus, foreign ions can modify the phase transformation kinetics so that particular mass transport reactions are facilitated or inhibited.

In connection with the effect of additives, Tichenor noted that ferric hydroxide additions to the nickel hydroxide decreased the electrode capacity. This effect has been found to depend on a reduction of the effective oxidation potential distribution within the electrode. The oxygen overvoltage can be sufficiently reduced so that the interior nickel hydroxide is not oxidized. This type of phenomena is undoubtedly encountered in the porous plaque nickel electrodes which even on extensive overcharge are difficult to oxidize to the alpha phase state at the usual electrolyte concentrations.

This study does not provide a pat explanation for the role of lithium in the electrode processes. The data do emphasize the extreme care necessary in describing the influence of additives upon electrode processes. The effects may involve perturbations in electronic or mass transport processes in the solid phases, modifications in the Helmholtz electrical double-layer structure, space-charge field distributions in the solid or the electrolyte phases, or modifications in the local electrochemical exchange currents, not only for the phase transformation reactions, but also for the gas evolution processes.

Equipotential surface effects.—At the completion of electrode formation the electrochemical capacity had become relatively independent of the discharge rate. This contrasts with the observations of Kuchinski and Ershler (18) on the charge and discharge of a $Ni(OH)_2$ grain. They observed that the oxidation proceeds from the metal contact region into the grain starting at the three-phase contact area metal-electrolyte-nickel hydroxide. No rate-sensitivity effects were observed during charge. High rate discharge led to the isolation of active phase through the formation of an insulating layer near the metal contact. Placing a metal probe in contact with the surface opposite to the original contact area permitted discharge of the isolated phase. The implied conclusion is that the charged phase is a good electronic conductor, but the discharged phase is not.

In this forming study the oxidation progressed in a similar fashion proceeding into the porous matrix from the metal contact. The initial reaction is the formation of a surface-covering layer of a higher valence nickelate over the $Ni(OH)_2$ surface. This is followed by a migration of the reaction front into the nickel hydroxide to form beta phase. As anticipated, the initial gross reaction proceeds from the metal contact into the layer and from the periphery to the center of the tube. The oxidation state is highest at the periphery and lowest in the center.

After electrode formation the electrochemical capacity does not show the discharge rate sensitivity observed by Kuchinski and Ershler. The absence of rate sensitivity can be partially attributed to a change in the equipotential surface distribution for ionic conduction through the electrolyte in the porous bed and the electronic conduction through the active phase. The formed active material is in intimate electronic contact with the nickel flake layers which are oriented parallel to the ionic conduction paths. During formation the particulate structure of the original $Ni(OH)_2$ is formed into a fairly continuous porous bed. Thus, during discharge the electronic conduction path through beta phase moves from the periphery toward the center as the higher electrical resistivity discharge phase is formed from the periphery toward the center. This structure contrasts sharply with the point contact electrode present in Kuchinski and Ershler's experiments (18) or with the nickelate coating on a metallic substrate used in the thin film studies (19). An additional factor not to be neglected is the formation of an active material state which has a sufficiently large exchange current to maintain the required high local current densities.

Electrochemical kinetics.—Now turn to a discussion of the electrochemical process involved in active material oxidation reduction. Although solution-precipitation mechanisms can be postulated for the oxidation reduction of nickel oxides, the experimental evidence is that the phase transformations proceed primarily as a solid-state reaction, not depending on the solution of nickel ions. This is strongly supported by the observation that microcrystalline $Ni(OH)_2$ remains microcrystalline and macrocrystalline material remains macrocrystalline over long periods of cycling. Furthermore, in a cell very little material transport occurs between electrodes over a cycle life of many years.

Conway and Bourgault described the electrical behavior of the nickel electrode during open-circuit oxygen evolution as a large pseudocapacitance due to the discharge or desorption of oxygen containing radicals on its surface (20). The process is characterized as an electrochemical reaction rather than as a simple non-electrochemical decomposition or desorption of a surface phase from the nickelic oxide. During oxygen evolution on charging a large adsorption or pseudocapacitance was observed so that appreciable time was required for the potential to stabilize after a change in the applied current.

Conway and Gileadi (12), on the other hand, observed the presence of three distinct regions in the active material during charging, namely: (*a*) the initial charging of a surface phase, (*b*) the transition from a surface to a bulk-charging process, and (*c*) the bulk phase charging. This model is analogous to Foerster's (9) and Glemser-Einerhand's (2) model postulated to explain the difference between the anodic and cathodic potential curves. They assumed that oxidation produced primarily an NiO_2 phase with the trivalent oxide forming subsequently either through a decomposition process or by reaction with the divalent phase.

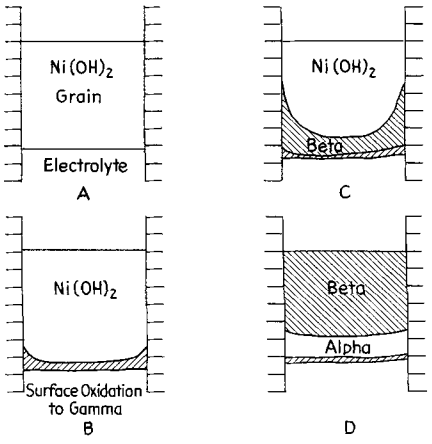

Fig. 11. Physical model for $Ni(OH)_2$ grain oxidation: (A) initial state; (B) surface layer charged to gamma phase; (C) beta phase formation; and (D) alpha phase formation.

This evidence implies an electrochemical process model based on a set of solid-state processes within the framework outlined by Croft and Tuomi (21) for reversible electrodes. Clearly a simple model will not adequately describe the complex data.

The gross features for the anodic conversion of a nickel hydroxide grain are illustrated in Fig. 11. The first stage involves the propagation of an electronic and ionic conductor high-nickel valence surface-oxide film from the three phase interface across the nickel hydroxide-electrolyte interface, *i.e.*, gamma phase. This is followed by a bulk phase process producing beta phase, also a mixed electronic and ionic conductor. Finally, the surface beta phase region is converted to alpha phase, and oxygen evolution occurs in the Helmholtz double layer surface region.

During the phase transformation process lattice imperfections must be introduced into the crystals so that the mass transport necessary for crystalline phase oxidation and reduction can proceed at a significant rate. The physical model must incorporate a driving force to convert the crystalline electronic insulator $Ni(OH)_2$ to an electronic-ionic conductor beta phase without dropping the electrical field across the insulating phase. Furthermore, a mechanism is needed for converting the semiconductor, beta, to a new semiconductor, alpha, without solution of the nickel ions.

For this discussion the discharge phase, $Ni(OH)_2$ is assumed to behave as a covalently bonded layer-lattice structure. The structure is formed from a divalent nickel layer octahedrally coordinated to two opposing oxygen layers. The layer configuration is maintained as electrically neutral by a hydrogen ion layer between two oxygen layers coordinated to separate nickel layers. The band structure corresponds to a large gap electrical insulator.

The oxidized phases in contact with the electrolyte are assumed to exist as low electronic resistance n-type semiconductors. Detailed Seebeck voltage measurements on the more crystalline beta phase from hot LiOH electrolytes showed that the charge phase was an n-type, low electronic resistance nickelate (22). Thus, lithium addition effects are not validly described by models based on the p-type lithium doped nickel oxide (5).

The beta phase, analogous to $LiNiO_2$ (4), is viewed as a $CsCl_2I$-type layer lattice structure. This is equivalent to a trivalent nickel layer octahedrally coordinated to a pair of oxygen layers. The electrical neutrality of layers is maintained by a set of cations (H^+, Li^+, K^+, Na^+) distributed on appropriate sites between the two layers of oxygen octahedrally coordinated to separate Ni layers.

In a general fashion the anodization of $Ni(OH)_2$ is considered to involve the oxidation of the divalent nickel layer to the tri- and tetravalent states without a reconstructive lattice transformation. The change in the Ni layer valence is equivalent in the octahedrally coordinated oxygen layer to a decrease in the required positive charge to maintain electrical neutrality from a $+2$ for $Ni(OH)_2$ to $+1$ for the trivalent state, to zero for the tetravalent Ni configuration. Thus, the mass transport process involved in the phase transformation proceeds in the H^+, OH^- layer region of $Ni(OH)_2$. The layer configurations are viewed as involving a combination of interlayer-interstitial compound structure along with tunnel and layer compound structures (23), depending on the state of oxidation. In other words, an ideal crystal lattice model would not give a valid representation. A reaction process, throughout which the nickel ion remains octahedrally coordinated to oxygen, is postulated. The nickel valence state is characteristic of the Ni-O bond, rather than corresponding to the classical viewpoint of an ionic lattice, *i.e.*, the Ni-O bonds are covalent.

The electrochemical processes involve the sequence: (i) an electrochemical exchange at the solid electrolyte interface involving a set of electronic-ionic lattice imperfections, (ii) electron transport through the oxidized phase region to the metallic contact, (iii) mass transport through the oxidized phase to the lower valence phase at the second interface, and (iv) electrochemical exchange at the second solid phase interface functioning as a source or sink for the ionic-electronic imperfections necessary to maintain the mass and charge balance.

Although a detailed model is difficult to describe, a hypothesis can be presented on several system characteristics which are necessary for self-consistency in the observed properties. The basic postulate is that a three-phase three-interface process is involved. An electrochemical exchange reaction at the solid electrolyte interface produces an internal space charge field, as well as being a source and sink for atomic and electronic imperfections. The electronic charge transport occurs through the higher valence state oxides contacting the metallic-electronic conductor. The driving force for the phase transformation depends on the source and sink characteristics of the two phase interface for both electronic and atomic imperfections. The space charge fields within the solid phases contribute to the required mass transport process.

The first oxidation stage is forming a covering layer of oxide or nickelate over the nickel hydroxide surface adjacent to the electrolyte. The nickel valence state in this surface film corresponds to a nonequilibrium distribution. The Helmholtz double layer is not visualized as a two or three atom layer region, but rather as a volume element extending into the solid as well as into the electrolyte. The surface region involves primarily adsorbed hydroxyl and alkali ions and water molecules. The electrochemical exchange process involves a complex set of phenomena. Through the injection of holes a surface space charge region of high valence state nickel atoms is formed. Accompanying this hole-trapping process, a proton depletion layer extending a diffusion length into the hydroxyl layer is produced, and lattice vacancies, alkali ions, and other imperfections are introduced. The mass transport processes are controlled by the lattice imperfection generating and consuming processes involved in the detailed balancing of the exchange reaction.

Using the notation summarized by Rees (24) and outlined by Croft and Tuomi (21) the following exchange reactions are contributing to the Helmholtz double layer exchange processes

$$OH_l^- + \square_s^- \rightleftharpoons OH^-/\square_s^-$$

$$\square_s^+ + H^+/\square_o^+ \rightleftharpoons \square_o^+ + H^+/\square_s^+$$

$$H^+/\square_s^+ + OH^-/\square_s^- \rightleftharpoons H_2O_l + \square_s^+ + \square_s^- + n$$

$$H^+/\square_s^+ + p + OH^-/\square_s^+ \rightleftharpoons H_2O_l + \square_s^+ + \square_s^-$$

$$K_l^+ + \square_s^+ \rightleftharpoons K^+/\square_s^+$$

$$Li_l^+ + \square_s^+ \rightleftharpoons Li^+/\square_s^+$$

where $\square_o$ is an interior site; $\square_s$, a surface site; the superscript + or — distinguishes cation or anion sites; and the subscript l the liquid phase. The p and n refer to the holes and/or electrons involved in the local site charge neutrality change due to the removal of local site anions near nickel ions. On interior sites the reactions may be described as

$$Ni^{+2}/\square_o^+ + p \rightleftharpoons Ni^{+3}/\square_o^+$$
$$Ni^{+2}/\square_o^+ \rightarrow Ni^{+3}/\square_o^+ + n$$

the charge carrier type depending on the semiconductor properties. Complementary reactions would include the mass transport processes

$$K^+/\square_s^+ + \square_o^+ \rightleftharpoons K^+/\square_o^+ + \square_s^+$$
$$Li^+/\square_s^+ + \square_o^+ \rightleftharpoons Li^+/\square_o^+ + \square_s^+$$
$$OH^-/\square_s^- + \square_o^- \rightleftharpoons OH^-/\square_o^- + \square_s^-$$
$$H^+/\square_o^+ + OH^-/\square_o^- \rightleftharpoons (H_2O/\square_o^+)\square_o^-$$

Within this framework the surface exchange processes produce an oxidized nickel layer without requiring solution or significant diffusion of the nickel ions. The distributed space-charge field does not correspond to a local field sufficiently large to result in oxygen evolution from electrolyte decomposition.

The electrochemical exchange reactions generate a surface region with a high electronic and atomic imperfection density. As a result, the nickel atoms in the region adjacent to the electrolyte will have an average valence state determined by a combination of factors. During anodization the local space-charge density of electrons will be decreased, corresponding to an increase in the nickel valence state. The actual space charge density will depend on the rate of atom movements tending to eliminate the space charge. Thus, during anodization a surface region p-n semiconductor junction is formed within a system containing mobile doping atoms.

During the initial oxidation stages rapid diffusional exchange proceeds between the interface and a diffusion length depth into the solid. As charging proceeds, the solid phase begins to show bulk semiconductor properties. An internal space charge region extending from the solid-electrolyte interface to the metal-semiconductor contact and to the beta-nickel hydroxide interface can be formed. Within beta the nickel valence state varies from an upper solid solution limit at the electrolyte interface to nearly the lower limit at the nickel hydroxide interface. The trapping of electrons from the divalent nickel in $Ni(OH)_2$ in the beta phase produces a local electric field at the beta-$Ni(OH)_2$ interface. This interface is a sink for holes generated at the electrolyte interface and a source and sink for the imperfections required for the mass transport process completing the electrochemical oxidation reaction.

A group of electrochemical exchange reactions at the beta-$Ni(OH)_2$ interface can be formulated as follows

$$Ni^{+2}/\square_{OH}^+ + p \rightleftharpoons Ni^{+3}/\square_{OH}^+$$
$$Ni^{+3}/\square_o^+ \rightleftharpoons Ni^{+2}/\square_o^+ + p$$
$$Ni^{+3}/\square_o^+ + Ni^{+2}/\square_{OH}^+ \rightleftharpoons Ni^{+2}/\square_{OH}^+ + Ni^{+2}/\square_o^+$$
$$OH^-/\square_{OH}^+ + \square_o^+ \rightleftharpoons OH^-/\square_o^+ + \square_{OH}^+$$
$$H^+/\square_{OH}^+ + \square_o^+ \rightleftharpoons H^+/\square_o^+ + \square_{OH}^+$$
$$Li^+/\square_o^+ + \square_{OH}^+ \rightleftharpoons Li^+/\square_{OH}^+ + \square_o^+$$
$$K^+/\square_o^+ + \square_{OH}^+ \rightleftharpoons K^+/\square_{OH}^+ + \square_o^+$$

where the first three reactions represent local valence changes in beta and $Ni(OH)_2$ and the remainder form the mass transport processes necessary to maintain local electrical neutrality.

During constant current charge a sequence of effects appears. The surface double layer region is first charged, producing a local interior space-charge field. With an extension of the semiconductor charge phase into the interior a distributed space charge field is formed. This field is characterized by a combination of the semiconductor band structure and the mobility of dopant imperfections. As the state of charge increases the magnitude of the space charge diminishes so that at the end of charge there is only an iR loss in the solid and the applied field is largely at the solid electrolyte interface. If charging is continued until steady-state oxygen evolution is reached, the distributed space charge will have vanished. The semiconductor is characterized by a flat band potential. If the electrode is placed on open circuit, the space charge field will gradually decay through atom movements in the solid phase, and a flat band potential condition will be approached.

In this model the anomalous relationships between the charge and discharge potentials are related to the space charge fields within the charged phases which contribute to mass and charge transport during cycling. Through their effects the nickel hydroxide could be oxidized to the high valence states without actually dropping the electric field across the nickel hydroxide. This distinguishes the Ni electrode oxidation reduction process from that in cadmium oxidation where a covering $Cd(OH)_2$ layer is formed over the cadmium.

When the electrode is placed on open circuit after charging, a local cell system is formed by a coupling of the oxygen evolution reaction on the semiconductor surface with a decay in the nickel valence state in the oxide. This decay process for isolated electrodes does not necessarily decrease the valence below 3.0 even on very long open-circuit stands. Though the oxygen evolution process is closely related to the "steady state" electrode potentials, the data do not give insight into the mechanism of nickel valence reduction. In certain isolated charged electrodes left on open circuit for several years, the nickel valence showed only a negligible decay although the normal rate capacity had decreased to a low value, *i.e.*, self-discharge had occurred. The electrodes, however, could be fully discharged at very low rates. An extended overcharge of the electrodes restored the original capacity. Considering the extent of overcharge required, it seemed unreasonable simply to postulate a surface-covering layer reduction. The results suggested that the imperfection density necessary for mass transport during discharge had diminished during open-circuit stand.

The experimental data suggest that the lattice imperfections involved in the mass transport are introduced into the solid phase during the charging process. Their characteristics depend on the forming conditions and electrolyte composition. The correlation of the oxygen evolution with the electrode potential may reflect mass transport limitations through the Helmholtz double layer into the solid at virtually flat band potential conditions. The experimental problem is to characterize the surface mass and charge transfer sites as a function of the solid phase structure. With a wide variety of structures experimentally accessible in the nickel electrode such detailed studies are practical.

Additives such as Li^+, K^+, Na^+, or Bi and other elements produce a number of subtle changes in the Helmholtz double layer structure and the electrochemical exchange reactions at the solid electrolyte interface. The ready transport of lithium into the electrode during charge implies that either a strong activity effect is involved or that only a small opposing electrical field is formed at the solid electrolyte interface on anodization.

For the transformation of beta to alpha phase the mass transport processes involve atom migration within good electronic conductors, 1 ohm-cm resistivities. The mass transport involves a separation of the oxygen-octahedrally coordinated nickel layers by the insertion of a K^+-H_2O layer between the opposing oxygen layers. Systematic studies of the structural relationships for the various electrolyte and impurity combinations should provide insight into the factors controlling the reaction kinetics. It is insufficient to describe the effects simply in terms of oxygen over-

voltage displacements and surface area variations or in terms of simple mixed potential functions.

The forming process study has shown that material which appears to be very disordered, and even amorphous, may have a variable electrochemical capacity. The existence of an amorphous structure does not assure the presence of many lattice imperfections capable of contributing to mass transport under the relatively low internal electric field conditions necessarily present in a practical active material for use in batteries. Definite local site symmetry boundary conditions exist, limiting the transition probabilities for atom jumps into neighboring vacant sites.

The research outlined in this report has emphasized the critical role played by electrochemical exchange reactions involving minor system components even in solid phases not having a high degree of lattice perfection. Studies over a large enough temperature range to define limiting conditions are of particular importance. There is no doubt that the electrolyte component can exert equally profound effects on the solid-state transformations encountered in many other corrosion systems.

Although a well-defined model cannot yet be formulated for the nickel electrode reactions, the experimental data clearly show that solid-state phase transformations are relevant. From a composite approach involving structural chemistry, solid-state physics, and electrochemistry, sufficiently extensive and varied data should become available to bring clarity and simplicity into the relevant physical mechanisms.

Summary

This study of forming processes in the nickel positive electrode has clarified several facets of the art. In summary, the main results obtained are as follows:

1. In LiOH and dilute KOH and NaOH electrolytes nickel hydroxide is readily oxidized to a trivalent state designated as beta phase nickelate.

2. In concentrated KOH or NaOH electrolytes the beta phase can be further oxidized to a tetravalent state designated as alpha phase nickelate.

3. The crystallinity of the oxidized phases depends on the crystallinity of the initial $Ni(OH)_2$ phase.

4. The effective electrochemical exchange current of alpha phase is smaller than for beta phase. Consequently, under normal conditions alpha is not efficiently cycled.

5. At elevated temperatures in LiOH electrolytes the $Ni(OH)_2$ is oxidized to a trivalent phase having the $LiNiO_2$ crystalline structure.

6. The effect of the lithium addition to KOH electrolytes is to eliminate alpha phase as a system component.

7. The variable potential characteristics during charge and discharge are related in part to solid solution ranges for di- and tetravalent nickel in the trivalent phase and, in part, to the distributed potential within the semiconductor phases constituting the active material.

8. Additive effects on the electrode properties may involve changes in the phases formed as well as changes in the oxygen overpotential for the electrode.

9. The spatial distribution of the charge and discharge phases within a cycling electrode depends on the equipotential surface distributions for ionic and electronic conduction within the electrolyte and solid, respectively.

10. A general model based on solid-state mass and charge transport processes has been used to interrelate the observed data.

Acknowledgments

An extensive study such as implied by the outlined results clearly depends on the cooperation of a number of people. The experimental work was largely performed by L. Middlecamp and Mrs. V. Tierney. The analytical services were kindly provided by R. Arzapalo, M. Maffia, and Miss J. Sareski under the supervision of B. D. Brummet. The research benefited from frequent discussions with Drs. G. T. Croft, J. B. Johnson, A. Fleischer, and P. F. Grieger at the T. A. Edison Research Laboratory.

The continued support of Dr. D. W. Collier was appreciated. Special acknowledgment is due to W. W. Smith and R. H. Weeks, Jr. at the Nickel Alkaline Battery Division of The Electric Storage Battery Company for their support and encouragement during the preparation of this paper for publication.

Manuscript received Dec. 19, 1963; revised manuscript received Sept 2, 1964. This paper was presented in part at the Houston Meeting, Oct. 9-13, 1960.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

Oxides on the Silver Electrode

II. X-Ray Diffraction Studies of the Working Silver Electrode

Charles P. Wales and Jeanne Burbank

United States Naval Research Laboratory, Washington, D. C.

ABSTRACT

Silver electrodes were examined in 20-50% KOH using a cell permitting simultaneous x-ray diffraction and electrochemical studies. Highly oriented smooth rolled sheet Ag developed randomly oriented Ag on its surface during early cycles. Charge-discharge capacity increased to a maximum as surface area increased. AgO crystal size and amount formed varied inversely with charging c. d. High charge rates gave tight coatings of small AgO crystals that limited further oxidation. Reactions took place initially at the outer surface of the electrode. Oxidation to Ag_2O and AgO and reduction to Ag_2O and Ag occurred by formation of distinct crystals rather than expansion or contraction of preexisting crystal lattices. Discharge capacity at the AgO/Ag_2O potential plateau depended more on surface area than on quantity of AgO. A slow discharge produced smoother Ag surfaces, lowering capacity of the next cycle. There was never evidence of a suboxide, oxidation state higher than AgO, solid solution, or alloy of oxygen and silver.

Investigation of the silver electrode in KOH solution is of interest since silver oxides comprise the positive active material of charged Ag-Zn and Ag-Cd storage batteries. It is therefore desirable to know the reactions and products occurring in alkaline solutions when oxidized silver electrodes are reduced cathodically, and when metallic Ag electrodes are oxidized anodically. In the persent work an electrolytic cell was used that permitted x-ray diffraction examinations to be made of the working electrode during charge and discharge, instead of interrupting electrolysis and removing the electrode for x-ray examination as was done previously (1).

There is general agreement that Ag_2O having the Cu_2O type of face-centered cubic structure is formed at the first potential plateau when a silver electrode is anodically oxidized (charged) using constant current in alkaline solution. Although there have been claims that a silver suboxide may form on a silver electrode, its presence was not detected, and indeed the existence of silver suboxide itself is quite dubious (1). When silver is anodized in KOH solutions, the potential rises to a peak after charging at the first plateau for sufficient time, and then monoclinic AgO forms at a second potential plateau. Finally, the potential rises again and oxygen evolution takes place. There have been unsubstantiated reports of higher oxides of silver, presumably containing trivalent silver, forming just before or during oxygen evolution. Some confusion has been caused by the report of Jones and Thirsk of what they believed was the x-ray diffraction pattern of AgO (2). Their pattern has since been shown to be that of the so-called silver peroxysulfate $Ag_7O_8SO_4$ and not AgO (1). The x-ray diffraction pattern for monoclinic AgO is well established now and has been given by Scatturin, Bellon, and Zannetti (3) and by Graff and Stadelmaier (4), among others. Standard reference patterns for Ag and Ag_2O appear in the ASTM Powder Diffraction File.

Three additional oxides of silver have been reported recently. Tetragonal AgO, which appears to be a peroxide containing mono- and divalent Ag, has a diffraction pattern closely resembling that of monoclinic AgO and was prepared by McKie and Clark through the action of ozonized oxygen on hot silver powder (5). Vol and Shishakov have reported that a silver peroxide having the NaCl type of cubic lattice forms when silver is heated in oxygen (6). A modification of Ag_2O having the CdI_2 structure has been obtained by Kabalkina *et al.* using high pressure and temperature (7). Only the face-centered cubic Ag_2O and the monoclinic AgO have been definitely established as being present on the silver electrode in alkali (1, 8-10).

Experimental Procedure

The test electrode was a half-submerged rotating Ag disk 57 mm in diameter, mounted vertically in a cell designed for use on a horizontal circle x-ray spectrogoniometer (11). The method of mounting the disk covered its edge and back, leaving only one side to contact the electrolyte. X-ray diffraction patterns, using CuK_α radiation, were made from this side of the disk as it rotated out of the electrolyte. Initially the disk was cut from 0.25 mm thick Ag of 99.99+% purity. This disk was not perfectly flat despite pressing, since it had been cut from a roll of sheet silver. Consequently the recording of the diffraction pattern from this disk showed some variations with sample rotation because the sample surface was not all in the same plane. Disks cut from 1.6 mm thick flat sheet Ag of similar purity removed this difficulty, and these were used for most of the work reported here. Satisfactory patterns have also been obtained from disks of sintered Ag cut from a storage battery electrode, but due to the porosity of this material the electrochemical reactions were not limited to one side, as was the case with sheet Ag.

A counterelectrode of sintered Ag, wrapped in cellulosic separator material, faced the submerged part of the continuously rotating specimen disk. The cell also contained a reference electrode of Ag/Ag_2O. Some work was done in 20% and 50% KOH, but the usual electrolyte was 35% KOH at 23°-26°C, and this was used except where otherwise specified. Charge and discharge were carried out with a wide range of constant currents. The Ag sample rotated at 60 rpm and, therefore, the diffraction pattern was registered 0.25 sec after the sample left the electrolyte, with the total time out of solution being 0.5 sec. Current did not need to be interrupted during the x-ray examinations because the test Ag electrode was always partially submerged. This experimental arrangement permitted x-ray diffraction patterns to be made during charge and discharge of a working electrode simultaneously with electrochemical measurements and visual observations. The use of this cell lowered the possibility of an unstable crystalline compound being present but undetected by x-ray diffraction.

Results

Before the initial anodic oxidation of the disks that were cut from smooth rolled sheet Ag, x-ray diffraction patterns showed strong preferred orientation: the (110) planes lying in the surface of the 0.25 mm sheet,

and the (110) and (100) planes lying in the surface of the 1.6 mm sheet. The initial charge produced first a thin layer of Ag_2O and then a thicker layer of AgO. A little randomly oriented Ag formed in the first discharge.

The highly oriented Ag substrate showed strongly through the randomly oriented oxide films in x-ray diffraction patterns made during early charge-discharge cycles. The amount of dendritic randomly oriented polycrystalline Ag present after discharge and the surface roughness of the Ag both increased gradually during the early cycles, and at the same time the amount of Ag visible by x-ray diffraction through the oxide film after charging to gas evolution gradually decreased. Capacity rose from its initial value of about 5-10 mah and reached a maximum of about 65-75 mah as the electrodes were cycled in 35% KOH, and a rough surface of dendritic polycrystalline Ag was produced. Although this Ag was in good electrical contact with the base Ag, it was easily broken from the surface. Randomly oriented Ag could also be obtained by abrading a smooth Ag disk with a fine polishing cloth before anodization, but this was not accompanied by any marked increase in discharge capacity, in contrast to the results when polycrystalline Ag was produced through repeated cycling.

There was never evidence of a suboxide, solid solution, or alloy of oxygen and silver during charge or discharge. Ag_2O lines gradually appeared in addition to the Ag lines of the x-ray diffraction patterns while dendritic randomly oriented Ag was charging at the Ag/Ag_2O potential plateau at a moderate current, for example the 12-24 hr rate. The diffraction lines for Ag did not broaden or shift as Ag_2O formed. The Ag_2O diffraction patterns were in close agreement with the standard Ag_2O pattern. The Ag_2O pattern had become moderately strong by the end of the Ag/Ag_2O potential plateau and was about the same intensity as the metallic Ag pattern, which had decreased from its initial strength. The potential was usually 25-50 mv above the Ag/Ag_2O equilibrium during most of this plateau. Sometimes there was a secondary plateau at about 70-100 mv, after the electrode had charged about 1/4 or 1/3 of the normal amount of the Ag/Ag_2O plateau in 20% KOH. This secondary plateau was not observed in 35% or 50% KOH.

The AgO diffraction pattern could be detected when only a very small amount of AgO had formed, for example when the charge at the Ag_2O/AgO plateau was 0.3-0.5% of the total capacity. The Ag_2O pattern did not broaden or shift as Ag_2O was oxidized to AgO. The AgO diffraction patterns closely resembled the standard AgO pattern. An AgO pattern made in 20% KOH using the experimental method described here was given as Fig. 4a of ref. (11).

The gas evolution potential plateau of the rotating electrode was about 0.1v lower than normal for O_2 evolution on AgO. This lower potential was an effect of rotating the electrode in and out of the electrolyte. Using a stationary electrode, the potential continued to rise for about 0.1v after the onset of O_2 evolution. Despite extensive gassing using various current densities, no pattern was ever observed that could be attributed to an oxidation state higher than AgO. The potential usually dropped rapidly to the Ag_2O/AgO plateau after a charge was terminated, but following very low rate charges the potential dropped more slowly than normal.

Low charging currents (1-10 day rates) resulted in a granular surface of light gray AgO. There was specular reflection from what appeared to be large crystal facets. The base Ag was greatly obscured or even undetected in diffraction patterns made after reaching oxygen evolution under these conditions. High charge currents (2-120 min rates) gave a thinner coating of dark gray AgO having what appeared visually to be a much smoother surface. Diffraction patterns of this

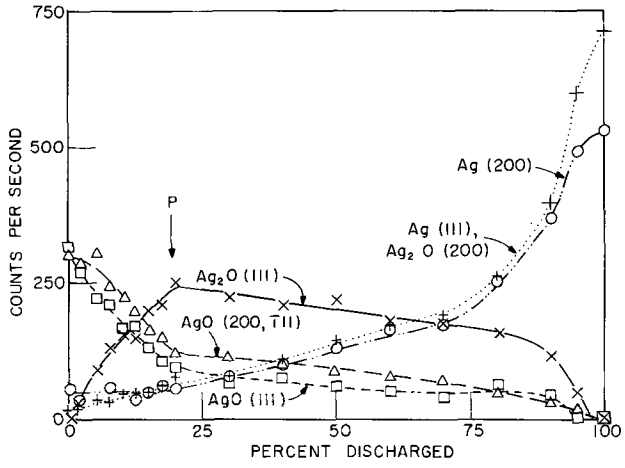

Fig. 1. Change in intensity of x-ray diffraction peaks during continuous discharge of AgO in 35% KOH. The Miller indices corresponding to the peaks are: AgO (111), □; AgO (200) and $(\bar{1}11)$, △; Ag_2O (111), X; Ag_2O (200) coincident with Ag (111), +; Ag (200), ○. The end of the first discharge plateau is indicated by the arrow at point P.

AgO were quite poor, and the randomly oriented Ag that had been produced through cycling was still detectable. Ag_2O was detectable after a moderate or high rate charge to gassing when using Ag that had developed the rough dendritic surface, but Ag_2O was not detected after low rate charges to gassing, or when using disks of smooth or sintered Ag. Oxides formed on a smooth Ag surface gave patterns of higher intensity than those obtained after the rough surface was developed. Strongest of all were the patterns from the sintered Ag disk.

Diffraction patterns were practically unchanged after an electrode was put on open circuit for 16 hr following a charge to 75% of capacity. After a fully charged electrode was on open circuit for 60 hr the AgO pattern was slightly weaker but Ag_2O was not definitely visible. The self-discharge rate was obviously quite low.

Ag_2O could be detected quite early in a discharge. It appeared to form first at areas that were the last to charge, where the AgO was thin. When using disks that had developed the rough dendritic surface, AgO was present in diffraction patterns until very near the end of discharge (Fig. 1). The first 2.5% of the discharge of Fig. 1 was done at the 40 hr rate following a charge at the 18 hr rate to oxygen evolution. X-ray diffraction patterns were made every ½% of discharge in this initial period, but for clarity only peaks when 0% and 2% discharged were included on Fig. 1. Current was increased to the 10 hr rate after the electrode was 2.5% discharged, and when 20% discharged, current was increased to the 2.5 hr rate. The Ag_2O/Ag potential plateau was reached after the discharge was 19.2% complete and is indicated by the arrow P. Total capacity of this discharge was 70.3 mah. Diffraction peaks for the (002) and $(\bar{2}02)$ reflections of AgO showed the same trend as the two AgO peaks plotted in Fig. 1, but with intensities about half as strong. The (220) reflection of Ag had peaks about 20 to 80 counts/sec stronger than the (200) peaks shown.

X-ray diffraction at the end of a discharge showed only metallic Ag, although at times small spots of Ag_2O could be seen visually. Rapid discharges (2 hr or faster rate) gave very good randomly oriented polycrystalline Ag patterns despite the speed of reduction. Slow discharges gave poorer Ag diffraction patterns having increased amounts of highly oriented Ag visible. The charge-discharge cycles following a slow discharge had less than normal capacity. Capacity could be restored by a low rate charge that required several days to reach gas evolution.

Charge-discharge efficiency was usually in the range 95-102% when using 35% KOH, but was only 70-80% in 20% KOH. This contrasted with results reported earlier in which only 0.5% loss was found in 20% KOH (12), and no loss in 35% KOH (13), when using Ag electrodes wrapped with semi-permeable separator material. Most of this loss was probably due to Ag going into solution during charge. Black particles that precipitated out of the 20% KOH were identified as metallic Ag.

Discussion

It was pointed out above that there were several changes in characteristics of the Ag electrode with cycling; charge-discharge capacity, surface roughness, and amount of randomly oriented Ag all increased, at least up to a degree. The capacity increase was caused by the increase in surface area and appeared to represent neither actual increase in oxidation depth nor an effect of oxidizing randomly oriented Ag instead of highly oriented Ag. A medium or slow rate discharge produced more highly oriented Ag and less capacity on the following cycle than did a rapid discharge, but this loss in capacity was due to a smoother surface resulting from a larger crystal size after using the lower discharge currents, rather than to an effect of Ag orientation.

The amount of oxides that was present after charging increased with cycling, as was indicated both by rising capacity and by Ag from the substrate gradually becoming weaker in x-ray patterns made during the initial cycling. Weaker diffraction patterns were obtained from the oxides after cycling, despite a 5-10 times increase in quantity, due to the great increase in surface roughness. The more porous surface absorbed and scattered the x-ray beam, resulting in less efficient diffraction. Surface roughness may be the cause of detecting Ag_2O at the end of some moderate or high rate charges after building up capacity, but not detecting Ag_2O in the thin films during the initial cycles of the smooth surface. Patterns of the rough surface, recorded from a porous mass of dendrites or spheroidal particles, may have viewed a greater effective cross section and thus given more intense Ag_2O patterns than a thin Ag_2O film on a smooth base could give. An alternative possibility was that roughness affected current density over the surface and deeper crevices were not charged as efficiently, with the result that Ag_2O remained on the electrode when charge current was high, but not when charge required at least ½ day for completion.

Ag_2O and AgO had random orientation regardless of whether they were formed on randomly or highly oriented Ag. Ag_2O formed as distinct crystals on the Ag surface and not through a gradual expansion of the Ag lattice as oxygen entered. A gradual expansion of the lattice was to be considered possible since both Ag and Ag_2O have a face-centered cubic lattice, but if this were the true mechanism of formation the diffraction lines for Ag should have broadened or shifted, with a progressive expansion of lattice parameters from metallic Ag to Ag_2O. Similar evidence showed that oxygen did not gradually distort or expand the Ag_2O crystal lattice in forming AgO, but AgO formed in its own definite crystal lattice. Finding AgO after charging 0.3-0.5% at the Ag_2O/AgO plateau indicated that initially AgO must be forming on the surface of the electrode next to the solution. The amount of AgO present at this point was less than that necessary for detecting one component of a mixture by x-ray diffraction, and this amount of AgO would not have been detected if it were distributed throughout the Ag_2O or were forming at the Ag-Ag_2O interface.

Assuming that AgO formed initially from Ag_2O and that no Ag was oxidizing simultaneously, the amounts of AgO and Ag_2O should be equal when the quantity of charge current exceeded that required to reach the beginning of the Ag_2O/AgO potential plateau by 50%. This was true, judging by the relative strengths of the Ag_2O and AgO diffraction patterns. This measurement was only sufficiently accurate to indicate that at least most current was oxidizing Ag_2O in this period, since a few per cent of the current could have oxidized Ag without it being detected. When the quantity of charge current was twice that required to reach the Ag_2O/AgO plateau, the Ag_2O pattern had become quite weak, but Ag_2O still being present indicated that additional Ag had oxidized by this point. It was calculated that 15-40% additional metallic Ag oxidized after reaching the Ag_2O/AgO plateau in typical low or medium rate charges.

The AgO coating obscured the base Ag much more at the end of a charge than did Ag_2O at the end of the Ag/Ag_2O plateau, even when the 15-40% additional oxide is considered. This may indicate a greatly increased thickness of AgO compared to Ag_2O. Yoshizawa and Takehara reported an oxide layer 1.5μ thick after oxidizing to the end of Ag_2O formation (electrode approximately 1/3 charged) and a layer 8μ thick after oxygen evolution (10). Since the base Ag was obscured to a large extent when heavy films of AgO were on the electrode, some Ag_2O may also be present at the Ag-AgO interface under these conditions, but masked by the AgO coating.

Charges at the 4-10 day rate were the most effective for oxidizing the Ag base and for building capacity up to the maximum reached by cycling. After dendritic randomly oriented Ag had been formed on the base Ag, low rate charges appeared to oxidize this polycrystalline Ag completely. The total amount of AgO and its crystal size both varied inversely with the charging current density. The best diffraction patterns were obtained after charging with medium currents, for example ½-1 day rates. This was probably the range of current densities giving the optimum particle size for x-ray diffraction. Oxygen evolution appeared to perfect crystallinity when using medium rates of charge, perhaps by perfecting the lattice or by changing the particle size.

The very poor diffraction patterns obtained after quite high charge rates were due to small AgO crystal size, and the AgO lattice may have been highly distorted. After charging the Ag electrode to oxygen evolution using a high current and then lowering the current, there was only a little further charge acceptance, AgO diffraction patterns remained poor, and the discharge capacity was less than if the low current had been used throughout the charge. The small AgO crystals made a more uniform coating and were more interlocking than the larger crystals obtained with slower charge rates. Thus OH^-, O^{--}, or Ag ions could not penetrate this tight AgO coating readily and further oxidation was limited. Nevertheless AgO of small particle size may be better in a primary or storage battery because the increased surface area may result in less polarization and improved electrical contact.

X-ray diffraction patterns indicated that during discharge Ag_2O formed as distinct crystals, and not by gradual shrinking of the AgO lattice. Ag_2O formed initially on the surface of the AgO, as was indicated by visual observations and by its early appearance in the patterns. A discharge reached the Ag_2O/Ag potential plateau after Ag_2O covered the electrode surface. Although only Ag_2O could be seen visually on the surface at this point, diffraction patterns often showed AgO also (Fig. 1). The amount of Ag_2O present decreased gradually from point P, as shown by the (111) reflection of Ag_2O. The apparent increase in Ag_2O (200) after point P was actually due to increase in the coincident Ag (111) reflection. The relative changes in the intensities of the diffraction peaks indicated that up to point P, while discharging at the upper plateau, the rate of growth of Ag_2O corresponded to the rate of discharge and covering over of the surface of AgO. The de-

crease in AgO counts per second by point P was largely due to Ag_2O covering the AgO, and represented only a 19% decrease in the total amount of AgO present. Beyond point P, the slopes for the Ag_2O (111) and the AgO (200, $\bar{1}11$ and 111) peaks indicated that both oxides were discharging simultaneously, with the layer of Ag_2O covering the AgO crystals remaining approximately the same thickness until near the end of the discharge. Ag did not trap any oxides during a discharge. When using the Ag electrode that had developed a rough surface, after Ag_2O had formed on the outer surface of the protrusions the discharge could then proceed from the inner surface outward, with relatively little Ag forming on the surface at first. Thus the diffraction patterns would continue to show Ag_2O and AgO until close to the end of discharge (Fig. 1). Smooth electrodes discharged more evenly.

It has been recognized that the discharge following a very slow charge exhibits an ususually short AgO/Ag_2O potential plateau, although the total discharge has a very large capacity. Explanations offered for this short plateau include assuming that the depth of oxidation was greater when charging with a low current due to AgO slowly reacting with base Ag. The resultant charged electrode then would have much Ag_2O in it, and Ag_2O could cover the surface after a relatively short discharge (12). As already mentioned above, however, no Ag_2O was detected after low rate charges. The slower fall in open-circuit potential to the AgO/Ag_2O plateau, following a low rate charge, could be another indication of little or no Ag_2O being present. Under these conditions Ag_2O must form before the AgO/Ag_2O potential was obtained. On the basis of the work reported here it is now believed that the unusually short higher potential plateau during discharge under these conditions resulted from having a coating of large AgO crystals on the electrode. Less Ag_2O needed to be formed to cover the AgO since the large crystals had a smaller surface area. Therefore the potential fell to the Ag_2O/Ag plateau during a discharge after relatively little AgO was reduced to Ag_2O, even though an unusually large amount of AgO was present. Another indication of a small surface area following a very slow charge was that the AgO plateau was entirely lacking during a rapid discharge; potential fell to a minimum at first and then rose to the Ag_2O/Ag plateau. Conditions differed when using a high rate charge, as then small AgO crystals formed having a large area, although a smaller total amount of AgO was present. It took longer to cover this surface with Ag_2O on discharge. The electrode contained considerably less AgO by the time the Ag_2O/Ag potential plateau was reached, and the lower plateau was relatively short.

Summary

The experimental method used permitted successful examination of a working electrode. It was found that reactions took place first on the surface of a silver electrode. Oxidation and reduction products formed as distinct crystals, rather than through expansion or contraction of existing crystal lattices. Surface area and crystal size, which depended on current density, were shown to be important in determining the charge-discharge characteristics of the silver electrode.

Manuscript received Aug. 5, 1964. This paper was prepared for delivery before the Washington Meeting, Oct. 11-15, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

Catalytic Decomposition of Aqueous Formic Acid on Platinum Electrodes

D. R. Rhodes and E. F. Steigelmann

California Research Corporation, Richmond, California

ABSTRACT

Formic acid in 1*N* H_2SO_4 at 30°C dissociatively adsorbs onto a platinum electrode to form a species that acts electrochemically like adsorbed CO. This species inhibits the oxidation of other compounds and, therefore, can act as a poison on an anode. It can be removed by anodic oxidation at relatively positive potentials. These effects were studied using a potential-sweep technique.

Formic acid is an intermediate in the electrolytic oxidation of aqueous methanol solutions. At platinized porous carbon anodes (1), methanol oxidizes first to formaldehyde, then to formic acid, and finally to CO_2. In acid solution the oxidation of formic acid to CO_2 is relatively rapid and complete, but in base, when formic acid is present as formate ion, the rate of reaction is slow.

Thermodynamic calculations from free energy of formation data show that CO_2, H_2, CO, and H_2O can be formed from the decomposition of formic acid in water. The values are as follows (2)

$$\underset{-85.1}{HCOOH\ (aq)} \rightleftharpoons \underset{-92.3}{CO_2\ (aq)} + H_2\ (g); \quad \Delta F_f = -7.2 \text{ kcal/mole} \quad [1]$$

$$\underset{-85.1}{HCOOH\ (aq)} \rightleftharpoons \underset{-32.8}{CO\ (g)} + \underset{-56.7}{H_2O\ (l)}; \quad \Delta F_f = -4.4 \text{ kcal/mole} \quad [2]$$

Because the values for the free energy of formation of H_2 (aq) and CO (aq) are not available, those for the gaseous state were used. The values of CO_2 (aq) and HCOOH (aq) differ from the gaseous state values by only 2-3 kcal/mole, so those used for H_2 (aq) and

CO (aq) should be close approximations. The data show that the formation of CO_2 and H_2 is thermodynamically favored.

In concentrated sulfuric acid, formic acid decomposes to form carbon monoxide and water (3), but, at concentrations of less than 85% sulfuric acid in water, the rate of this reaction is very slow.

In more dilute acid solutions, formic acid can be photochemically decomposed to carbon monoxide, carbon dioxide, water, and hydrogen (4). The rate of this reaction reaches a maximum at 0.1M formic acid in 0.1N H_2SO_4.

Formic acid in aqueous acid solution is also catalytically decomposed on various metals. The rate of decomposition is greatest on palladium dispersed on $BaSO_4$ and much slower on platinum and rhodium. Other metals which were tested were inactive (5). During the decomposition on metals, the open-circuit potential of the system goes through a maximum, while the rate of hydrogen production on the metal decreases to a small constant value (6). The electrooxidation of aqueous formic acid on a number of different metal surfaces has also been studied (7). Platinum, rhodium, and palladium give the greatest rate of oxidation.

Griffith and Buck (8) studied the electrochemical oxidation of aqueous formic acid on platinized platinum over a large pH range using potential-sweep methods and chronopotentiometry. They found that the rate of oxidation goes through two maxima in going from acidic to basic solution. Also, their chronopotentiograms showed an inhibition toward formic acid oxidation after the electrode had been allowed to stand in solution. They did not study this phenomenon further. Munson (9) also reported chronopotentiometric studies of the oxidation of formic acid and formate ion as a function of pH. He interpreted his results as indicating the presence of a slow preelectrochemical reaction. In the pH range 1.4-6.0, two transition times were obtained, but, above 6.0, only one was obtained. The first transition wave was attributed to direct electrooxidation following a slow homogeneous reaction and the second to oxidation of adsorbed formate species. All his results were with a short wait-time between runs; the effect of wait-time between chronopotentiograms was not studied.

Slott (10) reported work on the oxidation of formic acid using chronopotentiometry. He also measured the double-layer capacitance of a platinum electrode in formic acid solution. He concluded that some reaction takes place which involves the slow adsorption of species from solution onto the electrode surface. Thus, the amount adsorbed seems to be a function of wait-time between chronopotentiograms.

The adsorption of formic acid, oxygen, and hydrogen onto platinum in perchloric acid solutions has been studied by Breiter (11). The effect of the catalytic decomposition reaction on the electrochemistry of formic acid was not observed. However, a detailed study of the reaction of formic acid on platinum during electrooxidation was made.

Gilman (12) studied electrochemical oxidations of CO on a platinum anode and concluded that CO adsorbs at a relatively rapid rate and covers 75% of the platinum surface at equilibrium.

The above articles clearly indicate that formic acid reacts catalytically on the surface of some metal electrodes. During our initial studies with formic acid electrooxidation on platinum, we realized that this catalytic reaction occurs at a fast enough rate to complicate seriously any electrochemical studies. This present investigation is concerned with this catalytic reaction and how it affects the electrochemistry of formic acid.

Experimental

The anodic oxidation of formic acid was studied in a conventional three-compartment-type electrolytic cell. A glass frit was used between the working and counter-electrode compartments to retard mixing of the solutions in the compartments. The reference electrode compartment was in electrolytic contact with the anode compartment by means of a salt bridge which was constructed from glass tubing. A closed stopcock in the salt bridge hindered the electrolyte in the working electrode compartment from mixing with the solution in the reference electrode compartment, but allowed electrolytic contact between the two solutions.

The working electrode was a rotating platinum disk electrode as previously described (13). (Geometric area is 0.15 cm^2.) This electrode was always cleaned in hot acid-dichromate cleaning solution and rinsed with boiling distilled water before being used. The surface roughness of the electrode was determined from the coulombs necessary to reduce a platinum electrode after a voltage sweep up to 1.4v *vs.* SCE (14) (0.5 x 10^{-3} coulombs/cm^2). A simple platinum foil counter-electrode and a Beckman sleeve-type saturated calomel reference electrode were used. All potentials are given with respect to the saturated calomel electrode at room temperature.

The solutions were made in the cell. Formic acid in 1*N* H_2SO_4 solution was prepared by adding 100 ml of 1*N* H_2SO_4 to the cell, deaerating with purified nitrogen, and adding the necessary amount of concentrated formic acid from a microsyringe to make the solution 0.085M in formic acid. (The acidity of the solution essentially does not change because of the low ionization constant of formic acid.)

All formic acid solutions were made with Baker's Analyzed Reagent Grade formic acid. The mixed solution of formic acid and CO was prepared by adding 100 ml of 1*N* H_2SO_4 to the cell, saturating with CO, and adding the formic acid as before. The CO-saturated solutions were prepared by bubbling gas through 1*N* H_2SO_4 in the cell. It was assumed that CO has about the same solubility in either 1*N* H_2SO_4 or 0.085M formic acid plus 1*N* H_2SO_4. However, this point is not important since the results were only qualitative. All experiments were carried out at 30.0° ± 0.01°C.

Potential-sweep voltammetry measurements were used in these studies. A triangular voltage-time wave, from a generator built by our Electronics Development Group, was coupled with a Wenking potentiostat to obtain the potential sweeps. The current-voltage (or time) curves were recorded on a Type 502 Tektronix oscilloscope or a Sargent MR recorder. A Tektronix Polaroid-Land camera back was used to record permanently the current-voltage traces from the oscilloscope.

The electrode was rotated at 600 rpm during all measurements except where noted. In all cases, three continuous potential sweeps of the electrode were made. The wait-time between each set of three continuous potential sweeps was carefully controlled; for the adsorption measurements, it was 5 min. (As shown later the accurate measurement of wait-time is not important so long as it is greater than 20 sec.) During the wait-time the electrode was held at 0.0v *vs.* SCE. The areas under the curves were determined with a planimeter. The cell, equipment, and techniques used to obtain the current-voltage curves for CO were similar to those used for formic acid. Here also the wait-time between sweeps was 5 min under similar conditions. Gilman (12) has shown that adsorption is essentially complete in 1 min.

Results

The oxidation of formic acid was studied by investigating five different aspects of formic acid electrochemistry. These are: (*a*) the general shape of the formic acid current-voltage curve; (*b*) the effect of wait-time between sweeps on the relative heights of the current peaks; (c) the current-voltage curves of a mixed formic acid-CO-1*N* H_2SO_4 solution; (*d*) the peak-current voltage for CO and formic acid oxidation

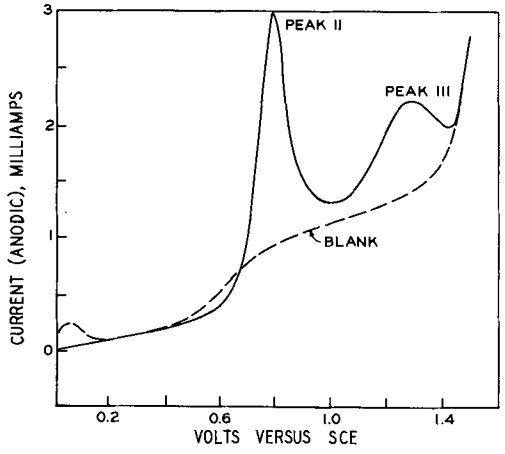

Fig. 1. First sweep of 0.085M HCO_2H in 1*N* H_2SO_4 at 30°C on a platinum disk electrode rotating at 600 rpm; 0.97 cm^2 real surface area; sweep rate of 1.2 v/sec.

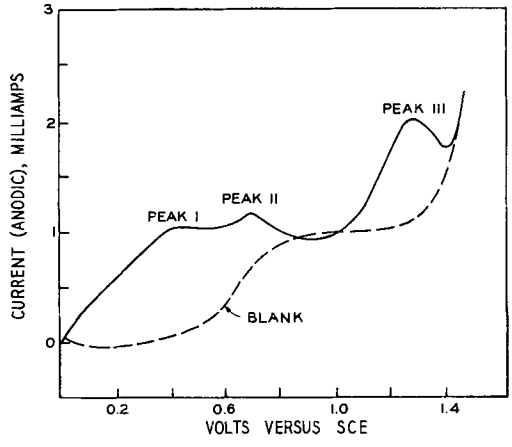

Fig. 2. Third consecutive sweep of 0.085M HCO_2H in 1*N* H_2SO_4 at 30°C on a platinum disk electrode rotating at 600 rpm; 0.97 cm^2 real surface area; sweep rate of 1.2 v/sec.

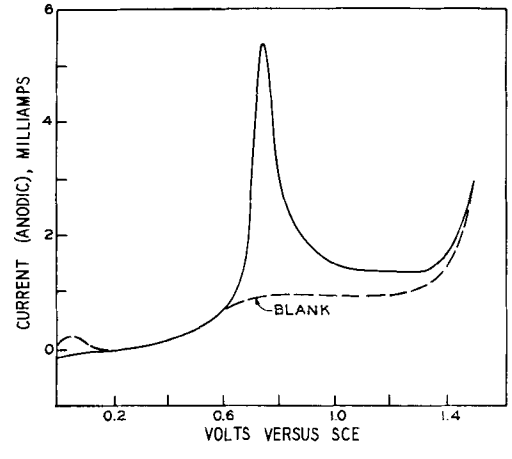

Fig. 3. First sweep of a saturated solution of CO in 1*N* H_2SO_4 at 30°C on a platinum disk electrode rotating at 600 rpm; 1.1 cm^2 real surface area; sweep rate of 1.2 v/sec.

as a function of sweep rate; (*e*) the coulombs necessary to oxidize adsorbed formic acid and CO.

In Fig. 1 to 4 are shown typical current-voltage curves for the oxidation of formic acid and CO in 1*N* H_2SO_4 at 30°C on platinum. The current-voltage curves for the platinum electrode in 1*N* H_2SO_4 (blank) are also shown for comparison. The blank curves for the first consecutive sweep (Fig. 1 and 3) are slightly different than those for the third consecutive sweep (Fig. 2 and 4). The small hydrogen wave at about +0.1v is absent during the sweep because hydrogen has no

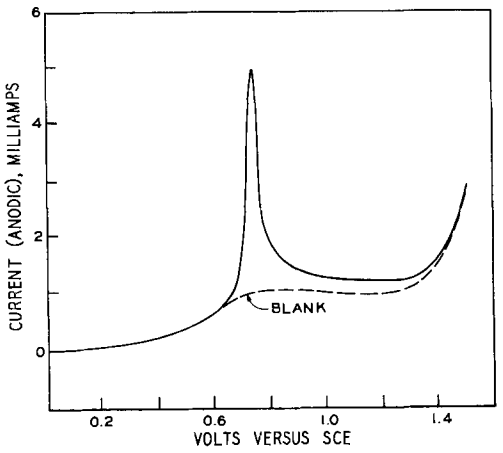

Fig. 4. Third consecutive sweep of a saturated solution of CO in 1*N* H_2SO_4 at 30°C on a platinum disk electrode rotating at 600 rpm; 1.1 cm^2 real surface area; sweep rate of 1.2 v/sec.

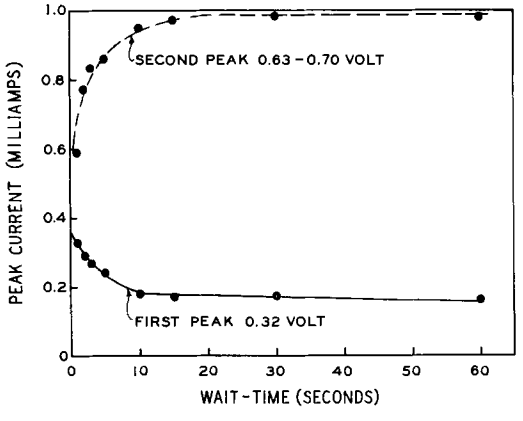

Fig. 5. Effect of wait-time between sets of sweeps on peak heights during first sweep; 0.085M HCO_2H-1*N* H_2SO_4; platinum disk electrode rotating at 600 rpm; 0.97 cm^2 real surface area; sweep rate of 0.26 v/sec.

opportunity to adsorb between sweeps. The blank curves in Fig. 1 and 3 or Fig. 2 and 4 are similar except for the difference in current levels. This was caused by a "real surface area" difference between the electrodes used in the formic acid and CO studies.

As shown in Fig. 2, three current peaks can be obtained for the oxidation of formic acid during the third consecutive sweep; peak I is at about 0.4v, peak II is at about 0.8v, and peak III is at about 1.3v. During the first consecutive sweep (Fig. 1), the peak at 0.4v is essentially gone. This and other effects led us to conclude that the relative heights of the three peaks are very sensitive to the recent history of the system.

Some of the variables which affect the current peak heights of formic acid oxidation on platinum in 1*N* H_2SO_4 at 30°C are:

1. *Sweep number.*—Three continuous sweeps were made. Peak I increased and peak II decreased from the first to the third sweep. Peak III remained relatively constant.

2. *Stirring.*—Peaks I and II decreased slightly when the solution was stirred by rotating the platinum disk electrode at 600 rpm; peak III increased significantly with stirring. Thus, the rate of oxidation of peak III is limited by diffusion. The decrease of current with stirring for peaks I and II might be caused by the forced diffusion of products from the nonelectrochemical adsorption reaction away from the electrode surface, *e.g.*, formic acid adsorbs to form CO and/or H_2 which are thrown away from the electrode surface by stirring before they can react.

3. *Wait-time between sweeps.*—The effect of wait-time between sweeps on the height of peaks I and II during the first sweep is shown in Fig. 5. The height

of peak I decreases, whereas, the height of peak II increases with increasing wait-time between sweeps. Evidently, an adsorbed layer is present which inhibits oxidation of peak I but is itself oxidized at peak II.

From previous literature and from these results we postulate that the following reactions take place. At open circuit or at about 0v (*vs.* SCE), formic acid in acid solution decomposes on a platinum electrode to form hydrogen atoms and/or other adsorbed species (3-10). At open circuit the adsorbed hydrogen atoms combine to form H_2 gas, whereas, when the electrode is held at 0.0v, the hydrogen atoms are ionized. Because hydrogen ionization is a relatively rapid process, the slow step must be the initial dissociative chemisorption of formic acid.

While this reaction is occurring, a competing but slower reaction takes place which results in the formation of a strongly adsorbed layer of material on the electrode surface. The adsorbed layer is oxidized during the second peak (0.8v); therefore, the longer the wait-time the more the material that dissociatively adsorbs and the larger the second peak. In contrast to this, the oxidation process giving the first peak (0.4v) cannot take place when the adsorbed layer is present. The height of the first peak decreases with increasing surface coverage by the adsorbed layer.

In Fig. 6 and 7 are shown potential sweeps of mixtures of formic acid and CO in H_2SO_4 at 30°C with and without stirring. These curves were at a potential sweep rate of 26 mv/sec. The peak at 0.7v for adsorbed formic acid and the peak for CO overlap. However, with stirring, a small postpeak shoulder is obtained on the peak at 0.7v for both sweeps. Gilman (12) indicated that the voltage of the CO peak for the adsorbed species is slightly more negative than the peak produced by CO diffusing to the surface and adsorbing during a peak. Also the decrease in height of peak I with stirring in Fig. 7 indicates that we have increased

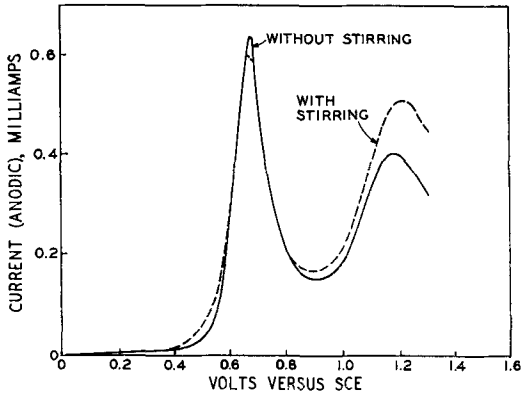

Fig. 6. First sweep of 0.085M HCO_2H in CO saturated 1*N* H_2SO_4 at 30°C on a platinum disk electrode rotating at 600 rpm; 0.97 cm^2 real surface area; sweep rate of 0.26 v/sec.

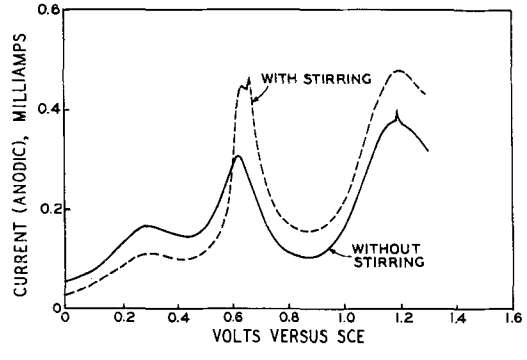

Fig. 7. Second consecutive sweep of 0.085M HCO_2H in CO saturated 1*N* H_2SO_4 at 30°C on a platinum disk electrode rotating at 600 rpm; 0.97 cm^2 real surface area; sweep rate of 0.26 v/sec.

Table I. Peak current voltage of CO and HCO_2H as function of sweep rate

Sweep rate, v/sec	CO, v *vs.* SCE	HCO_2H, v *vs.* SCE
0.13	0.69	0.68
0.26	0.70	0.68
0.64	0.73	0.70
1.2	0.76	0.73
2.4	0.79	0.76
5.8	0.85	0.80

the over-all rate of adsorption of the poisoning material by causing forced convection of the solution.

The peak voltages for the first sweep of CO and for peak II for the first sweep of formic acid are shown in Table I for various sweep rates. These results were obtained with stirring.

The coincidence of the current-voltage curves in Fig. 6 and 7 and the similar dependence on peak voltage as given in Table I suggest the possibility that the two peaks are caused by the oxidation of the same species. In Table I the formic acid peak is slightly more negative because of the influence of peak I and because CO is diffusing to the surface and adsorbing during a sweep. The potential of the current peak due to the oxidation of CO which has diffused to the surface is slightly more positive in potential than the current peak potential from the oxidation of CO already adsorbed on the surface. This was discussed earlier.

The adsorption of formic acid and that of CO were each studied as a function of sweep rate. The coulombs obtained during oxidation were measured by integrating the area under a selected portion of the current-voltage curve. For formic acid the area was determined up to a 0.26v increment beyond the peak at 0.7v. This was necessary to eliminate the third peak which is diffusion controlled and because the current peak shifts with sweep rate for a slow electrochemical process. The number of coulombs for the oxidation of CO was determined by integrating the area of the current-voltage (time) curves to the same ΔE increment beyond the peak.

Because these two peaks are not diffusion controlled, we can assume that

$$Q_{FA} = Q_{(FA+PtO)} - Q_{PtO} = Q_{ads} + Q_{film} \qquad [3]$$

where Q_{ads} is for the material which adsorbs during a sweep, Q_{film} is for the material which is adsorbed before the sweep begins, Q_{PtO} is the number of coulombs obtained during a blank sweep, and Q_{FA+PtO} is the number of coulombs obtained from the oxidation of formic acid and platinum. For this equation to be valid, we must assume that:

1. All the species which can be oxidized through the ΔE potential range are oxidized, regardless of sweep rate.
2. Because of efficient stirring with the rotating disk electrode, diffusion does not limit the reaction during either fast or slow sweeps.
3. The same number of coulombs is necssary to charge the double layer for the blank solution and the formic acid solutions or the blank solution and the CO solution. This is valid since even large double layer capacities gives small amounts compared to those obtained in these studies ($< 5\%$).
4. The formation of adsorbed oxygen on platinum is not hindered or changed in the presence of the compound being oxidized (11).

According to these assumptions, Q_{film} should be a constant for a given electrode and solution and independent of sweep rate. Q_{PtO} is determined for each condition and subtracted from $Q_{(FA+PtO)}$.

If it is assumed that at the bulk concentration of formic acid used in these experiments the adsorption rate is first order with respect to formic acid or CO concentration and free surface area, but independent of electrode potential, then in electrochemical units

$$i_{ads} = nFAk_fC_{FA}\,(1-\theta) \qquad [4]$$

where the electrochemical terms have their usual significance: C_{FA} is the concentration of formic acid at the electrode surface, θ is the fraction of surface covered with adsorbed formic acid, and k_f is a convenient rate constant which includes all effects due to potential, etc. The bulk concentration can be used instead of the surface concentration because they are essentially equal under these conditions of stirring. The reaction in the reverse direction is ignored.

The amount of material adsorbed during a sweep is given by

$$Q_{ads} = \int_{t=0}^{t=\tau} i_{ads}\,dt = \int_{t=0}^{t=\tau} nFAk_fC_{FA}\,(1-\theta)\,dt \qquad [5]$$

where τ is the time interval of a sweep. We assume that during a sweep the surface has constant coverage up to the peak at about 0.7v (11, 12). Beyond this point the coverage drops rapidly to a low value and becomes constant for the rest of the sweep. Because we integrate to a ΔE beyond the peak, we can consider the surface to have minimum coverage during about one fourth of the total sweep. It is reasonable to assume that an average surface coverage independent of sweep rate may be used. Then the amount adsorbed during a sweep may be expressed as follows

$$Q_{ads} = K\tau = K'/v \qquad [6]$$

where K and K' are constants and V is the sweep rate. (The total voltage interval is kept constant.) Equation [6] combined with [3] gives

$$Q_{FA} = Q_{(FA+PtO)} - Q_{PtO} = K'/v + Q_{film} \qquad [7]$$

A plot of Q_{FA} *vs.* $1/v$ should give a straight line with intercept at Q_{film} and with a slope equal to K'.

The same discussion holds for determining Q_{CO}.

In Fig. 8 are shown plots of Q_{FA} and Q_{CO} *vs.* the reciprocal of sweep rate. A straight line was drawn through these data points for each oxidation process. Extrapolation of these lines to infinite sweep rate ($1/v = 0$) gives Q_{film} which is an indication of the amount of adsorbed material on the electrode before the potential sweep was started. These lines intersect the Q axis at about the same point. Therefore, we conclude that the same number of coulombs is required to oxidize both adsorbed CO and the adsorbed intermediate from the catalytic decomposition of formic acid on platinum. Because the curves were not integrated over the entire potential sweep to oxygen evolution, Q_{film} does not give the total amount adsorbed on the surface.

This technique for determining surface coverage can be compared to that used by Breiter for formic acid (11) and Gilman for CO (12). A comparison of the results of the two authors shows that they also obtained about equal surface coverages of carbon monoxide and formic acid. If one assumes that oxygen adsorption on platinum gives 0.5 x 10^{-3} coulombs/cm^2, then Breiter obtains about 0.25 mc/cm^2 of real area for the oxidation of adsorbed formic acid. If a surface roughness of 1.8 is assumed, Gilman obtained about 0.28 x 10^{-3} coulombs/cm^2 of real surface area for the oxidation of adsorbed carbon monoxide. Our results give a value of 0.15-2.0 x 10^{-3} coulombs/cm^2. If one considers that we only integrated to a voltage increment beyond the peak and did not integrate to oxygen evaluation, the results of Breiter, Gilman, and this work compare quite well. The technique used in this study is better suited for comparing the two compounds since it eliminates the effect of the third peak of formic acid oxidation.

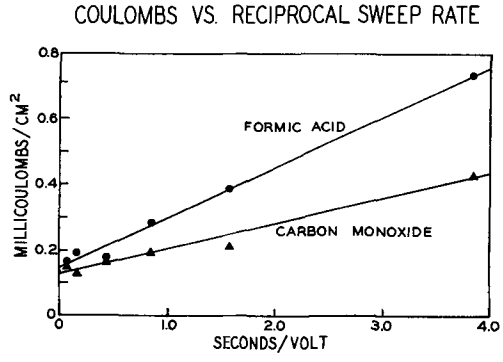

Fig. 8. Coulombs *vs.* reciprocal sweep rate for 0.085M HCO_2H in 1*N* H_2SO_4 or CO saturated solution in 1N H_2SO_4 at 30°C on a platinum disk electrode rotating at 600 rpm.

Conclusions

It is known from prior work that (5-7), on certain metal catalysts in aqueous solutions, formic acid decomposes to adsorbed hydrogen and an adsorbed carboxylate group. Hydrogen gas is given off from the surface until the surface is completely covered with the carboxylate groups. The open-circuit potential of such a metal goes through a maximum when the rate of hydrogen production decreases to a small constant value. Carbon monoxide is known to adsorb on platinum and to be oxidized electrochemically to carbon dioxide.

It is shown in this paper that formic acid reacts with the platinum electrode in aqueous solution to form an adsorbed species which behaves in a way similar to carbon monoxide. This adsorbed species blocks the surface of the electrode and prevents the adsorption of other species. This means that, if formic acid is present at an appreciable concentration, the surface of the electrode will become poisoned while the electrode is under no-load conditions. The electrode can be cleaned by allowing the voltage of the electrode to increase to about that for platinum oxide formation (about 0.7v) where the adsorbed species is oxidized. These conclusions are based on the following observations:

1. Some intermediate from the catalytic decomposition of formic acid adsorbs on the platinum surface and prevents the oxidation of formic acid at 0.4v.
2. Free energy calculations show that formic acid can decompose to H_2O and CO. However, this can happen at appreciable rates only on a catalyst.
3. The adsorbed intermediate can be oxidized at 0.8v. Its current-voltage curve is very similar to the CO curve; the peak voltages of the two curves are about the same over a large sweep-rate range.
4. The oxidation of adsorbed formic acid intermediate and of CO gives the same number of coulombs. During the adsorption of formic acid, adsorbed hydrogen is formed which can be oxidized to hydrogen ions when the electrode is held at 0v *vs.* SCE. The rate of this reaction is relatively slow because either there is a slow rate of adsorption of formic acid or there is a slow rate of dissociation of the adsorbed formic acid into species similar to carbon monoxide.

Acknowledgment

The authors gratefully acknowledge the support of the Army Materiel Command, Harry Diamond Laboratories, Washington, D. C., and the Advanced Research Projects Agency. They are indebted to Mr. Paul M. Abrahamson for a large part of the experimental work and wish to thank Doctors G. H. Denison, R. T. Macdonald, M. J. Schlatter, and L. R. Griffith for helpful discussions of this work.

Manuscript received Dec. 26, 1963; revised manuscript received July 1, 1964. This paper was presented at the Toronto Meeting, May 3-7, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

The Effect of Ultraviolet Light on the Anodic Oxidation of Formic Acid

E. F. Steigelmann[1] and D. R. Rhodes

California Research Corporation, Richmond, California

ABSTRACT

The effect of 2537Å ultraviolet light on the anodic oxidation of formic acid was examined in 1*N* H_2SO_4 electrolyte on a platinum gauze anode. At potentials more negative than 0.5v *vs.* SCE when the uv light is turned on, the current increases for a short time before it decreases to a near-zero value. At potentials more positive than 0.5v, the current increases to a maximum value, the largest increase being at 0.65v *vs.* SCE. Most of the uv effects are due to the reaction of the photolysis products at the anode. At potentials more positive than 1.0v *vs.* SCE, electrode activation by uv light may be a factor.

Both the photolysis and the anodic oxidation of formic acid have been discussed extensively, but the effect of photolysis on the anodic oxidation of formic acid has not been discussed.

Of the many articles on the anodic oxidation of formic acid (1) some have reported that in acid electrolyte, formic acid is oxidized completely to carbon dioxide and water (2, 3). Recently Munson (4) studied the reaction of formic acid on a smooth platinum anode in acid electrolyte and found two different oxidation paths. The first was a direct electrooxidation without prior adsorption; the second was oxidation of an adsorbed formate species. Rhodes and Steigelmann (5) found a slow, preelectrochemical decomposition of formic acid on a platinum anode in acid electrolyte. One of the decomposition products reacts very much like carbon monoxide.

The photolysis of formic acid in aqueous H_2SO_4 electrolyte has also been extensively discussed (6, 7). The photolysis proceeds by radical intermediates which react further to yield carbon dioxide, carbon monoxide, formaldehyde, hydrogen, and water (6).

Dolin *et al.* (8) studied the effect of x-rays and ultraviolet light (wavelengths between 3000 and 4000Å) on the anodic oxidation of formic acid. When formic acid is oxidized anodically, it exhibits three peaks in the potential sweep-current curves; these peaks are centered near 0.4, 0.7, and 1.3v *vs.* SCE (5, 9). Dolin (8) showed that x-rays significantly increase the current at the first and third peaks in the potential sweep-current curves for formic acid. They attributed these effects to two different processes. The first process, which increased both peaks, was shown to be the reaction of the radiolysis products of water; the second (this one increases only the third peak) was shown to be electrode activation. In addition to using x-rays, Dolin also used uv light (wavelengths between 3000 and 4000Å). While light of these wavelengths does not decompose formic acid, Dolin did find a current increase at the third peak; this increase he ascribed to photoexcitation of the platinum oxides on the electrode surface.

While Dolin used two different energy regions to excite formic acid, *i.e.*, the very energetic x-rays and the near uv radiation, he did not use the far uv region (wavelengths between 2000 and 3000Å). This radiation can decompose formic acid and should have marked effects on its anodic oxidation. Therefore, in the experiments described here, the effects of 2537Å light on the anodic oxidation of formic acid were examined.

Experimental

Apparatus and materials.—The cell potential was controlled during the potential-sweep and potentiostatic experiments by a Wenking potentiostat which had a triangular-wave, potential-sweep generator connected to it. All measurements of the current-time curves were recorded on a Sargent MR recorder.

Before each experiment, the cell was thermally equilibrated in a constant temperature water bath (30.00° ± 0.05°C). The cell itself was the typical three-electrode cell of H design with anode and cathode compartments separated by a medium porosity glass frit. The cathode was a 1-cm^2 of platinum foil. The reference electrode was a Beckman sleeve-type, saturated calomel electrode and was connected to the anode compartment through a Luggin capillary. Flow of liquid between the reference and anode compartments was prevented by a Nalfilm-1 (National Aluminate Company) ion exchange membrane.

The essentially monochromatic (2537Å) source was a low-pressure, mercury-arc lamp. Around this was fitted a 52-mesh platinum gauze cylinder, 1 in. in length and ½ in. in diameter. This served as anode. The formic acid was Baker's AR grade, and the electrolyte was 1*N* H_2SO_4.

Experimental design.—Because of the many factors studied in the potential-sweep experiment, the principles of "experimental design" (10) were applied. Five factors were involved: the concentration of formic acid,

[1] Present address: The American Oil Company, Whiting, Indiana.

carbon monoxide, hydrogen, and oxygen, and the intensity of the uv light. The experiments consisted of all possible combinations of the five factors with formic acid being at zero and 6.6 millimolar, the gases at zero and one-fourth saturation at room temperature, and uv light off and on. (One volume of electrolyte saturated at atmospheric pressure with a given gas was mixed with three volumes of helium-saturated electrolyte to produce a one-fourth saturated solution. The saturated solutions were made by bubbling for 20 min the appropriate gas through the electrolyte.) The entire design was duplicated so that the number of trials (experiments) equaled 64.

Since the total number of trials is far greater than can be done on any one day, the daily electrode activity variation becomes important. This varaition is, at times, sufficiently large so as to mask some of the effects being sought. However, by "confounding" the design, this variation was eliminated. In each replicate, one 4-factor and two 3-factor interactions were sacrificed by confounding. More than likely these interactions are very small, if not zero; therefore, little, if any, information is lost by this process. The experiment was divided into eight blocks of eight trials each, and the order of the trials within each block was randomized. All the trials within each block were done on one day. Among the trials of a block, every effort was made to keep the electrode activity constant.

Experimental procedure.—Before any block of potential-sweep experiments was done, the cell and the two platinum electrodes were cleaned thoroughly in chromic acid cleaning solution and rinsed exhaustively with distilled water followed by 1*N* H_2SO_4 electrolyte. In order to minimize variation of the electrode activity between trials of a block, the glassware and electrodes were rinsed only with distilled water and 1*N* H_2SO_4; no cleaning solution was used. Since the order of the trials was random, any "history effect" introduced by not using the chromic acid does not prejudice the results.

Before each trial, the electrode was pretreated in the cell by twice cycling the electrode potential between 0 and 1.25v *vs.* SCE. Ten minutes were then allowed for the cell to come to equilibrium. Four successive potential sweeps between 0.1 and 1.25v were then made and the current-time curve was recorded. The sweep rate was constant at 0.92 v/min. The solution was not stirred.

In the potentiostatic experiments, the same cleaning procedure was used as above. Two electrode potentials were investigated, 0.40 and 0.65v *vs.* SCE; the formic acid concentration was 0.1M, but all other conditions were identical with those in the potential-sweep experiments. In a potentiostatic experiment, the current-time curve was recorded for 20 min before the uv light was turned on. This time interval allowed the cell to approach steady-state conditions. The light was then turned on for 10 min. After the light was turned off, the cell was allowed to run for an additional 20 min to again approach the off-light steady-state conditions.

Analysis of the Potential-Sweep Data

In the potential-sweep experiments, the anodic portion of the current-time curve was characterized by four measured variable quantities: the number of coulombs passed between 0.1 and 1.25v *vs.* SCE and the currents at the three formic acid potential peaks. Since the values for the above variable quantities are different for successive sweeps, the sweep number is an additional factor (at four levels, *i.e.*, the first four sweeps) which brings to 128 the total number of values for each variable (not including replication).

The data were analyzed in the usual manner with the fourth, fifth, and sixth order interactions comprising the variance. The results of these calculations and the 95% confidence limits for each value are given in Tables I through IV. Table I contains values of the variables describing the anodic oxidation of formic acid. Tables II, III, and IV cite the increases in each of these variables above its Table I value caused by hydrogen, carbon monoxide, and uv light, respectively.

Table I. Values for the variables describing the anodic oxidation of formic acid

Discussion

The four following possible mechanisms for the current changes caused by uv light are considered in detail: (i) a thermal effect, if the lamp heats the electrode; (ii) oxidation of the radical intermediates from the photolysis of formic acid; (iii) uv activation of the electrode surface similar to that discussed by Dolin (8); and (iv) oxidation of some of the stable products of the formic acid photolysis, *i.e.*, carbon monoxide, hydrogen, and formaldehyde.

It will be shown that, at potentials less positive than 1.0v *vs.* SCE, the oxidation of the stable decomposition products (mechanism iv) accounts for all observed uv effects. At potentials more positive than 1.0v, both the oxidation of the photolysis products and electrode activation (mechanism iii and iv) contribute to the uv effect. But we have no way of separating these two mechanisms to assess their relative importances. Later we will show that mechanisms i and ii do not explain the observed current changes.

The oxidation of the stable photolysis products could cause the current changes in one of two ways: (*a*) diffusion gradients are set up next to the anode such that the total fuel concentration at the anode increases when the light is turned on, and (*b*) the photolysis products are more reactive than formic acid. It can be shown that when the lamp is turned on, the total con-

centration of reactants at the anode decreases. Therefore, only path (*b*) can account for the uv effect.

Of all the formic acid photolysis products, only hydrogen, formaldehyde, and carbon monoxide are oxidized anodically. Hydrogen is more reactive anodically than is formic acid. Buck and Griffith (3) have shown that formaldehyde is more reactive than formic acid in acid electrolyte. It can be shown that the carbon monoxide also is more reactive than formic acid at potentials greater than 0.6v *vs.* SCE (5, 9, 11). Thus, the uv effect can be explained simply on the basis that the reactivity of the anode fuel has been increased.

If the above mechanism is correct, results of experiments where the photolysis products were added one at a time should predict the effect of uv light. Conclusions drawn from the additive experiments are only qualitative since they do not duplicate the photolysis product concentration. In the additive experiments, the molar concentrations of CO and H_2 are calculated from their solubilities in water to be about 2.1×10^{-4} and 1.9×10^{-4}, respectively (12). It can be shown that the photochemical rates of production of CO and H_2 at the electrode are 2.1×10^{-4} and 1.5×10^{-4} moles liter^{-1} min^{-1}, respectively. [These values were calculated using the following information: (i) the lamp intensity is 4 μw cm^{-2} at 1 meter, (ii) the formic acid extinction coefficient assumed to equal its vapor phase extinction coefficient is 40 (13), and (iii) ϕ (H_2) and ϕ (CO) are 0.110 and 0.142, respectively (7).] In the photochemical experiment, the complex diffusion patterns of the different molecular species at the electrode do not lend to accurate calculation of H_2 and CO concentrations at the electrode. However, the photochemical rates for H_2 and CO are sufficient to make the concentrations of these species at the electrode as large as they are in the additive experiments.

In the experiment where hydrogen is added to the electrolyte (Table II), no significant increase in any of the formic acid peaks is evident, while an increase in the total number of coulombs is seen. In the carbon monoxide additive experiment (Table III), the only significant increases were seen at the 0.65 and 1.25v peaks, the largest one being at 0.65v, sweep No. 1. We did not perform an additive experiment for formaldehyde; but, from the work of Buck and Griffith (3), it appears that formaldehyde should be similar to carbon monoxide in its affect on the formic acid oxidation.

The results from the above additive experiments indicate that the uv light should cause the following changes in the anodic oxidation of formic acid:

1. The number of coulombs as evidenced by the area under the anodic portion of the potential-sweep curve should increase. Probably, this would be caused primarily by hydrogen oxidation.
2. Carbon monoxide and formaldehyde should affect the peak currents. The current at 0.65v should show the largest increase.

The results for the uv effect follow the trends predicted by the additive experiments, and the effect uv light has on the formic acid oxidation may be summarized from Table IV as follows:

1. The number of coulombs is increased by about 60%.
2. The current at 0.25v is increased but only during the third and fourth consecutive sweeps.
3. The current at 0.65v is increased greatly (greater than 100% during the second, third, and fourth sweeps).
4. The current at 1.20v is increased slightly.

Therefore, the predictions of the mechanism and the effect of uv light are consistent in the potential-sweep experiments.

Potentiostatic Experiments

In the potentiostatic experiments, the effect of uv light is different at 0.40v than at 0.65v. At 0.40v (Fig. 1) a transitory current surge is seen immediately after the light is turned on (point A). The current goes

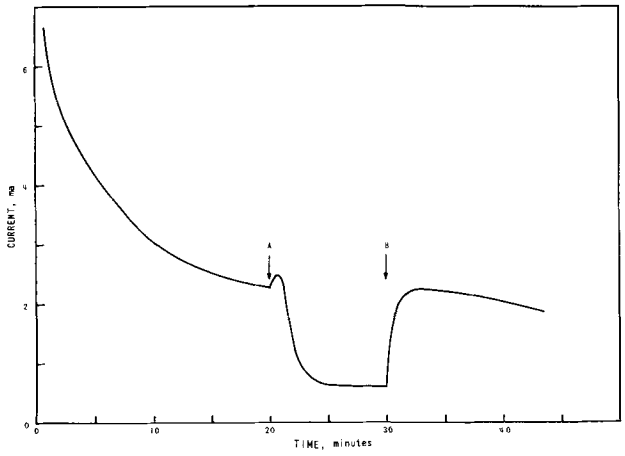

Fig. 1. Effect of uv light on the current during the oxidation of formic acid at 0.40v *vs.* SCE. A, Light on; B, light off.

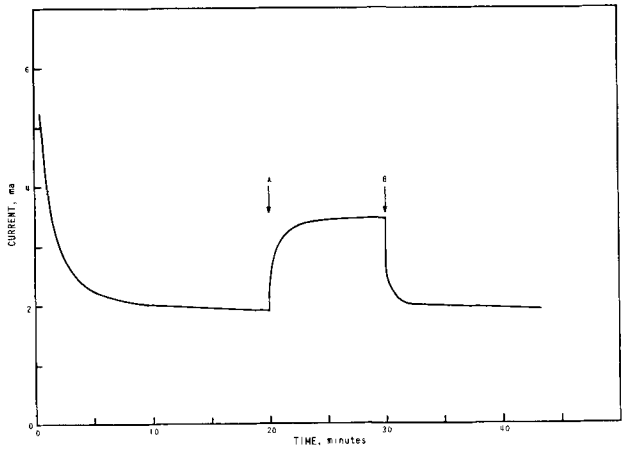

Fig. 2. Effect of uv light on current during the oxidation of formic acid at 0.65v *vs.* SCE. A, Light on; B, light off.

through a maximum and decays to 25% of the "off-light" value. At 0.65v (Fig. 2) after the light is turned on, the current increases to a steady-state value 80% greater than the "off-light" steady-state current. In both cases when the light is turned off, the current resumes its "off-light" value within a few minutes.

The mechanism at 0.40v would appear to be as follows. After the light is turned on, hydrogen, carbon monoxide, and formaldehyde are formed near the electrode. Of these, only hydrogen is oxidized appreciably, and its oxidation probably accounts for the current surge at this potential. Carbon monoxide, on the other hand, does not oxidize at any appreciable rate at 0.40v but does adsorb on the anode to block formic acid oxidation (5, 11). Probably, it is this adsorption and blocking (of the formic acid oxidation) which cause the current to decay.

At 0.65v (Fig. 2), the current increase caused by uv light may be explained in the following manner. All three photolysis products (including carbon monoxide) are oxidized at this potential, and the reactivity of the fuel mixture offsets not only any possible current decrease due to a decrease in the anode fuel concentration but causes the observed current increase. Thus, our mechanism for the uv effect can explain the potentiostatic results at 0.40v and 0.65v *vs.* SCE.

Other Mechanisms

The following mechanisms also were considered to explain the effect of uv radiation of the anodic oxidation of formic acid: (i) a thermal effect, if the lamp heats the electrode; (ii) uv activation of the electrode surface at potentials less than 1.0v; (iii) oxidation of

radical intermediates from the photolysis of formic acid.

None of these were able to account for the uv effect for the following reasons.

After the uv lamp was turned on, a 3.0°C temperature rise was measured at the electrode by a chromel-alumel thermocouple. The electrode will not experience greater localized heating than the thermocouple probe because of their relative sizes. Therefore, the lamp causes, at the most, a 3.0°C increase in electrode temperature. A 10°-20°C increase in electrode temperature would be required if electrode heating by the uv lamp caused the observed current increases.

Dolin *et al.* (9) suggested that both x-rays and uv light (between 3000 and 4000Å) activate a platinum electrode only at potentials greater than 1.0v. We used ethylene to check for electrode activation by 2537Å light at potentials more negative than 1.0v. No activation was found. From this, it seems likely that in the anodic oxidation of formic acid, electrode activation by 2537Å light is unimportant at potentials less positive than 1.0v *vs.* SCE.

The oxidation of the radical intermediates of formic acid photolysis could not account for the ultraviolet effect. In the potentiostatic experiments (Fig. 1 and 2), the current takes several minutes to regain the "off-light" value after the lamp is turned off. This slow recovery time does not suggest radical decay but, rather, diffusion of stable products away from the electrode.

Conclusion

We have seen that the anodic oxidation of formic acid is greatly altered by uv light. At potentials less than 1.0v, the effects of uv light are most likely caused by the anodic reaction of some of the formic acid photolysis products; these are carbon monoxide, formaldehyde, and hydrogen.

Acknowledgment

The authors gratefully acknowledge the support by the Harry Diamond Laboratories of the Army Materiel Command and by the Advanced Research Projects Agency. They are indebted to Professor Peter W. M. John, of the University of California at Davis, California, for designing the statistical experiment and to Mr. Louis J. Painter for the use of his computer program to do the statistical calculations. They also would like to thank Doctors G. H. Denison, R. T. Macdonald, and M. J. Schlatter for their many suggestions.

Manuscript received Feb. 11, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

The Specific Effects of Chloride and Sulfate Ions on Oxide Covered Aluminum

M. A. Heine, D. S. Keir, and M. J. Pryor

Metals Research Laboratories, Olin Mathieson Chemical Corporation, New Haven, Connecticut

ABSTRACT

The distribution of a-c resistance throughout the thickness of oxide film on aluminum specimens, conditioned by pre-exposure to 1.0*N* solutions of sodium chloride and sulfate, has been determined by an electrical method. This method involves measurement of series capacitance and dielectric loss of the oxide covered aluminum as the surface films thin slowly in a slightly alkaline, passivating, sodium chromate solution. Results show that chloride ions become included at certain selected locations in the oxide film, create additional current carriers, and lower the ionic resistance of the film. Sulfate ions do not appear to become included in aluminum oxide films under these conditions and do not lower the film resistance. Aluminum oxide films containing chloride ions dissolve more rapidly in the chromate solution than similar untreated films or films that have been treated in sodium sulfate solution. These observations are held to throw new light on the well defined tendency of oxide covered aluminum to pit severely in nearly neutral sodium chloride solutions.

One of the more widely investigated subjects in aqueous corrosion has been the specific effects exercised by various anions on the rate and form of metallic corrosion. Underlying many of these investigations is the desire to clarify the mechanism by which chloride ions, in particular, exercise such harmful specific effects on metals such as iron and aluminum.

In one of the earliest studies of specific anion effects on aluminum, Britton and Evans (1) measured the increase in current produced at an aluminum anode

maintained in an otherwise passivating chromate solution by the addition of standard amounts of normally corrosive salts. They were thus able to estimate from these experiments a "film penetrating power" of various added anions. In decreasing order, this was found to be Cl', Br', I', F', SO_4'', NO_3', and HPO_4''. Later one of the authors of this paper (2) determined the corrosion rate of super-purity aluminum after 2 and 4 weeks immersion in molar solutions of the sodium halides in the absence of chromate additions. Here it was found that the corrosion rate decreased in order of severity with the series F', Cl', Br', I' with the exception of the longer immersion time in sodium iodide where an enhanced rate of corrosion accompanied the formation of some elemental iodine in solution. The most heavily corroded specimens in the sodium fluoride solution also showed the deepest pitting which was even more severe than that in sodium chloride solution.

Probably the most definitive past study of the specific effect of chloride ions in pitting aluminum was that carried out by Edeleanu and Evans (3). This work confirmed a substantial *p*H drop at aluminum anodes during anodic polarization in potassium chloride solution. By calibration with an inert platinum anode, in similar solutions, it was found that a substantial proportion of soluble reaction product was formed at an aluminum anode in potassium chloride solution and that a much lesser quantity of the soluble product was formed under similar conditions in the less aggressive sodium sulfate solution. This work led to the formation of the "autocatalytic" mechanism for the pitting of aluminum in chloride solutions.

Despite the similarity in terms of acid strength of sulfuric and hydrochloric acids and despite the similarity in electrolytic conductivity of sodium sulfate and sodium chloride solutions of similar concentration, the former solution is substantially less corrosive to aluminum (4, 5) and has lesser tendency to promote aggressive pitting. This is consistent with the well-known ability to anodize aluminum in sulfate solutions, and with the observations of Petrocelli (6) on the stability of thin oxide films on aluminum immersed in sulfuric acid at potentials between −1.0 and +3.0v SCE scale.

The present work is primarily an investigation of the change in a-c resistance of oxide films on aluminum during immersion in sodium chloride and sodium sulfate solutions. Previously a-c capacitance bridge techniques over a wide range of frequency were applied to a study of the effect of immersing super-purity aluminum covered with various thicknesses of γ-Al_2O_3 film in sodium chloride solution at *p*H 6 (7, 8). The results showed that the a-c resistance of a γ-Al_2O_3 film on aluminum, measured at a frequency of 1000 cps, decreased with time to a constant value during contact with the sodium chloride solution; this resistance drop was obtained under conditions where gross corrosion did not occur and where the film thickness, crystal structure, and topography were not detectably changed. At the same time, similar immersion in chloride solution was without effect on the a-c film resistance measured at high frequency (100,000 cps and above). These results were interpreted as meaning that chloride ions entered the anion lattice of γ-Al_2O_3, thereby creating additional current carriers which appeared to lower the ionic resistance of the oxide film without changing the electronic resistance.

A further technique developed by two of the authors (9) has permitted determination of the distribution of a-c resistance throughout the thickness of γ-Al_2O_3 films on aluminum. This method involved measurement of capacitance and loss during the slow and reproducible thinning of γ-Al_2O_3 films by slightly alkaline, passivating, chromate solutions. It was established that contact with this solution did not introduce defects into the film that modified its resistance. The ultimate film thickness that can be achieved is the passive film thickness (around 25Å) which makes the method mainly applicable to the study of thicker compact alumina films. Accordingly, this technique has been employed in the present investigation to determine the magnitude and location of resistance changes in 240Å thick γ-Al_2O_3 films on super-purity aluminum following immersion in 1.0*N* solutions of sodium chloride and sulfate at *p*H 6 for times insufficient to cause detectable corrosion. Because of the earlier establishment of full frequency dispersion curves from 100-1,000,000 cps for these films the present work was confined to the two frequencies of 1000 and 100,000 cps which are particularly pertinent in the chloride substituted alumina system. Results are considered to throw new light on the specific effects of these anions on the corrosion rate of aluminum and serve to provide additional clarification of the cause of the strong tendency of chloride ions to promote pitting attack.

Experimental and Results

Materials.—The aluminum used in this investigation was 99.997% pure and contained 0.001% iron, 0.001% silicon, and 0.001% copper. Specimens used in electrical experiments conducted at a frequency of 1000 cps were in the form of annealed wire having a diameter of 2.5 mm. Specimens used in electrical experiments conducted at frequency of 100,000 cps were in the form of annealed sheet having a thickness of 0.37 mm. The 1.0*N* sodium chloride and sodium sulfate solutions were made up from CP chemicals and demineralized, distilled water and had their *p*H adjusted to 6.0 by the addition of the appropriate acid. The sodium chromate solution was made up from CP sodium chromate and demineralized, distilled water and had its *p*H adjusted to a value of 7.1 by the addition of sodium dichromate.

Sample preparation.—The wire specimens for the low-frequency capacitance and dielectric loss determination were degreased with benzene and etched with 1.0*N* sodium hydroxide for 10 min. They were then rinsed in demineralized distilled water, then in methanol, and finally masked with Tygon paint in order to leave a cylindrical surface area of 0.2 cm^2 exposed. The masked specimens were then stored for 24 hr over calcium sulfate before further treatment. Sheet specimens for electrical experiments at 100,000 cps were similarly etched and then anodized before being masked with the Minnesota Mining and Manufacturing Company's pressure sensitive Electroplaters Tape No. 470 from which a small hole of 0.02 cm^2 area had been punched.

The oxide films investigated in this study were composed of γ-Al_2O_3 and were formed anodically in an electrolyte consisting of 3% by weight of ammonium tartrate dissolved in demineralized distilled water. The *p*H of the solution was adjusted to 7.0 by the addition of a few drops of dilute ammonium hydroxide, so that anodizing conditions favored the formation of compact, uniform, anodic films. The anodizing method was identical to that used in previous studies (7-9). All films were formed at 20v and at 25° ± 0.05°C giving a thickness of approximately 240Å. The forming voltage was raised incrementally and at a fixed rate to the maximum value. The maximum permitted current surge and leakage current values were identical to those previously described (8, 9).

Experimental method.—Masked and anodized wire and sheet samples were first conditioned by immersion in either 1.0N sodium chloride or sodium sulfate solution, at *p*H 6, and at 25° ± 0.05°C for a period of 960 min; the *p*H values of these solutions remained at their original value to within an accuracy of ±0.5 *p*H units. During immersion, no detectable corrosion of the film covered aluminum occurred. Neither could any change in thickness, topography, or crystal structure of the outer surfaces of the 240Å thick films be detected by a combination of electron microscopy and reflection electron diffraction.

Following the above conditioning in either sodium chloride or sulfate solution the oxide covered speci-

mens were washed thoroughly and then immersed in 1.0M sodium chromate solution at pH 7.1 and at 25° ± 0.05°C together with unconditioned but otherwise similar control specimens. Measurement of the initial series capacitances and dielectric losses at different frequencies permitted determination of the total a-c resistance of the oxide films at the appropriate frequency. However, in this solution the films thinned uniformly and slowly, as described previously (9), to an ultimate film thickness of around 25Å, usually within a period of around 3000 min. Successive similar measurement of capacitance and dielectric loss at determined intervals of time during the slow film thinning permitted calculation of the resistance distribution throughout the various aluminum oxide films. The electrical properties of the various oxide films on aluminum were measured during thinning in separate, fresh, chromate solutions at the same pH and temperature (25° ± 0.05°C) in order to eliminate any possibility of interference from the small amounts of dissolved aluminum oxide (10).

A General Radio 716-C capacitance bridge assembly was used for the electrical determinations described in this paper. A constant, 50 mv p-p signal was applied to the oxide covered aluminum specimens in all measurements. A 3.2 cm diameter platinum gauze cylinder was used as a second conducting electrode, with the chromate solution acting as a solution electrode for the centrally located aluminum specimen. Electrical shielding of the measuring assembly was achieved by surrounding it with aluminum foil.[1] When experiments were conducted at a frequency of 1000 cps, the multiplying range of the 716-C bridge was used in order to obtain a suitably large capacitance range for specimens with an area of 0.2 cm². When experiments were conducted at 100,000 cps, where the multiplying range is not operative, a smaller specimen area of 0.02 cm² was employed together with a low loss external series capacitor (0.001 μF) to bring the capacitance of the series combination within the bridge range. In this case a 716-P4 guard circuit, which eliminated lead and other stray capacitances, was employed to develop maximum sensitivity. The current flow in the films due to the application of the AC signal was much less than 1% of the d-c anodic leakage current.

The low-frequency measurements at 1000 cps (50 mv p-p signal) provided direct values of the series capacitance (C_s) and the dielectric loss (D) of the cell containing the slowly thinning, oxide covered aluminum specimen. Previous work (9) showed that series resistance effects from the chromate solution and platinum electrode could be safely ignored at 1000 cps since they were less than 1% of the minimum resistance of the fully thinned oxide films. Accordingly, the average resistivity (ohm-cm) of the oxide film (ρ) could be calculated at any given thickness level from the relationship

$$\rho = \frac{4\pi}{K\omega D} \qquad [1]$$

where K is the dielectric constant of the oxide film,[2] D its dielectric loss at that thickness, and ω the angular frequency of the a-c signal. Using the analog of a capacitor with a parallel reistance, the average oxide film thickness at any given time, could be calculated from the parallel capacitance (C_p). C_p is related to the measured series capacitance (C_s) by

$$C_p = \frac{C_s}{1 + D^2} \qquad [2]$$

Since D never exceeded a value of 0.07 at 1000 cps (see for instance Fig. 1) the average film thickness at 1000 cps could be calculated directly from uncorrected values of C_s without incurring errors greater than 0.5%.

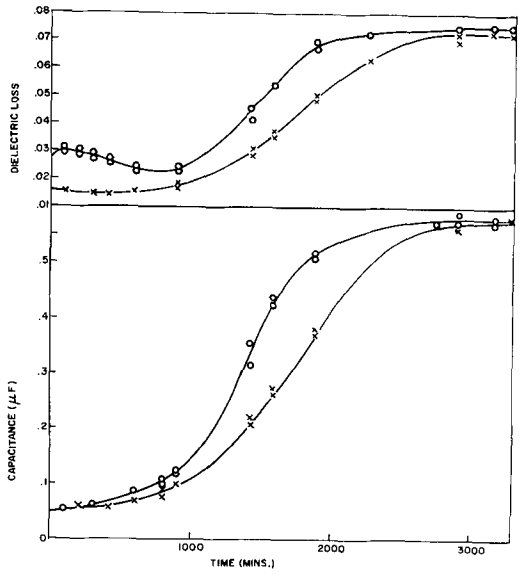

Fig. 1. Variation with time of the series capacitance and dielectric loss of chloride treated and untreated γ-Al_2O_3 films during their thinning in 1.0M sodium chromate solution at pH 7.1 at 25°C: X—X, original film; O—O, chloride treated film.

The foregoing method of calculating the average resistivity of a slowly thinning aluminum oxide film is not sufficiently accurate at higher frequencies of 100,000 cps (50 mv p-p signal). Here the measured C_s and D values include significant contributions not only from the oxide film itself, but also from the adsorbed double layers and chromate solution, together with the external low loss series capacitor. The effect of the external series capacitor can be measured and eliminated as described in a previous publication (9). The resulting corrected values of C_s and D for the oxide film plus chromate solution and associated double layers permit calculation of the parallel a-c resistance R_p ohms cm² of this combination from

$$R_p = \frac{1 + D^2}{D\omega C_s} \qquad [3]$$

The previous work (9) also developed values for the parallel a-c resistance of the chromate solution and associated double layers in the identical measuring cell and over a wide range of frequencies. This was achieved by substituting a smooth platinum specimen of the same area (0.02 cm²) in the same measuring cell for the oxide covered aluminum specimen. The parallel resistance of the solution component of R_p may be subtracted from the combination value in Eq. [3] thereby permitting calculation of the a-c resistance (ohm-cm²) of the oxide film alone at various thickness levels. Resistivity (ohm-cm) and parallel resistance (ohm-cm²) at any given thickness are, of course, directly related by the appropriate value of film thickness in centimeters.

Results.—The resistivity[3] of duplicate specimens of the original 20v γ-Al_2O_3 films was found to be around 1.5 x 10^{10} ohm-cm at 1000 cps and 1.5 x 10^7 ohm-cm at 100,000 cps. These values are quite similar to those determined at the same frequencies in earlier work (8). After immersion for 960 min in 1.0*N* NaCl solution at pH 6.0 and at 25° ± 0.05°C (during which no detectable corrosion or film thickening occurred) the average resistivity of duplicate specimens at 1000 cps decreased to a value of 7.7 x 10^9 ohm-cm whereas the average resistivity at 100,000 cps was unchanged. Simi-

[1] See Fig. 1 of ref. (8) for details.

[2] It has been shown previously (7, 8) that Cl' substitution in compact anodic films on aluminum does not significantly change the value of K.

[3] All resistance values are expressed as parallel resistances.

lar immersion of duplicate specimens in 1.0*N* sodium sulfate solution at the same *p*H and temperature and for the same time resulted in no significant decrease in resistivity either at 1000 or 100,000 cps.

Duplicate aluminum specimens carrying the original 20v films and similar specimens carrying originally similar films which had been immersed in sodium chloride and sulfate solutions as described above, were then immersed in 1.0M Na_2CrO_4 solution at *p*H 7.1 and at 25° ± 0.05°C in order to thin the films and thereby permit calculation of the resistance *vs.* thickness curves. Figure 1 shows the measured changes with time of the series capacitance and dielectric loss at 1000 cps of specimens carrying the original γ-Al_2O_3 films and of those specimens carrying similar films which had then been immersed in the sodium chloride solution. These experiments were conducted on masked wire specimens with an area of 0.2 cm^2 exposed to the various electrolytes. The curves for duplicate specimens carrying 20v films that had been immersed in sodium sulfate solution are not contained in Fig. 1 because the capacitance and dielectric loss *vs.* time curves are almost indistinguishable from those of the specimens carrying the original "as-formed" γ-Al_2O_3 films.

The results in Fig. 1 are depicted in Fig. 2 as curves relating film thickness to the average or cumulative resistivity (ohm-cm) of the three oxide films (calculated directly from Eq. [1]) at 1000 cps. Figure 3 depicts the relationship between film thickness and a-c resistance (ohm-cm^2) at 1000 cps; this curve is calculated from the "best fit" curves for the three conditions in Fig. 2 by multiplying the cumulative resistivity by the film thickness.

It may be immediately seen from Fig. 2 and 3 that immersion of the oxide covered aluminum specimens in sodium chloride solution, following film formation and prior to film thinning, results in a significant decrease in the a-c resistance of the oxide films at 1000 cps and that this resistance drop is confined to the outer 170Å of the 240Å thick film. However, similar immersion in sodium sulfate solution is without major effect on the resistance of the film, with the small changes in the outer 30Å of the film adjacent to the original oxide-solution interface being of doubtful experimental significance.

Immersion in either sodium chloride or sodium sulfate after film formation failed to reduce the a-c resistance at 100,000 cps of the original 20v oxide film. Accordingly, thinning experiments in 1.0M sodium chromate solution at *p*H 7.1 were performed only on duplicate specimens of the original 20v film and similar specimens that had been subsequently immersed in 1.0*N* NaCl solution at *p*H 6 for 960 min. Figure 4 shows the relationship between thickness and a-c resistance (ohm-cm^2) at 100,000 cps for both sets of films. The results were obtained using the smaller (0.02 cm^2) masked sheet specimens in combination with the low loss external capacitor. The results in Fig. 4 have been corrected for the external capacitor and for solution and double layer resistance as described earlier (9). As would be anticipated from the measurements on the initial unthinned films, immersion in sodium chloride (or sodium sulfate) solution has no effect on the dis-

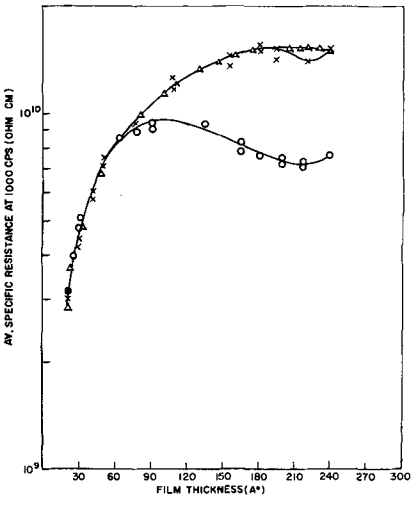

Fig. 2. Relationship between average specific resistance at 1000 cps and thickness of untreated γ-Al_2O_3 films 240Å thick and similar films which have been treated by 16 hr immersion in either 1.0*N* sodium chloride or sulfate solution at *p*H 6 and at 25°C: X—X, original film; O—O, chloride treated film; △—△, sulfate treated film.

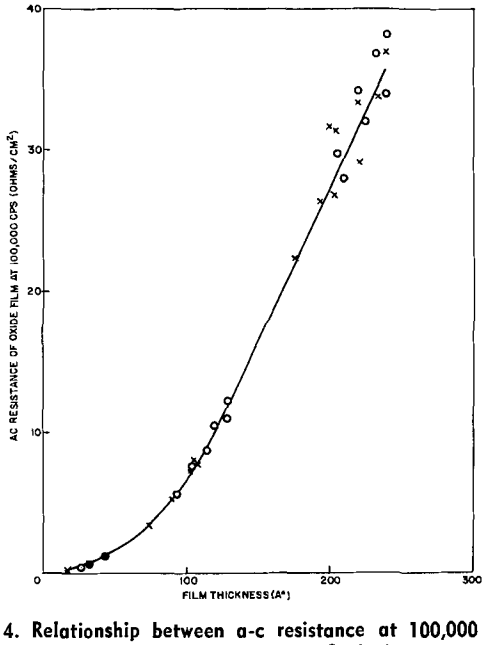

Fig. 4. Relationship between a-c resistance at 100,000 cps and thickness of untreated γ-Al_2O_3 films 240Å thick and similar films which have been treated by 16 hr immersion in 1.0*N* sodium chloride at *p*H 6 and at 25°C: X—X, original film; O—O, chloride treated film.

tribution of a-c resistance at 100,000 cps throughout the thickness of the film. Figure 5 shows the common relationship between average or cumulative resistivity (ohm-cm) at 100,000 cps and thickness for both the original and substituted aluminum oxide films. Figure 5 is calculated from the smoothed common curve in Fig. 4 and can be compared directly with the similar results at lower frequency in Fig. 2.

The results in Fig. 1-5 confirm earlier observations that immersion of oxide covered aluminum specimens in sodium chloride solution results in a decrease in a-c resistance of the oxide film only at bridge frequencies below 100,000 cps. This decrease in resistance occurs under the experimental conditions described (8) above without film thinning, contamination, and structural or topographical changes. However, Fig. 2 and 3 show that similar immersion in sodium sulfate solution produces no significant change in the distribution of a-c resistance at 1000 cps throughout the thickness of the film. Neither solution produces a significant change in the high (100,000 cps) frequency resistance distribution through the film thickness.

Figures 2 and 3 throw new light on the primary location of the low-frequency resistance change in oxide films exposed to sodium chloride. From these figures the resistance drop is clearly confined to the outer 170Å of the film adjacent to the original oxide-solution interface. The resistance decrease is considered to be due to the additional current carriers introduced by chloride ion substitution in the outer portion of the oxide film. Since the reciprocal resistivity, *i.e.*, conductivity, of a semiconductor is directly proportional to the number of current carriers, information on the distribution of additional current carriers introduced by Cl' substitution can be obtained by plotting the conductivity (cotangent to Fig. 3) of the original and chloride treated films as a function of film thickness. This plot is contained in Fig. 6 for the two oxide films. The difference in conductivity, *i.e.*, the dotted curve, represents the distribution of current carrier introduced by chloride ion substitution and therefore is directly proportional to the retained chloride ion concentration in the film.

It is also evident from Fig. 1 and also from similar results obtained at 100,000 cps, that the series capacitance of the chloride treated film increases more rapidly with time than that of the original film or the sulfate treated film. Since immersion in the sodium chloride does not significantly change the dielectric constant of the oxide film (8), the results in Fig. 1 indicate that the chloride treated films dissolve more rapidly in the chromate solution than either the untreated or the sulfate treated films. Figure 7 shows the relationship between the thickness of the two treated and the untreated aluminum oxide films and time of immersion in 1.0M Na_2CrO_4 solution at *p*H 7.1.

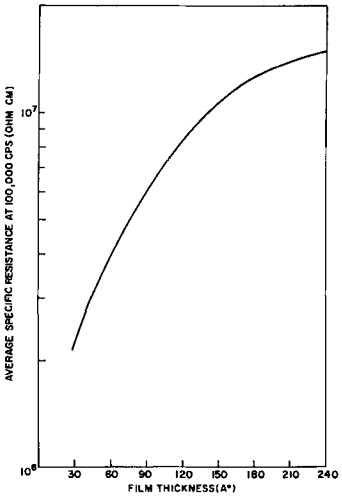

Fig. 5. Common curve relating average specific resistance at 100,000 cps to thickness of γ-Al_2O_3 films 240Å thick both with and without treatment in 1.0*N* sodium chloride solution for 16 hr at *p*H 6 and at 25°C.

Discussion

Initial electrical experiments on unthinned, 240Å thick γ-Al_2O_3 films before and after 16 hr immersion in sodium chloride solution, confirmed previous results (7, 8) that this chloride treatment decreases the average resistivity of the oxide films determined at 1000 cps. The magnitude of the decrease in resistivity in 1000 cps was also similar to that previously reported (7). These initial experiments showed that otherwise similar immersion in sodium sulfate solution had no significant effect on the average resistivity of the γ-Al_2O_3 films at 1000 cps. Neither did immersion in the chloride or sulfate solutions change the capacitance of the oxide covered aluminum specimens, and therefore, the oxide film thickness from the initial value.

Initial electrical experiments on similar unthinned films at 100,000 cps also gave resistance values identical to those determined in earlier work (8, 9) at this frequency, and confirmed that 16 hr immersion in sodium chloride and also sodium sulfate solution produced no change in the high-frequency resistance or capacitance of the oxide films.

Structure of the original oxide films.—The film thinning experiments give a great deal of more useful information on the variation of resistance throughout the thickness of these anodic γ-Al_2O_3 films formed by the rising voltage method and, in particular, how this nonuniform resistance distribution is modified by intervening treatment with sodium chloride or sulfate solutions. Figure 3 shows the relationship between a-c resistance (ohm-cm^2) at 1000 cps and thickness of the original 240Å thick γ-Al_2O_3 film formed at 20v in neutral ammonium tartrate solution. This resistance *vs.* thickness curve is similar to that established earlier (9) and consists of four distinct regions which have previously been described as follows:

1. A low resistivity[4] region some 60-80Å thick immediately adjacent to the oxide-metal interface where the resistivity increases from 5×10^9 ohm-cm at a distance of 25Å from the oxide metal interface to 2×10^{10} ohm-cm at 80Å from the oxide metal interface;
2. A characteristic overlying region around 100Å thick in which the resistivity at 1000 cps is constant at 2×10^{10} ohm-cm;
3. A 40Å thick region extending from 180 to 220Å from the oxide-metal interface in which the low-frequency resistivity decreases with increasing distance from the oxide-metal interface to as little as 5×10^9 ohm-cm; and
4. An outer region some 20Å thick, immediately adjacent to the oxide-solution interface, where the resistivity at 1000 cps is unusually high (5×10^{10} ohm-cm).

Figure 4 shows the much simpler relationship between a-c resistance of the original 240Å thick γ-Al_2O_3 films at 100,000 cps and thickness. This is also identical to the results of earlier work on similar films (9) and contains only two regions as follows: (i) a region around 80Å thick immediately adjacent to the oxide-metal interface in which the resistivity is as low as 3×10^6 ohm-cm and increases with increasing distance from the oxide metal interface, and (ii) a residual zone of constant resistivity (2.2×10^7 ohm-cm) extending from around 100Å from the oxide-metal interface out to the oxide-solution interface.

An explanation was offered earlier (9) for the presence of these zones of variable resistivity and for the strong effect of frequency. This explanation is briefly

[4] Obtained from the slope of the tangent to the a-c resistance (ohm-cm^2) *vs.* thickness (cm) curve at the appropriate film thickness value.

summarized below. Studies of dispersion peaks in dry γ-Al_2O_3 films at varying frequency and temperature (7) suggested that the relaxation time of defects introduced by impurity substitution of hydroxyl ions was somewhat less than 10^{-5} sec. It was later suggested (8, 9) that the measurement of C_s and D at frequencies of 100,000 cps and above would be mainly sensitive to electronic relaxation effects resulting from gross impurity substitution (including substantial departure from stoichiometry) and that similar measurements at lower frequencies than 100,000 cps would be sensitive to both ionic and electronic relaxation effects resulting from these causes.[5] Indirect evidence (8) was introduced to show that electronic and ionic relaxation effects, detected by these means, could be qualitatively related to the electronic and ionic resistances respectively of the aluminum oxide film. This view receives some support from the recent work of Strickler and Carlson (25).

Accordingly, the low resistivity region of the γ-Al_2O_3 film depicted in Fig. 4 at 100,000 cps was attributed primarily to electronic relaxation effects resulting from the anticipated presence of excess metal ions in the vicinity of the oxide-metal interface. Probably there exists an n-type defect structure in this region similar to the F′ defect structure proposed earlier by Grunberg and Wright (11). A similar low-resistivity region is seen in the vicinity of the oxide-metal interface at the lower frequency of 1000 cps (Fig. 3). It is believed that this lower frequency effect is also due primarily to electronic relaxation effects from the nonstoichiometric excess metal structure, although it is not possible to rule out some contribution from ionic relaxation effects. It was, however, suggested that these ionic effects are not predominant at 1000 cps in this region of the oxide film.

The zones of constant resistivity, which encompass the remainder of the oxide film at 100,000 cps (Fig. 4) and a 100Å thick zone at 1000 cps (Fig. 3) were previously defined as showing the characteristic resistivities of the γ-Al_2O_3 film at the two frequencies. The remaining two outer zones of varying resistivity at 1000 cps were attributed to ionic relaxation effects resulting from impurity substitution. The intermediate 40Å thick zone (3) of reduced specific resistance was believed to be due to field-aided entry of hydroxyl ions into the γ-Al_2O_3 structure during formation of the anodic film. This proposition finds good support in the recent elegant Xe^{125} marker studies of Davies *et al.* (12), who demonstrated clearly the existence of substantial inward migration of anions during the formation of similar anodic aluminum oxide films. One-for-one substitution of singly charged hydroxyl ions for doubly charged oxygen ions in the anion lattice should result in the creation of additional current carriers, a more strongly n-type defect structure, and an increase in ionic relaxation effects. The outer region (4) of very high specific resistance at 1000 cps (5×10^{10} ohm-cm) was attributed to the existence of a saturated anion lattice, due to the strongly oxidizing conditions during film formation; this outer area of the film was considered to exhibit a more strongly p-type character (9, 13). Again this structure modification resulted in a modification of ionic rather than electronic relaxation characteristics.

Changes in structure resulting from immersion in sodium chloride or sulfate solutions.—After this summary of the probable resistivity characteristics of the original oxide film, any changes resulting from immersion in sodium sulfate or chloride can now be considered in more detail. It should first be re-emphasized that the immersion times in these solutions were deliberately held to a sufficiently low value (16 hr at 25°C) that no detectable corrosion of the oxide covered aluminum occurred. Furthermore, no film thinning, contamination, or change in the surface topography was detected in the capacitance studies or in the electron microscopical studies reported previously (8, 9).

Immersion of aluminum covered with a 240Å thick aluminum oxide film having the foregoing structural characteristics in 1.0*N* Na_2SO_4 solution of *p*H 6 for 16 hr and at 25°C resulted in no change in thickness, in average resistivity, or in the a-c resistance distribution throughout the thickness of the oxide film at 100,000 cps. Therefore, treatment in the sulfate solution modifies neither the defect structure of the excess metal oxide adjacent to the oxide-metal interface, nor the characteristic high frequency resistivity of the remaining oxide. At the lower frequency of 1000 cps, the average resistivity of the unthinned oxide was again not changed by the 16 hr immersion in sodium sulfate. Thinning experiments on films pretreated with sodium sulfate solution again showed that there was no change in film thickness, in the characteristic zone of constant resistivity, or in the excess metal region of the oxide film adjacent to the oxide-metal interface (Fig. 2 and 3). Minor modifications in resistivity appear to have been made in the outer 40Å of the oxide film adjacent to the solution-oxide interface (Fig. 2). The experimental significance of these small changes is uncertain; however, they might be due to the entry of small concentrations of OH′ ions specifically adsorbed on the oxide surface (8), since the changes seem basically similar to those in zone 3 of the original film. Alternately, the slight modifications in the resistance *vs.* thickness curve which are seen in the outer 40Å of the film, may be due to partial annihilation of the mobile carriers in the two diverse defect structures in zones 3 and 4 of the original film (9, 13). Accordingly, the low-frequency results in Fig. 2 and 3 are held to imply either that sulfate ions themselves do not substitute in γ-Al_2O_3 structure to any significant degree, or else that any substitution in the γ-Al_2O_3 structure is unaccompanied by a significant change in a-c resistance, either at high or low frequency. The latter alternative is considered to be less likely.

When the a-c resistance *vs.* thickness curves are determined at 100,000 cps following similar treatment of oxide covered aluminum specimens with sodium chloride solution (where again no corrosion or detectable film thinning, etc., occurs), no change in the resistance distribution with thickness is again detected (Fig. 4). This observation is consistent with earlier work on unthinned films (8) and suggests that any chloride ion substitution obtained in these experiments has no added effect on the electronic relaxation characteristics of the γ-Al_2O_3 films. The situation is vastly different when the effect of treatment with sodium chloride solution on the a-c resistance *vs.* thickness curve at 1000 cps is determined (Fig. 3). Here the immersion in the sodium chloride solution results in a major decrease in resistance without film thinning and, of course, without corrosion. The change in the resistance distribution with thickness occasioned by the immersion in sodium chloride solution can be summarized as follows:

1. The low-resistivity zone adjacent to the oxide-metal interface is completely unaffected by chloride immersion. This is due only to the selection of a relatively thick initial film through which complete penetration of chloride ions was not anticipated.

2. The characteristic zone of constant low-frequency resistivity is completely eliminated.

3. The penultimate zone 3 of decreasing specific resistance with increasing film thickness, believed to be due to OH′ entry, is reinforced, magnified, and deepened to within 70Å of the oxide-metal interface.

[5] The experimental technique appears to be best adapted to investigation of the changes in resistance resulting from deliberately perturbing the original as-formed oxide. The major significance is, therefore, obtained by comparison of the resistance of the "perturbed" oxide with the original film which may be essentially regarded as a background. Electrical resonance effects that are easily detected are these with large relaxation times less than 10^{-5} sec.

4. The former outer zone of maximum specific resistance is largely suppressed, but is still detectable.

The actual a-c resistance distribution in chloride substituted γ-Al_2O_3 is therefore more complicated than the simple two zone (completely substituted and completely unsubstituted) model proposed earlier by MacMullen and Pryor (7) (dotted curve in Fig. 3) where the large variation in resistivity of the original film with thickness was not realized.

The results in Fig. 3 appear to be completely consistent with the already proposed entry of chloride ions into the aluminum oxide structure and their exchange with oxygen ions in the anion lattice (7, 8). The authors believe that this postulate is further supported by the evident reinforcement, by chloride treatment of the penultimate zone 3 in the original film, where original resistivity was believed to be lowered by hydroxyl entry during film formation. This zone from Fig. 3 becomes extended inward by around 110Å to within 70Å of the oxide-metal interface. Since these strong resistance effects of chloride substitution are seen only at frequencies below 100,000 cps (8), they should represent enhanced ionic relaxation effects from Cl′ substitution and should manifest themselves as a substantially decreased ionic resistance of the over-all oxide film. If a one to one chloride ion-oxygen ion exchange or substitution is visualized, the substituted oxide should exhibit a much stronger n-type defect structure. Support for the inclusion of chloride ions in aluminum oxide films during simple immersion in sodium chloride solution is also provided to some degree by the previous radiochemical studies of Verkerk (14).

The aqueous sodium chloride solution employed in this investigation, of course, contains hydroxyl ions as well as chloride ions. Both anions appear to be able to enter the γ-Al_2O_3 film structure, substitute for oxygen ions, and therefore produce the same number of additional current carriers for an equivalent number of substitutions. Since the relaxation times of the resulting defects could well be quite similar, the present experimental work does not permit quantitative assignment of the proportion of the total resistance drop in Fig. 3 to one or the other of these individual anions.

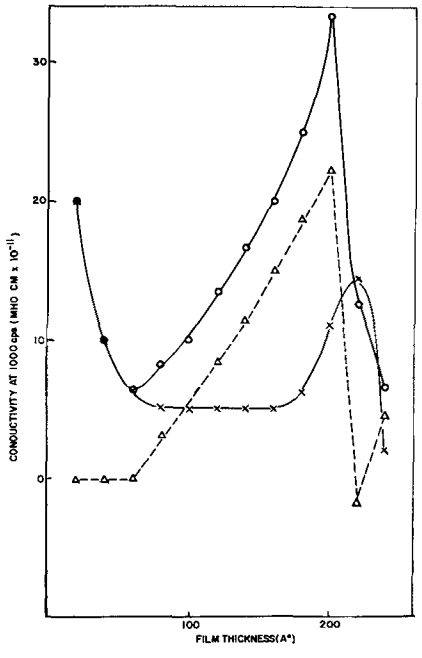

Fig. 6. Relationship between conductivity at 1000 cps and thickness of γ-Al_2O_3 films 240Å thick both with and without prior immersion in 1.0*N* sodium chloride solution for 16 hr at pH 6 and at 25°C: X—X, original film; O—O, chloride treated film; △—△, difference curve.

However, from the results in Fig. 3 on the effects of immersion in 1.0*N* Na_2SO_4 solution, which contained the same concentration of OH′ ions as the 1.0*N* NaCl solution, it appears that any effect of hydroxyl substitution during the immersion experiments is small compared with that resulting from Cl′ substitution.

The present work can now be applied to estimating the distribution of additional current carriers introduced into the aluminum oxide films by chloride treatment. In a semiconductor the number of current carriers is directly proportional to the reciprocal resistivity, *i.e.*, the conductivity or cotangent to Fig. 3. The conductivity distribution with film thickness at 1000 cps in the original untreated aluminum oxide film and in the otherwise similar chloride treated aluminum oxide film is shown in Fig. 6. The difference in conductivity at a given thickness should be directly proportional to the number of additional current carriers introduced by chloride treatment and therefore to the concentration of Cl′ (with possibly OH′) ions in the oxide film at that location; *i.e.*, the dotted difference curve in Fig. 6. It may be seen that the concentration of chloride ions in the outer 20Å of the oxide film is very low. The apparently "negative" concentration observed 20Å from the oxide-solution interface is probably due to the annihilation of the mobile carriers in the vicinity of the p-n junction. A low concentration of Cl′ in the p type layer is consistent with the view that this layer contains an essentially saturated anion lattice and that the early rapid entry of chloride ions primarily occurs at vacant sites in the anion lattice (7). The concentration of chloride ions increases sharply at the outer edge of the n-type zone in the aluminum oxide film and thereafter appears to decrease in an approximately linear fashion with increasing distance from the oxide-solution interface. The reasons for this approximately linear decrease in Cl′ ion concentration are at present not completely understood, and the present work does not permit a unique explanation of this phenomenon.

Effect of chloride ion substitution on the dissolution kinetics of aluminum oxide films.—Of particular significance from the standpoint of corrosion mechanisms is the higher dissolution rate exhibited by the γ-Al_2O_3 films pretreated in sodium chloride solution (Fig. 7). Probably the small difference in dissolution rate between the original films and those pretreated in sodium sulfate solution is not experimentally significant. However, in all experiments an enhanced dissolution rate of the films pretreated in sodium chloride solution was observed. From studies of the zeta potential of various oxides of aluminum (15, 16), it appears that the hydroxyl ions should be specifically adsorbed at *p*H 7.1 on aluminum oxide films in much greater numbers than hydrogen ions. Therefore, it is probable that the

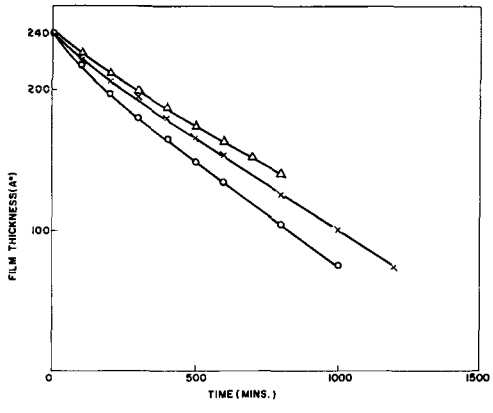

Fig. 7. Thickness of γ-Al_2O_3 films in the untreated condition and after treatment for 16 hr in either 1.0*N* sodium chloride or sodium sulfate solution as a function of time of immersion in 1.0*M* sodium chromate solution at *p*H 7.1 and at 25°C: X—X, original film; O—O, chloride treated film; △—△, sulfate treated film.

combination of specifically adsorbed hydroxyl ions with aluminum ions in the lattice of the aluminum oxide film and the removal of a combined species from the surface constitutes the rate-controlling step during dissolution of the oxide films in the thinning solution. Earlier studies on the mechanism of direct dissolution of α-Fe_2O_3 in noncomplexing acids (17) (where the rate-controlling step is the combination of adsorbed hydrogen ions with oxygen ions in the oxide lattice) showed that an increasing number of oxygen ion vacancies in the anion lattice favored more rapid dissolution of the oxide. This effect was attributed to a relaxation of the force-field around surface oxygen ions in the vicinity of oxygen ion vacancies thereby facilitating their removal from the crystal lattice. By analogy, substitution of the γ-Al_2O_3 films with chloride ions would be expected to create additional aluminum ion vacancies, thereby facilitating the removal of aluminum ions from the alumina lattice; under given dissolution conditions, this factor should speed the rate of dissolution. The results in Fig. 7 appear to be consistent with this suggestion.

Modifications of the aluminum oxide structure and its relation to pitting of aluminum in nearly neutral solutions.—The foregoing observations can be now applied to improving the understanding of why aluminum covered with its natural oxide film is much more susceptible to pitting corrosion in sodium chloride solution than in sodium sulfate solution. When film-covered aluminum is immersed in sodium chloride solution, the first reaction occurring in the induction period before gross corrosion begins should be the adsorption and entry of Cl′ ions into the oxide lattice. This should create additional current carriers and/or additional aluminum ion vacancies in the cation lattice and thereby reduce the ionic resistance of the oxide film. In turn, this will result in a reduction of anodic polarization and should permit more rapid outward diffusion of aluminum ions into the solution. Concurrently, the electronic resistance of the oxide film, which is important in controlling cathodic polarization (18), is probably not significantly changed as long as the over-all film thickness remains constant. In the natural oxide film, penetration of the chloride ions down to the oxide-metal interface must be anticipated from Fig. 2 and 3, and indeed earlier work (7) on thinner films shows this view to be justified. Furthermore, the chloride ions can hardly be distributed uniformly throughout the film, but instead should be concentrated at certain selected areas such as grain boundaries, dislocations, and other internal surfaces in the oxide film where rapid exchange and substitution has been anticipated (7, 8). At the local areas of highest Cl′ ion concentration in the film, not only will the resistance of the film (per unit of thickness) to the outward passage of aluminum ions be lowest, but also the film itself will be specially sensitive to enhanced dissolution. This will became even more pronounced as aluminum ions enter the solution, become precipitated as a hydrated aluminum oxide, thereby generating local concentrations of hydrogen ions around the anodic locations as shown by Edeleanu and Evans (3). Under these conditions, the microscopic areas of high chloride ion concentration could well be enlarged to macroscopic pits by the speeding action of the higher locally generated H^+ ion concentration but extreme localization of attack on a macroscopic scale must be anticipated since the oxide film at the local areas containing the highest concentrations of substituted Cl′ ions not only exhibit the lowest ionic resistivity, but also under steady-state conditions of film dissolution and repair, must exhibit a locally lower thickness than adjacent areas not containing as high a concentration of substituted chloride ions. In the truest sense, the pitting of aluminum in chloride solutions becomes "autocatalytic" due to these local, thin areas of maximum Cl′ concentration and lowest ionic resistivity in the film.

The state of affairs is entirely different when similar specimens are immersed in sodium sulfate solution at the same *p*H and temperature. The sulfate ions probably do not enter the lattice of the thin surface oxide films to a significant degree. Accordingly, prolonged contact of the oxide covered aluminum with sodium sulfate solution does not serve either to reduce the ionic resistivity of the surface film or to increase its dissolution rate. Therefore, although the specimen will corrode and the film may thin or thicken slowly with time, only local variations of *p*H and small metallurgical differences in the metal substrate, inherited in the oxide film, tend to localize the corrosion. The two primary oxide film factors of local reduction in ionic resistivity and superimposed local sensitivity to enhanced dissolution, so clearly produced by substituted chloride ions, are conspicuously absent during immersion in sodium sulfate solution. The major difference between the effects of Cl′ and SO_4'' ions on the oxide film may well also account for Edeleanu and Evans' (3) observation that anodic treatment of aluminum in sodium chloride solution produces more soluble anodic reaction products at between *p*H 5 and 6 than similar anodic treatment of aluminum in sodium sulfate solution.

It is tempting to apply the above reasoning to the pitting of aluminum in other aqueous solutions and to the pitting of other metals normally covered with thin oxide films. This extrapolation must be cautiously conducted in the absence of pertinent supporting data. Nearly neutral solutions of sodium fluoride pit aluminum even more readily than chloride (2). Doubtless, the explanation of this phenomenon also lies in the changes wrought by fluoride ions on the oxide film. Fluoride ions can be included in γ-Al_2O_3 films on aluminum to a substantially higher degree than chloride ions and, thereby, produce a greater decrease in low frequency resistivity (7, 8). It must also be anticipated that greater inclusion of substituted F′ ions will result in a further significant substantial increase in dissolution rate of the surface oxide film. These two factors, in combination, can be held to offer a satisfactory explanation of the more aggressive pitting action of sodium fluoride solutions upon aluminum.

Application of these concepts to the pitting of iron in chloride solutions raises many more uncertainties. Although the recent work of Engell and Stolica (19) on the effect of Cl′ ions on iron passivated anodically in sulfuric acid, is strikingly similar to the present work on the relative effects of Cl′ and SO_4'' ions on aluminum, there exists another powerful means of destroying the protective action of oxide film on iron, *i.e.*, reductive dissolution (20-22); this reaction must be carefully considered in relation to any film breakdown phenomena on iron. In solutions having *p*H values below 7.0 it may well be that the relationship between impurity substitution, including departure from stoichiometry, and the reductive dissolution characteristics of a substituted iron oxide film governs the choice between localized film breakdown and pitting, on one hand, and passivity on the other. Some preliminary consideration has been given to the problem (13, 23, 24), but insufficient data appear to exist at this time to permit real understanding of the complex atomic processes involved.

An Investigation of Porous Anodic Oxide Films on Aluminum by Comparative Adsorption, Gravimetric and Electronoptical Measurements

G. Paolini, M. Masoero, F. Sacchi, and M. Paganelli

Istituto Sperimentale dei Metalli Leggeri, Milano, Italy

ABSTRACT

Results of BET adsorption measurements on a-c and d-c sulfuric acid anodic films on aluminum have been compared with results of pore counts and with coating ratio figures. Both real surface and volume were measured. A roughness factor should be introduced in order to obtain an agreement between data from different sources.

Several means are available to investigate the porous structure of anodic films on aluminum, such as are industrially produced in dilute sulfuric acid. Direct examination by the electron microscope, gravimetric determinations of the oxide weight, density measurements, adsorption techniques (e.g., by the BET method), refraction properties, permeability, and electrical capacity measurements are some of the methods which have been employed for this purpose.

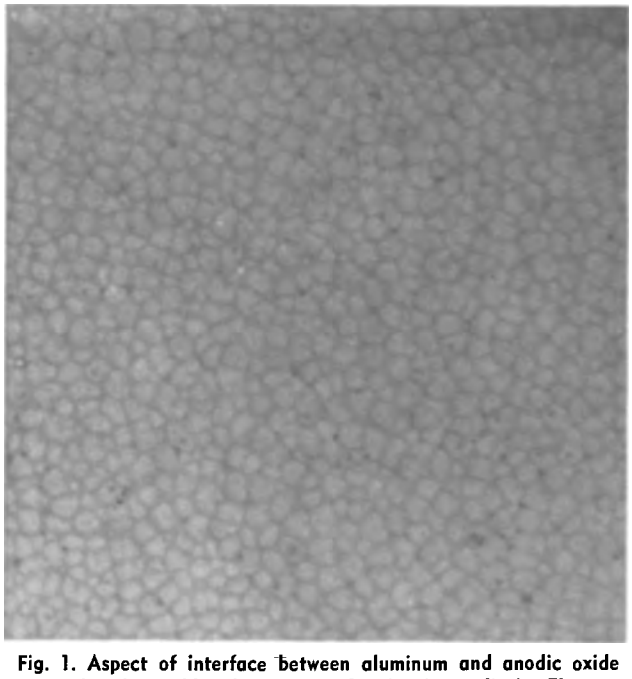

Fig. 1. Aspect of interface between aluminum and anodic oxide film produced at 30v d.c. in H_3PO_4 (oxide replica). Electron magnification 10,000X; total magnification 30,000X.

By comparing the results obtained with different methods, more information can be gained than by any single method taken by itself; unfortunately, in many cases the results obtained by one laboratory on one set of samples have to be compared with results obtained by other laboratories on different sets of samples.

The object of the present research was to apply gravimetric, electronoptical, and adsorption methods to a whole range of films that had been formed under strictly controlled conditions in order to delineate with closer accuracy the fine structure of the pore system.

Physical Methods

A first approximation to the pore structure could be easily obtained by simple physical methods:

Electron microscopy.—(1-3) By examining replicas of the cell structure engraved into the oxide-metal interface (Fig. 1), the number of cells, *i.e.* pores, can be counted; a confirmation can be had by direct transmission observation of thin porous films detached from the metal (Fig. 2, 3);

Gravimetric method.—The weight of oxide existing on the sample can be calculated by double weighing (before and after dissolving the oxide away in phosphochromic solution which does not dissolve the metal);

Geometric method.—The real oxide thickness can be measured directly on an Abbe micrometer, as the difference between the sample thickness before and after dissolving the oxide film.

Based on such measurements, a schematic pore structure can be drawn, provided the pore shape be considered as uniform and regular (cylindrical as a first approximation).

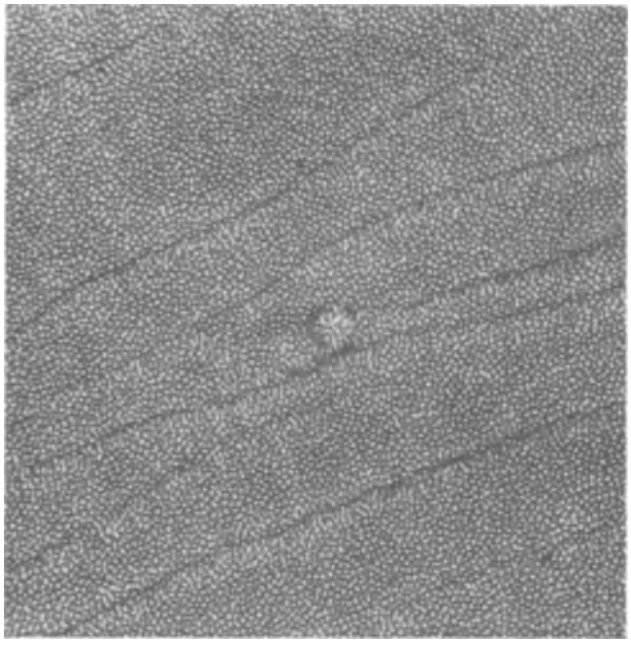

Fig. 2. Transmission electron micrograph of anodic film produced in H_2SO_4 d.c., 1 amp/dm^2. Pores were enlarged by attack in anodizing bath itself. Electron magnification 10,000X; total magnification 30,000X.

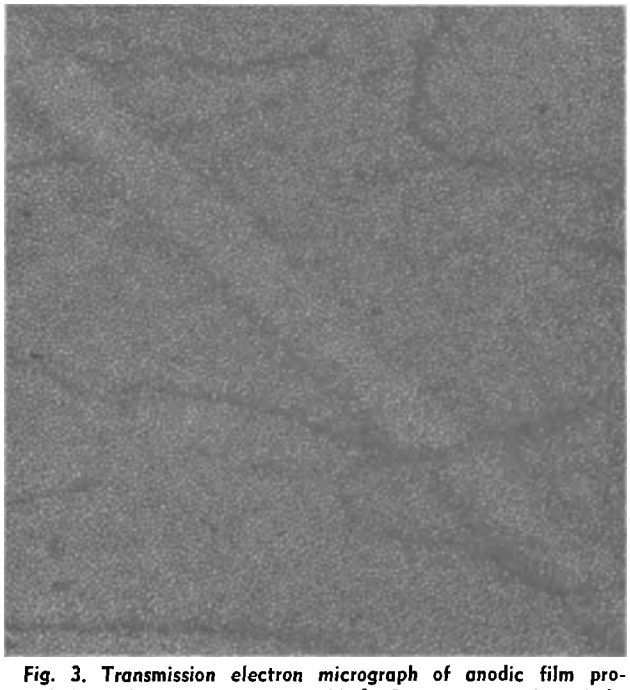

Fig. 3. Transmission electron micrograph of anodic film produced in H_2SO_4 a.c., 1.54 amp/dm^2. Pores were enlarged by attack in anodizing bath itself. Electron magnification 10,000X; total magnification 30,000X.

Let us call N the number of pores per cm^2 counted on the electron microscope, δ the density of the compact oxide forming the pore walls, h the film thickness measured on the Abbe micrometer, and P the oxide weight.

One can then calculate the over-all pore volume V_s and the average pore radius $\bar{R}$

$$V_s = \frac{\delta h - P}{\delta} \qquad [1]$$

$$\bar{R} = \sqrt{\frac{V_s}{\pi N h}} \qquad [2]$$

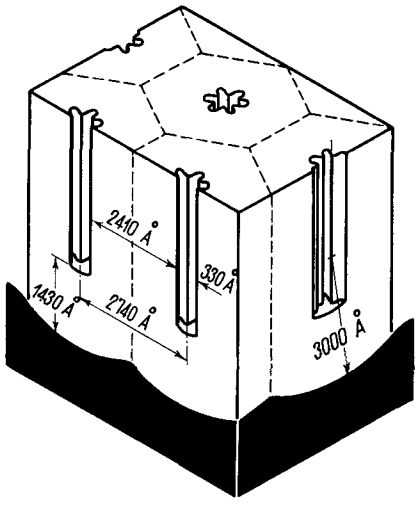

Fig. 4. Model of 120v H_3PO_4 film according to Keller

Fig. 5. Electron micrograph of aluminum oxide interface of 99.99% Al anodized in H_2SO_4. Oxide replica shadowed with Cr. Electron magnification 6000X; total magnification 18,000X.

Moreover, as the pore base radius has been calculated by Keller *et al.* (1), the taper of the pore can be deduced, as well as the real surface S_s

$$S_s = 2\pi\bar{R}Nh \qquad [3]$$

The accuracy of the data obtained by this way is somewhat limited by several difficulties.

The first difficulties arise when counting the pore numbers in the usual films formed in H_2SO_4; such films, as distinguished from H_3PO_4 films which form large cells (Fig. 4) have a very minute cellular structure which hardly allows for an exact direct counting of the cell number (Fig. 5, 6). Good direct counting on these films is only obtained by transmission observation of very thin oxide films detached from the metal and partially redissolved by a reaction which widens the pores (Fig. 2 and 3). This method, on the other hand, gives rise to several doubts: the pore count is somewhat uncertain because of the small pore size; some walls between the cells may be eaten up in the reaction, and some pores may be thus obliterated; such films which are examined by transmission must have a very reduced thickness and are produced by anodizing for a very short time (*e.g.*, 45 sec), which is of the same order of magnitude as the initial unstable stage of any anodizing process: the structure of such very thin films therefore might not be the same as for normal films formed under stable electrical conditions (Fig. 7).

Another source of error is the value of the density of the pore wall: according to Spooner (4) the value of 3.2 given by Russell for alumina should be assumed; however, hydrostatic measurements by Prati in 1953 (5) gave a figure in the neighborhood of 2.77. The large

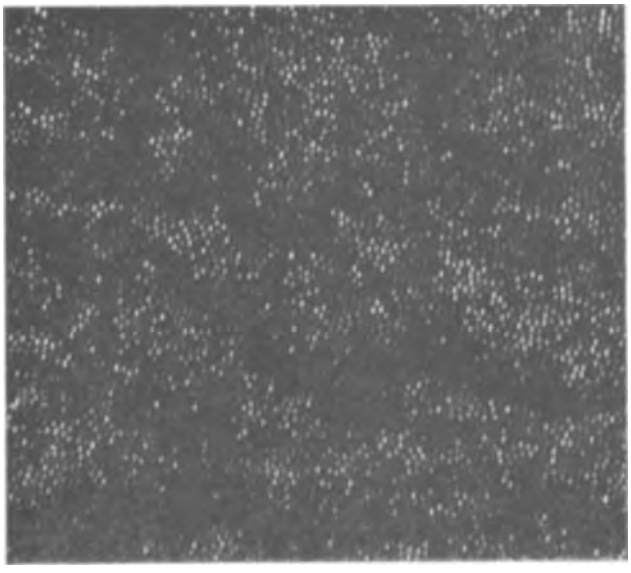

Fig. 6. Transmission electron micrograph of d-c H_2SO_4 film. The oxide films were not chemically attacked, and the pores cannot be counted clearly. Electron magnification 10,000X; total magnification 30,000X.

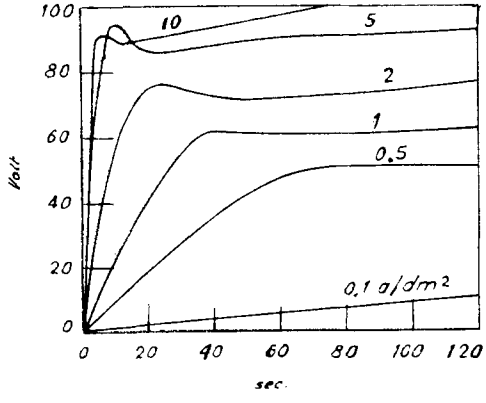

Fig. 7. Initial voltage-time relationships at constant current density for oxalic acid anodizing.

uncertainty in this value reflects on the geometrical considerations which can be deduced by the given formulas.

A further uncertainty is introduced by the hypothesis of cylindrical pores (which can be easily modified to account for gradual redissolution of the outer portion to a truncated conical shape). This hypothesis is assumed, but it has not been proven.

The adsorption method.—The above considerations show that in order to obtain a more precise definition of the pore structure, the over-all pore volumes and surfaces should be independently measured.

The most accurate method available in order to measure directly the pore volume and surface is the adsorption method.

The details of the Brunauer, Emmett, and Teller (BET) method for measuring the surface areas by means of low-temperature isotherms are well known.

Burwell *et al.* (7) report results of surface area obtained on an anodized aluminum sample by nitrogen and ethylene adsorption, and they also compare the three main methods of calculation: BET equation, "point B" and Harkins and Jura equation.

The value they accept as final is the one derived from BET equation and "point B" applied to nitrogen isotherms. On a single sample they also measure the pore volume at saturation and derive the pore diameter (107Å) from the ratio $2V/S$, as for perfect and smooth pores.

Some authors have calculated the pore diameter and the general film structure starting from the above adsorption measurements; however, more accurate conclusions can be obtained only if the pore volume is also known for a number of samples, and if the pore number is actually counted on the same samples that have been used for the adsorption test.

The present investigation is aimed at clarifying this point, in the meanwhile taking into account the influence of fundamental operating variables of the process itself, *i.e.*, current density, type of current (d.c. and a.c.), and film thickness.

Preparation of samples.—The samples used were 75 x 10 x 1 mm, 99.99% rolled Al with 70% cold-work.

Surface preparation was identical (etching in 10% NaOH at 50°C for 30 sec); concentration (20% by weight), and temperature (20°C) of the 200 liter sulfuric acid anodizing bath were also kept constant throughout the tests, and slight agitation by blown air was maintained.

Each anodizing condition was applied to 90 samples, suspended by means of 99.5 Al racks of known surface area.

The different treatments applied appear in the first four columns of Table I; as can be seen, an anodizing time of 30 min has been generally adopted, and the current density and type have been varied. However, current densities were not the same for a.c. as for d.c., as a previous reseach had shown the electrochemical efficiency of the a-c treatment to be markedly inferior. The current densities adopted therefore have been 1, 1.5, and 2.5 amp/dm² for d.c., and 1.54, 2.3, 3.8 amp/dm² for a.c. in order to obtain the same film thickness with the latter in the same time.

As a further precaution, any slight difference in film thickness has been compensated in the diagrams by plotting the properties against the "metal loss," *i.e.*, the amount of metal consumed in anodizing, which is faradaic, and is an accurate measure of the amount of electricity passed through the anode surface (10). In one case (d.c. at 1.5 amp/dm²) the time of treatment has been also extended to 60 min in order to observe the variations caused by doubling the film thickness, other conditions being kept constant.

For each set of conditions, some further samples were anodized separately in identical conditions, but the treatment was interrupted after 45 sec, whereby very thin films were produced, which could be detached and observed by transmission in the electron microscope.

Table I. Results of gravimetric and adsorption tests

Type of current	Current density, amp/dm²	Voltage eff.	Anodizing time, min	Abbe thickness, μ	Oxide weight, g/cm² · 10⁻⁴	Coating ratio, C_R	Experimental volume, V_s, cm³/cm² · 10⁻⁴	Experimental surface, S_s, cm²/cm²
d.c.	1	11.9	30	9.1	20.62	1.30	1.706	597
d.c.	1.5	14.1	30	14.6	33.04	1.342	2.590	880
d.c.	1.5	14.1	60	29.2	52.66	1.246	7.572	2093
d.c.	2.5	16.1	30	24.25	55.94	1.395	4.133	1230
a.c.	1.54	18*	30	9.35	19.83	1.263	—	716
a.c.	2.3	20*	30	14.8	31.96	1.310	—	1006
a.c.	3.8	23*	30	26.3	57.59	1.355	—	1473

* These voltages should be reduced to about half, as a-c anodizing is carried out between two aluminum electrodes and the oxide film is crossed twice by the current.

For each batch of 90 samples anodized under the same conditions, 10 samples were weighed before and after treatment, then their thickness was measured with the Abbe micrometer; subsequently, the samples were deoxidized in the phosphochromic solution and were weighed and measured again.

It was thus possible to calculate the average oxide weight and thickness formed on unit surface and the average metal loss which is a measure of electricity passed through the surface.

The main bulk of 80 samples for each batch was introduced in the container of the adsorption apparatus.

Results of Gravimetric and Micrometric Measurements

Results of gravimetric and micrometer measurements are shown in Table I, columns 5, 6, and 7.

It is apparent that films of practically identical thickness and weight have been obtained in equivalent processes with d.c. and a.c. by increasing the current density of the latter in the proportion found necessary to balance its lower oxide-forming efficiency.

The "coating ratio," *i.e.*, the ratio of oxide weight to the weight of metal consumed, has also been calculated (column 7): this figure has been widely used in the technical literature (9, 10) to give an idea of the efficiency of the anodizing process.

On the whole, the oxide thickness investigated ranges from 9 to 29μ, the oxide weight from 20 to 62 x 10^{-4} g/cm^2, and the coating ratio from 1.24 to 1.39: these values cover the range that is found with normal industrial processes.

Electron microscopy.—In order to count the pore number of the very thin films employed to this purpose, it was found to be necessary that the pores should be enlarged by dissolution in a chemical reagent.

This was accomplished by leaving the samples in the anodizing bath for 2 min after interrupting the anodizing current. The films slightly attacked by the sulfuric acid electrolyte were detached from the metal by the mercuric chloride method and were observed by transmission in the electron microscope.

Pore numbers were counted on micrographs of the type shown in Fig. 2-3, and are shown in Table III and Fig. 9, in comparison with numbers found by Keller *et al.* (1) on d-c films (no previous data were found for a-c films).

The pore numbers were quite reproducible on different areas of the same specimen (at least three samples from the same specimen were considered). As the metal was in the cold-worked state, it had a subgrain structure in the order of magnitude of 1μ, with no appreciable difference in pore numbers between the several subgrains appearing in the microscope field.

In this case, no "grain" effect was observed of the type described by Franklin and Stirland (11) for annealed material.

Cell size has been deduced from pore numbers, and has been plotted against anodizing voltage, in order to allow a comparison to be made with data similarly plotted by Keller *et al.* (Fig. 8). As can be seen in this figure, in the present case the pore numbers lie on a straight line, parallel to the line drawn by Keller *et al.*, and at a distance corresponding to a 15-20% increase in pore number or to a 2v increase in voltage.

Adsorption Measurements

These measurements were carried out by standard methods, employing a classical BET apparatus, provided with a cell large enough to contain the samples.

The isotherm given in Fig. 17 is typical of samples for which volume is reported, which required determining the whole isotherm.

Mathematical analysis of adsorption and desorption curves was not done, but the steepness of the isotherms at a relative pressure of 0.85 ÷ 0.90 indicates that the pore dimensions for such systems are quite monodisperse.

Results of volume and surface measurements are shown in Table I.

Results of volume measurements.—Volume measurements were carried out only on d-c films; the main purpose of these measurements was to obtain an independent confirmation of the density of the material forming the pore walls.

Results obtained are shown in Table I, column 8.

Volumes are comprised between extreme values of 1.7 and 7.5 x 10^{-4} cm^3/cm^2; of course, the pore volume is strongly dependent on film thickness: in order to allow comparison on an equal basis, unit volumes are given in column 4, Table II, *i.e.*, the volume of unit oxide thickness, which range between 0.17 and 0.26 10^{-4} cm^3/cm^2/μ.

The continuous lines in Fig. 10-11, showing total volume and unit volume variations for 30 min cc films, have good regularity, and repetition of the measurement for the highest current density confirmed the

* These values were calculated for δ = 2.78 and Vuc = Vus.
** These values were calculated for δ = 2.78 and Vuc = Vus and for N ISML reduced 15% (difference observed between ISML and ALCOA values in the case of d.c.)

straight line determined by single measurements for the two lower current densities.

In Fig. 10-11 the dotted lines for unit and total volumes of a-c films are not based on experimental values, but were calculated from geometrical considerations to be described in detail.

The good reproducibility of experimental values for 30 min films enables us to accept with confidence also the volume value obtained for the 60 min film, which does not appear in the figures.

Results of surface measurements.—A larger number of surface measurements were carried out, as these measurements are easier and quicker to make than volume measurements.

Results obtained for total and "unit" (per unit film thickness, μ) surface are shown in column 9, Table I, column 6, Table II, and Fig. 12-13.

The data obtained are more scattered than the volume data, because of the intrinsic nature of surface measurements discussed earlier.

However, the trends are clearly defined in Fig. 12-13, and average values entered in Tables I and II are reasonably acceptable.

Total surfaces vary between 600 and 2100 cm²/cm² as a function of film thickness and other properties;

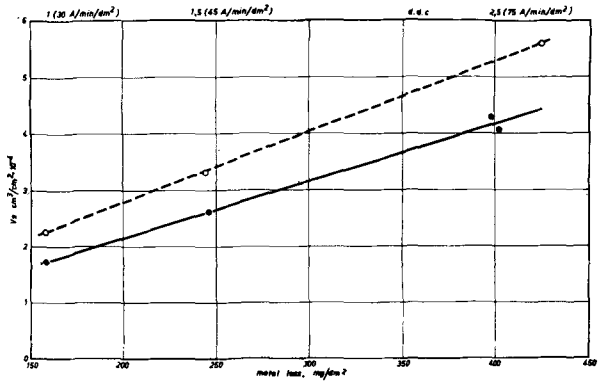

Fig. 10. Total pore volume vs. metal loss; — — —, a.c.; ———, d.c.

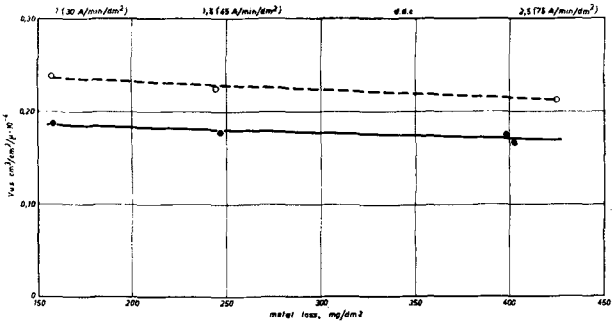

Fig. 11. Unit pore volume vs. metal loss; — — —, a.c.; ———, d.c.

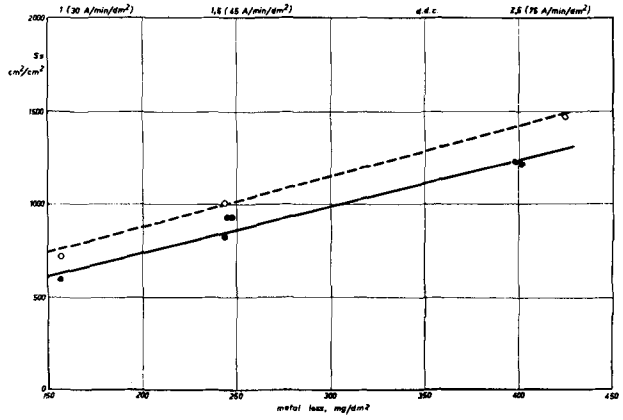

Fig. 12. Total pore surface vs. metal loss; — — —, a.c.; ———, d.c.

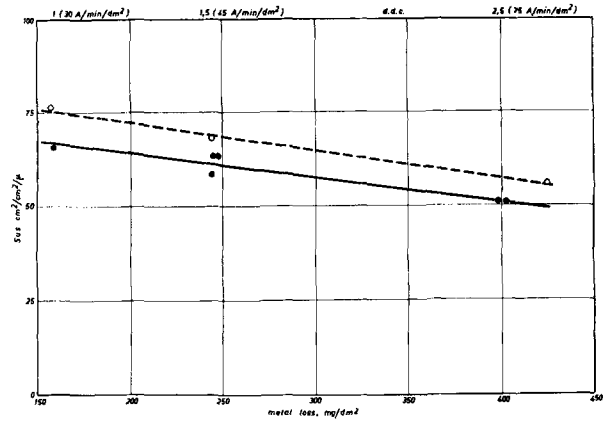

Fig. 13. Unit pore surface vs. metal loss; — — —, a.c.; ———, d.c.

unit surfaces vary between 50 and 77 cm²/cm²/μ of thickness.

A comparison may be made between films produced in cc at 1 and 1.5 amp/dm², and the Burwell-Smudsky-May films which were produced in similar conditions: our surfaces and volumes were about 20% higher, and the difference may be explained perhaps by the higher acid concentration employed in the present tests (20% instead of 15%).

Geometrical considerations.—The knowledge of real surfaces and volumes makes possible an independent calculation of the density of the material in the pore walls; the validity of the cylindrical pore model may also be controlled by applying the three equations [1], [2], [3] already mentioned.

If the pore could be assumed as cylindrical, then not only δ, but also $\overline{R}$ and N might be calculated from the above equations.

Calculation of δ.—δ values are immediately given by adsorption values through Eq. [1].

Table III. Comparison of pore numbers observed by electronoptical measurements (ISML and ALCOA) and pore numbers calculated by adsorption measurement supposing a cylindrical shape

Current type	Current density, amp/dm²	Voltage	Anodizing time, min	I.S.M.L. pore number, · 10¹⁰/cm²	Pore number from adsorption results, · 10¹⁰/cm²

a.c.	3.8	23*	30	7.58	—

* See footnote Table II.

Values of δ obtained in d-c tests are given in Table II, column 9. The values are between 2.75 and 2.89; the latter value, however, is the only one substantially different from average values, and it belongs to the 60 min film.

Apart from this case, a figure of 2.78 may be proposed for the oxide density (at least for 30 min films): this value is markedly lower than those given by several authors, but it is practically coincident with values reported by Prati in hydrostatic balance measurements (5).

If a value of 2.78 is chosen for δ, the pore volume can be calculated, by means of Eq. [1], also for a-c films: unit volumes so calculated are given in Table II, column 5. In the same table calculated values are also given for d-c films in order to show the good agreement between gravimetric and adsorption volumes that is obtained when a value of 2.78 is chosen for δ.

It can be seen that unit volumes of a-c films are in the range of $0.22 \pm 0.01 \times 10^{-4}$ cm³/cm²/μ and are about 20% greater than the volumes of corresponding d-c films. (An exception is the 60 min d-c film which has a larger unit volume, comparable to a-c films, because of attack on the pore walls caused by prolonged exposure to the anodizing solution.)

On the other hand, unit volumes were not appreciably influenced by the different current densities employed.

Pore distortion.—Values of real volumes and surfaces can be introduced in Eq. [2] and [3], and $\overline{R}$ and N values can be thus calculated (Table III), which are based on the assumption of a regular straight cylindrical pore.

Should these $\overline{R}$ and N values be inconsistent with values obtained by other methods, some modification of the pore shape would have to be introduced in order to account for the difference.

This is indeed the case when "adsorption" $\overline{R}$ and N values are compared with the values found by gravimetric and electronoptical values.

Adsorption values for N are definitely higher, and cell sizes do not follow a straight line in the Keller diagram; moreover, the two films produced in identical conditions for different times of 30 and 60 min should have different pore numbers, which would contrast with the accepted fact that identical voltages correspond to identical pore numbers.

A disagreement is also found in the case of $\overline{R}$, as "adsorption" $\overline{R}$ values are rather small, and in some case are smaller than Keller's base radius.

The hypothesis of cylindrical regular pores has therefore to be modified. The starting point is the volume measurements and the electronoptical pore numbers, which are considered to be the most reliable experimental data.

By introducing these values in Eq. [2], acceptable $\overline{R}$ values are obtained both when Alcoa and I.S.M.L. N values are used. However, when the $\overline{R}$ values so calculated are introduced in Eq. [3] along with electronoptical N values, surface values are obtained which are definitely smaller than the experimental ones.

This may be explained either by supposing that the shape of the pore section be distorted from the circular shape, or by slanting and distortion of the pore axis (11, 12). The latter is thought to have a minor influence, as the average angle should not be much different from 10° (11), which would cause a difference of only 1-2%.

Tentatively, a "roughness factor" might be introduced

$$F_r = \frac{S_s}{S_v} = \frac{SR_v}{2V}$$

where S_v is the theoretical surface calculated from adsorption volume measurements (*i.e.*, calculated from the average radius $\overline{R}$ obtained from volume measurements), and S_s is the real surface calculated by adsorption surface measurements.

The roughness factors shown in Table II, column 8, have been calculated both by assuming Alcoa and ISML values for the pore numbers; for a-c films, a 15% difference between the two numbers has been assumed, by analogy with d-c films, and calculated adsorption volumes have been assumed as in the preceding chapter.

The values of the roughness factors lie in the following regions:

1.345 ± 0.030 if calculated by Alcoa numbers

1.250 ± 0.035 if calculated by ISML numbers

Deviations from the mean value are quite small and in the order of magnitude of 3%, as if the pore "roughness" were independent from anodizing conditions.

Some examples of typical deviations from the circular shape, which would account for observed roughness factors in the worst case (Alcoa pore numbers) are shown in Fig. 14.

By introducing a roughness factor in Eq. [3], this becomes

$$\frac{S_s}{F_r} = S_v = 2\pi\overline{R}Nh \qquad [3a]$$

and the three equations [1], [2], and [3a] can be employed.

Pore "conicity".—The mean radii $\overline{R}_v$ calculated by the above reasoning are referred to cylindrical pores, and from now on they will be designated as $\overline{R}_{cyl}$.

Actually, the pores are not expected to be cylindrical because of progressive attack at the orifices; they are rather expected to be conical, so that their real mean radius $\overline{R}_{con}$ should be different from the mean radius calculated in the cylindrical hypothesis: the difference, however, is practically irrelevant.

Indeed, assuming a value of 60Å for the radius at the pore base (as calculated by Keller):

$$\overline{R}_{con} = 15 \cdot 10^{-8} + \frac{1}{2} \cdot \sqrt{3\,\overline{R}_{cyl}^2 - 2700 \cdot 10^{-16}}$$

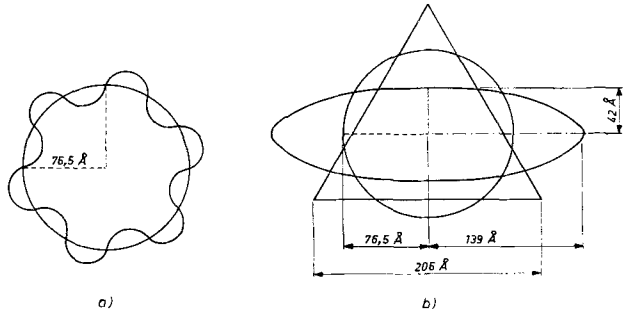

Fig. 14. Typical pore sections which give same volume as circular section, but increased area to satisfy relation $S_v = F_r S_s$.

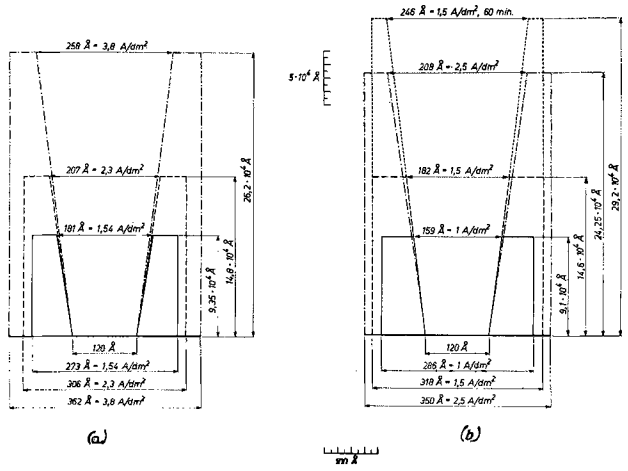

Fig. 15. Dimensional schemes for a-c films (a) and d-c films (b)

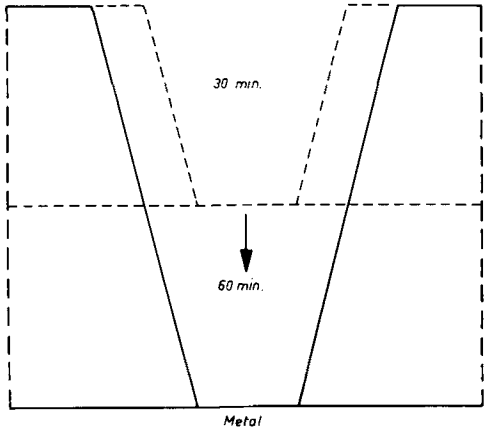

Fig. 16. Oxide growth into base metal by doubling anodizing time

By introducing in this formula the calculated values of $\overline{R}_{cil}$ (ranging from $70 \cdot 10^{-8}$ cm to $100 \cdot 10^{-8}$ cm), the maximum difference between R_{con} and R_{cyl} turns out to be about 2%. This can be disregarded, and in discussing the conical pore its mean radius can be assumed as equal to the calculated radius of the cylindrical pore.

Figure 15 shows the resulting dimensions for the different films. The slant of the pore walls is very slight in all cases (the vertical scale in Fig. 16 is 500 times reduced relative to the abscissas scale) and is practically the same for films produced at the same current density.

In general, pore walls are thicker for high current densities, for d-c films, and for the shorter anodizing time.

Nonhomogeneity of pore wall.—In an earlier paragraph it was shown that the pore wall density was nearly constant for all 30 min films, but increased for the 60 min film.

The 30 min film is expected to develop into the 60 min film as shown in Fig. 16: in this case, at the end of 60 min, the lower part of the pore will have taken up the same shape as the upper part had after the first 30 min, and the latter will have suffered surface dissolution causing enlargement of the outer radius.

The higher wall density of the thicker film may thus be explained by supposing that the pore wall be made up with material of increasing density from the pore surface to the interior; this might be connected with observations on barrier layers, which indicated

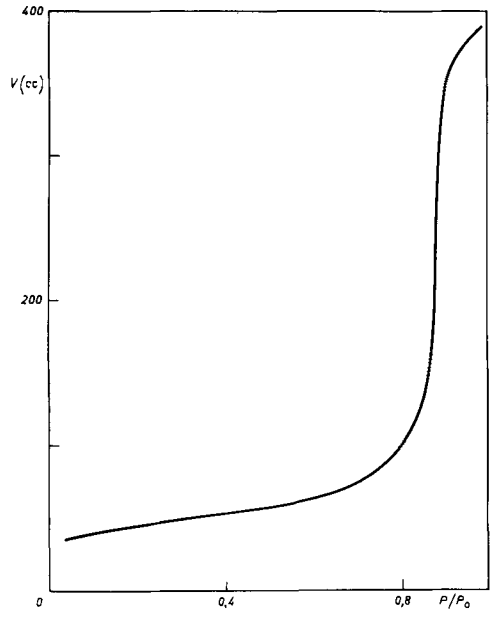

Fig. 17. Typical adsorption isotherm on sample 4 (N_2, -195°C)

that a more soluble material exists in the center of the cell (13).

Conclusions

An accurate description of the fine pore structure can be obtained by supplementing electronoptical and gravimetric measurements with adsorption techniques.

The real surface turns out to be 25-35% higher than that calculated from volume measurements; this discrepancy can be accounted for by deformation of the circular section.

The average density of the material in the pore walls is about 2.78 for 30 min films, higher for 60 min films.

All facts are in good agreement with the picture of the pores as truncated cones, with very slightly slanting walls. The wall slant does not vary considerably with the film thickness.

Mechanism of the Oxidation of Zirconium in Oxygen and Liquid Sodium

Tennyson Smith

North American Aviation Science Center, Thousand Oaks, California

ABSTRACT

A rigorous analysis using Fick's second law diffusion equation (for film growth and diffusion into the metal) is given which explains the observed variation of apparent activation energy between about 28 and 50 kcal/mole for the oxidation process. This analysis also explains the observed differences between oxidation in oxygen and oxidation by oxygen in liquid sodium. An empirical equation is given that will accurately describe the experimental data of weight gain *vs.* time (for Zr, Ti, and Cu) as this relationship goes from approximately parabolic, to quasi-cubic, to parabolic again. The derivation of this equation stems from the hypothesis that the diffusion coefficient (for oxygen into the metal) decreases as the oxygen consumption increases.

From the many experimental studies (1-10) of the oxidation of zirconium and its alloys in oxygen and in liquid sodium, the following current problems have arisen as to the mechanism.

Oxide vs. metal diffusion control.—There has been some question as to whether the rate of oxidation of zirconium is controlled by the diffusion of oxygen through the oxide film or whether it is controlled by diffusion into the metal. Is oxidation controlled by one of these processes or can these concepts be expressed quantitatively so that the importance of each process (diffusion in the oxide layer and diffusion in the metal) can be evaluated at a given temperature and will this explain the wide variation of reported activation energies in the literature (18 to about 50 kcal/mole)?

Oxidation in liquid sodium.—It has been observed that zirconium oxidation in liquid sodium follows an approximate parabolic law and has an activation energy (10) of about 52 kcal/mole. What is the mechanism of oxidation in sodium and why is the rate constant about a factor of 100 larger (at 600°C) for oxidation in oxygen than for oxidation in liquid sodium?

Quasi-cubic rate law.—The oxidation process has been observed to follow approximately linear, parabolic, and cubic-rate laws. The word approximately is used because the exponent n in the equation

$$W^n = kt + C$$

has been found to vary from 1 to about 3.6 under various conditions, rather than to be the integers 1, 2, or 3. The various authors have been inclined to refer to the rate laws as linear, parabolic, or cubic if n was in the range 1, 2, 3, respectively. Is it necessary that n be an integer?

Although a theoretical basis has been proposed for parabolic oxidation of zirconium at the time this paper was written, no basis for the apparent cubic law was known to the author. However, it has been brought to the attention of the author that Kofstad and Hauffe (11) have proposed qualitatively a similar mechanism for the approximate cubic law as is expressed quantitatively in this paper.

Theoretical Analysis and Experimental Results

Metal or Oxide Diffusion Control

It is our purpose first to show under what conditions and at what temperatures oxidation shifts from primarily diffusion in the film to primarily diffusion in the metal. To do this we must calculate the parabolic rate constant in terms of the diffusion coefficient for oxygen in the oxide and in the metal. Since oxidation of zirconium has been shown to obey approximately linear and cubic rate laws, as well as parabolic, we wish to determine if the dissolution process in addition to film growth can account for this.

We assume that the mechanism of oxidation is the same for all oxide thicknesses, that is, that oxygen dissolves into the metal at all temperatures and that with an existing oxide film, this dissolution process creates anion vacancies which in turn allow oxygen diffusion across the film. For this mechanism, exposure of oxide-free zirconium to oxygen will cause dissolution of oxygen into what is essentially a semi-infinite medium as in Fig. 1a. In Fig. 1, $C_1(O)$ represents the oxygen concentration at the oxide-gas interface for stoichiometric oxide, $C_1(\delta)$ represents the oxygen concentration in the oxide at the oxide-metal interface, and $C_2(\delta)$ represents the oxygen concentration in the metal at the metal-oxide interface. Curves t_1, t_2, and t_3 in Fig. 1a represent the oxygen concentration profile in the metal at increasing time. When enough time has elapsed for the metal to become supersaturated with oxygen [concentration between $C_2(\delta)$ and $C_1(\delta)$] and for nucleation to occur, an oxide film will form as shown in Fig. 1b. The value of the oxygen concentration in the metal at the metal-oxide interface in Fig. 1b will be between $C_1(\delta)$ and $C_2(\delta)$, depending on the degree of supersaturation needed to form oxide (*e.g.*, if very little supersaturation is needed, curve 1 is appropriate at a particular time, for a large supersaturation curve 2 is appropriate).

Let us assume that attainment of equilibrium at the oxide-metal interface is rapid with respect to oxygen absorption by the oxide-metal system. Once an oxide film has been formed, the following consideration can be made. The oxygen dissolves into the metal and if the rate of transport through the film is faster than dissolution, supersaturation will occur at the oxide-metal interface and more film will be formed. If the dissolution is faster than transport through the film, then the oxygen concentration in the metal will fall below the equilibrium value, and the film will begin to dissolve.

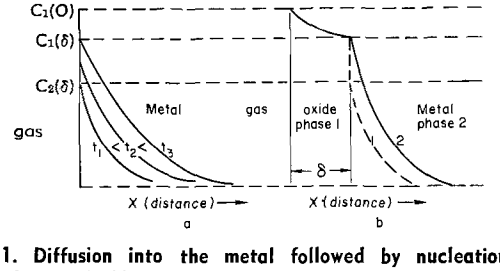

Fig. 1. Diffusion into the metal followed by nucleation and growth of an oxide film.

The process of diffusion through an oxide film and into the underlying metal, as illustrated in Fig. 1, is analyzed as a moving boundary problem in Appendix A. With the one assumption that D is independent of concentration, it is concluded in Appendix A that the parabolic rate equation can be expressed in terms of the two diffusion processes as follows

$$\frac{W^2}{t} = \frac{(M_1 + M_2)^2}{t} = k_p = [2\rho_1 f_{(O)} \alpha\sqrt{D_1} + B_2{}^1\sqrt{D_2}]^2 \quad [1]$$

where M_1 and M_2 are the weight (per square centimeter) of oxygen in the oxide film and metal, respectively, at time t, k_p is the parabolic rate constant, D_1 and D_2 are the diffusion coefficients for oxygen in the oxide film and the metal, respectively, $W = M_1 + M_2$, and the other symbols are constants defined in Appendix A. From Appendix A we have M_1, M_2, and k_p as a function of temperature

$$M_1 \approx 5.6 \times 10^3 \, e^{-\frac{14{,}600}{RT}} \quad [2]$$

$$M_2 \approx 1.6 \times 10^6 \, e^{-\frac{24{,}500}{RT}} \quad [3]$$

where M_1 and M_2 are expressed as mg/cm² at $t = 24$ hr, and

$$k_p \approx \left[19\, e^{-\frac{14{,}600}{RT}} + 5.5 \times 10^3 \, e^{-\frac{24{,}500}{RT}}\right]^2 (\text{mg/cm}^2)^2/\text{sec} \quad [4]$$

It is seen from Eq. [1] and [4] that at high temperatures $k_p \rightarrow M_2{}^2/t$ and the activation energy should approach 49 kcal/mole while at low temperatures $k_p \rightarrow M_1{}^2/t$ and the activation energy should approach 29 kcal/mole. At intermediate temperatures the apparent activation energy should increase from 29 to 49 kcal/mole.

Table I gives the experimental data of Debuigne and Lehr (12) for M_1, M_2, and W as a function of time and temperature. The calculation of W^2/t from the values of W at various times shows that the parabolic law is only approximated since the apparent k_p decreases slightly with increasing time. Values of M_1, M_2, and W^2/t from Table I are plotted in Fig. 2. The theoretical curves for M_1, M_2, and k_p (Eq. [2], [3], and [4]) are also plotted in Fig. 2. It is seen that if theoretical values of M_1, M_2, are multiplied by factors 1/2.5, 1/10, respectively, that the theoretical and experimental values correlate very well. It is not surprising to find that theoretical values differ in absolute value from experimental, considering the inaccuracy of the absolute values of D_1 and D_2. Also, it can be seen from Table I that the ratio M_1/M_2 is not constant with time as it should be if the parabolic law were strictly adhered to.

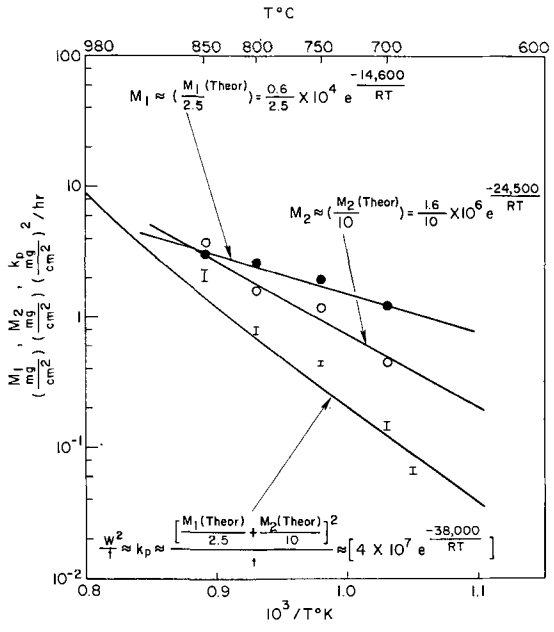

Fig. 2. Comparison of experimental data and theoretical equations for M_1, M_2, and k_p.

It is seen that M_1/M_2 becomes constant in less time as the temperature is increased. Since in the theoretical analysis the parabolic rate law was assumed over the entire time of the experiments, it is expected that some deviation would exist between the absolute values of the theoretical and experimental results. However, the fact that the experimental activation energies are predicted for M_1, M_2, and k_p as a function of temperature is considered to be confirmation of the theory.

From Eq. [2] and [3] at 24 hr

$$\frac{M_1}{M_2} \approx 3.5 \times 10^{-3} \, e^{\frac{9{,}900}{RT}} \quad [5]$$

and this ratio is plotted in Fig. 3 along with the experimental values from the data of various workers (9, 13, 14), and estimated from Table I at 24 hr. It is seen (Fig. 3) that an excellent correlation exists between the predicted curve and the experimental data. It is seen from Eq. [5] that $M_1/M_2 = 10$ at 450°C and $M_1/M_2 = 0.1$ at 1210°C, *i.e.*, 90% of the oxygen is going

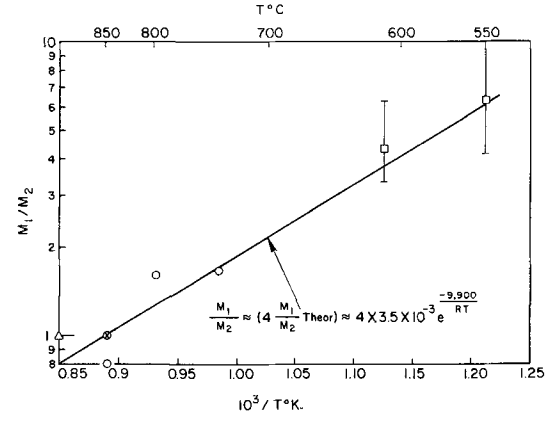

Fig. 3. Arrhenius plots of (M_1/M_2) vs. $1/T$ for the oxidation of zirconium (M_1 = wt of oxygen in the oxide film and M_2 = wt of oxygen in the metal) from the data of Debuigne and Lehr (12), Porte *et al.* (9), Pemsler (13), and Hussey and Smeltzer (14). The solid line is the predicted theoretical curve multiplied by a correction factor of 4. ○, Debuigne and Lehr (12), 24 hr; △, Porte *et al.* (9); circle with X, Pemsler (13); □, Hussey and Smeltzer (14).

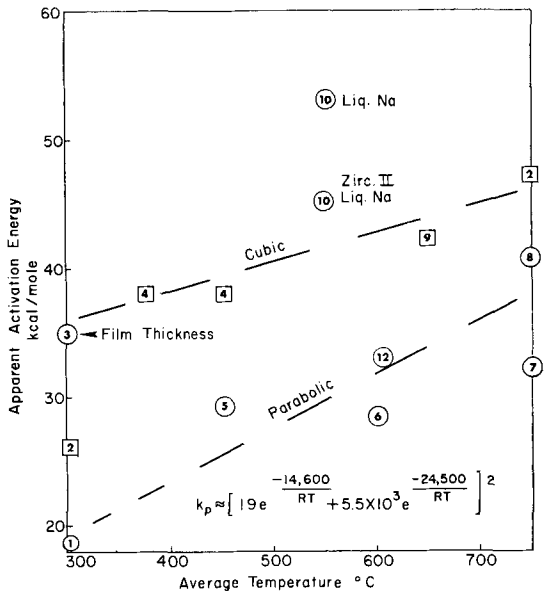

Fig. 4. Apparent activation energies for increasing temperature range from the literature. (Number identifies reference.) The circles indicate that an approximate parabolic rate law was followed; the squares indicate that an approximate cubic law was followed. The dashed lines indicate the trend of increased apparent activation energy for the parabolic and cubic data. The special case of oxidation in liquid sodium is given at the top of the figure.

into the oxide film at 450°C and 90% of the oxygen is going into the metal at 1210°C, if the mechanism holds for β zirconium above 862°C. Between these two temperatures both processes will be important. Since most of the experimental work has been done between 300° and 1000°C, it must be concluded that one cannot speak of diffusion control in the metal or diffusion control in the oxide but that each process plays a more or less important role, depending on the temperature. The quantitative contribution of each process is given by Eq. [4]. It is predicted that the effective activation energy will increase with temperature. For example, the curve W^2/t in Fig. 2 can be expressed as 10^7 exp $(-35{,}200/RT)$ in the low temperature region and 7×10^9 exp $(-40{,}600/RT)$ in the high temperature region. The curvature in the Arrhenius plot is within experimental error and would not have been detected from the experimental plot of W^2/t *vs.* $1/T$. In Fig. 4 values of apparent activation energy, reported by various authors, are plotted *vs.* the mean value of the temperature range of the oxidation study. It is seen that the apparent activation energy does increase as the temperature is increased, especially in the cases for which the parabolic law was approximately obeyed. We shall consider the effect of α in Eq. [1], on the oxidation of zirconium in liquid sodium next.

Oxidation in Liquid Sodium

An equation relating the rate constant for oxidation of zirconium in sodium, $k(\mathrm{Na})$, and temperature from Mackay's data (10) is

$$k(\mathrm{Na}) = 4.0 \times 10^{10}\, e^{-\frac{52{,}900}{RT}} \ (\mathrm{mg/cm^2})^2\ \mathrm{hr}^{-1} \qquad [6]$$

where $k(\mathrm{Na})$ is obtained from the equation

$$W^2 = k(\mathrm{Na})t \qquad [7]$$

and W is the weight gain (mg/cm²).

Equation [6] is within a factor of two of k_p from the theoretical Eq. [4] for the high temperature region ($M_2 >> M_1$) where diffusion into the metal is dominant.

The rate of film growth is proportional to α which is directly related to ΔC_1. For oxidation in oxygen this is just equal to the vacancy concentration in the oxide at the metal-oxide interface, $C(\square, \delta)$, since the vacancy concentration at the oxide-gas interface, $C(\square, o)$, is essentially zero. However, in liquid sodium, the reaction at the sodium-oxide interface is expressed by the equation

$$\mathrm{O(Na)} + 2e^- + \square(\mathrm{Na}) \overset{K(\mathrm{Na})}{\rightleftharpoons} \mathrm{O^=} \qquad [8]$$

where O(Na) represents the oxygen dissolved in sodium, e^- represents electrons in the oxide, $\square$(Na) represents oxygen vacancies in the oxide (in contact with Na), and $O^=$ represents lattice anions in the oxide. If we choose unit concentration as the standard state for $\square$(Na) and e^-, we can write

$$C(\square, \mathrm{Na}) = \left[\frac{a(\mathrm{O^=})}{4a(\mathrm{O, Na})\ K(\mathrm{Na})}\right]^{1/3} \qquad [9]$$

since $C(e^-) = 2C(\square, \mathrm{Na})$. A similar equation is obtained for the oxide-oxygen (gas) reaction except a (O,Na) is replaced by the activity (or partial pressure of oxygen) and K(Na) by the equilibrium constant $K(O_2, \mathrm{gas})$. It is because $[a(O_2, \mathrm{gas})\ K(O_2, \mathrm{gas})]$ is extremely large that $C(\square, o)$ approaches zero at the gas-oxide interface. Although $[a(\mathrm{O, Na})\ K(\mathrm{Na})]$ is not known, it is without doubt that

$$a(\mathrm{O, Na})\ K(\mathrm{Na}) << a(O_2, \mathrm{gas})\ K(O_2, \mathrm{gas}) \qquad [10]$$

and so

$$C(\square, \mathrm{Na}) >> C(\square, o) \qquad [11]$$

It is predicted that

$$\Delta C_1(\mathrm{Na}) \equiv |C(\square, \mathrm{Na}) - C(\square, \delta)| < C(\square, \delta) \qquad [12]$$

and the rate would be less than for oxidation in oxygen.

Since ΔC_1(Na) is predicted to be much smaller than ΔC_1 (oxygen), it follows that $\alpha(\mathrm{Na}) << \alpha(O_2)$. Consequently, W is shifted to predominantly M_2 with the resultant activation energy of 52 kcal/mole. In Mackay's experiments the rate law was between parabolic and cubic ($n \sim 2.3$ to 2.5). To verify this analysis, observe that from Mackay's work at 408°C and 500 hr, the film thickness proved to be 450 to 630Å (by comparison with a calibrated color step gauge) and had a total weight gain of 0.0158 mg/cm². With the equation, $M_1 = \rho_1 f_{(O)} \delta$ and an average value of $\delta \approx 540$Å, we calculate the weight of oxygen in the oxide film to be

$$M_1 \approx 5.83 \times 0.26 \times 5.4 \times 10^{-6} = 8.1 \times 10^{-6}\ \mathrm{g(O)/cm^2}$$

or 0.0081 mg/cm². It follows that the weight of oxygen in the metal was

$$M_2 \approx 0.0158 - 0.0081 = 0.0077\ \mathrm{mg/cm^2}$$

so that $M_1/M_2 \approx 1$. From Fig. 3 for oxidation in oxygen, it is predicted that the ratio of $M_1/M_2 \approx 20$. It is concluded that in liquid sodium, M_1 is much smaller than it would have been in oxygen at the same time and temperature, as predicted. Table II gives values for the

Table II. Comparison of the rate constants for the oxidation of zirconium in liquid sodium and in oxygen at approximately 600°C

	Oxidation of Zr in liquid Na at 630°C after Mackay (10)			Oxidation of Zr in O_2 gas at 600°C			
	$k(\mathrm{Na})$ $(\mathrm{mg/cm^2})^n/\mathrm{hr}$	n		Gas	$k(\mathrm{gas})$ $(\mathrm{mg/cm^2})^n/\mathrm{hr}$	n	Ref.
Pure Zr	3.2×10^{-4}	2.3	Zr	O_2	5.5×10^{-3}	2.9	9
			Zr	O_2	4×10^{-3}	2.0	3
Zircaloy II	3.2×10^{-4}	2.5	Zr(carbon melted)	O_2	1.4×10^{-1}	2.0	15
			Zr(carbon melted)	CO_2	4×10^{-3}	1.8	15

rate constants at about 600°C for oxidation of zirconium and its alloys in liquid sodium and for zirconium in oxygen. At 600°C, $W \approx M_1$ for oxidation in oxygen and $W \approx M_2$ in sodium so that $M_1/M_2 \approx [k(\text{oxygen})/k(\text{Na})]^{1/2} \approx 15$, from Table II. The predicted value of M_1/M_2 from Fig. 3 is ~4.

From Eq. [33A] for small α, $B_2' \approx C_2(\delta)$, and we calculate the diffusion coefficient for oxygen in the metal at 408°C and 500 hr to be

$$D_2 = \frac{M_2^2 \pi}{[C_2(\delta)]^2 4t} \approx \left(\frac{7.7 \times 10^{-3}}{1.14 \times 10^3}\right)^2 \cdot \frac{\pi}{4 \times 500 \times 3600} = 2 \times 10^{-17} \text{ cm}^2/\text{sec} \quad [13]$$

from Eq. [31A].

If we assume that the oxidation of zirconium in liquid sodium is due primarily to the diffusion of oxygen into the metal, then the diffusion coefficient, calculated from the sodium work should have the same relation to temperature as that found by Pemsler (16) for the diffusion of oxygen into zirconium metal, *i.e.*,

$$D_2 = 9.4e^{-\frac{51{,}780}{RT}} \text{ cm}^2/\text{sec} \quad [14]$$

It is seen from Mackay's results that the activation energy for oxidation in liquid sodium is approximately the same (52.9 kcal/mole) as for diffusion in the metal (51.78 kcal/mole). With Mackay's value of 52.9 kcal/mole and the value of D_2 at 408°C (Eq. [13]), we get

$$D_2 \approx 2e^{-\frac{52{,}900}{RT}} \text{ cm}^2/\text{sec} \quad [15]$$

for oxidation in liquid sodium, and this correlates very well with Eq. [14]. It is concluded that oxidation in liquid sodium is indeed due primarily to diffusion of oxygen in the metal for the temperature range of Mackay's work (about 400°-900°C). Table III gives a comparison of experimental values for the pre-exponential factor $D_{2,0}$, the diffusion activation energy Q_2, and D_2 at 386°C for pure zirconium and for Zircaloy 2 and Zircaloy 3. The fact that the activation energy for the oxidation of Zircaloy 2 in liquid sodium (~45 kcal/mole) compares well with independent measurements yielding a value of about 41 kcal/mole, is further evidence that oxidation in sodium is due to diffusion in the metal.

Quasi-cubic Rate Law

We wish to consider next a possible explanation for the fact that in a number of investigations (3, 9, 11, 20, 21) it has been found that the oxidation of zirconium, titanium, and copper, obey a rate law such as

$$W^n = k_c t \quad [16]$$

where n varies between 2 and about 3. It can be seen that according to Eq. [1] the parabolic law should be obeyed whether dissolution occurred or not. It is hoped that the following discussion (although speculative in nature) may point out important parameters for future investigation.

In the case of interstitial diffusion of oxygen in the metal, the diffusion coefficient should be proportional to the probability that an adjacent interstice is vacant. Consequently, the diffusion coefficient may be concentration dependent, as pointed out in Appendix A. A rigorous test to determine whether the quasi-cubic rate law can be attributed to this concentration dependency, must await an accurate investigation of the relation between D_2 and C_2. However, if $D_2(x)$ is proportional to the concentration of vacant sites at distance x in the metal, we may express an approximate local value as

$$D_2(x) \approx D_2^\circ (1 - C_2/C_2^1) \quad [17]$$

where D_2° is the diffusion coefficient at $M_2 = 0$ and C_2^1 is an effective value of C_2 for which $D_2(x) \to 0$. Placing the value for $D_2(x)$ (now a function of concentration) into Eq. [2A] yields a solution in numerical, rather than closed, form. Even though Eq. [17] has basis in theory, it is felt that the numerical analysis is unwarranted until the experimental relation between D_2 and C_2 has been determined. In the meantime, we can draw some conclusions concerning the quasi-cubic rate law as follows:

We know that C_2 is an increasing function of M_2 and as a working hypothesis we will make the assumption that $C_2/C_2^1 \equiv M_2/M_2^1$. Now, since M_1/M_2 is essentially constant at constant temperature, it follows that $C_2/C_2^1 \equiv W/W^1$, if the previous assumption is true. An approximate equation for an effective average value of D_2 is

$$\overline{D_2} \approx D_2^\circ (1 - W/W^1) \quad [18]$$

A more general equation than Eq. [1], which includes the property of concentration dependency (to a first approximation) can be written

$$W_c = W/[A + B(1 - W/W^1)] = t^{1/2} \quad [19]$$

where

$$A = 2\rho_1 f_{(O)} \alpha D_1^{1/2} \quad [20]$$

$$B = B_2^1 (D_2^\circ)^{1/2} \quad [21]$$

W^1 is the effective value of W at which $\overline{D_2} \to 0$, and W_c is defined as W divided by the term in brackets. Equation [19] has the property that at short time when

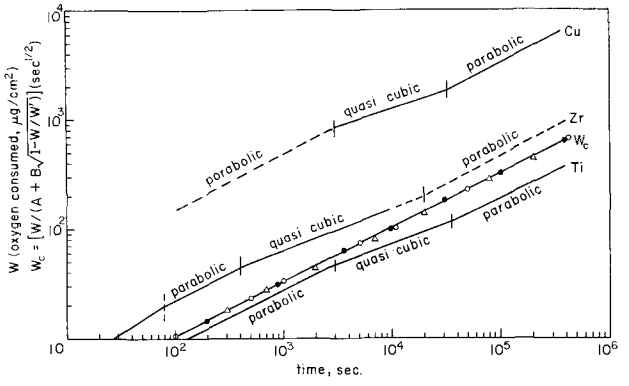

Fig. 5. Log log plot of W (weight oxygen consumed) vs. time (sec) for Zr, Ti, and Cu. The theoretical curve, $W_c = t^{1/2}$, is also plotted, where $W_c = W/[A + B\ (1 - W/W^1)]$. ○, Cu, 520°C, Tylecote; △, Zr, 500°C, Sense; •, Ti, 600°C, Kofstad and Hauffe.

$W << W^1$, $W_c = W/[A + B]$ and when $W \approx W^1$, $W_c = W/A$. Therefore at short and long time a log log plot of W *vs.* t should have a slope of 0.5 (parabolic), while at intermediate times as W/W^1 varies between approximately zero and unity the slope should be less than 0.5 (perhaps approximately 0.33 or quasi cubic). A log log plot of W_c *vs.* t should have a slope of 0.5 through the whole time period.

To illustrate that Eq. [19] has the correct form, we need values for A, B and W^1. Figure 5 shows a log log plot of W *vs.* t for the oxidation of Zr, Ti, and Cu, all of which dissolve oxygen to an appreciable extent. The solid lines labeled Zr, Ti, and Cu represent experimental data reported by Sense (20), Kofstad and Hauffe (11), and Tylecote (21), respectively. These curves have been divided into time periods for which approximate parabolic and cubic laws appeared to be obeyed. It is seen that the Ti curve follows the sequence parabolic, quasi-cubic, parabolic as predicted by Eq. [19]. The Zr curve is parabolic followed by quasi-cubic and the Cu curve is quasi-cubic followed by parabolic (the dashed lines represent presumed data, had it been reported in these time periods).

Let us first consider the zirconium experiment. From Eq. [20], [26A], and [27A] we obtain a value 1.45 $\mu g/cm^2\text{-}sec^{1/2}$ for A and from Eq. [21], [33A], and [28A] we obtain a value of approximately 0.8 for B, at 500°C. The experimental value of $A + B$ ($= W/t^{1/2}$, $t \sim 100$ to 400 sec) from Fig. 5 is about 2.2, which checks with the theoretical value. With these values for A and B and a value of 140 $\mu g/cm^2$ for the adjustable parameter W^1, values of W_c have been calculated and plotted (△) in Fig. 5. It is seen that the data falls close to the theoretical curve ($W_c = t^{1/2}$) in spite of the quasi-cubic period of the W *vs.* t curve.

It should be pointed out that D_2 in Eq. [28A] should be approximately equal to $D_2°$ in Eq. [21] because Pemsler (16) used pure crystal bar zirconium with anodized films. Calculation of M_2 for his experiments ($\sim 2 \times 10^{-5}$ cm oxide dissolved during an experiment) yields values of <30 $\mu g/cm^2$. As seen for the Zr curve in Fig. 5, this corresponds to the region where $W << W^1$. Consequently Pemsler's (16) experiments are not expected to show the concentration dependency. Kearns and Chirigos (22) also measured the diffusion coefficient of oxygen in zirconium and obtained results in accord with Pemsler. Although they state that they found no concentration dependency below 1.9 a/o (atomic per cent) oxygen, this would not invalidate Eq. [7]. For example, $C_2{}^1$ is probably of the order of 29 a/o (solubility of oxygen in zirconium) so that the change of $D_2(x)$ would be less than about 10% if C_2 varied between 0 and 2.9 a/o. This variation of $D_2(x)$ is probably less than experimental error in the Kearns and Chirigos experiments.

For the case of Ti oxidation, we have no theoretical values for A, B, and W^1, but we can obtain them from the experimental curves in Fig. 5. From a value of W during the short time (parabolic curve) we get $A + B \approx 0.87$, from the long time (parabolic curve) we get $A \approx 0.60$ so that $B \approx 0.27$. We know that the curve will change from quasi-cubic to parabolic as $W \to W^1$ and pick approximately 100 for W^1 from the Ti curve in Fig. 5. With these values for A, B, and W^1 values for W_c (solid points in Fig. 5) fall on the theoretical curve (W_c *vs.* t) over the whole experimental time period.

Simnad *et al.* (23) measured the rate of oxidation of both saturated (with oxygen) and unsaturated titanium as a function of temperature (800°-1200°C). They showed that the rate of oxidation was definitely a function of the oxygen content of the metal. From their data, we can obtain.

$$A\ (\mu g/cm^2\text{-}sec^{1/2}) = 1.2 \times 10^6\, e^{-\frac{25{,}000}{RT}}$$

for the saturated titanium. If we assume that in the high temperature range (800°-1200°C) that most of the oxygen enters the unsaturated metal we obtain

$$B \approx 2.3 \times 10^7\, e^{-\frac{32{,}000}{RT}}$$

At 600°C we calculate values for A and B of 0.7 and 0.25, respectively. These values are in excellent agreement with the values calculated above (0.6 and 0.27).

For the case of copper oxidation we can obtain values for A (~ 10 $\mu g/cm^2\text{-}sec^{1/2}$), W^1 ($\sim 1.8 \times 10^3$ $\mu g/cm^2$) but we cannot obtain B because the experimental data are not reported in the very short time period. However, if we assume that the parabolic curve would have been valid immediately proceeding the beginning of the reported data (~ 3000 sec) we obtain a value for $A + B$ of about 15 $\mu g/cm^2\text{-}sec^{1/2}$ so that B would be about 5. Calculated values of W_c for Cu (open circles in Fig. 5) also fall close to the theoretical curve.

Certainly an empirical equation having the form of Eq. [19], satisfactorily describes experimental data for which a quasi-cubic law seems to be obeyed. Equation [17] has theoretical basis and it is predicted from this analysis that an equation having the form of Eq. [18] will be valid for the diffusion of oxygen into Zr, Ti, and Cu, and perhaps other metals that dissolve oxygen. However, the substantiation of this prediction must await an experimental test.

It should be noted that it is predicted from Eq. [19] that when the quasi-cubic period is over ($W \to W^1$) that dissolution into the metal is essentially complete, the rest of the oxygen going into the film. If it is found experimentally that oxygen does continue to dissolve into the metal during the parabolic period (following the quasi-cubic period) the theory will remain essentially unchanged by multiplying $D_2°$ by a factor ($\gamma - W/W^1$) in Eq. [18] where γ is a constant greater than unity. In this case the constants A, B, and W^1 would be altered slightly.

It is seen then, that for metals that dissolve oxygen to an appreciable extent such as Zr, Ti, and Cu, a quasi-cubic rate law may be expected to be observed in some instances but not in others, depending on the values of A, B, and W^1, how long the experiment was allowed to continue, and the temperature range. The important parameters in A are α and D_1 and in B they are α, D_1/D_2 and $C_2(\delta)$. From Eq. [25A] and [33A] we see that low values of α will increase B but decrease A, so that α becomes a very important parameter with respect to which process will dominate at a given temperature. Equation [26A] reveals that α is directly related to ΔC, (the difference in defect concentration across the oxide film). According to Eq. [19] the quasi-

cubic law will not be observed unless the M_2 term is significant. However, regardless of the temperature range, if the M_2 term is significant, the apparent activation energy will tend to be closer to 49 kcal/mole (see Eq. [1] and [4]). This is seen to be the case in Fig. 4.

Conclusions

It is concluded that the mechanism of the oxidation of zirconium (and probably other metals such as titanium, hafnium, copper, tantalum, and perhaps niobium and vanadium, all of which dissolve oxygen to varying amounts) may be explained in detail by analysis of the diffusion of oxygen through an oxide film and diffusion of oxygen into the metal at all temperatures. Such an analysis reveals that both parabolic and higher order rate laws are to be expected during the oxidation of zirconium depending on experimental conditions. It is also concluded that apparent activation energies are expected to increase from about 30 kcal/mole at low temperatures to about 50 kcal/mole at high temperatures for experiments that obey the approximate parabolic law. For experiments that follow a higher order law (approximately cubic), it is expected that the activation energy would be closer to 50 kcal/mole at all temperatures.

Essentially all of the observed kinetic behavior can be explained from the unified theory presented, including oxidation in liquid sodium. However, the role of the concentration dependency of the diffusion coefficient must await experimental evidence before the explanation of the quasi-cubic nature is clearly established.

APPENDIX A

Solution of Fick's Second Law

Let us consider the moving boundary problem illustrated in Fig. 1 We let the oxide-gas interface be at $X = 0$ and the oxide-metal interface be at $X = \delta$. The oxygen concentration in the oxide (phase 1) is C_1 and in the metal (phase 2) is C_2. Since the density of the oxide is different from that of the metal saturated with oxygen, we will follow the method of Carlslaw and Jaeger (24). Consider the movement of the oxide-metal boundary in the X direction a distance $d\delta$. The mass of oxide $\rho_1 d\delta$ formed per unit area has been derived from a thickness $(\rho_1/\rho_2)\ d\delta$ of metal (saturated with oxygen). Thus the metal moves with a velocity v along the x-axis given by

$$v = -\left(\frac{\rho_1}{\rho_2} - 1\right)\frac{d\delta}{dt} \qquad [1A]$$

and Fick's second law can be written

$$D_2\left(\frac{\partial^2 C_2}{\partial X^2}\right) - \left(\frac{\rho_2 - \rho_1}{\rho_2}\right)\frac{d\delta}{dt}\cdot\frac{\partial C_2}{\partial X} = \frac{\partial C_2}{\partial t} \qquad [2A]$$

for diffusion in the metal. Since the diffusion coefficient for interstitial diffusion of oxygen would be concentration dependent, Eq. [2A] is only approximate.

Fick's second law for diffusion in the oxide can be expressed

$$D_1\left(\frac{\partial^2 C_1}{\partial X^2}\right) = \frac{\partial C_1}{\partial t} \qquad [3A]$$

The initial condition is

$$C_2 = C_2(\infty), X > 0, t = 0 \qquad [4A]$$

and the boundary conditions are

$$C_1 = C_1(O),\ X = 0, t > 0 \qquad [5A]$$

$$C_1 = C_1(\delta),\ X = \delta - 0,\ t > 0 \qquad [6A]$$

$$C_2 = C_2(\delta),\ X = \delta + 0,\ t > 0 \qquad [7A]$$

Conservation of mass gives

$$-D_1\frac{\partial C_1}{\partial X}\bigg|_{x=\delta-o} + D_2\frac{\partial C_2}{\partial X}\bigg|_{x=\delta+o} = C_1(\delta)\frac{d\delta}{dt} - C_2(\delta)\frac{d\delta}{dt} \qquad [8A]$$

The solution of Eq. [3A] satisfying the conditions [5A] and [6A] is

$$C_1 = C_1(O) - B_1\, erf\left(\frac{X}{2\sqrt{D_1 t}}\right) \qquad [9A]$$

which yields

$$C_1(\delta) = C_1(O) - B_1\, erf\left(\frac{\delta}{2\sqrt{D_1 t}}\right) \qquad [10A]$$

at $X = \delta$, and where B_1 is a constant with time. Since $C_1(\delta)$, $C_1(O)$, and B_1 are constant with time, then $\delta/\sqrt{t}$ must be constant. We let

$$\frac{\delta}{2\sqrt{D_1 t}} = \alpha \qquad [11A]$$

where α is a constant independent of time.

From Eq. [2A] and [11A]

$$D_2\left(\frac{\partial^2 C_2}{\partial \chi^2}\right) - \left(\frac{\rho_2 - \rho_1}{\rho_2}\right)\alpha\left(\frac{D_1}{t}\right)^{1/2}\frac{\partial C_2}{\partial X} = \frac{\partial C_2}{\partial t} \qquad [12A]$$

which has the solution

$$C_2 = C_2(\infty) + B_2\, erfc\left[\frac{X}{2\sqrt{D_2 t}} - \left(\frac{\rho_2 - \rho_1}{\rho_2}\right)\alpha\left(\frac{D_1}{D_2}\right)^{1/2}\right] \qquad [13A]$$

At $X = \delta$

$$C_2(\delta) = C_2(\infty) + B_2\, erfc\left[\alpha\phi^{1/2}\left(\frac{\rho_1}{\rho_2}\right)\right] \qquad [14A]$$

where $\phi = (D_1/D_2)$ and B_2 is a constant with time. According to Reddick and Miller (25), if

$$F(\alpha) = \int_{a(\alpha)}^{b(\alpha)} f(\chi, \alpha)\, d\chi \qquad [15A]$$

then

$$\frac{dF(\alpha)}{d\alpha} = \int_{a(\alpha)}^{b(\alpha)}\frac{\partial f(X,\alpha)}{\partial \alpha}\, dx - f(a,\alpha)\frac{da}{d\alpha} + f(b,\alpha)\frac{db}{d\alpha} \qquad [16A]$$

It follows from Eq. [16A] that

$$-D_1\frac{\partial C_1}{\partial \chi} = B_1\left(\frac{D_1}{\pi t}\right)^{1/2} e^{-\frac{X^2}{4D_1 t}} \qquad [17A]$$

and

$$-D_2\frac{\partial C_2}{\partial \chi} = B_2\left(\frac{D_2}{\pi t}\right)^{1/2} e^{-\left[\frac{X}{2\sqrt{D_2 t}} - \left(\frac{\rho_2 - \rho_1}{\rho_2}\right)\phi^{1/2}\alpha\right]^2} \qquad [18A]$$

so that

$$B_1\left(\frac{D_1}{\pi t}\right)^{1/2} e^{-\alpha^2} - B_2\left(\frac{D_2}{\pi t}\right)^{1/2} e^{-\alpha^2(\rho_1/\rho_2)^2\phi} = [C_1(\delta) - C_2(\delta)]\,\alpha\left(\frac{D_1}{t}\right)^{1/2}$$

or

$$B_1 e^{-\alpha^2} - \left(B_2 e^{-\alpha^2(\rho_1/\rho_2)^2\phi}\right)/\phi^{1/2} = [C_1(\delta) - C_2(\delta)]\,\alpha\sqrt{\pi} \qquad [19A]$$

Eliminating the constants B_1 and B_2 with Eq. [10A] and [14A], we get the transcendental equation for α

$$\frac{e^{-\alpha^2}}{erf\,\alpha} - \frac{[C_2(\delta) - C_2(\infty)]e^{-\alpha^2(\rho_1/\rho_2)^2\phi}}{[C_1(O) - C_1(\delta)]\phi^{1/2}\, erfc\,[\alpha\phi^{1/2}(\rho_1/\rho_2)]} = \left(\frac{C_1(\delta) - C_2(\delta)}{C_1(O) - C_1(\delta)}\right)\alpha\sqrt{\pi} \qquad [20A]$$

These equations are identical to those derived by Wagner (26) except for the factor ρ_1/ρ_2 since he did not consider the effect of change in density.

The parameters in Eq. [20A] have the following approximate values: $C_2(\delta) \approx 1.14$ g/cm^3, $C_2(\infty) = 0$, $C_1(O) \approx 1.46$ g/cm^3, $\rho_1 = 5.83$ g/cm^3, $\rho_2 = 6.72$ g/cm^3, and $\phi \approx$ (10-100).

From the thermodynamic data of Domagala and McPherson (27) and by choosing the appropriate standard states (*i.e.*, the concentration of the various species at 386°C), we get for the anion vacancy concentration at the oxide-metal interface

$$C(\square, \delta) \approx C(\square, \delta) \text{ (at 386°C) } K_v^{1/3} \approx 0.11\, e^{\frac{\Delta\bar{S}^\circ(v)}{3R}}\, e^{-\frac{\Delta\bar{H}^\circ(v)}{3RT}} \quad [21A]$$

Here $\Delta\bar{S}^\circ(v)$ and $\Delta\bar{H}^\circ(v)$ are the partial molar entropy and enthalpy of vacancy formation which prove to be 11 ± 0.3 e.u. and 7.1 ± 0.3 kcal/mole, respectively. In Eq. [21A], $C(\square, \delta)$ has been expressed in the units g/cm^3 rather than mole/cm^3.

It follows that

$$C(\square, \delta) = |C_1(O) - C_1(\delta)| \approx 0.7\, e^{-\frac{2{,}400}{RT}} \text{ g/cm}^3 \quad [22A]$$

and at 727°C, $|C_1(O) - C_1(\delta)| \approx 0.2$ and $C_1(\delta) \approx 1.26$ g/cm^3. An estimate of α from Eq. [20A] is about 0.2. Another way to obtain α is as follows: Let M_1 and M_2 be the quantity of oxygen in the oxide film and the metal per cm^2, respectively, at time t_1 ($W = M_1 + M_2$). If we assume diffusion through the film to obey Fick's first law, that the concentration gradient is essentially linear, and that D_1 is concentration independent, then at low temperatures when $M_2 << M_1$

$$\frac{dM_1}{dt} = \frac{\rho_1 f_{(o)} \Delta C_1 D_1}{M_1} \quad [23A]$$

where $f_{(o)}$ is the weight fraction of oxygen in zirconium dioxide. It follows that

$$M_1 = (2\rho_1 f_{(o)} \Delta C_1 D_1 t)^{1/2} \quad [24A]$$

From Eq. [11A]

$$M_1 = 2\rho_1 f_{(o)} \alpha (D_1 t)^{1/2} \quad [25A]$$

so that at 386°C

$$\alpha = \left(\frac{\Delta C_1}{2\rho_1 f_{(o)}}\right)^{1/2} = \left(\frac{0.11}{3.02}\right)^{1/2} \approx 0.2 \quad [26A]$$

which checks with the value obtained from Eq. [20A].

At 386°C the value for B_1 proves to be 0.05 and $B_2 \sim$ (3-70) depending on the absolute value of ϕ.

From Table III we choose the following as being the best approximate equations for D_1 and D_2

$$D_1 \approx 10^{-3}\, e^{-\frac{29{,}300}{RT}} \text{ cm}^2/\text{sec} \quad [27A]$$

$$D_2 \approx 10\, e^{-\frac{51{,}800}{RT}} \text{ cm}^2/\text{sec} \quad [28A]$$

Then

$$\phi = D_1/D_2 \approx 10^{-4}\, e^{\frac{22{,}500}{RT}} \quad [29A]$$

The values of $D_{1,o}$ and Q_1 in Eq. [27A] were chosen because they result from experiments for oxide films on zirconium; whereas, the work of Douglass was for sintered oxide powder and the work of Kingery *et al.* was for stabilized zirconia. The values of $D_{2,o}$ and Q_2 in Eq. [28A] were chosen because they result from direct measurement of oxygen into the metal.

Expressing M_1 as a function of temperature, at a time of 24 hr, yields

$$M_1 \approx 5.6 \times 10^3\, e^{-\frac{14{,}600}{RT}} \quad [30A]$$

where M_1 is in mg/cm^2.

The quantity of oxygen that has entered the zirconium metal at t is

$$M_2 = \int_o^t \left(-D_2 \frac{\partial C_2}{\partial X}\Big|_{x=\delta+o}\right) dt = 2B_2 \left(\frac{D_2 t}{\pi}\right)^{1/2} e^{-\alpha^2(\rho_1/\rho_2)^2\phi} \quad [31A]$$

At 24 hr

$$M_2 \approx 10^3\, B_2^1\, e^{-\frac{26{,}000}{RT}} \quad [32A]$$

where

$$B_2^1 = \frac{2}{\sqrt{\pi}} B_2\, e^{-\alpha^2(\rho_1/\rho_2)^2\phi} = \left[\frac{C_2(\delta)\, e^{-\alpha^2(\rho_1/\rho_2)^2\phi}}{erfc\,[\alpha\phi^{1/2}(\rho_1/\rho_2)]}\right] \frac{2}{\sqrt{\pi}} \quad [33A]$$

It is seen that at high temperatures when ϕ is small $B_2^1 \to C_2(\delta)$, while at low temperatures when ϕ is large, $B_2^1 \to C_2(\delta)\ \alpha\ (\rho_1/\rho_2)(\pi\phi)^{1/2}$, since for $y > 2$, $erfcy \approx e^{-y^2}/y\sqrt{\pi}$. In the temperature range 500° to 1000°C, B_2^1 can be expressed by the approximate equation

$$B_2^1 \approx 1.6\, e^{+\frac{1{,}500}{RT}} \quad [34A]$$

so that (changing to mg/cm^2)

$$M_2 \approx 1.6 \times 10^6\, e^{-\frac{24{,}500}{RT}} \text{ mg/cm}^2 \quad [35A]$$

in this temperature range.

From Eq. [25A] and [31A], we have

$$\frac{W^2}{t} = k_p = [2\rho_1 f_{(o)} \alpha \sqrt{D_1} + B_2^1 \sqrt{(D_2)}]^2 \quad [36A]$$

where k_p is the parabolic rate constant.

Acknowledgment

The author would like to acknowledge the help of Dr. J. H. Bick of the North American Aviation Science Center Mathematics Department for his help in solving Eq. [2A].

Manuscript received Feb. 10, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

Measurement of Overpotential Parameters on Passive Electrodes

J. L. Ord

Department of Physics, University of Waterloo, Waterloo, Ontario, Canada

ABSTRACT

Experimental measurements of overpotential parameters on passive electrodes often give results which depend on the technique used for the measurement. This dependence is illustrated for the widely studied system of a passive iron electrode in 1*N* H_2SO_4 at 25°C. Three different experimental techniques, all employing galvanostatic transients, are used for the measurements. The first method determines the overpotential parameters from the shape of the capacitive transient observed when the circuit is opened. In the second method the current is switched from one constant value to another, and the parameters are determined from the resulting potential shift. The third method determines the parameters from an analysis of the current dependence of the slopes of galvanostatic oxidation curves. The results obtained by the three methods differ significantly.

Studies of passivity commonly employ electrical measurements to study the state of the surface of the passive electrode. The properties of the electrode, such as layer thickness, are then deduced from the values of the electrical parameters measured. Many of the electrical measurements are concerned with the overpotential, measured from a Flade potential, and the dependence of current density on it, although some measurements, such as cathodic reduction, are concerned only with the removal of the passive layer. This investigation is designed to illustrate the results obtained when a number of techniques are used to study the overpotential on a passive electrode. The system studied is a passive iron electrode in 1*N* H_2SO_4 at 25°C. This system is used because a great deal of work has been done on it by a number of workers, and, although it is not suggested that the results obtained can be extrapolated to other systems, problems similar to those encountered in this system arise in most passive systems.

The three methods used in this investigation all employ galvanostatic transients. The first method determines the overpotential parameters from the shape of the capacitive transient observed when the circuit is opened. This method, referred to as the open-circuit method in this paper, is also known as the current-interrupter method (1, 2). In the second method, known as the rapid method (3), the current is switched from one constant value to another, and the parameters are determined from the resulting potential shift. The third method determines the parameters from a technique of analyzing galvanostatic oxidation transients which uses the current dependence of the slope of the oxidation curve, rather than the displacement between curves obtained at different charging currents. Galvanostatic oxidation transients have been used extensively in studies of passivity (4-6).

Experimental

Iron electrodes were prepared from high-purity vacuum-melted iron rods obtained from a number of sources. The only difference noted between electrodes prepared from different samples of iron was that only the highest purity iron could be heat treated to produce large uniform grains. Cylindrical electrodes with 0.2 cm^2 cross-sectional area were coated with epoxy, then mechanically and electrolytically polished to expose one end surface which was mounted vertically in the cell. The coating operation is critical with this geometry of electrode, and great care was taken to avoid leakage between the iron and the epoxy at the exposed surface. A jacketed five-neck flask with standard-taper joints was used as a cell. Electrodes, gas inlet tubes, and thermometers were all mounted on standard-taper adapters so that the cell could be sealed and yet be completely demountable. The cell was kept at 25° ± 0.1°C. The electrolyte used in the work reported here was hydrogen-saturated 1*N* H_2SO_4. Coiled platinum wire was used as a cathode, and a mercurous sulfate reference electrode was used in place of the more common calomel electrode in order to exclude chlorine ions from the electrolyte. All potentials were measured using the reference electrode then converted to the normal hydrogen electrode scale.

Potential is measured and recorded using a potentiometer, operated on voltage output, in series with a pair of electrometers connected in parallel. One of the electrometers is used as a VTVM with 8 mv maximum full-scale sensitivity, enabling potentials of greater than a volt to be read to fractions of a millivolt with high (10^4 ohm) input impedance. The other electrometer acts as the input coupler for the chopper-stabilized preamplifier of a fast (150 cps) recorder. The potentiometer can be used as a calibrated blocking voltage for the recorder. Currents are measured on an electrometer used as a micromicroammeter with a 3 mv full-scale voltage drop. The potentiostatic and galvanostatic supply circuits both use batteries and are connected in series. For potentiostatic measurements a relay shorts out the galvanostat. Galvanostatic transients are applied simply by opening this relay.

The results of electrical measurements in this system depend to a certain extent on the manner in which the electrode surface is prepared and also on the precise manner in which it is passivated. A description of this dependence is beyond the scope of this paper. The

results reported here were obtained using cathodic reduction as a final electrolytic pretreatment followed immediately by passivation using the potentiostatic circuitry. The electrode takes approximately 4 sec to reach the passive state. The electrolyte is then changed to remove reaction products. The electrical parameters, with the exception of the capacitance, reach their steady-state values quickly using this procedure. The large-grained electrode used for most of the measurements exhibited a steady-state current density of 5.5 $\pm$ 0.5 μa/cm^2 for passivating potentials between 0.9 and 1.4v, and 8.3 μa/cm^2 at a passivating potential of 0.71v. Other workers (7) report a current density of 7 μa/cm^2 for passivating potentials between 0.9 and 1.4v in this system.

Results

Experimental studies (4, 6, 8) on passive electrodes indicate that the current density, i, is exponentially related to the overpotential, V. This exponential dependence can be written most simply in the form

$$i = i_0 \exp(V/V_0) \quad [1]$$

where the parameters i_0 and V_0 have the same dimensions and units as the measured quantities i and V. Most other exponential expressions can be written in this simple form. For example (6), the expression

$$i = k \exp(\beta V - Q/B) \quad [2]$$

can be put into the form of Eq. [1] by setting $k \exp(-Q/B) = i_0$, and $\beta = 1/V_0$. The exponential dependence is experimentally found to be valid for transients in which V does not fall much below V_0. This result is consistent with the assumption that Eq. [1] describes an activation-controlled process at an overpotential which is high enough so that the reverse current can be ignored. Of the transients used in this work, only the open-circuit transient extends beyond the region of validity of Eq. [1], and its analysis is not carried beyond this region.

The open-circuit transient uses the fact that the overpotential appears across a capacitance. The differential equation of the transient is

$$C\,dV/dt + i_0 \exp(V/V_0) = 0 \quad [3]$$

and its solution is

$$V = V_0 \ln(CV_0/i_0) - V_0 \ln(t + CV_0/i_1) \quad [4]$$

where i_1 is the current density before the circuit is opened, in this case the steady-state current density, 5.5 μa/cm^2. In Fig. 1 an open-circuit transient is plotted on linear and logarithmic time scales. The time origin is adjusted on the logarithmic scale until the transient becomes linear. For the transient shown in Fig. 1 this time is 1.0 sec, and hence from Eq. [4] $CV_0/i_1 = 1.0$ sec. The slope of the logarithmic plot gives $V_0 = 0.186$v,

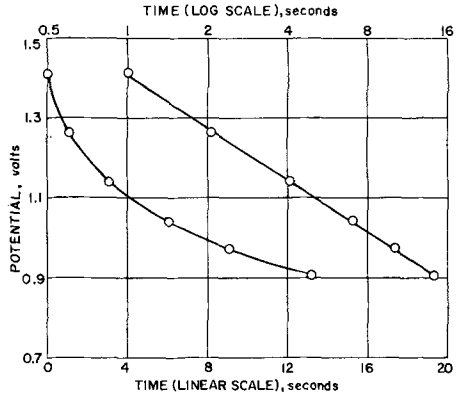

Fig. 1. Open-circuit transient from an initial passivating potential of 1.412v. The lower curve is plotted on a linear time scale; the upper curve, displaced 1 sec, is plotted on a logarithmic time scale.

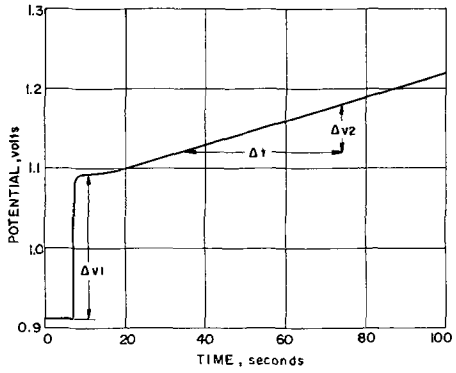

Fig. 2. Galvanostatic transient from a passivating potential of 0.912v at an anodic current density of 50 μa/cm^2. The rapid method determines V_0 from ΔV_1; the galvanostatic oxidation method studies the slope $\Delta V_2/\Delta t$ and its dependence on current density.

and therefore both C and V_0 can be determined. This transient cannot be fitted to a single exponential curve, and hence the electrode cannot be represented by a resistance in parallel with a capacitance. The transient can be fitted by a sum of exponentials to an accuracy dependent on the number of exponentials in the sum. This procedure gives an equivalent circuit which represents the electrode by a number of parallel R-C elements arranged in series. This approach is not taken here because other information, such as rapid-method measurements, indicates that current is exponentially related to overpotential through an equation of the form of Eq. [1].

Figure 2 shows a typical galvanostatic oxidation curve. The initial potential change, ΔV_1, enables V_0 to be determined. Since the value obtained does not agree with the value obtained from open-circuit transients, this value is designated V_0', and is obtained from

$$V_0' = \Delta V_1 / \ln(i_2/i_1) \quad [5]$$

where i_1 is the initial current, as in Eq. [4], and i_2 is the current of the oxidation transient. Equation [5] follows directly from Eq. [1]. In the rapid method complete oxidation transients generally are not recorded. The current is switched to another value as soon as the capacitive transient is complete, so that an average value for V_0' can be determined from a number of potential changes. The transient shown in Fig. 2 shows some initial overshoot. A complete oxidation curve can be analyzed either by taking ΔV_1 as shown in the figure or by extrapolating the linear portion of the curve back to intersect the initial rise to determine ΔV for use in Eq. [5]. In the rapid method the linear portion of the curve is not recorded, and hence ΔV_1 is used in Eq. [5] to determine V_0'. If the extrapolation technique is used, the difference between V_0' and the open-circuit V_0 is even greater than is indicated by the rapid method.

Complete galvanostatic oxidation curves are usually analyzed (4, 6) by plotting potential *vs.* the excess charge reaching the electrode, $(i_2 - i_1)t$, for a number of oxidation curves with different oxidation currents. The displacement between these curves for fixed values of the charge effectively gives V_0 through an equation of the form of Eq. [5]. This enables V_0 to be determined as a function of the excess charge reaching the electrode, rather than as a function of the steady-state passivating potential. This analysis assumes that the passive layer continues to dissolve at a rate equivalent to the steady-state current even when the electrode is not in a steady state. The passive layer is assumed to change its thickness in proportion to the excess charge reaching the electrode. The technique of analyzing the data outlined above is not used here because the displacement between curves is due, at least in part, to

the initial potential shift analyzed by the rapid method. Only the slopes of the galvanostatic oxidation curves are used in this work in order to obtain independent data from the rapid and oxidation methods.

The open-circuit and rapid methods are based on the assumption that the parameters i_0 and V_0 are unchanged over the course of the transient. The galvanostatic oxidation transient involves changes in i_0, V_0, or both. If V_0 changes and i_0 remains constant, Eq. [1] can be differentiated to give

$$dV/dq = dV_0/dq \ln(i_2/i_0) \quad [6]$$

If, on the other hand, i_0 changes and V_0 remains constant, differentiation of Eq. [1] yields

$$dV/dq = -V_0/i_0 \, di_0/dq \quad [7]$$

If analysis of the experimental data indicates that dV/dq is linearly dependent on $\ln(i_2)$, Eq. [6] is assumed valid, whereas if dV/dq is found to be independent of i, Eq. [7] is assumed valid. In systems where i_0 is large, such as the system under study in this paper, the factor $\ln(i_2/i_0)$ in Eq. [6] can be varied significantly by a suitable choice of oxidation currents. In systems where i_0 is small, such as in neutral electrolytes (6), the experiments must be performed with extreme care to enable the difference between Eq. [6] and [7] to be detected. This difference is important, since Eq. [6] and [7] lead to different models of a passive electrode. Integration of Eq. [7] casts Eq. [1] into the form of Eq. [2].

In Fig. 3 the values for V_0 obtained by the open-circuit and rapid methods are plotted *vs.* steady-state passivating potential. The two curves differ significantly, especially in their slopes. Fitting the data to straight lines using least squares gives

$$V_0 = 0.221 \ (V_p - 0.552) \text{ volts} \quad [8]$$

$$V_0' = 0.0664 \ (V_p + 0.408) \text{ volts} \quad [9]$$

where V_p is the steady-state passivating potential. If i_0 is assumed independent of passivating potential, it can be calculated directly from the steady-state current density and the slope of the V_0 *vs.* V_p curve. The measured values of i_1 are approximately independent of V_p, and if it is assumed that i_0 is also independent of V_p, Eq. [1] implies that the steady-state overpotential is equal to a constant times V_0. This constant is just the reciprocal of the slope of the V_0 *vs.* V_p curve plotted in Fig. 3. The assumption that i_0 is independent of V_p is equivalent to assuming that the zero of overpotential can be determined by extrapolating the V_0 *vs.* V_p curve in Fig. 3 to intersect the V_p axis. This assumption appears reasonable for the results of the open-circuit method, but not for the results of the rapid method. Using $i_1 = 5.5$ μa/cm^2 in Eq. [1], the open-circuit method gives $i_0 = 0.06$ μa/cm^2, and the rapid method gives $i_0 = 1.6 \times 10^{-6}$ μa/cm^2.

The open-circuit method enables the capacitance to be determined in addition to i_0 and V_0. The reciprocal

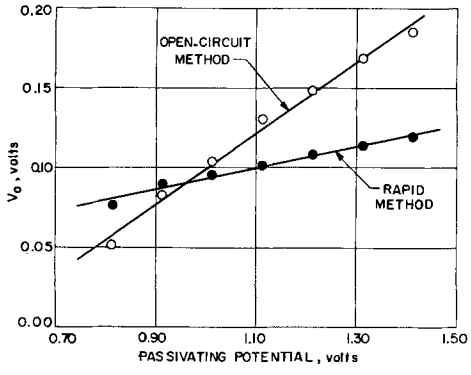

Fig. 3. Dependence of V_0 on passivating potential as determined by the open-circuit method and the rapid method.

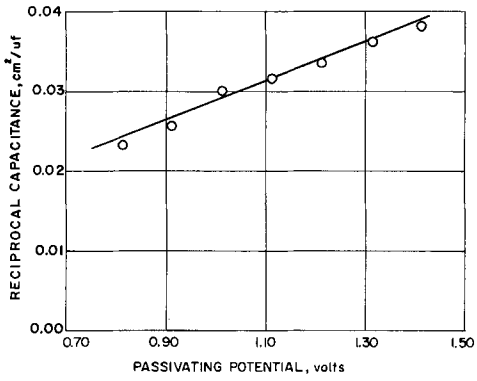

Fig. 4. Dependence of 1/C on passivating potential as determined by the open-circuit method.

capacitance is plotted *vs.* passivating potential in Fig. 4. A least squares fit of the data to a straight line gives

$$1/C = 0.0246 \ (V_p + 0.174) \text{ cm}^2/\mu\text{f} \quad [10]$$

The reciprocal capacitance changes by a factor of only 1.6 for a range of passivating potential over which V_0, measured by the same technique, changes by a factor of 3.6; hence both of these parameters cannot be proportional to the thickness of a layer on the electrode. The other methods do not enable capacitance to be determined, so no comparison is possible. It should be noted that capacitance is the parameter which is most sensitive to the history of the electrode, *i.e.*, the way in which the electrode is passivated, and the time spent at various passivating potentials. This behavior complicates the interpretation of capacitance measurements.

The results of the galvanostatic oxidation measurements are plotted in Fig. 5. In this figure and in calculations based on it, currents are expressed as multiples of the steady-state current, i_1. When currents are expressed in this manner, the data can be analyzed and compared with the results of the other methods without assuming a roughness factor. If Eq. [6] is multiplied through by i_1, one obtains

$$i_1/(i_2 - i_1) \, dV/dt = i_1 \, dV_0/dq [\ln(i_2/i_1) + \ln(i_1/i_0)] \quad [11]$$

In Fig. 5 the left hand side of Eq. [11] is plotted *vs.* $\ln(i_2/i_1)$. The linear dependence on $\ln(i_2/i_1)$ indicates that Eq. [6] rather than Eq. [7] describes galvanostatic oxidation transients. Fitting the data by least squares, one obtains

$$i_1/(i_2 - i_1) \, dV/dt = 0.0621 \ [\ln(i_2/i_1) + 0.843] \text{ mv/sec} \quad [12]$$

Using Eq. [11] and [12], one can compare this result with the results obtained by the other two methods by noting that $\ln(i_1/i_0)$ is just the reciprocal of the V_0 *vs.* V_p slope. The oxidation method gives this slope as

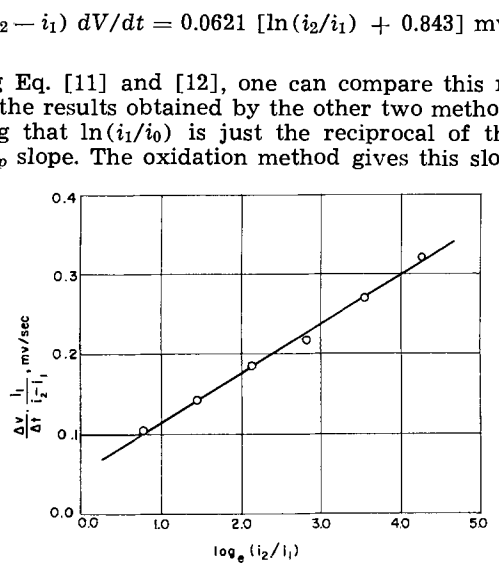

Fig. 5. Results of galvanostatic oxidation measurements from an initial passivating potential of 0.912v. i_1 is the initial steady-state current density, 5.5 μa/cm^2, and i_2 is the current density of the oxidation transient.

1.19, whereas the open-circuit method gave 0.221 and the rapid method gave 0.0664. These results differ significantly, and hence any conclusions concerning the variation in thickness of the passive layer with passivating potential must be drawn with great care. The difference between oxidation and rapid-method results can be obscured if the oxidation curves are analyzed by the more usual technique employing the displacement between curves, for this displacement has as one component the potential shift analyzed by the rapid method. The two techniques of analyzing oxidation curves will give consistent results only if the rapid method and oxidation method themselves give consistent results.

The results presented here cannot be extrapolated to other passive systems, but in most systems a similar study might be of value before an interpretation of the measured parameters is attempted. Ord and Bartlett (8), studying the passivity of iron in $2N$ H_2SO_4 at 20°C, attempt to interpret a wide range of measurements in terms of the state of the electrode and use a series of complex transients to study the reason for the difference between the values obtained by different methods.

Acknowledgment

The Reaction of Hydrogen with Graphite at 1200° to 1650°C

Earl A. Gulbransen, Kenneth F. Andrew, and Fred A. Brassart

Physical Chemistry Department, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

The reaction was studied at 19 Torr pressure under static and flow conditions. Rates of reaction up to 6.0 x 10^{17} atoms of C per cm^2-sec were measured at 1650°C and 19 Torr. The rates of reaction were nearly independent of flow and pressure. The kinetic data could be fitted to an Arrhenius-type equation $dn'/dt = Ke^{-\Delta H/RT}$, where $\Delta H = 72 \pm 2$ kcal/mole. Mass spectrometer studies of the reacted gases in the flow experiments showed no evidence for methane and other carbon-hydrogen gases. This was interpreted as evidence for the decomposition of carbon-hydrogen compounds immediately after reaction. Since the reaction products cannot form a barrier layer, a chemical mechanism was proposed for the reaction for both flow and static conditions.

Graphite reacts with hydrogen at an appreciable rate at 1600°C although the reaction products methane and other hydrocarbons are unstable. The kinetics and mechanism of the graphite-hydrogen reaction at high temperatures is of scientific and technical interest since graphite has been proposed as a material in nuclear reactors operating in hydrogen atmospheres at high temperatures.

This paper will report a study of the kinetics of the graphite-hydrogen reaction using both static and flow conditions. Vacuum microbalance methods are used to study the kinetics of the reaction, and mass spectrometer methods are used to study the composition of the reaction products.

Clark, Woodley, and DeHalas (1) have given a review of the published work. Low-temperature carbon chars were used in the early kinetic studies (2). Carney and Thomas (3) and Blackwood (4-6) have studied the reaction of various carbons including graphite below 950°C. Blackwood (4-6) used a packed annular bed of carbon and hydrogen at pressures up to 40 atm. The rate of methane formation was found to be a linear function of pressure. For graphite, an energy of activation of 43 kcal/mole was found (4) for the temperature range 650°-950°C. A reaction mechanism was suggested (6) which involves the formation of $>CH_2$ groups on the carbon surface and subsequent reaction with H_2 to form methane.

Thermochemical Calculations

Table I shows three types of reactions which involve the specimen and reacting gas. The first group are reactions between hydrogen and carbon, the second group are vaporization reactions of carbon atoms and molecules, and the third reaction is the dissociation of hydrogen molecules. Heats of formation and equilibrium constants are tabulated for each of these reactions in Table II for temperature of 527°-1727°C (7). Except for the methane reaction all of the reactions show large positive heats of formation and negative values of the logarithms of the equilibrium constants. Molecular hydrogen is slightly dissociated at the higher temperatures.

Table III shows a second series of reactions. These are side reactions including the dissociation of the alumina furnace tube in vacua and the reactions of hydrogen and methane with alumina. These are undesirable reactions and their effects on the primary reactions must be carefully evaluated. Equilibrium constants are given for the reaction at 1627°C (1900°K).

The dissociation of Al_2O_3 to Al_2O and O_2 gases is the least unfavorable of the dissociation reactions. An oxygen pressure of 10^{-8} Torr is calculated at 1627°C.

The reactions of molecular hydrogen with alumina are not feasible even at 1627°C. However, the reactions of atomic hydrogen with alumina are feasible. Due to the small concentration of atomic hydrogen in equilibrium with molecular hydrogen the reduction of alumina by hydrogen is not important at 1627°C.

The direct reaction of methane with alumina to form the metal or the suboxide Al_2O is favorable at 1627°C. This reaction is of special interest since methane is probably the major reaction product of the carbon-hydrogen reaction.

Experimental

The apparatus and method have been described (8-9). Spectroscopic grade of high-purity graphite (AGKSP) was used. The cylindrical shaped specimens weighed 0.05g and had surface areas of 0.55 cm^2. Ultra pure hydrogen containing 99.97% H_2 and 0.03% CO or N_2 was used in all of the experiments.

The furnace tube was a 2 cm I.D. high-density alumina tube. The specimens were supported centrally in the tube from one end of a Cahn microbalance by a tungsten wire. Temperature was measured at a point inside the furnace tube adjacent to the sample. The hydrogen gas was preheated in the furnace tube before coming into contact with the sample.

Results

Time and temperature.—Weight loss *vs.* time experiments were made at 19 Torr pressure and for temperatures between 1200° and 1650°C. Both static and flow environments were used. Flow rates of 0.84 to 2 x 10^{20} hydrogen molecules per second were used. These rates correspond to 256-610 cm/sec flow velocities at 1650°C.

Linear weight loss *vs.* time curves were found except at the highest temperatures where surface area changes occurred. Rates of reaction were evaluated from the initial part of the curve in units of grams of C/sec and in atoms of C/cm^2-sec. Geometrical surface areas were used in the calculations. Independent weight checks were made using an external microbalance.

Calculations could also be based on the real area of the graphite sample. Here the rates of reaction calculated on the geometrical area basis would be divided by the ratio of real surface area to the geometrical surface areas. This factor is of the order of 1000 for the size of specimens used and for the particular grade of graphite.

Table IV summarizes the kinetic results. For comparison flow rates are given in units of atoms of hydrogen per sec. Figure 1 shows a log rate *vs.* $1/T$ plot

Table IV. Rate of reaction, graphite and hydrogen 19 Torr, 0.050g sample, 0.545 cm^2

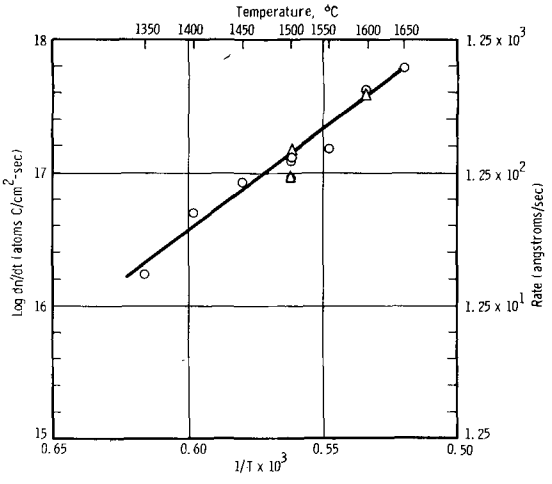

Fig. 1. Log *dn/dt* graphite + hydrogen, 19 Torr; ○, flow conditions; △, static conditions, samples 0.545 cm², ΔH = 72 ± 2 kcal/mole.

of the data. Rates are given in both atoms of C/cm²-sec and in angstroms of C/sec. At 1650°C and 19 Torr a reaction rate of 6.0 x 10^{17} atoms of C/cm²-sec or 10^3 Å/sec was measured. This rate is equivalent to an ablation rate of 0.86 cm of C/day.

Temperatures given are those of a thermocouple placed inside the furnace tube and adjacent to the sample. No temperature change was noted on adding hydrogen. This indicates that the hydrogen was adequately preheated and that the heat of reaction was not appreciably raising the surface temperature.

The results of both flow and static experiments fit the same straight line in Fig. 1. A heat of activation of 72 ± 2 kcal/mole was calculated.

Effect of pressure.—Table V shows a series of experiments made at 1500°C for pressures of 9.5 to 38 Torr for both static and flow conditions. The effect of pressure is small.

Mass spectrometer studies—Flow experiments.—Samples of the reacted gases were analyzed in both the flow and static experiments. Table VI shows the gas analyses for three flow experiments. From the rate of carbon reaction the expected methane concentrations should be 0.10, 0.03, and 0.01% for the 1500°, 1400°, and 1200°C experiments. No methane was found. The accuracy of the analyses was 0.01%. No evidence was found for either carbon monoxide or carbon dioxide.

Static experiments.—Table VII shows the results for the static experiments at 1500°C. Carbon monoxide was the major product of reaction. The cc-Torrs of carbon monoxide in the system could be related to the expected cc-Torrs from the amount of carbon reacted. No methane was found. The only source of oxygen in the reaction system was the alumina furnace tube. These experiments suggest that the carbon-hydrogen reaction products react with the alumina furnace tube wall at 1500°C to give carbon monoxide and hydrogen. This can only happen in a static experiment where sufficient time is available. In the flow experiments where velocities up to 615 cm/sec are used, the reacted gases are in the hot zone of the tube for less than 10^{-2} sec. This time is not sufficient for the reaction to form carbon monoxide. Since no methane or other carbon-hydrogen molecules are observed in the flow experiment, we propose that the carbon-hydrogen reaction products decompose to carbon and hydrogen immediately after formation. Carbon soot was observed in the exit line.

Table V. Effect of pressure on rates of hydrogen + carbon reaction, 9.5-38 Torr, 1500°C, 0.050g sample, 0.545 cm² area

P, Torr	Flow, H atoms/sec	*dw/dt*, g/sec	*dn'/dt*, atoms C/cm²-sec
9.5	3.6 x 10^{20}	8.9 x 10^{-7}	8.1 x 16^{16}
9.5	3.6 x 10^{20}	9.4 x 10^{-7}	8.6 x 10^{16}
19	3.6 x 10^{20}	9.9 x 10^{-7}	9.0 x 10^{16}
19	3.1 x 10^{20}	1.5 x 10^{-6}	1.4 x 10^{17}
38	4.0 x 10^{20}	1.4 x 10^{-6}	1.3 x 10^{17}
38	3.9 x 10^{20}	1.5 x 10^{-6}	1.4 x 10^{17}

Alternative mechanisms.—Two alternative explanations may be given which must be considered. First, alumina dissociates giving oxygen and the gaseous suboxide Al_2O. The oxygen then reacts with the graphite sample giving carbon monoxide. Thermochemical data from Table III shows that the dissociation reactions do not occur at 1627°C to give a sufficient oxygen pressure to account for the rate of reaction. Leak rate studies on the reaction system also show that gas sources cannot account for more than 1% of the required oxygen. Second, hydrogen reacts with alumina to give the suboxide and water. The water then reacts with graphite to give carbon monoxide and hydrogen. Thermochemical data show that this reaction is not possible at 1627°C. To prove that this reaction is not contributing we exposed sheet specimens of pure alumina to hydrogen in a static system at 1500°C and 19 Torr pressure. No reaction occurred.

Alumina + methane reaction.—Thermochemical calculations given in Table III show that methane can react with alumina at 1627°C. To prove that this reaction is possible we added pure methane gas to the alumina furnace tube at 10 Torr and at 1600°C. A gas sample was taken after allowing the reaction to proceed for 30 min. The gas analyses showed 57.86% H_2, 18.12% CO, 0.03% CO_2, 23.83% methane, and 0.016% C_2H_2. 43% of the original methane was reacted. This experiment is not quantitative since only 40 cc of the 5000 cc volume was in the hot zone. In addition most of the gas source was connected to the furnace tube by 8 mm sections of stainless steel or nickel tubing. We conclude that methane can react with the alumina furnace tube at 1600°C.

Discussion

The kinetic data obtained in this study will be used in two ways. First, we will estimate the efficiency of the reaction and the fraction of kinetic theory collisions which result in reaction. Second, we will apply Blackwood's analyses (6) of the carbon + hydrogen reaction to our high temperature data.

Efficiency of reaction.—The efficiency E of a reaction is given by the equation

$$E = 4\frac{dn''/F}{dt} \qquad [23]$$

Here F is the flow rate in units of H atoms/sec, dn''/dt is the actual rate of reaction in the system and the factor 4 comes from the ratio of hydrogen to carbon atoms in methane. At 1650°C and 19 Torr, we calculate from Table IV an efficiency of 0.24%. Compared to the high efficiencies of 25-30% for the oxidation reaction only a small fraction of the hydrogen atoms passing over the sample react.

Kinetic theory.—Equation [24] gives the number of collisions n of hydrogen molecules with a 1 cm² surface

$$n = 3.5 \times 10^{22} \frac{P}{(MT)^{1/2}} \qquad [24]$$

Here P is the pressure in Torr, T is the absolute temperature in °K, and M is the molecular weight. At 1650°C and 19 Torr, a collision rate of 1.07×10^{22} molecules/cm²-sec is calculated. If the reaction product is methane, we calculate a maximum theoretical rate of reaction of 5.03×10^{21} carbon atoms per cm²-sec. The actual rate was 6×10^{17}. The fraction of the theoretical maximum was 0.0108.

Mechanism.—The kinetic study and the mass spectrometer analyses of the reaction products suggests a chemical mechanism is rate controlling in both static and flow environments. A barrier layer of gaseous reaction products is not formed since the methane is removed by dissociation or by reaction with the alumina furnace tube.

Blackwood (6) has proposed a three-step mechanism. The first step is the adsorption of two hydrogen atoms with one being attached to an active site and the other reacting anywhere on the surface including the original site.

$$C + H_2 \underset{j_1}{\overset{i_1}{\rightleftarrows}} (CH)H \qquad [25]$$

Here the activity of the surface is unaffected by the hydrogen atom. The second step is a rearrangement.

$$(CH)H \underset{j_2}{\overset{i_2}{\rightleftarrows}} (CH_2) \qquad [26]$$

The third step is the direct separation of methane from the surface by reaction with molecular hydrogen.

$$H_2 + (CH_2) + \underset{j_3}{\overset{i_3}{\rightleftarrows}} CH_4\uparrow \qquad [27]$$

The small letters refer to the velocities of the forward and reverse directions for the respective reactions.

Equations can be set up for the formation and decomposition of each intermediate and for methane in terms of the velocities of the several reactions and the fraction of surface occupied. These equations can be used to calculate the rate of formation of methane R. For low methane concentrations, we have

$$R = \frac{k_1 P_{H_2}^2}{1 + k_3 P_{H_2} + k_4 P_{H_2}^2} \qquad [28]$$

k_1, k_3, and k_4 are rate constants and are given by the following equations

$$k_1 = \frac{i_1 i_2 i_3}{j_1 j_2 + i_2 i_2} \qquad [29]$$

$$k_3 = \frac{i_1 i_2 + i_1 j_2 + i_3 j_1 + i_2 i_3}{j_1 j_2 + i_2 i_2} \qquad [30]$$

$$k_4 = \frac{i_1 i_3}{j_1 j_2 + i_2 i_2} \qquad [31]$$

Between 650° and 870°C, Blackwood found that R was a linear function of the pressure. Therefore, in Eq. [28], $k_3 P_{H_2} >> 1$ and $k_4 P_{H_2} << k_3 P_{H_2}$.

At 1600°C we find R to be nearly independent of pressure. In Eq. [28], $k_4 P_{H_2}^2 > 1 + k_3 P_{H_2}$. Equation [28] for these conditions is

$$R = \frac{k_1}{k_4} \simeq i_2 \qquad [32]$$

This suggests that the rate-limiting mechanism at high temperatures is a surface rearrangement of hydrogen atoms on the surface following reaction [26].

Summary

Equilibrium thermochemical calculations show that methane and other carbon-hydrogen compounds are not formed when graphite and hydrogen are reacted between 1200° and 1600°C. Reaction can occur if the products of reaction are removed from the furnace tube or by decomposition.

A kinetic study was made using ultra pure hydrogen and high-purity graphite. A sensitive microbalance was used to follow the weight loss-time curves as a function of temperature, pressure, and flow. A mass spectrometer study was made of the products of reaction.

Rates of reaction were studied both under flow and under static reaction conditions. Flow rates up to 2×10^{20} molecules of hydrogen were used at 19 Torr pressure. At 1650°C and 19 Torr a rate of reaction of 6×10^{17} atoms of C/cm²-sec was measured. This corresponds to an ablation rate of 1000 Å/sec. In terms of hydrogen flow the efficiency of reaction was 0.24%. In terms of kinetic theory collision calculations, 0.0108% of the maximum theoretical rate was measured.

Methane was not found in the products of reaction under flow conditions. Carbon monoxide was found in experiments carried out under static conditions. To explain these results we studied (i) the dissociation of alumina at 1600°C, (ii) the reaction of hydrogen with alumina, and (iii) the reaction of methane with the alumina furnace wall. Methane was found to react with alumina at 1600°C to give carbon monoxide. An analysis based on these studies showed that methane decomposes without reacting with alumina in flow environments. In static environments methane reacts with alumina to give carbon monoxide.

The graphite-hydrogen reaction showed an exponential temperature behavior with a heat of activation of 72 ± 2 kcal/mole. The rates of reaction were nearly independent of flow and of pressure.

Blackwood's kinetic interpretation of the graphite-hydrogen reaction was used to explain the data.

Manuscript received July 22, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

The Role of Adsorbed CN Groups in the Hydrogen Embrittlement of Steel

W. Beck,[1] A. L. Glass, and E. Taylor

Aeronautical Materials Laboratory, Naval Air Engineering Center, Philadelphia, Pennsylvania

ABSTRACT

Specimens of ultra high strength steel were charged cathodically with hydrogen or immersed without charging in a NaOH solution of $NaC^{14}N$ and the adsorption of $C^{14}N$ groups determined by means of radioactivity measurements. In addition, the desorption of adsorbed $C^{14}N$ groups was also studied. Heats, designated heats of adsorption, energies of activation, and the surface coverage with $C^{14}N$ were calculated. Hydrogen embrittlement by measurement of bend ductility, negative overvoltage, and the relative hydrogen coverage were determined under similar conditions and with similar materials. It is concluded that $C^{14}N$ groups are strongly and preferentially adsorbed on highly active centers and the hydrogen recombination reaction retarded accordingly. The rapid increase in hydrogen embrittlement with increasing surface coverage by $C^{14}N$ is ascribed to a high surface concentration of the embrittling hydrogen atoms, followed by rapid migration into the steel.

It is most unfortunate that high strength steel parts, when plated from a cyanide bath, are badly embrittled, and in the presence of stress concentrations, their fatigue strengths and limits are reduced.

The transition from ductile to brittle is the result of presence of hydrogen atoms in the steel which have migrated into it during electroplating. Several mechanisms have been advanced which relate embrittlement induced by absorbed hydrogen atoms to changes in the submicroscopic metallographic structure (1).

It has been shown recently that there is a close relationship between hydrogen surface coverage and hydrogen embrittlement (2). Therefore, any embrittlement mechanism is not satisfactory in which the effect of the surface concentration of the embrittling hydrogen atoms on the inducement of hydrogen embrittlement is not integrated.

It has been reported that the CN group is adsorbed easily on metallic and nonmetallic solid surfaces, particularly iron, and effectively retards numerous decomposition and oxidation processes on them (3), as well as displacing less strongly adsorbed anions (4, 5).

The main objective of this study was the determination of whether CN groups were adsorbed on the steel surface, to obtain an idea about the strength of bonding of these groups to the metal, and to find out whether their presence increased the surface coverage of steel with atomic H.

The comparatively high surface concentration of hydrogen along with the marked embrittlement it induces in the steel in presence of CN groups was discussed in the light of an electrochemical mechanism.

Experimental Procedures

Materials.—The majority of measurements were conducted on a low alloy steel, AISI SAE 4340, which, heat treated to a strength level between 260 and 280 ksi UTS, becomes very sensitive to hydrogen embrittlement.

Some measurements were also made on AISI 1095 steel with a strength similar to that of the 4340 steel.

Hydrogen Embrittlement Production and Measurement

Standard test specimens (6) used for hydrogen embrittlement measurements in general were 2 in. diameter half rings having a width of 1 in. and a wall thickness of ⅛ in. Rings were embrittled by charging only the polished convex surface cathodically with hydrogen in a NaOH solution containing NaCN. Hydrogen embrittlement was evaluated by means of a compression bend test in a universal testing machine at a cross head speed of 0.01 in./min. The total cross head travel from the free height of the ring along the open diameter to the height at fracture is called deflection. This value, a measure of the ductility (embrittlement) of the specimen, was compared with the fracture deflection of an uncharged specimen and expressed in per cent reduction in deflection.

Measurement of Negative Overvoltage

Circular disks of 4340 steel were mounted in lucite, and metallographically polished to a high luster. Prior to immersion in the catholyte, the surface was degreased with benzene, rinsed with distilled water, and wiped with dry cotton.

The polarization cell assembly was composed of three Pyrex glass vessels which contained, respectively, a large platinum sheet anode, the steel disk cathode, and a Beckman calomel reference electrode. Electrolytic connection between the cathode and anode was by means of glass tubes, connected with Tygon tubing. The cathodic and anodic compartments were filled with 0.1M NaOH, and a 0.1M KCl agar bridge, kept a fixed distance of 1 mm from the steel surface, connected the cathodic compartment with the reference electrode.

A buret, inserted in the rubber stopper covering the container with the steel specimen, contained the NaCN solution.

Purified hydrogen was continuously bubbled into the agitated solution surrounding the steel electrode and over it. All containers were kept in a constant temperature bath at 30° ± 0.05°C.

A well-filtered rectifier supplied a constant current to the cell. The potential between cathode and reference electrode was recorded continuously by means of a sensitive potentiometer.

The experimental technique was similar to that used by Bockris and Conway (7) and also Amar and Awad (8). The direct method of measuring the overpotential was used, and new specimens with freshly prepared cyanide solutions were used for each run.

Immediately after immersion in the hydrogen presaturated NaOH solution, the specimen was polarized cathodically until attainment of a steady state, which was considered reached when the change of the potential did not exced 5 mv within a 15 min period. A small volume of the concentrated NaCN solution was then added from the buret to give the desired NaCN concentration and a new steady state polarization potential

[1] At temporary duty at the Office of Naval Research, Branch Office, London, England.

was then recorded. During addition of NaCN, the polarizing current was not interrupted but maintained constant by means of a variac on the power supply.

Relative Hydrogen Coverage

Devanathan, Stachurski, and Beck (2) have shown that if one side of a thin steel membrane is cathodically polarized, the current required for ionization of the hydrogen, which permeates the membrane and reaches the other anodically polarized side, is proportional to the hydrogen coverage of the cathode surface. With this apparatus, the hydrogen coverage of the cathode side of the membrane is maintained at a certain fixed level, whereas on the anode side, because of rapid H ionization, the H coverage is at about zero level. According to Faraday's law, the current in the anode circuit is a direct measure of the instantaneous rate of hydrogen permeation and hence of the rate controlling hydrogen coverage. The catholyte contained NaCN, the anolyte consisted of 0.1M NaOH solution.

The galvanostatically maintained cathode current density was 10 ma/cm^2. The membrane, 1 mm thick, consisted of ultra high strength AISI 4340 steel.

The relative hydrogen coverage Q_T is obtained from the following expression

$$Q_T = \frac{i_t}{i_{st}} \qquad [1]$$

where i_{st} signifies the permeation current, determined for conditions when the assumed coverage approaches unity and i_t is the measured steady permeation current.

Adsorption of $C^{14}N$ on Nonpolarized Surfaces

Since the adsorbed layers were found to be easily desorbed during rinsing, this phase of the investigation was conducted as follows: a Tracerlab Tg-C-4 Geiger tube was modified (9) by replacing its 1 in. diameter mica end window with a 0.5 mil thick Mylar sheet, covered with a thin iron layer.[2] This layer, produced by vacuum deposition of 4340 steel, had a bright and shiny appearance. The iron-coated Mylar sheets used were of a uniform thickness and their selection was based on the relative opacity which was determined photometrically.

The radioactivity of the sodium cyanide-C-14 solution was determined by moving the platform, containing the solution in the hot stage, up to the iron-Mylar window of the Geiger tube, and at fixed distances (3 in., 2 in., 1 in., etc.) between the Mylar window and the surface of the solution counts per minute were determined.

A curve was obtained by plotting these distances *vs.* the counts per minute at each distance. The curve was extrapolated to zero distance and the solution radioactivity determined as the intercept on the counts per minute axis. The solution temperature was regulated by means of a hot stage and when contact was finally made between the iron coating and the solution, the counter was simultaneously started. Counts per minute were obtained periodically until no increase was observed. Therefore, the radioactivity induced in the iron layer was the difference between the maximum counts per minute obtained on contact of layer with solution and the solution counts per minute. The specific activity of the $NaC^{14}N$ was 5.8 μc/mg or 1.28 x 10^7 dpm/mg. All measurements were conducted with hydrogen saturated solutions and a fresh specimen was used for every run.

Corrections for self adsorption and back scattering for these very low counts were deemed unnecessary. However, only those measurements were considered which satisfied the requirement for uniformity by the Chauvenet criterion.

[2] It is recognized that iron coatings vapor deposited on a Mylar film do not have the physical properties of the steel disks employed in the adsorption studies on polarized surfaces. However, electron diffraction patterns of the coatings and the surfaces of the polished steel disks showed no significant chemical differences.

Adsorption of $C^{14}N$ on Cathodically Polarized Surfaces

The experiments were conducted with 2 in. diameter 4340 steel disks, metallographically polished to a mirror finish. The polarization cell consisted of a 2¼ in. diameter petri dish with the electrodes arranged horizontally; the platinum anode was at the bottom of the dish and the steel cathode ⅛ to ¼ in. above the anode, was kept in position by a magnet. The constant current density was 10 ma/cm^2.

After completion of the polarization run the specimen was removed from the solution, rinsed, dried, and the radioactivity determined in a gas flow counter. The standard rinsing procedure consisted of a 5 min rinse in a slow stream of tap water, followed by two 2 min rinses in distilled water, and two short rinses in methyl alcohol.

All counts were corrected for background, backscattering and resolving time of the counter, and the averages, from three separately made measurements, were used in graphs and calculations. Counts/minute were converted to gCN/cm^2.

The specific activity of the solution was 25.4 mc/mM. Using radioactive sodium cyanide and the above radiochemical procedures, the surface concentration of CN was determined with respect to variations in solution concentrations (0.002 to 0.2M), temperature (20°-40°C) and immersion time (see graphs).

Desorption of CN from Pre-polarized and Non-polarized Surfaces

A part of this desorption study dealt with potential decay measurements on steel surfaces in order to determine the possible effect of desorption of CN on the surface concentration of hydrogen and hence the potential. However, the potential on a charged specimen is also affected by the hydrogen slowly diffusing out of the steel disk into the surrounding solution. As has been found, the quantity of hydrogen accumulating inside of the specimen depends on its thickness and is sharply decreased by reducing it. Since it was very difficult to obtain the necessary quantity of very thin high strength 4340 steel strips, those of AISI 1095 steel were used.

The specimens consisted of small strips of feeler gauge (AISI 1095 steel) with a bright and smooth surface finish. They were completely covered with an insulating plastic coating and immediately preceding a polarization run, a square window about 1/16 in. was cut out of the coating on each side of the strip.

The exposed metal area was solvent degreased, rinsed with distilled water, and finally with the solution to be used for the polarization run. After completion of polarization, the specimen was immediately removed from the solution, rinsed for 2 min in 0.1M NaOH and reimmersed either in a NaOH solution or a NaOH solution with NaCN. Potential measurements were started 2 min after reimmersion.

Desorption by means of radioactivity measurements was determined with an exposed area of 0.5 x 1 in. After polarization in the 0.1M NaOH solution of 0.02M $NaC^{14}N$, specimens were rinsed for 2 min in distilled H_2O and reimmersed into 5 ml 0.1M NaOH.

At predetermined time intervals, 0.1 ml samples were withdrawn and the radioactivity determined by means of liquid scintillation counting techniques at —14°C.

The total quantity of CN adsorbed on similar sheet specimens, after polarization and rinsing as described above, was determined in a gas flow counter. From this determination, and the counts obtained by liquid scintillation counting, the loss in surface concentration of CN due to desorption was determined at the various time intervals.

The desorption of $C^{14}N$ from nonpolarized iron films was determined by means of the technique described under "Adsorption of $C^{14}N$ on Nonpolarized Surfaces."

After attainment of maximum adsorption, the Geiger tube was immersed in 800 ml of NaOH solution and simultaneously, the recorder was turned on at a set

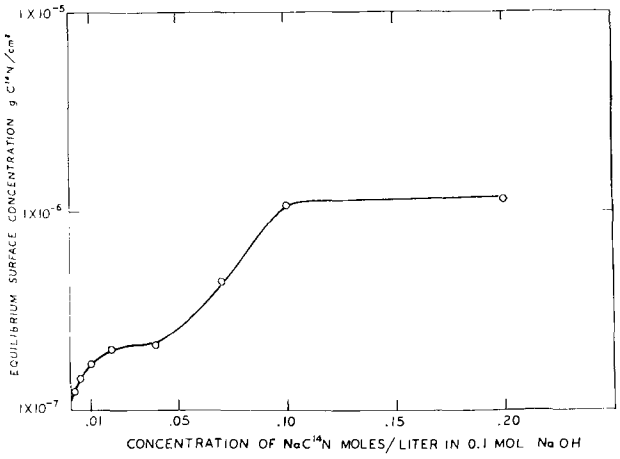

Fig. 1. Adsorption isotherm recorded at 20°C on specimens immersed in 0.1M NaOH solution containing $NaC^{14}N$ in various concentrations.

speed. The rapid decrease of counts with time was recorded until the background count was obtained.

Experimental Results

Effect of Concentration of Dissolved NaCN *and Temperature on the Surface Concentration of* $C^{14}N$ *Groups*

The "S" shaped curve in Fig. 1 indicates that in the range of low concentrations of NaCN (to about 0.04M), the adsorption may have the characteristics of a Freundlich or Tempkin isotherm. At concentrations exceeding this value, surface coverage increases rapidly and finally, beyond 0.1M, the adsorption on the nonpolarized surface approaches saturation conditions.

A log-log plot of the values of the surface concentration of $C^{14}N$ taken from the "S" shaped section of the curve in Fig. 1 (to a concentration of NaCN of about 0.04M) *vs.* the solution concentrations is almost linear. The deviations from the linearity appear to be more marked in a semilogarithmic plot, consisting of a plot of the log of the surface concentration of $C^{14}N$ or of the heat designated heat of adsorption *vs.* solution concentration of NaCN. This might indicate that the values fit more closely a Freundlich than a Tempkin adsorption isotherm.

The above analysis is quite preliminary in nature and was only presented because of the fact that the rapid drop in ductility is limited to a range of rather low concentrations of NaCN, actually appreciably below 0.04M.

With polarization (Fig. 2), the curve approaches linearity and begins to sweep upwards toward a saturation at a concentration of 0.2M NaCN, which is usually observed in an adsorption isotherm.

The curve illustrating the dependency of surface concentration of cyanide on adsorption temperature for a polarized surface (Fig. 3) increases linearly whereas the inverse is true with nonpolarized steel.

Heat, Designated Heat of Adsorption of $C^{14}N$

The heat of surface processes associated with the adsorption of systems containing the CN group (ΔH) was calculated for the polarized surface as a differential heat of adsorption (10).

Calculations by means of the Fisher, Hirschfelder, Taylor atom models have indicated high coverage of the polarized surface with CN, and ΔH actually may have been generated by several surface processes as will be discussed in another paper. The integrated form of the Clausius Clapeyron equation was used for these calculations

$$\Delta H = 4.574 \left(\frac{T_1 T_2}{T_2 - T_1} \right) \log c_2 - \log c_1 \qquad [2]$$

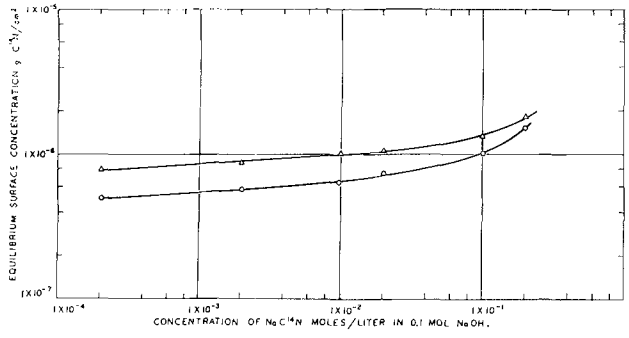

Fig. 2. Adsorption isotherms recorded at two different temperatures on specimens polarized cathodically at 10 ma/cm² for 30 min in 0.1M NaOH solution containing $NaC^{14}N$ in various concentrations. ○, Solution temperature 20°C; △, solution temperature 40°C.

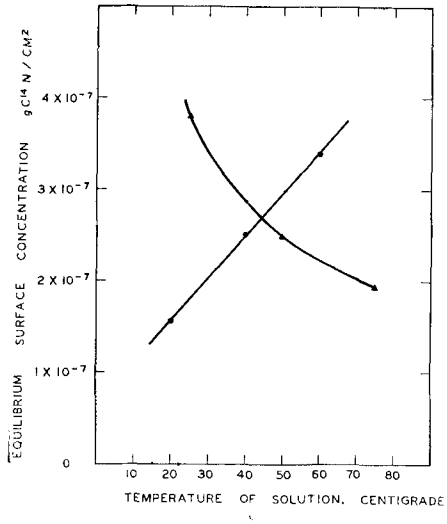

Fig. 3. Relationship between solution temperature and surface concentration of $C^{14}N$. ▲, Specimens immersed into a solution consisting of 0.02M NaCN + 0.1M NaOH until attainment of adsorption equilibrium; ●, specimens polarized cathodically in same solution at 10 ma/cm² for 30 min.

The two solution concentrations of NaCN, c_1 and c_2, necessary for production of the same surface concentration of CN at the absolute temperatures T_1 and T_2, respectively, are obtained graphically from the adsorption isotherms presented in Fig. 2. These values were substituted into the Clausius Clapeyron equation and the differential heat of adsorption (ΔH) was calculated. The above method is used extensively in gas adsorption.

The plot of ΔH *vs.* surface concentration of CN is depicted in Fig. 4. Its decrease with increasing surface concentration of CN is considered to be caused by the hetergeneous structure of the adsorbing steel surface. The first quantity of CN interacting with the most active sites reacts vigorously as indicated by the highly exothermic heat values. As the surface process progresses and the less active sites also become involved, the reaction diminishes and the heat values become less exothermic.

Additional information may be obtained from the ΔH curve in Fig. 4. The point corresponding to —10 kcal/mole represents an adsorption of 10.3×10^{-8} $gC^{14}N/cm^2$. When this value is subtracted from 14.7×10^{-8} $gC^{14}N/cm^2$, which is the total quantity of CN on the surface depicted by this curve, the remaining 4.4×10^{-8} $gC^{14}N/cm^2$ obviously represents a layer formed at heats less than —10 kcal/mole and is 22.4% of the total surface concentration. Therefore, since it may be expected that $C^{14}N$ is more easily desorbed from sites of comparatively low activity, and since

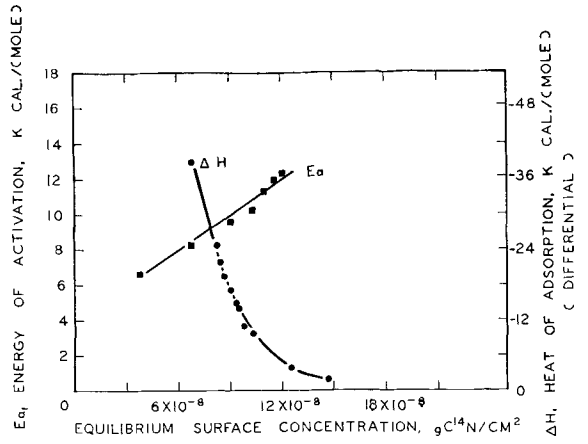

Fig. 4. Plot of ΔH and E_a vs. surface concentration of CN. As discussed in the paper, several surface processes are contributing to the generation of heat, designated in this figure as "Heat of Adsorption."

heats of adsorption less than —10 kcal/mole represent such sites, remarkable correlation is established between the fixation of CN on less active sites, as calculated above, and that actually found by radiochemical determination (25%) (comp. p. 57). The value of —10 kcal/mole is selected since many investigators equate heat of adsorption below this figure with comparatively weak adsorption that may occur on less active sites.

Energy of Activation for Adsorption of $C^{14}N$

In gas adsorption, the energy of activation E_a (11) is calculated from the Arrhenius equation. Tentative calculations of this energy were made from the integrated Arrhenius equation.

$$E_a = \ln\left(\frac{t_1}{t_2}\right)\left(\frac{R}{1/T_1 - 1/T_2}\right) \qquad [3]$$

Here t_1 and t_2 are the times required for adsorption of a given quantity of CN at the absolute temperatures T_1 and T_2, respectively. A plot of E_a *vs.* the surface concentration of CN is shown in Fig. 4. The E_a increases from 6.7 kcal/mole for the low level CN adsorption to about 13.0 kcal/mole for the higher concentrations of CN on the steel surface. This is considered strong evidence that with progressively increasing coverage, first the more active sites are covered in the adsorption process, since they require lower activation energies. Subsequently, those sites with less activity requiring comparatively higher activation energies are covered.

The Rate of Adsorption and Desorption of $C^{14}N$ *Groups*

The times and the surface concentrations of $C^{14}N$ plotted in Fig. 5 and 10 (to be shown below) were converted into rate values. Since bilogarithmic plots of these values gave straight lines, the adsorption or desorption can be represented mathematically by the following equation

$$y = at^n \qquad [4]$$

The constants a and n were obtained statistically by the least squares method. By differentiating the equations with respect to time, the rate of cyanide adsorbing on or desorbing from the steel surface can be computed at any given time.

As can be seen from Fig. 6, the rate of adsorption on polarized surfaces decreases rather rapidly with increasing time and increases moderately with temperature. The rapid decrease of the rate of adsorption again is considered a strong indication that with increasing time, the number of active areas decreases markedly. Selected rate values at various temperatures are listed in Table I.

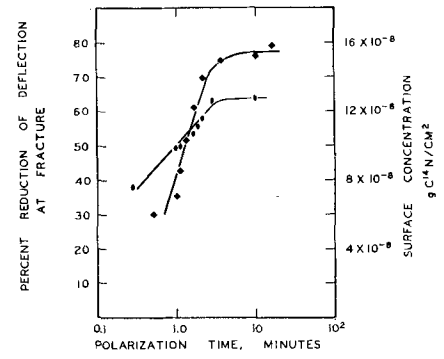

Fig. 5. Effect of polarization time on fracture deflection and surface concentration of $C^{14}N$. Fig. 7. Effect of time on rate of desorption of $C^{14}N$ and desorption potentials. X, Desorption of $C^{14}N$; •, desorption potential.

The rate of desorption from and respectively the rate of adsorption on nonpolarized surfaces was not calculated since the instrumentation employed did not yield sufficiently reproducible results for these fast reaction rates. However, we were able to determine that the reproducibility of the time necessary for maximum $C^{14}N$ coverage was satisfactory, and therefore, these values are incorporated in Table I.

The slope of the desorption curve in Fig. 7 is slightly higher than that for the adsorption curve in Fig. 6. This indicates the rate of desorption is decreasing faster than the rate of adsorption. In order to explain this phenomena, it may be speculated again that the $C^{14}N$ desorbed was largely physically adsorbed on less active sites and the CN which remains adsorbed is mainly held by strong bonds to the active areas.

Comparison of Significant Data

In Fig. 5, the effect of polarization time on reduction in deflection and surface concentration of CN can be compared. The trend of the two curves show the steep increase within an initial polarization period of about 5 min, and the final attainment of saturated conditions.

Figure 8 demonstrates the effect of temperature on reduction in deflection as well as surface concentration of CN. The trends of these curves are generally comparable between 20° and 60°C.

The plot in Fig. 9 is typical for the effect on NaCN concentration on the negative overvoltage of steel. Immediately upon addition of NaCN, the overvoltage rises rapidly and is higher for greater cyanide concentrations. In general, steady state in the pure NaOH

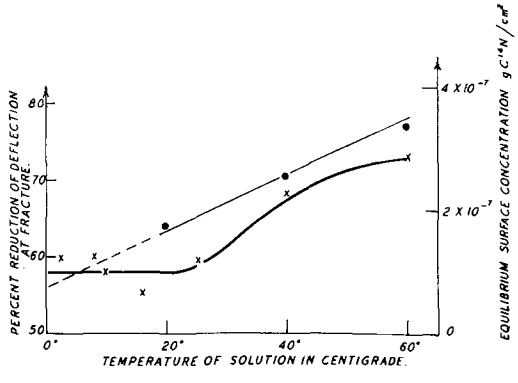

Fig. 8. Effect of solution temperature on equilibrium surface concentration of $C^{14}N$ and fracture deflection. Solution consisted of 0.02M NaCN + 0.1M NaOH. Potential at zero time between X-1250 and X-1300 mv (SCS). Equilibrium surface concentration at zero time is 1.30 x 10^{-7} g$C^{14}N$/cm². •, Specimens reimmersed in solution consisting of 0.02M NaCN + 0.1M NaOH; □, ○, specimens reimmersed in 0.1M NaOH sol; •, □, potential measurements; ○, radioactivity measurements.

solution is attained after 160 min. However, after addition of NaCN, about 70 min more are required.

The curves presented in Fig. 10 illustrate the effect of time on surface concentration and potential. After polarization, the specimens were reimmersed in a NaOH solution in the presence and absence of NaCN, respectively. The polarization time was selected to be 5 hr because shorter times resulted in a fast shift of the potential in the cathodic direction and poorly reproducible measurements.

As can be seen from Fig. 10, the slope of the line depicting the slow decay of the potential in 0.1M NaOH within a period of about 100 min is steeper than that for a NaOH solution of NaCN. The potential within this 100 min interval is more anodic in solutions containing NaCN than in those without this compound added and the lines depicting the fall of the potential or the decay of radioactivity have quite similar slopes. However, exceeding this 100 min period, dissimilarities in the trends of the curves occur.

Radioactivity measurements have indicated that the decrease in the surface concentration of $C^{14}N$ did not exceed 25% of the quantity of the totally adsorbed CN attained after an immersion period of 40 min. This value could not be exceeded, even when the specimen was immersed for a period as long as 20 hr at 20°C.

Adsorption and desorption studies on nonpolarized surfaces were conducted on a comparatively limited

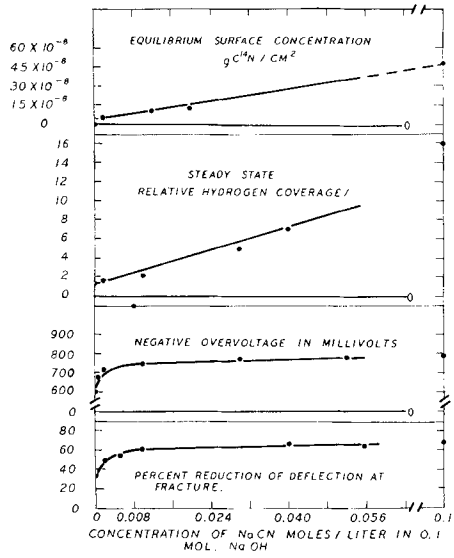

Fig. 11. Effect of solution concentration of $NaC^{14}N$ on a number of variables. Overvoltage measurements at 30°C; all other measurements at 20°C; polarizing current, 10 ma/cm².

basis and pertinent results will be presented in the Discussion Section.

As demonstrated in Table I, on cathodically polarized specimens, the times for attainment of adsorption equilibria are markedly longer than on nonpolarized surfaces, ΔH and E_a are strongly increased and desorption is very slow and incomplete.

These differences in the data presented herein are considered strong evidence that cathodic polarization when associated with $C^{14}N$ adsorption induces certain surface reactions which do not proceed on nonpolarized surfaces.

Finally, Fig. 11 demonstrates the effects of NaCN concentration on a number of variables. In all cases, an increase occurs as the NaCN concentration is increased to about 0.01M. Particularly, the similarity in the trend of the curves is noted with those depicting the concentration dependency of overvoltage and reduction in deflection and also those depicting the effect of CN solution concentration on cyanide surface concentration, and hydrogen coverage. Comparing the results obtained with 0.01M NaCN solution, at which reduction in deflection reached its maximum value, with those at zero concentration, the following may be seen:

The deflection is decreased from about 25 to 62%, the steady state relative hydrogen coverage has increased from 1 to 4, the negative overpotential changes from 600 to about 750 mv and surface concentration of CN goes from 0 to 7.5 x 10^{-8} g/cm².

Discussion

A mechanism is now discussed for the generation on and migration of the embrittling hydrogen atoms into the steel, based on the above presented discussion of the radiochemical data and those of electrochemical and ductility measurements.

Since a solution with an alkalinity as high as pH-13 has a negligibly low H ion concentration, it appears probable that the first step (a) in the formation of atomic H is a slow discharge of a solvated proton from a water molecule. Because of the comparatively low order of the negative overvoltage (12) determined in this study (<750 mv), it is further concluded that the desorption step (b) consists in a fast Tafel recombination.[3]

This reaction would proceed predominantly on places where the heat of H adsorption is high but the activation energy for H recombination relatively low. These highly active sites are designated Fe^B areas contrary to the Fe^A areas with relatively low surface activity.

Under idealized conditions, the total area of the steel surface Fe involved in the adsorption of H is

$$Fe = \Sigma Fe^A + \Sigma Fe^B \qquad [5]$$

The discharge reaction (a) and the catalytic cycle (b) on the highly active Fe^B sites may then be represented by the following equations (12)

$$\text{(a)}\quad 2H_2O + 2e_o^- \rightarrow 2\,OH^- + 2H$$

$$\text{(b)}\quad 2Fe^B + 2H \rightarrow 2Fe^B\text{——}H \rightarrow 2Fe^B + H_2 \qquad [6]$$

When k_R signifies the rate constant for the H recombination reaction in electrical units, C_{Hads} the surface concentration of the H adatoms, and i_c the constant density of the polarizing current, the following equation holds true, if the applicability of Tafel recombination is anticipated.

$$i_c = k_R\, C_{Hads}^2 \qquad [7]$$

However, in the presence of cyanide compounds, apparently due to their strong preferential adsorption, the number of active sites (as discussed above) still available for H adsorption is drastically reduced. Hence, the activation energy for H recombination is increased, and the rate of this reaction retarded accordingly. At constant density of the polarizing current i_c, the surface concentration of the H adatoms, C_{Hads}, must rise in order to compensate for the decrease in the rate constant k_R.

According to the diffusion laws (2, 14), the quantity of H absorbed in the steel specimen during unit time is proportional to C_{Hads}, and by increasing this concentration, the velocity of migration of the embrittling H atoms into the metal is also increased and embrittlement accelerated accordingly.

If the above discussed mechanism applies, it would be expected that a reactivation of the Tafel recombination can be brought about by preferential desorption of CN. As can be seen from Fig. 7 plotting the rate of increase of the potential and that of the CN desorption, *vs.* the time of immersion in a 0.1M NaOH solution, overlapping curves result. The intimate relationship between these two variables strongly indicates that the potential is determined by desorption of CN. In other words, the increase in potential is caused by CN progressively desorbing from the steel surface, and therefore this potential has to be considered a desorption potential. This process is also in agreement with the requirements of basic Eq. [6] and [7] because the increase in k_R is compensated for by the decrease in C_{Hads}. These facts indirectly confirm the above postulated mechanism of inhibition of hydrogen recombination.

Therefore, it is inferred that a desorption of CN, even as limited as 25%, is sufficient to reactivate (at least to a certain degree) the reaction necessary for recombination of H atoms.

Other investigators (2) have correlated hydrogen coverage of a cathodically polarized steel membrane surface with the hydrogen permeating through it. Fisher and Bärmann (15, 16) studied embrittlement by plating Cd from the cyanide bath or by cathodically charging high strength steel specimens in various sodium cyanide solutions. Even though the current density employed was tenfold greater than that reported herein and the embrittlement was evaluated by repeated flexure to fracture, their hydrogen embrittlement results in general are in agreement with those presented in this paper.

The reliability of their overvoltage measurements and, therefore, all pertinent conclusions seem to be doubtful, because they were conducted in presence of oxygen and it is open to question whether steady state

[3] Makrides (13) has advanced the concept that, with small fractional H coverage, the exchange rates for discharge and recombination in strongly alkaline solutions at equilibrium are about equal on Ni (and perhaps as well on Fe).

potentials ever had been attained. The assumption of a cathodic reduction of NaCN at higher concentrations, at the comparatively low potential at which hydrogen was charged into the steel is hardly conceivable. This assumption is not in agreement with the radiochemically determined increase in the surface concentration of cyanide with increased cyanide solution concentration.

The effect of adsorbed CN anions on the overvoltage may be explained by Frumkin's theory of the retarded hydrogen discharge (17, 18).

In the presence of specifically adsorbed anions, the ψ' potential, that is the potential of the external Helmholtz layer which represents the mean potential value at a distance of one ionic radius from the electrode surface, becomes more negative.

Replacing Eq. [7] by the following Eq. (1_b), one obtains for the polarizing current, i_c, when hydrogen atoms are generated by protonic discharge of water molecules, [Eq. (1_a)]

$$(1_a) \quad H_2O + e_0^- \rightarrow H_{ads} + OH^-$$
$$(1_b) \quad i_c = K_{a_{H_2O}} \exp(-\alpha F[\phi - \psi']/RT$$

One obtains further for the overvoltage

$$(2) \quad \eta = a_{CN^-} - \psi' - \frac{RT}{F} \ln OH^- + \frac{RT}{\alpha F} \ln i_c$$

and from this equation

$$(3) \quad \left(\frac{d\eta}{d \ln a_{CN^-}}\right)_{PH;\ i_c} = -\left(\frac{d\psi'}{d \ln a_{CN^-}}\right)_{PH;\ i_c}$$

The overvoltage, η, increase with increasing ψ' potential which is caused by increased adsorption of CN ions due to the increased solution activity of CN^-.

As can be clearly seen from Eq. (1_b), the rate of the hydrogen evolution reaction depends on the term $(\phi - \psi')$ on which again depends the activation energy. Since this energy increases linearly with the increase of $(\phi - \psi')$, it follows that the more negative ψ', the greater becomes the activation energy and the more marked the retardation of the reaction rate as indicated by the increase in the overvoltage η.

Acknowledgments

The authors are much indebted to Mr. N. Promisel, Head, Special Materials Branch, Bureau of Naval Weapons, for the great and continual interest taken in this study; to Mr. F. S. Williams, Superintendent, Metallurgical Division, Dr. G. K. Holmes, Superintendent, Chemical Engineering Division, and Mr. J. Smith, Head, Chemistry Branch, of the Aeronautical Materials Laboratory, Naval Air Engineering Center, for their helpful assistance. Gratefully acknowledged are the valuable discussions with Dr. H. Wroblowa and Z. Stachurski, both formerly with the Electrochemical Laboratory of the John Harrison Laboratory of Chemistry at the University of Pennsylvania. Thanks are also due to Mr. B. Baker for assistance with the experimental work during the initial phase of this investigation.

Manuscript received Dec. 13, 1963; revised manuscript received Aug. 31, 1964. This paper was presented at the Boston Meeting, Sept. 16-20, 1962.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

June 1965 Discussion Section

A Discussion Section, covering papers published in the July-December 1964 JOURNALS, is scheduled for publication in the June 1965 issue. Any discussion which did not reach the Editor in time for the December 1964 Discussion Section will be included in the June 1965 issue.

Those who plan to contribute remarks for this Discussion Section should submit their comments or questions in triplicate to the Managing Editor of the JOURNAL, 30 East 42 St., New York, N. Y., 10017, *not later than March 1, 1965*. All discussion will be forwarded to the author(s) for reply before being printed in the JOURNAL.

Exchange of Silver Ions at Single Crystal/Solution Interfaces

Irvine I. Tingley

Mines Branch, Department of Mines and Technical Surveys, Ottawa, Ontario, Canada

ABSTRACT

The exchange of silver ions between the (111), (100), (110), and (311) surfaces of single-crystal silver and silver nitrate solutions has been studied, using Ag^{110} as tracer. The initial step is very rapid and is probably largely adsorption, since much of the radioactivity acquired during the first few seconds can be removed by soaking in distilled water. After about 15 min the rate-controlling process appears to be diffusion in the solid. In 0.01M $AgNO_3$ solution the radioactivity uptake continues steadily if the surfaces are frequently desorbed with distilled water, but if the adsorbed ions are allowed to remain, the rate of uptake is reduced. In 0.1M $AgNO_3$ solution the radioactivity on the surfaces reaches constant values after 4 days, whether or not desorption is carried out. The penetration profile and diffusion coefficient in the metal were obtained by "chemical sectioning." It was found that diffusion occurred by means of "dislocation pipes," and resembled grain boundary diffusion rather than lattice diffusion by a vacancy mechanism which occurs at high temperatures.

The exchange of silver ions between polycrystalline silver metal surfaces and aqueous solutions of silver salts has been investigated by a number of workers using radioactive silver isotopes as tracers (1-11). In general, all agree that a rapid exchange involving only a few atom layers takes place in the first few seconds, followed by a slower process which is affected by the concentration of the solution, the state of the surface, and the temperature. This slower uptake of ions from the solution is held to be controlled by diffusion in the solid. King and Levy (2) found that surfaces that were removed from the solution, and washed frequently, underwent more exchange than surfaces that were left undisturbed; they attributed this to the removal of adsorbed salt that slowed down the exchange. However, King and McKinney (3) concluded that the increased exchange was due, more likely, to increased diffusion caused by a rise in temperature due to the hot water used in the washing. They calculated a grain boundary diffusion coefficient of the order of 10^{-21} cm^2/sec. Sandor (8), who removed the radioactivity by electroetching, obtained a value of 1.37×10^{-20} cm^2/sec for the grain boundary diffusion coefficient.

The present work was undertaken to ascertain the behavior of specific single-crystal surfaces with respect to the exchange of silver ions with aqueous silver nitrate solutions, and to obtain a value for the room temperature volume diffusion coefficient.

Experimental Details

The single crystals of silver were grown in a horizontal furnace by the method of Chalmers (12), using 99.999% pure silver obtained from Johnson, Matthey and Mallory Limited, Toronto. The crystals were then sectioned and oriented along the desired direction, and the resulting surfaces were electroetched and/or chemically etched and polished, as described below. Most cuts were made using a spark cutter, but two specimens were cut by means of an "acid saw." The orientation of the surfaces was obtained by x-ray diffraction, and the cuts were made to within 5° of the plane desired. The disturbed material on the surfaces was removed by electroetching with the cyanide electropolishing solution of Gilbertson and Fortner (13), with a current of 4 ma/cm^2 and/or by chemical etching with 55% HNO_3 or with a solution of 15 ml of 30% H_2O_2 plus 25 ml of concentrated NH_4OH. The surfaces were then electropolished by the method of Gilbertson and Fortner (13), or chemically polished by the chromic acid-hydrochloric acid method of Levinstein and Robinson (14). Both of these methods produce very smooth surfaces with a minimum of microscopic imperfections. Square or rectangular specimens, with a small tab for handling, similar to those used by Sandor (8), were cut using an "Airbrasive" machine (S. S. White Dental Manufacturing Company, New York). These specimens had an area of 1 cm^2 on the surface exposed to the solution. The radioactive silver isotope was Ag^{110}; the radioactive metal was dissolved in nitric acid, evaporated to dryness, taken up in distilled water, evaporated to dryness again, redissolved in water, and made up to the required concentration with reagent grade silver nitrate. These solutions had a pH of 5.5.

The specimens were cemented onto a glass disk with paraffin, and their edges painted with paraffin to expose only the one surface. The surfaces were then wiped very carefully with absorbent cotton moistened with chloroform to remove any paraffin and grease immediately before being immersed in the radioactive solution. After removal from the solution, the disk, with the specimens on it, was rinsed with distilled water to remove any adhering solution. The specimens were then removed from the paraffin mounts, rinsed thoroughly with distilled water and then with chloroform before being counted. The chloroform rinse was made to remove any small pieces of paraffin which might adhere to the edges of the specimen and make a crevice where liquid might be entrained.

Counting was done with a well-type NaI(Tl) scintillation counter, the specimens being counted at the bottom of the well. Corrections for decay of the Ag^{110} and for day-to-day variation in the counter efficiency were made by comparing with counts taken on standards prepared by electroplating specimens in a radioactive silver nitrate solution at the beginning of these experiments. Corrections for absorption were not necessary because of the small distance penetrated and the energies of the γ-rays.

Experimental Results

The radioactivity taken up by polycrystalline silver surfaces during long periods of immersion in radioactive silver nitrate solution is shown in Fig. 1. Results for two electropolished polycrystalline surfaces that were immersed in 0.1M $AgNO_3$ solution that had a specific activity of 252,000 cpm/ml, are plotted for various periods totaling 46 days. The line was drawn by the method of least squares. The radioactivity uptake is seen to be proportional to the square root of the time, as it should be if a diffusion process is occurring.

During the first few minutes, however, the uptake of radioactivity follows a different pattern. Figure 2 shows this for (111), (100), and (110) surfaces immersed in a 0.01M solution of $AgNO_3$ having a specific activity of 984,000 cpm/ml. The rate of uptake of radioactivity is seen to be very rapid during the first few

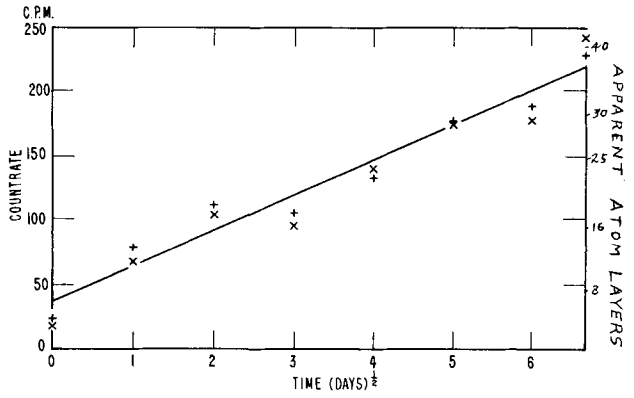

Fig. 1. Radioactivity uptake in polycrystalline silver, 0.1M $AgNO_3$ solution, 6 cpm = 1 apparent layer.

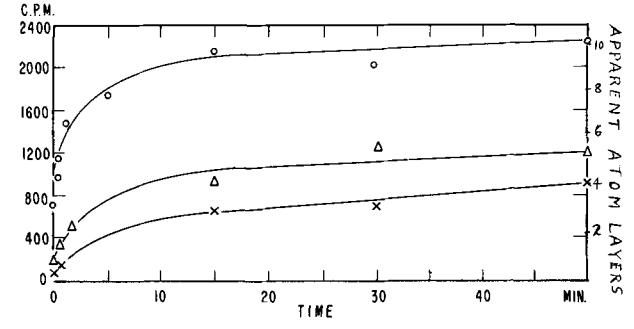

Fig. 2. Radioactivity uptake at beginning of exchange, 0.01M $AgNO_3$ solution, 226 cpm = 1 apparent layer: O, 111; △, 100; ×, 110.

seconds, then to decrease until after 15 min it becomes constant, and the curves become linear with the square root of the time. The curves for polycrystalline surfaces are very similar for the short times of immersion. The data for the single-crystal surfaces show that the initial uptake on the (111) surface is much greater than that on the (100) surface, and the uptake on the (110) and (311) surfaces follow in that order, the differences between the last three being much smaller than that between the (111) and (100) surfaces, however.

With longer periods of immersion in 0.01M $AgNO_3$ solution, the extent and manner of the radioactivity uptake depend on whether or not desorption of silver and nitrate ions is carried out. Figure 3 shows curves for (111), (100), and (110) surfaces, exposed for periods up to 9 days in 0.01M $AgNO_3$ solution, with desorption carried out after each immersion by soaking the specimens in distilled water for three 24-hr periods. Similar curves for an experiment with (111) and (100) surfaces show this linearity of uptake, when plotted against the square root of the time, for periods totaling 100 days. This indicates that diffusion of the radioactive silver atoms into the metal takes place after the surface exchange, and that these atoms are replaced by more radioactive silver ions from the solution, after desorption of inactive ions from the surface, thus causing the radioactivity of the specimen to increase.

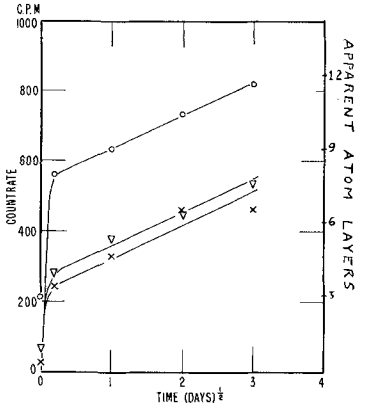

Fig. 3 Radioactivity uptake on single crystal surfaces with desorption at intervals, 0.01M $AgNO_3$ solution, 70 cpm = 1 apparent layer: O, 111; ▽, 100; ×, 110.

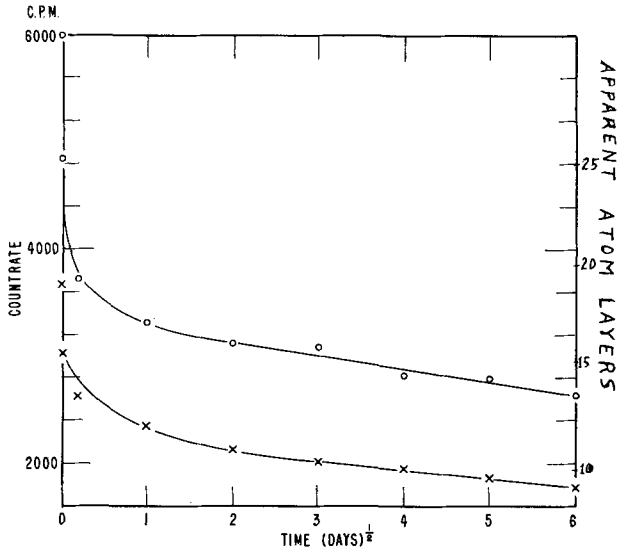

Fig. 4. Reverse exchange on single crystal surfaces, 0.01M $AgNO_3$ solution, 192 cpm = 1 apparent layer: O, 111; ×100.

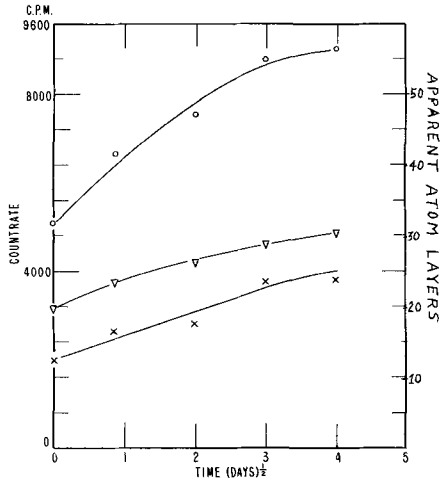

Fig. 5. Radioactivity uptake on single crystal surfaces without desorption, 0.01M $AgNO_3$ solution, 158 cpm = 1 apparent layer: O, 111; ▽, 100; ×, 110.

That the whole process is an exchange is shown by Fig. 4, in which surfaces that had become radioactive in radioactive solution are seen to lose their radioactivity in a similar manner when immersed in nonradioactive solution. If the surfaces are not desorbed after each immersion, however, the radioactivity uptake does not obey the same relation, but its rate decreases more rapidly, as shown in Fig. 5.

With 0.1M $AgNO_3$ solutions, however, an equilibrium point seems to be reached when the surfaces had been immersed for a total of 4 days. This is shown in Fig. 6, which contains the data for four differential planar surfaces. Again, desorption of these surfaces between immersions does not have the effect observed with surfaces exposed to 0.01M $AgNO_3$ solutions. The total uptake is reduced, but equilibrium is reached at about the same time. It would appear that, because of the higher concentration of ions in the solution, the adsorption of ions takes place much more rapidly than the

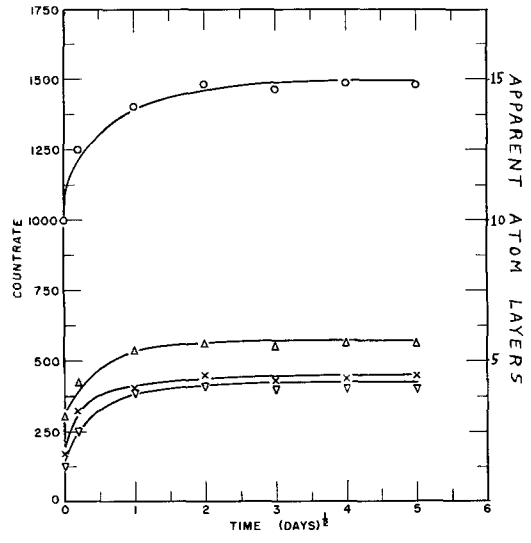

Fig. 6. Radioactivity uptake on single crystal surfaces, 0.1M $AgNO_3$ solution, 100 cpm = 1 atomic layer: ○, 111; △, 100; ×, 110; ▽, 311.

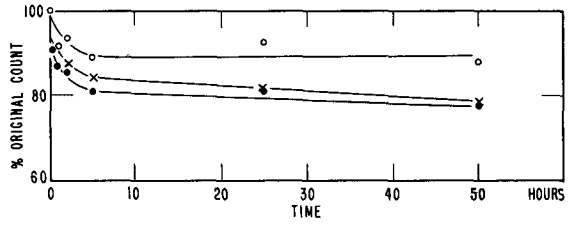

Fig. 7. Desorption of single crystal surfaces with distilled water: •, 100; ○, 111; ×, 110.

reverse process, even after restoration of the surface by massive desorption before immersion.

The extent of desorption by distilled water is shown in Fig. 7. One surface of each type was made radioactive by immersion for nine days, with desorptions between the immersion periods (*i.e.*, after 1, 4, and 9 days), and then a further immersion for 16 days without desorptions. The per cent removal of the radioactivity by desorptions with distilled water is shown. From surfaces immersed in radioactive solution for only very short periods, up to 30, 40, and 50% of the radioactivity can be desorbed by distilled water from the (111), (100), and (110) surfaces, respectively.

To obtain a diffusion profile, small "slices" of the specimens were removed by etching with a solution containing 20g of CrO_3 and 10g of H_2SO_4 in 2000g of distilled water. The technique of "chemical sectioning" has been described by Barr *et al.* (15). The solution that they used for copper, however, was found to pit silver surfaces, and so the chromic-sulfuric acid solution was substituted. It was found that a 5-sec dip in this solution, while it was boiling, followed by rinsing in distilled water, removed an amount of silver from a polished surface corresponding to a thickness of 0.2μ. The silver was removed very evenly, leaving the surface still polished, and the process was reproducible. The sides of the specimens were lightly ground to remove any silver that had diffused down along these surfaces, and the exposed surfaces were then etched in small beakers containing the solution. Both the solution and the specimen were counted and the results agreed within the experimental errors. Apart from the first slice, the logarithm of the removed activity was proportional to the thickness of metal removed, rather than to the square of the thickness as it would be if it followed the error function complement equation which holds for volume diffusion at temperatures above 600°C. The penetration curves obtained are shown in

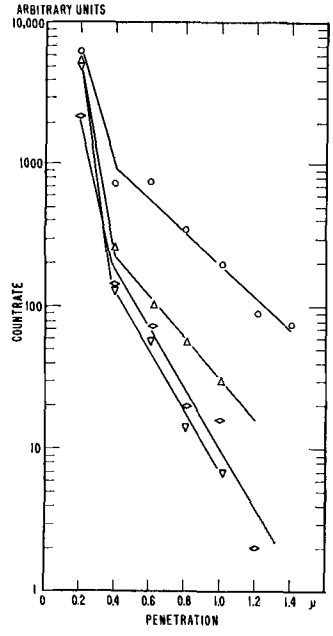

Fig. 8. Penetration profile of silver specimens with different plane surfaces: ○, (111); △, (100); ▽, (110); ◇, (311).

Fig. 8, in which the lines are drawn by the method of least squares.

Calculation of Diffusion Coefficient

The fact that the penetration of radioactive silver atoms into single-crystal specimens at room temperature follows a relation similar to that for grain-boundary diffusion rather than to that for volume diffusion at high temperatures suggests that silver diffuses at room temperature along dislocation "pipes," which behave like tiny grain boundaries. The equation derived by Fisher (16) for grain-boundary diffusion may then be used to calculate the diffusion coefficient. This equation is

$$D_d = 2D_v^{1/2}(\log e)^2 \Big/ \delta\left(\frac{d \log a_x}{dx}\right)^2 (\pi t)^{1/2}$$

where D_d will be the dislocation diffusion coefficient, D_v the volume diffusion coefficient, e the base of natural logarithms, δ the width of the dislocation pipe, a_x the radioactivity, x the distance penetrated normal to the surface, and t the time. Tomizuka and Sonder (17) obtained the equation

$$D = 0.4 \exp \frac{-44{,}100}{RT}$$

for the self-diffusion of silver in single crystals at high temperatures. Extrapolated to room temperature (25°C) this gives a value

$$D_v = 4.5 \times 10^{-33} \text{ cm}^2/\text{sec}$$

Using this value and 1.44×10^{-8} (the effective atomic radius of silver) for the width of a dislocation pipe the value for the dislocation diffusion coefficient at 25°C in silver is

$D_d = 2.1 \times 10^{-21}$ cm^2/sec for (111) surfaces

$= 1.5 \times 10^{-21}$ cm^2/sec for (100) surfaces

$= 6.1 \times 10^{-22}$ cm^2/sec for (110) and (311) surfaces

Discussion

The ease of removal, by soaking in distilled water, of a large proportion of the radioactivity acquired by these silver surfaces, suggests that the first step in the exchange process is adsorption of silver ions from the solution onto the top layers of atoms in the metal lattice. The number of atoms in 1 cm^2 of (111), (100), 110),

and (311) planes in silver is 1.4 x 10^{15}, 1.2 x 10^{15}, 8.5 x 10^{14}, and 7.2 x 10^{14}, respectively. The number of silver ions taken up by these surfaces is roughly proportional to the densities of atoms on the surfaces, *i.e.*, decreasing in magnitude from (111) through (100) and (110) to (311), but the fact that they are not exactly proportional shows that factors other than merely the number of adsorption sites, such as adsorption and exchange energies, are operating. This is also indicated by the ease of removal of freshly adsorbed ions by soaking in distilled water, which is inversely proportional to the quantities adsorbed, *i.e.*, decreasing in magnitude from (311) through (110) and (100) to (111).

That a certain time elapses before exchange is complete between the adsorbed ions and those in the metal lattice is shown by the fact that specimens immersed for longer periods (or even stored after exchange) are not desorbed to the same extent as those freshly activated by short periods of immersion. Referring to Fig. 2, it would seem that the initial very rapid uptake during the first few seconds is due to adsorption; the increase from the first few seconds until about 15 min is the result of exchange between adsorbed ions and atoms in the metal, followed by exchange between adsorbed inactive ions and radioactive ions in the solution, and then the slower increase of radioactivity after the first 15 min is due to diffusion of radioactive atoms along the surface and into the metal and their replacement on the surface by other radioactive atoms going through the processes of adsorption, exchange and diffusion into the metal.

The inhibition of the exchange by adsorbed ions, shown in Fig. 5 and 6, may be due to the formation of a double layer of silver and nitrate ions, the anion part of which tends to prevent the exchange of silver ions between the surface (or adsorbed layer) and the solution. Attempts to investigate the adsorption of nitrate ions on silver surfaces proved inconclusive. However, King and Schochet have shown that silver nitrate, as such, is adsorbed on silver surfaces (18).

Alternatively, if adsorption leads to a smaller effective surface, or the filling of "active sites" such as kinks, incomplete rows, steps *etc.*, this also might retard further adsorption. No sign of corrosion was observed on the surfaces used in the experiments reported in this paper. These surfaces were very smooth (14), were very carefully handled, and remained very smooth to microscopic observation and without a sign of tarnish throughout the duration of the experiments. Because of improper electropolishing, some surfaces were prepared which did tarnish slightly after several days. The pickup curves for these surfaces always showed an upward curvature, which is easily explained, because exchange between the solution and silver oxide and sulfide is more rapid than with the metal, and also because the corrosion roughened the surface and thus caused its area to gradually increase. The linearity of the pick-up curves in Fig. 3 and 6, and the lack of any visual corrosion, indicates that corrosion did not occur to such an extent that it affected the exchange.

As mentioned above, the self-diffusion of silver at high temperatures takes place by a vacancy mechanism, and may be represented by Fick's Second Law, for constant surface concentration, by the equation

$$C_{(x,\,t)} = C_0\, erfc \frac{x}{2\sqrt{Dt}}$$

where $C_{(x,\,t)}$ is the concentration of diffusant at thickness x and time t, C_0 is the constant concentration of the diffusant at the surface, and D is the diffusion coefficient (19). However, it was found that the diffusion at room temperature does not obey this equation, but instead follows the same law as grain-boundary diffusion. Extrapolation of the Arrhenius equation which obtains for silver at high temperatures would indicate that the atoms moved only 10^{-13} cm in the present experiment. This also indicates a different mechanism for the room temperature diffusion. On the other hand, the actual area of the surface is probably many times the measured area, due to vacancies, steps, *etc.*, and there is evidence that the dislocation density can vary extremely rapidly near the surface. Several papers during the last year or so have reported very low volume diffusion coefficients near the surface of a metal, indicating that the structure of the metal is markedly different in that region from what it is in the interior of the metal. For these reasons a calculation of the area of diffusion from the difference in radioactivity between the surface and planes in the interior seems impossible. If diffusion occurs along dislocation networks or pipes, the area through which diffusion is occurring is actually very much less than the geometrical area of the surface.

Hoffman and Turnbull studied grain-boundary self-diffusion in silver, and obtained curves similar to Fig. 8 (21). The high values in the first slice they explained as due to surface radioactivity which had not diffused. It now appears that the greater slope at the beginning of these diffusion profiles is due to the lower diffusion coefficient near the surface, mentioned above. They proposed a dislocation pipe theory to explain grain-boundary diffusion, and obtained an Arrhenius equation which covered the diffusion from 400° to 525°C. This equation is

$$D_b = 0.14 \exp \frac{-19{,}700}{RT}$$

Extrapolation of this equation to 25°C gives a value for D_b of 3.2 x 10^{-15} cm^2/sec, which is 5 to 6 orders of magnitude greater than those obtained by Sandor and by King *et al.* The experimental results fall between those obtained by this equation and those obtained by extrapolating the Arrhenius equation for volume diffusion at high temperatures.

Calculating from the amount of exchange, King obtained, for single crystal silver at room temperature, values of the self-diffusion coefficient from 1.3 to 1.5 (x10^{-21}) cm^2/sec, in good agreement with those obtained in the present work (22).

An alternative method for determining the actual area through which diffusion occurs is suggested in a paper by Foster *et al.* (23). Ag^{110} is not suitable for this purpose, because of its γ-emission, but Ag^{111} could be used, perhaps.

Acknowledgments

Electrodeposited Nickel-Iron-Molybdenum Thin Magnetic Films

W. O. Freitag and J. S. Mathias

UNIVAC, Division of Sperry Rand Corporation, Research & Engineering Center, Blue Bell, Pennsylvania

ABSTRACT

Thin magnetic films of nickel-iron-molybdenum, 600-800Å thick, were electrodeposited from citrate complexed solutions containing sodium molybdate, nickel sulfate, and iron sulfate. The variation of magnetic properties of the films was determined as a function of the composition of the film, the *p*H of the plating solution, and the current density. All experiments were carried out at room temperature. Glass slides with vacuum evaporated chromium-gold layers were used as substrates. Magnetic films with H_k values of 1.0 oe have been obtained from these solutions.

The Ni-Fe-Mo alloy system was investigated as part of a program of continued development of thin magnetic films for computer memory use. The objective was to develop magnetic films having a low anisotropy field (H_k). The anisotropy field is the magnetic field required to saturate the film in a direction normal to the easy axis.

Most magnetic film memories now in use or being designed operate at drive currents of several hundred milliamperes (1). Techniques have been developed in our laboratories for the fabrication of memories which can operate at 20-30 ma (2) and which, therefore, will be compatible with molecular-type integrated circuits. One of the requirements for the design of such a low power memory was the availability of magnetic thin film material with anisotropy field on the order of 1 oe. This paper describes research directed toward this goal.

Engleman and Hardwick (3) have reported the preparation of thin films of permalloy having an H_k as low as 1.5 oe by a vacuum evaporation technique. Francombe and Noreika (4) have obtained magnetic films having an H_k of 2.5-4.0 oe by cathodic sputtering.

Wolf (5) has electrodeposited binary nickel-iron alloy films 1000Å in thickness which show an H_k of 3.5-4.0 oe. Electrodeposited Ni-Fe-P films having an H_k as low as 2 oe have been prepared in our laboratories and have been discussed previously (6). Exploratory work with electrodeposited Ni-Fe-Mo alloy films indicated that this alloy showed considerable promise with respect to producing films with H_k values to 1.0 oe.

Experimental

The plating apparatus was similar to that described previously (6) and consisted of a rectangular plastic vessel which was fitted with a suitable means of holding the cathode rigidly in a removable holder. Anodes were fabricated from high-purity nickel sheet. The bath was surrounded by a coil which generated a uniform vertical magnetic field of about 35 oe. The plating current was provided by a constant current regulated power supply. All experiments were carried out at room temperature without agitation.

The cathodes were Corning Microsheet approximately 8 mils in thickness measuring 43 mm x 50 mm and coated with evaporated layers of chromium and gold 1000-1200Å and 800-1000Å in thickness, respectively. Evaporations were carried out at about 1×10^{-5} Torr.

The electrolyte was a citrate complexed solution of nickel and iron sulfates containing sodium molybdate; bath compositions are shown in Table I.

Magnetic properties, coercive force, H_c and anisotropy field, H_k, were measured on a 60 cycle hysteresograph. A qualitative estimate of magnetostriction was made by flexing the film samples within the sense coil of the hysteresograph during H_k measurement. Since the hysteresograph was designed for samples of another size, only the sign of the H_k change was recorded, and no values for magnetostrictive coefficient are given in this work.

Deposits were analyzed by dissolving a known film area, diluting to volume, and applying standard colorimetric micromethods for Fe, Ni, and Mo. Thicknesses were estimated from the total amounts of metal found and are believed accurate to ±10%. Film compositions

Table I. Composition of electrolytes

Component, g/l	Solution Series 1	Series 2	62-27	62-51
$NiSO_4 \cdot 6H_2O$	60	80	60	80
$FeSO_4 \cdot 7H_2O$	1 to 8	2 to 5	3.5	4.0
$Na_2MoO_4 \cdot 2H_2O$	¼ to 2	1 to 2	1.5	1.5
Citric acid monohydrate	66	60	72	80
Saccharine	0.8	0.8	0.8	0.8
Na lauryl sulfate	0.4	0.2	0.4	0.2
NaCl	10	10	10	10
$NaOH/H_2SO_4$	As required to adjust to pH 5.2

up to about 30 wt. % Fe and 20 wt. % Mo were investigated.

Control of Film Composition

The composition of the deposit was controlled primarily by the composition of the plating bath. The data shown in Fig. 1 to 3 were obtained using solutions of Series I, Table I. The plating time was 60 sec at a current density of 6 ma/cm^2. Ferrous sulfate heptahydrate and sodium molybdate concentrations were varied giving a series of solutions having Ni^{++}/Fe^{++} ionic ratios of 63.3-7.9, and Ni^{++}/MoO_4^{--} ratios of 228 to 37.

Figure 1 shows a plot of film thickness obtained at a constant deposition time of 60 sec *vs.* iron content of the electrolyte, at two levels of molybdate concentration. No effort was made to determine cathode current efficiency quantitatively although a 60 sec plating cycle was calculated to yield a film about 1100-1200Å in thickness at 100% efficiency. We note from Fig. 1 that the efficiency is roughly independent of the iron content of the solution (except at very low iron) and is slightly better at higher molybdenum concentrations.

Figure 2 shows the relationship between the ionic ratio of nickel and iron in the electrolyte and the atomic ratio of nickel and iron in the deposit. A change in sodium molybdate concentration did not appear to affect the relative deposition rates of nickel or iron under our plating conditions. The vertical spread of the experimental points shows the range of Ni-Fe atomic ratios obtained at the four different levels of molybdenum concentration in the electrolyte. However, the four lines that result when one plots these data separately for each molybdenum concentration are very nearly the same line, and no systematic effect of molybdate concentration can be determined. Therefore, within the limits of accuracy of these data, the amount of molybdate ion present in the solution has no effect on the Ni/Fe ratio in the deposit, and the latter is a function only of the ratio of the nickel and iron ions in the electrolyte.

Figure 3 relates the nickel-molybdenum ratios for the same films. Again there is considerable experimental spread, but there was evidence that for solutions having low Ni/Mo ionic ratios, increasing amounts of iron sulfate gave decreasing Ni/Mo atomic ratios in the deposit. This effect was not sufficiently clear-cut to permit graphic presentation, however, and did not appear at all at the higher Ni/Mo ratios.

Variation of Deposit Composition with Plating Time

During the simultaneous discharge of more than one ionic species at a cathode, the relative deposition rates of the individual ions will vary at the start of the deposition cycle as their relative concentrations vary in the cathode double layer. The interplay of relative depletion rates in this double layer and diffusion rates into this layer eventually results in some equilibrium composition. During the deposition of these thin films, the total deposition time is not much longer than the time required to achieve this equilibrium. As a result composition gradients appear across the thickness of the films, and a film 500Å thick could have an average composition quite different from one 1000Å thick plated under exactly the same conditions. This effect has been discussed with respect to binary Ni-Fe films by several workers (7, 8). The ternary system Ni-Fe-P was studied by the present authors (6). During the deposition of Ni-Fe from uncomplexed sulfate solutions, the initial film layers are more iron-rich than layers deposited subsequently. The effect is ameliorated by the presence of sodium hypophosphite in the Ni-Fe-P system.

Figure 4 shows the average iron concentration as a function of plating time for Ni-Fe-Mo films. The initial layers of deposit are relatively more iron-rich than those deposited later as is the case in the nickel-iron deposition. Figure 5 shows the data for molybdenum content of these same films. The initial layers are Mo-rich, but an equilibrium composition is soon reached.

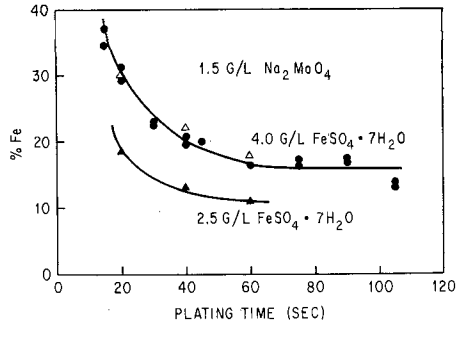

Fig. 4. Variation of average iron content of Ni-Fe-Mo films with plating time (film thickness) at a constant molybdate concentration. Two levels of ferrous sulfate concentration are shown. Current density was 6 ma/cm^2. Triangular points were from solutions of Series 2, round points from Solution 62-51 (Table I).

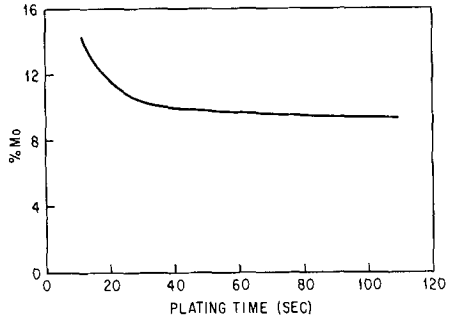

Fig. 5. Variation of average molybdenum content of Ni-Fe-Mo films with plating time (film thickness) for films deposited from solution 62-51, Table I: 1.5 g/l $Na_2MoO_4 \cdot 2H_2O$; 4.0 g/l $FeSO_4 \cdot 7H_2O$.

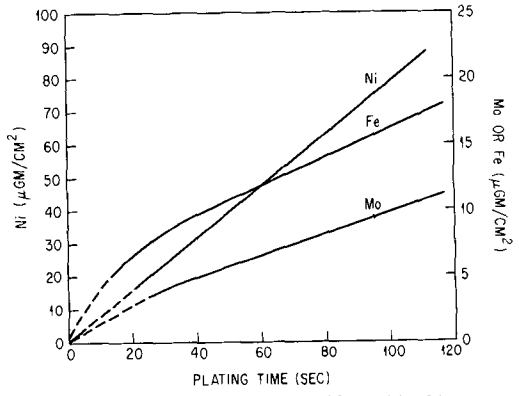

Fig. 6. Amount of each component in Ni-Fe-Mo films vs. plating time from solution 62-51. Current density was 6 ma/cm^2; 1.5 g/l $Na_2MoO_4 \cdot 2H_2O$; 4.0 g/l $FeSO_4 \cdot 7H_2O$.

These data are presented in a more significant manner in Fig. 6. The compositions are expressed in micrograms of each component per unit area of film and are plotted against plating time. When an equilibrium state is reached in the cathode double layer and some constant composition is being deposited, the rate of increase of the amount of each alloy component in the film should be a constant and the curve will be linear. This is seen to be the case for each metal species here. Iron approaches its straight line portion corresponding to a constant deposition rate in about 40-50 sec. Nickel, however, appears to deposit at a uniform rate from the beginning. This is not unexpected, since nickel is present in relatively larger amounts.

The slopes of the straight line portions of these curves yield the equilibrium deposition rates of the three components. These values are 0.085, 0.108, and 0.78 μg/cm^2/sec for Mo, Fe, and Ni, respectively. The equilibrium composition is therefore 9% Mo, 11% Fe, and 80% Ni for this solution. Assuming that the reduction of each Ni or Fe ion requires two electrons, and each molybdate ion requires six, one calculates that the current efficiency for this equilibrium deposit is about 57%.

Furthermore, since the slopes of the Fe and Mo lines in Fig. 6, that is, the deposition rates, are greater at a plating time less than that required for establishing the equilibrium deposit, the current efficiencies should be somewhat greater for thinner films. That this is indeed the case was shown by plotting total deposit thickness as a function of plating time; the slope of this curve, which should be a straight line, was greater in the region 15-40 sec than it was in the region greater than 40 sec.

It appears that after about 40 sec of plating, equilibrium concentration conditions are achieved in the cathode double layer, and after this a constant composition alloy is deposited.

Effect of Composition on Magnetic Properties

The variation of magnetic parameters with electrolyte and deposit composition is shown in Fig. 7 and 8. Figure 7 shows the effect of the ionic ratio of nickel to molybdate in the solution on the H_k of a 60 sec deposit. Several iron concentrations, expressed as ionic ratio of nickel to iron in the bath, are represented. For solutions high in iron, that is having a Ni/Fe ratio of 10 or lower, high H_k values are obtained at all molybdenum levels, although H_k decreases as the molybdate content is increased. Minimum H_k films were obtained at Ni/Fe ratios of 20 to 30 and at nickel to molybdate ratios of 35 to 50. At higher Ni/Fe ratio there is a sharp increase in H_k values.

The data shown in Fig. 7 are a composite of two sets of experiments, one based on Series 1 solutions (Table I), the other on Series 2 solutions. The two sets of data agreed well, showing that under the conditions used (which involved no agitation, a current density of 6 ma/cm^2, a plating time of 60 sec, and a pH of 5.2) the H_k of the film is dependent on the composition of the plating bath and hence on the composition of the deposit.

Figure 8 relates H_k to film composition directly. The low Fe, low Mo corner of the ternary Ni-Fe-Mo composition diagram is shown. The points represent the composition of films in the thickness range 600-800Å as determined by wet analysis. The points along the 0% Mo axis (binary Ni-Fe alloy) were taken from Wolf's data for 500Å films (5). These were included even though they do not fall within the thickness range of our data since Wolf showed no appreciable H_k change with thickness in this thickness range. The dashed lines roughly map out areas of points having the indicated H_k values.

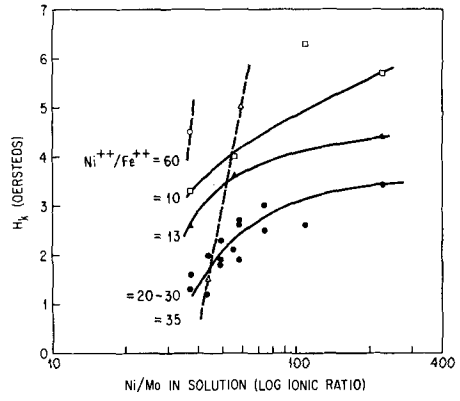

Fig. 7. Anisotropy fields of 60 sec deposits as a function of ionic ratio in electrolyte. Films plated from solutions of both Series I and II are represented; c.d. = 6 ma/cm^2; plating time 60 sec.

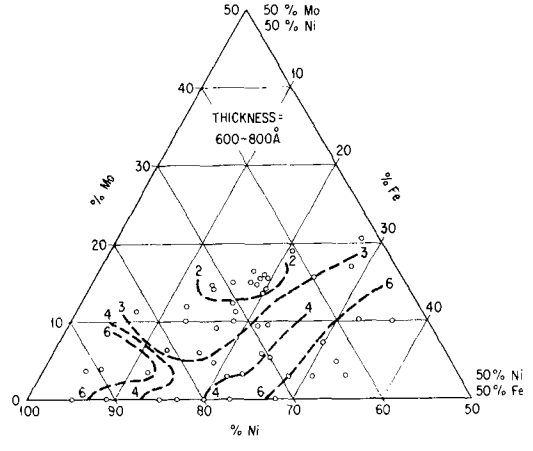

Fig. 8. Anisotropy field as a function of film composition. The dashed lines roughly map out areas of composition having the range of H_k values shown. A field of $H_k < 2$ oe appears at 15% Mo, 15-20% Fe.

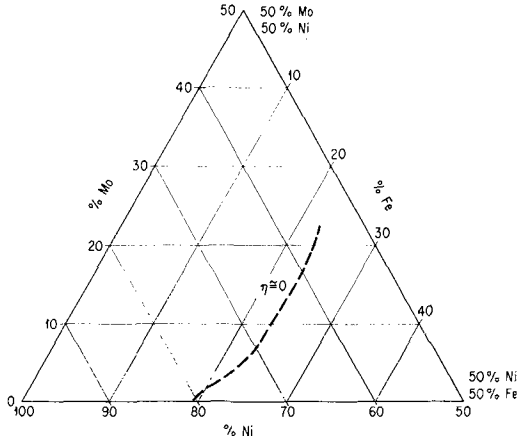

Fig. 9. Approximate locus of Ni-Fe-Mo film compositions having zero magnetostriction in the 600-800Å thickness range.

An area of minimum H_k (H_k — 1.0 to 2.0 oe) appears at approximately 15% Mo, 15 to 20% Fe, and 65 to 70% Ni.

Figure 9 shows the approximate locus of compositions with zero magnetostriction. Note that this line misses the area of minimum H_k; all films with suitably low H_k values were highly magnetostrictive.

Effect of Plating Conditions on Magnetic Properties

The magnetic properties of the electrodeposited Fe-Ni-Mo films are sensitive to the current density and pH during deposition. It is shown below that for a limited current density range the variation of H_k of the films with current density is traceable to variations in relative deposition rates of the three component metals. However, film quality as reflected by the squareness of BH loops deteriorated at higher current densities.

The effect of current density was studied with solution 62-27 (Table I). Current density was varied from 2 to 14 ma/cm^2 at a constant 360 ma-sec/cm^2. No deposit was obtained at 2, and incomplete coverage was found at 4 ma/cm^2. Films with "well-behaved" BH loops were found up to about 10 ma/cm^2; above this current density, distorted loops were obtained. The variation of H_k for these films is indicated in Fig. 10 which shows a slight increase in H_k as current density increases. Analysis of these films gave the results shown in Fig. 11. Both the iron and molybdenum contents of the deposits decrease as current density increases, and, as can be seen from Fig. 8, as the Fe concentration falls an increase in H_k is to be expected. Note also an increase in cathode current efficiency as current density is increased as expressed by the rising deposit thickness, even though a constant total charge was passed through the cell.

The effect of pH on the magnetic properties of the electroplate is striking and requires further study. Figure 12 illustrates the behavior observed for solution 62-27, and is typical of all solutions tested. Minimum H_k values are observed at pH of 5.2. Below pH 4, only films with distorted BH loops were obtained; no deposits were formed at pH 6 or above.

Summary

We have shown that the Ni-Fe-Mo alloy films can be deposited from mixed sulfate solutions complexed with citrate ion and containing sodium molybdate. The composition of the films may be controlled by controlling the plating time and the composition of the solutions. Magnetic films having anisotropy fields as low as 1.0 oe can be prepared, but these are highly magnetostrictive in the thickness range investigated.

Acknowledgments

The authors wish to express their appreciation to Guy DiGuilio, Charles Bell, and Victor Suchodoloski for fabrication of the films and the magnetic measurements, and to Edwin Schneider for the chemical analyses.

Extremely Intense Light Sources with Narrow-Band Spectral Emission

Jenny E. Rosenthal and Charles F. Eyer

Melpar, Inc., Falls Church, Virginia

ABSTRACT

The effect of a microwave field at 2.45 kMc on a sodium seeded oxyhydrogen flame is studied in some detail in the case when the microwave power is only about 1/8th of the thermal power of the flame. An average brightness enhancement by two orders of magnitude is observed raising the level to 2 million foot-lamberts. The enhanced emission is limited to the vicinity of the resonance lines which show quite extreme broadening with narrow reversal. Under pulsed operation, the light pulse is synchronized with the microwave pulse. Qualitative data are given for the enhancement at 10 kMc. Possible explanations of the observed effects are considered.

This is a report on work done toward the development of a lamp of high efficiency and high brightness level radiating over practically the entire range of 4π steradians. Operation can be either continuous or at any desired pulse rate up to a few kilocycles and possibly higher. Most of the emission is concentrated in a spectral band of the order of 50-300Å.

The operation can be illustrated by the following example: A sodium seeded flame is a light source activated by a cheap form of power. However, the efficiency, *i.e.*, the ratio of luminous power out to thermal power in, is less than 1%. If this light source is subjected to a microwave field whose power is only about ⅛th of the initial thermal power due to combustion, the result is more than a hundred fold increase in the brightness of the light source with an over-all operating efficiency approaching 50%. The enhancement is not limited to flames seeded with alkali metals, but appears to be a much more widespread phenomenon. A report on the more general aspects is deferred to a later date.

Experimental Arrangement and Results

The microwave field is produced inside a waveguide in the TE_{10} mode by a magnetron operating at 2.45 kMc with an average power output of nearly 1 kw. The waveguide has a cross section of 4.3 x 2.6 in., is open at the end, and has holes drilled to permit insertion of the flame with its axis perpendicular to the direction of the electric vector (see Fig. 1). A special tuning mechanism is provided to concentrate the microwave energy in the region of the flame. This arrangement is estimated to provide about 25% coupling between the flame and the microwave field, *i.e.*, some 250w are absorbed by the flame, the rest being reflected. According to calculations based on Stratton's book (1, 2), redesign of the microwave cavity and of the plasma envelope should bring the coupling up to 90%.

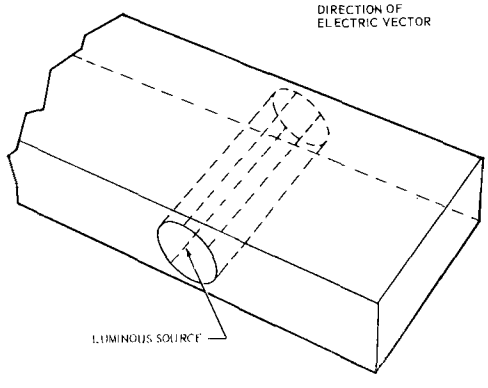

Fig. 1. Schematic of experimental set-up

The light source is formed by an oxyhydrogen torch confined laterally inside a quartz tube containing a charge of small NaCl crystals. This arrangement provides a simple way for impregnating the flame with sodium as the NaCl charge keeps being replenished.

The entire set-up is placed inside an exhaust cabinet which serves to exhaust the liberated chlorine and other gases that may be present and in addition provides shielding against microwaves. Viewing can be done either from the side or from the front through suitable openings in the walls of the exhaust cabinet, which are covered by a wire mesh for radiation shielding. A Spectra Spot Brightness Meter placed in front of the open end of the waveguide and focused on a small area of the quartz tube is used to measure the brightness of the lamp. It should be emphasized that the meter is sufficiently far away to keep any minor changes in its position from affecting the readings, given in ft-L.

When the torch is lit but the magnetron is not turned on, the brightness reading for a flame saturated with salt is of the order of 15,000 ft-L. When the magnetron is turned on, pulsed at 60 cycles, the brightness reading on the meter, which gives a time average, is increased by a factor of 130 to a value of 2 million ft-L. To study the behavior of the emitted light as a function of time, the light pulse is detected by a photodiode and displayed on an oscilloscope. Figures 2A and 2B show oscilloscope traces of the enhanced

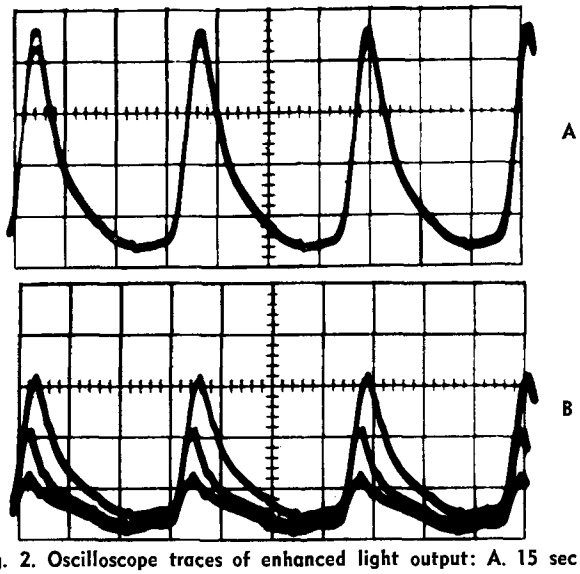

Fig. 2. Oscilloscope traces of enhanced light output: A. 15 sec after ignition; B. 3, 5, and 7 min after ignition.

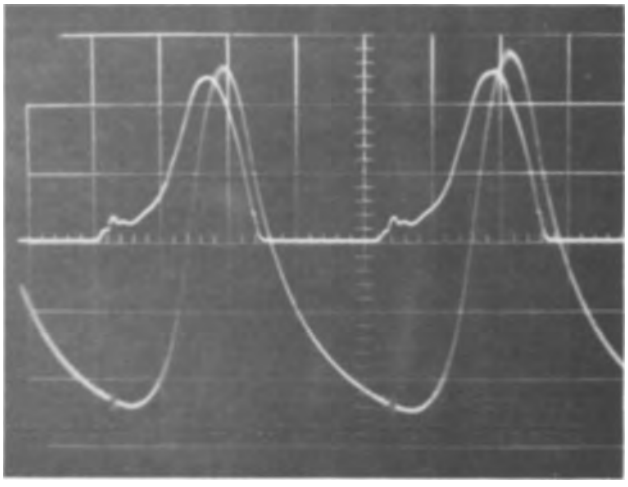

Fig. 3. Comparison of light pulse and magnetron pulse

light output at a 60 cycle pulsing rate. Each horizontal division represents 5 msec, the vertical (intensity) scale is arbitrary. Figure 2A represents conditions 15 sec after ignition and simultaneous turning on of the magnetron. With the arrangement used, the salt is slowly blown out through the open ends of the quartz tube. The three curves in Fig. 2B are oscilloscope traces of the light output at successive stages of salt depletion, 3, 5, and 7 min after ignition, respectively.

Since increased seeding raises the flame conductivity, the above data mean that enhancement increases with flame conductivity, *i.e.*, with plasma density. The higher the brightness of the flame before it is subjected to the microwave field, the greater the enhancement factor.

The following studies were carried out to obtain a better understanding of the observed basic phenomenon of enhancement.

The first set pertains to the time relationship between the emitted light pulse and the magnetron pulse. Figure 3 shows the degree of synchronization between the two. Different baselines were chosen to make the comparison more clear cut. Pulsing is at 120 cycles. The microwave pulse is referred to the upper line and the light pulse to the bottom one. Each horizontal division corresponds to 2 msec. We see that the enhanced light pulse does not start till the microwave pulse has reached a certain level, however, it continues to rise past the peak of the microwave pulse and proceeds to decay much more slowly. Pulsing rates as high as 2 kc have been used with 0.75 μsec pulse duration and a peak power of 1 kw. The emitted light was found to be pulsed at the same rate though the time-averaged enhancement was too low to be detected visually. This is to be expected in view of the very low duty cycle.

With regard to spectroscopic data, visual observation did not reveal OH bands under any operating conditions. In the absence of a microwave field, the observed spectrum is that of atomic sodium with such broadening characteristics as would be expected in a flame operating around 2500°C, the temperature listed (3) for a hydrogen-rich oxyhydrogen flame. These results are to be contrasted with the appearance of the spectrum in Fig. 4 produced by a flame subjected to the action of the microwave field. The spectrogram extends over the range from the sodium D-lines to the sodium green line, which would appear at the position indicated by the arrow. It is visible on the original plate but may be too faint to be seen in reproduction. Thus enhancement does not affect transitions other than the resonance lines. Reversal indicates the normal position of the D-lines. Broadening is obviously quite extreme.

Under certain conditions which are not yet fully understood, we also observed a faint continuum or

Fig. 4. Spectrogram of enhanced sodium flame

possibly a very dense band system extending for a few hundred angstroms on each side of the D-lines. This may be a secondary effect. In any case, the ratio of the intensity in the vicinity of the D-lines to that of the continuum is estimated to be at least of the order of 100. This is to be compared with conditions in the mercury high pressure lamp where the ratio of the intensity of the mercury green line to that of the surrounding continuum is less than 10.

Enhancement is also observed at 10 kMc. However, no quantitative comparison is possible with the 2.45 kMc case since the entire power output of the high frequency magnetron is only 250w.

No coupling has been observed between a d-c discharge and a microwave field even though the shape and orientation of the electrodes are chosen so as to prevent microwave reflection from them. The voltage and current values used were in the range required for an arc discharge. However, when the d-c discharge was combined with the microwave field, no enhancement could be noticed visually.

Discussion

The following salient facts appear from the experiments above:

1. The microwave energy acts as a trigger which permits efficient utilization of thermal energy in the production of visible radiation.
2. Enhancement appears to be restricted to the first excited state.
3. The broadening of the enhanced lines is quite extreme while the reversed portions at the center remain quite narrow.
4. No coupling is observed between a d-c discharge and a microwave field.

The following comments appear to be pertinent with regard to these facts:

a. Temperature rise has to be excluded as the cause of the enhancement since the temperature would rise only by about 1000°C even if the entire 250w of microwave energy were used for heating the gases in the flame. Calculations based on Planck's radiation function show that this increase in temperature would cause only a nine-fold increase in the radiation from a blackbody at the wavelength of the Na D-lines. Furthermore, at the higher temperature, the wavelength of a maximum emission from a blackbody would be shifted. If instead of a blackbody, we consider the actual case of an atom emitting discrete

lines, the temperature rise would increase the population of the more highly excited states and thus increase the intensity of transitions from these states relative to the intensity of the resonance radiation. As mentioned above, this is contrary to observations.

b. It is obvious that Doppler broadening at the existing temperatures is several orders of magnitude smaller than that shown in Fig. 4. Using conventional notation, the standard formula for collision broadening is (4)

$$\Delta\lambda/\lambda = N'd^2\lambda\sqrt{(3kT/4Mc^2)} \quad [1]$$

where $\Delta\lambda$ is the width of the line at half the intensity of the maximum, N' the number of atoms per unit volume, and d the effective diameter for a collision sufficiently close to affect the radiation process. To get this formula to agree with experiment, we must postulate a value for d some thirty times larger than its value obtained from kinetic theory. While results of this nature have been observed previously (5, 6), it should be emphasized that in our experiments the large increase in collision cross section occurs only under microwave action. The narrow width of the reversed lines indicates that whatever "perturbation" takes place, it affects solely the excited state.

Comparison with Other High Intensity Sources

In order to evaluate the usefulness of the microwave enhanced plasma source for practical applications, it is necessary to compare it with conventional high brightness sources, such as the Hanovia short arc xenon lamps. The performance of these conventional lamps is usually measured in terms of their luminous flux or their intensity. Since we measured the output of our enhanced sodium flame in terms of its brightness, it is necessary to correlate the two sets of parameters. For this purpose we use the expressions

$$B = 929L/4A,\ L/4\pi = C \quad [2]$$

where A is the source area in cm^2, B the brightness in ft-L, C the intensity in candles, and L the luminous flux in lumens. Strictly speaking, the relations in Eq. [2] are applicable only to sources radiating uniformly over a sphere. However, they should provide at least a good estimate of data for the sodium flame. The results of this comparison are listed in Table I. The value listed for the total power input into the enhanced flame is the sum of the thermal power input of 2.2 kw into the flame and the electrical power input of 2 kw into the magnetron. It is seen from the table that even for this total power input the efficiency of the enhanced sodium flame is far higher than that of either of the xenon lamps. Allowing for the fact that the coupling between the microwave field and the flame is only 25%, but with proper design can be made 90%, we can place the effective power input at only about 2.7 kw. The efficiency of the energy transformation is therefore as high as 220 lumens/w. Furthermore, since the enhanced sodium flame emits primarily in the region of the D-lines, it constitutes a source with the highest number of lumens per watt per angstrom. It has the additional attractive feature that it is capable of being pulsed to fit any desired pulse pattern.

Table I. Comparison of data for sodium flame

	Na flame	Xe arc, Lamp 1	Xe arc, Lamp 2
Power consumption (watts)	4,200	2,200	5,000
Luminous flux (lumens)	600,000	66,000	200,000
Intensity (candles)	50,000	5,300*	21,500
Efficiency (lumens/watt)	140	30	40

* Calculated from manufacturer's data using formula in Eq. [2].

Practical Considerations

No matter how efficient a lamp, it is not suitable for practical applications if it requires auxiliary gas tanks or a vacuum arrangement. We have therefore started work on simulating a flame by a completely self-contained system. The resonating cavity and the plasma enclosure are also in the process of being redesigned to provide more efficient coupling and to permit eliminating the tuning mechanisms.

Manuscript received July 8, 1964. This paper was presented at the Toronto Meeting, May 4-7, 1964.

Any discussion of this paper will appear in Discussion Section to be published in the December 1965 JOURNAL.

On the Luminescent Properties of the Rare Earth Vanadates

L. H. Brixner and E. Abramson

Pigments Department and Central Research Department, respectively, E. I. du Pont de Nemours and Company, Inc., Wilmington, Delaware

ABSTRACT

X-ray examination of several Ln_2O_3/V_2O_5 systems indicated that compounds of the $LnVO_4$ type are the only ones formed by the rare earth sesquioxides and vanadium pentoxide. On the basis of this finding, we developed a flux-growing technique employing a V_2O_5 melt for the preparation of all rare earth vanadates in single crystalline form. With such monocrystals as well as with polycrystalline material we studied the fluorescent emission of the rare earth vanadates, and these data are reported and discussed.

The fact that YVO_4 crystallizes in the D_{4h}^{19}-I4/amd space group of zircon ($ZrSiO_4$) was first recognized by Broch (1), and since the ion radius of Y^{3+} is generally placed between Dy^{3+} and Ho^{3+} it was to be expected that at least some of the rare earth vanadates would crystallize in the same structure. Milligan, Watt, Rachford, and Vernon (2, 3) prepared all rare earth vanadates of the $LnVO_4$ type and found that with the exception of $LaVO_4$ they do indeed all crystallize in the $ZrSiO_4$ structure. Gambino and Guare (4) later con-

firmed these structures. Carron *et al.* (5) found that $LaVO_4$ has the monazite structure, which recently was confirmed by Schwarz (6) who conducted a comparative crystallographic study of all rare earth phosphates, arsenates, and vanadates.

The only information concerning the luminescent properties of the rare earth vanadates is given by Van Uitert (7) who investigated the $Y_{1-x}Eu_xVO_4$ system during a study on the role of f-orbital electron wave function mixing in the concentration quenching of Eu^{3+}. He used a $NaVO_3$ flux for the preparation of rare earth vanadates, but did not state anything about the size or quality of the obtained crystals. It still appeared desirable to look at the luminescent properties of all rare earth vanadates, particularly since the considerable thermal stability could make them excellent candidate materials for host lattices for optical maser materials if they can be grown in single crystal form by flame-fusion, Verneuil, or some other appropriate technique.

Experimental

All rare earth vanadates were prepared directly from high-purity V_2O_5 (obtained from the Vanadium Corporation of America), and the corresponding rare earth sesquioxides were obtained in 99.9% purity from the Lindsay Chemical Division of the American Potash and Chemical Corporation. Reaction was generally effected in two steps: first the stoichiometrically mixed powders of —200 mesh particle size were prereacted at 680°C (just below the melting point of V_2O_5) for some 10-14 hr. This reaction product was then ballmilled in a mechanical agate ballmill under acetone, dried, pressed into a 1-in. diameter pellet, and fired in a second step for some 10-14 hr at 1200°C. After this treatment, completely reacted, homogeneous materials were obtained, which failed to show any of the lines of the components upon x-ray examination. Weight losses for approximately 10g charges were generally below 0.1%. $CeVO_4$ and $PrVO_4$ were prepared under an inert atmosphere to avoid the possibility of oxidation of the trivalent rare earths to a higher valence state. Tb^{3+} in $TbVO_4$, which also forms higher oxides, did not show any tendency to oxidize and could be handled in air.

Small single crystals of all rare earth vanadates can be obtained from a V_2O_5 flux at 1000°C by simply charging a small quantity of any rare earth oxide (except Ce, Pr) into the V_2O_5 melt and letting it react for about 10-14 hr. Although crystals obtained in this fashion are rather small (up to 1 mm in cross section) they are of fair optical quality as an inspection under the microscope and in polarized light indicated. The major portion of the excess melt can be poured off while the remaining small quantity of V_2O_5 can be leached away with ammonia. Specifically for the systems Y_2O_3/V_2O_5 and Gd_2O_3/V_2O_5, we demonstrated that the $LnVO_4$ compound is the only existing phase by preparing eight different compositions of $Ln_2O_3:V_2O_5$ varying from 4:1 to 1:4. In each case, the $LnVO_4$ compound was the only new phase in addition to the excess component. Larger single crystals up to 1 cm long can be obtained by establishing a small temperature gradient in the flux and using a platinum wire seed, immersed about ¼ in. into the melt, as a "cold finger." Figures 1 and 2 show some single crystals of YVO_4 and $GdVO_4$, grown without seed in the above described way. Figure 3 gives a typical crystal cluster as obtained with the Pt seed.

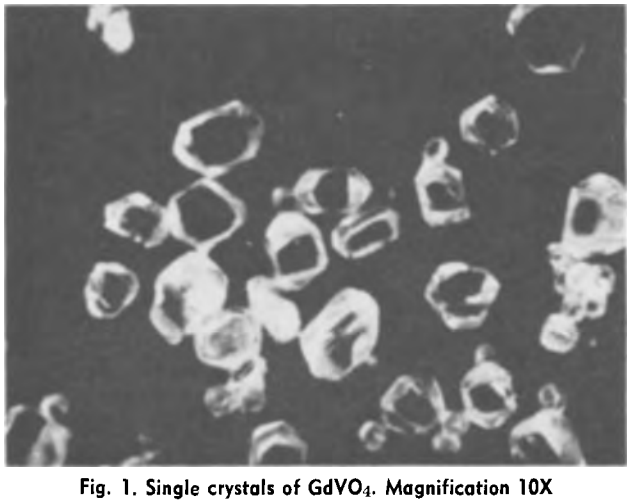

Fig. 1. Single crystals of $GdVO_4$. Magnification 10X

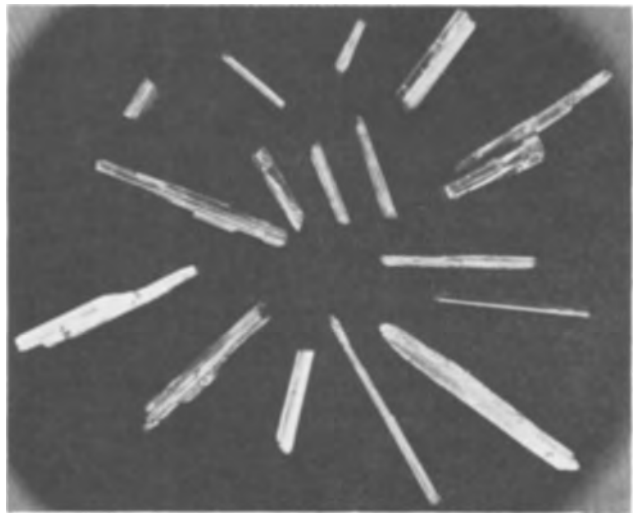

Fig. 2. Single crystals of YVO_4. Magnification approximately 7X

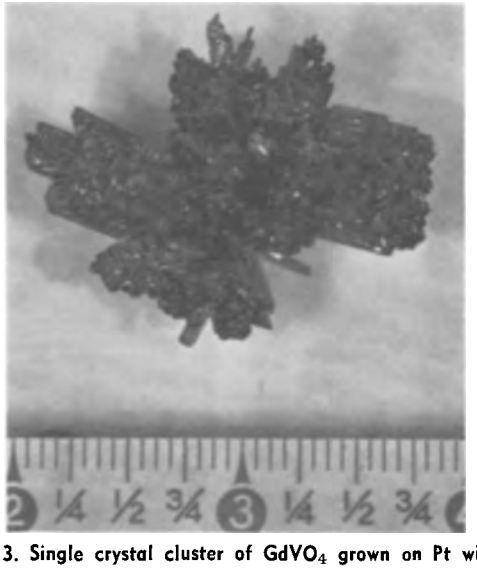

Fig. 3. Single crystal cluster of $GdVO_4$ grown on Pt wire

X-ray powder diffraction patterns were taken with a Philips 114.6 mm diameter camera at 25°C. The samples were sealed in 0.2 mm diameter Lindemann glass capillaries and were exposed to the K_α radiation of copper ($\lambda = 1.5418$Å) for 2-6 hr. Accurate parameters were obtained by extrapolation according to Nelson (8). Lattice dimensions and space groups of single crystals were determined by the rotating-crystal technique.

Crystallographic and Luminescent Properties

The measured lattice parameters are summarized in Table I, the asterisk denoting values obtained from single crystals. These parameters are in good agreement with those reported by Schwarz (*loc. cit.*)

Fluorescent emission in the visible region was first observed qualitatively under excitation by a 2537Å or

3660Å u.v. mineral light. Coarse quantitative fluorescent scans were made with a Beckman DK2 recording spectrometer with a mercury and phosphor lamp F4T5/BL (General Electric Company designation) through a Schott UG-11 filter which cuts off above 4000Å. Thus, excitation was between 3000 and 4000Å. The detector used was a photomultiplier tube 1P28 (Radio Corporation of America). These observations are also summarized in Table I.

More refined spectra were taken with samples excited by a filtered AH-3 mercury discharge lamp (primarily 3660Å radiation) with a Leeds and Northrup 0.5 meter Ebert mount grating spectrometer using again a 1P28 photomultiplier detector. Representative spectra of YVO_4 and $GdVO_4$ are shown in Fig. 4 and 5, and the characteristic fluorescent wavelengths of all the compounds so examined are summarized in Table II. The numbers in parentheses on the spectra give the relative intensity of the lines after correction for the spectral response of the detector.

The excitation spectrum (fluorescence intensity as a function of exciting wavelength) of $GdVO_4$, shown in Fig. 6, indicates that the principal excitation of this material occurred in a strong band whose half-maximum points are at 2500 and 3250Å. Since Gd^{3+} does not have strong, broad absorption bands in this wavelength region, the excitation of fluorescence must involve the VO_4^{3-} complex. This same absorption band must exist in all of the rare earth vanadates and be responsible for the major portion of their excitation.

Reference to Fig. 4 and 5 and to Table II shows that a number of the observed fluorescence multiplets, namely those centered about 4800, 5250, 5550, and 5750Å, are common to many of the compounds which emitted visible light. These multiplets may be due to the presence of rare earth impurities. In particular, the emission at 4800 and 5750Å could be ascribed to Dy^{3+} and that at 5450Å to Tb^{3+}. Although the two remaining multiplets at 5250 and 5550Å do not closely match known fluorescent transitions in any of the trivalent rare earth ions, it is possible that they are due, respectively, to Pr^{3+} and Er^{3+} impurities. That the muliplets may be inherent to the vanadate compound cannot, however, be completely ruled out except by the investigation of compounds prepared with controlled dopings of trivalent rare earth ions. This has been done only in the case of Eu^{3+} as an impurity.

Although Tm^{3+} has energy levels at a separation corresponding to 4750Å, the 4f-4f transitions of trivalent rare earth ions are not known to occur in other than relatively sharp line multiplets. Hence, the broad band generally observed at 4750Å probably arises from

a "molecular" transition, and is further discussed later on. Some of the compounds also exhibit very bright, sharp line (a few angstroms wide) emission at 5950 and 6175Å. These lines are suspiciously close to the positions of the $^5D_0 \rightarrow {}^7F_1$ and $^5D_0 \rightarrow {}^7F_2$ transitions of Eu^{3+} in $Eu/LaCl_3$ (9), and hence we strongly suspected that in our case they are due to small amounts of Eu^{3+} contamination. This suspicion was further supported by the recently published fluorescent emission spectrum of $Eu_2(WO_4)_3$ (10), which is very similar to our $GdVO_4$ spectrum. The 5380Å line in our $GdVO_4$ spectrum is near the position of the $^5D_1 \rightarrow {}^7F_1$ transition of Eu^{3+}. Careful analysis by optical emission and x-ray spectroscopy confirmed the suspicion by establishing the presence of 0.06% Eu_2O_3 in Gd_2O_3. This analysis was in good agreement with the certified data later on supplied by the American Potash and Chemical Company, who gave 0.053% Eu_2O_3 in Gd_2O_3. The fact that Eu^{3+} did enter $GdVO_4$ via the flux growing technique indicated that the segregation coefficients of Eu_2O_3 and Gd_2O_3 are not different enough to effect purification during the growth of crystals. Eu^{3+} contamination of the other rare-earth sesquioxides was not investigated, but is presumably present to some extent.

In view of the observations regarding europium contamiantion, and because of the sharpness of these Eu^{3+} lines, we studied the system $Gd_xEu_{1-x}VO_4$ in more detail to establish the optimum fluorescent emission as a function of x. We prepared samples by the previously outlined technique with x varying from 0.002 to 0.2. A typical high resolution spectrum of $Eu/GdVO_4$ is reproduced in Fig. 7. Note that while the 5380, 5950, and 6175Å emission is still strong, the remainder of the lines have been quenched. The fluorescence emission intensity as a function of x is plotted in Fig. 8. This rather typical curve shows an increase of intensity with concentration at low concentrations followed by a maximum at $x = 0.08$, and then a gradual dropping off (concentration quenching) toward higher concentrations. While the characteristic shape of such

curves is almost always identical even for such widely differing systems as $CaMoO_4$:Dy (11), $CaWO_4$:Tb (11), βAl_2O_3:Mn (12), $CaWO_4$:Eu (13), Mg-Li-tungstate:Mn (14), the optimum of the activator concentration varies over considerable ranges. In some of our own studies (15), we could show specifically for Eu^{3+} that the maximum emission can occur at as little as 0.5 mole % Eu^{3+} in $CaMoO_4$ for instance or at as high as 40 mole % in $GdPO_4$. Other examples for optimum Eu^{3+} activator concentrations are given by Borchardt (16) with 40 mole % in $Gd_2(WO_4)_3$ or 10 mole % in Y_2WO_6.

Discussion

Some of the rare earth vanadates described in this paper constitute interesting luminescing materials, which might find use in general fluorescent applications, such as fluorescent lamps or high-pressure mercury vapor lamps. Since the fluorescence did not quench up to 300°C, the latter applications, which require temperature stable phosphors, could be of especial interest. A most intriguing application would, of course, be as a solid state optical maser, particularly in the case of Eu^{3+} in $GdVO_4$. Preliminary melt experiments, however, indicated that if congruent melting occurs at all the melting point is above 1700°C. We could not obtain a melt in a 60% Pt-40% Rh crucible, which generally is quite suitable for the melting of $CaWO_4$ (mp 1630°C). Attempts to melt vanadates in iridium crucibles indicated that $GdVO_4$ can be homogeneously melted at approximately 1750°C at which temperature Ir metal evaporates at a rapid rate. This strongly suggests that some flame fusion process is necessary for the preparation of single-crystal $GdVO_4$ boules. Another problem which will have to be anticipated is the loss of oxygen from Eu_2O_3 which commonly occurs even in a $CaWO_4$ melt, turning crystals deep red, due to the presence of Eu^{2+}. Other parameters such as quantum efficiencies, fluorescent lifetime, excitation and absorption spectra, will also have to be determined before a complete evaluation of the $Eu_xGd_{1-x}VO_4$ system is possible as a laser material. The strong line at 6192Å would be the most likely one for laser emission.

In the case of YVO_4, the fluorescence is associated with either impurities or the VO_4^{3-} anion. The most intense fluorescence here is at 5750Å in a multiplet with a total width of 50Å. More interesting, however, is the wide multiplet near 4800Å. If these lines could be sufficiently pumped, there is the possibility that one might obtain laser action with a minimum transfer of heat energy to the lattice.

As a general speculation for the mechanism of fluorescence in the rare-earth vanadates, we postulate a mechanism similar to that invoked by Borchardt (17) for the rare-earth tungstates and 1:1 oxytungstates: ultraviolet energy is absorbed either by the VO_4^{3-}

anionic group of the material or by a "charge transfer" transition involving the rare earth ion and a neighboring oxygen. With the present data, no choice between these two possibilities can be made. Excitation is then transferred predominantly to the lowest energy fluorescent levels, from which emission occurs. If the fluorescent energy levels of the principal rare-earth ion lie lower than those of the vanadate ion, most of the excitation energy is transferred to the rare-earth ion, which then emits its characteristic spectrum provided that concentration quenching is not too severe. $EuVO_4$ is an example of this process. If rare-earth ions with levels lower than those of the principal rare earth ion are present as dilute impurities in a host of the YVO_4 type, only a portion of the energy will be transferred to the lowest energy level as exemplified by the $Eu_xGd_{1-x}VO_4$ series. The broad fluorescence band generally evident at 4750Å may be due to a Stokes-shifted transition from the absorbing level to the ground state. The relative intensity of such a band would depend on the ratio between its transition probability and the probability of energy transfer to rare earth ions.

Acknowledgment

The authors would like to thank Dr. G. Teufer of the Engineering Research Laboratory for obtaining single crystal data and Mr. A. T. Weinmann for his assistance in obtaining powder data. We are also grateful to Messrs. L. S. Brooks and J. S. Ariganello for running the fluorescent emission spectra and to Mr. F. Y. Tse for taking the excitation spectra.

Manuscript received July 8, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

Chemical and Optical Studies of Samarium Doped CaF_2 Type Single Crystals

P. F. Weller, J. D. Axe*, and G. D. Pettit

Thomas J. Watson Research Center, International Business Machines Corporation, Yorktown Heights, New York

ABSTRACT

Single crystals of CaF_2 and $Ca_{1-x}Sr_xF_2$ were grown by the Czochralski technique and doped with varying concentrations of samarium. Complete solid solution was found in the CaF_2-SrF_2 pseudobinary system with a minimum near 50% CaF_2 at 1330° ± 10°C. The concentration of Sm^{+2} depended on the melt concentrations of SmF_3 and Sm metal, and the samarium segregation coefficient did not change significantly with samarium concentration. The fluorescence efficiency of Sm^{+2} as a function of Sm^{+2} concentration appeared to go to a broad maximum at about 0.1% Sm^{+2}. The fluorescent emission in $Ca_{1-x}Sr_xF_2$: Sm^{+2} showed pronounced inhomogeneous line broadening.

The discovery of a CaF_2:Sm^{+2} laser (1) stimulated interest in the CaF_2-Sm system. In order to optimize laser efficiency, it seemed necessary to obtain more perfect crystals with better control of the doping levels, oxidation state ratios, and homogeneity. We have used the Czochralski technique to grow samarium doped CaF_2 and $Ca_{1-x}Sr_xF_2$ crystals (2). Crystal perfection has been indicated by the number of imperfections appearing as voids and growth "streamers," the number of dislocations, and the amount of light scattering that occurred in the crystals. Oxidation state variations were achieved by varying the amount of reducing agent, samarium metal, added to the sample charge. Doping homogeneity was improved considerably by a samarium segregation coefficient near unity which was essentially concentration independent over the range studied. However, crystal growth parameters such as the ratios of crystal diameter to crucible diameter and melt surface to melt volume did affect Sm^{+2} homogeneity considerably. Optimum Sm^{+2} doping levels for maximum fluorescence efficiency were indicated by studying the efficiency as a function of Sm^{+2} concentration. The strong effect of certain impurities on the Sm^{+2} fluorescence was shown by the severe line broadening in the $Ca_{1-x}Sr_xF_2$:Sm^{+2} fluorescence experiments.

* This research has been supported in part by the Army Research Office, Durham, North Carolina.

Crystal Growth

Starting materials.—CaF_2 was obtained from the Harshaw Chemical Company as random cut chips (highest quality). SrF_2 was prepared synthetically using a flux method (3).

$$SrCl_2 + 2KF \rightarrow SrF_2 + 2KCl \qquad [1]$$

The SrF_2 was then carefully fired in flowing HF gas at about 1300°C for several hours or crystallized using a Bridgman-Stockbarger technique with a PbF_2 oxygen "scavenger" added (4).

Samarium trifluoride and metal were obtained from the Lindsay Division of American Potash and Chemical Company. SmF_3 was HF fired at about 1200°C, and the samarium metal was H_2 fired at about 1000°C.

Growth procedure.—The crystals were grown in an apparatus described previously (5). Graphite, platinum, and molybdenum crucibles were used with molybdenum being most satisfactory. A graphite sus-

ceptor, inductively heated, held the crucibles. The dry, nitrogen atmosphere was either flowing at 1-2 liter/min or static at a pressure slightly greater than 1 atm.

Crystals were nucleated on single crystal seeds or on a platinum wire and pulled at speeds ranging between ½ and 4 in./hr with rotation speeds of around 60 rpm. Generally, the crystals were 1 to 4 in. long, ⅛ to ½ in. in diameter, and grew with random orientation around the [110] and [111] directions when not nucleated on an oriented seed. No cracking of any of the crystals was observed (6), regardless of size or of the Ca/Sr ratio, even though they were cooled to room temperature in 1 to 2 hr.

Crystal Perfection

CaF_2:Sm^{+2}.—*Light scattering.*—Experiments similar to those of Kaiser and Keck (7) showed that in the best CaF_2:Sm crystals less than 1% Tyndall scattering was observed; while in the worst, about 30% of the incident light was scattered by a crystal ½ cm long.

Imperfections.—Voids and gaseous inclusions were generally formed when the crystal diameter was changing rapidly and the growth speed was 2 in./hr or more.

Growth streamers, white, feather-like webbings that run along the growth direction angling out from the center, were present quite often, regardless of pull conditions. They were eliminated only when oxides were not present in the starting materials and H_2O was not present during growth.

Examination with a light microscope equipped with two nicol prisms detected no macroscopic strains in the grown crystals.

Dislocations were observed by etching the crystals with a warm, 20% HCl solution for 10 to 30 sec (8). Generally, between 10^5 and 10^6 triangular pits/cm^2 were observed. This same, randomly distributed, pit density was found for doped and undoped crystals and for Bridgman-grown crystals obtained from Harshaw, Optovac, and our own laboratory. No correlations could be made between growth conditions and pit counts.

Mixed crystals.—$Ca_{1-x}Sr_xF_2$ crystals were grown with x = 0.05, 0.1, 0.3, 0.5, 0.7, and 0.9. The crystals were 1 to 2 in. long and about ¼ in. in diameter. In all cases complete solid solution was found with no detectable segregation either radially or longitudinally along the crystal, as shown by x-ray diffraction powder patterns. These x-ray data, the sample compositions, and the melting points of the various mixtures determined during crystal growth yielded a tentative CaF_2-SrF_2 pseudobinary phase diagram with a minimum near 50% CaF_2 at 1330° ± 10°C, as shown in Fig. 1. Sm^{+2} fluorescence in this mixed system is discussed below.

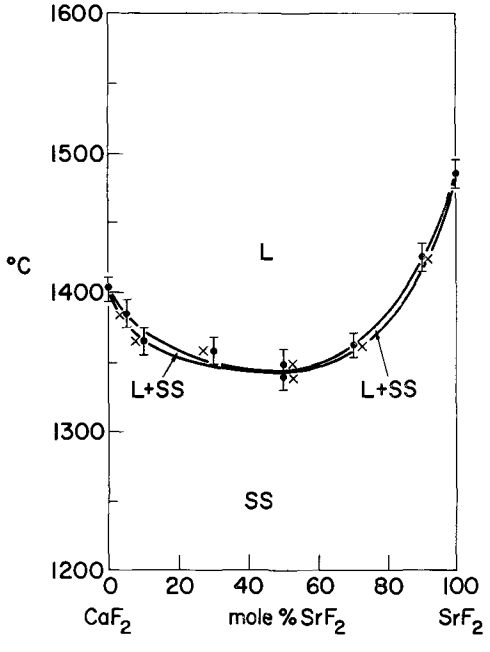

Fig. 1. Tentative phase diagram for CaF_2-SrF_2 solid solutions. •, Sample composition melting points; x, first solid to freeze.

Crystal Doping

Sm^{+2}/Sm^{+3} *ratios.*—Generally samarium was added to the sample charge as SmF_3 or SmF_3 and Sm in varying ratios. It was found that the concentration of Sm^{+2} obtained was a function of the amounts of SmF_3 and Sm present in the melt, as can be seen from Table I. The situation is complicated by the fact that Sm^{+2} is also produced when SmF_3 is present alone, as is shown in Table I. This indicates two methods for producing Sm^{+2}. The most obvious ones are

$$2SmF_3 + Sm \rightarrow 3SmF_2 \quad [2]$$

and

$$2SmF_3 \rightarrow 2SmF_2 + F_2 \quad [3]$$

The data in Table I, however, indicate a strong dependence of Sm^{+2} concentration on the amount of samarium metal added and a much weaker dependence on the amount of SmF_3. This is contrary to what the above equilibria predict, i.e., the concentration of Sm^{+2}, $[Sm^{+2}]$, should depend on $[SmF_3]^{2/3}$ and $[Sm]^{1/3}$ (assuming complete solution of the samarium metal). It seems, then, that either equilibrium has not been attained and Sm^{+2} production is kinetically controlled or that the equilibria involved are more complex and, for example, involve direct oxidation of the samarium metal by very small amounts of O_2 in the growth atmosphere. In any event, Eq. [2] and [3] above do not describe the situation satisfactorily.

Divalent samarium production can also, of course, be affected by impurities in the starting materials. As seen in Table I only about 0.002% Sm^{+2} is obtained when CaF_2 is doped with 0.1% SmF_3. This small amount of Sm^{+2} can be completely oxidized by impurities such as Eu^{+3} and Cd^{+2} according to the following equations

$$Sm^{+2} + Eu^{+3} \rightarrow Sm^{+3} + Eu^{+2} \quad [4]$$

and

$$2Sm^{+2} + Cd^{+2} \rightarrow 2Sm^{+3} + Cd \quad [5]$$

We have grown CaF_2 crystals containing no detectable Sm^{+2} by adding 0.01% EuF_3 or 0.01% CdF_2 to the sample charge along with 0.1% SmF_3. Eu^{+2} is easily observed so that the impurity can be noticed immediately in the case of europium contamination. With CdF_2, however, detection is difficult. Since many other chemical impurities can undergo similar reactions, the purity of the starting materials is quite critical in obtaining reproducible Sm^{+2} concentrations.

Doping homogeneity.—Variations of samarium concentration along the length of a crystal caused by

Table I. Sm^{+2} production as affected by varying Sm^{+3}/Sm ratios added to sample charge

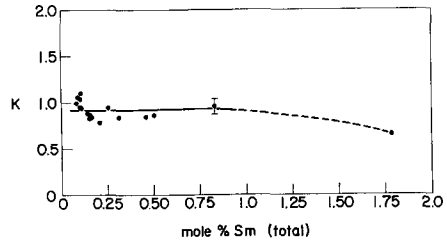

Fig. 2. Samarium segregation coefficient, $K = C_S/C_l$, as a function of total samarium concentration. The dotted portion of the curve is tentative. The approximate error is given only at the 0.83 mole % point for the sake of clarity.

segregation were not large since the segregation coefficient was about 0.90, and essentially independent of concentration as is shown in Fig. 2. The decrease in K between 1.0 and 1.8 mole % Sm is questionable since the x-ray fluorescence measurements are suspect in the high concentration region.

Divalent samarium concentrations, however, increased by as much as a factor of 3 from crystal top to bottom (2 to 3 in.) unless growth procedures were carefully controlled. The largest effects were caused by crystal diameter differences, with larger diameters giving more Sm^{+2}, and crystallization of a large portion of the melt. The latter effect can be seen for experiment No. 47 in Table I. In this experiment the crystal size was similar to that in No. 20, 21, 23, and 37, but the melt volume was about twice as great. The explanation for these observations is not obvious. The Sm^{+2} gradients are not caused by segregation ($K = 0.9$) nor does reoxidation to Sm^{+3} of the hot, growing boule seem appropriate since radial Sm^{+3} gradients were undetected except for the very outermost "skin" of the crystal. The most critical parameter appears to be the amount of samarium reaching the melt surface since increased crystal diameters increase stirring and a decrease in melt volume increases the melt surface to volume ratio. Variations of Sm^{+2} concentration can be kept to a minimum by using seeds to obtain relatively small and constant crystal diameters and by pulling small crystals from large melts.

Optical Properties

Absorption coefficients.—The absorption coefficients for Sm^{+2} and Sm^{+3} were obtained in the following way. A CaF_2:Sm single crystal was cut into three sections, the first 1 mm thick, the second 1 cm thick, the third 1 mm thick. Absorption spectra were run at 77°K on the thin slices for Sm^{+2} and for Sm^{+3} on the thick section (9), which was then carefully fired in flowing HF gas at 1200°C to oxidize all of the Sm^{+2}. The Sm^{+3} absorption spectrum was then rerun and the sample analyzed for total samarium content by x-ray fluorescence. Selected absorption coefficients for Sm^{+2} and Sm^{+3} are given in Table II. These values are smaller, by about a factor of five, than those reported by Kaiser, Garrett, and Wood (10) at 4°K. The greater portion of the discrepancy must be attributed to the determination of the Sm^{+2} concentration. We estimate that our error was ±10%.

Table II. Selected absorption coefficients for Sm^{+2} and Sm^{+3} at 77°K

Species	Wavelength (A)	$\alpha = \frac{1}{t}\log_{10}\frac{I_o}{I}$ (cm^{-1})	Concentration (mole %)
Sm^{+2}	6,905	9.0	0.12
	6,363	64	
	5,083	7.2	
	4,468	30	
	4,251	58	
Sm^{+3}	12,130	0.52	0.27
	12,260	0.37	
	12,373	0.37	

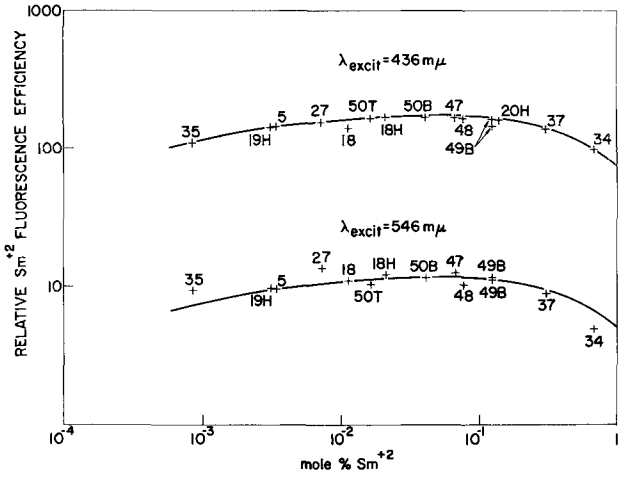

Fig. 3. Relative Sm^{+2} fluorescence efficiency vs. Sm^{+2} concentration at 77°K. The difference in fluorescence efficiency between the two excitation wavelengths is only approximate. The very similar concentration dependence of the two sets of points is shown by the identical curves drawn through them.

Fluorescence.—Some studies were made at 77°K of the relative fluorescence efficiency of Sm^{+2}, particularly as a function of Sm^{+2} concentration. For this purpose polished sections of crystals with previously determined absorption were excited by green (λ = 546 mμ) and blue (λ = 436 mμ) light from a high pressure Hg discharge which was rendered nearly monochromatic by a small grating monochromator. The resulting red emission was isolated by suitable filters and a fraction, g, detected with a photomultiplier. The relative emission intensity per absorbed photon, $g\ I(\text{incident})\left[\frac{I(\text{emitted})}{I(\text{absorbed})}\right]$, is shown in Fig. 3 for two incident wavelengths. The efficiencies at the two wavelengths have not been corrected for the wavelength dependence of I(incident). The decreasing efficiency at high concentration is a common characteristic of many fluorescence systems. The decreasing efficiency at the very low concentrations was an unexpected feature. One tentative explanation is that there are a small number of energetically favored Sm^{+2} sites in which the ions fluoresce either poorly or not at all, and that these sites become saturated at relatively low concentrations.

We have found no detectable influence of Sm^{+3} on the Sm^{+2} fluorescence efficiency although the Sm^{+2}/Sm^{+3} ratio in the samples investigated varied between 0.01 and 1.0. No attempt was made to determine an absolute quantum efficiency. Kaiser, Garrett, and Wood (10) indicate that under similar conditions the quantum efficiency is close to unity for Sm^{+2} doping of about 0.01 mole %.

Mixed crystals.—It is now well established (11) that the initial level of the Sm^{+2} fluorescence transition in CaF_2 is of the $4f^55d$ configuration whereas in SrF_2 the initial level is the $^5D_0$ state of the $4f^6$ configuration. Wood and Kaiser (11) have noted that the addition of small amounts of SrF_2 to CaF_2:Sm^{+2} has a strong influence on the Sm^{+2} emission. We thought it to be of some interest to investigate the Sm^{+2} fluorescence behavior over the entire range of compositions $Ca_{1-x}Sr_xF_2$. The emission characteristics of representative samples are shown in Fig. 4. For the purpose of this figure the integrated emission intensities of the various samples were approximately normalized. However, the fluorescence efficiency falls off noticeably with dilution at either extreme, the

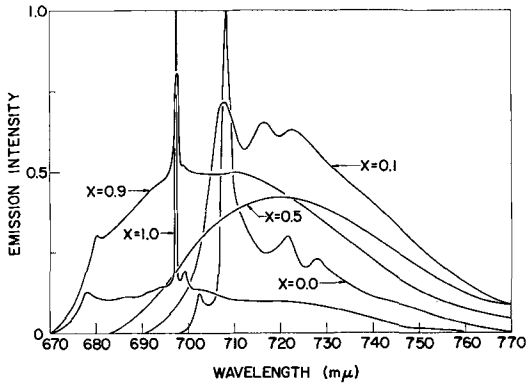

Fig. 4. Spectral emission characteristics of Sm^{+2} in $Ca_{1-x}Sr_xF_2$ at 77°K.

equimolar mixture being less efficient by more than one order of magnitude. The pronounced broadening of the emission bands must certainly be associated with the superposition of spectra of ions in nonequivalent environments. It appears, however, that no simple explanation based on a small number of possible near neighbor arrangements can account for the semicontinuous nature of the emission of the equimolar mixture. Obviously there seems to be little hope of "tuning" the frequency of the Sm^{+2} laser by continuous variation of the lattice composition.

Conclusions

1. CaF_2 type crystals of high optical quality can be grown easily and quickly using the Czochralski technique. Crystals with little or no light scattering can be obtained by eliminating O_2 and H_2O from the growth atmosphere and oxide impurities from the starting materials.

2. Divalent samarium concentrations are affected not only by oxygen containing impurities, but by other easily reduced impurities such as CdF_2 and EuF_3.

3. Varying Sm^{+2}/Sm^{+3} ratios can be obtained by using different amounts of SmF_3 and reducing agent, Sm. Sm^{+2} concentrations are more strongly dependent on the Sm metal than on the SmF_3 concentration. This seems to indicate that Sm^{+2} formation is more complicated than is shown in Eq. [2] and [3].

4. Although the samarium segregation coefficient in CaF_2 is 0.9, Sm^{+2} concentration variations can be caused by varying crystal diameters and melt volumes.

5. Absorption coefficients for Sm^{+2} and Sm^{+3} were determined at 77°K, and selected values are listed in Table II.

6. The fluorescence efficiency of Sm^{+2} as a function of Sm^{+2} concentration appears to go through a broad maximum at about 0.1% Sm^{+2}.

7. The fluorescent emission in $Ca_{1-x}Sr_xF_2:Sm^{+2}$ shows pronounced inhomogeneous line broadening.

8. The CaF_2-SrF_2 pseudobinary system showed solid solutions over the entire composition range. A tentative phase diagram was determined with a minimum near 50% CaF_2 at 1330° ± 10°C.

The Preparation of High-Purity Rhenium Single Crystals

R. R. Soden, G. F. Brennert, and E. Buehler

Bell Telephone Laboratories, Inc., Murray Hill, New Jersey

ABSTRACT

Rhenium single crystals have been prepared by electron beam float zone melting with resistance ratios (R273°K/R4.2°K) exceeding 30,000. In one crystal a ratio in excess of 55,000 was obtained. It appears that purification occurs both by selective vaporization and zone refining.

Very high purity metal single crystals are necessary for the experimental determination of their intrinsic electronic properties. Zone refining techniques have made it possible to obtain a number of metals with the required purities and as a result, significant advances have been made in the understanding of their electronic structure. Electron beam floating zone refining is particularly useful for the purification and growth of refractory metal crystals. Crucible contamination is eliminated, the zone length is readily controlled, and the high vacuum, which is required for the electron beam, enhances the volatilization of impurities.

Ideally, one would like the impurities in a source material to have distribution coefficients favorable for zone refining or partial vapor pressures which will allow them to be removed by selective vaporization. Hence, the specific impurities present in the original material will specify the ease and rate of purification. Even if these ideal conditions exist, care must be taken before and during zone refining to keep contamination from outside sources to a minimum. This care includes the reduction of contamination by backstreaming oil vapor from the diffusion pump orifice in the vacuum station and contact by the molten zone or hot crystal to the electron gun mechanism. The technique used to preform a rod suitable for zone refining is also very important and has become quite evident in the present work on high purity rhenium.

Several investigators have prepared rhenium, single crystals by electron beam zone refining (1-5). The purest rhenium crystals grown previously, as determined by resistance ratio measurements (6), were by Hauser and Buehler (7) and by Sell (8) of Westinghouse Electric Corporation. Resistance ratios of 4000

and 6000 were obtained, respectively, by these workers. We have prepared Re single crystals by electron beam floating zone melting with resistance ratios exceeding 30,000 and in one crystal, a ratio in excess of 55,000 was obtained. A discussion of this work is presented in this paper.

Floating Zone Melting Apparatus

The vacuum floating zone melting apparatus was previously described (9). However, for this work, the rf coil was replaced by an electron gun which consists of a circular 0.0115-in. diameter thoriated tungsten filament and molybdenum focusing plates on the top and bottom. A mechanically driven variac control similar to that described by Schadler (10) was used to control the emission current.

The kinetics of purification by vaporization are often dependent on the ultimate vacuum attainable, especially in cases where solute partial pressures are significantly greater than the partial pressure of the solvent. Thus, a series of liquid nitrogen cooled traps was installed in the station to enhance the vacuum and to cut down back-diffusion of oil vapor from the diffusion pump orifice. These consisted of a baffle plate covering the diffusion pump orifice and a large coil extending up into the station. A vacuum of 2 to 8 x 10^{-6} mm of Hg was thus readily maintained during zone refining.

Material Preparation, Zone Melting, and Crystal Growth

High purity rhenium powder was obtained from the Johnson-Matthey Company. Spectroscopic analysis reveals this powder to contain less than one hundred parts per million total metallic impurities (Table I). The powder was received after the supplier's final purification step. No further manipulation was performed on the powder to produce, for example, a specific particle size.

A preformed rod of this powder was obtained by pressing it at approximately 30,000 psi in a ¼ by ¼ by 3-in. hardened split steel die. To the best of our knowledge, no contamination with Fe occurs during this operation. Since the compact is extremely fragile, it is carefully placed on a water cooled silver boat and sintered at approximately 1900°C by rf heating in a purified argon atmosphere (11). The temperature is increased during sintering in approximately 200°C steps every 10 min and held at 1900°C for 15 min. Multicolored deposits of mixed oxides of rhenium are formed on the quartz tube between 400° and 1500°C. The density of the sintered compact is ≅11 g/cc.

This technique for preforming the rod for floating zone melting has the following advantages:

1. Handling of the material is kept under laboratory control and hence no unnecessary contamination is introduced.
2. The preheat-treatment under argon reduces the problems associated with sputtering during zone melting due to adsorbed gases in the powder. The porous compact provides a large surface area for vaporization of oxide impurities.
3. High purity powder can be used as it comes from the final purification step of the supplier. Since the compact will be float zone melted into a single crystal, the only necessary prerequisite for the powder is that some form of rod can be prepared for suspension in the apparatus. Particular particle sizes are not required and a precise density is not necessary after the heat treatment.

* The transition region is that portion of the zone melted rod between the "tail" end and unmelted portion.

The sintered compact is suspended in the vacuum station from a quartz hook by notching the rhenium bar and attaching a loop of five mil rhenium wire. The bottom of the compact is allowed to make contact to a rhenium rod (in most cases, a single crystal seed) held by an adjustable chuck. Focusing plates with large openings (~⅝-in. diameter) are used on the electron gun in order to accommodate the ¼-in. square bar. After an initial minimum 2-hr pump down, two fast passes, one up and one down, are made at temperatures of approximately 2000°C and just below the melting point of rhenium (3150°C) at 3000°C, to outgas the rod and to heat up the station and thus outgas the parts inside the bell jar. The tip of the bar is then melted into the seed. For the samples denoted as R (random seed orientation) in Table II, the gun was moved one-half inch up the sintered bar (after welding to the seed) before zone melting. The melting of the sintered bar is done progressively, since the molten metal which forms on the edges is drawn into the sintered compact by surface tension. This results in instability of the molten zone and, consequently, there is danger of losing the zone. Two or three passes are thus necessary to completely melt through the sintered rod. The emission current is controlled manually through these periods. New focusing plates (with openings of usually 1.4 times the rod diameter) are then placed on the gun and zone melting is started after evacuating the system. The molten zone travel rates employed are one, and one and one-half mils per second. No difference in the purification rate was noted for either travel speed. With the liquid nitrogen traps in operation, a vacuum of between 2 to 8 x 10^{-6} mm of Hg is maintained during zone melting and crystal growth. A typical sintered compact and a zone melted rhenium single crystal are shown in Fig. 1.

Resistance Ratio Measurements

We have used measurements of the residual resistance or resistance ratios ($R_{298°K}/R_{4.2°K}$) to determine

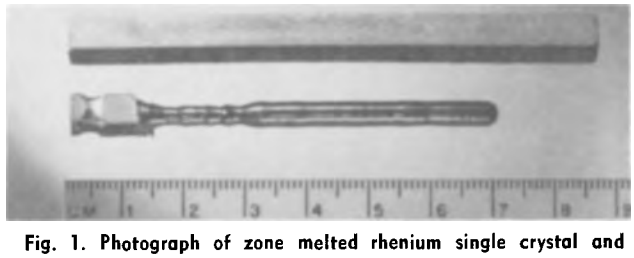

Fig. 1. Photograph of zone melted rhenium single crystal and sintered rhenium bar.

the extent of purification because standard analytical techniques are not adequate in determining the purity of very high purity metals. The resistance ratio technique and apparatus were described by Kunzler and Wernick (6). Each zone melted rod was prepared for measurement by ultrasonically soldering copper leads with an indium alloy solder at desired intervals along the sample axis. The specimens were then mounted on a phenolic holder assembly. Potentials were measured at room temperature and 4.2°K with a Beckman model 14 breaker amplifier, Leeds Northrup Wenner potentiometer and recorder. A constant d-c current source of 0.01 amp was employed for the room temperature meaurements, while 4.0 or 10.0 amp, depending on the size and purity of the sample, was used at 4.2°K. Our resistance ratio results are shown in Table II. Extrapolation of a plot of resistance ratio *vs.* the number of zone passes on sample 56 indicates the resistance ratio of the starting material (Table I) to be approximately 2000.

Discussion

Examination of the resistance ratio data in Table II, particularly the transition region, shows that some purification was accomplished by the movement of impurities, which have distribution coefficients less than one, to the tail end of the rod. Since the resistance ratio of the starting material is approximately 2000, it is apparent that purification by volatilization has also occurred.

The high melting point of rhenium is favorable for the selective vaporization of impurities. This is especially true when the ratio of the product of the partial pressure of the pure solute and its activity in the solvent rhenium to the partial pressure of pure rhenium is significantly greater than unity. Examination of the available vapor presure data for the impurities which were detected (Table I) shows that all except possibly iron and silicon, which are at the 5 to 10 ppm level, should be completely removed by vaporization at the melting point of rhenium if one assumes ideal solution behavior. The partial pressure of the i^{th} component over the solution, P_i, is K_iX_i (as $X_i \rightarrow 0$) where X_i is the mole fraction of the i^{th} component and K_i is the Henry's law constant at low values of X_i. This constant can equal p_i^*, the vapor pressure of pure i at the given temperature if the solvent and solute are similar in behavior; however, K_i usually deviates from p_i^*, although at these low levels of impurity content, the deviation should be very small. In the case of iron, and silicon, the only detected metallic impurities with vapor pressures close to rhenium, a plot of p_i *vs.* X_i at low concentrations as $K_i \rightarrow p_i^*$ shows that selective vaporization of these impurities may occur down to a minimum concentration of approximately 1 to 2 ppm. Even if the slope K_i deviates significantly from the assumed slope p_i^*, these impurities should be removed by selective vaporization to at least the 5 ppm level.

The resistance ratio increases nearly linearly with the number of passes as is evidenced by sample 56. There appears, however, to be an anisotropy effect on the rate of purification. Four samples were prepared of $[11\bar{2}0]$ orientation to work up to an 18,000 ratio seed before the 30,000 ratio on the fifteen-pass area of sample 56 was obtained. This was done because of the low ratio (~4000) of the initial $[11\bar{2}0]$ seed (sample 53). Sample 58 was prepared using an [0001] seed with approximately a 2000 ratio, and was made ostensibly to get a seed of suitably high ratio to grow a high purity crystal in the vicinity of 30,000; however, after fifteen passes, even with the relatively impure seed, 30,000 was obtained. Samples 59 and 60 were grown to prepare a third orientation ($[10\bar{1}0]$) of 30,000 resistance ratio. The rate of purification, however, is even slower than in the case of the $[11\bar{2}0]$ orientation. The ease of purification thus appears to increase with orientation of the crystal axis as $[10\bar{1}0] < [11\bar{2}0] < [0001]$. It is not known at this time whether this orientation effect on purification, as indicated by the resistance ratio data, is related to the anisotropy of the material (different temperature coefficients of resistivities) or is related to the mechanism of crystal growth. The data on sample 61, which was the lead end of sample 59 reoriented with one zone pass from $[11\bar{2}0]$ to [0001], would suggest that the effect is not due to different temperature coefficients of resistivity for the various crystal directions since the resistance ratio was virtually unchanged in this reoriented sample.

The data obtained during the course of this work suggests the need for a continued effort in ascertaining the specific purification parameters. The apparent effect of orientation on the purification needs further study and the role of zone refining also needs more definition since there are indications that impurities with segregation coefficients greater than unity are involved.

Summary

We have shown that extremely high purity rhenium crystals can be prepared consistently with resistence ratios above 30,000. Purification occurs both by selective vaporization and zone refining. The nature of the source material and the manner in which it is handled are important factors in determining the extent of purification.

Indium Antimonide of High Perfection

Sidney G. Parker, Oran W. Wilson, and Bill H. Barbee

Texas Instruments Incorporated, Dallas, Texas

ABSTRACT

InSb having mobilities at liquid nitrogen temperature of approximately 1 x 10^6 cm^2/v-sec with excess carrier concentrations in the $10^{13}/cm^3$ range was produced by extensive purification steps followed by controlled crystal growth. The number of dislocations was less than $500/cm^2$ as revealed by etch techniques.

Efforts have been made (1-4, 6-7, 13) to prepare indium antimonide (InSb) of high purity, but the effects of dislocations on electrical properties such as mobility of carriers have been neglected. Our goal was to prepare high perfection InSb by increasing the chemical purity and decreasing the number of crystalline imperfections. Extensive purification of In and Sb before compounding, followed by zone refining of the InSb, was planned. Further, the InSb was to be zone refined in single crystal form. Single crystals were to be grown by various techniques (2, 5) to study the effects of dislocations on electrical properties.

Source of materials.—Special Research Grade (SRG) In and Sb (99.9999% pure) and material of 99.999% purity were obtained from Consolidated Mining and Smelting Company. All acids and other reagents used for etching, degreasing, and rinsing were "Reagent Grade;" distilled water was used for preparing etch solutions and for rinsing. Pure H_2, the ambient during zone refining, was obtained by diffusion through hot Pd.

Quartz boats, sandblasted to provide a rough inside surface, were used during zone refining. These boats were thoroughly etched with a solution of $HF\text{-}HNO_3$, rinsed with distilled water, and air-dried in a dust free atmosphere. Quartz boats covered with a carbon coating formed by thermal decomposition of toluene or acetone, or graphite boats were used initially. The carbon coating was used to prevent wetting of the quartz; however, it was found that none of the materials (In, Sb, or InSb) would wet quartz if the system were dry. Since the carbon deposit contained traces of impurities, the uncoated quartz boats were preferable.

Compounding of InSb.—During the early phases of the program, InSb ingots were compounded singly from small ingots or pieces of In and Sb. These ingots varied in composition, which made it difficult to evaluate purification procedures, and an apparatus (8) was built to cast up to ten, 250g, InSb ingots from the same melt.

In this apparatus the In and Sb were melted and mixed together under an inert atmosphere, then transferred to quartz boats. The boats were held in a brass holder while being loaded. Chilled water circulating through the boat holder caused the melt to freeze instantly upon striking the chilled boats.

Ingots cast from this apparatus were homogeneous, and uniformity between ingots was achieved.

Purification of In *and* Sb.—An effort was made to improve the InSb by purifying In and Sb before compounding. These elements were distilled and zone refined, but the purities attained were no better than 99.9999%, the purity of the initial starting material in some experiments. Hence, the Special Research Grade materials were used without further purification.

Effects of Zone Refining InSb

Palladium-purified H_2 was used during zone refining because tank H_2 contained impurities that would yield highly compensated material. The H_2 atmosphere in the zone refining system reduced the loss of Sb by evaporation and provided a reducing ambient. Some impurities were probably volatilized from the molten zone, and the H_2 served as a carrier to sweep out these materials. The direction of H_2 flow, whether concurrent or countercurrent to the direction of zone refining, did not affect the purity. No differences were noted in InSb purity for H_2 flows over the range of 300 to 1500 cc/min, although one might expect increased losses of Sb and impurities at the greater flows.

Zone refining InSb at 1 in./hr gave more high purity, n-type material than did zone refining at greater speeds. Table I shows some of the variations in purity as reflected by resistivities, mobilities, and excess carrier concentrations for InSb ingots zone refined at various speeds. Ingots refined more slowly gave material with higher mobilities and less compensation. More efficient purification was also indicated in ingots zone refined slowly by the appearance of p-type regions on the last portion of freeze, because the impurities have more time to mix and establish true equilibrium conditions between the solid and the molten zone. Single crystal growth during zone refining is enhanced by slow zone travel speed. The zone width was about 1 in., and the melt-solid interface was planar.

The optimum zone refining speed for obtaining the highest purity InSb was not determined, and even slower speeds might give still better purification. Purity is a function of zone refining speed, the number of passes, and the crystalline state (polycrystalline *vs.* single crystal). The least number of zone passes at a specified refining speed needed to attain a certain purity could not be calculated because neither all the impurities nor their segregation coefficients were known. The optimum number of zone passes must be found by trial or by determining effective segregation coefficients at various zone refining speeds.

It had been reported (9) that material transfer over the edge of the boat by the last portion to freeze during zone refining aided purification; however, we did not find this true for InSb. With one exception, all ingots in which material was carried from the boat contained mixed regions of p-type and n-type material. Further, the n-type material from these ingots was highly compensated. Constant volume changes during material transfer probably caused the concentration of impurities to vary widely, hence the difficulty in maintaining the system at equilibrium.

* Single crystal regions were used for all measurements, even on polycrystalline material; all samples cut from near the center of the n-type region.
** Crystal orientation taken as normal to length of ingots.

The cropping (9) of a boat 1½ in. from each end of the ingot after 10 or 15 passes, followed by further zone refining, did reduce the total number of passes needed to attain a certain purity level and did improve the yield of high mobility n-type material. Cropping allowed greater purification because impurities which segregate to the ends were removed and did not back-diffuse into the ingot.

Zone refining in single crystal states greatly increased the mobility over that obtained by zone refining in the polycrystalline state, as illustrated in Table II. The material with highest mobility and lowest excess carrier concentration was found in ingots 68 and 69, which had the most passes in the single crystal state. It can readily be seen that greater mobility can be obtained with fewer passes for single crystal zone refining. Zone refining polycrystalline material is less effective for purification because impurities probably segregate at grain boundaries. Experiments with InSb ingots containing radioactive Zn showed that the segregation coefficient for Zn was 1.2 for polycrystalline zone refining but 1.9 for single crystal refining. It was difficult to obtain material with a mobility greater than 500,000 cm²/v-sec at 80°K by polycrystalline refining, even with 100 passes.

Uniformity of Zone Refined Ingots

The ingots produced by zone refining, even in single crystal form, vary in composition over the length of the ingot. The resistivity profile of such an ingot is shown in Fig. 1. This ingot, which was zone refined single crystalline for 30 passes, is rather uniform in resistivity over approximately 4 in. of its length.

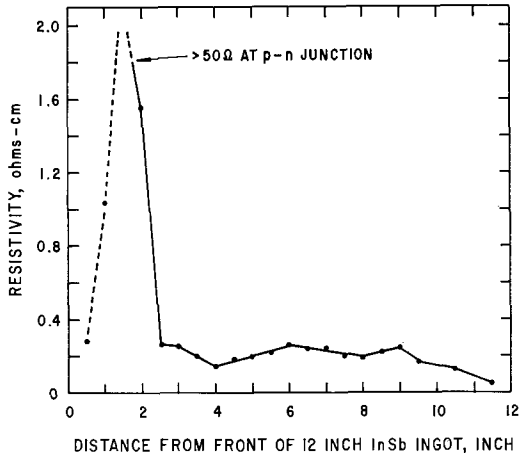

Fig. 1. Resistivity profile of zone refined InSb ingot. Measurements made by 4-point probe at 80°K; — — —, p-type; ———, n-type.

* Total length of ingot was 12 in. Zone refined single crystal in <111> orientation for 30 passes. Measurements made at 80°K on n-type material.

Hall bars were cut from the ingots parallel to the growth face or normal to the length. Electrical measurements on samples taken from a refined ingot are shown in Table III. A wide variation in mobility is noted and indicates the degree of nonuniformity in the n-type material. However, there are regions of considerable uniformity, as shown by the resistivity profile. Samples were usually selected from these uniform resistivity regions.

An unsuccessful effort was made to form homogeneous ingots from high purity, n-type material by zone leveling. For material containing 10^{15}/cm³ excess carriers or more it was possible to obtain homogeneous ingots by zone leveling, but with n-type ingots containing fewer excess carriers, zone leveling produced very nonuniform ingots, as revealed by resistivity profiles. N-type InSb containing 10^{14}/cm³ excess carriers produced areas mixed with n-type material after zone leveling. Small variations in growth conditions and volume greatly influence the distribution of impurities during zone leveling. These subtle variations which arise in crystal growth with a moving molten zone are perhaps more noticeable at the lower carrier concentrations.

Effects of Dislocations on Mobility

The high purity InSb produced by zone refining in single crystal form exhibited rather high mobilities (600,000 to 919,000 cm²/v-sec), but the number of dislocations revealed by etch techniques was in the range of 10^4 to 10^5 per cm². Because it was known that dislocations usually cause decreased mobilities (13), it was thought that the mobilities could be increased still further by decreasing the number of dislocations. Horizontal growth of single crystal ingots in quartz boats gave a minimum of 10^4/cm² dislocations. Obviously, the growth conditions in a boat were not conducive to crystalline perfection.

By taking the n-type regions from the zone refined bars, loading into a vertical type puller, and using the Czochralski technique to grow a single crystal, we were able to reduce the dislocations to less than 500/cm² (Table IV) and in most cases to increase the mobility. With ingot 68 it was found that the mobility increased in the pulled crystal even though the num-

* Zone refined for 30 passes in single crystal form.
** Zone refined in polycrystalline form with single crystal sample taken for measurements.
*** Zone refined in single crystal form, but sample not cut out for analysis until after crystal grown by pulling.

ber of excess carriers increased. This increase in mobility has been attributed to the decrease in the number of dislocations. One pulled crystal gave a mobility of 1,200,000 cm^2/v-sec at 80°K on material which had previously been zone refined in single crystal form for about 40 passes. It appears that zone refining in single crystal form followed by crystal growth in a vertical puller to reduce dislocations produces InSb crystals of greatest perfection. The number of dislocations occurring even in crystals grown with a vertical puller was dependent on the number of dislocations present in the seed crystal. It was necessary to select InSb seed crystals containing a minimum of dislocations.

Discussion

It was not possible to obtain purities much greater than 99.9999% by vacuum distillation and zone refining of In and Sb. Whether continued zone refining or vacuum outgassing would produce In or Sb of greater purity is debatable, for the chance for pickup of impurities from the containers and ambient increases with time. The use of pure H_2 during zone refining was necessary to produce high purity, uncompensated material.

As anticipated, the zone refining conditions of the InSb ingots had a marked effect on chemical purity and electrical properties. The more slowly the zone refiner was run, the greater the purity. With a slow zone travel speed there is adequate time for establishment of equilibrium between the solid and liquid phase; there is also improved mixing. Zone refining in single crystalline rather than in polycrystalline form contributed greatly to improved purity and increased mobility. There also seemed to be preferred growth planes on the single crystal seeds used to initiate growth. Certain crystal faces were able to sustain single crystal growth, while the opposite faces fostered polycrystalline growth. The size of atomic and/or ionic radii of the incoming elements and the bonding energies involved determine the probability of incorporation of atoms into the lattice.

Nonuniformity of ingots over the length of the crystals may be attributed to differences in growth conditions, such as volume of the molten zone and nucleating centers on the boat wall. As one might expect, polycrystalline ingots, because of the tendency for impurities to segregate at grain boundaries, showed less uniformity than single crystal ingots. Crystal dislocations contributed to nonuniformity, since such defects often tend to behave as segregation centers.

Crystal dislocations affected the mobility of InSb, an effect that was also found with such materials as Ge (12). Dislocations may serve not only as scattering centers but also as traps for the carriers and might therefore influence the carrier mobility. Certain types of dislocations seemed to propagate during crystal growth, although the nature of these dislocations was not determined.

Some Properties of GeTe-PbTe Alloys

J. C. Woolley[1] and P. Nikolic[2]

Department of Physics, University of Nottingham, Nottingham, England

ABSTRACT

Solid solution between PbTe and GeTe of stoichiometric composition has been studied. It is found that for samples annealed at 600°C for periods of up to four weeks and then air quenched, single phase condition can be obtained at all alloy compositions, and the lattice shows a continuous transition from cubic to rhombohedral form. Room temperature values of lattice parameter a_0 and rhombohedral angle α, positive hole concentration p and mobility μ and optical energy gap E_g have been determined as a function of composition. The variation in percentage of vacant sites on the germanium sublattice, as determined from p, is correlated with the difference in cell volume for cubic and rhombohedral structures.

Although the properties of PbTe have been well studied in the past, it is only recently that any appreciable work has been carried out on GeTe and SnTe and on the pseudobinary alloy systems derived from the three compounds. The investigation of the properties of GeTe and SnTe has been complicated by the fact that each corresponds to a narrow single phase field in the corresponding metal-tellurium binary diagram; hence the electrical properties may vary considerably with the method of preparation.

In the case of GeTe, it has been shown (1) that the congruently melting alloy has a composition corresponding to $GeTe_{1.025}$. The material with a stoichiometric composition of GeTe is found (2) to have a positive hole concentration of 7.0×10^{20}/cc; if it is assumed that one lattice vacancy on the germanium sublattice produces two positive holes, this indicates the

[1] Present address: Department of Physics, University of Ottawa, Ottawa, Ontario, Canada.

[2] Present address: University of Belgrade, Belgrade, Yugoslavia.

presence of almost 2% vacancies on germanium sites with the corresponding amount of germanium present as a second phase. For PbTe, the range of solid solution of the individual elements in the compound is considerably less. The material of stoichiometric composition PbTe is usually found to be p-type at room temperature but with a considerably smaller carrier concentration of the order 10^{18}/cc (3).

When solid solution between the three compounds is considered, an important factor is that PbTe and SnTe have the cubic rock salt structure while GeTe shows this structure only above 430°C, below this temperature being rhombohedrally distorted. It has been shown that single phase solid solution across the whole range of composition is obtained for PbTe-SnTe (4-6) and for GeTe-SnTe alloys (5, 7, 8), but in the case of GeTe-PbTe alloys Mazelsky *et al.* (5) report only a very limited range of solid solubility of either compound in the other, the limits being temperature dependent.

Mazelsky and Lubell (2, 9) have also considered the solubility in GeTe, PbTe, and SnTe of the cross-substitutionally derived ternaries $TlSbTe_2$ and $TlBiTe_2$, finding a considerable range of solid solution in each case. They have investigated the effects of this solid solution on the carrier concentration and electrical properties of the binary compounds. Rosi *et al.* (10) have made similar investigations of the alloys of GeTe, PbTe, and SnTe with the derived ternary $AgSbTe_2$.

Experimental Procedure

Preparation of alloys.—The GeTe and PbTe were each synthesized separately from the elements which were 99.999% pure, and the alloys were then prepared by melting together appropriate amounts of the two compounds. The resulting ingots were annealed at 600°C until equilibrium at that temperature was obtained; they were then air quenched to room temperature. The necessary annealing time was determined by taking x-ray powder photographs of control samples after various times of annealing, the criterion for equilibrium being that no further change in the x-ray photograph could be observed with continued annealing. X-ray powder photographs of the test samples were then used to determine the variation of lattice parameters with composition.

Physical measurements.—Measurements were made at room temperature of the Hall coefficient and electrical conductivity for various alloy compositions, and also, where possible, infrared transmission measurements were made to determine the optical energy gap. The apparatus and methods used here were the same as described previously for other alloy systems (11).

Results and Discussion

Lattice parameter data.—The variation of lattice parameters with composition is shown in Fig. 1. In contrast to the results of Mazelsky *et al.* (5), single phase solid solution was obtained at all compositions when alloys were annealed at 600°C and then air quenched. However, while an annealing time of one week was sufficient to give good equilibrium conditions in the alloys near the ends of the composition range, alloys near the center of the range had to be annealed for at least four weeks and even then showed some blurring of the high angle x-ray lines. It is seen that there is a continuous transition from the cubic form of PbTe to the rhombohedral form of GeTe. The parameter a_0 varies almost linearly with composition, while the rhombohedral angle α has a value of 90° (*i.e.*, cubic) from 0 to 30 mole % GeTe and then varies continuously to the value of 88° 16′ for GeTe.

The difference from the data of Mazelsky *et al.* can probably be accounted for in terms of difference in treatment of the alloys. Mazelsky *et al.* showed for an alloy $Ge_{0.96}Pb_{0.04}Te$ that while this alloy was two phase at room temperature, at 275°C a single phase rhombohedral structure was observed which transformed to cubic at 390°C. In the present results, prolonged annealing produced a single phase condition in all alloys and this was quenched in at room temperature. Thus, our specimens most likely represent equilibrium conditions at 600°C. It is not clear therefore what is the room temperature equilibrium condition.

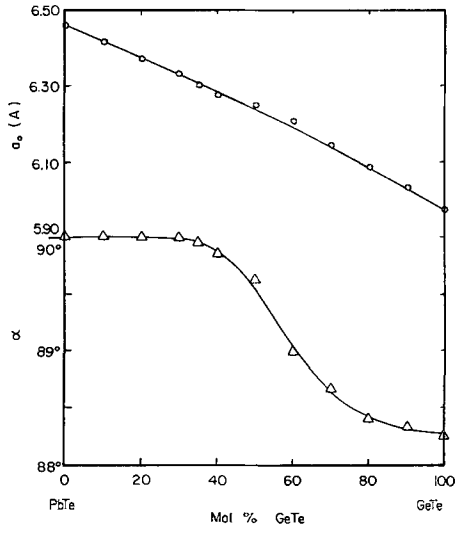

Fig. 1. Variation of room temperature values of rhombohedral lattice parameters a_0 and α as a function of composition.

Electrical data.—Measurements of Hall coefficient R_H showed that all alloys were p-type. The variation of positive hole concentration p $(= 1/eR_H)$ with composition is shown in Fig. 2, in addition to the value of Hall mobility $\mu (= \sigma R_H)$ as a function of composition. These electrical results show an interesting correlation with the crystallographic data in Fig. 1. Thus p remains at a value similar to that for the PbTe used here (*i.e.*, less than 10^{19}/cc) while the structure is cubic. Then it increases rapidly with GeTe content when the structure becomes rhombohedral, reaching a value of 6.5×10^{20}/cc for GeTe itself. This is in good agreement with the results of Mazelsky and Lubell for a material of stoichiometric composition GeTe. Similarly the mobility falls continuously from a value of 600 cm^2/v sec to 60 cm^2/v sec in the range of cubic structure, but then remains reasonably constant over the composition range where the structure is rhombohedral.

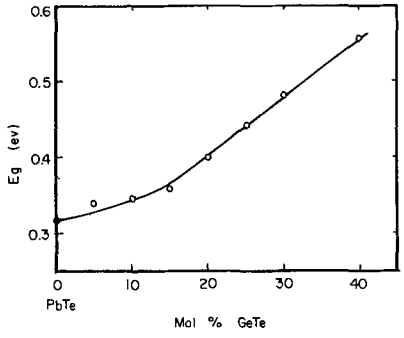

Fig. 4. Variation of room temperature values of optical energy gap E_g as a function of composition.

Consider first the carrier concentration data. It is clear that the increase in p is related to the onset of rhombohedral distortion in the lattice; assuming, as in the case of GeTe, that the positive holes are due to lattice vacancies on the (Pb, Ge) sublattice, this would indicate a correlation between lattice vacancy density and rhombohedral distortion. Since a_o varies almost linearly with GeTe content, the important factor appears to be the variation of the rhombohedral angle α or the corresponding variation in unit cell volume. To represent this volume variation, a parameter $\Delta V/V_c$ has been calculated, where ΔV is the difference between the volume of the rhombohedral cell and the volume V_c of the cubic cell with the same value of a_o. From the value of p, assuming two positive holes per lattice vacancy (2), the ratio of concentration of lattice vacancies to concentration of germanium atoms on the (Pb, Ge) sublattice has been calculated and expressed as percentage germanium sites vacant. The variation of this quantity with $\Delta V/V_c$ is shown in Fig. 3. This graph is linear over a large range of rhombohedral structure, showing deviations only at the onset of rhombohedral behavior and near to GeTe itself. This indicates that the number of lattice vacancies occurring is directly dependent on the volume defect $\Delta V/V_c$.

To check this suggestion, similar parameters can be calculated from the data of Mazelsky and Lubell (2) on the solid solution of Tl(Sb, Bi)Te_2 in GeTe. In this case, there is a range of solid solution of only 8 mole % $TlSbTe_2$ or $TlBiTe_2$ in GeTe, but this causes a rapid change in α toward the cubic condition. Since the positive hole concentration in the ternaries themselves is approximately 2 x 10^{19}/cc, which is small compared with the 7 x 10^{20}/cc for GeTe, again the variation in carrier concentration in the alloys can be attributed to changes in the vacancy concentration on the germanium lattice sites. Points corresponding to this data have been plotted in Fig. 3. Although it is not possible to obtain accurate figures from the published data, it is seen that the results for the Tl(Sb, Bi)Te_2 solid solution are in reasonable agreement with the data presented here.

Turning to the mobility data, this also can be correlated with the presence of lattice vacancies which must be considered effectively as ionized acceptors. Over the range from 0-40 mole % GeTe, the increase in p is small and hence the reduction in μ with increased GeTe content must be attributed to a considerable extent to alloy scattering, *i.e.*, to the introduction of increased disorder on the (Pb, Ge) sublattice. In the absence of any other major scattering effects, such alloy scattering might be expected to give a minimum mobility at approximately the equimolar composition. The mobility would rise again beyond this point as the degree of disorder decreases, *i.e.*, in this range the (Pb, Ge) sublattice is occupied predominantly by germanium atoms. However, although in the range 50-100 mole % GeTe the scattering due to the presence of lead atoms on the germanium sublattice decreases with increased GeTe content, this is compensated by an increase in ionized acceptor scattering. Thus the value of μ does not in fact increase, but remains roughly constant with alloy composition. A very approximate calculation from the values of p and lead content indicates that to obtain this result the scattering cross section of the vacancies must be of the order of 35 times that of lead atoms in the germanium sublattice.

Optical data.—Figure 4 shows the variation of room temperature optical energy gap E_g with alloy composition in the range 0-40 mole % GeTe. For alloys of higher GeTe content it was not possible to determine values of E_g as the absorption of the samples greatly increased with the rapid increase in carrier concentration. Over the range 15-40 mole % GeTe, the value of E_g varies approximately linearly with GeTe content; extrapolation of this line gives a value of 1.0 ev for GeTe itself in reasonable agreement with the expected value for GeTe.

Cadmium Selenide Thin Film Field Effect Transistors

Herbert L. Wilson and William A. Gutierrez

Melpar, Inc., Falls Church, Virginia

ABSTRACT

All thin film, insulated gate, field effect transistors (triodes) have been formed by standard vacuum deposition techniques. Comparison of the electrical parameters of devices formed with CdS, CdSe, or CdTe semiconductor layers indicated certain advantages, namely, higher mobility and better stability, of the CdSe units. Stability and life of CdSe devices was improved by use of aluminum rather than gold for the gate electrode. A preliminary investigation of the use of various materials for use as the dielectric layer indicates many compounds are suitable.

The transverse field effect phenomenon appears to be for amplifying thin film devices the most immediately utilizable of various suggested phenomena. The typical structure consists of two electrodes contacting a semiconductor with a third electrode being separated by a dielectric. Disclosures of field effect devices by Lilienfield (1) in 1930 and of completely thin film, nonjunction devices by Heil (2) in 1935 pointed out with amazing accuracy many device requirements. These early devices, however, never became popular despite the intensive effort to find solid-state amplifying devices in the ensuing years. The prime limitation of the thin film devices was the low sensitivity of the semiconductor to the applied transverse field. Shockley and Pearson's (3) efforts in 1948 to modulate the conductivity of germanium films, together with Bardeen's (4) theory of surface states, indicated that surface states may have a major influence on the field effect in materials. Nevertheless, despite the deleterious effects of surface states, Feldman (5) in 1961 reported thin film devices consisting of germanium semiconductor films and later Wilson, Layton, Gutierrez, and Feldman (6), in 1962 obtained germanium film devices that exhibited useful current and power gains.

The thin film cadmium sulfide devices of Weimer (7, 8) exhibited voltage gains in addition to current and power gains. Useful values of transconductance, voltage amplification, and other electrical characteristics indicated the practical applications of the devices to numerous circuits.

In the present investigation, cadmium selenide and cadmium telluride films have been employed in field effect devices and compared with cadmium sulfide devices. In addition, several metal and dielectric materials have been employed as gate and dielectric layers.

Experimental

The device formation was carried out in vacuum at pressures of 10^{-5} to 10^{-7} mm Hg. The semiconductor films were deposited from undoped semiconductor materials of 99.99+% purity (Harshaw, Light). A graphite crucible (heated by a close fitting tantalum heater) was utilized in the semiconductor evaporations. A quartz-wool filter was used to prevent spattering or loss of material. The insulator and electrode films were deposited from tantalum and tungsten boats, respectively. A relatively pure source material (> 99%) was used for these evaporations.

Drawn, amorphous glass, 25 mm square and approximately 0.5 mm thick, was used as substrates (Corning 0211). These were cleaned by standard ultrasonic procedures. The substrates were then outgassed in vacuum at 350°C for approximately 5 min before the initial deposition.

Standard heating, shuttering, and masking techniques were employed. The source to substrate distance used was about 20 cm.

Figure 1 shows a cross section of a basic thin-film, insulated-gate, field effect triode (transistor). Various film layers are identified and will be referred to in the text of this paper. The film thickness given for the electrodes are typical. The ranges of dielectric and semiconductor thickness are typical for the materials used. These thicknesses were varied to obtain the desired device characteristics. The results of alternate sequences, such as reversal of the layer order, structures involving gate electrodes above and below the semiconductor layer, etc., are not reported here. Five to one hundred such devices were deposited singularly or as "pairs" on a substrate. Figure 2 is a photograph of the top view of sixteen "pairs" of devices deposited with a common source electrode (CS) for each pair. A source-drain electrode spacing of 12μ was used ex-

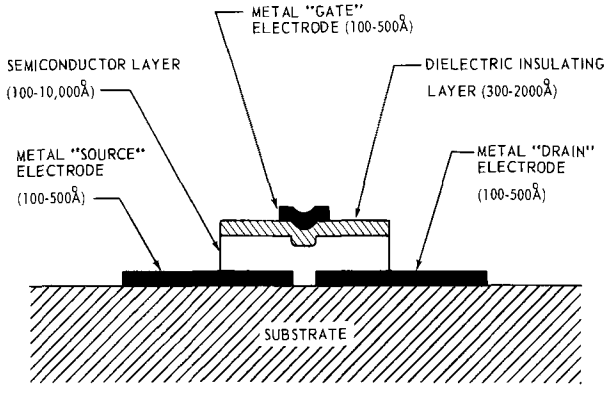

Fig. 1. Cross-sectional view of a thin film field effect triode

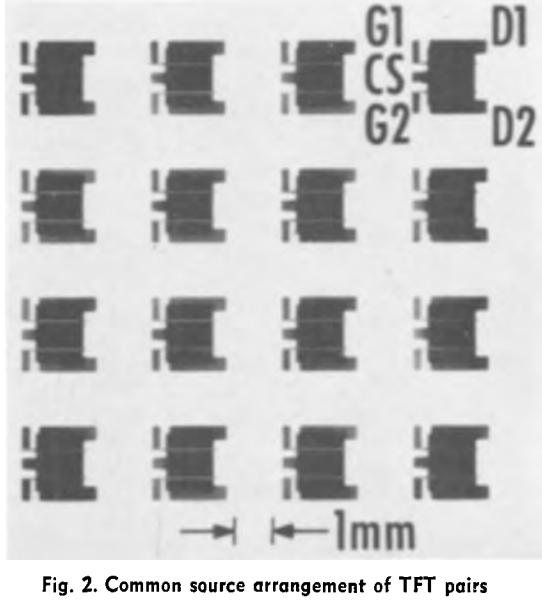

Fig. 2. Common source arrangement of TFT pairs

clusively. The width (gate electrode length) ranged from 1 to 5 mm.

The semiconductor films were deposited at a rate of approximately 10,000 Å/min. It appeared as though a rapid deposition of the semiconductor layer (all other parameters held constant) generally resulted in films of lower resistivity. This is believed due to either a more congruent evaporation of the elements or to a lesser reaction with oxygen during the formation of the film. Depending on the method used, a rapid deposition rate seemed preferable in obtaining field sensitive films. This may be due to the reasons mentioned above. The ability to make rapid depositions was achieved by the use of relatively large charges (up to 5g) dispersed in a shallow manner over the bottom of a large crucible. This appeared preferable to fast deposits by excessive heating in which considerable dissociation of smaller charges in smaller crucibles took place. A crucible temperature of about 900°C was used to evaporate the semiconductor material.

The semiconductor films were deposited over the previously deposited source-drain electrodes. Samples for Hall effect measurements and material analysis were generally of another configuration. No attempts were made to form single crystal layers. Dielectric film deposition ranged from 200 Å/min for Dy_2O_3 to 4000 Å/min for SiO. Rates were restricted somewhat by the relative ease of evaporation of the material used. The dielectric deposition was initiated at a substrate temperature of 25°C (room temperature). Due to source radiation it was noted that increases in substrate temperatures to 100°C occurred during the deposition of the higher temperature dielectrics. It appeared that a rapid deposition of oxide dielectrics was preferable in obtaining a decrease in the semiconductor film resistivity. This phenomena is discussed later in this paper. Metallic electrode depositions were made at rates of approximately 2000 Å/min.

Etched molybdenum or electroformed nickel masks were used to form the different film configurations. To achieve a high resolution fine gap between source and drain electrodes, tungsten wires (12μ in diameter) were spot welded to the basic masks. The device characteristics shown in this paper are photographs taken from a Tektronic, type 570, characteristic curve tracer. Values of μ, g_m, and r_D are readily calculated from these display curves.

The life and reliability tests on the devices were conducted by either observing their performance in an astable multivibrator circuit or by observing the change in their display characteristics with time on the curve tracer. These were continuous operation tests.

Results and Discussion

In the device fabrication, it was found that source-drain electrodes of gold were easily damaged in handling or mask movement. Therefore, several other materials, including platinum, indium, nichrome, chromium, nickel, copper, and aluminum, were investigated. Nichrome, chromium, and nickel formed hard films when deposited at a substrate temperature greater than 200°C and were not as subject to damage as were electrodes formed from the other materials. For various reasons not gone into here, nichrome was used extensively for source-drain electrodes. Any further heating of these nichrome electrodes such as the outgassing cycle shown in Fig. 6 required good vacuum of less than 10^{-5} mm Hg to prevent harmful surface oxidation.

In general SiO was used as the dielectric layer. Other dielectrics were investigated and compared with SiO. Thus far films formed from such oxides as SiO_2, La_2O_3, Yb_2O_3, Nd_2O_3, and Dy_2O_3 were found suitable for device use. Another oxide B_2O_3 was found very suitable for devices in that excellent high dielectric breakdown characteristics were obtained ($> 2 \times 10^6$ v/cm). This high breakdown strength was noted despite the fact that the evaporation was made from direct contact to a tantalum boat. Owing to the hydroscopic nature of B_2O_3 however, this film was utilized either sandwiched between or as a mixture with other dielectrics mentioned. The use of fluoride dielectrics such as AlF_3 and MgF_2 in addition to CaF_2 (9) were also successfully utilized. It appears that any material possessing reasonable dielectric properties in thin film form may be used unless, of course, it is destructively reactive in the atmosphere or with other contacting layers.

It was observed that different dielectric layers may influence the electrical properties of the semiconductor layer. The substrate temperature during deposition of the dielectric was also found to be a contributory factor. In addition, the manner in which the semiconductor layer was formed also determined the influence of the dielectric layer on its properties.

It was found that large drops of semiconductor resistivity ($> 100/1$) with the application of an overlying SiO dielectric layer (substrate held near room temperature and without previous air baking) assured that the semiconductor layer would exhibit high sensitivity to field effect. If no drop in resistivity was noted, the eventual device formed exhibited either poor sensitivity (transconductance) or required appreciable positive bias for good sensitivity. Other similarly formed semiconductor layers (*i.e.*, formed in the same run as those used with SiO dielectrics) exhibited similar response to the other oxide dielectrics listed. Fluoride dielectrics tested appeared less influential on the semiconductor layer resistivity. Use of either a sulfide (ZnS) or selenium as the dielectric layer usually resulted in an increase of the semiconductor resistivity. This latter experiment appears to coincide somewhat with the findings of Shallcross (10) in experiments involving use of selenium vapor on CdSe films. Devices utilizing ZnS or Se dielectric layers exhibited poor sensitivity characteristics.

At first, gold was used for the gate electrode. Life tests conducted on devices (to be discussed later) indicated, however, that use of another material would be preferable. Use of some materials, such as nichrome and nickel, created undesirable stresses in the underlying dielectric layer, and the resultant devices frequently exhibited gate area film peeling and/or a low dielectric-breakdown voltage. Devices with aluminum gate electrodes have thus far exhibited superior stability and reliability.

Of the three semiconductors studied, devices using CdTe were the most difficult to fabricate. The CdTe films generally exhibited resistivities which were too high for device applications. There was no apparent relation between film resistivity and film appearance. CdTe films were black and reflective, regardless of wide ranges of deposition rate and substrate temperature. In some cases crystal growth was observed.

Three techniques were used in forming lower resistivity CdTe films. The films were either heavily doped with cadmium or rapidly deposited on substrates cooled below room temperature, or baked in atmosphere. Doping with Cd was the most successful method although reproducibility was very difficult to achieve.

The CdTe films which exhibited field effect response were deposited at a substrate temperature of about 200°C. These films were doped by adding cadmium (about 1% by weight) to the high-purity CdTe source. After deposition, these films were annealed at 300°C in vacuum or at 500°C in air for approximately 5 min. At these anneal temperatures, crystal growth was observed, as shown in Fig. 3. These crystals often cause weak spots in the overlying dielectric layer. The films were usually deposited to a thickness of 5000Å. Figure 4 shows the I-V characteristics of a CdTe device. Saturation of drain current required voltages beyond the breakdown strength of the dielectric layer. The elec-

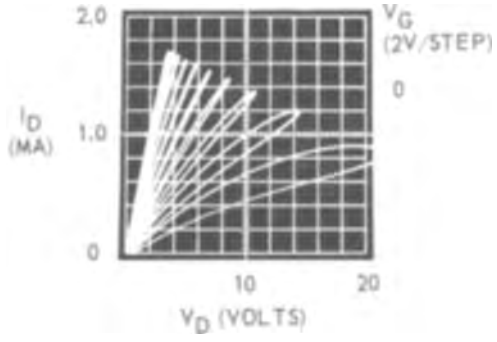

Fig. 4. Drain current *vs.* drain voltage characteristics of a CdTe device; $r_D \sim 16.7$ kohm; $g_m \sim 150$ μmhos; $\mu \sim 2.5$; $C_{in} \sim 100$ pf; $R_{in} > 50$ mohm; GB ~ 250 kc.

trical characteristics exhibited a rather unusual hysteresis effect. It was not uncommon to observe similar effects in CdS and CdSe devices. It appears that this hysteresis phenomena is associated principally with interelectrode RC time constants. Heating effects, surface states, and polarization are other possible causes.

CdTe devices generally exhibited low transconductances (g_m) of about 150 micro-mhos, amplification factors (μ) of about 5, and gain bandwidth products of about 200 kc. Most of the devices operated preferably in the enhancement mode (7).

The resistivity of a vacuum-deposited CdS film was generally related to its color. A dark brown or black film indicated a relatively low resistivity (<0.05 ohm-cm). Low resistivity films were formed by depositing at a substrate temperature of less than 50°C. Fast depositions also resulted in lower resistivity films. Such films were found to contain excess cadmium.

An orange-colored CdS film was usually of medium resistivity (0.5 to 500 ohm-cm). These films were formed by annealing dark films as described above by raising the temperature above 100°C for a time which is dependent on the anneal temperature. Another method was to deposit at a substrate temperature of about 70°-200°C.

The resistivity of yellow CdS films was usually high (> 5000 ohm-cm). These films were formed either by annealing the orange films for a longer time or by depositing at substrate temperatures above 200°C. Such films were found to contain excess sulfur.

The relation between color and resistivity for vacuum deposited CdS films was a general observation and no consideration has been given to the degree of crystallization or phase composition of the films.

The best CdS films for device use were obtained by depositing dark films (3000-6000Å thick) and annealing them in a vacuum at a temperature of about 200°C. The films were usually annealed until they appeared similar in color to the source material before evaporation. The Hall mobilities of these films were usually below 5 cm²/volt sec.

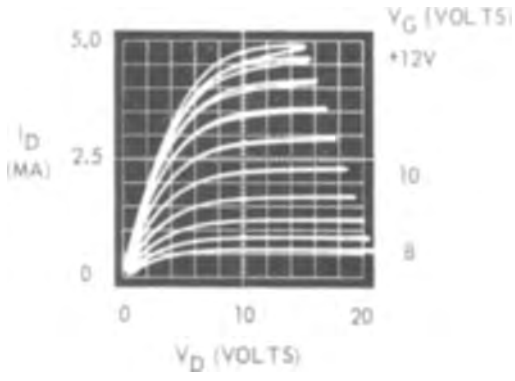

Fig. 5. Characteristics of a CdS field effect device operating in the enhancement mode; $r_D \sim 200$ kohms; $g_m \sim 1000$ μmhos; $\mu \sim 200$; $C_{in} \sim 100$ pf; $R_{in} > 100$ mohms; GB ~ 1.6 MC.

Figure 5 is a photograph of the I-V characteristics of a CdS device. The device parameters did not exhibit the quality of performance reported by Weimer (7). Perhaps this is due in part to the relative dielectric thickness utilized and the ability to form more sensitive CdS layers in atmospheric heat treatments (not utilized here). The device of Fig. 5 measured 2.5 mm width with 12μ spacing between source drain contacts. The CdS and SiO layers were approximately 5000 and 1500Å, respectively. Most of the CdS devices operated preferably in the enhancement mode. Transconductances (g_m) values up to 1500 micromhos, amplification factors (μ) greater than 200, and gain bandwidth products greater than 1 Mc were measured.

The color of a CdSe film did not strongly indicate its relative resistivity. The films were usually brown. In general, however, the lighter colored films were lower in resistivity, higher in mobility, and probably had a higher cadmium content than darker films of comparable thickness. The CdSe films had Hall mobilities ranging up to 50 cm²/volt sec. On the average, mobility values for CdSe were 5-10 times that of CdS films.

CdSe films were deposited to a thickness of up to 10,000Å at a substrate temperature of about 80°C. Postdeposition treatment consisted of three basic annealing procedures (the annealing procedure as used here includes the dielectric deposition). In the first procedure, the films were annealed in vacuum at a temperature of about 250°C for 2 to 3 min. After this part of the annealing, an increase in film resistivity (to a value above the pre-anneal value) was observed as the film cooled. This increase in resistivity is attributed to the absorption of oxygen (regardless of the vacuum utilized) as discussed by Bube (11) and by Somorjai (12). After allowing the film to cool in vacuum to about 50°C, the dielectric layer was then deposited. A significant drop in the resistivity of the CdSe film was noted upon the deposition of the SiO dielectric. Drops in resistivity of about a hundredfold were not uncommon. This phenomena as discussed later is not yet fully understood. Figure 8 shows the typical I-V characteristics of a CdSe device annealed in this manner.

The second type of annealing procedure was similar to that of the first except that a break in vacuum was made before the dielectric layer was deposited. An increase in resistivity was observed when the film was exposed to air. This was attributed to oxygen absorption. The film was then returned to the vacuum chamber and the dielectric deposited on it. Resistivity drops of a thousandfold were observed. This greater drop in resistivity was attributed to the relative exposure to atmospheric oxygen before the dielectric deposition. Figure 6 is a graph (second method) of substrate tem-

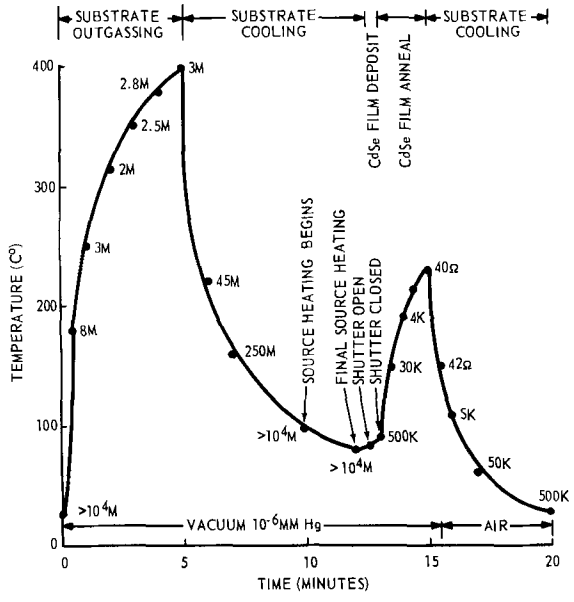

Fig. 6. Typical temperature and source-drain resistance values monitored in substrate outgassing and formation of a CdSe film.

perature *vs.* time during the substrate outgassing cycle, CdSe film deposition, CdSe film anneal, and withdrawal from vacuum. Values of resistance existing between source and drain electrodes (1/200 square) were monitored and are also shown on this graph.

At room temperature (25°C) the resistance between the source and drain electrodes is greater than 10,000 megohms. Upon heating via infrared quartz lamps the resistance decreased rapidly to 2 megohms at 315°C. This is explained by the thermal effect on the conductivity of the substrate (0.5 mm glass). A rise in resistance to 3 megohms was observed as the temperature further rose to 400°C. This appeared to be due to the desired removal of surface impurities, etc. With the outgas cycle completed the substrate is allowed to cool to the vicinity of 80°C (T = 12 min). At this temperature, the resistance between the source and drain electrodes is again greater than 10,000 megohms. At this point, the source containing the CdSe was elevated to 900°C. (Previously heated to 600°C from T = 10 min to T = 12 min). An additional time of 30 sec was allowed for the source to attain a temperature in the vicinity of 900°C. At this time (T = 12.5 min) the previously shuttered CdSe vapor is allowed to deposit on the substrate. After a 30-sec deposition, the substrate is again shuttered and the source heat turned off. The resistance of the deposited film was 500 kohms at this point. An anneal cycle was immediately initiated for 2 min (T = 15 min) during which the substrate attained a temperature of 230°C and the film resistance dropped to 40 ohms (at least half of this resistance is believed to be electrode resistance). Retention of the substrate in vacuum for 30 sec and cooling to 150°C resulted in only a very slight rise in film resistance (42 ohms). Removal of the substrate from vacuum and cooling to the vicinity of room temperature caused an increase in resistance of the film to 500 kohms.

Not shown on the graph, but of extreme importance, was the drop in resistance noted on the CdSe film upon deposition of the overlying dielectric layer. In this case the CdSe film resistance dropped to 3 kohms and remained at this value throughout device formation. The I-V characteristics of devices annealed in this manner are shown in Fig. 5, 7, 9, and 10.

With these first two methods of anneal, it was found that annealing at too high a temperature or for too long a time resulted in poor devices. It was also found that if the annealing was at too high a temperature or for too long a time, the resistivity of the semiconductor did not change appreciably when the dielectric was deposited. Such devices generally exhibited small values of transconductances or operated best in the enhancement mode ($V_G > +6v$). If the anneal was too low in temperature or for too short a time, the resultant device showed small values of amplification factor and large pinch-off voltages. These devices operated best in the depletion mode.

The third method of anneal was similar to the second method. However, it involved not only a break in vacuum, but also a further anneal in atmosphere before the deposition of the dielectric. The anneal in atmosphere was performed in an oven for 3 to 5 min at a temperature of 500°C. The heating in atmosphere reduced the resistivity of the film (100/1). The film was then placed in the vacuum chamber and the dielectric deposited on it. A decrease in resistivity of about tenfold was noted on application of the dielectric. The films annealed in this manner generally resulted in devices with unusually large hysteresis loops in their characteristic curves, short operational lifetimes, and comparably low dielectric breakdown voltages. In the formation of sensitive device structures it was noted that in each of the three methods of semiconductor formation discussed application of an overlying oxide dielectric caused a significant decrease in the semiconductor resistivity. This phenomena was noted for CdS and CdTe as well as for CdSe films. For devices operating in or near depletion mode it appears that this phenomena is a critical final activation phase of the semiconductor layer. Analysis of this phenomenon suggests either one or both of two physical changes in the semiconductor film structure is responsible.

It has been noted in previous reports by Bube (11) and Somorjai (12) and in the investigation of this paper that the increase in the resistivity of CdSe films on exposure to atmosphere is attributed to absorption of oxygen. It therefore appears reasonable that a drop in resistivity of the CdSe film on the dielectric deposition might be attributed in turn to the desorption of the oxygen either by bombardment of dielectric molecules or by chemical absorption of this oxygen by the dielectric layer. However, several questions are as yet not satisfied by this theory, *i.e.*, pertaining to the resistivity drop. The theory of oxygen desorption in the investigations carried out in this paper indicates chemical absorption of the oxygen atoms lying on the semiconductor surface by the dielectric layer. This is supported by the fact that thus far the greatest drops in resistivity of CdSe films have been noted when oxide dielectrics have been used. However, several reservations on this theory have continued to appear. One such reservation is the fact that CdSe films deposited to thicknesses of greater than 1μ and formed in the same manner as films of less thickness have more often shown little change in resistivity on dielectric deposition. This cannot be attributed to the film thickness due to the relative magnitudes of resistivity involved. In addition, thinner films formed with only slightly longer anneal cycles and with initial resistivities of less than one order of magnitude larger have also shown little influence by the dielectric film on their resistivity. These irregularities suggest that another theory might be justified. It is known that both the semiconductor layer and dielectric layer are under stress (revealed by occasional substrate breakage by the individual films involved). It is therefore possible that stress (known to influence semiconduction) produced in the semiconductor layer by the dielectric layer is possibly responsible for at least part of the resistivity drop. From many observations of electrical behavior change on the deposition of the dielectric layer this later theory of change of film stress appears reasonable. For instance it is somewhat more reasonable that some CdSe films do or do not change resistivity on dielectric application due to relative stress conditions within the films in-

volved rather than explanation of oxygen desorption. Conclusive evidence as to the exact phenomenon may be difficult to distinguish since stress itself may be the creation of oxygen exchange between layers.

Figure 7 shows the Id *vs.* Vd characteristics of a CdSe device utilizing a Dy_2O_3 dielectric. This device measured 1.5 mm in width with 12μ source-drain spacing. The CdSe and Dy_2O_3 layer thickness measured approximately 6000 and 700Å, respectively. These characteristics indicate as do those of Shallcross (13) that CdSe devices are comparable in performance to CdS units (7, 8, 14).

It has been reported that improvement in device pinch off characteristics could be obtained by use of a glow discharge cleaning of the substrate (15). This technique has not been utilized in the formation of devices reported in this paper. Initial experiments at this facility, however, tend to confirm the value of a proper glow discharge (16) cleaning in this respect.

Figure 8 illustrates the device characteristics of a CdSe unit utilizing very thin layers. This particular device had a semiconductor thickness of less than 400Å and an SiO_2 dielectric which was about 400Å. The over-all device thickness (4 layers) was less than 1000Å. This device illustrates the use of very thin layers and was almost completely photoinsensitive. The photosensitivity of the devices was highly dependent on the thickness of the semiconductor and on its annealing cycle. The thinner films which were annealed for a longer time in vacuum were found to be the more photoinsensitive. Preliminary tests have shown that the thinner, more photoinsensitive films were also more resistant to radiation effects. It is found, however, that better reproducibility of device parameters was achieved if a semiconductor thickness of about 8000Å was used.

Figure 9 shows a CdSe device which can be made to operate with high transconductance in either the depletion or the enhancement mode. This device measured 5 mm in width with 12μ spacing. It appeared that in forming CdS, CdSe, or CdTe devices by the methods used that it was easier to form CdSe units exhibiting the ability to operate either in the enhancement or depletion mode. Depletion mode CdSe units were fabricated by forming thicker CdSe films, reducing the CdSe anneal, and use of an oxide dielectric. In addition, use of thinner dielectrics (higher field intensity) reduced any bias requirement.

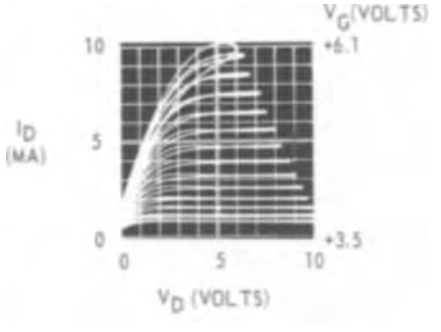

Fig. 7. Characteristic Id *vs.* Vd curves for a CdSe unit operating in the enhancement mode; $r_D \sim$ 100K; $g_m \sim$ 5000 μmhos; $\mu >$ 500; $C_{in} \sim$ 50 pf; $R_{in} >$ 500 mohms; GB $\sim$ 16 MC.

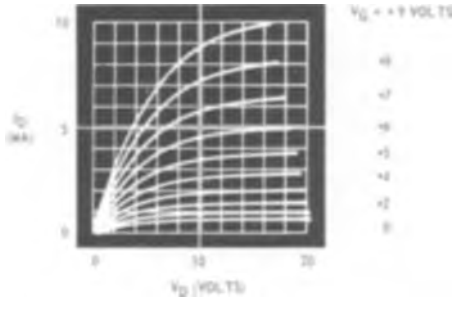

Fig. 8. Id *vs.* Vd characteristics of a very thin TFT structure; $r_D \sim$ 100 kohms; $g_m \sim$ 1000 μmhos; $\mu \sim$ 100; $C_{in} \sim$ 100 pf; $R_{in} >$ 100 mohms; GB $\sim$ 2 MC.

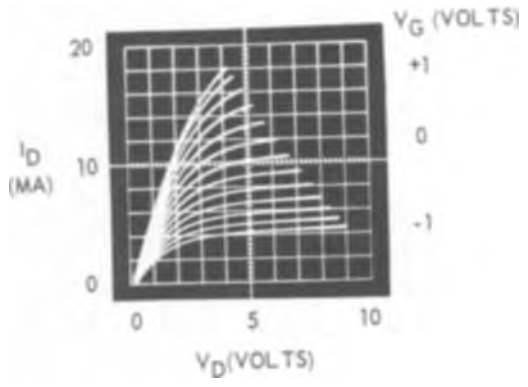

Fig. 9. Characteristics of a CdSe unit of relatively large transconductance operating in both enhancement and depletion mode; $r_D \sim$ 7 kohms; $g_m \sim$ 8000 μmhos; $\mu \sim$ 56; $C_{in} \sim$ 150 pf; $R_{in} >$ 100 mohms; GB $\sim$ 8.5 MC.

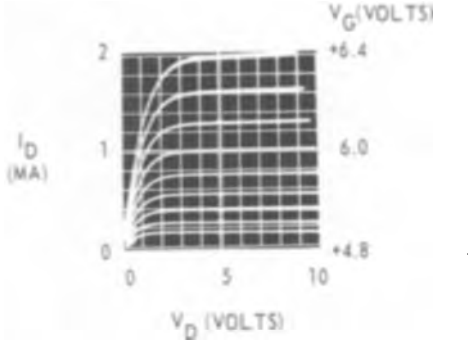

Fig. 10. Device characteristics of a CdSe unit utilizing a B_2O_3-SiO dielectric; $r_D =$ 250 Kohms; $g_m =$ 2000 μmhos; $\mu =$ 500; $C_{in} \sim$ 50 pf; $R_{in} >$ 100 megohms; GB $\sim$ 6.4 MC.

Special devices exhibiting large transconductance values in excess of 20,000 micromhos were formed utilizing a CdSe semiconductor layer. This was accomplished by either paralleling smaller devices, use of thinner dielectrics, decrease in source-drain spacing, harder driving of the device (increase drain and gate voltages), or combination of the above. As can be appreciated this improvement in transconductance was accompanied by various other degradations in device characteristics not gone into here.

The ability to fabricate devices of similar characteristics during the same deposition run was found to be primarily a problem of uneven heating of the substrates. It appeared that a slight variation of temperatures existing in areas of deposition caused variations in the semiconductor film properties.

Reproducibility from deposition to deposition was found dependent on the similarity of deposition parameters as expected. The most difficult parameter to control was that of the added influence of the graphite crucible in the semiconductor deposition. It appeared that oxidation or contamination of the graphite by one of the elements of the compound would affect the semiconductor films in differing amounts in succeeding

Figure 10 illustrates the more typical parameters obtained from 1.5 mm wide devices (12μ source-drain spacing). Although this device did not exhibit ultra-high transconductance, etc., it exhibited reasonably good characteristics coupled with good stability and life. This device utilizes a CdSe layer of approximately 5000Å thickness with a SiO and B_2O_3 dielectric of a total thickness of approximately 1000Å (approximately 500Å each).

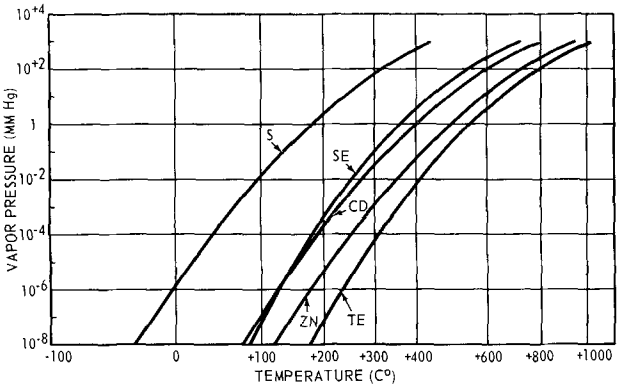

Fig. 11. Vapor pressure curves of elements of some II-VI compounds (after R. Honig).

evaporations. This was true regardless of whether the source charge (CdSe) was replaced with new material for each evaporation or if the same charge was used in succeeding depositions. Up to ten evaporations were made from each crucible before appreciable contamination (less sensitive CdSe layers). Good sensitivity of CdSe layers was obtained from the same charge for up to six depositions.

CdSe vs. CdS and CdTe Devices

By the techniques used CdSe semiconductor depositions appeared to result in a lesser contamination of the vacuum system interior. Devices utilizing the CdSe semiconductor layer were also more easily formed and reproduced. This later experience is attributed, in part to the relative closeness of the vapor pressure curves of Cd and Se as reported by Honig (17). Figure 11 shows these curves. The exact percentage of dissociation that occurs in a compound, in the vapor phase, is not known. Several investigators of CdSe (18, 19) have reported complete dissociation of the compound in the vapor phase. Investigators of CdS (20) have reported a dissociation of the compound which is dependent on the source temperature. Because of the dissociation that appears to occur, the more compatible vapor pressures of Cd and Se indicate a more congruent evaporation of the compound is possible. Experiments of Somarjai (21) have indicated this. It may therefore be possible to deposit CdSe films of closer stoichiometric ratio. X-ray diffraction studies have indicated that the deposited CdSe films were polycrystalline. It is not known whether a reformation of the compound had occurred on the substrate.

The bulk electron mobility of CdSe is reported greater than CdS (22). It might also be noted that photocells of CdSe are reported to have faster response times than CdS cells (23). Because of the lower resistivity of CdSe films, CdSe devices could conceivably be made smaller and thinner than CdS devices of comparable electrical characteristics. Preliminary tests at this facility have indicated the parameters of a thin device to be more resistant to radiation. The bulk electron mobility of CdTe is reported to be greater than that of either CdSe or CdS (22, 24). High mobility CdTe films however appear to be more difficult to form. Formation of CdTe films for use in TFT's seems at the present to be limited by reproducibilty of sensitive layers.

Life tests indicated CdSe devices to be more durable than CdS devices (gold gates). CdS units usually malfunctioned within a few hours under continuous operation. One such failure first appears as a rupturing of field plate. This is followed by an eventual decay in transconductance value, and finally a gate-drain breakdown occurs. Another type of failure noted was an increase with time of the source-drain resistance due probably to the growth of a barrier at one or both of these contacts. This phenomenon caused crowding of the Id *vs.* Vd characteristics or reduction of transconductance (9). Increase in positive bias was found to recover temporarily some of the loss, but often degradation continued. Although some CdSe devices exhibited the same type of failure as CdS devices it appears as though a method of formation is possible whereby a considerable life expectancy is realized. This is probably true for CdS devices as well. The CdSe devices which exhibited no substantial change in parameters after 24 hr of continuous operation appear able to have long life expectancies at room temperatures. Circuits employing CdSe devices have been operating continuously for over 5000 hr with only a 3000Å protective SiO layer over the device. Life tests were conducted in a room without humidity control. Other devices have been stored under nonoperating conditions for like periods of time and have not shown significant changes in characteristics. It was observed that CdSe devices with aluminum gate electrodes were more stable and had longer lifetimes than devices with gold gate electrodes.

The CdSe devices were used successfully in experimental thin-film integrated circuits, *i.e.*, multivibrators, oscillators, differential and operational amplifiers, logic elements, etc. These devices were also studied and used as current limiters (25).

Summary

Thin films, field effect triodes were formed with standard vacuum equipment. This was done to study the feasibility of using methods compatible with the formation of thin-film passive elements, for integrated thin-film circuits. In addition, materials other than those previously used by other investigators were studied. Devices were formed with CdTe, CdS, and CdSe as the semiconductor layer. CdTe devices were difficult to form principally because of the high resistivity encountered. Cadmium doping resulted in some operational devices, but reproducibility was inferior to CdS and CdSe devices.

Operational CdSe devices were the easiest to fabricate. These devices exhibited characteristics comparable to CdS devices. In general, the ability to use thinner and higher mobility CdSe layers indicate that higher frequencies of operation and improvements in microminiaturization and radiation resistance can be realized. The fabrication of operational CdSe devices was found to be compatible with standard vacuum techniques. This was attributed in part to the relative closeness of the vapor pressures of Cd and Se.

In the formation of devices it was found that under certain conditions a significant drop in semiconductor resistivity occurred when an oxide dielectric layer was deposited over it. Sensitive devices of long life generally exhibited this behavior during their processing.

The ability to reproduce devices of similar parameters was found to be strongly dependent on the use of identical deposition parameters.

Acknowledgments

The authors wish to express their appreciation to Dr. Charles Feldman and Wilbur T. Layton for their encouragement and suggestions, and to Kenneth Hoggarth, who formed some of the devices studied.

Electrical Resistivity and Diffusionless Phase Transformations of Zirconia at High Temperatures and Ultrahigh Pressures

E. Dow Whitney

Research and Development Division, The Carborundum Company, Niagara Falls, New York

ABSTRACT

The resistivity of chemically pure monoclinic zirconia has been investigated at pressures to 45,000 bars and temperatures to 1200°C. Measurements were made on thin, prepressed wafers of ZrO_2 situated between the opposed, cemented carbide Bridgman anvils of a uniaxial Griggs and Kennedy simple squeezer. Observation of discontinuous changes in electrical resistance at various temperatures under isobaric conditions have been used to define the phase diagram. The pressure dependence of the temperature of the reversible monoclinic $\rightleftharpoons$ tetragonal phase transition in zirconium dioxide agreed with the slope of the P-T equilibrium curve up to 15 kilobars as calculated from thermodynamics, *i.e.*, $dT/dP = -3.02 \times 10^{-2}$ degrees bar^{-1} (1). Activation energy for electrical conduction followed the Arrhenius equation and was found to be pressure dependent, decreasing from 3.56 ev at atmospheric pressure to an apparently constant value of 0.86 ev from 30 to 45 kilobars.

The existence of two structural modifications of zirconia was first reported by van Arkel (2) in 1924. Several years later Ruff and Ebert (3) definitely established the phenomenon of polymorphism in this material by measuring the lattice constants and densities of both the monoclinic (density = 5.68 g/cm^3), and tetragonal (d = 6.10 g/cm^3) forms. The existence of a modification of zirconia with hexagonal symmetry reported a decade later by Cohn (4) has never been confirmed, however. The reaction

$$\text{monoclinic } ZrO_2 \rightleftarrows \text{tetragonal } ZrO_2$$

at ~1200°C is reversible, and all attempts to stabilize the high-temperature tetragonal modification by rapid quenching have been unsuccessful to date (5, 6). Prior to 1962 it was generally assumed that a cubic modification of chemically pure zirconia could not exist (7-9). Very recent data have now indicated, however, that above 2200°C the reversible formation of a cubic form of ZrO_2 is indeed possible (10, 11).

The monoclinic $\rightleftharpoons$ tetragonal transition in zirconia occurs at a definite temperature and pressure and possesses a latent heat of transformation, involves a change of structural ordering, and therefore is a phase transition "of the first kind." Furthermore, as Wolten has pointed out (11), the ZrO_2 transformation is indeed both diffusionless, i.e., all atoms have the same neighbors in either phase, and is also of the martensitic-type."

In spite of the voluminous literature on zirconia, the influence of hydrostatic pressure, along with high temperatures on the course of the monoclinic-tetragonal transformation has received relatively little attention, although the fusion of ZrO_2 at 65,000 atm in a carbon tube has been reported (12). Vahldiek, Robinson, and Lynch have investigated the influence of pressure and temperature on the phase transformation of zirconia (13). They found that samples of chemically pure monoclinic zirconia after hot pressing at approximately 20,000 atm at temperatures of 1800°C and then rapidly quenched to room temperature, followed by decompression, subsequently exhibited a lower monoclinic-tetragonal phase transformation temperature on reheating. The new phase transition range was found to be 900°-1020°C compared with 1000°-1200°C before compression.

This author recently considered the thermodynamics of the monoclinic-tetragonal transition, and has presented a calculated P-T phase diagram of zirconia (1). The calculated pressure coefficient of the equilibrium transition temperature was found to be

$$dT/dP = -3.02 \times 10^{-2} \text{ deg/bar} \qquad [1]$$

Berezhnoi (14) has also calculated the slope of the monoclinic-tetragonal equilibrium curve from available thermodynamic data and has proposed a P-T diagram for pure ZrO_2. His value of $dT/dP = -3.58 \times 10^{-2}$ deg/bar^{-1} is in fair agreement with this author's, considering the assumptions involved in both calculations.

The purpose of this investigation was to experimentally verify the calculated P-T phase diagram for pure zirconia within the limits of the ultra-high pressure ap-

paratus described below. The monoclinic-tetragonal phase transition was detected by observing the discontinuous change in electrical resistivity associated with the crystallographic transformation (15-17).

Experimental

Monoclinic zirconium dioxide was prepared from recrystallized (from concentrated HCl solutions) low hafnium zirconyl chloride octahydrate ($ZrOCl_2 \cdot SH_2O$), obtained from the Carborundum Metals Division, The Carborundum Company, Akron, New York. The white crystalline solid was partially dehydrated by heating to constant weight in air under an infrared lamp, the temperature of the zirconyl salt being held at about 70°C. The product was a free-flowing white powder which analyzed to be $ZrOCl_2 \cdot 4H_2O$ in agreement with the studies of Komissarova *et al.* (18). The tetrahydrate was ignited in air in platinum dishes in a Harper electric furnace at 1200° for 3 to 4 hr. The resulting product was 100% monoclinic zirconia as determined by x-ray diffraction analysis. Emission spectrographic analysis of the material is given in Table I. Chemical analysis of the product gave: ZrO_2, 99.9%; water soluble chlorides, 0.1%.

The method of applying pressure was based on Bridgman's opposed anvil technique. Bridgman has shown that in such systems the stress developed in the compressed sample may be assumed to be hydrostatic if the thickness of the pressed sample disk is quite small. To a first approximation, then, the pressure on the sample can then be determined simply by the ratio of the load developed by the hydraulic rams and the working area of the tungsten carbide Bridgman anvils. The specific equipment employed in this study, referred to commonly as the "simple squeezer," has been described by Griggs and Kennedy (19) and is principally the Bridgman anvil unit modified to permit heating of the sample by means of an external furnace. Specimens were in the form of thin disks approximately 0.4 mm thick and 6.4 mm in diameter. These were prepared by prepressing monoclinic ZrO_2 to approximately 40,000 bars in the high-pressure apparatus. Working faces of the carbide pistons were faced with very thin disks (0.0004 in. thick x 0.250 in. in diameter) of platinum-10% rhodium foil to prevent possible contamination of the ZrO_2 samples. After pressing, the zirconia samples were found to be hard, lusterless white disks with a measured density of 97-100% of theoretical (x-ray) for monoclinic ZrO_2.

Myers, Dachille, and Roy have recently shown (20) that a "pressure multiplication effect" of as high as 2 to 2.5 times the nominal load pressure can occur when using Bridgman anvils, and that this "multiplication effect" is dependent on the diameter-to-thickness ratio of the sample undergoing compression. From their studies it was established that no pressure intensification occurred when the $d:t$ ratio was approximately 16:1, whereas a gain of over 2.5 times could be realized by reducing this ratio to 7:1, *i.e.*, the use of thicker samples. In the work reported here the $d:t$ ratio of the zirconia compacts was very close to 16:1.

The ZrO_2 disks, after being faced with platinum foil, were placed between the carbide anvils of the press, one anvil of the assembly being insulated from ground.

Table I. Spectrochemical analysis of ZrO_2

Element detected	Concentration in ppm	Element detected	Concentration in ppm
Ca	<10	Hf	not detected
Mg	<20	Co	<20
Ti	<20	Ni	<20
V	<20	Cu	<10
Cr	<20	B	20
Mn	<20	Al	<10
Fe	<100	Si + Pb	<20

The load developed by the hydraulic press was increased until the desired pressure was obtained on the sample. Pressures were calculated directly from press loads determined previously by calibration with a Type CXX SR-4 Baldwin-Lima-Hamilton Corporation precision load cell against a Heise, 0 to 10,000 lb/in.^{2} pressure gauge and areas of the high-pressure faces of the carbide anvils as determined with a precision cathetometer.

Temperature measurement and control were achieved by means of a L&N Speedomax® H recorder coupled with an L&N program control unit. Since the method employed for calibration of sample temperatures exactly followed the procedure given by Griggs and Kennedy, it need not be further described here. Resistance readings were taken at various temperatures with a General Radio Impedance Bridge, Model 650A using 1000 cps a.c. to avoid electrode polarization effects. A Ballatine Laboratories vacuum tube a-c voltmeter proved to be a sensitive external null detector. At the conclusion of a run the ZrO_2 disk was removed from the press, and the diameter and thickness of the compact measured with a micrometer. Resistivity values were calculated from the resistance readings and the final area/thickness ratios. It was not possible, however, to obtain resistivity values at the conclusion of every experiment. In several experiments severe deformation or destructive failure of the pistons occurred. When this happened the zirconia samples usually shattered, and final measurement of the samples was not possible. For this reason resistance data are given in terms of relative values only.

In some preliminary studies the monoclinic zirconia pellets were pressed within a retaining ring of unfired pyrophyllite, which is the usual procedure in conducting experiments with uniaxial-type high-pressure equipment. This, however, led to rather erratic results. The resistivity of pyrophyllite as a function of temperature at ambient and high pressures has been measured by Hall and Bundy (21) and is of the same order of magnitude as that of zirconia. Consequently, the problem of "parallel resistance" was avoided by eliminating the use of pyrophyllite rings in the experiments reported here.

Results and Discussion

Plots of relative resistance (R/R_o), *vs.* reciprocal temperature at various applied pressures ranging from atmospheric (1 bar) to 45 kilobars are shown in Fig. 1 where R_o represents the resistance of the samples at room temperature and constant pressure. Temperatures at which discontinuous breaks in the R/R_o *vs.* $1/T$ curves occurred are given in Table II. No discontinuous changes in the resistance of the zirconia samples with increasing temperature were observed at pressures higher than 15 kilobars. In experiments conducted at 20, 30, and 45 kilobars, sample temperatures were slowly increased up to the point of piston failure.

It will be noted in Fig. 1 that at each pressure deviations from the Arrhenius equation occurred at the lower temperatures. This curvature is indicative of two competing conduction mechanisms which in the case of unstabilized ZrO_2 is both ionic and electronic conduction. Both mechanisms will have different activation energies and will be influenced differently by temperature.

Figure 2 is a plot of the pressure dependence of the resistance of ZrO_2 at various temperatures. From this plot the initially rapid decrease of resistance with applied pressure is apparent, as are the discontinuities in the relative resistance curves up to 15 kilobars. Of particular interest is the leveling off of the resistance curves at the higher pressures indicating a rapidly decreasing pressure dependence of the resistance at pressures above ~30 kilobars.

The calculated phase diagram of zirconia showing regions of thermodynamic stability of the monoclinic-tetragonal crystallographic forms on the P-T plane is given in Fig. 3. Good agreement was found at 5, 10, and 15 kilobars between the points of observed discontinuities in resistance and the predicted monoclinic-tetragonal ZrO_2 equilibrium curve. It is reasonable to

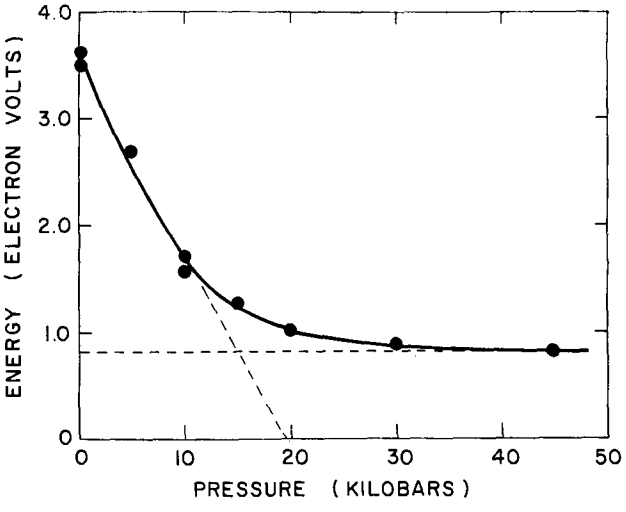

Fig. 4. Activation energy for electrical conduction in ZrO_2 vs. pressure.

assume, therefore, that such sudden changes in resistance are the result of crystallographic transformation of the zirconia lattice, and that in the pressure range 1-15,000 bars the theoretical monoclinic $ZrO_2 \rightleftarrows$ tetragonal ZrO_2 equilibrium curve has been verified. Indeed, the atmospheric pressure transition temperature of 1205° reported here is in excellent agreement with the sharp transition point temperature of 1200° reported by Kofstad and Ruzicka (16).

However, as has been mentioned previously, between 20 and 45 kilobars no breaks in the relative resistance curves were observed. This may be due in part to failure of the system to achieve equilibrium at these lower temperatures.

In Fig. 4 is shown the variation of activation energy for electrical conduction in zirconia as a function of applied pressure. Activation energies were calculated from linear portions of the curves shown in Fig. 1 via the Arrhenius equation which may be expressed as a function of pressure, *viz.*,

$$r(P) = r_o(P) \exp [E(P)/kT] \qquad [2]$$

Numerical values for the interesting pre-exponential term, $r_o(P)$, the electrical resistance of zirconia at infinite temperature as a function of pressure, could not be determined in many instances since, as mentioned previously, resistivity values were not always available.

At atmospheric pressure the activation energy in the monoclinic phase was found to be 3.56 ev in good agreement with a value of 3.8 ev for high-purity ZrO_2 found by Johansen and Cleary (22). With increasing pressure the activation energy decreased more or less exponentially reaching an apparently constant value of approximately 0.86 ev at 45,000 bars. Experiments were run in duplicate, and duplicate activation energies were found to agree within ±10%. The over-all activation energy *vs.* pressure curve in the monoclinic region may be decomposed into two linear relationships

$$\text{monoclinic } ZrO_2 \; dE/dP = -1.94 \times 10^{-4} \text{ ev/bar-mole} = -4.47 \text{ cal/bar-mole} \quad [3]$$

and

$$dE/dP = 0 \quad [4]$$

It is of interest to note that the former linear change of activation energy with applied pressure intersects the 0 activation energy level at approximately 20 kilobars. It would appear, therefore, that the particular conduction mechanism responsible for this slope is no longer operative at this pressure. Above 20 kilobars the second mechanism (apparently independent of pressure) is predominant.

Tien and Subbarao (23) determined the activation energy for conduction in ZrO_2-CaO cubic solid solutions over the concentration range 13-20 mole % CaO. Extrapolation of their data to zero CaO concentration yields an activation energy of 0.84 ev for conduction in chemically pure "cubic" ZrO_2. The decrease in E with pressure observed in this work may be due to a change in structure with the smaller molar volume cubic form of ZrO_2 being formed at high pressures.

Summary

1. By means of electrical resistance measurements the calculated P-T equilibrium curve for the reversible transformation monoclinic $ZrO_2 \rightleftharpoons$ tetragonal ZrO_2 has been experimentally verified up to 15 kilobars.

2. Activation energy for conduction in ZrO_2, obtained as a function of applied pressure, was found to decrease from 3.56 ev at atmospheric pressure to an apparently constant value of 0.86 ev in the range 30-45 kilobars.

Acknowledgments

The author acknowledges with thanks the assistance of several people during the course of this work. They are Professor Watt W. Webb for his valuable contributions and critical review of the manuscript, and H. Dean Batha for his keen interest and encouragement from the inception of this study to its conclusion. The very careful and thorough work of Dale D. Russell in conducting the electrical measurements and maintaining the high-pressure equipment in excellent working order is also gratefully acknowledged.

Manuscript received May 27, 1963. This paper was presented at the New York Meeting, Sept. 30-Oct. 3, 1963.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

Electrochemical Pseudo-Inductances

F. Gutmann[1]

The Electrochemistry Laboratory, The University of Pennsylvania, Philadelphia, Pennsylvania

ABSTRACT

The meaning of inductance is reviewed. Evidence is adduced that electrochemical systems may exhibit lagging currents, and it is proposed to explain this in terms of a pseudo-inductance, which is defined as the capability of a space to store electrical energy reversibly and kinetically. The kinetic process is ascribed to the visco-elastic behavior exhibited particularly at higher frequencies and/or in highly viscous systems as, *e.g.*, dry-cells. The relaxation time of ions may be calculated from the phase angle by means of visco-elastic theory. It is suggested that the pseudo-inductance may cancel out all or part of the capacitive time delay inherent in the transmission of nerve impulses across synaptic junctions and thus may play a significant part in such processes.

Impedance measurements are a well-known method for the study of electrochemical systems. A measurement at any one frequency yields, in effect, values for the components of an equivalent circuit consisting of a reactance, X, and a resistance, R, either in series or in parallel, depending on the method employed. Since the double layer represents a very large capacitance (1),

[1] On Leave from the Department of Physical Chemistry, The University of New South Wales, Sydney, Australia.

in the order of 16 $\mu F/cm^2$, it is assumed that X is purely capacitive.

Extension of the measurements over a range of frequencies shows that this simple model, while perfectly valid for any one frequency, fails to account for the observed change in the values of R and X with frequency, thus requiring the design of more complicated equivalent circuits.

These, however, are invariably thought to be made up of only linear resistive and capacitive elements, though it is well known that no such equivalent circuit can be devised which accurately represents the observed frequency dependence of X as well as of R (2). This matter will be further discussed in a later paper.

In measurements at higher frequencies, and/or on active electrochemical systems it is often found (3-7) that these behave as negative capacitances or exhibit a negative component of the imaginary part of the complex conductance. Both statements are tantamount to saying that the system behaves as an inductance, and indeed in some cases (6) equivalent circuits including an inductance have been devised.

In this paper we wish to adduce evidence for the general presence of inductive effects in electrochemical processes; we shall interpret these effects in terms of the visco-elastic properties of the system.

The Meaning of Inductance

Before discussing the—to electrochemists—perhaps less familiar concept of inductance, let us consider what is meant by a capacitance C; we can say that this is a property of an element of space dv which is capable of storing, reversibly, electrostatic energy, W

$$W = \int \frac{q^2}{C} dv \qquad [1]$$

where $q = f(v)$ is the local (space-) charge density. It should be emphasized that, of course, the seat of the stored energy is the dielectric and that thus the concept of capacitance has nothing to do with the presence, or absence, of electrodes. Even a measurement involving no electrodes whatever permits the evaluation of the capacitance of a region of space, which can be defined from Eq. [1].

Alternatively, we can define a capacitance in terms of the phase difference between an applied voltage and the current produced. Consider a sealed box with two terminals. The current through the box may be either in phase with the applied voltage, or be leading or lagging the same. If the current leads or lags the voltage by exactly 90°, one deals with pure capacitance or pure inductance, respectively. In all other cases, where the phase angle is less than ±90° the circuit element must contain a mechanism for the dissipation as well as for the storage of energy.

It should be emphasized that the concept of inductance has nothing to do with "coils of wire" or, more accurately, with the interaction of a conductor with an electromagnetic field. Exactly as two plates with an interposed dielectric are a sufficient, but not a necessary condition for exhibiting a capacitance, so is such an interaction a sufficient, but not a necessary condition for exhibiting an inductance.

We thus define inductance as the property of a region of space capable of reversibly storing electric energy kinetically.

We cannot conclude from a measurement at any one frequency only that the sealed box contains only one type of reactance, since all or part of a capacitive reactance may be cancelled by all or part of an inductive reactance which may also be present. Should both reactances cancel exactly, we speak of resonance.

This now permits us to illustrate our argument thus: consider a piezoelectric crystal, say quartz or thiourea. This crystal will exhibit a very sharp resonance if it is excited at its mechanical resonance frequency; such excitation need not necessarily involve even the application of electrodes to the crystal. At resonance, the crystal behaves as a pure resistance. Below resonance it behaves as a capacitance and above resonance as an inductance: in brief it behaves like a resonant circuit consisting of a capacitance and an inductance in series. There is kinetic storage of energy in the elastic deformation of the crystal, but there are no coils of wire and the interaction of the highly insulating crystal, considered as a conductor, with the current is quite negligible. In fact, this inductive behavior of piezoelectric crystals above resonance is being seriously considered to be used practically in integrated circuitry.

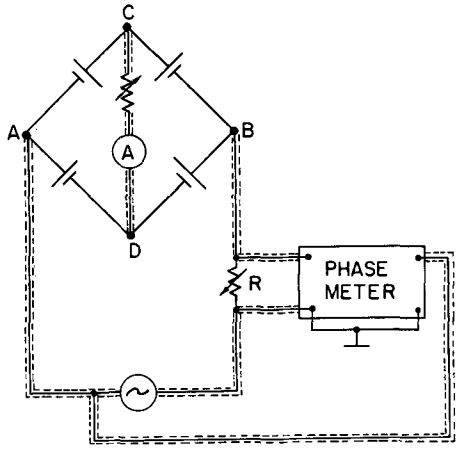

Fig. 1. Circuit for phase relation measurements on batteries

Experimental

We have carried out measurements on 1.5v Leclanchè type dry batteries (commercial Eveready dry cells) which were connected as shown in Fig. 1.

It is seen that there is no d-c voltage across the test terminals, A and B, and there is no a-c voltage between the current terminals, C and D, assuming the four cells to be identical. All leads were screened and tied to a single earthing point at the ground terminal of an Ad-Yu phase meter. This measures the time interval between the instants of intersection with the time axis, of the voltage wave and of the current wave. The read-out is directly in terms of the phase angle and is independent of waveform as long as the wave does not intersect the time axis more than twice every cycle. This property is important in view of the highly non-sinusoidal shape of the current wave.

The oscillator was a beat frequency signal generator with a range of up to 100 kc/sec and a rather constant output voltage of about 22v. The resistance, R, was adjusted to give a voltage drop of approximately 0.5v at the highest frequency employed in each run: thus about 98% of the total applied alternating voltage appeared across the system. The alternating voltage across each 1.5v dry cell thus at all times was considerably higher than the d-c voltage, being about 10v rms or more.

At low values of direct current, in the order of 1 ma, the phase angle remained substantially constant at 45°, as to be expected in a diffusion controlled electrochemical system (8). As the direct current drain was increased, the phase angle commenced to drop with increasing frequency, the onset of this effect shifting to lower frequency values as the current drain was raised. At a direct current of about 1.5 amp, the phase angle reached zero at a frequency of about 80 kc/sec and thence became inductive, increasing monotonically with increasing frequency.

These high values of current are rather excessive for the dry cells employed; it was difficult to maintain the current for any length of time, and the batteries were invariably discharged and rather unserviceable at the

Table I. Data from Powell and Rasmussen (3)

Frequency f = 300 kc/sec; temperature T = 24°C

Substance	Concentration, moles/liter	σ' in mhos/meter	σ'' in mhos/meter
CsCl	5	41.5	−0.4
$BaBr_2$	2.5	21.7	−0.2
CdI_2	1.25	2.92	−0.15
CdI_2	0.625	1.92	−0.09
$Pb(NO_3)_2$	1.25	7.72	−0.63
$Pb(NO_3)_2$	0.625	5.05	−0.19
Bi film	5.05×10^{-6} in. thick	4.33×10^{4}	-0.14×10^{4}
Sb film	3.3×10^{-6} in. thick	2.37×10^{5}	$+0.41 \times 10^{5}$

end of a run. The phase meter reading also tended to fluctuate by about 10% at high values of direct current, although the qualitative features of the experiment remained quite clear, *viz.*, that the impedance of the cells went through a true resonance at about 80 kc/sec and thence became inductive.

This rather surprising result prompted a search of literature in order to secure further corroborating evidence.

Further Experimental Evidence from Literature

Perhaps the most accurate quantitative data have been obtained by Powell and Rasmussen (3) at the National Bureau of Standards, Boulder, Colorado. They report that "measurements of strong electrolytic solutions have shown that the conductivity has a strong out-of-phase component which can be either leading or lagging, depending on the nature of the solution, and thus contributes either a positive or negative component to the permittivity." It should be pointed out that these authors employ a transformer bridge in which the unknown forms a single turn loop; the electrolyte is contained in a ring shaped container and no electrodes are required. There are no metal surfaces at all in contact with the electrolyte. The data in Table I were obtained at 300 kc/sec and 24°C. The table evaluates the electrolyte impedance in terms of a complex conductivity σ^* defined as

$$\sigma^* = \sigma' + j\sigma'' = jK_0\omega K^* \quad [2]$$

where

$$K^* = k' + jk'' \quad [3]$$

K^* being the complex permittivity, or dielectric constant, of the medium. A negative value of σ'' indicates a lagging current, *viz.*, the unknown behaves as an inductance.

It is seen that the impedance of the electrolyte becomes more inductive as the concentration rises and as the weight of the cation increases. It should be noted that also evaporated bismuth films exhibit a lagging current, while those of antimony, *e.g.*, do not.

A study of lead-acid storage battery impedances by Willihnganz and Rohner (6) showed that "the battery also possesses a measurable inductance" and "when large batteries are studied, the effect of inductance assumes a major importance." The battery was represented by an equivalent circuit as shown in Fig. 2, and the results are summarized in Fig. 3. It is seen that, for a 180 amp-hr battery, the two reactances become equal at about 80 c/sec; above that resonance, as would be expected in a series resonant circuit, the inductive reactance exceeds the capacitive reactance, resulting in a lagging current.

The resonance frequency is found to be independent of battery size, thus indicating that both reactances follow closely similar geometric relations.

Papers read at the recent 124th Meeting of the Electrochemical Society by Brodd (7) and by Lurie *et al.* (5) also report that the phase angle of primary and secondary cells becomes inductive at higher frequencies. They relate the changes in phase angle to the amount of charge stored in the device; Lurie *et al.* (5) report that the impedance of a Ni-Cd battery shows a

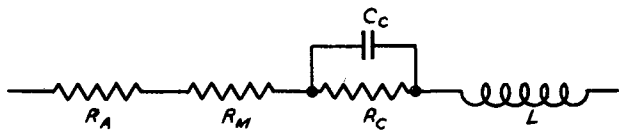

Fig. 2. Equivalent circuit of a lead-acid accumulator [after Willihnganz and Rohner, ref. (6)]. R_A here represents the resistance of the electrolyte, and R_M that of the metal plates of the battery. C_C and L represent the effective capacitance and inductance, respectively. The capacitance C_C shunted by a leakage resistance R_C.

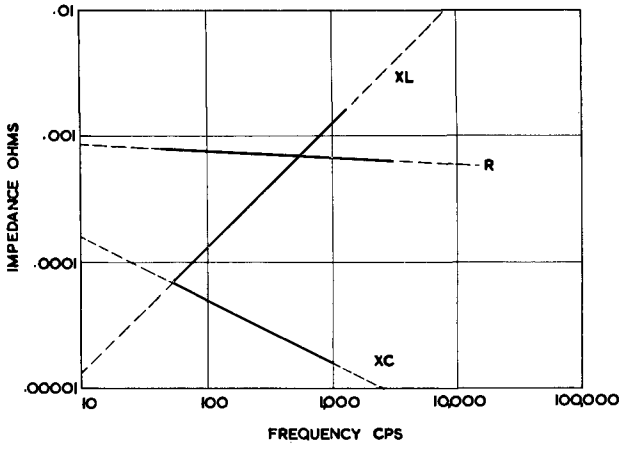

Fig. 3. Impedance components; 180 amp-hr lead-acid accumulator [after Willihnganz and Rohner, ref. (6)].

shallow minimum at about 1000 cps followed by a steep rise; this is equivalent to the presence of an inductance in the order of microhenries.

It is important to note that exactly the same effect occurs in nerve membranes (9): the parallel impedance of squid nerve membranes is strongly inductive at low frequencies, going through a resonance at about 100 cps and thence becomes capacitive. This behavior is illustrated in Fig. 4. It should be pointed out that these are parallel admittance components, referring to a parallel tuned circuit. Transposing these to a series equivalent circuit shows that well below resonance the equivalent series reactance approaches a limiting value of $-\omega Lp$, being capacitive, while above resonance the opposite holds, *i.e.*, a parallel L-C circuit behaves as a capacitance. Thus the behavior depicted in Fig. 4 for a

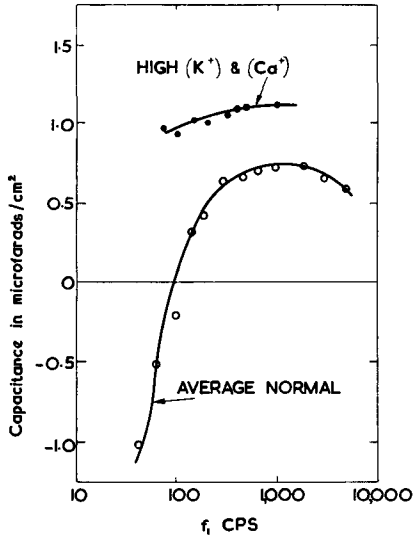

Fig. 4. Admittance components in squid nerve membranes [after Schmitt, ref. (9)]. The capacitance here refers to an equivalent circuit consisting of conductance and capacitance in parallel.

parallel L-C circuit is the mirror image of that valid for the series circuit thus far considered, with the sign of the ordinate reversed.

Electrochemical or Pseudo-Inductances

Exactly as a capacitance may arise from a variety of processes, so can an inductance be due to any one of many different mechanisms, the common factor being a reversible storage of electric kinetic energy. We shall apply the term pseudo-inductance to inductances arising in the course of electrochemical reactions in parallelism to the pseudocapacitance due to such reactions.

In the case of an active circuit element, a pseudo-inductance may arise from any energy yielding process containing a time delay. Carson (10) has pointed out that such a process would occur in a battery which is subjected to an alternating voltage of an amplitude substantially in excess of its direct terminal voltage: the battery is then alternately charged and discharged from the a-c source, and the lagging current is a consequence of the inherent time delay between a charge q being put into the battery and q being released again.

Another mechanism has been pointed out by Conway (11): In some adsorption experiments under quasi-equilibrium conditions the surface coverage θ may vary with the applied potential so that $d\theta/dV$ is negative, *i.e.*, an increase in potential shifts the equilibrium toward a desorption process. Since the charge q is proportional to θ this means that the dynamic capacitance dq/dV will also become negative and thus equivalent to a pseudo-inductance. The process can be readily interpreted along the lines suggested before. An increase in the applied potential causes a drop in adsorption because part of the energy supplied is being stored kinetically in desorbing some of the adsorbate, the process being reversible since reducing the potential causes re-adsorption, *i.e.*, release of the stored energy. This is in exact parallelism to kinetic electrode processes where a dynamic equilibrium between two equal and opposing exchange currents is attained at a certain potential.

The general differential equation for a diffusion-controlled electrochemical process is

$$\frac{\partial a}{\partial t} = D\frac{\partial^2 a}{\partial x^2} \qquad [4]$$

where a is the activity and D the diffusion coefficient of the reactant ion species. D is related to the viscosity η of the medium by the Einstein-Townsend relation

$$D = \frac{zkT}{6\pi\eta r_o} \qquad [5]$$

where z is the valency and r_o the mean radius of the ions, considered to be spherical.

The standard treatment (8) of electrode kinetics applies the following boundary conditions

$$a = a_{\text{Bulk}} \text{ for } x \to \infty$$
$$\frac{I \sin \omega t}{zF} = -D\left[\frac{\partial a}{\partial t}\right]_{x=0} \qquad [6]$$

The second condition implies that the current $i = I \sin \omega t$ at the electrode-solution interface is in phase with the diffusion wave. This treatment then yields the well known $\omega^{-1/2}$ dependence for the impedance of the system, which appears as an R/C combination at any one value of frequency.

However, this relation of the diffusion wave to the current need not necessarily hold and is inherently unlikely to hold at higher values of current, at higher frequencies, and in a visco-elastic medium.

The theory of visco-elasticity (12) treats the viscosity as a complex quantity, η^*. However, if one introduces

$$\eta^* = \eta_1 + j\eta_2 \qquad [7]$$

into Eq. [4] for the diffusion coefficient D, then the resulting differential equation

$$\frac{\partial a}{\partial t} = D^*\frac{\partial^2 a}{\partial x^2} \qquad [8]$$

no longer permits a solution in a closed form; also the boundary condition Eq. [6] no longer strictly applies because the viscosity now becomes a function of frequency. A computer solution, though, can, of course, be derived.

In Powell and Rasmussen's (3) careful conductivity measurements, no electrodes were in contact with the solution, and there is no question of any polarization effects. The system thus is truly diffusion or viscosity controlled, and the only forces limiting the motion of the ions are viscous forces.

It is thus reasonable to assume that the electrical impedance components are proportional to the components of the mechanical impedance as determined from conventional visco-elastic theory (12). Thus, the electric phase angle must equal the visco-elastic phase angle

$$\tan \phi = \sigma''/\sigma' = \eta_2/\eta_1 \qquad [9]$$

assuming a parallel circuit. The conductivity components, σ'' and σ', were defined in Eq. [1].

Powell and Rasmussen's data yield a value of 0.084 radians = 4°52′, for the lagging phase angle ϕ in a 1.25M lead nitrate solution. Transposing this into an equivalent series circuit, as in Fig. 2, yields for the pseudo-inductance L a value of 0.57 microhenries.

Representing the visco-elastic system by a Maxwell Model, it follows that

$$\tan \phi = \omega\tau \qquad [10]$$

where ω is the angular frequency, *i.e.*, $2\pi 3 \times 10^5$ cps and τ stands for the ionic relaxation time. For the present case, $\tau = 4.5 \times 10^{-8}$ seconds, which is certainly a reasonable value.

In general, the mechanical impedance Z_m is defined as

$$Z_m = \text{Force/Velocity} = b\eta^* \qquad [11]$$

where η^* is the complex viscosity and b a constant.

Let us consider a lamina vibrating in the x-direction in a liquid of density ρ and viscosity η. Let l denote the distance from the lamina at which the velocity has reached zero, *i.e.*, where the liquid may be considered stationary. Since viscosity necessarily involves the transfer of momentum in a direction perpendicular to the direction of motion, we can then say, following the treatment given by Correlli and Porreca (13), that a damped transverse viscosity wave spreads into the liquid in the y-direction, reaching zero amplitude for $y = l$, and having wave front surfaces parallel to the x—z plane of the lamina. The oscillation of the lamina then has been shown (11) to be determined by a mechanical impedance Z_m given by

$$Z_m = \eta\beta\frac{\sinh 2\beta l + \sin 2\beta l}{\cosh 2\beta l - \cos 2\beta l} + j\eta\beta\frac{\sinh 2\beta l - \sin 2\beta l}{\cosh 2\beta l - \cos 2\beta l}$$
$$j \equiv \sqrt{-1};\ \beta \equiv \left[\frac{\omega\rho}{2\eta}\right]^{1/2} \qquad [12]$$

If the viscosity η exceeds about 6 poises and the frequency remains below about 1 Mc/sec, then a series development yields

$$Z_m \cong \frac{\eta}{l} + j\omega\rho l/3 \qquad [13]$$

Thus, it is seen that the pseudo-inductance will be proportional to the frequency, the density of the ionized medium, and to the quantity l. The latter can be identified with the thickness of the diffusion layer, S, known from kinetic theory (14) to have a value in the order of 0.05 cm.

While the evaluation of a proportionality factor converting the mechanical into an electrical impedance, in terms of material constants, will be discussed in a later communication, it can be readily seen that Eq. [13] is in at least qualitative agreement with the experimental results: the pseudo-inductance increases with frequency and with the current passing.

For systems of low viscosity and measurements at higher frequencies (above 25 kc/sec for $\eta \cong 0.01$ poises) $\sinh \beta l \cong \cosh \beta l$ and the mechanical impedance can be approximated by

$$Z \cong \eta\beta + j\eta\beta \qquad [14]$$

so that the pseudo-inductance follows from $L = \dfrac{\eta\beta}{\omega}$ as

$$L = K\left[\frac{\eta\rho}{2\omega}\right]^{1/2} \qquad [15]$$

where K is a constant of proportionality depending on the physical dimensions of the system.

Since actually the reactance $X_L = \omega L$ is the measured quantity, it is again seen that the pseudo-inductive reactance increases with frequency and with the viscosity and density of the ionized medium. It should be pointed out that Eq. [15] also follows from conventional visco-elastic theory as a limiting case for a pure liquid; it is seen that then the phase angle will be 45° lagging at all frequencies. This refers to an ideal electrodeless and purely viscosity-controlled system: the counterpart to the ideal diffusion-controlled electrode reaction, which exhibits a phase angle of 45° leading current.

Matters are far more complicated in active systems which include physical electrodes, since the double layer capacitance as well as the pseudocapacitances arising at these interfaces will have to be compensated by the pseudo-inductance until, a resonance, and at frequencies above that, a lagging current can be observed.

Pseudo-Inductance and Synaptic Transmission

It has been pointed out by Schmitt (9) that "in a typical biological membrane the reactive element will for the most part include polarization phenomena, the physical capacitance of the membrane AND SOME OF THE ACTIVE PROCESSES (own capitals)." Now, the sharp leading edge of the action-potential spike represents a high-frequency component. If the signal transmission across the synaptic junction is indeed associated with the transport of acetylcholine across the junction which then triggers a signal, then it should be expected that the time delay due to the pseudo-inductance should be of importance. Its magnitude should affect the speed of the transmission process and *vice versa*. Any process, and any substance introduced into the snyaptic region, which interferes with the complex viscosity of that region thus should also affect the synaptic transmission by causing a time delay and altering the phase relation of the signal. The very fact that an impulse can be triggered by a signal transmitted across the synapsis in such a short time indicates that perhaps some sort of a physical resonance mechanism might be at work in which the capacitive time delay inherent in the junction is balanced by a pseudo-inductance caused by the out-of-phase component of the complex viscosity: energy is stored in a visco-elastic stress and suddenly released on arrival of the signal in order to make up for the capacitive time delay. In other words, we propose, in the synapsis, a visco-elastic energy storage mechanism governed by a storage modulus, which is in phase with the stress.

The Effect of Composition and Structure on the Electrochemical Reactivity of Nickel

G. A. Di Bari and J. V. Petrocelli[1]

Paul D. Merica Research Laboratory, The International Nickel Company, Inc., Sterling Forest, Suffern, New York

ABSTRACT

The electrochemical reactivity of nickel is defined in terms of the parameters of the anodic polarization curve as determined potentiostatically. The effect of structure and the effect of the additives carbon, silicon, sulfur, selenium, tellurium, and phosphorus on the parameters of the polarization curve have been determined. It is concluded that small amounts of these elements affect the reactivity of nickel to a greater extent than large changes in structure. They increase the reactivity of nickel and inhibit passivity significantly.

Passivity is a general phenomenon of metals, accounting for some commercially useful properties of many of the primary metals and their alloys (1). The passive behavior of iron (2), nickel (3), and chromium (4), has been studied by many investigators. Great progress has been made in understanding the electrochemical behavior of iron and detailed information on the thickness, chemical composition, and structure of the passive film is available (5, 6). Similarly detailed information is not yet available for nickel.

In studying the passivity of nickel, Greene (7) indicated the complex polarization characteristics of nickel as compared to other metals. This complex behavior is probably partly responsible for the existing controversy over the significance and interpretation of the Flade potential of nickel. Vetter (3) has suggested that some of the apparent discrepancies in the reported behavior of nickel might be traced to the presence of impurities. Trumpler (8) has studied the effect of impurities on the electrochemical behavior of nickel. Hospadaruk and Petrocelli (9) in a determination of the relative reactivity of nickel electrodeposits, concluded that the reactivity and pitting tendency of nickel increase as the sulfur content increases. Wesley (10) described the effect of sulfur, and his discussion of the reactivity of nickel is especially pertinent to this study. In discussing the electrochemistry of dissolution processes, Petrocelli (11) noted that imperfections or zones of disarray might affect the rates of dissolution of metals. In this study, the electrochemical reactivity of nickel, as affected by structure and impurities, has been investigated.

Procedure and Nomenclature

Electrochemical reactivity.—The electrochemical reactivity of nickel may be defined in terms of the parameters of the anodic polarization curve as determined potentiostatically. A schematic semi-logarithmic curve of the anodic dissolution current as a function of potential is shown in Fig. 1. The indicated behavior is typical of metals that corrode actively on immersion in a given electrolyte and are readily passivated on anodic polarization. We will consider three regions:

1. *The Active Region, AB,* is characterized by the corrosion potential, E_{oc}, the corrosion current, i_{oc}, and the slope of the linear portion of the curve (the Tafel slope).

2. *The Active to Passive Transition Region, BC,* is defined by the parameters of the principal peak, E_{pp}-i_{pp}, which indicate the tendency to passivate. The slope of this descending curve is given significant meaning in Mueller's (12) treatment of the transition region, where the slope is related to the kinetics of film formation.

3. *The Passive Region begins at C* and is characterized by the passive potential, E_p, and the rate of dissolution in the passive region, i_p. The pertinent parameters in this region may be considered a measure of the extent of passivation.

In terms of the operational approach described, the object of this study was to determine how the parameters of the anodic polarization curve for nickel are affected by (i) structural changes, specifically changes in grain size, and (ii) the presence of electronegative elements in nickel.

Specimens.—Three kinds of pure nickel were included in this study: high-purity nickel prepared by Wesley (13), conventional electronickel deposited from a typical refinery-type electrolyte, and commercial wrought nickel (Nickel 200). To study the effects of structure, conventional electronickel was subjected to various degrees of cold-working and heat-treatments to obtain a variety of grain sizes. The nickel specimens containing sulfur, selenium, tellurium, and phosphorus were prepared by electrodeposition from nickel electrolytes containing suitable additives. Specimens containing silicon and carbon were prepared by casting *in vacuo* without the use of deoxidizers.

Test method.—The various nickel electrodes were mounted in Lucite and polished using standard metallographic techniques. Data obtained with silicon-bearing nickel in the presence and absence of Lucite were identical. The effect of Lucite was therefore judged to be negligible. The specimens were then etched in 1:1 nitric-acetic acid and photographed. The speci-

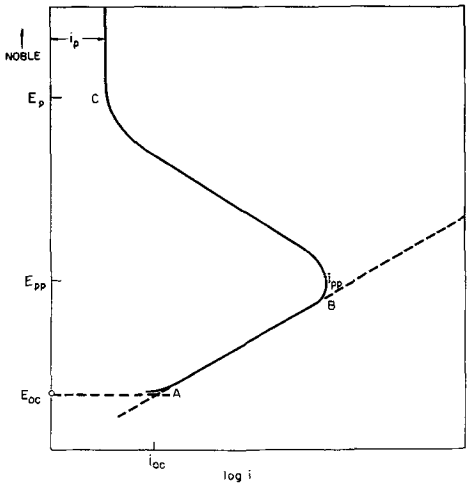

Fig. 1. Schematic anodic polarization curve

[1] Applied Research Office, Ford Motor Company, Dearborn, Michigan.

mens were repolished and etched prior to placing them in the polarization cell. The mounts were marked so that the same area could be examined and photographed after polarization.

Electrical contact to the specimen was made by means of a nickel rod that screwed into the Lucite mount. The specimen (exposed area of 1 cm^2, usually) was placed in a conventional two-compartment cell. Anodic polarization was begun after 30 min, or when the open-circuit potentials became steady.

The electrode potentials and polarization curves were determined by the direct method (14) using a Luggin capillary. The potentials were controlled within $\pm$ 1 mv by means of a Fairport potentiostat. The cell currents were automatically recorded (L&N Speedomax G). When the current reached a steady value, the potential was increased, usually by 10 mv. In the active region, a steady value of the current was obtained after about 2 min. In the transition and passive regions, the currents became steady slowly (greater than 1 hr). The reproducibility of the curves was excellent, except as will be noted later.

The test solution contained one mole per liter of nickel sulfate and the chloride concentration was maintained at less than 3 millimoles per liter. The temperature was controlled at 25° $\pm$ 0.1°C. The *p*H of the electrolyte was 2.0. The solutions were air-saturated. Oxygen may complicate the interpretation of polarization data. But at a *p*H value of 2.0, the effect of oxygen on the anodic polarization characteristics of nickel is negligible. All potentials were measured *vs.* a saturated calomel electrode and are so reported.

Results

High-purity vs. conventional electronickel.—A typical microstructure of conventional electronickel is given in Fig. 2. The as-deposited structure of the high-purity material was similar, although finer grained. The effect of annealing the electrodeposited nickel was to increase grain size and to destroy the dendritic structure characteristic of the as-deposited material. This can be seen in Fig. 3 which shows the structure of the high-purity material after annealing in hydrogen at 2000°F for 2 hr plus annealing *in vacuo* at 2000°F for 1 hr. The annealed high-purity nickel had an ASTM grain size of 4. The conventional electronickel which was heated in argon at 2200°F for 5 hr had an average grain size of 3 and the two materials were considered to have similar structures.

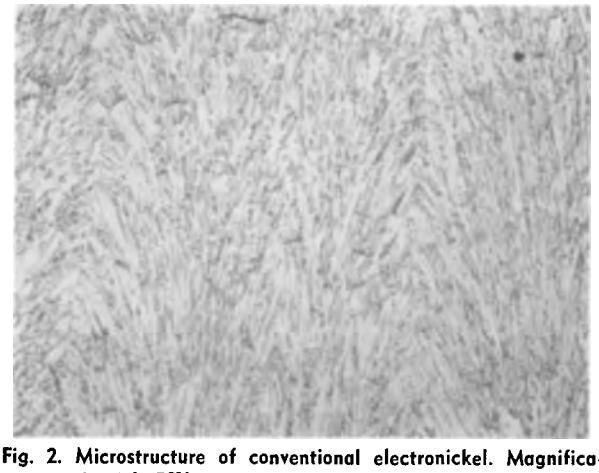

Fig. 2. Microstructure of conventional electronickel. Magnification approximately 50X.

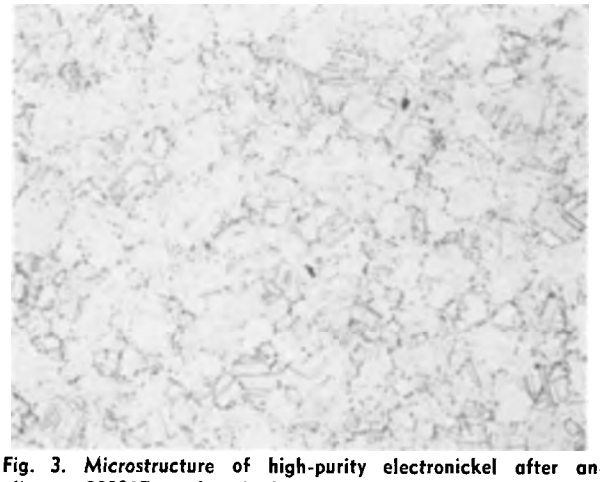

Fig. 3. Microstructure of high-purity electronickel after annealing at 2000°F, as-deposited. Magnification approximately 50X.

The anodic polarization curves of the as-deposited and annealed high-purity nickel, given in Figure 4, differed slightly. The value of the peak current, i_{pp} was somewhat higher for the annealed material, but the transition from the active to passive state was more abrupt. The values of E_{oc}, i_p and the Tafel slope were almost identical, however.

The corresponding data for the conventional electronickel before and after annealing, Fig. 5, indicated that it was more reactive than the high-purity nickel. The open-circuit potentials were shifted in the active direction and the values of i_{pp} and i_p were larger for the conventional material. The value of i_p was increased from 15 to 50 $\mu a/cm^2$ after annealing.

The results strongly indicate that the differences in reactivity were due to the differences in purity. The

differences in reactivity may have been due to localized activity. For example, after polarization, the as-deposited conventional electronickel showed a general etched surface, while the annealed material evidenced greater pitting-type corrosion (Fig. 6). The surface was covered with numerous tiny pits and several large circular ones. No pitting of the high-purity nickel was observed after polarization.

Effect of grain size.—To study the effects of structure further, the conventional electronickel was melted and cast *in vacuo*. The resultant material had a larger grain size (ASTM 1) than either of the annealed specimens described above.

The polarization data of the as-deposited and as-cast nickel are compared in Fig. 7. The cast material showed a change in the passive region. The value of E_p was shifted from 0.15v to 0.30v and i_p increased with potential.

Further variations in grain size were effected by combining cold-working and annealing treatments. Conventional electronickel was pre-annealed at 1200°F for 30 min and was then cold-worked to a 50% reduction in thickness. A portion of the material was stress-relieved at 350°F for 1 hr. Little change in the microstructure resulted. Some of the cold-worked material was also annealed at 800°F for 1 hr. The latter treatment resulted in very fine equiaxed grains having an ASTM grain size rating of 10.

The principal effect of cold-working and annealing on the polarization characteristics, as given in Fig. 8, was on the active to passive transition region. The

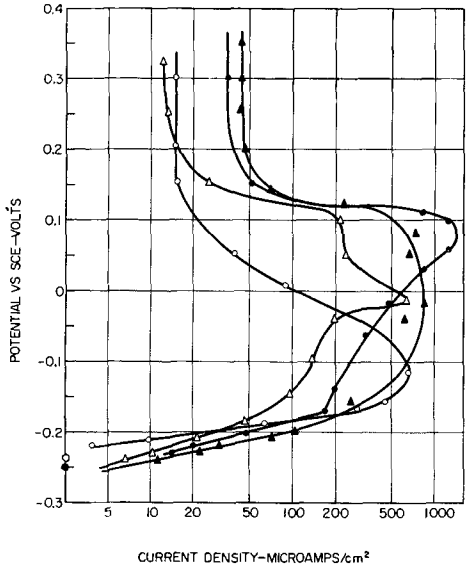

Fig. 8. Anodic polarization curves of conventional electronickel as affected by cold-working and annealing, in 1.0M $NiSO_4$, pH 2.0, 25°C. ○, As-deposited; △, 50% cold work; ▲, 50% cold work and stress relief, 350°F; ●, 50% cold work and annealed, 800°F.

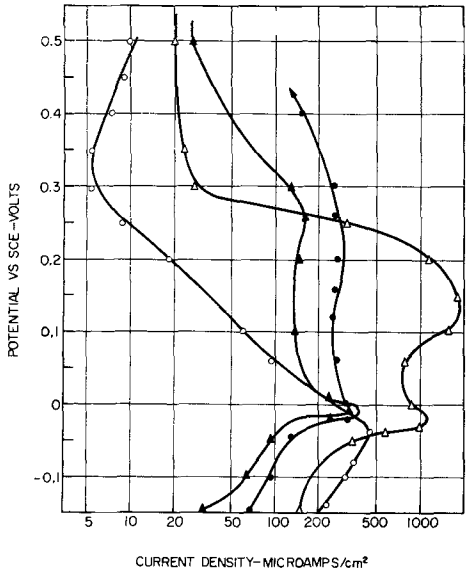

Fig. 9. Effect of silicon on the anodic polarization of cast nickel in 1.0M $NiSO_4$, pH 2.0, 25°C; per cent silicon: ○, 0.004; ▲, 0.3; ●, 0.6; △, 1.1.

dissolution rates (current densities) remained high over a broader potential range for the cold-worked material. The values of i_p were higher for the specimens which were stress-relieved or annealed. The reproducibility of the data presented in Fig. 8 was not determined. There was a tendency for the currents to increase with time in the active to passive transition region.

Commercial wrought nickel (Nickel 200).—The polarization characteristics of Nickel 200 were studied in the cold-rolled and annealed states (2200°F for 5 hr). The polarization curves were very similar to those for the cold-worked and annealed conventional electronickel given in Fig. 8. However, in the cold-rolled state extensive pitting occurred. The extent of pitting was markedly reduced by annealing.

Effect of electronegative elements.—The results with relatively pure nickel indicated that minor changes in the degree of purity affected the over-all reactivity of nickel. It was of interest to determine the effects of controlled amounts of added impurities. The impurities studied were silicon, carbon, sulfur, selenium, tellurium, and phosphorus.

Silicon.—The polarization curves of cast nickel containing various amounts of silicon are compared in Fig. 9. The effect of silicon on the polarization of nickel was to increase the current in the active to passive transition region and in the passive region. The result was that silicon tended to inhibit passivity. The silicon-containing material had an increased tendency for pit formation (Fig. 10).

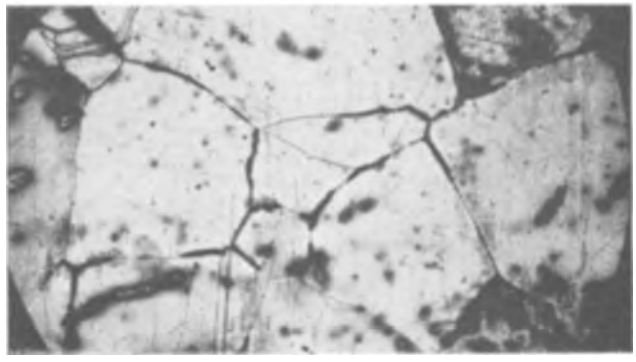

Fig. 12. Microstructure after polarization of cast nickel containing 0.47% carbon. Magnification approximately 50X.

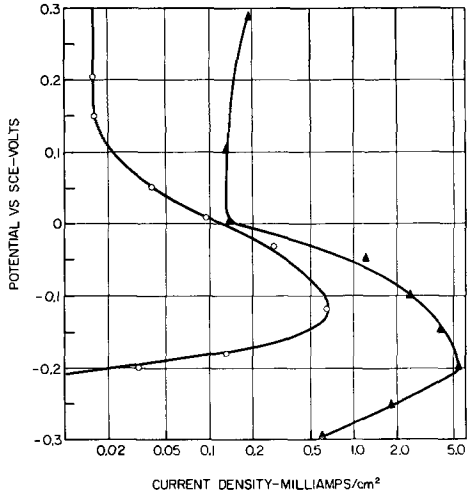

Fig. 13. Effect of phosphorus on the anodic polarization of electrodeposited nickel in 1.0M $NiSO_4$, pH 2.0, 25°C; ○, conventional electronickel; ▲, 0.05% phosphorus.

Carbon.—The effect of carbon on the polarization of cast nickel is shown in Fig. 11. The increased values of the primary passive current, i_{pp}, are indicative of the reduced tendency for carbon-bearing nickel to become passive. At the 0.47% level, carbon caused considerable increase in the passive current, i_p. The effect of carbon at the 0.47% level was to increase markedly the extent of intergranular dissolution (Fig. 12).

Phosphorus, selenium, tellurium, and sulfur.—The elements phosphorus, selenium, tellurium, and sulfur, unlike silicon and carbon, caused significant changes in reactivity in the active region. The open-circuit potentials were shifted in the active direction, as is evident in Fig. 13, 14, and 15.

The reduced tendency for passivation is indicated by the increased values of i_{pp}. Phosphorus increased the value of i_{pp} from about 0.6 to 5.0 ma/cm², selenium from about 0.6 to 5.0 ma/cm², tellurium from 0.6 to 1.0 ma/cm², and sulfur from 0.6 to 50 ma/cm².

The additives affected the rates of dissolution in the passive region as well. Small amounts of selenium and tellurium maintained the current in the passive region very close to the primary passive current, i_{pp}. While phosphorus-bearing nickel appeared to passivate, the value of i_p was higher than for conventional electronickel. Sulfur-bearing electronickel, however, did finally attain as low a value of i_p as did the conventional material, but at higher potentials.

The nickel containing phosphorus, selenium, tellurium, or sulfur had a somewhat increased tendency for pit formation.

Discussion

Effect of structure.—The increased reactivity of the conventional electronickel, as opposed to the high-

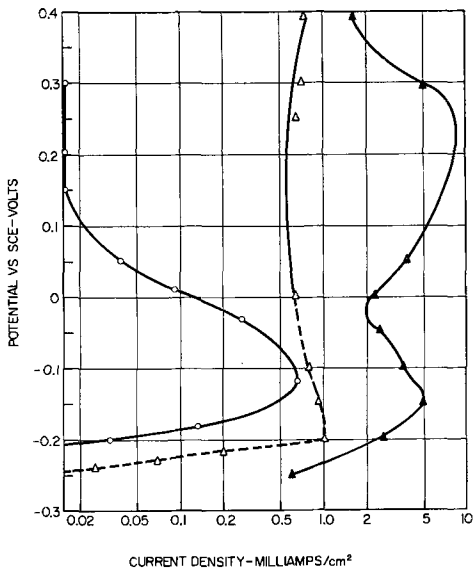

Fig. 14. Effect of selenium and tellurium on the anodic polarization of nickel in 1.0M $NiSO_4$, pH 2.0, 25°C; ○, conventional electronickel; ▲, 0.018% Se; △, 0.016% Te.

purity nickel, was probably due to the minor differences in purity, since the materials were of comparable microstructure. Although large changes in grain size resulted from annealing electronickel at 2200°F, minor effects on reactivity were observed. High-temperature annealing of the conventional electronickel increased the extent of localized corrosion, perhaps indicating an effect of distribution of impurities. The effect of impurities in increasing localized corrosion was particularly evident in the behavior of the wrought nickel.

The cold-working of electronickel interfered with its tendency to become passive. The effect of cold-work can be appreciated from a mechanism of conversion from active to passive states recently presented by Mueller (12). The model described is based on the relative rates of two opposing reactions, (i) the anodic dissolution of the metal in the active region as determined by the Tafel relation, and (ii) the rate of formation of a passivating film. The familiar S-shaped curve is then the resultant of these two opposing reactions. The data presented in Fig. 4 and 5 are in fair agreement with the proposed model. The effect of cold-work, in terms of Mueller's analysis, is to interfere with the ease of formation of the passivating film. Cold-work would be expected to increase the number of lattice imperfections. This is consistent with the retardation of film formation evident in the polarization data and agrees with the suggestions of Petrocelli (15) that lattice imperfections at or near the metal surface must be influential in determining the properties of the passivating film. Imperfections will influence the initiation and growth of the film.

Effect of Additives

With the exception of silicon, the additives studied have limited solid solubilities in nickel. Less than 0.03% carbon dissolves in nickel at room temperature, the excess segregating at grain boundaries as graphite when slowly cooled from annealing temperatures. The increased intergranular dissolution noted in nickel containing 0.47% carbon is indicative of this limited solubility. Sulfur, selenium, tellurium, and phosphorus dissolve to the extent of less than 0.001%, and the formation of intermetallic compounds is possible.

The effects of the additives on the anodic polarization characteristics, especially on the values of the primary passivating current, i_{pp}, make it possible to determine the relative effectiveness of the additives in increasing the electrochemical reactivity of nickel. Thus, it appears that at equal atomic concentrations the order of effectiveness is

$$S > Se > Te > P > C > Si$$

The effect of silicon is believed to be a specific one. The effect of silicon, at least up to 0.6%, appears to be confined solely to the passive region. The electrochemical dissolution of silicon and its subsequent precipitation as an amorphous silica gel has been observed while studying the anodic behavior of silicon-containing nickel. The reactions of silicon involved may be written

$$Si \rightarrow Si^{n+} + ne^-$$
$$Si^{n+} + n\,(OH^-) \rightarrow Si\,(OH)_n \downarrow$$

Thus the oxidation of silicon and its subsequent reaction would remove hydroxyl ions from the anode film. This specific effect of silicon would be consistent with the known pH dependence of the Flade potential. Further the effect of silicon indicates that the hydroxyl group is directly involved in the passivation of nickel.

The effect of impurities on the reactivity of nickel has been discussed by Wesley (10). He proposed that the observed electrochemical behavior of nickel might be usefully explained in terms of the electronic structure of the nickel atom. The fundamental cause of the passivation tendencies and the high anodic overvoltage for the dissolution of nickel lies in the existence of vacancies in the 3d orbitals. This view is consistent with Piontelli's classification (16) of metals. The "inert" metals, *e.g.*, nickel, cobalt, rhodium, palladium, platinum, chromium, all have incomplete electron subshells. Additional correlation between passivation tendencies and electronic structure may be found by considering the initiation of passivation as involving chemisorption of some species from solution. The usual order of decreasing heat of chemisorption values is

$$Ta > W > Cr > Fe > Ni > Rh > Cu > Au$$

Trapnell (17) has pointed out that this sequence correlates well with that of decreasing d-electron character of the metal bond. It should be pointed out that this sequence also correlates well with the known passivation tendencies of these metals.

As has been emphasized by Wesley, the outer electronic arrangement in the "free" nickel atom would be $(3d)^8\,(4s)^2$. However, in solid nickel the outer electronic arrangement on a statistical basis (18) would be $(3d)^{9.4}\,(4s)^{0.6}$. This then allows for the existence of atoms of nickel with configurations $(3d)^{10}\,(4s)^0$, $(3d)^9\,(4s)^1$ and $(3d)^8\,(4s)^2$. The first two configurations have been shown to predominate. In solution, the nickel-aquo complex has eight electrons in 3d orbitals. The high activation overvoltage of nickel is due to the rearrangement of the outer electronic structure [*e.g.*, $(3d)^{10}\,(4s)^0 \rightarrow (3d)^8\,(4s)^2$] necessary before the nickel atom goes into solution. The role of impurities then

was pictured as catalyzing the electron rearrangement and transfer. On this basis, Wesley concluded that the desirable impurity should be one which can accept an electron.

The ability of an atom to attract or accept electrons is the usual definition of electronegativity. A logical extension of the above ideas is that the effectiveness of an element in increasing reactivity should be related to its electronegativity. The electronegativities of some of the elements have been calculated using a new method (19) and the values are in good agreement with those calculated by Mulliken who defined electronegativity as the average of the sum of the first ionization potential and the electron affinity.

With respect to electronegativity, the relative effectiveness of the additives studied would be

$$S > P > C > Si$$

which is in agreement with the order deduced from the polarization studies. The electronegativities of selenium and tellurium would be expected to fall between those of sulfur and phosphorus.

A detailed mechanism for the activation effects cannot be offered on the basis of the evidence presented. The discussion in terms of electronic structure, however, does not preclude a mechanism involving specific adsorption of anions. Unpublished data indicate that adsorption of an anionic species containing one of the Group VI elements would account for the effects of the additives on the reactivity of nickel.

Conclusions

Small amounts of impurities have considerably greater effect on the reactivity of nickel than large changes in structure. Cold-working of nickel interferes with its tendency to passivate on anodic polarization.

The elements sulfur, selenium, tellurium, and phosphorus increase the reactivity of nickel and inhibit passivity significantly. The relative effectiveness of the additives is related to their electronegativities.

Acknowledgments

The authors acknowledge with appreciation the permission of The International Nickel Company, Inc., to publish the data in this paper. They would also like to dedicate this paper to Dr. W. A. Wesley on the occasion of his retirement from the Research Laboratory.

Manuscript received April 30, 1964; revised manuscript received Sept. 25, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

Nonaqueous $AgNO_3$ Solutions: Electrical Conductance and Viscosity in CH_3CN and C_6H_5CN

George J. Janz, A. E. Marcinkowsky, and Iqbal Ahmad

Department of Chemistry, Rensselaer Polytechnic Institute, Troy, New York

ABSTRACT

The electrical conductance, viscosity, and density of silver nitrate solutions in anhydrous acetonitrile and benzonitrile in the concentration range up to 6M at 25°C are reported. The Bjerrum and Fuoss- Kraus criteria for ionic aggregates clearly confirm the formation of ion pairs as the concentration increases from the dilute range, with evidence for higher aggregates (triple ions) with further concentration increase. The partial molar volume data support the view that CH_3CN has a more open solvent structure than either C_6H_5CN or H_2O. The solvation interactions, and the equivalent conductances are examined from current semi-empirical viewpoints and discussed relative to aqueous solutions of comparable $AgNO_3$ concentrations.

In nonaqueous media the inorganic solutes are, all too frequently, sparingly soluble. Selection of electrolytes for the investigation of concentrated solution in organic media is more limited than in aqueous media. Silver nitrate is one of the few inorganic solutes having a high solubility in polar organic solvents, such as acetonitrile (12 moles liter^{-1}) and benzonitrile (> than 4 mole liter^{-1}). The present communication reports the results of conductance and viscosity measurements for $AgNO_3$ in these two solvents up to 6M concentrations. In the very dilute range Walden and Birr (1), and Griffith and Lawrence (2) have reported

data for $AgNO_3$ in CH_3CN and C_6H_5CN; results for the concentrated range are almost nonexistent. Concentrated aqueous solutions of $AgNO_3$ have been thoroughly investigated, especially by Campbell and Kartzmark (3). The present results are examined in light of current viewpoints for ionic interactions and solvation in concentrated electrolytes.

Experimental

The procedures for the purification of CH_3CN and C_6H_5CN have already been described (4, 5). The physical constants of the solvents used were as follows: CH_3CN; bp 81.7°C; $d^{25/4}$, 0.7768; κ, 5.9×10^{-8} ohm^{-1} cm^{-1}; η, 0.359 cp; C_6H_5CN; bp 190.7°C; $d^{25/4}$, 1.0088; κ, 7.6×10^{-8}; η, 1.024.

Silver nitrate (analytical grade) was vacuum dried at moderately high temperatures (120°C) and stored over $Mg(ClO_4)_2$ until required.

The conductance measurements were made with a Jones bridge (L&N) with accessories. The cell constants of the cells were 32.177, 1.258, and 0.054 cm^{-1}. Correction for polarization effects at the bright platinum electrodes was by extrapolation to infinite frequency, and all measurements were also corrected for the conductance of the solvent. Values of equivalent conductance of the two series of the solutions are in Table I. The phoreograms[1] are in Fig. 1 and 2.

Densities were determined to an accuracy of ±0.004% (25°±0.02°C) using a 25 ml pycnometer (Fisher Scientific Company, Weld Type). Viscosity measurements (25°±0.02°C) for the $AgNO_3$ solutions (CH_3CN and C_6H_5CN) were with Ostwald viscometers (Cannon Fenske design, Fisher Scientific Company). Calibrations were with conductivity water and benzene (Fisher Reagent Grade) as standards. Exits to room atmosphere were vented through $Mg(ClO_4)_2$ guard tubes. The viscosities were corrected for the kinetic energy term by calculation (6). Tables II and III summarize the results.

Strict precautions were observed to maintain anhydrous conditions during all solvent and solution transfers.

Discussion

An estimate of the solute-solvent interactions can be gained from a knowledge of the molar volumes of the solvated electrolyte. Using the extension of Einstein's theory of viscosity (7) for solutions by Vand (8), it follows that the expression

$$\log \eta_{rel} = \frac{AC}{1 + Q'C} \quad [1]$$

may be used to gain $\overline{V}$, the effective molar volume of the solvated electrolyte. Here η_{rel} is the relative viscosity of the solutions, A and Q' are 2.5 $\overline{V}$/2.303 and $Q\overline{V}$, respectively.[2] Using the data in Tables II and III, values for $\overline{V}$ for $AgNO_3$ in CH_3CN and C_6H_5CN are, respectively, 0.230 and 0.293 liter mole^{-1}. Correcting for the molar volume of $AgNO_3$ (0.039) and dividing by the molar volume of the solvent, the solvation number in the two solvents are found to be 3.7 and 2.5, respectively. These solvation numbers appear valid for increasing concentrations up to 5M for CH_3CN and 4M for C_6H_5CN. Above 5M in CH_3CN, the molecular ratio ($CH_3CN/AgNO_3$) is less than 3 (*e.g.*, at 6.2M, this ratio is 2.6). At still higher concentrations the solvent may well be present almost entirely as "bound" solvent, *i.e.*, the ions are dispersed in a solvent medium present almost entirely as primary solvation sheath solvent. Discussion of the properties of $AgNO_3$ in this concentration range awaits completion of vibrational and magnetic resonance spectroscopic studies in progress in this laboratory.

The question of solvation interactions for $AgNO_3$ has been investigated by Strehlow and Kopp (9) using CH_3CN solutions in Hittorf-type electrolyses. It is recognized (10) that such measurements give an estimate of the total solvation number as distinct from the number bound in the primary solvation sheath. Values of 9 and 4 were thus reported for the Ag^+ ion and NO_3^- ion, respectively, in CH_3CN solutions. This very marked solvation undoubtedly contributes directly to the high solubility of this solute in CH_3CN. Comparable measurements have not been reported for $AgNO_3$ solutions in C_6H_5CN.

From the densities of the solutions given in Table III, the apparent molal volumes of the solution were calculated from the expression (11)

[1] Refer "Nomenclature For Conductance," *J. Chem. Ed.*, **32**, 527 (1955). A phoreogram is defined as the curve in which the equivalent conductance is plotted against the square root of the concentration.

[2] Q is an interaction parameter dealing with mutual interference between the particles and with their Brownian motion; various authors agree only that it does not differ greatly from unity.

$$\Phi_V = \frac{1000}{cd_o}(d_o - d) + \frac{M_2}{d_o} \qquad [2]$$

where Φ_V is apparent molal volume, c is concentration in mole liter^{-1}, d_o and d are the densities of the solvent and the solution, respectively, and M_2 is the molecular weight of the solute. The Φ_V values thus calculated are given in Table III. Inspection shows that Φ_V in CH_3CN varies from 16.3-21.4 ml mole^{-1} in the conc. range 1-4 mole liter^{-1}, while in C_6H_5CN it varies from 27.2 to 28.2 from 0.5-3 mole liter^{-1}; this is to be compared with aqueous solutions where it increases from 31.6-34.4 cc mole^{-1} in the conc. range 1-6 mole liter^{-1}. The theoretical significance of the partial molal volumes relative to the solute and solvent have been reviewed by Stern and Amis (10). Two points may be noted in the present results. The value for Φ_V for comparable concentrations is considerably smaller in CH_3CN than in C_6H_5CN and aqueous solutions, and less than the molar volume for $AgNO_3$ in the solid state (39.0). The concentration dependence for Φ_V is much larger in CH_3CN solutions. It follows from the relatively small values of Φ_V in the dilute concentration range in CH_3CN that this solvent has a more open or "loose" structure than either C_6H_5CN or H_2O.

Comparison of the electrical conductivities for $AgNO_3$ in CH_3CN and C_6H_5CN with the corresponding aqueous concentration range in light of the solvent viscosities is of interest. The high value for Λ_o, 188.8$_0$, in CH_3CN undoubtedly reflects directly the relatively low values for viscosity, 0.36 cp and dielectric constant, 35. (cg. H_2O. η, 0.897 c.p., ϵ, 78.5 Λ_o, 133.3$_6$). Comparison of the Λ_o values for $AgNO_3$ in CH_3CN and C_6H_5CN (ϵ, 25; η, 1.024) shows more clearly the viscosity effect since the latter has a dielectric constant more nearly that of CH_3CN and viscosity closely comparable to H_2O. The values for Λ_o in CH_3CN and C_6H_5CN are, respectively, 188.8$_0$ and 52.4. Similarly the marked decrease of Λ with increasing concentrations (6M: 4.5 and 40 for $AgNO_3$ in CH_3CN and H_2O, respectively) also correlates with the viscosity changes (6M: 10.4 and 1.7 cp for $AgNO_3$ in CH_3CN and H_2O, respectively). Any attempt at a complete description of the properties of electrical conductance for $AgNO_3$ in these nonaqueous media must take due cognizance of these factors. An evaluation of the semi-empirical Wishaw-Stokes conductance equation (12)

$$\Lambda = \left(\Lambda_o - \frac{\beta\sqrt{c}}{1 + Ba\sqrt{c}}\right)\left(1 - \frac{\delta\sqrt{c}F}{1 + Ba\sqrt{c}}\right)\frac{\eta_o}{\eta} \qquad [3]$$

is nevertheless of interest in view of its moderate success for concentrated aqueous solutions. As with aqueous $AgNO_3$ solutions (3), calculations show that the experimental data are approached if moderately small values for a (2.3Å) are used in Eq. [3] for the dilute region; at concentrations greater than about 2 mole l^{-1}, an ion size parameter of 4.35Å must be used to approximate the experimental values. Larger values for a (*e.g.*, 6-8Å) give poorer agreement in this concentration range. Values for a for comparable $AgNO_3$ aqueous concentrations found by Campbell and Kartzmark (3) were, respectively 2.3 and 4.35Å. The calculations serve to emphasize the empirical nature for the values of a in this conductance equation. Inspection of the phoreograms for the CH_3CN, C_6H_5CN, and H_2O solutions, Fig. 1(i), 2(i), and 3 (i), respectively, shows that the former two are quite characteristic of highly associated electrolyte solutions. The criteria for ion-pair and triple-ion aggregates based on the Bjerrum and Fuoss-Kraus ionic interaction schemes (13-15) are illustrated by the log Λ-log c graphs, and the effect of taking cognizance of the viscosity differences, *i.e.*, log $\Lambda\eta/\eta_o$, is also shown, Fig. 1(ii), 2(ii), and 3(ii), for these three solvent systems.

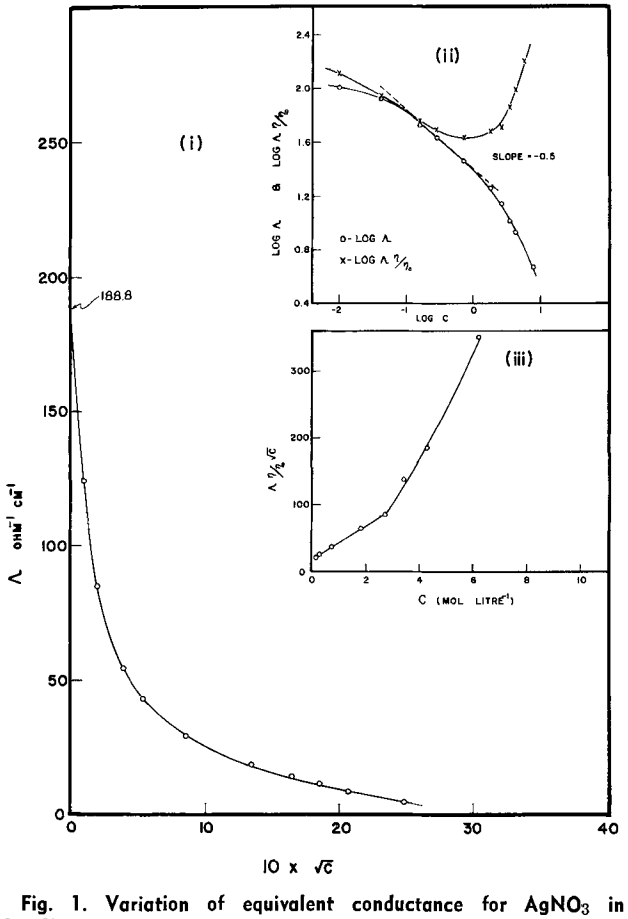

Fig. 1. Variation of equivalent conductance for $AgNO_3$ in CH_3CN, 25°C.

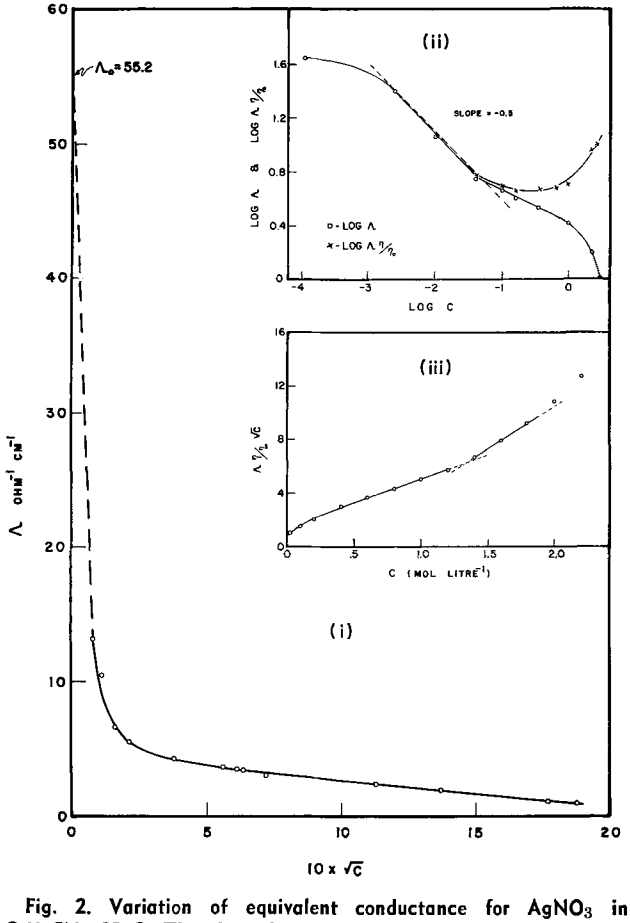

Fig. 2. Variation of equivalent conductance for $AgNO_3$ in C_6H_5CN, 25°C. The dashed extrapolation to infinite dilution is the data of Griffiths, Lawrence, and Pearce (2).

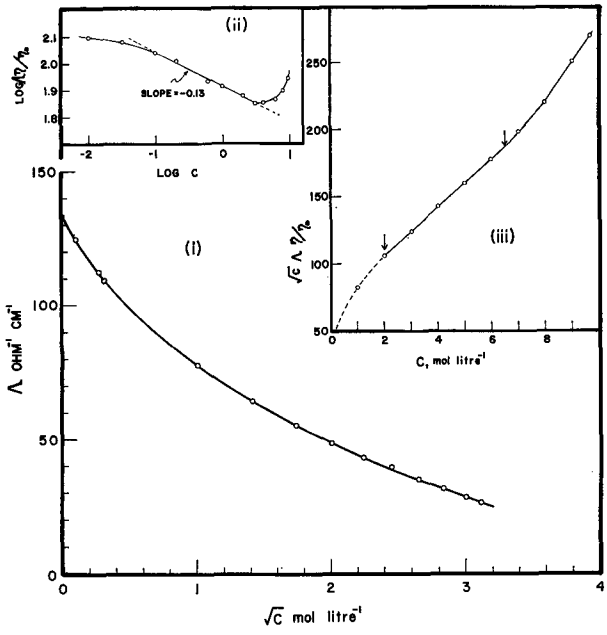

Fig. 3. Variation of equivalent conductance for $AgNO_3$ in water, 25°C, based on the data of Campbell and Kartzmark (3). The arrows (3.1A) indicate the limits proposed for triple-ion formation.

It is seen that in both the nonaqueous systems the value of the slope predicted for ion-pair formation, namely, $-\frac{1}{2}$, holds for a short range as the concentration is increased from the very dilute range. With increasing concentrations the log $(\Lambda\eta/\eta_0)$, curves show the minimum characteristic of triple-ion aggregate formation (8, 9). For the corresponding aqueous solutions, Fig. 3(ii), the log Λ and log $(\Lambda\eta/\eta_0)$ graphs are quite similar, but the value for the slope of the linear region prior to the minimum is markedly less than $-\frac{1}{2}$.

The minima in the log $(\Lambda\eta/\eta_0)$ curves, Fig. 1-3(ii), shift to higher concentrations as the dielectric constant of the solvent increases; this is in accord with the prediction for ionic interactions based on the solvent dielectric properties.

A possible additional empirical criterion for ion aggregate formation in electrolytes is the $(\Lambda\eta/\eta_0)\sqrt{c}$-c graphical analysis illustrated as (iii) in Fig. 1-3, respectively. The linear regions correlate well with the regions for ionic association (c.f. Fig. 1-3, ii), pairwise and higher aggregates; the inflexion point corresponds approximately with the transition from the region of predominant ion-pair aggregates to triple-ion aggregates in these solutions.

Technical Notes

Intergranular Corrosion Penetration in an Age-Hardenable Aluminum Alloy

H. Nichols and W. Rostoker

Metals and Ceramics Division, IIT Research Institute, Chicago, Illinois

It is common knowledge that the commercial aluminum alloy 2024 (nominally 4.5% Cu, 1.5% Mg, 0.6% Mn) is susceptible to stress corrosion cracking in saline solutions. Even in the absence of stress, the loss of tensile strength from protracted immersion in these solutions is appreciable (1). This latter effect results from a form of intergranular attack which is generally termed intergranular corrosion. As may be seen in Fig. 1, whereas the stress corrosion cracks follow a fairly sharply directed intergranular path, the intergranular corrosion zone moves in from the surface as a plane front behind which the individual grains have been separated from their neighbors. It is to be noted also that the depth of the zone of intergranular separations is often not much less deep than the maximum penetration of the stress corrosion cracks.

This paper describes the unusual temperature dependence of the penetration of this intergranular penetration zone in the absence of externally applied stress. Small coupons were cut from commercial sheet of 0.125 in. thickness. The edges were carefully machined and the coupons were re-heat-treated after machining to size so that the metallurgical condition at the edges was restored to that of the bulk of the material and residual macrostresses from the manufacturing history were eliminated. The oxide film from heat-treatment was dissolved off by a brief immersion in dilute caustic solution. The washed and dried specimens were totally immersed for 70 min in a solution containing 53 g/l of NaCl, 50 g/l of Na_2CrO_4 and HCl in amount sufficient to adjust the *p*H to about 2. Upon removal, washing, and drying, the specimens were sectioned and the depth of penetration of the intergranular attack measured with a metallurgical microscope. Because of the friability of the surface, the depth of penetration was calculated from the center section between the two approaching zones of intergranular penetration. The temperature of the solution was varied between 0° and 80°C. Results are summarized in Fig. 2 (a, b, c) for three states of aging.

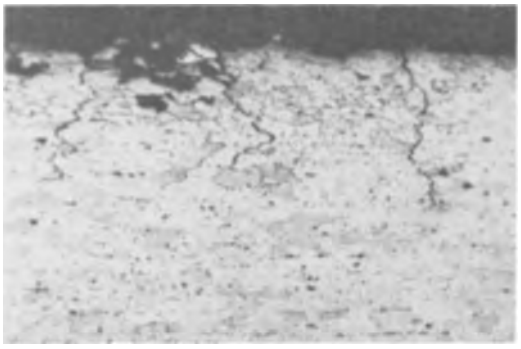

Fig. 1. Illustration of intergranular penetration of stress corrosion cracks in a tensile specimen of age-hardened Al 2024 alloy which had been immersed under stress in a $NaCl\text{-}Na_2CrO_4\text{-}HCl$ solution. Magnification 75X.

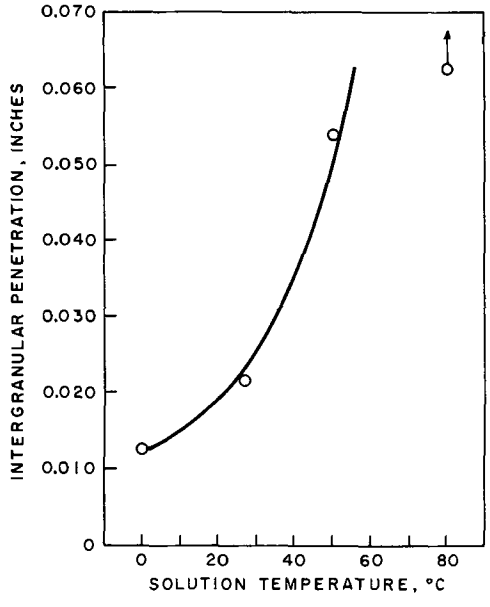

Fig. 2a. Intergranular penetration of Al 2024 alloy in three heat-treated states; solution $NaCl\text{-}Na_2CrO_4\text{-}HCl$; immersion time, 70 min; alloy annealed (furnace cool).

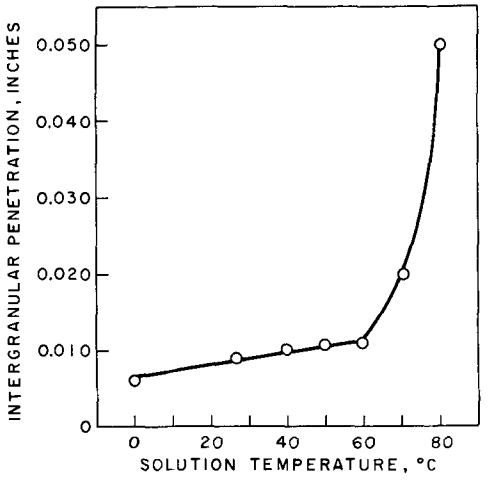

Fig. 2b. Alloy aged 210°C, 30 min

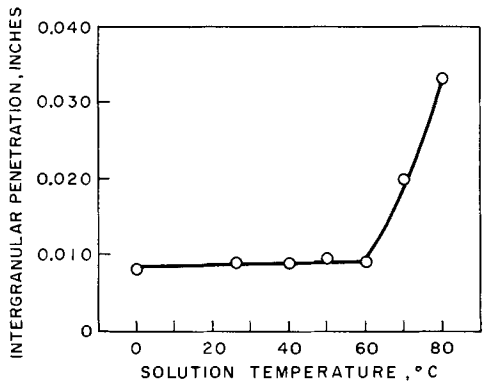

Fig. 2c. Alloy aged 100°C, 30 min

The trends have some unusual aspects. For the 100°C aged condition, intergranular penetration is finite but independent of temperature from 0° to 60°C. Above 60°C, the rate of penetration increases abruptly. For the 210°C aged condition, there is a slight temperature dependence between 0° and 60°C and, again, above 60°C an abrupt increase. For the annealed condition, a strong temperature dependence exists over the whole range of temperatures. The data point with the arrow at 80°C in Fig. 2(a) indicates that intergranular attack in 70 min had penetrated to the center of the specimen which, in fact, had disintegrated. From these observations we may deduce that two processes are operative, one of which is limited to the lower range of temperatures and is peculiar to the age-hardened state.

In that a strong temperature dependence is operative over the whole range of temperatures, the behavior of the annealed state conforms to the expectation of a corrosion process. The independence (or near independence) of the age-hardened states in the temperature range of 0°-60°C is clearly not the expected behavior of a corrosion process.

The temperature independence of the intergranular penetration rate is, however, closely similar to the corresponding behavior of cracking under externally applied stress (2). In this previous publication it was shown that stress corrosion cracking rates for this alloy in the same state of heat-treatment are constant in the same temperature range. It seems reasonable, therefore, to consider the role of internally existing stresses. We postulate that in the age-hardened state, significant stresses exist transverse to grain boundaries and that at the lower temperatures, intergranular penetration is a process of stress corrosion cracking on a microscale. For this material, microscale, stress corrosion cracking is more rapid in the range 0°-60°C but not being appreciably temperature dependent is supplanted at some higher temperature by a process of selective corrosion along intergranular paths which is strongly temperature dependent.

It is inescapable that a question should be raised as to the compatibility between a demonstrated, temperature-independent process of intergranular penetration and the theory of stress corrosion cracking which is based on an intergranular corrosion mechanism (3). It is the purpose of this paper to do just this.

Shaped Electrode Design

F. H. Edelman and R. W. Klopfenstein

RCA Laboratories, Radio Corporation of America, Princeton, New Jersey

In the deposition of a magnetic alloy film on to a metallized glass capillary, it was found that there were large compositional and thickness gradients along the length of the tube which could be attributed to the substrate resistance. The cell used is shown in Fig. 1. The cathode is rotated during the electrodeposition and is surrounded by the stationary concentric cylindrical anode. The cell is essentially one of concentric cylindrical electrodes whose ends are insulating planes at right angles to their common axis. This configuration

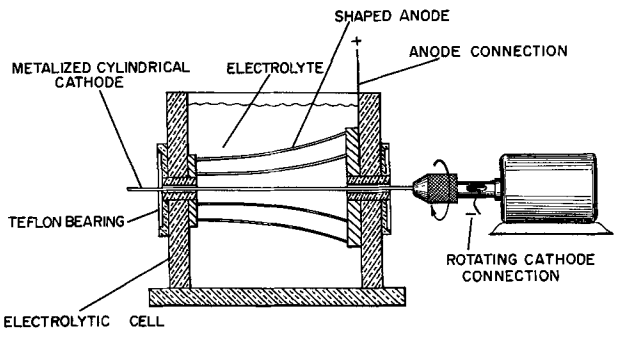

Fig. 1. Shaped anode cell

using electrodes of negligible resistance results in a uniform primary current distribution.

Methods for calculating the effect of an appreciable electrode resistance on current density distribution in an electrolytic cell, for substrates of various geometries, have been proposed (1-3). Waber, assuming that the overvoltage was a linear function of the current density, added a polarization term (4) and showed that for concentric cylinders the change of current along the length of the electrode takes the form of

$$\frac{d^2 I}{dx^2} - \frac{\rho_m}{2\pi a t\left[\frac{\rho_e}{2\pi}\ln\left(\frac{b}{a}\right) + \frac{1}{p}\right]} I = 0 \quad [1]$$

It is seen from Eq. [1] that a knowledge of the polarization is required in order to calculate the current distribution.

One method for compensating for the high cathode resistance is to shape the electrode in such a manner that the annular space between the electrodes is made to vary with the distance from the plating contact in a predetermined manner which will be derived.

In the following development, the assumption is made that the electrolytic current flows entirely in a radial direction. There will, in fact, always be a small

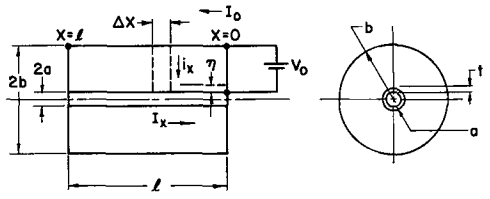

Fig. 2. Electrolytic circuit

component of current flow in the axial direction near the shaped electrode. The effect of this axial component will be quite small, however, when the change of conductor shape is reasonably gradual. The same type of approximation is often introduced in other similar design problems as in the design of tapered transmission lines (5).

Referring to Fig. 2, the voltage drop per unit length along the thin layer conductor

$$\frac{dV}{dx} = -\frac{I\rho_m}{2\pi at} \qquad [2]$$

and $\rho_m/2\pi at$ is the resistance of the metallized conductor. The electrolytic current is equal to the decrease in current per unit length

$$i = -\frac{dI}{dx} \qquad [3]$$

The voltage drop in the electrolytic system at a point x is

$$V = \eta + \left[\frac{\rho_e}{2\pi}\ln\left(\frac{b}{a}\right)\right] i \qquad [4]$$

where polarization is a function of the electrolytic current density

$$\eta = f(i) \qquad [5]$$

and $\rho_e/2\pi \ln b/a$ is the resistance per unit length of the electrolyte between concentric cylindrical electrodes of radius a and b.

Differentiating [4] with respect to distance

$$\frac{dV}{dx} = \frac{d\eta}{di}\frac{di}{dx} + \frac{\rho_e}{2\pi}\ln\left(\frac{b}{a}\right)\frac{di}{dx} + \frac{1}{b}\frac{\rho_e}{2\pi} i \frac{db}{dx} = -\frac{\rho_m}{2\pi at} I \qquad [6]$$

where the outer radius b is a function of x but the inner radius a is constant. For uniform current density

$$\frac{dI}{dx} = K = -\frac{I_o}{l} \qquad [7]$$

It follows from [7] that

$$I = I_o\left(1 - \frac{x}{l}\right) \qquad [8]$$

and substituting [3] in [6]

$$\frac{d\eta}{di}\frac{d^2I}{dx^2} + \frac{\rho_e}{2\pi}\ln\left(\frac{b}{a}\right)\frac{d^2I}{dx^2} + \frac{\rho_e}{2\pi b}\left(\frac{db}{dx}\right)\left(\frac{dI}{dx}\right) = \frac{\rho_m}{2\pi at} I \qquad [9]$$

Substituting [7] and [8] into [9] and rearranging

$$\int_{b_o}^{b}\frac{db}{b} = \int_{o}^{x} -\frac{\rho_m(l-x)}{at\,\rho_e}dx \qquad [10]$$

Integrating

$$\ln\frac{b}{b_o} = -\frac{\rho_m x\left(l - \frac{x}{2}\right)}{at\,\rho_e} \qquad [11]$$

and letting

$$A = \frac{\rho_m}{at\,\rho_e} \qquad [12]$$

$$b = b_o \exp\left[-Ax\left(l - \frac{x}{2}\right)\right] \qquad [13]$$

It is interesting to note that there is no polarization term in Eq. [13], which describes the change in radius of the anode along its length in order to achieve a uniform current density. Under the condition of uniform current density, the effect of polarization is to introduce a constant voltage drop along the line (no assumption concerning the linearity of the relationship between polarization and current density need be made). Polarization, therefore, has no influence on the shape of the electrode required to produce uniform current. When the ratio of the specific resistivity of the electrode to that of the electrolyte is very small (as is the case for bulk conductors), the value of A in Eq. [13] approaches zero. This results in b being almost identical with b_o, and no shaping of the electrode is required for uniform current density.

Fluorescent Properties of Red-Emitting Europium-Activated Phosphors with Cathode Ray Excitation

A. Bril, W. L. Wanmaker, and C. D. J. C. de Laat

N. V. Philips'Gloeilampenfabrieken, Eindhoven, Netherlands

Some years ago data were reported on the efficiencies of phosphors for color television tubes and, moreover, the lumen contributions of the blue, green, and red phosphors required for obtaining a white fluorescence were calculated (1, 2). These calculations were made for various sets of primary phosphors for color television.

The factors which together determine the lumen contributions for each primary phosphor are: (*a*) the radiant efficiency; (*b*) the lumen equivalent (*i.e.*, the lumen efficiency for 100% radiant efficiency); (c) the "weight" of a lumen, which is proportional to $1/y$ (where y is the C.I.E. chromaticity coordinate of the light emitted by the phosphor). For red phosphors used at present, *viz.*, $Zn_3(PO_4)_2$-Mn and (0.2 Zn, 0.8 Cd) S-Ag, the second factor was rather unfavorable due to the broad emission band of these phosphors and the third because of the relatively high y-value of the phosphors.

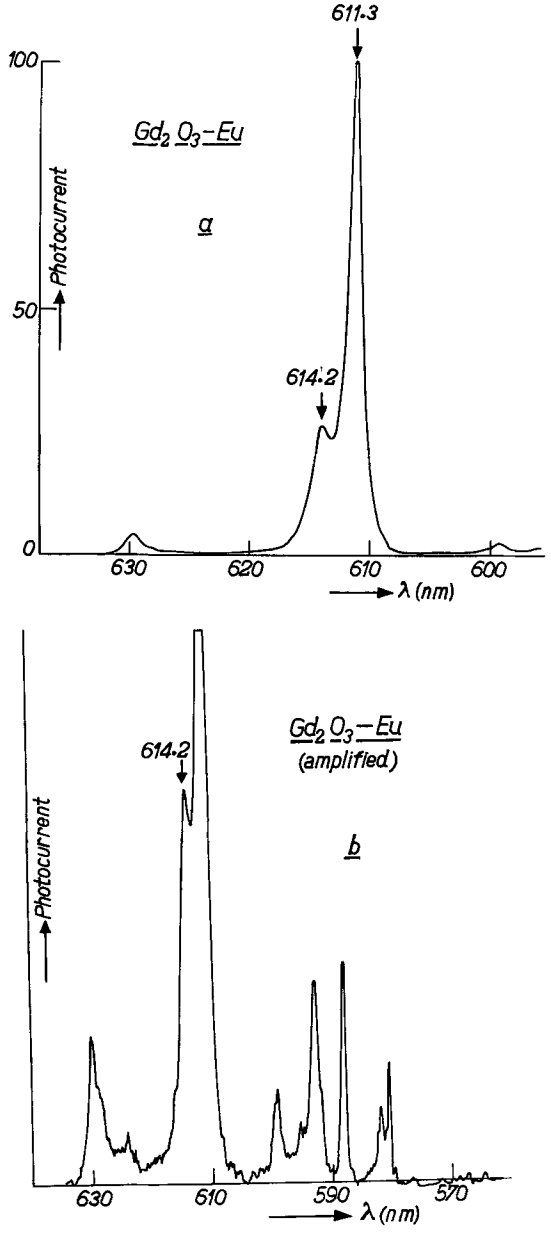

Fig. 1a and b. Spectral energy distribution curve of the emission of Gd_2O_3-Eu. Cathode-ray excitation. Many weak lines in green and blue are also present.

From the much higher lumen efficiency of the sulphide phosphor, we concluded that this phosphor was more suitable as a red component than the $Zn_3(PO_4)_2$-Mn phosphor [See ref. (1) and (2)].

We stated in ref. (1) that, when searching for better red phosphors, one should keep in mind that, apart from having a good efficiency, the phosphor should have a narrow band emission peaking at about 610 nm, because the color coordinates corresponding to this wavelength are about the same as those chosen for the red primary, being about $x = 0.66$, $y = 0.34$. However, at that time such phosphors were not known.

Later on we found though, that phosphors activated with europium have emission lines quite near 610 nm, corresponding to transitions from the $^5D_0$ to the $^7F_2$ energy level. For more details we refer to ref. (3). Many other lines also occur due to the fact that the ground level of the Eu^{3+} ion is split sevenfold, while further splitting of the levels occurs owing to the crystal field (Stark splitting). In many Eu-activated phosphors, then, orange lines in the region 580-590 nm are as strong as or even stronger than the lines near 610 nm.

We found that europium-activated gadolinium-oxide and yttrium-oxide are very favorable for the purpose described above, the red lines at 611.3 and 614.2 nm being very much stronger than the other lines. The photoluminescence of these phosphors, which was first described by Urbain (4), has also been studied by Wickersheim and Lefever (5), by Ropp (6), and by Chang (7). Y_2O_3-Eu, like the Gd_2O_3-Eu, shows a very strong 611.3 nm emission peak, being about 10 times more intense than the 580-590 nm emission lines. In europium-activated Gd-borates, $GdPO_4$, La-borates and $EuPO_4$ studied by us (3), the orange lines are much stronger than in Gd_2O_3-Eu. In Fig. 1 the spectral energy distribution of Gd_2O_3-0.06 Eu for 20 kv cathode ray excitation is given. The spectral energy distribution of Y_2O_3-Eu is quite similar to that of Gd_2O_3-Eu. The location of the emission peaks in various host lattices is about the same; apparently the transition probabilities are much more sensitive to the effects of the surroundings of the Eu-ions than the position of the energy levels. The width of the lines is about 1.0 nm at room temperature.

In the preparation of the Eu phosphors we started with EuF_3 (99.9%), La_2O_3 (99.99%), and Y_2O_3 (99.9%) as obtained from the Lindsay Chemical Division of American Potash and Chemical Corporation; Gd_2O_3 (99.9%) and Eu_2O_3 (99.9%) were obtained from Michigan Chemical Corporation. In general, the thoroughly mixed starting materials were fired once or twice for 2 hr at a temperature of 1200°C. Better results were obtained when a fluorine compound was added to the firing mixture. The fluorine was added as ammonium-fluoride and europium-fluoride. In Fig. 2 data are given for some phosphors made with various amounts of

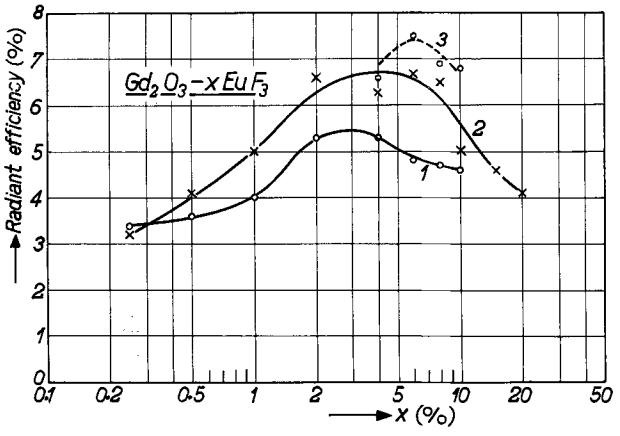

Fig. 2. Effect of Eu- content added on the radiant efficiency (cathode ray excitation) of Gd_2O_3-Eu phosphors: curve 1, firing once; curve 2, firing twice; curve 3, firing three times; all for 2 hr at 1200°C.

europium-fluoride added; moreover, before firing 0.10 mole of ammonium-fluoride per mole of Gd_2O_3 was added to each sample.

In Table I, a comparison is given of the efficiency of Eu-activated Gd_2O_3, Y_2O_3, and La_2O_3. Furthermore, some figures are given for Gd_2O_3-Eu prepared with Eu_2O_3, Eu_2O_3 + NH_4F, and EuF_3, respectively. With a low Eu-content, *viz.*, lower than about 0.04-0.06 gram atom Eu per mole rare earth oxide, the intensity of the 580-590 nm emission lines becomes more intense. The preparation conditions also have an influence on this effect.

Table II presents the efficiency of Gd_2O_3-Eu together with the efficiencies of the red fluorescent phosphors, which are used to-day as a red primary in color television tubes.

The radiant efficiency of Gd_2O_3-Eu is as high as or even higher than efficient manganese-activated phosphors, like willemite and zinc phosphate. It can be seen further from Table II that Gd_2O_3-Eu, due to its high lumen equivalent, has a much higher lumen efficiency than the (0.2 Zn, 0.8 Cd) S-Ag phosphor, in spite of its lower radiant efficiency compared with the latter phosphor. This means, too, that the lumen efficiency of a white color obtained with the blue, green, and red primaries (for equal signal ratio) increases to the same extent when Gd_2O_3-Eu is used (*i.e.*, the light output is about 100% higher than with the use of zinc cadmium sulfide).

The red zinc cadmium sulfide phosphor, activated with silver, has not only a higher light output, but also a much shorter decay time (about 0.04 msec) than $Zn_3(PO_4)_2$-Mn (about 12 msec). This is of advantage

Table I. Radiant efficiency (cathode ray excitation) of europium activated rare earth oxides

Cathode rays at 20,000v and 1 μa/cm². RE_2O_3 = Rare Earth Oxide. Phosphors fired twice for 2 hr at 1200°C.

Phosphor	Moles added/mole RE_2O_3 Eu_2O_3	EuF_3	NH_4F	Radiant efficiency, %
Gd_2O_3-Eu	0.04	—	—	5.1
	0.04	—	0.24	5.9
	—	0.08	—	5.9
Y_2O_3-Eu	—	0.06	0.10	5.8
La_2O_3-Eu	—	0.06	—	2.2

Table II. Characteristics of red-emitting cathode ray phosphors

Cathode rays at 20,000v and 1 μa/cm²

Phosphor	Radiant efficiency η, %	Lumen equivalent L, lm/w	Lumen efficiency l, lm/w	Decay time τ, msec
$Zn_3(PO_4)_2$-Mn	5.5	140	7.7	12-30
(0.2 Zn, 0.8 Cd) S-Ag	17	75	13	0.04
Gd_2O_3-0.06 Eu	8	330	26	0.9

in the case of slowly moving objects in television pictures. When the decay time becomes too long (of the order of the time in which one image is described) trailing of pictures occurs.

The Eu-activated phosphors have an exponential decay with $1/e$ value of 0.9 msec. This is not so short as the decay time of sulfides but, as far as we can see, short enough to give no troubles with moving objects.

Acknowledgments

The authors wish to express their thanks to Mr. J. G. Verlijsdonk and Mr. A. A. L. Sleutjes for preparing the phosphors and to Mr. J. A. A. Bertens for the assistance in the measurement of the spectral distribution.

Manuscript received Aug. 20, 1964.

Solid Solubility in the System GaSb-GaAs

M. E. Straumanis and C. D. Kim

Department of Metallurgical Engineering, School of Mines and Metallurgy, University of Missouri at Rolla, Rolla, Missouri

No data have been published until recently (1, 2) on the mutual solubility in the system GaSb-GaAs. However, in one article (1) only one point in the solid solubility region is mentioned.

Ivanov-Omskii and Kolomiets (3) reported that the zone equilibration method is an effective one to achieve an equilibrium condition for GaSb and InSb solid solutions. Since zone equilibration causes a change of composition in the heat-treatment ingot (GaAs may decompose), this method could not be used where the same stoichiometric composition had to be retained throughout the sample. Therefore, the method of long time annealing was used for all samples.

GaSb and GaAs were prepared from the elements of 99.99-99.999% purity and mixed to provide the compositions shown in Fig. 1. Small quartz vials were nearly filled with the finely ground powders, evacuated, and sealed. The small size was necessary in order to heat the vials uniformly from all sides to prevent segregation (4).

Each of the mixtures was initially heated at constant temperatures between 670° and 720°C for periods of

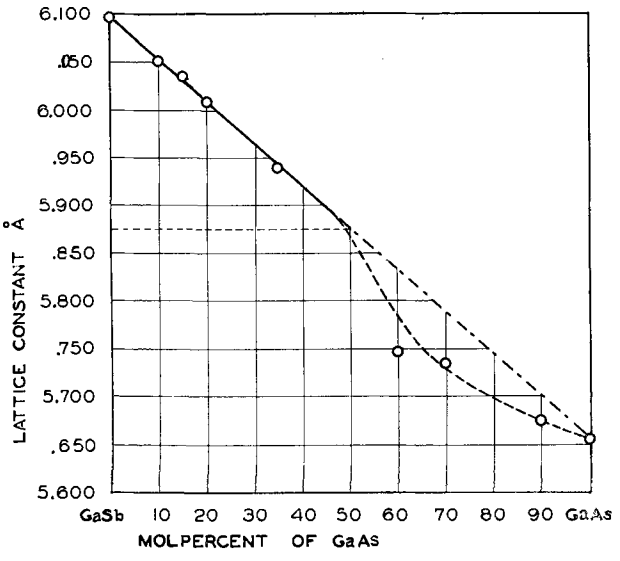

Fig. 1. Change of lattice constant a within the system GaSb-GaAs

5-10 days, and then quenched in ice water. On detection of lines of the starting products on x-ray powder photographs, the grinding and heating procedure was repeated until a uniform end product was achieved. The heating temperature was raised slightly from cycle to cycle. However, temperatures higher than 760°C cannot be applied because of decomposition.

The lattice parameters were determined at constant temperature of the sample (± 0.05°C) by placing the powder camera (64 mm in diameter) into a thermostated jacket. Asymmetric patterns, requiring no knowledge of the camera diameter for Bragg angle measurements, were obtained using Cr $K\alpha_1$, radiation ($\lambda = 2.28965$Å). As the powder mounts were very thin and nearly transparent for x-rays (about 0.2 mm in diameter) no absorption correction was made. The exposure time was about 50 min. The lattice parameter determination procedure has been described previously (5, 6).

The lattice constant of each cubic sample was computed from the last single line, which was $422\alpha_1$ (Bragg angle ~ 82°) for GaAs and $333\alpha_1$, (Bragg angle ~ 78°) for GaSb. The solid solutions yielded the same back reflection lines. Although these lines were fairly broad, the lattice parameter was determined with sufficient precision (± 0.0004Å). Figure 1 shows the changes in lattice parameters *vs.* composition of the solid solutions.

The lattice constants of the starting substances with the refraction correction included were:

GaSb $a = 6.09592 \pm 0.00004$Å at 25°C

GaAs $a = 5.65321 \pm 0.00003$ at 25°C

These lattice constants agree with those calculated from the tetrahedral atomic radii of Ga, As, and Sb for homopolar compounds (7). The lattice constants of all the solid solutions were in between these two values.

Due to the decomposition of the solid solutions above 760°C (the melting points of GaAs and of GaSb are 1237° and 712°C, respectively), their formation arises through solid-state diffusion reactions. Thus long periods of reaction are necessary. The same was observed for the system InAs-InSb (8).

It was interesting to note that the GaAs reacted much faster with the GaSb than the latter with the former to form the solid solutions; thus, the uptake of GaSb by pure GaAs was very slow. It took 20 days to dissolve 65 mole % GaSb in 35 of GaAs at temperatures up to 720°C. Nevertheless, weak lines of the pure GaAs were still present on the patterns. Assuming that the amount of unreacted GaAs was about 3 mole %, the lattice parameter of this composition is about 0.013Å too high. On the other hand, for the 50-50 point a value of 5.87 ± 0.02Å was obtained by Müller and Richards (1), which is nearly on the Vegard line. Therefore, a straight line was drawn through the first 5 points (there were no GaAs lines on the patterns for samples containing more than 65% GaSb), extending nearly to the 50-50 composition (Fig. 1). Beyond this point there is still solid solubility, but homogeneity could not be reached. There is a deviation from Vegard's law. It would be interesting to find whether equilibrium solid solutions with high GaAs content could be prepared by the flash evaporation method (2).

The difficult solid solubility is in agreement with the large difference of more than 15% in the atomic radii of Sb (1.36Å) and of As (1.18Å). Evidently upon contact of the GaSb and GaAs grains, the compounds diffuse into each other only very slowly because of the large size of their molecules. The initial diffusion is molecular because otherwise free Ga would remain, but none was observed in the x-ray patterns. Furthermore, it has been shown that Ga does not dissolve in GaSb and only in very small amounts in GaAs (9). After the formation of an extremely thin solid solution surface layer, the As atoms diffuse at a considerably more rapid rate than Sb into the grains causing a lattice contraction. This process is also faster than molecular diffusion. Thereby the replacement of the larger Sb atoms of the ternary system by the smaller As atoms (with resulting shrinkage of the lattice) is easier. The reverse process (Sb into GaAs) must be much slower, which explains the difficulty of formation of ternary solid solutions rich in As.

The Effect of Ionic Species on the Etching of Germanium

J. W. Faust, Jr.

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

The basic ingredient of most etchants is an oxidizing agent (1). In some cases, particularly semiconductors, a complexing agent is necessary to take the oxidized species into solution. Other ingredients, for example heavy metal ions, are sometimes added to vary the surface appearance. If cupric nitrate is added to a mixture of HF and HNO_3 (in the ratio of HF:HNO_3:5% $Cu(NO_3)_2$; 4:2:4), a chemical polish is obtained (2); the same mixture without the cupric nitrate yields a surface completely covered with terraced pyramidal pits. On the other hand, if silver nitrate is added, a preferential etch results whose pits are faceted by {111} planes (3). In studies directed toward deducing the etching mechanism of such etchants, the question arose as to what species was actually responsible for the preferential nature of the silver etch; one would naturally suspect the silver ion. In an effort to clarify this question, the following study was undertaken. Since the HF in this solution is a complexing agent and thus plays only a passive role in the dissolution mechanism, it was decided to investigate the other ions, *i.e.*, the hydrogen, nitrate, and heavy metal ions.

It has already been shown that certain of the heavy metal ions plate out on germanium (4); removal of the plated material yields a deeply pitted and nondescript surface. It was found, however, that the use of ultrasonic vibration during etching prevented the heavy metal from building up a deposit on the germanium thus leaving a fresh surface for further attack. It was thus possible to obtain etching of germanium by heavy metal ions (acting as the oxidizing agent) by the use of water as a complexing agent. For these experiments, two ultrasonic generators were used (*a*) a 400-watt unit operating at 20 kc, and (*b*) a 65-watt unit operating at 40 kc. Both units gave similar results. For actual operation, the beaker containing the etching solution was placed in the water bath of the ultrasonic generator and the power adjusted until cavitation resulted. Water solutions of the ions investigated are given in Table I along with their etch rates on {111} surfaces and a description of the surface.

As can be seen from Table I, the basic nitrate and the Cu ions give a nondescript etch pattern as shown by Fig. 1. The acid nitrate, however, gives excellent {111} planes parallel to the surface as shown in Fig. 2. All other etchants gave reasonably well-defined {111} etch patterns as shown in Fig. 3. The etch rate data is included only for comparison purposes, since the ultrasonic agitation generally increased the temperature of the etchant approximately 25° during the etching time. It is interesting to note, however, that the effectiveness of the ions in removing germanium (*i.e.*, the etch rates) is roughly in the order one would expect from free energy calculations based on such a reaction (*i.e.*, galvanic). The theoretical sequence is

$$Au > Pd > Ag > Hg > Cu >> Na$$

Table I shows only Pd out of place. It should also be

pointed out that these etch rates are very much higher than those obtained by Harvey and Gatos (5) for dissolved oxygen in water showing that this is a negligible factor compared to the galvanic attack.

The results indicate that neither the hydrogen, nitrate, hydroxyl, nor copper ions are responsible for the preferential attack on the {111} planes. Several heavy metal ions, in addition to silver, were found to give preferential attack on these planes. Furthermore, the results indicate that the use of ultrasonics in etching may be a very important parameter.

Manuscripts and Abstracts for Fall 1965 Meeting

Papers are being solicited for the Fall Meeting of the Society, to be held at the Statler-Hilton Hotel in Buffalo, N. Y., October 10, 11, 12, 13, and 14, 1965. Technical sessions probably will be scheduled on: Batteries (including symposia on Charging Characteristics of Batteries and Characteristics of Electrodes during Charging, Corrosion, Electrodeposition (including Symposium on Thin Film Technology), Electronics—Semiconductors, Electrothermics & Metallurgy (including a Symposium on Zirconium and Its Alloys).

To be considered for this meeting, **triplicate copies of the usual 75-word abstract, as well as of an extended abstract of 500-1000 words** (see notice on page 274C of the December 1964 issue), must be received at The Electrochemical Society, 30 East 42 St., New York, N. Y., 10017, *not later than May 14, 1965.* (Papers solely sponsored by the Corrosion Division **do not** require an extended abstract.) *Please indicate on 75-word abstract for which Division's symposium the paper is to be scheduled, and underline the name of the author who will present the paper.* No paper will be placed on the program unless one of the authors, or a qualified person designated by the authors, has agreed to present it in person. Clearance for presentation of a paper at the meeting should be obtained before the abstract is submitted. An author who wishes his paper considered for publication in the JOURNAL or ELECTROCHEMICAL TECHNOLOGY should send triplicate copies of the manuscript to the Managing Editor of the appropriate publication 30 East 42 St., New York, N. Y., 10017. Concerning papers to be published in the JOURNAL, see notice on per page charge on page 14C of this issue.

Presentation of a paper at a technical meeting of the Society does not guarantee publication in the JOURNAL or ELECTROCHEMICAL TECHNOLOGY. However, all papers so presented become the property of The Electrochemical Society, and may not be published elsewhere, either in whole or in part, unless permission for release is requested of and granted by the Editor. Papers already published elsewhere, or submitted for publication elsewhere, are not acceptable for oral presentation except on invitation by a Divisional program Chairman.

A New High-Performance Fuel Cell Employing Conducting-Porous-Teflon Electrodes and Liquid Electrolytes

L. W. Niedrach and H. R. Alford

Research Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

A low-temperature, aqueous electrolyte fuel cell employing new, "conducting-porous-Teflon electrodes" is described. The new electrodes show excellent performance characteristics with a variety of fuels (including hydrocarbons) and with both oxygen and air as the oxidant. Preparation methods are discussed, and performance data obtained with ambient temperature, hydrogen-oxygen and hydrogen-air cells are presented to illustrate their properties.

In earlier publications the use of "Conducting-Porous-Teflon Electrodes" in regenerative, matrix-type cells has been described (1, 2). While these cells are of some interest, particularly for applications in gravity-free space, they have not been given serious consideration for operation on a continuous feed basis. Under the latter conditions the matrix is responsible for some operational disadvantages; *e.g.*, at high current densities concentration polarization can occur at the electrodes, maintenance of the proper water balance in the electrolyte introduces design problems, and the internal resistances of the cells are higher than desired. In order to overcome these difficulties, work was directed at modifying and improving the original electrode structure so that the matrix could be eliminated. This has resulted in a new, high-performance fuel cell which operates with an aqueous electrolyte.

In seeking this objective two important restrictions concerning operation were deliberately imposed as being desirable: (i) The fuel (oxidant) gas-electrolyte interface was to be established within the electrode structure by "controlled wetting," and (ii) the electrodes were to be capable of operation at ambient atmospheric pressure. In addition emphasis was placed on retaining a relatively thin structure.

The new electrodes which are 5-10 mils thick, consist of a Teflon-catalyst mix that is pressed and sintered onto a suitable supporting screen which also serves as an excellent electronic conductor to carry current to the terminals of the cell. A porous Teflon film on the gas side of the electrode provides for proper control of wetting so that both the electrolyte and reacting gas have satisfactory access to the catalyst incorporated into the electrode. While alternative means of preparing electrodes were considered, *e.g.*, use of high Teflon-to-catalyst ratios and laminar structures with two different Teflon-to-catalyst ratios, the results obtained with the film covered electrodes were by far the most encouraging. These electrodes were found to be exceedingly reliable and readily manufactured in the laboratory. It was therefore elected to concentrate on electrodes of this type. The present paper is devoted to a discussion of their preparation and properties as exemplified by their performance in ambient temperature, hydrogen-oxygen and hydrogen-air cells. Platinum black was used almost exclusively as the electrocatalyst in the work to be reviewed and 6*N* KOH and 5*N* H_2SO_4 were the principal electrolytes.

The electrodes are exceedingly versatile, and some performance data obtained with other fuels and electrolytes have already been published. Thus, excellent performances have been reported for a variety of hydrocarbons, with a sulfuric acid electrolyte up to 89°C (3) and with a phosphoric acid electrolyte up to 200°C (3-5). In addition they have also been used effectively with methanol and a cesium carbonate electrolyte at temperatures up to 185°C (6).

Structure of the New Electrodes

Examples of the new electrodes are shown in Fig. 1. These were prepared by bonding platinum black-Teflon mixtures to the central areas of nickel screens. One quarter-inch-wide rings of 5-mil-thick Teflon sheet (du Pont's FEP Fluorocarbon Film) were used as seals around the peripheries. In mounting the electrodes in cell housings these seals are buried under the gaskets that are used. In another version the outer ring has been eliminated and the catalyst-Teflon mix has been spread uniformly over the entire circular area of the screen. Such electrodes perform equally well electrically and retain the electrolyte more reliably.

The important differences in the two surfaces of the electrodes are shown clearly in Fig. 1. The surface of the electrode on the left is coated with the porous Teflon film and is obviously exceedingly hydrophobic. In operation this side faces one of the gases. The untreated, electrolyte side of the electrode on the right has been wetted by drops of water placed upon it.

The photomicrograph in Fig. 2 brings out additional details of the electrode structure. It shows the surface film clearly at the top. As shown by the wire at the left, the screen is entirely imbedded in the catalyst-Teflon mix. It is pertinent to note that the starting catalyst consists of agglomerates of particles about 0.01μ in size. The ultimate size of the Teflon particles is about 0.2-0.5μ.

Experimental

Preparation of electrodes.—Most of the electrodes used in this work were prepared by a standard procedure. A Teflon suspension (du Pont's Teflon-30, which contained 59.6% solids by weight) was the

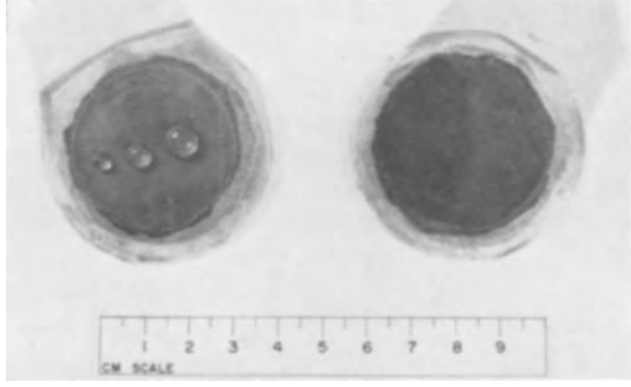

Fig. 1. Typical electrodes showing wetting characteristics

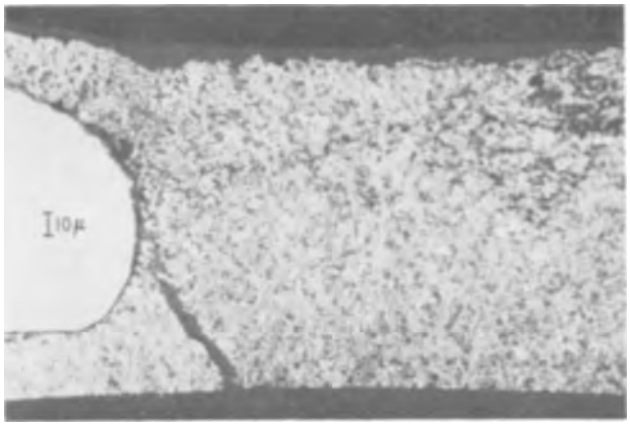

Fig. 2. Photomicrograph of a sectioned electrode showing the surface film on one side. Electrode No. 375. Body: 34 mg Pt black, 3.1 mg Teflon/cm^2; film: 2.4 mg Teflon/cm^2; nickel screen, 40 mesh; 4.5 mil wire. Magnification approximately 330X.

source of the binding material. Platinum black from Engelhard Industries, Inc., was used as the catalyst in most cases, but a few other catalysts were also used. Screen materials that were employed are listed in Table I. The nickel and silver were satisfactory in alkaline cells while the platinum screens could be used with the acidic cells as well.

While electrodes can be made with finer mesh screens of smaller wire size, it has been found that their resistances are high enough to be unattractive. In most of the work, therefore, 40- to 45-mesh screen made of 5- to 8-mil wire was used. In order to minimize the thickness of the electrodes, such screens were regularly rolled to a thickness corresponding to that of the individual wires. It was found necessary to leave wide tabs on the screens in order to reduce ohmic losses during operation of cells at high current densities.

Before making the electrodes themselves, a supply of Teflon films was prepared for use as surface coatings. This was done by spraying a Teflon-30 suspension diluted with seven volumes of water onto an aluminum foil using an air brush (Paasche, Type V). Films corresponding to 0.79, 1.6, 2.4, and 3.9 mg Teflon per cm^2 were used. In preparing these films a 5- by 5-in.^{2} area was marked on the aluminum foil, and an appropriate amount of the diluted Teflon suspension was used to coat this area to the desired thickness. Before spraying, a pattern of four circles having the diameter of the ultimately desired electrodes was scribed within the square to facilitate later steps in the preparation.

A fine spray was used so that several retracings of the pattern could be made in order to obtain a uniform thickness. During application, the aluminum foil was mounted on the bed of a hot plate which was maintained at 120°-150°C to facilitate evaporation of the water from the spray. The rate of application was such that wet areas did not develop and run on the foil.

Following the spraying, the foil was placed on the bed of the press (6-in. bed Carver press with individually heated platens) at 350°C and the jaws were closed to a gap of about ⅛ in. for about a minute. During this treatment the nonionic wetting agent in the Teflon suspension was rejected, and sintering of the Teflon particles occurred to form the desired film (7).

Spreads of platinum black (or other catalyst) with the Teflon-30 suspension were then prepared on circular areas on two aluminum foils, one of which had previously been coated with Teflon as described above. In preparing a typical spread to cover the entire circular area of the screen (17.7 cm^2), a 0.03 cc aliquot of the Teflon-30 suspension was first placed on the foil along with a suitable volume of dilution water, about 0.6 cc. After mixing, 0.3g of platinum black (previously sifted through a 325-mesh screen) was added and a thin, cream-like slurry was made by mixing with a small spatula. This was then dispersed as uniformly as possible over the area and slowly dried on a hot plate. It was necessary to raise the temperature very slowly during the initial phases to obtain a satisfactory deposit. Ultimately, however, the bed of the hot plate was raised to 250°-350°C to dispel the wetting agent as white fumes from the Teflon suspension.

The screen having a tab was then centered over one of the spreads, and a strip of Teflon sheet was placed across the tab as a seal. The second spread was then placed on top of the screen with the catalyst mix again facing the screen. This assembly, with the two aluminum foils facing outward, was sandwiched between two ferrotype plates and placed on the bed of the press. Sintering was performed at 350°C for 2 min at the desired pressure, usually 1800-3000 lb/in^2 of electrode surface.

Following the heat treatment, the aluminum foil was dissolved from the electrode with warm 20% NaOH. A water rinse and an air drying then resulted in a finished electrode. In most of the work, electrodes, either with or without the peripheral Teflon rings, were prepared as outlined above. The occasional variations that were introduced will be described as they arise.

Test cell.—The completed electrodes were housed as shown in the exploded view of a cell in Fig. 3. The two electrodes were separated by a ⅛-in. thick spacer which formed a 1½-in. diameter pocket for the free electrolyte. Appropriate gaskets and face plates formed chambers for the fuel and oxidant gases. All plastic parts were of Lucite, and gaskets were of silicone rubber or poly(ethylene-butene) copolymer. Gasketing was such that the effective working areas of the electrodes were 1½-in. diameter circles. Platinum and Teflon tubing were used for the connections that encountered electrolyte. Gases were flowed through polyethylene tubing. For operation on air one of the faceplates contained a 1½-in. diameter hole. This gave free access of air to the electrode.

Electrolytic hydrogen and purified oxygen were employed during operation. At low current densities static gases could be used, but at high current densities (>250 ma/cm^2) it was generally found desirable to maintain slow flows of the gases through a cell. This was particularly true of the oxygen which contained enough nitrogen and argon as impurities to accumulate rapidly in the cell chambers and cause "smothering."

Table I. Reinforcing screens used in electrode fabrication

Silver	40	7.5

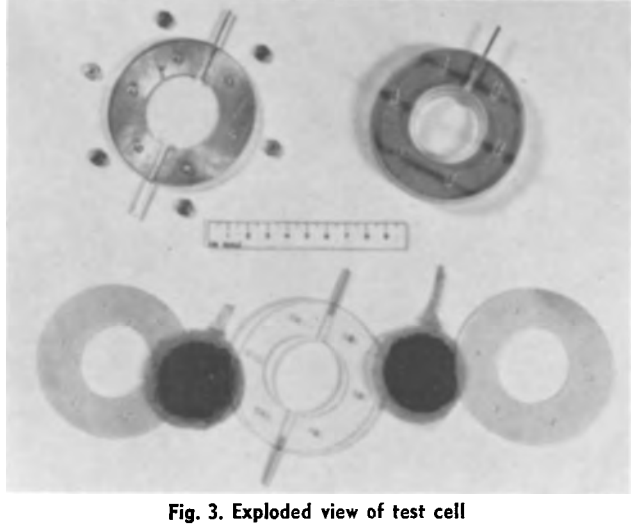

Fig. 3. Exploded view of test cell

In order to prevent the water produced in the cell reaction from diluting the electrolyte excessively, the electrolyte was circulated between the cell and a relatively large reservoir. In initial experiments, forced circulation was achieved by means of gravity flow from a reservoir above the cell level. Electrolyte which drained from the cell was then returned to the reservoir with the aid of a Teflon bellows pump.

It was soon found that the circulation provided by means of a thermal loop was adequate to maintain the cell performance. This simpler arrangement was therefore used for most of the work. A polyethylene bottle connected to the cell with Teflon tubing served as the reservoir.

A reference electrode was prepared by mounting one of the new-type electrodes in a separate housing and exposing one side to hydrogen. Electrolyte in the other chamber of the reference cell then made contact with the working system, *via* a bridge of Teflon tubing filled with the common electrolyte. Individual electrode performances in the cell under test were then obtained *vs.* the reference from measurements with a Kordesch-Marko bridge (8). Use of the bridge also permitted the measurement of IR-free voltages.

Although most of the measurements were made with the aid of the Kordesch-Marko bridge, over-all polarization curves were frequently obtained during direct discharge of cells through resistive loads. These invariably agreed well with the over-all curves obtained with the pulsating current derived from the bridge.

Results and Discussion

Before examining the effects of a number of individual parameters, it is of interest to consider the general performance characteristics of the new cells with alkaline and acidic electrolytes. For this purpose polarization curves for cells employing 6*M* KOH and 5*N* H_2SO_4 electrolytes are shown in Fig. 4 and 5, respectively. It is significant to note that current densities as high as 1000 ma/cm² have been delivered by the alkaline cells operating on hydrogen and oxygen. At such high current densities, of course, considerable internal heating occurs, and operation is therefore not isothermal. For example, electrolyte and electrode temperatures of about 70°C have been measured on both acidic and alkaline, hydrogen-oxygen cells at current densities of about 500 ma/cm². While the voltage (and hence efficiency) is low at these high current densities, the polarization curve gives assurance that the new electrodes will be able to handle surge currents well above the 100-200 ma/cm² that might be considered as the normal operating range. The performance of hydrogen-oxygen cells with acidic electrolytes is similar to that observed with the alkaline electrolyte.

Even when air is used as the oxidant, relatively high current densities can be obtained with the new cell before evidence of mass transfer polarization appears in the form of a sharp decline in the voltage with increasing load. Somewhat lower voltages are observed when air is substituted for oxygen, *e.g.*, at 200 ma/cm² 0.70v *vs.* 0.76v for the alkaline cell and 0.60v *vs.* 0.69v for the acidic cell. While partially resulting from the concentration effect involved in the Nernst equation, the lower voltages obtained with air probably also reflect the fact that better cooling is accomplished during air operation. As a result, internal resistances are higher and electrode reactions are more sluggish than when oxygen is used and higher temperatures are reached in the cell.

The new electrodes also do an excellent job of retaining the aqueous electrolytes. A small amount of seepage has, however, been observed with all the electrodes tested to date. In practice then, it may be necessary to provide some means of recycling the seepage.

Effect of the thickness of the surface film.—The first series of experiments was devoted to an examination of the effect of the thickness of the Teflon surface film on cell performance. All electrodes used in this series were prepared with rolled 40-mesh nickel screens having wire diameters of 4.5 mils. Two identical electrodes with peripheral Teflon rings were used in each of the test cells. Surface films of 0.79, 1.6, 2.4, and 3.9 mg Teflon/cm² were tested. All of the experiments were performed with alkaline electrolytes, 6*M* KOH. Most of the polarization data shown in Fig. 6 and 7 were obtained with the Kordesch-Marko bridge and show the potentials of the fuel and oxidant electrodes against the hydrogen reference. Also shown are the over-all performance curves (IR drop included) for the cells

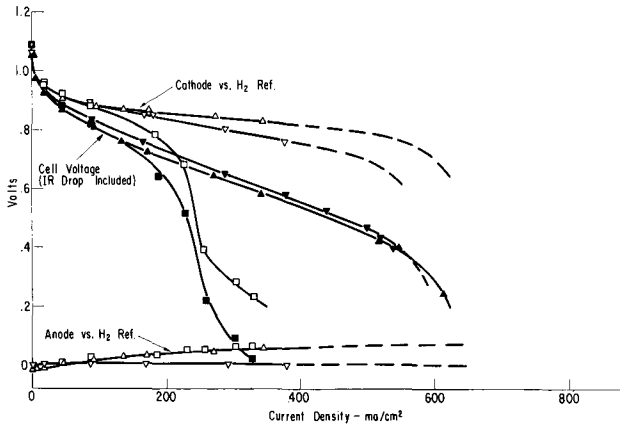

Fig. 7. Effect of film thickness on performance with H_2 and air. Electrolyte, 6M KOH; electrodes, body (35 mg Pt, 3.2 mg Teflon)/cm²; film: △, ▲, 1.6 mg Teflon/cm² LFC-267 (9); ▽, ▼, 2.4 mg Teflon/cm² LFC-271; □, ■, 3.9 mg Teflon/cm² LFC-275.

operating on oxygen and on air. At the time that these tests were made the bridge could handle a maximum current of about 4.5 amp. The data obtained at higher current densities were therefore obtained by direct discharge of the cells through resistive loads. The agreement between both types of data attest to the satisfactory functioning of the system.

It is seen that the effect of the film thickness on the performance of oxygen and hydrogen electrodes is not very pronounced. With air as the oxidant, however, it is evident from the data in Fig. 7 that the thinner films result in better performances. This is reasonable in view of the lower permeability that would be anticipated for the heavier films, and hence the greater tendency toward blockage with nitrogen.

Since an important purpose served by the film is the prevention of electrode drowning, as well as gross leakage of the electrolyte through larger pores, a word is in order about these aspects of performance. Electrode drowning manifests itself by severe polarization over a narrow range of current density. It is therefore evident from the data for the hydrogen and oxygen electrodes in Fig. 6 and 7 that drowning is not a problem.

Some electrolyte leakage occurred with all of the electrodes used in this series of tests, but it was found to be concentrated in the boundary region between the active area and the peripheral Teflon rings. It was therefore impossible to obtain meaningful quantitative data. Qualitatively, however, it was observed that the active electrode areas were freer from seepage droplets, the thicker the film.

It would therefore appear that practical electrodes, particularly air electrodes, will require an optimization between rate of seepage and gas accessibility. From the above, as well as repeated experiments with similar electrodes, it is our opinion that at the present state of development, film thicknesses between 0.79 and 2.4 mg Teflon/cm² are the most attractive with regard to over-all performance.

Effect of Other Electrode Parameters and Processing Variables

With the platinum black catalyst several other electrode parameters and processing variables were examined briefly. These included: (*a*) effect of screen wire size, mesh, and material; (*b*) effect of pressure used in final sintering; (*c*) effect of ratio of catalyst to Teflon; (*d*) effect of amount of platinum and Teflon; and (*e*) effect of using a commercially available Teflon film for the surface layer.

Screen characteristics.—Changes in the supporting screens manifested themselves by affecting the cell resistance and the associated IR drop. Even in the small laboratory cells, electrodes constructed with 80-mesh, 3-mil platinum wire screens showed excessively high ohmic drops, particularly when electrodes with narrow tabs were used. At the other extreme were electrodes employing low-resistance silver screens with 7.5-mil wires and wide tabs. The 40- to 45-mesh platinum and nickel screens that were used in most of the work were intermediate in performance.

Sintering pressure.—Variation in the pressure used in preparing electrodes was not examined in detail nor over a wide range. Those prepared at the lowest pressure tested, 180 lb/in.² were lacking in strength, although their electrical performance was excellent. With these electrodes, however, the gaskets from the cell were capable of inducing appreciable flow of the catalyst-Teflon mix and failures occurred around the edges. In general, pressures of the order of 1800 to 3000 lb/in.² were considered most satisfactory for the preparation of electrodes.

Ratio of catalyst to binder.—Electrodes of satisfactory strength and performance can be obtained within the range of platinum-to-Teflon weight ratios from 1:0.05 to 1:0.5. Most of the work was done with the ratio 1:0.09 (*i.e.*, 1g platinum black to 0.10 cc Teflon-30 solution).

Amount of platinum and Teflon.—Experiments were run with alkaline cells using electrodes containing from 17 to 45 mg platinum/cm² (a constant weight ratio of platinum-to-Teflon binder of 1:0.09 was used and the film thickness was maintained at 2.4 mg Teflon/cm²). Pronounced effects were not observed although the thinnest electrodes leaked excessively. Electrodes containing in the range 30-40 mg platinum/cm² appeared to be quite satisfactory and were adopted for most of the remaining work.

Commercial films as surface coatings.—While the major portion of the effort employed sprayed films of Teflon, a few electrodes were made with commercially available Teflon films that had a nominal thickness of ⅛ mil (obtained from Dielectrix, Inc.). These electrodes were prepared in the standard fashion except that the film was added in an extra pressing operation at the end of the regular procedures. At 200 ma/cm² hydrogen-oxygen cell potentials of greater than 0.70v can be realized with such electrodes. Current densities of 500 to 600 ma/cm² can be supported on hydrogen and oxygen but at greatly reduced potentials.

In this connection it is of interest to note that the permeation rates shown in Table II were obtained for the film with the mass spectrometer.[1] Because all spectrometer peaks were established rapidly on placing the gases on the high-pressure side of the film, it was concluded that pores were present. Assuming linear relationships, the tabulated data correspond to permeation rates of 0.073 and 0.063 cc (STP)/min/cm² of the ⅛-mil film for hydrogen and oxygen, respectively, at a pressure differential of 1 atm. The observed currents

[1] The authors are indebted to Dr. F. J. Norton for these measurements.

Table II. Permeation rates for Dielectrix, Inc., ⅛-mil Teflon film

permeation rate, p, in $\frac{\text{cm}^3\text{(STP)}}{\text{sec}} \cdot \frac{\text{mm thickness}}{\text{cm}^2\text{ area} \cdot \text{cm Hg pres.}}$

Temp, °C	H_2	He	O_2	N_2	Ar	SF_6
28	5.1×10^{-8}	2.7×10^{-8}	4.4×10^{-8}	6.8×10^{-8}	2.45×10^{-8}	—
53	2.4×10^{-7}	1.6×10^{-7}	1.45×10^{-7}	1.3×10^{-7}	1.2×10^{-7}	2.55×10^{-8}

of about 500 ma/cm² call for gas consumption rates of about 3.4 and 1.75 cc/min for the hydrogen and oxygen. This would indicate that the film ruptured sufficiently during processing to permit the passage of the additional gas to the catalyst.

While the electrical properties of these electrodes were comparable with the others, seepage of electrolyte through the pores was also comparable.

Effect of Operating Conditions on Cell Performance

Several important operating parameters were varied during the course of the work. In particular, the effects of the liquid and gas pressure heads were considered, as was the effect of the electrolyte concentration. In addition, tests were made to determine the need for an external circulation loop and reservoir.

Effect of electrolyte head.—Polarization data were obtained for several alkaline cells as the electrolyte heads were varied over the range 3-24 in. above the tops of the electrodes. During these tests the circulating loop to the reservoir was not closed. Instead, a "standpipe" arrangement was used with a thin tube filled with electrolyte serving to provide the hydrostatic pressure. Hydrogen and oxygen gas pressures of about 2-3 in. of water were used. The range of pressures covered should easily include the highest excess electrolyte pressures which will be encountered in practical size cells having electrodes up to 20 in. on a side.

Increasing the liquid head results in little change in the electrical performance of the cell or in that of the individual electrodes. A slightly poorer over-all polarization curve obtained with the largest liquid head does, however, appear to be real and may reflect some penetration of the electrolyte into the pores of the electrodes. Reduction of the pressure reversed this effect.

In the small laboratory cells the pressure gradient varies by only 1½ in. from the top of the electrode to the bottom. In a practical device, with its larger electrodes, the gradient will vary considerably more. These experiments indicate, however, that the electrical performance at the different levels will not differ significantly.

Effect of gas pressure.—In looking at the effect of gas pressure on cell performance, a range from 1 to 22 in. of water was covered. The cells were arranged with the electrolyte in a closed loop with a head of 2 or 6 in. above the tops of the electrodes. In these tests a ⅜ in. thick spacer was used between the electrodes to minimize the danger of bridging the gap should gases bubble into the electrolyte. The cells therefore had a somewhat higher internal resistance than normal. As a result the over-all polarization curves obtained with these cells were slightly inferior to others in this paper. It was found that the cells could be operated with gas pressures exceeding the hydraulic head of the electrolyte by as much as 20 in. of water without bubbling into the electrolyte occurring. No pronounced effects that can be attributed directly to changes in the gas pressures were encountered. Indeed, the data were exceptionally reproducible even at the higher current densities.

At the higher current densities the temperatures in the cells were also high. For example, with a cell containing 6*M* KOH as electrolyte at a current density of 580 ma/cm², an electrolyte temperature of 83°C was measured. Under these conditions the anode and cathode temperatures were 82° and 88°C, respectively, and the reservoir measured 38°C. Similar temperatures were obtained with acidic electrolytes. At such temperatures the partial pressure of water is fairly high, particularly at the water-producing electrode where the electrolyte is diluted. For this reason, as well as the fact that cell performance at high current densities is sensitive to gas flow rate, it appears highly likely that steam blanketing of the electrodes may occur.

Effect of the electrolyte concentration.—As noted in the previous section, some cells operating on hydrogen and oxygen and employing 6*M* KOH or 5*N* H_2SO_4 as the electrolytes have shown evidence of some steam blanketing at the electrodes. In an effort to reduce this effect, a number of cells were run with more concentrated electrolytes over which the vapor pressure of water was considerably less.

When 12*M* KOH was used there was, indeed, a slight improvement in performance at high current densities. Unfortunately, however, because of its higher resistivity, this electrolyte tended to heat more than 6*M KOH* at corresponding current densities. In addition, its higher viscosity resulted in less circulation through the external loop and this also contributed to a higher temperature in the cell, *e.g.*, 96° *vs.* 83°C at a current density of 580 ma/cm². This attempt to reduce the vapor pressure of the water was therefore largely self-defeating. In general, however, 12*M* KOH appeared to be an attractive electrolyte. In particular, its higher viscosity resulted in lower seepage rates through the electrodes than were seen with 6*M* KOH.

Attempts to examine the effect of increasing the electrolyte concentration with the acid were unsatisfactory. Sulfuric acid is less effective than potassium hydroxide in reducing the vapor pressure of water, and a 23*N* solution is required to accomplish the reduction equivalent to 12*M* KOH. This concentration of acid proved unsatisfactory. When it heated to a temperature of 60°-70°C, direct reaction with the hydrogen occurred, and hydrogen sulfide formed and poisoned the fuel electrode. A similar behavior was observed with 17*N* H_2SO_4, but in this case when the temperature reached 80°-90°C.

Effect of electrolyte circulation.—Because an external circulation loop such as that used in much of the present work may prove cumbersome in the designing of practical cells, it was of interest to determine whether this is required for satisfactory operation. For this purpose an air-breathing, acid cell was placed in operation without any external circulation. Instead, a small funnel was attached to the top inlet tube on the electrolyte chamber, and water (to compensate for evaporation losses) was added directly to the cell chamber.

That adequate mixing of the electrolyte can be achieved in this way was clearly attested to by steady operation at 0.68 ± 0.02v when the current was held constant at 88 ma/cm². The steady potential was maintained for 25-hr periods both during operation of the cell in this fashion and during operation with a thermal loop when the makeup water was added to the reservoir. Even with larger cells, thermal mixing within the electrolyte chamber should be more than adequate to prevent stratification of the electrolyte when the water is introduced at the top. If stratification were to occur and a water layer formed at the top, the resistance across that layer would be much greater than in the lower acidic region. The current would therefore be concentrated at the bottom of the cell and more power would be dissipated there than at the top. The heat so generated would therefore be distributed in a way to promote convective mixing and thereby destroy concentration gradients within the electrolyte.

If desired, however, makeup water could be introduced at the bottom of the cell chamber. In this case density differences between the makeup water and the electrolyte already in the cell would contribute to the mixing.

Alternative Electrocatalysts

A few exploratory experiments were performed with alternative electrocatalysts. These included silver and activated carbons. Electrodes of both types performed reasonably well with oxygen. This is shown by the data in Fig. 8. The silver electrode used in cell LFC-264 contained approximately 70 mg Silflake-131 (Handy and Harmon) and 7 mg Teflon binder/cm². It was coated with a surface film containing 2.4 mg Teflon/cm². The platinized carbon electrode of cell LFC-282 contained 17 mg amorphous carbon containing 10%

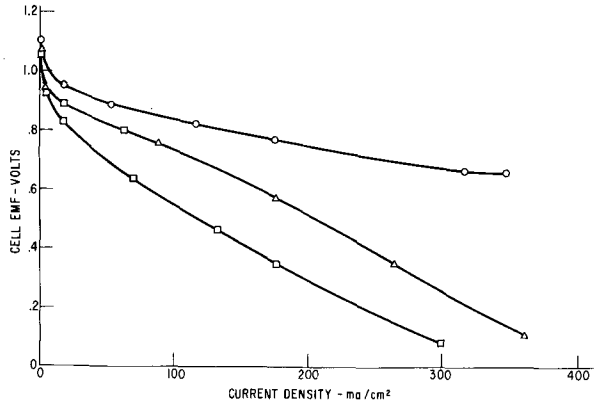

Fig. 8. Performance of cells with various oxygen electrode catalysts. Electrolyte, 6M KOH; anodes, Pt black; cathodes: ○, Pt black LFC-269; △, 10% Pt on amorphous carbon LFC-282; □, Silflake LFC-264; IR drop included.

platinum and 3 mg Teflon binder/cm². It too was coated with a surface film containing 2.4 mg Teflon/cm². The anodes in both of these cells were made with platinum black.

These data are included merely to indicate the promise of some of these less expensive materials as practical electrocatalysts. Actually, the carbon-base material has shown even better performance with both oxygen and hydrogen in the earlier matrix type cells (9). This implies strongly that the carbon electrode of the present example does not represent the optimum in wetting control.

Alternative Electrolytes

In most applications it is desirable to be able to operate a fuel cell on air. With an acidic electrolyte this is no problem since carbon dioxide from the air is not absorbed. However, such electrolytes are more corrosive than caustic electrolytes, and the latter therefore have some advantages in practical cells. These electrolytes, however, are converted to carbonates by the carbon dioxide in the air.

While the resistances of carbonate electrolytes are higher than those of caustics or acids, the difference is not enough to preclude their consideration for use in fuel cells (6,10, 11). It was therefore of interest to examine the performances of a number of them covering the range of compositions that might be encountered as equilibrium electrolytes in air-breathing cells. Room temperature polarization curves for a family of electrolytes from KOH to K_2CO_3 are shown in Fig. 9. The ohmic drop has been eliminated from all of these

Table IV. Phosphate solutions tested as fuel cell electrolytes

Solution No.	Electrolyte and concentration	pH
1	5*M* H_3PO_4	<0.0
2	2.5*M* H_3PO_4-2.5*M* NaH_2PO_4	0.8
3	5*M* NaH_2PO_4	3.4
4	2.5*M* NaH_2PO_4-2.5*M* K_2HPO_4	7
5	1.25*M* NaH_2PO_4-1.25*M* K_2HPO_4	7
6	5*M* K_2HPO_4	9

curves, but in no case was the total cell resistance greater than 0.08 ohm.

It is evident that the carbonate has a pronounced effect on performance, largely in the form of adverse effects on electrode polarization. From work with carbonate and bicarbonate electrolytes in the older, low-temperature, matrix-type cells, it was found that the hydrogen electrode is the one that is strongly affected; this appears to be the result of direct reaction between hydrogen and carbonate to form CO or a related species on the electrode surface which then inhibits the electrooxidation of hydrogen (9).

Because of the volatility of CO_2 the composition of the equilibrium electrolyte in an operating cell will be affected by such parameters as temperature, current density, concentration and volume of electrolyte, and other variables. From the data presently available, it is therefore impossible to predict the magnitude of inhibition that will be experienced with such an electrolyte under practical conditions. It is possible, however, that an appreciable penalty will be paid.

In view of the adverse effect of carbonate on cell performance, some attention was given to the possibility of using phosphate solutions as CO_2 rejecting electrolytes. Some of the solutions tested had moderate buffer capacity in the intermediate *p*H region where corrosion problems would be less severe than with strong acids. The electrolytes in Table IV were examined.

It is to be noted that the sodium and potassium salts were chosen for solutions 3 and 6, respectively, on the basis of solubility considerations. The mixture used for solution 4 was also chosen in an effort to avoid precipitation. This was not entirely successful, and some precipitate formed slowly. The less concentrated solution 5 was therefore prepared for additional tests at essentially the same *p*H.

At ambient temperature all of these phosphate electrolytes were inferior to sulfuric acid. In part this was a result of their higher resistances, but there were also pronounced effects on electrode behavior. The oxygen electrode was affected more strongly than the hydrogen electrode, and the effect became more pronounced as the *p*H increased. It is possible that these effects were caused by adsorbed phosphate ions (especially $HPO^{-}{}_4$-), but a straight *p*H effect cannot be precluded. In either case, phosphate solutions, with the exception of those containing phosphoric acid, do not appear attractive as electrolytes.

Performance during Continuous Operation

Seven cells were placed on continuous operation at current densities of 88, 176, or 263 ma/cm² for periods of from 5 days to over 5 months. The first cell was operated with forced circulation of the electrolyte. All of the remaining units were operated with thermal loops.

The hydrogen supply was sufficiently pure to permit operation on static heads of gas with an occasional short purge (a few seconds) to sweep out impurities that slowly accumulated in the fuel electrode's gas chamber. Because the impurity level of the oxygen was higher, it was necessary to continuously vent a slow stream of oxygen from the cells; a rate of less than 1 cc/min was maintained.

Graduated traps in the vent lines permitted the collection of liquid that accumulated in the gas chambers. This included seepage as well as water which distilled from the electrodes to the faceplates of the cells. All

was recycled back to the reservoirs. To minimize seepage, electrolyte heads were held to about 1 in. above the tops of the electrodes.

During air operation with a fully exposed electrode, more water was evaporated than was produced in the cell reaction. In such cases makeup water was added periodically to the reservoir.

During operation on oxygen the water formed in the cell reaction gradually diluted the electrolyte so that periodic replacement was required. The need for replacement was generally indicated by a decline in cell performance; the response of the cell to fresh electrolyte was immediate. During early tests about 80 cc of electrolyte were used in charging a system. Later this was increased to about 250 cc in order to extend the periods between replacements.

Some representative performance data are summarized in Fig. 10 through 13. Shown are cell voltages on load as well as polarization curves obtained after various periods of operation. No cell failures occurred during these tests apart from leaks which developed in cell housings.

Cell LFC-260 was one of the first cells to be assembled. Its electrodes are reinforced with 80-mesh, 3-mil wire, platinum screens having narrow tabs. As a result its internal resistance was high, 0.12 ohm, and a drop of about 0.15v occurred in the tabs themselves at the operating current of 2 amp (176 ma/cm^2). Nevertheless, this acid cell gave excellent performance on hydrogen and air for over 160 days as attested to by the data in Fig. 10 and 11.

A word is in order about the performance of this cell during the first 52 days. During this period silicone rubber gaskets were used on the cell. Gradual attack from the acid produced silica which accumulated in the pores of the electrodes. On the 52nd day the cell was disassembled and the electrodes were leached with warm sodium hydroxide. After reassembly with poly(ethylene-butene) copolymer gaskets, the cell performed excellently for over 110 additional days.

Cell LFC-269 contained the same electrodes as provided the data in Fig. 4. They were reinforced with 40-mesh, 4.5-mil wire, rolled nickel screens having wide tabs. This alkaline cell had a considerably lower resistance than LFC-260, *i.e.*, 0.06 ohm. It was operated on hydrogen and oxygen for over 140 days at the current densities indicated in Fig. 12. During the first 19 days a small reservoir charged with 80 ml of electrolyte was used. This was subsequently changed to a larger reservoir with charges of about 250 ml of fresh electrolyte, although the amount was reduced again upon switching to 12*M* KOH. In general, the performance of this cell was excellent, and as shown by the polarization data in Fig. 13 there was no decline in its ability to handle overloads.

Summary and Conclusions

The structure of conducting-porous-Teflon electrodes has been improved with regard to strength, conductivity, and wetting characteristics. In their new form these very thin electrodes (5-10 mils thick) may be employed with aqueous electrolytes without the need for the matrix-type support previously used. The result is a fuel cell having excellent performance characteristics. These include an ability to operate on air at practical current densities of 100-200 ma/cm^2. In other work the new electrodes have also been shown to have excellent performance characteristics with hydrocarbon fuels and with methanol.

The new cells may be operated with the electrolyte circulated through an external loop by thermal pumping, or the electrolyte may be used without such circulation.

A number of cells have been operated continuously for periods of months with encouraging results. One of our first hydrogen-oxygen cells was operated with an acid electrolyte and air as oxidant at a current density

of 176 ma/cm² for over 5 months. A similar alkaline cell was operated on hydrogen and oxygen at current densities of 263 and 88 ma/cm² for a similar period.

Acknowledgments

The authors are indebted to H. A. Liebhafsky, E. J. Cairns, and W. T. Grubb for helpful discussions during the course of this investigation. They also appreciate the assistance of F. J. Norton who measured the permeability of one of the Teflon films, and that of E. F. Koch and R. R. Russell who obtained the photomicrographs of electrodes.

Manuscript received July 1, 1964. This paper was presented at the Washington Meeting, Oct. 11-15, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

The Active Iron Electrode

I. Iron Dissolution and Hydrogen Evolution Reactions in Acidic Sulfate Solutions[1]

Eugene J. Kelly

The Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

ABSTRACT

The *p*H and potential dependencies of the steady-state iron dissolution and hydrogen evolution reactions were determined for zone-refined iron in H_2-saturated acidic sulfate solutions. The mechanistic significance of the data is examined in detail. The results of this investigation serve to resolve the conflict concerning the mechanism of iron dissolution in noninhibiting media and to provide an experimental and mechanistic base for the interpretation of the electrochemical behavior of the active iron electrode in inhibiting media.

A comparative study has been made of the electrochemical behavior of the active iron electrode in typical inhibiting and noninhibiting media. The purpose of the investigation was to determine the changes produced in the kinetics and mechanistics of a noninhibited system as a result of specific adsorption of an inhibitor. Such information is not only essential to the understanding of corrosion inhibition, but is also relevant to the interpretation of kinetic data for other electrode processes involving adsorption.

The many recent investigations of the active iron electrode in noninhibiting media such as deoxygenated acidic sulfate, perchlorate, and chloride solutions have led to a variety of conflicting results. According to Bonhoeffer (1, 2) and Heusler (1-3), the mechanism of the iron dissolution reaction in sulfate and perchlorate solutions is given by Eq. [1]-[3],

$$Fe + OH^- \rightleftharpoons (FeOH)_{ads} + e^- \quad [1]$$

$$Fe + OH^- + (FeOH)_{ads} \rightarrow (FeOH)_{ads} + (FeOH)^+ + 2e^- \quad [2]$$

$$(FeOH)^+ + H^+ = Fe^{++} + H_2O \quad [3]$$

in which the surface species, $(FeOH)_{ads}$, serves simply as a catalyst for reaction [2]. This system of reactions may be described by Eq. [4] and [5]

$$i_a/\mathbf{F} = \bar{k}_1 a_{(OH^-)}(1-\theta) - \bar{k}_{-1}\beta\theta + 2\bar{k}_2 a_{(OH^-)}\beta\theta \quad [4]$$

$$\beta d\theta/dt = \bar{k}_1 a_{(OH^-)}(1-\theta) - \bar{k}_{-1}\beta\theta \quad [5]$$

where i_a is the net anodic current density corresponding to the iron dissolution reaction, and $\bar{k}_j$ are electrochemical rate constants which, assuming transfer coefficients of ½, are equal to $k_j \exp(\pm\lambda_j \mathbf{F}E/2RT)$, where λ_j is the number of electrons transferred per occurrence of the j^{th} reaction, and the plus and minus signs refer to anodic and cathodic processes, respectively. The definitions of β and θ follow from $(FeOH)_{ads} = \beta\theta$, where $(FeOH)_{ads}$ is the concentration of the catalyst expressed in moles/cm², θ is the fraction of the surface occupied by the catalyst, and β is a proportionality constant. The other symbols have their customary meanings. If $2\bar{k}_2 a_{(OH^-)}\beta\theta >> \bar{k}_1 a_{(OH^-)}(1-\theta) - \bar{k}_{-1}\beta\theta$, *i.e.*, if the contribution of reaction [1] to the net anodic current density is negligible compared to that of reaction [2], then Eq. [4] reduces to Eq. [6]

$$i_a/\mathbf{F} = 2\bar{k}_a a_{(OH^-)}\beta\theta \quad [6]$$

With $d\theta/dt$ equal to zero and $(1-\theta) \approx 1$, Eq. [5] and [6] lead to the steady-state solution

$$\frac{i_{a,\infty}}{\mathbf{F}} = 2k_2\left(\frac{k_1}{k_{-1}}\right) a^2_{(OH^-)} \exp(2\mathbf{F}E/RT) \quad [7]$$

i.e., the steady-state system should be characterized by an anodic Tafel slope of 30 mv/decade, 2.303 $RT/2\mathbf{F}$, and a second order dependency on the hydroxyl ion activity. Using fast polarization techniques, these authors were also able to observe a transient anodic Tafel line having a slope of 60 mv/decade, 2.303 $RT/\mathbf{F}$. This result was accounted for assuming that during the short time interval required to fix the transient anodic Tafel

[1] Research sponsored by U.S. Atomic Energy Commission under contract with the Union Carbide Corporation.

line, θ remains constant at θ_o. Then Eq. [6] becomes Eq. [8]

$$i_{a,o}/\mathbf{F} = 2k_2 a_{(OH^-)}\beta\theta_o \exp(\mathbf{F}E/RT) \quad [8]$$

which shows the first order dependency of reaction [2] on the hydroxyl ion activity, as well as the observed effect of potential on this reaction.

According to Bockris *et al.* (4-6), in sulfate solution the steady-state anodic dissolution reaction is characterized by an anodic Tafel slope of 40 mv/decade, (2/3)(2.303 $RT/\mathbf{F}$), and a first order dependency on the hydroxyl ion activity. To account for their results, they suggested the mechanism

$$Fe + H_2O \rightleftharpoons (FeOH)_{ads} + H^+ + e^- \quad [9]$$

$$(FeOH)_{ads} \rightarrow (FeOH)^+ + e^- \text{ (rate-determining)} \quad [10]$$

$$(FeOH)^+ + H^+ = Fe^{++} + H_2O \quad [11]$$

in which the surface species, $(FeOH)_{ads}$, acts as a reaction intermediate rather than a catalyst. This reaction mechanism is described by Eq. [12] and [13]

$$i_a/\mathbf{F} = \bar{k}_1(1-\theta) - \bar{k}_{-1}a_{(H^+)}\beta\theta + \bar{k}_2\beta\theta \quad [12]$$

$$\beta d\theta/dt = \bar{k}_1(1-\theta) - \bar{k}_{-1}a_{(H^+)}\beta\theta - \bar{k}_2\beta\theta \quad [13]$$

where $a_{(H^+)}$ is the proton activity, and the other symbols retain their previous definitions. For the steady-state case, $d\theta/dt$ is equal to zero. Then, if $\bar{k}_{-1}a_{(H^+)}\beta\theta >> \bar{k}_2\beta\theta$ and $(1-\theta) \approx 1$, Eq. [12] reduces to Eq. [14]

$$\frac{i_{a,\infty}}{\mathbf{F}} = 2\frac{k_1k_2}{k_{-1}a_{(H^+)}}\exp(3\mathbf{F}E/2RT) \quad [14]$$

which is consistent with the observed 40 mv/decade Tafel slope and the first order dependency on the hydroxyl ion activity. These authors also reported a transient anodic Tafel line having a slope of approximately 2.303 $RT/\mathbf{F}$. This was interpreted by assuming that in the process of anodic charging, reaction [9] rapidly attains a state of pseudo-equilibrium, during the attainment of which, the diffusion of protons from the double layer to the bulk of the solution is negligible. Consequently, Eq. [14] gives the current density corresponding to the pseudo-equilibrium state, but with $a_{(H^+)}$ now referring to the pseudo-equilibrium activity of protons, $a_{(H^+),o}$, in the double layer. If the change in potential is sufficiently large to justify the approximation, $a_{(H^+),o} = \beta\theta_o$, then Eq. [14] may be written as Eq. [15]

$$i_{a,0} = i_{a,1}\left(\frac{a_{(H^+)}}{\beta\theta}\right)_1^{1/2}\exp\left[\frac{\mathbf{F}}{RT}(E-E_1)\right] \quad [15]$$

where the subscript one refers to the initial steady state from which the transient measurements originate.

In partial confirmation of the Heusler mechanism, Heusler and Cartledge (7) reported steady-state and transient anodic Tafel slopes of 30 mv/decade and 60 mv/decade, respectively, in 0.5f H_2SO_4, and used the mechanism of reactions [1]-[3] as a basis for the interpretation of the inhibition of iron dissolution by iodide ion and carbon monoxide. Lorenz, Yamaoka, and Fischer (8) reported a steady-state anodic Tafel slope of 30 mv/decade in HCl and (HCl + KCl) solutions, subject to the condition that pH > 1.5 and pH > 2 for the two types of solutions, respectively. These authors criticized the mechanism of Bockris and co-workers, who had earlier criticized the Heusler mechanism. In sulfate and chloride solutions, Hoar (9) and Hurlen (9, 10) found a 30 mv/decade steady-state anodic Tafel line, but a first rather than second order dependency of the anodic reaction on the hydroxyl ion activity. Steady-state anodic Tafel slopes of 30-40 and 50-60 mv/decade in sulfate solution have been reported by Makrides (11), 30 mv/decade in perchlorate solution by Kaesche (12), approximately 100 mv/decade in sulfate solution by Okamoto *et al.* (13), 54 mv/decade in chloride solution by Makrides *et al.* (15), and 68 mv/decade in chloride solution by Stern and Roth (14). Neither order determinations nor detailed mechanisms were included in this latter group of studies.

There is general agreement that the cathodic Tafel line corresponding to the hydrogen evolution reaction in these media has a slope of —120 mv/decade, —2(2.303 $RT/\mathbf{F}$). That the reaction is first order in proton activity would also appear to be reasonably well-established (4, 10). The steady-state current density, $i_{c,\infty}$, is therefore given by Eq. [16]

$$|i_{c,\infty}|/\mathbf{F} = k_c a_{(H^+)}\exp(-\mathbf{F}E/2RT) \quad [16]$$

The mechanistic significance of this equation will be considered in the discussion section.

Relations between the corrosion potential and pH and the corrosion current density and pH may be determined by equating the expressions for the steady-state anodic and cathodic current densities, for example, Eq. [7] and [16] or Eq. [14] and [16]. Bockris and co-workers reported values of —60 mv/pH or —2.303 $RT/\mathbf{F}$ and —½ for (dE_{corr}/dpH) and (d log i_{corr}/dpH), respectively, values which are consistent with Eq. [14] and [16]. Hurlen gave corresponding values of —48 mv/pH or —(4/5)(2.303 $RT/\mathbf{F}$) and —3/5, values which are consistent with Eq. [16] and his expression for the steady-state anodic current density

$$i_{a,\infty}/\mathbf{F} = k_a a_{(OH^-)}\exp(2\mathbf{F}E/RT) \quad [17]$$

On the other hand, Bonhoeffer and Heusler found the corrosion rate to be independent of pH, in agreement with Stern (16), and reported a value of —45 mv/pH for (dE_{corr}/dpH). An inspection of Eq. [7] and [16] shows these observations to be internally inconsistent with the mechanism proposed by these authors, a fact noted by Bockris *et al.* (4). A few of the many other values reported for (dE_{corr}/dpH) are —60 mv/pH by D'Ans and Breckheimer (17), —56 mv/pH by Stern (16) who emphasized the fact that the result was less than —2.303 $RT/\mathbf{F}$, —52 mv/pH by Kaesche (12), and —47 mv/pH by Makrides *et al.* (15) who also reported a logarithmic relation between the corrosion rate and pH.

The preceding review clearly suggests that, prior to attempting to resolve the more complicated inhibited systems, the electrochemical behavior of active iron in noninhibiting media should be re-examined. This paper reports on the results obtained in acidic sulfate solution.

Experimental

In order to circumvent contamination problems associated with the use of rubber, lubricants, etc., the entire cell assembly was made of Pyrex glass and Teflon. The apparatus was so designed that essential operations, such as rapid addition of pre-electrolyzed solutions and the removal of used solutions, could be accomplished without opening the apparatus to the atmosphere. The test electrode compartment, a flat-bottomed cylinder, was fashioned from the male component of a 55/50 TS ground glass joint. The ground surface was carefully removed by fire-polishing, and the rest of the cylinder was provided with a glass jacket by means of which, in conjunction with a circulating water bath, a constant solution temperature of 25.00° ± 0.03°C was maintained. The cap was machined from Teflon, and had a total of nine ports, four standard-taper ports for electrode holders and the remainder for variable position hydrogen inlet and outlet tubes, solution inlet tubes, and a Haber-Luggin capillary probe. These tubes were connected *via* flexible Teflon "spaghetti" tubing (1/16 or 1/8 in. ID) to a hydrogen manifold, reservoirs containing pre-electrolyzed, hydrogen-saturated solutions, and an external reference electrode compartment, respectively. The

reference electrode compartment, holding a saturated calomel electrode, was also jacketed and maintained at 25.00° ± 0.03°C. A tube passed from the bottom of the test electrode compartment, through the wall of the jacket, to a Teflon "T-bore" stopcock. The second arm of the stopcock led to an external counterelectrode compartment, while the third arm served to drain both compartments. A Teflon coated bar-magnet provided stirring in the test electrode compartment.

Iron electrodes studied in this investigation were machined from a small ingot of high-purity, zone-refined electrolytic iron.[2] The analysis of the ingot (Bar 27, Specimen D, Lot 7) in parts per million was as follows: C(10), N(2), H(0.1), S(5), Al(15), Cr(5), Co(1), Cu(2), Mn(0.5), Ni(12), Si(10), and (Sb, As, Ca, Cd, Pb, Mo, Sn, Ti, W, Va, Zn, Zr) not detected.[3] The electrodes were cylindrical, ½ in. long, and either ⅛ (small) or ¼ (large) in. in diameter. The electrodes were mounted on conventional Teflon electrode holders (19).

Sulfuric acid and sodium sulfate solutions were prepared from reagent grade materials and triply distilled water. All solutions were pre-electrolyzed, using an iron cathode, and saturated with hydrogen. Electrolytic hydrogen was purified at 450°C over copper and palladium, and presaturated with water vapor at 25°C.

In a typical experiment, the cell and auxiliary apparatus were cleaned in hot acid solution (equal parts of concentrated H_2SO_4, concentrated HNO_3, and distilled water), rinsed in distilled water, assembled, and leached with test solution. Test electrodes were initially etched in the same acid solution, rinsed in distilled water, and transferred to the cell. Test electrodes remained in test solution from one to several days prior to recording any data, during which period the test solution was replaced frequently by fresh solution from a reservoir. A well-behaved system exhibited no polarization hysteresis phenomena, and this fact was used as the basic criterion by which the suitability of the system for investigation was determined.

Potentials were measured with a high impedance (10^{11} ohms) L&N Model 7664 *p*H and EMF meter, and recorded with a 10 mv Brown recorder. In this investigation, concerned only with the steady-state behavior of iron, a galvanostat was employed in the determination of polarization curves. Steady-states were established within the response time of the recorder, *i.e.*, approximately 3 sec full-scale. For current densities in excess of roughly 1 ma/cm², it was necessary to employ an internal iron counterelectrode in place of the external counterelectrode. A stream of hydrogen through the test solution was maintained at all times, enabling the solution *p*H to be measured with a platinum-hydrogen electrode. The platinum was immersed in the solution only momentarily and then retracted to a position above the solution in order to prevent contamination. Ferrous ion concentration was held to a negligible level by frequent change of the test solution.

Results

A Tafel diagram of typical data obtained in 0.5M H_2SO_4 is shown in Fig. 1, in which the absolute value of the net current density, $|i_n|$, is represented by the solid line passing through the encircled experimental points. The partial cathodic current density, $|i_c|$, corresponding to the hydrogen evolution reaction, exhibits Tafel behavior with the cathodic Tafel line (dashed) having a slope of $-2(2.303\ RT/\mathbf{F})$. Concentration polarization accounts for the deviation from Tafel behavior at high cathodic current densities. The partial anodic current density, i_a, corresponding to the iron dissolution reaction, shows a Tafel region over which the slope is 40 mv/decade, *i.e.*, $(2/3)(2.303\ RT/\mathbf{F})$. No concentration polarization is observed on the anodic side, but at current densities above those shown in Fig. 1, deviation from Tafel behavior as a result of IR-drop becomes significant. The extrapolated anodic and cathodic Tafel lines (dashed) intersect at the observed open-circuit potential, E_{corr}, and fix the magnitude of the corrosion current density, i_{corr}. The partial and net current densities satisfy the relation, $i_n = i_a + i_c$.

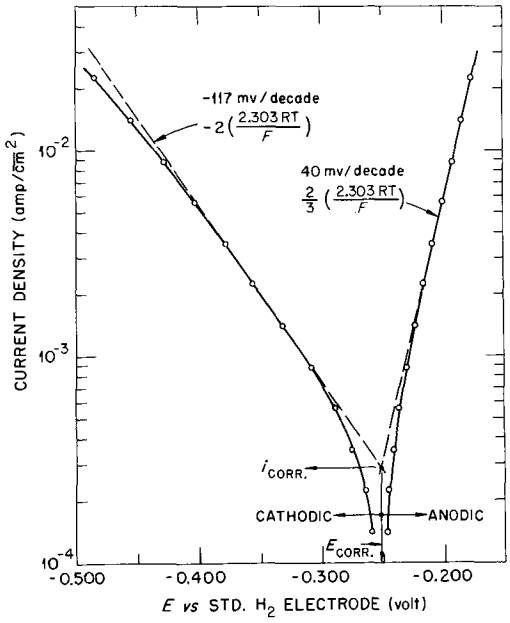

Fig. 1. Polarization of iron in H_2-saturated 0.50M H_2SO_4; T = 30°C.

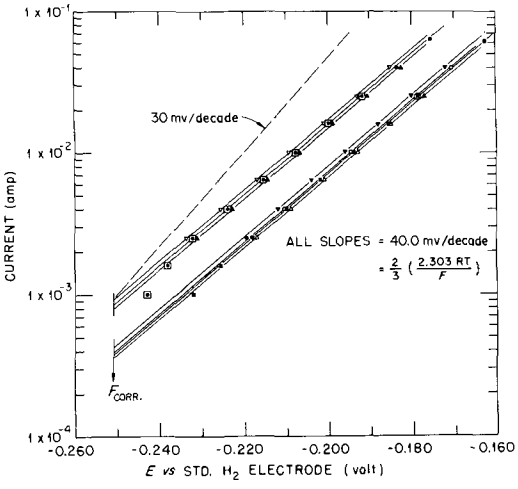

Fig. 2. Anodic polarization of iron in H_2-saturated 0.50M H_2SO_4 (T = 30°C). Data shown for 4 large and 4 small electrodes, each in freshly prepared solution; initial apparent area ratio = 2.86 cm²/1.35 cm² = 2.12.

The purpose of the experiment summarized in Fig. 2 was to resolve the conflict concerning the magnitude of the steady-state anodic Tafel slope. To this end, the anodic polarization characteristics of numerous iron electrodes, each in freshly prepared 0.5M H_2SO_4, were determined. The results clearly show that the steady-state anodic Tafel slope is 40 mv/decade, *i.e.*, $(2/3)(2.303\ RT/\mathbf{F})$, and not 30 mv/decade, as frequently reported, or some other value of less diagnostic significance. For comparative purposes, a line having a slope of 30 mv/decade has been included in Fig. 2. The results also show that a rather high degree of accuracy may be expected when comparing polarization data for different electrodes on the basis of apparent surface areas. At a given potential, the ratio of the average current for the four large electrodes to

[3] See Table I of ref. (18) for limits of detection.

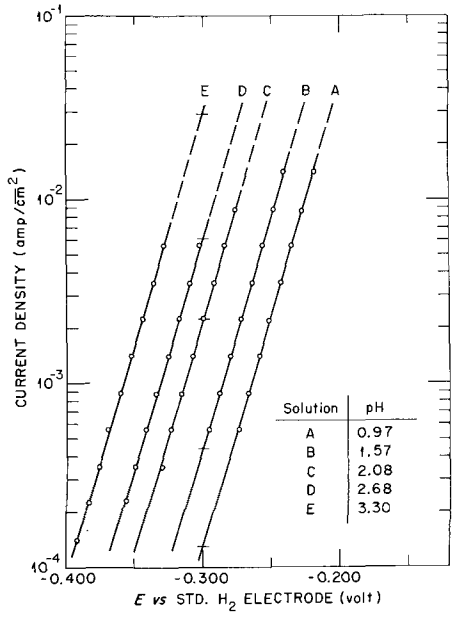

Fig. 3. Anodic polarization of iron in H_2-saturated 0.50M (H_2SO_4 + Na_2SO_4) at various pH values; T = 30°C.

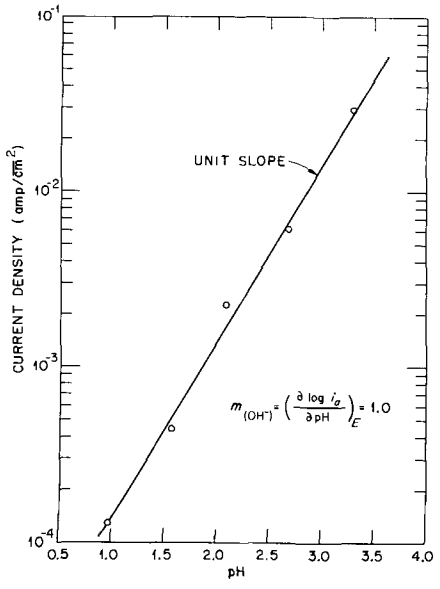

Fig. 4. Anodic current density of iron electrode as function of pH at constant potential (E = —0.300v vs. std. H_2 electrode) in H_2-saturated 0.50M (H_2SO_4 + Na_2SO_4); T = 30°C.

that for the four small electrodes is 2.19, while the apparent area ratio of the large and small electrodes is 2.12. Contamination of the electrode surface by solution impurities, as evidenced by the presence of slow polarization hysteresis phenomena, was occasionally encountered in studies at higher pH values, *i.e.*, in solutions prepared from Na_2SO_4. In such cases, the electrode was found to be less polarizable than normal, and no true Tafel behavior was observed. Normal behavior was restored by replacing the solution and re-etching the test electrode.

On the basis of the results just described, the partial anodic and cathodic current densities may be expressed by Eq. [18] and [19], respectively

$$i_a = k_a a_{(OH^-)}^m \exp(3\mathbf{F}E/2RT) \quad [18]$$

$$|i_c| = k_c a_{(H^+)}^n \exp(-\mathbf{F}E/2RT) \quad [19]$$

in which the reaction orders, m and n, remain to be determined. A direct evaluation of the order of the anodic reaction with respect to the hydroxyl ion activity was made. A single test electrode was placed in solution having a pH of 3.30, and the anodic Tafel line was determined. The pH was then lowered by running H_2-saturated, pre-electrolyzed dilute sulfuric acid directly from a storage reservoir into the cell *via* Teflon tubing and stopcocks connecting the two compartments. In this fashion, the system was maintained in a completely closed state. At each pH, the anodic Tafel line was determined. The results of this experiment are summarized in Fig. 3 which shows the displacement of the anodic Tafel line accompanying changes in solution pH. According to Eq. [18], the reaction order is given by Eq. [20]

$$m = (\partial \log i_a/\partial \mathrm{pH})_E \quad [20]$$

Using the current densities observed at E = —0.300v (marked in Fig. 3 by a horizontal bar), the order plot shown in Fig. 4 was constructed. As the figure shows, a straight line drawn with a unit slope fits the data very closely. Consequently, the anodic reaction is first order in hydroxyl ion activity, and not second order.

According to Eq. [21], which follows directly from Eq. [18]

$$(\partial E/\partial \mathrm{pH})_{i_a} = -(2m/3)(2.303\ RT/\mathbf{F}) \quad [21]$$

the electrode potential at a constant anodic current density should be a linear function of pH and, if m = 1, the proportionality constant should be equal to —40 mv/pH. Using this approach, the results of anodic order determinations performed on several different electrodes are conveniently summarized in Fig. 5. The straight line drawn with a slope of —40 mv/pH fits the data, further confirming the fact that m = 1.

A satisfactory direct evaluation of n, the order of the hydrogen evolution reaction with respect to proton activity, is precluded by concentration polarization. However, at open-circuit, $i_a = |i_c| = i_{corr}$, and $E = E_{corr}$. Consequently, it follows from Eq. [18] and [19] that

$$(dE_{corr}/d\mathrm{pH}) = -(m + n)(2.303\ RT/2\mathbf{F}) \quad [22]$$

i.e., a plot of E_{corr} *vs.* pH should yield a straight line having a slope of $-(m + n)(2.303\ RT/2\mathbf{F})$. Since it has already been established that m = 1, this approach allows an indirect evaluation of n to be made. The results of experiments performed on several different electrodes are shown in Fig. 6. In some instances the data were obtained in a matter of minutes by following the procedure used to determine m, *i.e.*, by starting at the highest pH and then reducing the pH in steps by running H_2SO_4 into the cell from a reservoir. In other cases, the electrodes remained several days at each pH, during which time they were subjected to various polarization experiments. The results confirm the linear

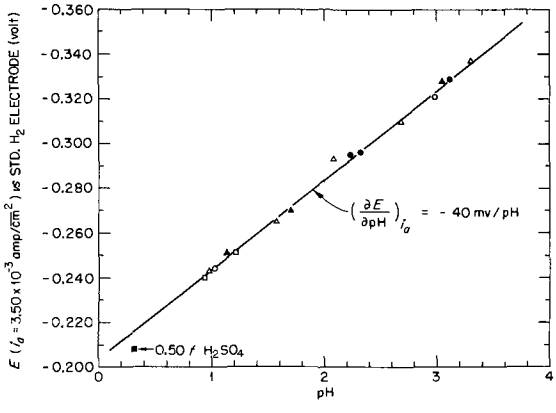

Fig. 5. Variation of the potential corresponding to a partial anodic current density of 3.50 x 10^{-3} amp/cm² with pH for several iron electrodes in H_2-saturated 0.50M (H_2SO_4 + Na_2SO_4); T = 30°C.

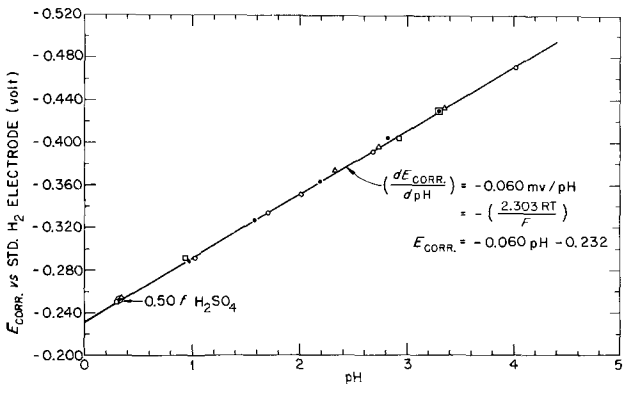

Fig. 6. Variation of the corrosion potential of iron with pH in H_2-saturated 0.50M (H_2SO_4 + Na_2SO_4); T = 30°C. Different electrodes are represented by different symbols (○ and • by fast technique).

relation between E_{corr} and pH and, according to Eq. [22], the observed slope of precisely —60 mv/pH, —2.303 $RT/\mathbf{F}$, means that the hydrogen evolution reaction is first order in proton activity.

Discussion

The experimental results of this investigation are summarized in the following set of self-consistent equations

$$i_{a,\infty} = k_a a_{(OH^-)} \exp(3\mathbf{F}E/2RT) \quad [23]$$

$$|i_{c,\infty}| = k_c a_{(H^+)} \exp(-\mathbf{F}E/2RT) \quad [24]$$

$$E_{corr} = -0.232 - (2.303\,RT/\mathbf{F})\,pH \quad [25]$$

$$\log i_{corr} = -3.15 - (1/2)\,pH \quad [26]$$

in which current densities are expressed in units of amp/cm², and the electrode potential, in volts, is referred to the standard hydrogen electrode. The value of the constant appearing in Eq. [26], —3.15, is based on data obtained in Na_2SO_4 solutions, Fig. 3-5. For 0.5M H_2SO_4, Fig. 1, 2, the constant has a slightly more negative value of —3.38. Equations [25] and [26] show that (dE_{corr}/pH) and (d log i_{corr}/pH) are equal to —60 mv/pH and —½, respectively, and these values may be compared with those cited in the introduction. As a matter of convenience, the hydrogen evolution and iron dissolution reactions are discussed separately.

Hydrogen evolution reaction.—The general reaction scheme for the hydrogen evolution reaction is given by Eq. [27]-[29]

$$H^+ + e^- \rightleftharpoons H_{ads} \quad [27]$$

$$H_{ads} + H^+ + e^- \rightarrow H_2 \quad [28]$$

$$2H_{ads} \rightarrow H_2 \quad [29]$$

in which for the prevailing experimental conditions, dissociation of H_2 can be neglected. If reaction [27] is coupled with reaction [28], the appropriate kinetic equations are Eq. [30] and [31]

$$-i_c/\mathbf{F} = \bar{k}_1 a_{(H^+)}(1-\theta_H) - \bar{k}_{-1}\beta_H\theta_H + \bar{k}_2 a_{(H^+)}\beta_H\theta_H \quad [30]$$

$$\beta_H d\theta_H/dt = \bar{k}_1 a_{(H^+)}(1-\theta_H) - \bar{k}_{-1}\beta_H\theta_H - \bar{k}_2 a_{(H^+)}\beta_H\theta_H \quad [31]$$

in which $\bar{k}_j$ are electrochemical rate constants. The definitions of β_H and θ_H derive from the relation, $[H_{ads}] = \beta_H\theta_H$, where $[H_{ads}]$ is the concentration of adsorbed hydrogen atoms expressed in mole/cm², θ_H is the fraction of the surface occupied by the hydrogen atoms, and β_H is a proportionality constant. In order to achieve agreement with Eq. [24], it is necessary that $(\bar{k}_1 a_{(H^+)} + \bar{k}_2 a_{(H^+)}\beta_H) >> \bar{k}_{-1}\beta_H$, in which case, with $d\theta_H/dt = 0$, Eq. [30] and [31] lead to the steady-state solution represented by Eq. [32] and [33]

$$\theta_{H,\infty} = k_1/(k_1 + k_2\beta_H) \quad [32]$$

$$-i_{c,\infty}/\mathbf{F} = 2\bar{k}_2 a_{(H^+)}\beta_H\theta_{H,\infty} = 2k_2 a_{(H^+)}\beta_H \left(\frac{k_1}{k_1 + k_2\beta_H}\right) \exp(-\mathbf{F}E/2RT) \quad [33]$$

If reaction [27] is coupled with reaction [29], the kinetics are described by Eq. [34] and [35]

$$-i_c/\mathbf{F} = \bar{k}_1 a_{(H^+)}(1-\theta_H) - \bar{k}_{-1}\beta_H\theta_H \quad [34]$$

$$\beta_H d\theta_H/dt = \bar{k}_1 a_{(H^+)}(1-\theta_H) - \bar{k}_{-1}\beta_H\theta_H - 2k_3\beta_H^2\theta_H^2 \quad [35]$$

In this case, agreement with Eq. [24] requires that $2k_3\beta_H^2\theta_H^2 >> \bar{k}_{-1}\beta_H\theta_H$ and $(1-\theta_H) \approx 1$. With these restrictions, the steady-state solution derived from Eq. [34] and [35] is given by Eq. [36] and [37]

$$\theta_{H,\infty} = (k_1 a_{(H^+)}/2k_3\beta_H^2)^{1/2} \exp(-\mathbf{F}E/4RT) \quad [36]$$

$$-i_{c,\infty}/\mathbf{F} = 2k_3\beta_H^2\theta_{H,\infty}^2 = k_1 a_{(H^+)} \exp(-\mathbf{F}E/2RT) \quad [37]$$

The preceding analysis shows that the observed results are consistent with three well-known mechanisms (20),

(*A*) slow discharge-fast electrochemical desorption; Eq. [32], [33], $k_2\beta_H >> k_1$, $(1-\theta_H) \approx 1$

(*B*) fast discharge-slow electrochemical desorption; Eq. [32], [33], $k_1 >> k_2\beta_H$, $\theta_H \approx 1$

(*C*) slow discharge-fast catalytic desorption; Eq. [36], [37], $(1-\theta_H) \approx 1$.

The inability to distinguish among these mechanisms merely on the basis of the dependence of the current density on pH and potential, the inaccessibility of a stoichiometric number for actively corroding iron, and the conflicting opinions generated by various theoretical attempts to establish the rate-determining step (21,22), have resulted in a dilemma which has only recently been resolved with any degree of certainty.

Under certain conditions (23), the steady-state flux of hydrogen atoms diffusing through an iron membrane electrode which divides a cell into two otherwise isolated compartments is given by Eq. [38]

$$f_\infty = \frac{Dk_i\theta_{H,\infty}/k_o l}{1 + (2D/k_o l)} \quad [38]$$

where D is the diffusion coefficient of hydrogen in iron, l is the thickness of the membrane, and k_i and k_o are rate constants associated with the transfer of adsorbed hydrogen atoms from the surface to the interior of the membrane and *vice versa*, respectively. The flux results in a net transfer of hydrogen atoms from the "polarization" side of the membrane, where the surface coverage by adsorbed hydrogen atoms is $\theta_{H,\infty}$, to the "diffusion" side of the membrane. According to Eq. [32], which applies to mechanisms (*A*) and (*B*), $\theta_{H,\infty}$ and, consequently, f_∞ are independent of the potential of the polarization side of the membrane. For mechanism (*C*), Eq. [36] applies and, therefore, $\partial \ln f_\infty/\partial E$ is equal to $-\mathbf{F}/4RT$. This latter result was observed by Devanathan (24), who employed an Armco iron membrane in acidic sulfate solution. At very large cathodic overvoltages, electrochemical desorption predominated, *i.e.*, mechanism (*C*) was replaced by mechanism (*A*). Again, according to Eq. [33], [37], and [38], the steady-state flux should be proportional to $|i_{c,\infty}|$ for mechanisms (*A*) and (*B*), and to $(|i_{c,\infty}|)^{1/2}$ for mechanism (*C*). The latter observation has been reported many times for Armco and comparable irons (23).

In experiments of the type just described, the kinetics of the hydrogen evolution reaction occurring on the polarization side of the membrane are examined. An alternative approach is to study the effects produced by diffusing atomic hydrogen on the kinetics of

the hydrogen evolution reaction occurring on the diffusion side of the membrane (25). Differentiation of Eq. 34 leads to Eq. [39]

$$\left(\frac{dE}{d\theta_H}\right)_{ic} = \frac{(-2RT/F)(\bar{k}_1 a_{(H^+)} + \bar{k}_{-1}\beta_H)}{\bar{k}_1 a_{(H^+)}(1-\theta_H) + \bar{k}_{-1}\beta_H\theta_H} \quad [39]$$

from which it is apparent that $(dE/d\theta_H)_{ic}$ is negative, *i.e.*, for mechanism (*C*) an increase in θ_H resulting from diffusion of hydrogen from the polarization side of the membrane to the diffusion side causes the potential of the latter surface, under cathodic polarization at a constant current density, to become less noble. Similarly, differentiation of Eq. [30] gives Eq. [40]

$$\left(\frac{dE}{d\theta_H}\right)_{ic} = \frac{(-2RT/F)(\bar{k}_1 a_{(H^+)} + \bar{k}_{-1}\beta_H - \bar{k}_2 a_{(H^+)}\beta_H)}{\bar{k}_1 a_{(H^+)}(1-\theta_H) + \bar{k}_{-1}\beta_H\theta_H + \bar{k}_2 a_{(H^+)}\beta_H\theta_H} \quad [40]$$

and if $\bar{k}_1 a_{(H^+)} > \bar{k}_2 a_{(H^+)}\beta_H$, as in mechanism (*B*), then $(dE/d\theta_H)_{ic}$ is again negative. On the other hand, if $\bar{k}_2 a_{(H^+)}\beta_H > \bar{k}_1 a_{(H^+)}$, then $(dE/d\theta_H)_{ic}$ is positive except for the unlikely case where $\bar{k}_2 a_{(H^+)}\beta_H - \bar{k}_1 a_{(H^+)} < \bar{k}_{-1}\beta_H$, a condition which when coupled with the restriction leading to Eq. [32], [33], $\bar{k}_1 a_{(H^+)} + \bar{k}_2 a_{(H^+)}\beta_H >> \bar{k}_{-1}\beta_H$, would require $k_1 \approx k_2\beta_H$. With $\bar{k}_2 a_{(H^+)}\beta_H >> \bar{k}_1 a_{(H^+)}$, as in mechanism (*A*), $(dE/d\theta_H)_{ic}$ is positive. Kovba and Bagotskaya (26) found that for zone-refined iron in 0.5M H_2SO_4, $(dE/d\theta_H)_{ic}$ is positive, *i.e.*, mechanism (*A*) prevails. For Armco iron in the same medium, the results were less definitive, but were interpreted as being indicative of mechanism (*C*), in agreement with Devanathan's findings.

Bockris and Koch (27) examined the relative rates of hydrogen and deuterium evolution on spectroscopically pure iron and found the results to be consistent only with a slow discharge mechanism. The absence of any significant pseudocapacity associated with changes in θ_H, together with the fact that $(1-\theta_H) \approx 1$, also establishes slow discharge as the rate-determining reaction, both on zone-refined (6) and Armco (24) iron.

Contrary to previous reports favoring slow electrochemical desorption as the rate-determining step, [28], [29], all of the results just described confirm slow proton discharge, $H^+ + e^- \rightarrow H_{ads}$, as the rate-determining reaction for hydrogen evolution on iron. For zone-refined iron, the preceding discussion indicates that the experimental results of the present investigation, Eq. [24], may be attributed to mechanism (*A*), slow discharge-fast electrochemical desorption.

Iron dissolution reaction.—As is shown by Eq. [23], the steady-state anodic Tafel slope, $(\partial E/\partial \log i_{a,\infty})_{pH}$, is equal to 40 mv/decade, *i.e.*, (2/3) (2.303 *RT*/**F**), and the reaction is first order in hydroxyl ion activity. These results are in agreement only with those of Bockris *et al.* (4-6), as may be seen by comparing Eq. [23] and [14]. Equation [23] may be interpreted in terms of the following mechanism

$$Fe + H_2O \rightleftharpoons Fe(H_2O)_{ads} \quad [41]$$

$$Fe(H_2O)_{ads} \rightleftharpoons Fe(OH^-)_{ads} + H^+ \quad [42]$$

$$Fe(OH^-)_{ads} \rightleftharpoons (FeOH)_{ads} + e^- \quad [43]$$

$$(FeOH)_{ads} \rightarrow (FeOH)^+ + e^- \text{ (rate-determining)} \quad [44]$$

$$(FeOH)^+ + H^+ = Fe^{++} + H_2O \quad [45]$$

which takes formal account of the simultaneous coverage of the electrode surface by adsorbed water molecules, hydroxyl ions, and the surface intermediate, $(FeOH)_{ads}$. A kinetic description of this mechanism is given by Eq. [46]-[49]

$$i_a/\mathbf{F} = \bar{k}_3\beta\theta_2 - \bar{k}_{-3}\beta\theta_3 + \bar{k}_4\beta\theta_3 \quad [46]$$

$$\beta d\theta_1/dt = \bar{k}_1(1-\theta_T) - \bar{k}_{-1}\beta\theta_1 - \bar{k}_2\beta\theta_1 + \bar{k}_{-2}a_{(H^+)}\beta\theta_2 \quad [47]$$

$$\beta d\theta_2/dt = \bar{k}_2\beta\theta_1 - \bar{k}_{-2}a_{(H^+)}\beta\theta_2 - \bar{k}_3\beta\theta_2 + \bar{k}_{-3}\beta\theta_3 \quad [48]$$

$$\beta d\theta_3/dt = \bar{k}_3\beta\theta_2 - \bar{k}_{-3}\beta\theta_3 - \bar{k}_4\beta\theta_3 \quad [49]$$

in which $\bar{k}_j$ are electrochemical rate constants, and θ_1, θ_2, and θ_3 represent the fractions of the electrode surface occupied by $Fe(H_2O)_{ads}$, $Fe(OH^-)_{ads}$, and $(FeOH)_{ads}$, respectively, *i.e.*,

$$Fe(H_2O)_{ads} = \beta\theta_1, \quad Fe(OH^-)_{ads} = \beta\theta_2, \quad (FeOH)_{ads} = \beta\theta_3$$

where the surface concentrations are expressed in mole/cm^2, and β is a proportionality constant. The total fraction of the surface occupied, θ_T, is equal to $(\theta_1 + \theta_2 + \theta_3)$. Equations [46]-[49] reduce to the steady-state solution

$$i_{a,\infty}/\mathbf{F} = 2k_4\beta\frac{k_3k_2}{k_{-3}k_{-2}a_{(H^+)}}\left(\frac{k_1}{k_1 + k_{-1}\beta}\right)\exp(3\mathbf{F}E/2RT) \quad [50]$$

which agrees with the observed results, Eq. [23]. The conditions leading to Eq. [50] are $\bar{k}_{-3} >> \bar{k}_4$ and $1 >> (\theta_2 + \theta_3)$. With $\theta_T \approx 1$, the latter condition means that $\theta_1 \approx 1$, *i.e.*, $k_1/(k_1 + k_{-1}\beta) \approx 1$. An alternative approach is to assume that for an instantaneous value of θ_3, the remainder of the occupied surface is divided between θ_1 and θ_2 in accordance with reaction [42] in equilibrium, *i.e.*, $\theta_1/\theta_2 = \bar{k}_{-2}a_{(H^+)}/\bar{k}_2$. Then, with $\theta_1/\theta_2 >> 1$ and $\theta_T \approx 1$, Eq. [46] and [49] reduce to Eq. [51] and [52].

$$i_a/\mathbf{F} = \bar{k}_3\beta(\bar{k}_2/\bar{k}_{-2}a_{(H^+)})(1-\theta_3) - \bar{k}_{-3}\beta\theta_3 + \bar{k}_4\beta\theta_3 \quad [51]$$

$$\beta d\theta_3/dt = \bar{k}_3\beta(\bar{k}_2/\bar{k}_{-2}a_{(H^+)})(1-\theta_3) - \bar{k}_{-3}\beta\theta_3 - \bar{k}_4\beta\theta_3 \quad [52]$$

If $\bar{k}_{-3} >> \bar{k}_4$ and $(1 - \theta_3) \approx 1$, then in the steady-state, $d\theta_3/dt = 0$, the current density is again given by Eq. [50].

A comparison of Eq. [51], [52], and [50] with Eq. [12], [13], and [14], respectively, reveals that the mechanism presented here, Eq. [41]-[45], is basically equivalent to that proposed by Bockris *et al.* (4-6), Eq. [9]-[11], in which the adsorption of water and hydroxyl ions was ignored. The necessity for taking into account the adsorption of these species becomes evident when specific adsorption of an anion inhibitor is considered, as in the second paper of this series. In advocating a modified form of the Heusler mechanism, Lorenz, Yamaoka, and Fischer (8) criticized the Bockris mechanism on several counts. Their objections may be dealt with more effectively if, first, the original and modified forms of the Heusler mechanism are examined. The modified version is shown by Eq. [53]-[56]

$$Fe + OH^- \rightleftharpoons (FeOH)_{ads} + e^- \quad \text{fast} \quad [53]$$

$$(FeOH)_{ads} + Fe \rightleftharpoons Fe(OHFe)_{ads} \equiv K \quad \text{slow} \quad [54]$$

$$Fe(OHFe)_{ads} + OH^- \rightleftharpoons FeOH^+ + (FeOH)_{ads} + 2e^- \quad \text{r.d.s.} \quad [55]$$

$$FeOH^+ + x\cdot H_2O \rightleftharpoons Fe^{++}\cdot aq + OH^- \quad \text{fast} \quad [56]$$

In both the original and modified versions, the steady-state and transient anodic current densities are given by Eq. [7] and [8], respectively, although in the modified version, $k_2\beta\theta_o$ is replaced by k_3K_o in Eq. [8] and k_2 is replaced by k_3k_2/k_{-2} in Eq. [7]. Equating $i_{a,\infty}$ and $|i_{c,\infty}|$, the latter being given by Eq. [19], one finds that $(dE_{corr}/dp\text{H})$ and $(d \log i_{corr}/dp\text{H})$ are equal to $-(2/5)(n+2)(2.303\ RT/\mathbf{F})$ and $-(4n-2)/5$, respectively. The order of the hydrogen evolution reaction with respect to proton activity was not determined by Heusler, but with the reported value of zero for $(d \log i_{corr}/dp\text{H})$, n would necessarily be equal to ½,

and (dE_{corr}/dpH) would then be $-2.303\ RT/\mathbf{F}$, *i.e.*, -60 mv/pH. Not only does $n = \frac{1}{2}$ have no theoretical basis, but it is now established that $n = 1$. With $n = 1$, (dE_{corr}/dpH) and $d \log i_{corr}/dpH)$ would be equal to $-(6/5)(2.303\ RT/\mathbf{F})$, *i.e.*, -70 mv/pH, and $-2/5$, respectively. The reported values of -45 mv/pH and 0 constitute an internal inconsistency in both versions of the mechanism. According to Eq. [7] and [8], the steady-state and transient current densities are second and first order in hydroxyl ion activity, respectively. In view of the discrepancies just cited, it is of interest to examine the method employed in determining these reaction orders. Equations [7] and [8] are of the form

$$i_a = k_a a_{(OH^-)}^m \exp(\alpha \mathbf{F}E/RT)$$

from which it follows that m is given by Eq. [57]

$$m = \left(\frac{\partial \log i_a}{\partial pH}\right)_E = -\left(\frac{\partial E}{\partial pH}\right)_{i_a} \Big/ \left(\frac{\partial E}{\partial \log i_a}\right)_{pH} \quad [57]$$

However, $(\partial E/\partial pH)_{i_a}$ was identified with (dE_{corr}/dpH), which is possible only if $(d \log i_{corr}/dpH)$ is zero. With (dE_{corr}/dpH) equal to -45 mv/pH and $(\partial E/\partial \log i_a)$ equal to 60 mv/decade and 30 mv/decade for the transient and steady-state, respectively, the corresponding reaction orders were 3/4 and 3/2. Conceding that (dE_{corr}/dpH) should probably be -60 mv/pH, the orders were promoted from 3/4 and 3/2 to 1 and 2. One can only conclude that either $n = \frac{1}{2}$, an experimentally and theoretically unacceptable value, or Eq. [7] and [8] are incorrect. A further discrepancy in the original Heusler mechanism is revealed by a consideration of anodic transients under potentiostatic conditions. Heusler found that at constant potential log $(i_{a,\infty} - i_{a,t})$ was a linear function of time. Data were presented for two values of the electrode potential, and a 40 mv increase in the potential was accompanied by a decrease in the time constant, $-dt/d\ln(i_{a,\infty} - i_{a,t})$, from 0.28 sec to 0.25 sec. At constant potential, Eq. [5] may be solved for θ as a function of time, and if the result is substituted into Eq. [4], the anodic current density is given by Eq. [58]

$$(i_{a,\infty} - i_{a,t}) = (i_{a,\infty} - i_{a,o}) \exp(-\bar{k}_{-1}t) \quad [58]$$

which shows that the time constant is actually $1/\bar{k}_{-1}$ and, consequently, potential-dependent. In contrast to the observed effect, an increase of 40 mv in the potential should have caused the time constant to increase by a factor of 4.64. In the modified version of the mechanism, this discrepancy, the existence of which was not noted, has been inadvertently overcome since in this formulation the time constant would be equal to $1/k_{-2}$ and, therefore, potential independent. An additional difficulty in either version arises from the fact that the hydroxyl ion concentration is far too low in acid solution to support the current densities observed. This problem is not circumvented by the suggestion (3) that the hydroxyl ion concentration at the electrode surface can be much greater than in the interior of the solution if hydroxyl ions are more strongly adsorbed than water dipoles for, from a kinetic viewpoint, it would still be necessary to replace Eq. [1] and [53] by Eq. [41]-[43], and OH^- by $Fe(OH^-)_{ads}$ in Eq. [2] and [55]. However, this would raise a question concerning the potential dependency of reactions [2] and [55], since the pre-electrode plane could no longer be identified with the outer Helmholtz plane. Finally, the use of two electron transfer reactions such as reactions [2] and [55] has been appropriately criticized by Bockris *et al.* (4). In reply to the criticism, it has been suggested (8) that two electron transfer reactions may be regarded as the sum of two parallel one electron transfer reactions, but this would result in the reaction having a potential dependency characteristic of a one electron transfer reaction, *i.e.*, $\mathbf{F}E/2RT$ and not $\mathbf{F}E/RT$.

In contrast to the serious defects present in the original and modified forms of the Heusler mechanism, the criticisms leveled by Lorenz, Yamaoka, and Fischer (8) against the Bockris mechanism and, by equability, the mechanism of Eq. [41]-[45], may be shown to be without substance. The following criticisms were leveled against the Bockris mechanism:

1. The steady-state relation derived from the transient current density-potential relation calls for a Tafel slope of 40 mv/decade instead of the reproducible experimental value of 30 mv/decade.
2. The steady-state relation also calls for an electrochemical reaction order with respect to hydroxyl ion activity of 1 instead of 2.
3. The transient current density-potential relation offers no precise statement concerning the electrochemical reaction order.
4. The initial polarization value in the potential-time curve does not disappear when an iron rotating-disk electrode ($\omega = 4800$ rpm) is used.

The first two points require no comment beyond pointing out that the steady-state results, Eq. [23], derive only from direct steady-state measurements and not from transient measurements. Interpretations of transient data which lead to a conflict with Eq. [23] must necessarily be incorrect. The present investigation, being limited to steady-state measurements, offers no direct experimental confirmation of the interpretation suggested by Bockris *et al.* (5, 6) for the transient anodic Tafel line. However, the feasibility of their interpretation, an interpretation which is not in conflict with steady-state results, is not lessened by the third and fourth criticisms listed above. The third point can only be regarded as a matter of semantics for, as was shown in the introduction, the relation between the anodic current density and proton activity is precisely defined, *i.e.*, the anodic current density is inversely proportional to the existing proton activity in the double layer, both in the transient and steady states. With regard to the fourth point, the interpretation of the transient Tafel line observed during anodic charging is based on the assumption that during the time required for reaction [9] to attain a pseudo-equilibrium state, $\bar{k}_{-1}\beta\theta_H a_{(H^+,D.L.)} >> f_{diff}$ (here f_{diff} represents the net diffusion flux of protons from the double layer, where the proton activity is $a_{(H^+,D.L.)}$, to the bulk of the solution). Rotation of the electrode does not necessarily invalidate this inequality and, consequently, although it would affect the rate of decay of the transient, it may have no effect whatsoever on the transient Tafel line, *i.e.*, the observation that the initial polarization value does not disappear (or diminish) can not be regarded as evidence against the interpretation proposed by Bockris *et al.* (5, 6) for the transient Tafel line.

The diversity in the results obtained by other investigators may be attributed to contamination of the electrode surface, as evidenced by the presence of slow polarization hysteresis phenomena. In such contaminated systems, illusory steady-state Tafel behavior is observed if the time lapse in the determination of log *i vs. E* curves is small compared to the time required to significantly alter the state of the electrode surface (30).

Summary

The electrochemical behavior of the active iron electrode in the absence of an inhibitor has been determined, and the results may serve as an experimental and mechanistic base for the interpretation of the electrochemical behavior of iron in inhibited systems. In addition, the results of this investigation suggest that the electrochemical behavior of cobalt in noninhibiting media be carefully re-examined since, in acidic sulfate solution, the system has been interpreted (31-32) in terms of the Heusler mechanism for iron, although there is earlier evidence (33) which indicates that the mechanism presented here may be more appropriate.

Acknowledgment

The author is especially indebted to Dr. G. H. Cartledge for his continued encouragement and resolute support. He also wishes to acknowledge the kind support of Dr. P. H. Emmett.

On the Initiation and Growth of Stress Corrosion Cracks in Tarnished Brass

A. J. McEvily, Jr., and A. P. Bond

Scientific Laboratory, Ford Motor Company, Dearborn, Michigan

ABSTRACT

Stress corrosion cracking of α-brass was studied in nearly neutral ammoniacal copper sulfate. Under the test conditions, this solution produced a thin, adherent oxide film on the brass. Microstructural studies of the fracture surfaces suggest that alternate formation and rupture of this film leads to initiation and propagation of stress corrosion cracks. Crack propagation rates were measured in sheet specimens with a central notch and found to be proportional to $\sigma_g^2 l$, where σ_g is the applied stress and l is the semicrack length.

Among the various mechanisms proposed for stress corrosion cracking are those based on film rupture (1), on structure sensitive sites together with dislocation interactions, on stacking faults, on short range order (2-7), on strain assisted anodic dissolution (8, 9), on stress-sorption (10), and on solid solution effects (11). Such a variety of proposals is an indication that no general mechanism exists, but that one or another is applicable under certain circumstances. However, the lack of a comprehensive study of the role of stress on the initiation and growth of stress corrosion cracks contributes to the uncertainty in deciding which of the many proposed mechanisms is applicable to a case at hand. In the present investigation the role of stress in crack initiation and growth was determined for the stress corrosion of α-brass in an ammoniacal solution. Since it has been suggested (12, 13) that the tarnish which forms on α-brass plays an important role in stress corrosion cracking, it appeared desirable to examine the characteristics of this tarnish in some detail.

Experimental

Materials.—α-brass (70 w/o Cu-30 w/o Zn) (w/o is weight per cent) in both the annealed as well as a cold-worked condition, was chosen for this study because information is available on its susceptibility to stress corrosion cracking under various environmental conditions (13, 14). Annealed specimens, obtained from sheet material, were 0.031 in. thick, and were heat-treated for 2 hr at 500°C in an argon atmosphere. The cold-worked specimens (75% reduction) were 0.015 in. thick. The tensile properties of the materials used were as follows:

	Proportional limit, psi	Yield strength, psi	Tensile strength, psi
Cold Rolled	60,000	95,000	98,000
Annealed	15,000	18,000	52,000

Specimens.—An electropolished tensile strip, ½ in. wide, was used primarily to study the characteristics of the tarnish. A second type of specimen, shown in Fig. 1, was used to study crack growth. A centrally located stress-raising slit localized the region of crack initiation and was made by drilling a hole and then slitting further in the width direction to the desired slit length. Slitting was accomplished by the reciprocating action of a thread impregnated with diamond paste, and provided a reproducible stress-raiser essentially free of

the residual stresses which are characteristic of machined slits or notches. The surfaces of these specimens were lightly polished using metallographic techniques to facilitate the observation of crack growth.

Solution.—The solution shown by Mattson (13) to lead to rapid stress corrosion cracking of α-brass was used. It was 0.05M in $CuSO_4$ and 0.48M in $(NH_4)_2SO_4$ with the *p*H adjusted to 7.25 ± 0.05 with NH_4OH. As Mattson noted (13), the reproducibility is somewhat improved by aging the solution about 24 hr. A small amount of precipitate is formed during this period, but little if any further precipitation was observed subsequently, even during long-time stress corrosion runs.

Tests.—Specimens were tested in a dead-weight, lever-type creep machine, load being transmitted to the specimen through a universal joint to eliminate bending stresses. A plexiglass container, sealed to the specimen below the notch by means of a rubber gasket, was filled with solution after loading. To minimize changes in solution composition, fresh solution was continuously introduced into the cell at a rate of about 80 ml/hr. Initial experiments revealed that attack was rapid at the solution-air interface. To avoid this effect, specimens were coated with Glyptal in the vicinity of the interface.

Crack growth was observed with a low-power microscope (30X) equipped with a micrometer eyepiece. A light source was used to illuminate the specimen surface, and cracks were easily visible through the solution. The lengths of the cracks developed from each end of the slit on both faces were recorded as a function of time. A timer equipped with a cut-off switch automatically recorded the total time to rupture. The applied load was fixed during most of the tests, but in a few instances was altered during a test in order to study the influence of prior load history on the rate of growth of the cracks.

Results

The tarnish.—Forty and Humble (12) concluded that tarnish consists of Cu_2O platelets in a dezincified matrix, with the volume of tarnish about the same as that of the brass replaced. Pickering and Swann (4) have also observed Cu_2O particles in the surface of α-brass exposed to an ammoniacal atmosphere. The tarnish is not the only corrosion product since our tarnished specimens exhibited a weight loss rather than a weight gain. Thus an appreciable fraction of the corrosion products is soluble.

The rate of formation of tarnish, measured by taper-sectioning unstressed specimens which had been immersed in the tarnishing solution for various periods of time, is shown in Fig. 2. Some difficulty was experienced in preparing these taper sections as a consequence of the weak and friable nature of the tarnish. The thickness of the tarnish, x, can be approximated by the equation

$$x = c\sqrt{t} \qquad [1]$$

where c is a constant equal to 1.1 x 10^{-4} in./$hr^{1/2}$, and t is the immersion time in hours. This relation indicates that the rate of tarnish formation is governed by a diffusion process. Figure 2 shows that the average rate of tarnish formation was about the same for annealed and cold-worked specimens, and this is consistent with Pickering and Swann's observation that static dislocations are not sites of preferential chemical attack. It has been reported that in annealed brass the rate of tarnish formation at grain boundaries is greater than within the grains (12).

A micrograph of a taper section through the tarnish layer is shown in Fig. 3. Electron micrographs of replicas stripped from the tarnished surfaces showed that the surface roughened with increasing exposure time.

In order to determine the effect of stress applied during tarnishing, tensile strips of cold-worked brass were loaded to various levels below the proportional limit, and the change in length was noted as a function of time. In the absence of the solution, no extension occurred. Results for tarnished specimens are shown in Fig. 4. Although the specimens were tested within the supposed elastic range, in each case the rate of extension of the specimens increased with time until rupture occurred. Examination of the specimens revealed distribution of cracks in the tarnish, so that the observed extension is a result of the growth of these cracks prior to

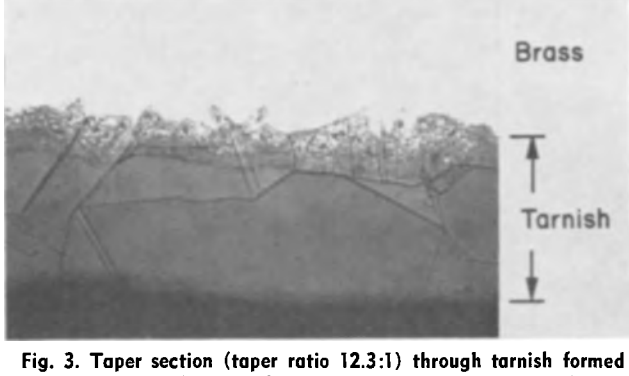

Fig. 3. Taper section (taper ratio 12.3:1) through tarnish formed on annealed brass by a 16 hr exposure to the tarnishing solution. Magnification approximately 300X.

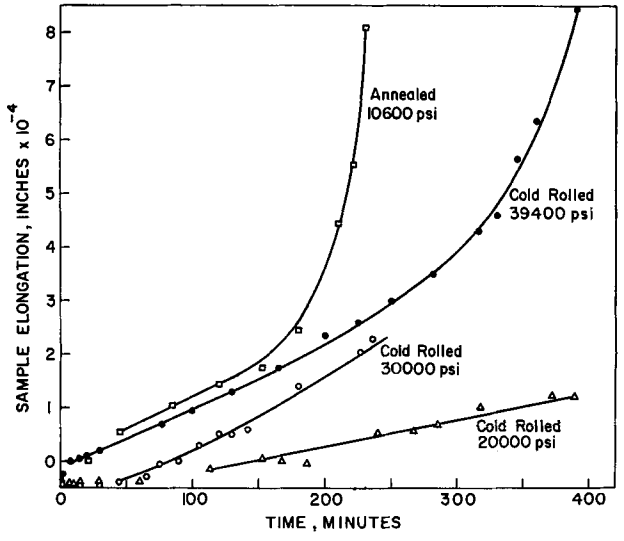

Fig. 4. Elongation of tensile specimens of brass exposed to the tarnishing solution at the indicated stress levels.

final rupture. This result was somewhat unexpected since the work of Forty and Humble, with annealed specimens, appears to indicate that plastic deformation involving slipbands in the brass substrate would be required to initiate cracking of the tarnish. To check on this further, an annealed specimen with a proportional limit of 15,000 psi was tested at 10,000 psi, and behavior similar to that for the cold-worked brass was observed, as shown in Fig. 4. Failure of annealed α-brass below the yield strength in an ammoniacal environment has been previously noted (3, 15). It appears therefore that, although the exact mode of failure is uncertain and may indeed involve dislocation motion on a microscale within the tarnish or at the tarnish-metal interface, massive plastic deformation associated with slip bands is not necessary. Massive plastic deformation can, of course, rupture a surface film, but this would be true for any surface film, such as aluminum oxide, whether or not the material is susceptible to stress-corrosion cracking.

As observed by Forty and Humble (12), the cracking appeared to be confined to the tarnish layer, with cracks being blunted and arrested at the interface between the brittle tarnish and the ductile substrate as shown in Fig. 5 for a cold-worked specimen.[1] It has been suggested (16) that pore formation due to dezincification of the brass might serve to advance the crack in a brittle manner beyond the tarnish layer. In order to obtain some indication of the effect of porosity on ductility, a brass specimen was dezincified by annealing for 30 hr in a vacuum at 850°C, which resulted in a void volume of 17%. Nevertheless, the material was quite ductile, thereby indicating that only the tarnish is brittle in the present case.

Short range order has also been considered to influence the process of stress corrosion cracking by providing a preferred path for corrosive attack due to the destruction of short range order by dislocation motion (4). To check on this point for brass, the time to rupture for tensile specimens of disordered material was compared with that for material possessing a degree of short range order. Disordered material was obtained by water quenching from an annealing temperature of 450°C (the bulk of the tests described in this paper involved disordered material); short range ordered material was obtained by heating quenched material to 190°C and maintaining that temperature for 24 hr (17). The times to failure at three stress levels of the disordered and short-range-ordered α-brass specimens in the tarnishing solution were as follows:

Condition	Applied stress, psi	Time to failure, hr
Short-range-ordered	16,000	4.2, 11.32
Disordered	16,000	2.5, 6.76
Short-range-ordered	18,600	2.77, 4.01
Disordered	18,600	3.0, 4.55
Short-range-ordered	22,700	2.0, 3.08
Disordered	22,700	1.75, 2.65

These results show no obvious correlation between degree of short range order and time to failure. The above results indicate that stress corrosion cracking occurs because of the weak nature of the protective tarnish film and that the strength of the tarnish does not depend on the condition of the underlying brass.

Crack growth.—The experimental approach employed in determining the rate of growth of cracks was similar to that used for fatigue cracks (18). In the latter case, a centrally located slit serves as a stress raiser at which cracks are initiated. The growth of the cracks is observed with a low power microscope and related to the number of load cycles applied; from these data the rate of growth is determined. It has been shown that the rate can be expressed as a single valued function of the parameter $\sigma_g\sqrt{l}$, where σ_g is the maximum applied gross-section stress in the loading cycle, and l is the semilength of the fatigue crack (19). This correlation is not unexpected, since $\sigma_g\sqrt{l}$ is related to the stress intensity at the tip of a growing crack (20) if the crack length is less than half the sheet width.

In the present study the rate is, of course, expressed as a function of time rather than of the number of load cycles.

General Observations

For annealed specimens, the level of stress required to initiate cracks in a short time also caused extensive plastic deformation in the vicinity of the central slit. As a consequence, many cracks appeared in time (Fig. 6). The main crack advanced by a linking up of the smaller cracks, a circumstance which made the determination of a crack front uncertain; therefore, quantitative information with annealed specimens could not be obtained. The cracks in these specimens were usually intergranular. As the cracks deepened, they became much more blunt (Fig. 7).

Crack growth along the surface of cold-worked brass

[1] These cracks are "transgranular," but it is noted that they do not penetrate the α-brass grains themselves.

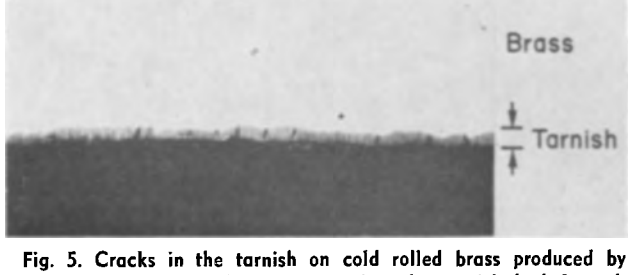

Fig. 5. Cracks in the tarnish on cold rolled brass produced by stressing the base metal in tension after the tarnish had formed. Note that cracks do not penetrate the untarnished metal. Magnification approximately 800X.

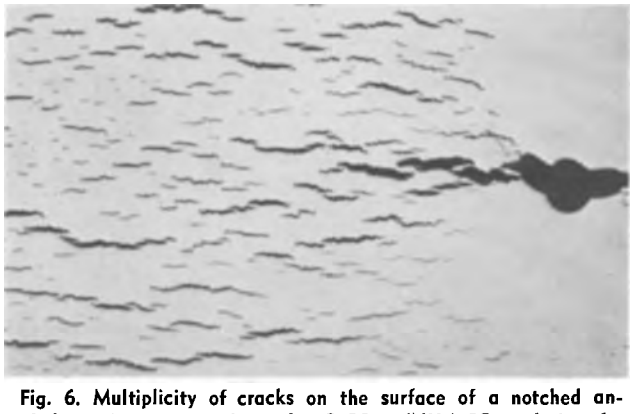

Fig. 6. Multiplicity of cracks on the surface of a notched annealed specimen exposed to the $CuSO_4$—$(NH_4)_2SO_4$ solution for 21 hr at a stress of 13,000 psi. Magnification approximately 7X.

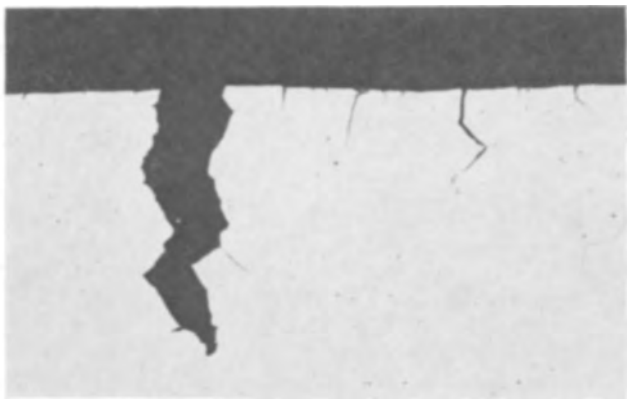

Fig. 7. Cross section of stress corrosion cracks in annealed brass. Magnification approximately 170X.

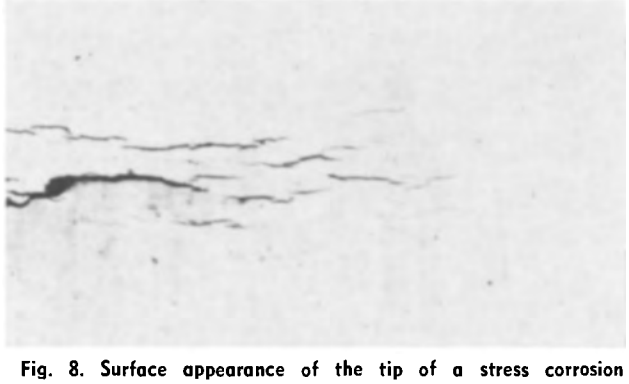

Fig. 8. Surface appearance of the tip of a stress corrosion crack growing in a notched, cold rolled brass specimen exposed 5 hr at 57,000 psi. Magnification approximately 170X.

was much easier to follow. A well-defined main crack advanced along the surface by linking up with microcracks formed in the small plastic zone at the tip of the crack. Microcracks were not visible through the low power microscope, and therefore only the advance of the main crack was recorded. An example of this microcracking is shown in Fig. 8.

In both the annealed and cold-worked specimens the plane of initial crack growth was perpendicular to the specimen surfaces. As the cracks increased in length, the average plane gradually shifted toward 45° to the specimen surfaces, the distance to the transition region being an inverse function of the applied stress. It is noted that the greater proportion of total crack life was spent in the first of these two modes. A shift in crack plane orientation is also observed in fatigue crack growth and can be explained (21) in terms of the size of the plastic zone at the tip of the crack. When the zone size is small with respect to the thickness of the sheet, plane strain conditions prevail at the tip and the fracture plane is normal to the surface. As the crack increases in length, the size of the plastic zone increases also, and when it approaches the sheet thickness a condition of plane stress exists in the plastic zone at the crack tip with the result that the fracture plane shifts to a 45° inclination with respect to the surface.

The shape of the crack front itself depended on the applied stress level. At low stresses, the cracks were well advanced along the surface with respect to the interior. As the stress level increased, the disparity between the two was considerably reduced. An extreme example of the crack leading at the surface was found in the case of a crack formed at 17,000 psi. This crack apparently stopped growing after developing along the surface to a length of 0.094 in. As shown in Fig. 9, its length in the interior was only 0.023 in.

As viewed through the microscope, the growth of cracks in both annealed and cold-worked specimens appeared to be continuous in time; that is, no pauses

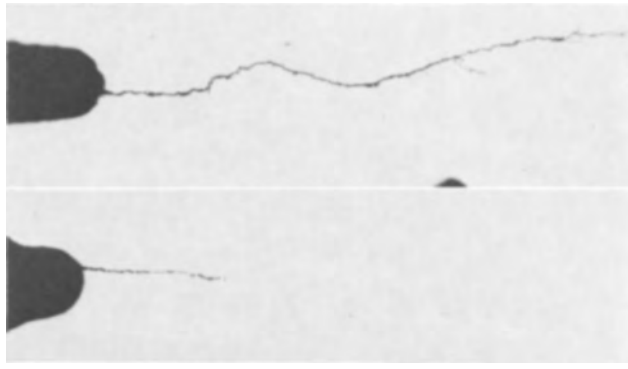

Fig. 9. Crack lengths in a notched, cold rolled brass specimen after 53 hr exposure to the cracking solution at a stress of 17,000 psi; (top), near surface; (bottom) near center of the specimen. Magnification approximately 30X.

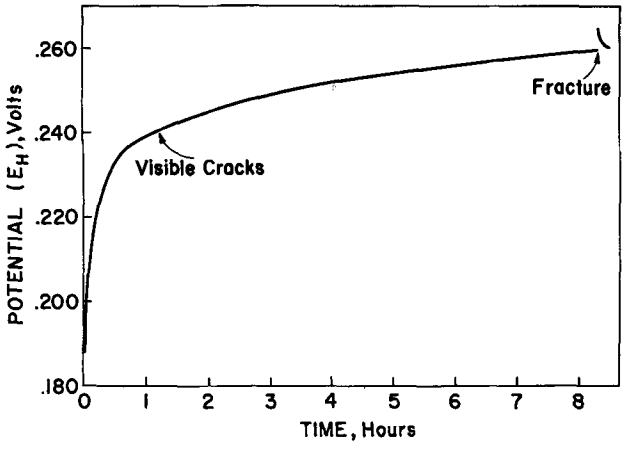

Fig. 10. Potential of a cold rolled, notched stress corrosion specimen as a function of time exposed in 0.05M $CuSO_4$ + 0.48M $(NH_4)_2SO_4$, pH = 7.25 at 50,000 psi.

and subsequent bursts of crack growth were noted. Electrode potential measurements, which have been reported to be sensitive to bursts of crack growth in other systems (22), did not show bursts of growth in the present instance. After an initial fairly rapid drift in the noble direction, the rate of potential change slowed considerably (Fig. 10). Except at fracture, no pronounced discontinuities were observed, and no detectable change in potential occurred at the onset of visible cracking, even though the Luggin capillary employed in these measurements was placed near the crack tip. These results suggest that any active metal surface exposed by the cracking process was too small a fraction of the total surface to have an appreciable effect on the electrode potential. Similar results were obtained for both annealed and cold-worked specimens. In all cases, the potential is in the region corresponding to Cu_2O as the reaction product according to Mattson's calculated potential-pH diagram for this system.

Replicas of the fracture surfaces examined in an electron microscope indicated that discontinuities in growth occurred on a very fine scale. An example of a fracture surface of an annealed specimen is shown in Fig. 11a. Figures 11b and 11c show the appearance of the fracture surfaces of cold-worked brass at two different stress levels. Scanning of the replicas showed that the fracture markings remained parallel over distances much larger than the grain diameter. These markings are similar to those observed on the fracture surfaces of fatigue specimens as a consequence of the advance and blunting of the fatigue crack during each loading cycle.

Rate of Crack Growth

The log of the rate of crack growth for cold-worked brass is a single valued function of the crack stress tip

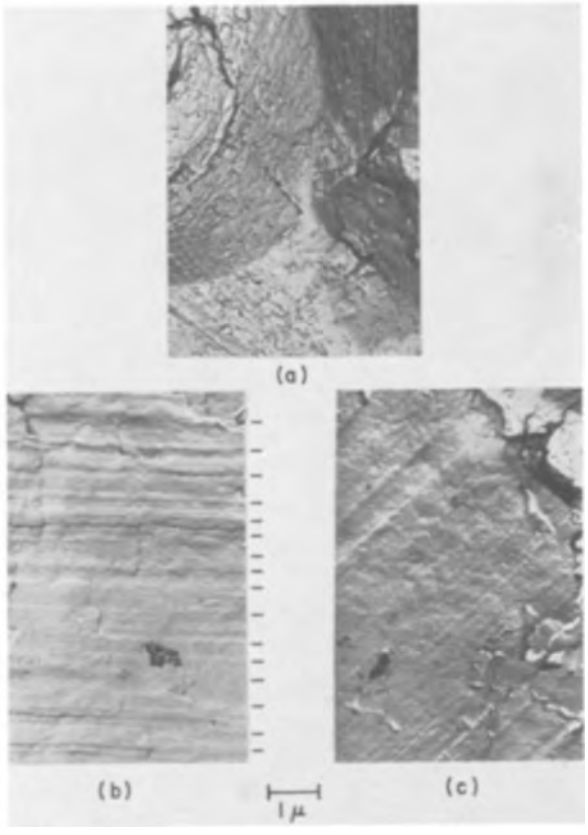

Fig. 11. Electron micrographs of replicas of stress corrosion fracture surfaces. (a) annealed brass at 14,600 psi; (b) cold rolled brass at 30,900 psi (main rupture markings indicated in margin); (c) cold rolled brass at 67,000 psi. Magnification approximately 7000X.

intensity parameter, $\sigma_g\sqrt{l}$, over a wide range of values (Fig. 12). The data can be approximated by a line whose equation is

$$\log dl/dt = \log A + 2 \log \sigma_g\sqrt{l} \qquad [2]$$

or

$$dl/dt = A\sigma_g{}^2 l \qquad [3]$$

where A is a material constant.

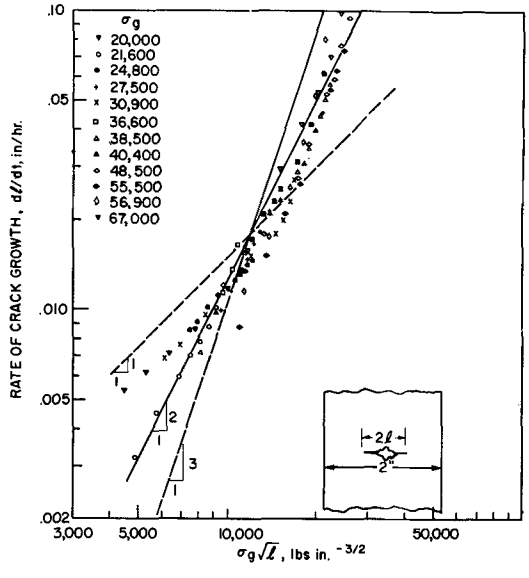

Fig. 12. Rate of stress corrosion crack propagation in cold rolled brass exposed to 0.05M $CuSO_4$ + 0.48M $(NH_4)_2SO_4$, pH = 7.25.

This equation holds for values of $\sigma_g\sqrt{l} > 4000$ lb-in.$^{-3/2}$. Below this value cracks propagate at a much slower rate than given by Eq. [3].

Equation [3] may be integrated to give

$$\ln l_R/l_o = A\sigma_g{}^2 t_R \qquad [4]$$

where t_R is the time to rupture, if crack initiation occurs instantaneously, l_o is the initial crack length, and l_R is the crack length at rupture. Since most of the time is spent in growing the crack at lengths much below l_R, variations in l_R, a number which would actually decrease with increasing applied stress, can be neglected with only small error. If this is done, then

$$t_R \propto \frac{1}{\sigma_g{}^2} \qquad [5]$$

A logarithmic plot of the data *vs.* time to rupture is given in Fig. 13; the observed slope of −2 shows that the time to rupture does indeed depend inversely on the square of the applied stress level. If the numerical value of A determined from the rate plot (Fig. 12) is used, then the quantitative prediction is with 20% of the measured value, indicating that the assumptions used above are reasonable.

Specimens which were prestressed in compression to introduce a state of residual tensile stress at the notch tip and an increase in notch sharpness, cracked at stress levels below the minimum for specimens not prestressed. Specimens prestressed in tension, required much longer times for development of cracking than in the absence of the preload.

When the amplitude of tensile loading was varied during the test the results also reflected the influence of prior load history. Denoting the time spent at the nth stress level as t_n and t_{Rn} as the time to rupture at the nth level, then changing from high loads to low increased the total life as given by

$$n = \sum_{1,2}^{n} \frac{t_n}{t_{Rn}} \qquad [6]$$

whereas going from a low load to a high had little effect on the rate of growth at the higher load level. It appears then that the above summation will yield a

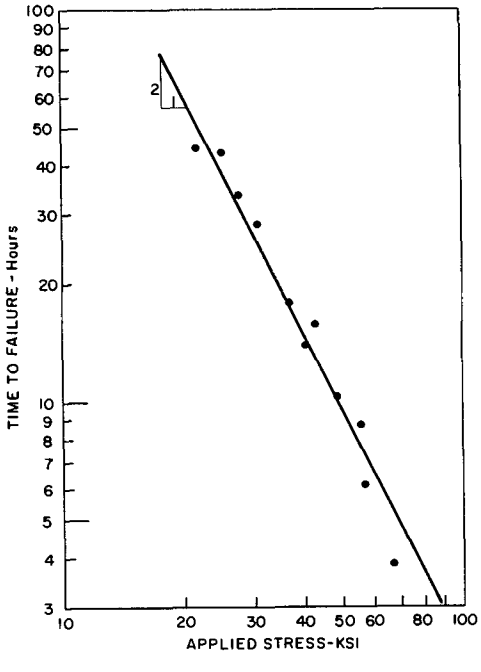

Fig. 13. Time to rupture as a function of applied stress for notched, cold rolled brass specimens exposed to the cracking solution.

value equal to or greater than unity for tensile loading. Therefore a simple prediction based on the time spent at each load level would lead to a conservative prediction of total lifetime. However, if a compressive load were applied, it would accelerate cracking in the next stage of tensile loading due to its effect on residual stresses and shape of the crack tip. In this event the above summation would be reduced. These effects of prior load history on the growth of stress corrosion cracks are similar to those observed in the case of fatigue crack growth.

Discussion

Of the various suggested mechanisms for stress corrosion cracking, our results are in best accord with the film rupture mechanism proposed by Logan (1). Exposure of brass to ammoniacal cupric sulfate solution rapidly produces a protective film, consisting mainly of cuprous oxide, which reduces the over-all corrosion rate to a fairly low level. Cracking of this film exposes a small area of bare metal which is anodic to the film. Rapid anodic attack on the exposed brass leads to reformation of the protective film. After the protective tarnish is again established its rate of thickening is expected to be controlled by diffusion processes within the film.

Stress corrosion cracking was found experimentally to consist of three steps: (*a*) crack initiation, followed by (*b*) crack advance along the surface into regions already tarnished, and simultaneously, (*c*) crack penetration from the surface into the interior of the specimen.

Crack initiation.—Cracks appeared in the notched specimens within the plastic zone at the tip of the stress raiser as the tarnish layer formed. It seems unlikely that the formation of an extremely thin film could have caused a motion of the static array of dislocations initially present in the substrate and thereby rupture the film. It seems more likely that rupture involved a decrease in resistance to fracture of the film with increasing thickness. That such a strength-thickness relationship exists is inferred from the work on thin films of silver and gold which has demonstrated that the fracture stress decreases sharply with increasing thickness up to about 1000Å (23, 24). In addition, epitaxial stresses in the tarnish, which would be expected to increase with thickness, may also lower the fracture resistance. Such an interpretation is consistent with the behavior of unnotched specimens which extended and failed, even in the nominally elastic range, at rates which increased with the stress level.

Crack growth along the surface.—This mode of crack advance in the plastic zone ahead of the main crack (Fig. 8) is associated with the advance of the crack into a region which has already been tarnished. Plastic deformation of the underlying brass results in the opening up of microcracks already present in the tarnish and the further cracking of the tarnish. The mechanism is probably similar to that described by Forty and Humble: planar glide, induced by a low stacking fault energy, introduces a severe stress concentration when blocked by the surface layer.

Crack growth in interior.—The cracking of the subsurface section of the specimens controls the over-all rate at which cracks propagate. Because of the accelerated cracking in the unconstrained plastic zones at the surface, the crack front takes on a curved shape which is more pronounced at low stress levels. Since cracks penetrate only to the tarnish-metal interface, the important step in crack propagation is the repeated formation and rupture of the tarnish layer along the crack front; therefore, the process of crack growth has much in common with crack initiation. This view is supported by the regular nature of the markings found on the fracture surface (Fig. 11). Such markings are not expected if a simple dissolution process or some random blocking of the crack tip occurred. These markings are thought to be due to the plastic deformation which occurs each time the tarnished film ruptures and the crack advances to the interface where it is arrested by plastic blunting, as shown in Fig. 14. The figure also indicates how secondary markings due to slip bands may be present on the fracture surface and between main markings.

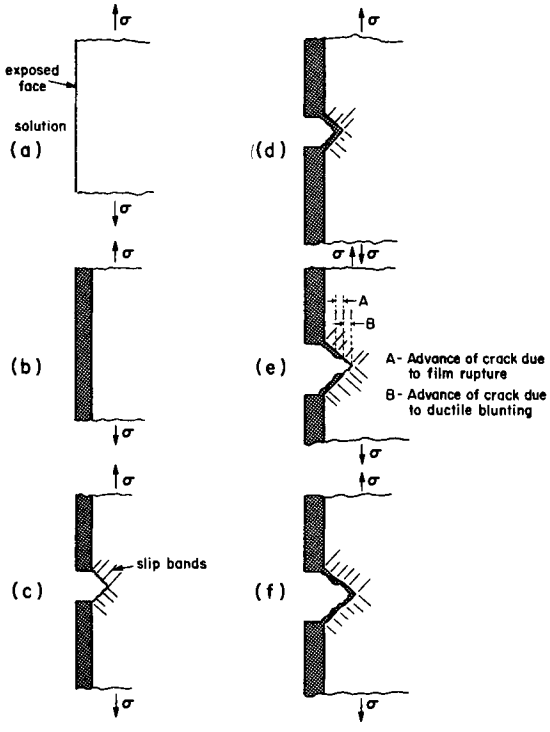

Fig. 14. Schematic representation of initiation and growth of stress corrosion cracks by the process of tarnish rupture.

The rate of formation of cracked area by such a mechanism is given by

$$r = B\frac{\Delta l}{\Delta t_R} = B\frac{\Delta l_T + \Delta l_B}{\Delta t_R} \qquad [7]$$

where B is a numerical factor that relates the shape of the crack front to the dimensions and shape of the specimen. This factor is considered in the present example to be independent of stress, but in fact does depend somewhat on the applied stress, particularly at low stress levels. Δl is the increment of crack growth due to tarnish rupture and plastic blunting (A + B, Fig. 14) and is the sum of the incremental advance due to tarnish rupture, Δl_T, plus that due to plastic blunting, Δl_B; and Δt_R is the time for the formation of the film measured from the end of one increment of crack advance until the tarnish ruptures again.

If we neglect the contribution of plastic blunting to the advance of the crack and assume the rate of thickening of the film at the tip is a diffusion controlled process, we can write

$$\Delta l = \Delta l_T = c\sqrt{\Delta t_R} \qquad [8]$$

With respect to this assumption, it is of course likely that when the film is very thin the rate of reaction is controlled by the activation polarization characteristics of the brass. It has been shown that copper can dissolve at very high anodic rates (25), and it is reasonable to expect that brass does also. In this case, the film soon thickens to the point that diffusion processes within the film become rate controlling so that during most of the period of film growth, the rate-determining step is diffusion within the film. However, another possibility to be considered is that diffusion within the crack of reactants to the tip or products to the bulk solution is rate controlling. Hines has shown that this concentration polarization is unlikely to be of im-

portance in the cracking of austenite stainless steels (9). In the present case the principal anodic reaction is $2Cu+H_2O \rightarrow Cu_2O+2H^+$. Thus the only reactant supplied by diffusion is water which is present in great excess and the only product removed by diffusion is the hydrogen ion which has the highest diffusivity of all ions. Also the buffer capacity of the electrolyte should minimize effects of changes in hydrogen ion concentration. This system is therefore less likely to be subject to considerable concentration polarization within the crack than would the stainless steel system considered by Hines so that concentration polarization does not seem to be rate controlling in the present case. It therefore appears reasonable that diffusion within the tarnish controls the rate at which the tarnish forms.

Upon substituting for Δt_R in Eq. [8] we obtain

$$r = \frac{Bc^2}{\Delta l_T} \qquad [9]$$

From the data on the rate of formation of the film, c^2 is equal to 1.2×10^{-8} in.^{2}/hr, assuming that a bulk measurement can be extended to the thin tarnish layer at a crack tip.[2] For a value of B close to unity, the rate of advance of the crack is given by

$$r = \frac{1.2 \times 10^{-8}}{\Delta l_T} \text{ in./hr} \qquad [10]$$

If the distance between the main markings in Fig. 11 is taken as the thickness of the tarnish film at the time it ruptures a calculation of the rate of crack advance can be made using Eq. [10]. This leads to rates of cracking of 0.0025 in./hr at a gross stress of 67,000 psi and 0.0006 in./hr at a gross stress of 30,900 psi. These replicas were taken close to the crack origin where the corresponding experimentally determined rates are about 0.017 and 0.004 in./hr, respectively. The observed and calculated rates could be brought into closer agreement if approximately one-half of the distance between markings were attributed to the advance due to plastic blunting. Because of uncertainties in the tarnishing process at the tip of a crack and in making measurements from the replicas it does not seem possible to make a more rigorous calculation of these rates at present.

From the experimental findings it has been shown that the rate of growth is proportional to $\sigma_g^2 l$. This indicates that the advance of the crack front is related to Eq. [7], and can be expressed as

$$\sigma_g^2 l \propto \frac{1}{\Delta l_T}\left(1 + \frac{\Delta l_B}{\Delta l_T}\right) \qquad [11]$$

If the advance due to blunting is linearly related to the advance due to tarnish rupture, then the above proportionality can be reduced to

$$\sigma_g^2 l \propto \frac{1}{\Delta l_T} \qquad [12]$$

A rationalization of this empirical relationship is not straightforward in that the factors responsible for the rupture of the film at the tip of a crack are quite complex. It is known, however, that the radius of a crack tip is directly related to the quantity $\sigma_g^2 l$ (26). The smaller the size of the radius the more the stress state will approach one of plane strain, a condition which would tend to cause a rapid decrease in shear stress immediately ahead of the curved crack front. Since tensile fracture usually is the result of shear deformation, fracture of the tarnish and the advance of the crack front may also depend on the magnitude of the shear stresses encountered as the film thickens and its fracture resistance decreases. The lower the value of $\sigma_g^2 l$, the greater will be the thickness attained before rupture because of the lower magnitude of shear stresses involved.

[2] Since the grain boundaries in annealed brass are replicated in the oxide (Fig. 4), enhanced diffusion along these oxide grain boundaries may be associated with the intergranular cracking mode in annealed brass. Heavy cold work would tend to reduce the structural difference between matrix and boundaries.

Concluding Remarks

1. It is concluded that both the initiation and propagation of stress corrosion cracking in tarnished α-brass involves the formation and rupture of a weak, protective film, and that cracking occurs because rupture of the film localizes the effects of stress and environment. This localized cracking process is avoided if the film is not sufficiently protective to restrict general corrosion. For example, we have observed this to be the case for copper in the ammoniacal copper sulfate solution. It can also be avoided if the film is strong enough to sustain the applied stress without rupturing.

2. The process of film rupture does not require massive plastic deformation of the substrate. This finding does not preclude the possibility that dislocation motion within the tarnish or on a microscale at the tarnish-brass interface occurs and is involved in the rupture process.

3. The rate of growth of stress corrosion cracks for a wide range of crack growth rates is a single valued function of the parameter $\sigma_g^2\sqrt{l}$, and the rate is proportional to $\sigma_g^2 l$. From this relationship it follows that the time to rupture varies inversely as the square of the applied stress level. σ_g.

Acknowledgment

The authors express their appreciation to Drs. T. L. Johnston, A. S. Tetelman, and G. F. Bolling for helpful discussions during the course of this investigation. The capable assistance of Mrs. P. McAlpine, Mr. R. Benoit, and Mr. J. Ingall is also acknowledged.

Manuscript received Aug. 10, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

ABSTRACT

The adsorption of 4-ethylpyridine, 4-ethylpiperidine, and very low molecular weight poly(4-vinylpyridines) was studied in cyclohexane solutions containing hydrogen reduced steel powder. Isotherms were obtained for the monomers at 30°C. They show that an amount equivalent to monolayer formation is adsorbed at equilibrium concentrations in the range 2.5 to 5.0 x 10^{-3}M. The polymer was adsorbed to a much greater extent. Using a specially designed chromatographic method, the heat of adsorption of the piperidine derivative from cyclohexane was determined. Simultaneous measurements of the adsorption of the polymer and the corrosion of the steel in aqueous hydrochloric acid have shown that the corrosion rate decreases by 80% as the polymer adsorbs to form a very incomplete layer. From these results, it is concluded that these compounds chemisorb to the steel surface and that the 4-ethylpiperidine is bonded at the nitrogen atom but that the 4-ethylpyridine is adsorbed in a position with the plane of the ring parallel to the steel surface. Attachment of polymer is at multiple sites in the molecule, but appreciable portions of the chains are left in the solution phase. The area which is deactivated toward corrosion by adsorption of poly(4-vinylpyridine) from HCl is considerably greater in extent than that which is physically covered by the adsorbed molecules, *i.e.*, a large neighboring area of steel surface is ennobled by the adsorbed polymer molecules.

In corrosion inhibitor research, it has long been recognized that preferential adsorption of organic inhibitors interferes with the reaction between the corrodant species and the metal surface. At first, this interference was believed to result from electrostatic attraction between cations and cathodic areas, or between anions and anodic areas. This concept alone has since been shown to be untenable (1), and other types of adsorption have had to be considered. In 1954 Hackerman and Makrides proposed a chemisorption mechanism of inhibitor action (2), and Finley and Hackerman showed that a persistent, inhibiting adsorption of amines could be obtained in benzene (3). Other investigators have discussed various other types of adsorption or combinations of types to account for the observed results (4, 5). Recently radiochemical and spectrophotometric measurements of the adsorption of thiourea derivatives have been reported (6, 7). However, solution adsorption measurements on steel surfaces for inhibitor amines with similar molecular character but dissimilar inhibitor action have been lacking.

The work reported here was undertaken in conjunction with an inhibition study (8) to examine the adsorption behavior of amine inhibitors and to elaborate the relationship between adsorption and inhibition. A dual approach was chosen: (i) a study of two simple compounds, 4-ethylpiperidine and 4-ethylpyridine, which are similar in size, base strength, solubility, and chemical nature, but which are not so similar as might be expected in their inhibitor effectiveness; and (ii) a study of the relative adsorbabilities of a monomer amine, 4-ethylpyridine, and a polymer, poly(4-vinylpyridine), which had very short chains and whose repeating units had the same structure as the monomer. To keep the reactions at the steel surface simple and therefore to focus attention on the adsorption, the adsorption experiments were carried out in cyclohexane on steel powder which was carefully freed of oxide by reduction in a hydrogen atmosphere.

Experimental Procedures

Static adsorption measurements.—These experiments were designed to study adsorption from cyclohexane solutions onto reduced steel powder in the absence of oxygen. The steel powder was reduced in hydrogen, weighed, and then introduced to the thermostated adsorption cell under the surface of the cyclohexane without exposure to air. In some cases, the adsorbable amine was present in the solution before the steel powder was added; in others, the amine was added later. There was no observable difference in the equilibrium amount adsorbed due to the different procedures. The adsorption cell was provided with a paddle stirrer and was maintained under a positive nitrogen pressure of 3 or 4 lb by means of a mercury columun on the exit line. Tank nitrogen was bubbled through a zinc-vanadyl sulfate tower to remove oxygen, then through a sulfuric acid scrubber to remove any water spray, and finally a Drierite tower to remove any acid spray. The nitrogen was then passed through a cyclohexane bubbler which was kept in the thermostated water bath with the adsorption cell. All of the connections between the bubbler and the adsorption cell were made of glass. Teflon sleeves were used to seal

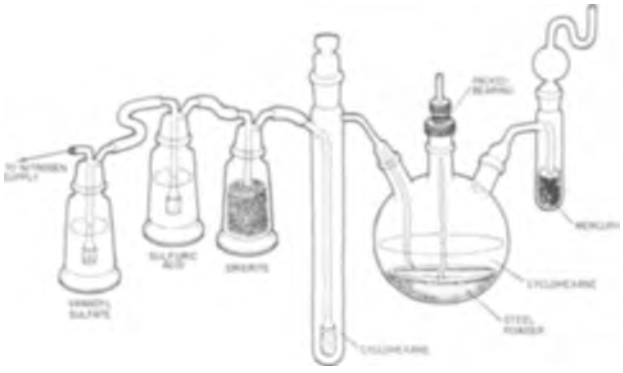

Fig. 1. Adsorption cell and gas train

the ground-glass joints. The arrangement of this equipment is shown in Fig. 1.

The adsorption cell was assembled from a one-liter, three-neck Morton flask with a Trubore packed stirrer bearing assembly[3] combined with a shop modified lubricant trap. When connected to a Waco stirrer motor to complete the apparatus, it could be kept sealed and operating continuously for at least as long as 30 days without a net loss of cyclohexane and without contamination of the solvent with lubricant or chemicals from the gas train.

The bubbler and the adsorption cell were immersed in a stirred water bath maintained at 30° ± 0.005°C by a Sargent Thermonitor, with water level in the bath maintained by a simple float valve arrangement. In the usual case, samples of the solution for analysis were taken systematically over a period of about 10 days and were used to determine the course of the adsorption process. Samples from a portion of the thermally equilibrated initial solution, taken before introduction of the steel, were used as standards for this comparison.

The steel powder used for these experiments was obtained from the Vanadium-Alloys Steel Corporation, Latrobe, Pennsylvania. Chemical analysis supplied by the manufacturer was in the typical range for the SAE 1020 composition. Sieve analysis produced 85.0% of the particles in the range 140-200 mesh or 74-105μ. BET determination showed 0.0571 m^2/g for the specific surface of the reduced powder. This indicates a surface roughness factor of 5.8.

The powder, contained in a Vycor tube, was prepared for the adsorption experiments by reducing it with hydrogen at 650°C maintained in a controlled temperature furnace, Completeness of reduction was determined by absorbing the water formed in a Drierite tower and weighing. Hydrogen, predried with Drierite, was used for the reduction. This procedure was adopted after several trials to determine the best compromise between absence of sintering and rapid reduction. Following reduction, the hydrogen flow was replaced with oxygen-free, dry argon, and the steel was maintained at temperature for several hours to allow any absorbed hydrogen to escape. Any oxidation was detected by the change in color of the powder.

Oxygen was removed from the argon by passage through a purification train similar to that used for the nitrogen in the adsorption system. For added insurance, before introduction to the powder samples, it was also passed through a steel powder bed held at temperature. The steel powder was transferred to the adsorption cell by means of a purified nitrogen stream which blew it out of the reduction tube and through a glass tube inserted into the adsorption cell under the surface of the cyclohexane. The weight of powder transferred was determined by weighing the reduction tube before and after transfer.

Spectrophotometric analysis was the method chosen for concentration determination. By appropriate adjustment of sample size and light-path length, a wide range of concentrations could be covered accurately. In some cases in which only a small relative concentration change occurred, the differential technique was applied. In general, the adsorption cell was filled with 200 ml of solution and a pipetted 4 ml sample was taken each time. This was split into triplicate 1 ml samples which were carried through the analysis scheme. Before contact with the steel, a portion of the amine solution was reserved to furnish the triplicate standards which were run concurrently with the samples.

For the experiments with 4-ethylpyridine and poly(vinylpyridine), spectrophotometric measurements were made on the diluted samples using the pyridine absorbance peak at 225 mμ and a prepared standard calibration curve.

For the experiments with 4-ethylpiperidine, it was necessary to introduce a chromophore into the molecules before the spectrophotometric measurements could be made. For this purpose, 2,4-dinitrofluorobenzene was used as a reagent to introduce a dinitrobenzene moiety at the nitrogen site (9). Contrary to the usual procedure, the reaction was carried out in cyclohexane held in a water bath at 60°C.

After the appropriate time for maximum color development and cooling to room temperature, spectrophotometric measurements were made at 352 mμ on the reacted solution without further treatment except to dilute to a known volume. The absorptivity of the unreacted 2,4-dinitrofluorobenzene is small enough at 352 mμ, and the reaction is sufficiently complete that, by using an excess of reagent, the background absorbance could be reliably blanked out using the same amount of reagent in the blank as in the sample. The concentration of piperidine in the measured volume was determined from a standard calibration curve.

From the analytical concentration, the sample volume, and the volume contained in the adsorption cell combined with the weight of steel contained in the cell, the amount adsorbed was calculated in terms of micromoles of amine per gram of steel. For the polymer, these calculations were in terms of micromoles of r-mer per gram of steel, since the analytical method produced this result. The number of micromoles of polymer per gram of steel were obtained from the molecular weight.

Measurement of adsorption from HCl.—Use of the spectrophotometric procedure for poly(vinylpyridine) in acid solutions is complicated by the general absorbance of the iron at the wavelengths of interest. Since corrosion of the steel continuously increased the iron concentration over the time period in which the polymer was adsorbing, a problem developed. However, by using the criteria cited by Mellon (10) for choosing the best wavelengths for measurement, a simultaneous method was developed for determining both iron and poly(vinylpyridine) concentrations by measuring at two wavelengths, 255 and 239 mμ. It was necessary to combine the spectrophotometric cell and adsorption cell because of the rapidity of the adsorption and corrosion phenomena. Also, because of the interrelationships between such factors as HCl concentration, rate of corrosion, solubility of poly(vinylpyridine) hydrochloride, and inhibitor effectiveness, it was found that an acid concentration of 0.01*N* gave the best compromise between time available for data taking and optimum range of concentrations measured.

The procedure was to start with a known volume of the uninhibited acid and a known weight of steel powder in a regular spectrophotometric cell and to take enough data to determine the corrosion rate. Then a known volume of a concentrated solution of the poly(vinylpyridine) hydrochloride in 0.01*N* HCl was added and the solution thoroughly agitated before spectrophotometric measurements (now including the simultaneous determination of the inhibitor) were resumed. These measurements were continued at short intervals over about an hour and were only terminated

[3] Obtained from Ace Glass Company, Vineland, New Jersey.

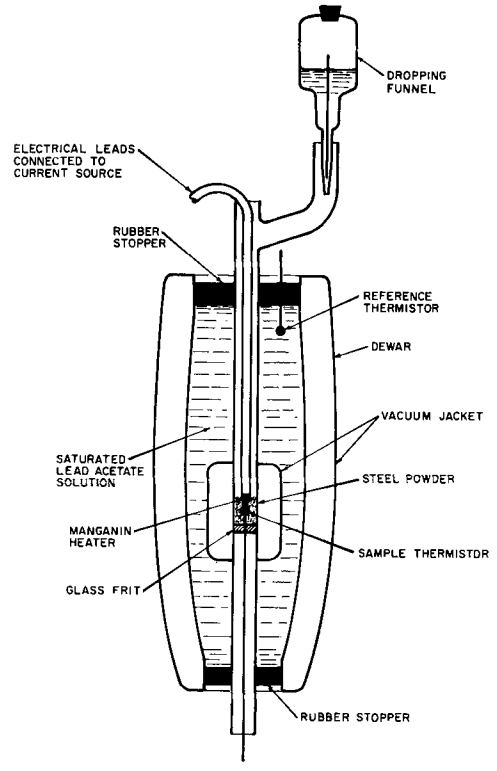

Fig. 2. Apparatus for dynamic adsorption measurements

when the absorbance increase due to iron dissolution pushed the total absorbance out of the range of the spectrophotometer. The concentrations of iron and of pyridine r-mers were determined by substituting the absorbance data into a set of simultaneous equations and solving in the usual way (11). The equations were derived and checked with standard solutions and mixtures.

Heat of adsorption measurements.—These experiments, based on a modification of the procedure of Groszek (12), were carried out in the flow calorimeter schematically outlined in Fig. 2. A known weight of steel powder rests on a glass frit with a glass-jacketed thermistor[4] inserted through a small hole drilled in its center. The steel was placed in the center of a double-walled bulb which was about halfway down a glass column. The thermistor was placed in the center of the mass of steel powder. A small coil of manganin heater wire was put in the steel on the same axis as the thermistor and slightly above. The heater was connected to a constant-current source. The column passed down the axis of a double-walled outer container, and the bulb was centered in this volume. The space between the walls of both the double-walled structures was evacuated. The large vessel was filled with a concentrated lead acetate solution to increase its heat capacity, and a second matching thermistor was located in this solution close to the outside wall of the column.

The thermistors were made part of a Wheatstone bridge circuit in combination with a set of mercury cells and with a Helipot which formed the third and fourth legs. The balance condition of the bridge was detected by a 5 mv stripchart recorder. A specially designed dropping funnel (which completes the apparatus) was used to obtain the slow flow rates required. In use, pure solvent was allowed to flow down the walls and adjusted to a rate of about 0.25 ml/min. The bridge, which was balanced initially, registered a large unbalance in the hot direction as the solvent reached the steel powder. Flow was continued until the balance condition was again obtained indicating that the heat released by solvent wetting had been removed from the inner bulb by the flowing solvent. At this time, the solvent funnel was quickly exchanged for a similar funnel containing a solution of the adsorbate in the same solvent and flowing at the same rate.

When this solution, temperature equilibrated by its contact with the thermostated column walls, reached the steel powder, a positive temperature excursion due to the heat of adsorption was registered by the recorder. It was followed by a somewhat slower fall in temperature as the continuing flow carried this heat out of the steel sample bulb. For calibration, a known constant-current pulse was then sent through the heater for a predetermined time, and a similar curve was traced by the recorder. Empirical adjustment of the geometrical arrangement of the heater wires and of the pulse time and magnitude were required to obtain a curve comparable to that produced by the amine solution so that the areas under the curves could be compared. This procedure gives a value which is the difference between the heat of adsorption of adsorbate and the heat of desorption of solvent.

Synthesis and characterization of the compounds used.—The 4-ethylpyridine was obtained from Reilly Tar and Chemical Company and was distilled immediately before use through a vacuum-jacketed, highly efficient column under a nitrogen atmosphere.

The poly(4-vinylpyridine) was prepared from freshly distilled 4-vinylpyridine (obtained from the same source) by polymerization in ethanol under nitrogen. A specially designed, high-dilution method was used in which the initiator, 2,2′-azoisobutyronitrile, and methanol solution were each added slowly to a large volume of an ethanol solution of the monomer held under nitrogen just below the reflux temperature. The resulting solution was then allowed to stand at temperature and under nitrogen for several days. Using this method, only slightly disperse samples of polymer were obtained. By properly adjusting the ratio of initiator to monomer and the over-all concentration of each, the molecular weights obtained could be controlled to give samples ranging from five r-mer units up to about one hundred. Molecular weights were determined with a Mechrolab Vapor Osmometer. Because the isolation procedures produced a partially hydrated polymer, it was necessary to use a dehydration procedure to obtain cyclohexane solutions. This procedure involved refluxing a solution of the polymer in methanol over calcium hydride followed by addition of cyclohexane and elimination of the methanol by repeated exhaustive distillation. The resulting cyclohexane solution was separated from the insoluble dehydration products (from hydrolysis of the hydride) by decantation.

Cyclohexane obtained from Phillips Petroleum Company (99 mole % minimum) was used for all of the experiments. It was distilled under nitrogen before use. A similar grade of n-heptane was used in some of the experiments.

The 4-ethylpiperidine used in the experiments was obtained by catalytic hydrogenation of purified 4-ethylpyridine in a Parr apparatus over palladium charcoal. It was purified by distillation in the vacuum-jacketed still, and the absence of the pyridine was verified by ultraviolet spectrophotometric analysis.

Results

Static adsorption experiments.—Adsorption-time curves illustrating the results of the adsorption experiments conducted in cyclohexane are presented in Fig. 3 for samples of poly(4-vinylpyridine) and for 4-ethylpyridine. The curves for 4-ethylpiperidine were similar. In the adsorption-time runs for the 4-ethylpyridine and 4-ethylpiperidine, the initial concentration of adsorbate was varied over a range sufficient to produce a change in the final, equilibrium concentration covering the range 5-50 x 10^{-4}M. These limits were estab-

lished by the limitations of the spectrophotometric analysis. In the case of the polymer solutions, it was not possible to cover so wide a range because of added limitations posed by the low solubility and high adsorbability of the polymers. Each point on the curves is the average of the differences between triplicate samples and triplicate standards. The standards were obtained from that portion of the original solution which was removed prior to introduction of the steel powder. No difference in the adsorption was observed between hydrogen-saturated steel and steel which had been outgassed in argon.

The adsorption levels indicated by the plateaus in the individual adsorption-time curves were used to define the isotherms for 30°C shown in Fig. 4 and 5. The average value for all of the points on the plateaus of the adsorption-time curves were used for the points on the isotherms. The points plotted in Fig. 4 are derived from at least two determinations of the adsorption-time curve, and the arrows reflect the composite standard derivation of the averages. The individual points from each of three polymer runs are included in Fig. 4 to show greater extent of adsorption at low concentrations.

Using the BET area of the steel powder and the amount adsorbed on the plateaus of the isotherms, the surface area available to each adsorbed molecule was calculated. These data are contained in Table I, along with a summary tabulation of the amount adsorbed, the projected area covered by each molecule, and the resulting number of layers of adsorbate.

The area/molecule figures in the table were obtained by arranging scale models of the molecules in the appropriate adsorption position using a flat surface to represent the steel surface. Several photographs of each molecule were then taken from a vertical position directly centered over the model. The total area covered by the molecule was computed by using the picture to outline the molecule on a grid and then counting the squares inside the outline. The scale dimensions of the squares (in terms of Å) were determined from the diameter of the hydrogen atoms.

For the polymer molecules, the area per ring was derived by dividing the total area by the number of rings. Multiple determinations on various photographs and models varied by 2%. Both possible arrangements

Table I. Summary of adsorption data

Compound	Amount adsorbed, μmoles/g	Area/molecule, Å²		No. of layers
		Experimental[a]	Model[b]

[a] Calculated using the number of amine rings removed from solution and the BET area of the steel powder.
[b] Projected area calculated from scale models: Assuming flat orientation for the pyridine rings in both monomer and polymer; assuming chain form for the piperidine rings.
[c] Calculated assuming perpendicular orientation of the pyridine ring.
NOTE: The values under the columns headed "Rings" are calculated on the basis of the pyridine ring concentrations; the values in the columns headed "Molecules" are calculated on the basis of polymer molecule concentrations. These values were not obtained from isotherms, but instead for individual adsorption-time runs.

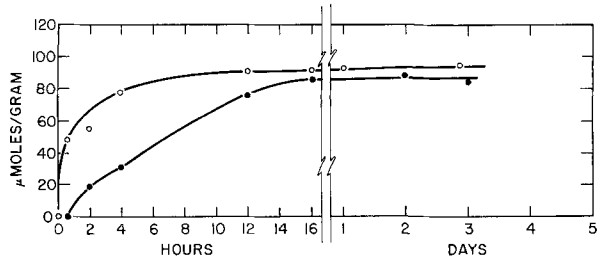

Fig. 6. Adsorption-time curves for 4-ethylpyridine on completely reduced (○) and lightly oxidized (●) steel powders.

for the pyridine, *i.e.*, with the plane of the ring perpendicular to the surface and parallel to the surface, are quoted in the table. For 4-ethylpiperidine, the chair form was assumed in the table, although all of the possible arrangements in either configuration covered essentially the same area within experimental error.

As an incidental observation, the adsorption behavior of 4-ethylpyridine was observed on a sample of steel powder which had been slightly oxidized by a brief exposure to a small amount of air while the steel was still hot, which resulted in a slight discoloration. The adsorption-time curve shown for this material is compared in Fig. 6 to the usual adsorption-time curve obtained on carefully protected (unoxidized) steel powder. It may be seen that the total amount of adsorption has not been affected (within experimental error), but that the rate of adsorption on the oxidized surface was appreciably slower.

Both of the analytical procedures for these experiments produced triplicate analyses (on the same sample) which were within the precision range of good analytical practice. In addition, the analyses of the standard solutions were consistent throughout the course of an experiment and conformed to Beer's law in experiments with different concentrations. The pooled standard deviations (representing the dispersion of the triplicates) over the course of a run in all these cases were in the range of 0.5-1.5% of the average. Triplicate analyses which were run on duplicate samples taken from the cell at the same time were also comparable to the over-all precision. In view of the good precision of the measurements of the individual points, the scatter exhibited in the adsorption-time curves is greater than expected, and it is concluded that the scatter must originate from the adsorption process itself. The deviations among multiple runs at

low concentration as shown in Fig. 5 also reflect this cause.

Adsorption of poly(vinylpyridine) from HCl.—Typical curves obtained in these experiments are presented in Fig. 7, and the results of four experiments are summarized in Table II. Curve A in Fig. 7 has been normalized by subtracting the amount of iron present at the time the polymer solution was added. Zero time, therefore, corresponds to the time at which the polymer solution was added. The data points in curve B were derived from the absorbance measurements by the procedure previously described for the cyclohexane solutions. The level portion of the adsorption curve (B) corresponds to 0.016 μmoles of polymer adsorbed per gram of steel. This amount is less than one-tenth monolayer (calculating as for Table I and assuming no appreciable area change).

The results from all of the experiments are summarized in Table II. The figures quoted in Table II in the column headed % Inhibition were derived from the equation

$$\% \text{ Inhibition} = \left(1 - \frac{\text{Rate inhibited}}{\text{Rate-uninhibited}}\right) \times 100$$

The corrosion rates used in this equation were derived from the slopes of the iron curves, in inhibited and uninhibited solution. In all cases, the initial polymer concentration was 3.9×10^{-5}M in terms of pyridine rings or 3.9×10^{-6}M in polymer molecules. Because the uninhibited rate falls off after a long time compared to the experimental interval, it is concluded that diffusion eventually limits both reactions.

Heat of adsorption experiments.—These experiments are briefly included here primarily to demonstrate further evidence for the chemisorption of 4-ethylpiperidine. Typical curves for the amine in cyclohexane and for a calibration experiment are reproduced in Fig. 8. In successive experiments using in-

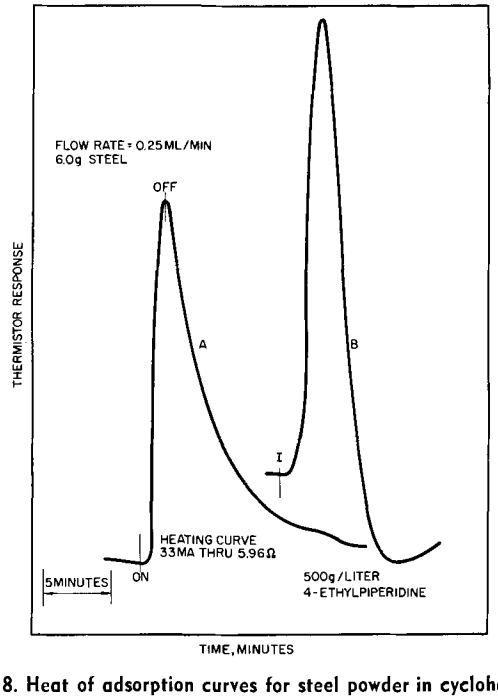

Fig. 8. Heat of adsorption curves for steel powder in cyclohexane

creasing concentrations of amine, the curves observed gradually became narrower and peaked at higher and higher temperatures until at 400 g/l, and thereafter their shape and height stabilized at that shown in Fig. 8. Above 400 g/l concentration, saturation is achieved and the coverage is assumed to be that obtained in the static experiments (Table I).

The calibration curve shown was developed empirically by adjusting the geometrical relationship between the heater and thermistor and by adjusting the magnitude and interval of current flow. The same amount of steel and the same rate of solvent flow were used as in the experiment with 4-ethylpiperidine. The current used to produce the calibration curve corresponds to 16.8 millicalories. Using this figure and assuming saturation of the steel at 0.24 μmoles of 4-ethylpiperidine adsorbed per gram of steel, the heat of differential adsorption is calculated to be 13 kcal per mole. This value was shown to be substantially free of heat-of-solution effects in an experiment using solvent only in the sample chamber. In this experiment 300 μl of the amine in one slug were injected into the solvent stream flowing into a 3.0 ml volume of the same solvent surrounding the thermistor. A small negative heat of solution was observed. However, this amount of heat is insignificant because the total quantity of amine available for adsorption is 3000 times the amount adsorbed at equilibrium.

In other experiments, a small positive heat of adsorption was observed for cyclohexane adsorbed onto steel from n-heptane (99 mole% minimum), and both benzene and 4-ethylpyridine were found to adsorb exothermically onto steel from cyclohexane. When n-heptane was used as solute in cyclohexane, its adsorption on steel is endothermic.

Discussion

From the data collected in Table I, it is concluded that both 4-ethylpiperidine and 4-ethylpyridine are adsorbed to the extent of an essentially complete monolayer.

It is concluded that the pyridine rings are adsorbed with the plane of the rings parallel to the local plane of the metal surface, primarily because the isotherm for 4-ethylpyridine shows monolayer formation when this position is assumed. The alternative vertical position would require participation of solvent molecules in the adsorbed layer which, in turn, would seem to require a close solvent-solute association, a conclusion which belies the closer association expected between the structurally similar cyclohexane and 4-ethylpiperidine molecules. Finally, both benzene and 4-ethylpyridine adsorb exothermically from cyclohexane, indicating that participation of the π-electron system does occur in adsorption bond formation.

The possibility that the apparent adsorption was really due to hydrogenation of the pyridine chromophore by hydrogen absorbed in the steel was investigated by treating samples from one run with the piperidine reagent (which will react with any primary or secondary nitrogen). There was no detectable reaction. Furthermore, there was no difference between adsorption runs with hydrogen-saturated steel and those with argon-degassed steel. Finally, it was observed during the synthesis work that pyridine ring reductions are difficult even with platinum metal catalysts and much higher temperatures and hydrogen pressures. For these reasons, it is concluded that the decrease in solution concentration during an adsorption run is truly the result of accumulation of pyridine molecules at the iron surface.

In the case of 4-ethylpiperidine adsorption the difference in projected areas covered by different orientations and different steric arrangements of the molecule are much smaller than experimental error due to the ball-like shape of the molecule. From the heat of adsorption data, it is concluded that the nitrogen atom participates strongly in the formation of the adsorption bond, and therefore the molecules at the surface are arranged with the nitrogen in close proximity to the surface and not with the ethyl tail down. This conclusion is supported by the recent observation by other investigators of a charge-transfer type spectrum for a long-chain amine adsorbed on chromium (13). Dehydrogenation reactions are ruled out in this case also because of the dual experiments with hydrogen-saturated and argon-degassed steel.

Even short poly(vinylpyridine) chains (4 units) are much more strongly adsorbed than the monomer. This is shown by the individual points included in Fig. 4 and by the data in Table I. There is a definite tendency for the adsorption to increase with time on the plateau portion of the adsorption-time curves. In addition, increasing the length of the chains greatly increases the adsorption tendency. Apparently, the polymer molecules all adsorb to about the same extent, as shown by the consistent values for amount adsorbed calculated in Table I in terms of molecules. This means that the number of rings removed from the solution by adsorption increases with chain length. It also means that all of the rings on a chain are not adsorbed, but some of them remain partly in the solution phase. However, adsorption of the polymers at more than one point in the molecule makes them very difficult to displace and accounts for the greatly increased inhibition by these molecules.

The aqueous solution measurements show that a considerable portion of the metal surface in excess of the amount covered is deactivated toward corrosion because adsorption of less than one-tenth monolayer produced 80% inhibition. This is probably the result of overlapping of domains of ennoblement when more than one ring is absorbed from a molecule in which they are close together.

Conclusions

1. Molecules of 4-ethylpiperidine are strongly chemisorbed on a steel surface to form a monolayer of molecules adsorbed in the chair configuration and bonded at nitrogen.
2. Molecules of 4-ethylpyridine are chemisorbed on steel in a monolayer and in a position with the plane of the ring parallel to the metal surface.
3. Adsorption of poly(vinylpyridine) molecules is by attachment at several of the adsorbable chain members so that strong adsorption is rapid and desorption is difficult even from solution in aqueous hydrochloric acid.
4. Adsorption of the polymers from acid solutions produces ennoblement of a much greater area of the steel surface than that which is physically covered.

Acknowledgment

The authors gratefully acknowledge the able assistance of Dr. J. S. Payne, Jr., and Mr. R. N. Foote, who carried out the syntheses and of Messrs. J. W. Dooley and D. H. McLendon and Mrs. Peggy Glass, who made many of the measurements. In addition, they thank Drs. P. D. Gardner and R. M. Roberts for their advice and constructive criticisms of the organic portions of the work. The work was done under Contract No. DA-23-072-ORD-1590 for the Army Research Office, Department of the Army. One of the authors (NH) expresses his appreciation of the support by the Robert A. Welch Foundation of Houston, Texas, and of the Office of Naval Research of the work in his laboratory which led in part to this research.

Manuscript received Sept. 3, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

ABSTRACT

Samples of three kinds of very low polymer amines were examined in aqueous HCl solutions to determine their inhibitor effectiveness. The results show that soluble molecules containing multiple repeating units which are identical in functionality are more efficient corrosion inhibitors than the corresponding monomers, presumably because of multiple adsorption bonding. The compounds used in these experiments are (i) poly(4-vinylpyridine), (ii) poly(4-vinylpiperidine), and (iii) polyethyleneamines. Chains four units in length and longer produce inhibition equivalent to monomer at concentrations which are nearly four orders of magnitude lower than those required for the monomer. This effect is due to the increased stability of the adsorption bonding and also to some overlapping of ennobled micro areas. In the high ranges, the inhibition is not linearly related to coverage. The differences in inhibitor effectiveness among the three monomers are retained in parallel by the polymers.

The experiments reported here are part of a study of the influence of molecular structure on inhibitor effectiveness. Previous work (1) has shown that in a series of saturated cyclic amines which have a progression in the orbital character of the secondary nitrogen atom, both the adsorption bonding and inhibitor effectiveness progressed in parallel. The present work sought to test the hypothesis that soluble molecules containing multiple repeating units with identical functionality would be more efficient corrosion inhibitors than the corresponding monomers because of multiple adsorption bonding. Accordingly, three series of compounds were examined for inhibitor effectiveness in hydrochloric acid: (i) 4-vinylpyridine polymers with 4-ethylpyridine as monomer, (ii) 4-vinylpiperidine polymers with 4-ethylpiperidine as monomer, and (iii) polyethyleneamines with ethylenediamine as monomer.

The experimental procedures were designed to give the best reproducibility of the data and to spread the results from the individual compounds so that reliable comparisons of their individual behavior could be made. They were so chosen that the comparisons among compounds would be valid, *i.e.*, so that identical conditions of solubility, H^+ concentration, etc., were obtained. In general, this required working in strong mineral acid solutions. A wide range of inhibitor concentration was investigated, and the three different polymer systems were tested to check the general applicability of the individual results.

Experimental Procedure

Weight-loss experiments.—Both belt polished SAE 1010 steel coupons with an area of about 15 cm^2 and hand polished low carbon shim steel coupons with much larger areas were corroded in 3*N* HCl for periods of time long enough to give an easily determined weight change even in highly inhibited solutions. The usual length of time was 2-4 hr for the small coupons and 1-2 hr for the large ones. Inhibition results were the same for both types of coupons. All coupons were run twelve at a time with at least triplicates of each concentration of inhibitor. Triplicate blanks always took up three out of the twelve coupons. In this manner, a large body of blank runs was collected during the course of the experiments, and any significant deviation of the blanks in a set of twelve coupons [determined statistically by the t-test (2)] was taken as cause for a rerun of that set of experiments.

Reproducibility was aided by running the experiments with the coupons and solutions contained in individual test tubes which were immersed in a controlled temperature bath. Gasometric checks of both the inhibited and uninhibited solution were performed by connecting the tube to a gas buret and measuring the volume of hydrogen evolved as a function of time over the course of the experiment. These plots were all linear and passed through the origin. The volume of gas evolved corresponded to the weight of metal lost according to stoichiometry.

Experiments were run in which the concentration of inhibitor[3] was changed from the order of 1*N* to

[3] Concentrations throughout this paper are expressed in terms of nitrogen atoms, *e.g.*, the equivalent weight of a molecule containing four nitrogen atoms = MW/4.

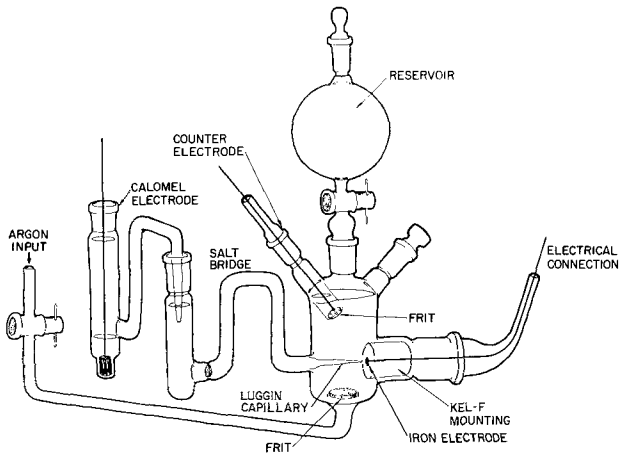

Fig. 1. Polarization cell

about $10^{-6}N$, or until acceleration of the corrosion reaction was observed. In the experiments with significant amounts of basic inhibitor present, the acid concentration was adjusted to maintain it at 3.0*N* in the inhibited solutions. All of the inhibitors were completely soluble under the conditions of the experiments.

Polarization experiments.—Polarization experiments were performed using the cell design shown in Fig. 1. The steel samples used were obtained by punching circular disks out of some of the small SAE 1020 coupons. A length of iron wire was spot welded to one face of each disk. A premolded Kel-F cylinder drilled axially to accept the wire was used to mount the iron disk electrode. The disk was mounted in the Kel-F and bonded to it by reheating and pressing in the original mold. Finally the wire end of the cylinder was turned on a lathe to a standard taper and the electrode face was polished uniformly with emery paper. The whole Kel-F electrode assembly was mounted in the cell by firmly seating it in the female portion of a demountable female-male double TS joint section.

Polarization curves were taken in the usual way using a platinum counterelectrode in a separate compartment and a calomel reference electrode connected through a salt bridge to a Luggin capillary. Placement of the bridge capillary was not extremely critical because the solutions were highly conducting. However, by adjustment of the over-all length of the Kel-F mounting, a distance of a few millimeters was maintained. Electric current was supplied by a parallel pair of 90v radio batteries operated through a variable high resistance to make them a constant-current source. Electrode potentials were measured with a potentiometer, and currents were measured by the IR drop through a standard resistance.

The usual procedure was to insert the polished electrode into the empty cell, fill it with degassed 1.0*N* HCl, and then wait to allow the open-circuit potential to stabilize while the solution was further degassed and stirred with argon. Polarization data were first taken in the cathodic (hydrogen evolution) direction, and then after rechecking the open-circuit potential, in the anodic (iron dissolution) direction. In most experiments with inhibitor, a weighed amount of inhibitor was added after the open-circuit potential had stabilized with a fresh electrode and then the polarization curves were taken. In some cases, uninhibited polarization curves were taken first and then the inhibitor added and the inhibited polarization curves taken. Repetitive experiments agreed well when a freshly polished electrode and a fresh solution bath were used each time a set of experiments was run. Changes in ferrous ion concentration throughout a run were not large enough to affect the potentials. After periods of continuous or consecutive exposure to the acid of several days' duration, the electrodes showed evidence of preferential corrosion around the edge of the metal. This corrosion proceeded from the flat side of the edge and not from the curved side which was effectively bonded to the Kel-F. The presence of these areas was indicated by distortions in the polarization curves.

Synthesis and purification of compounds used.—The polyethyleneamines were obtained from Distillation Products Industries and were distilled before use. The 4-ethylpyridine was obtained from Reilly Tar and Chemical Corporation, and before use it was distilled in a nitrogen atmosphere through a highly efficient, vacuum-jacketed still. It was also stored under nitrogen. The poly(4-vinylpyridine), poly(4-vinylpiperidine), and 4-ethylpiperidine were synthesized in the laboratory. The monopiperidine was obtained by catalytic hydrogenation in a Parr apparatus using a palladium-charcoal catalyst. After distillation in a nitrogen atmosphere, the product was checked spectrophotometrically for absence of the pyridine. This product was also stored under nitrogen.

After many trials, a procedure was designed for obtaining very low molecular weight poly(vinylpyridines) by polymerizing 4-vinylpyridine (obtained from Reilly Tar and Chemical Corporation and freshly distilled before use) using 2,2'-azoisobutyronitrile as initiator. The procedure finally adopted consisted in polymerizing in a very dilute ethanol solution which was kept under nitrogen almost at the reflux temperature. By properly adjusting the extent of dilution in the polymerization media and the ratio of monomer to initiator, polymer samples could be obtained which ranged in chain length from four to about one hundred units. Number average molecular weights were determined using a Mechrolab Vapor Osmometer. The number of initiator fragments per chain was determined by infrared spectral analysis. This indicated two fragments per chain.

The 4-vinylpiperidine polymers were obtained from the corresponding polypyridine by catalytic reduction in a high-pressure stainless steel autoclave. During the course of a great many trial reductions using different catalysts and at various operating temperatures and pressures, it was found that the necessary catalytic function was the ability to cause reduction at the lowest possible temperature so that degradation was a minimum. Using ruthenium on carbon and the highest hydrogen pressure safely obtainable in the autoclave at 250°C, a satisfactory reduction was obtained with only slight degradation. Only a very small percentage of unreduced pyridine units remained, but a

ruthenium-polymer complex was formed in the autoclave reaction. It was necessary to wash out the ruthenium by extraction into n-butanol from an acidic aqueous solution. Dicyclohexylthiourea was added to the butanol to force the extraction by competitive complexation of the ruthenium. The complex thus formed had a distinctive blue color and therefore could be used as its own indicator to signal complete removal of the ruthenium. The purified polymer was then recovered by making the solution basic, filtering, washing and vacuum drying.

Discussion of the Results

The curves obtained from the weight loss experiments for the three series of compounds are shown in Fig. 2, 3, 4, and 5. From these, it is readily seen that the hypothesis which was tested is indeed valid. Polymer chains above 3 to 4 units in length produce the same inhibition as the monomer at concentrations up to four

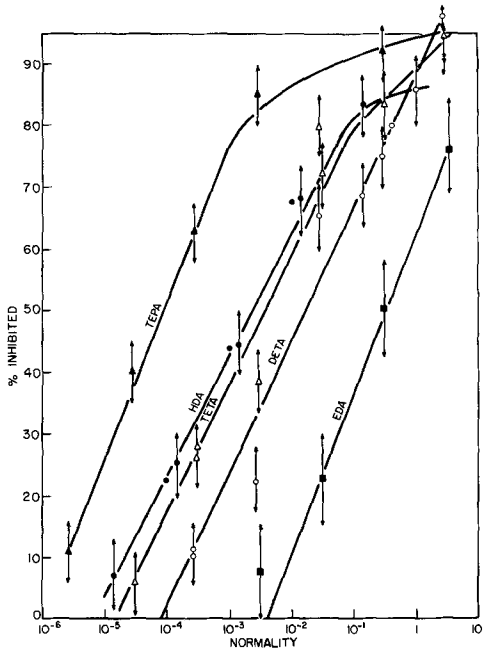

Fig. 5. Per cent inhibition *vs.* log concentration for mild steel at 40°C in 3.0*N* HCl; ●, hexamethylenediamine; ○, diethylenetriamine; ■, ethylenediamine; △, triethylenetetramine; ▲, tetraethylenepentamine.

powers of ten lower in magnitude. In all of the experiments, the inhibitor was completely soluble; no emulsions were used.

Because two and three unit polypyridines and polypiperidines were not available, one of the reasons for the work with the polyethyleneamine series was to determine whether the increase in inhibitor effectiveness of polymers is progressive from one up to four or five units. The data of Fig. 5 show that it is progressive up to four units, but the data of Fig. 3 show that this progression ceases above four units. These data show that the stability of the adsorption bonding to the metal determines the inhibitor effectiveness. That is, a soluble species which adsorbs readily and which is not easily removed when once adsorbed will be most effective. It is interesting to note that among the three types of compounds, the same trends in inhibitor effectiveness (in terms of the position of the curves on the log axis) exhibited by the monomers on the rising portion of the curve are retained by the polymers. This suggests that adsorption of polymers provides a multiplying effect to the relationships between the kind of individual adsorption bonds and the inhibitor effectiveness of that bond.

A possible alternative mechanism for the effectiveness of the polymers is the precipitation of a metal polymer complex in the immediate vicinity of the metal surface. This is rejected on the following grounds: (i) Complexes of hexamethylenediamine would be expected to be much less soluble (and therefore more effective) than those of either diethylenetriamine or triethylenetetramine, yet they all have nearly the same inhibition effect; (ii) in no case has a complex containing precipitate been observed in the presence of excess iron(II) or iron(III); (iii) a continuous tendency to precipitate and therefore to inhibit would be expected as the chain length is increased, particularly for very long chains and when several iron atoms are complexed by one chain; no such tendency was observed with the polypyridines or polypiperidines above the level of four units (Fig. 3); and (iv) no visible film was formed on the coupons under any inhibited conditions.

An unexpected feature of the results is the existence of the log-linear portion which extends over about two decades on the log concentration axis. This feature has

been found to be a general one for a wide variety of compounds tested in this laboratory. As shown in the 4-ethylpyridine curve (Fig. 2), even points which represent an increase in corrosion rate lie on the line when plotted in terms of negative inhibition. The negative numbers are derived on the same basis as the others, *i.e.*, from the equation

$$\% \text{ Inhibited} = \left(1 - \frac{\text{Rate inhibited}}{\text{Rate uninhibited}}\right) \times 100$$

where the rate terms are in the same units, *e.g.*, mg lost/hr/cm^2.

The fact that the curves for per cent inhibition as a function of log concentration are linear over an appreciable range for the polyethyleneamines, the polypiperidines, polypyridines, and other compounds indictate a linear relation between adsorption from acid solution and log concentration. Such a relationship is found in the Temkin isotherm (3, 4),

$$\theta = -\frac{RT}{\beta \Delta H_o} \ln AC$$

In this expression, β is a constant; A is a complex function of ΔH_o and other parameters; and ΔH_o is the heat of adsorption for very low coverage, (θ). For adsorption from dilute aqueous solution, ΔH_o will be influenced by contributions from the heats of desorption of solvent and of neutralization of the inhibitor conjugate acid.

The ionization constants for all of the polyethyleneamines have been published (5-8). Using these values, the normalities of amine, and the concentration of HCl, it can be shown that at the highest concentration plotted for tetraethylenepentamine, only 0.74% of the molecules are not fully protonated. The free amine (completely unprotonated) is present at a concentration of the order of $10^{-36}N$ at an analytical concentration (*i.e.*, amount of amine added per unit volume of solution) corresponding to good inhibition. Furthermore, under the experimental conditions of high, constant H^+ ion concentration, the concentration of any of the possible species, *i.e.*, from completely unprotonated to completely protonated, is a linear function of the analytical concentration. The base strengths in the polyethyleneamine series range upward from tetraethylenepentamine. The polypyridines and piperidines are expected to be quite similar for comparable chain-length. On this basis, if it can be assumed that per cent inhibition is proportional to per cent coverage (θ), then

$$\%I = K\theta = -\frac{KRT}{\beta \Delta H_o} \ln A - \frac{KRT}{\beta \Delta H_o} \ln C$$
$$= m \log C + \text{Constant}$$

where K is the proportionality constant. That is, the slope of the line, $\%I = F(\log C)$, is proportional to the reciprocal of the net heat of adsorption. Furthermore, since β is an independent constant, if the ΔH_o's, the K's, and the β's are similar, the slopes of the lines, $\%I = F(\log C)$, should be the same.

The data in Table I were obtained by a statistical treatment of the data shown graphically in Fig. 5 to get average values of the slopes of the rising portion of the individual curves. It can be seen that the slopes are very nearly uniform for all of the polyethyleneamines. This must mean that only small differences occur in the ΔH_o's and β's due to the different ratios

of the number of primary to secondary amino nitrogens. However, it may represent large contributions by the heats of neutralization and desorption of solvent which are the same for all the compounds. These may be masking the relatively smaller differences in the heat of formation of the chemisorption bond among the different compounds.

For comparison, the slopes of the curves from Fig. 2, 3, and 4 are included in Table II for polymer and monomer pyridines and piperidines. The higher slopes of these curves are consistent with either a large solvent contribution to the heats of reaction or with a difference of a factor of about two in either β or K, because the inhibitor effectiveness at saturation is not appreciably different for the two kinds of polymers. There is, however, a greater spread in the data of Table II, indicating a greater difference between monomer and polymer.

The factor, K, in the above discussion is used because adsorption experiments from acid solutions (9) have shown that in 0.01N HCl polypyridines are capable of producing 80% inhibition under conditions where less than one-tenth monolayer coverage is obtained. Furthermore, polarization curves taken with and without both monomer and polymer show that the metal is ennobled by 20 mv or more due to the adsorption of these inhibitors (10). An example of this is presented in Fig. 6. These observations strongly suggest that in the plateau portion of the polymer curves where θ ceases to be proportional to the per cent inhibition efficiency, the proportionality breaks down because the ennobled areas of the surface begin to overlap as θ increases, and thus K is no longer constant.

Conclusions

1. Very short chains of adsorbable groups improve inhibitor effectiveness by orders of magnitude compared to monomeric species.

2. This effect is interpreted in terms of a greatly increased stability of the net total adsorption bonding

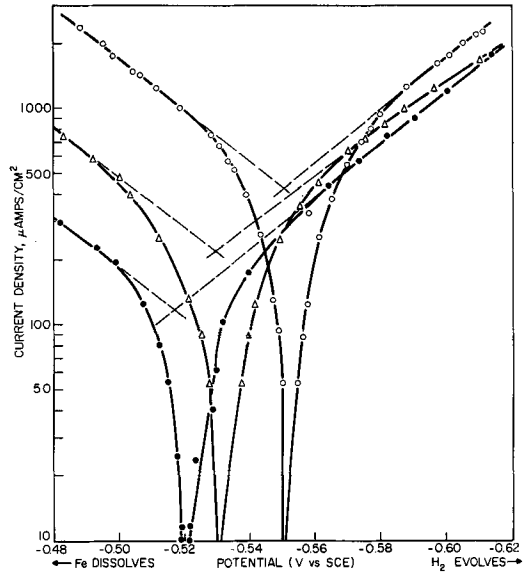

Fig. 6. Polarization curves for uninhibited monomer and polymer solutions; △—△, 0.1M 4-ethylpyridine in 1N HCl; ○—○, 1N HCl uninhibited; ●—●, 0.031M poly(vinylpyridine) 512 MW in 1N HCl.

in the polymer species, *i.e.*, a high tendency to adsorb, to stay adsorbed, and to form strong metal/inhibitor bonds which contribute an enhanced ennobling effect.

3. In the case of adsorption which ennobles the metal surface, the inhibition is not linearly related to coverage in the high inhibition ranges.

4. In agreement with 3, the variations in effectiveness of the individual adsorbable groups (exemplified by the monomers) are retained in the polymer.

Acknowledgment

The authors gratefully acknowledge the assistance of Dr. J. S. Payne, Jr., and Mr. R. N. Foote, who carried out the organic syntheses and of Dr. I. Y. Chang, who took the polarization data. This work was carried out under Contract No. DA-23-072-ORD-1590 for the Army Research Office, Department of the Army. One of the authors (NH) also expresses his appreciation to the Robert A. Welch Foundation of Houston, Texas, and to the Office of Naval Research for support of research in his laboratory over the years which in part led to this work.

Manuscript received Sept. 3, 1964. This paper was presented in part at the 20th Annual NACE Conference, March 1964, Chicago, Illinois.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

The Influence of Crystal Orientation on the Oxidation of Tungsten

R. W. Bartlett and J. W. McCamont

Philco Research Laboratories, Newport Beach, California

ABSTRACT

The oxidation of tungsten above 1800°C is described in terms of deviations from gas collision theory (Hertz-Knudsen equation). The probability that a colliding oxygen molecule will react with tungsten is strongly dependent on crystal orientation. Of the crystal faces examined, (100) surfaces oxidize most rapidly with a reaction probability of 0.4. (111) and (110) surfaces oxidize at approximately the same rate as polycrystalline tungsten. The morphology of oxidized (100) surfaces is smooth with the exception of occasional stepped octahedral pyramids each bound by {111} faces. The morphology of (111) surfaces is smooth except for numerous stepped tetrahedral pyramids each bound by {100} faces. Initiation of these shapes is not associated with dislocations or detectable impurities. However, dislocations subsequently cluster at mature octahedral pyramids. The morphology of oxidized (110) tungsten surfaces consists of extremely irregular surfaces and macroscopic ledges, but shapes clearly related to crystal geometry were not identified.

Oxidation of tungsten at temperatures above 1300°C involves collision, chemisorption of oxygen on the tungsten surface, chemical reaction, and evaporation of tungsten oxides. Oxidation rates are linear and have been determined from pressure measurements (1-4) and by measurements of sample dimension changes (5-7) taken during oxidation. Below approximately 1800°C the oxidation rate increases with temperature in an exponential manner characteristic of activated chemical processes. Above 1800°C the rate is independent of temperature except at very low pressures and high temperatures. There is evidence that oxygen atoms chemisorb in two distinct monolayers with different binding energies (2, 8). Oxide polymers, particularly $(WO_3)_3$ and $(WO_2)_3$, have been shown to be the predominant vapor species in equilibrium with tungsten oxides (9). However, a recent mass spectrometric study (10) indicates that monomers are the species evaporated from oxidizing tungsten surfaces. Polymerization evidently occurs later as a result of collisions in the gas phase. Above 2000°C the WO_2 monomer is produced in greater abundance than WO_3 (10).

The nonactivated oxidation rate behavior of tungsten has been explained in terms of deviations from the rate at which oxygen molecules collide with the tungsten surface, since this is the maximum possible rate. Using gas kinetic theory (Hertz-Knudsen equation)

$$J = \epsilon P_{O_2}/(2\pi mkT)^{1/2} \qquad [1]$$

Where J is the number of oxygen molecules which react each second and ϵ is the probability that each O_2 molecule striking the surface will react; $\epsilon \leq 1$. Since the rate is not limited by a prior or subsequent activated step or endothermic step, the reaction probability is equivalent to the sticking probability (condensation coefficient) of oxygen. In a previous study (7), with polycrystalline tungsten, rate data at oxygen pressures from 10^{-6} atm to 1 atm were described with a constant value of the reaction probability, $\epsilon = 0.06$. This correlation included an independent correction for the lowered oxygen pressure at the surface caused by the tungsten oxide gas boundary layer which is present at high pressures. This correction was based on free convection theory.

A study of the effect of metal crystal orientation on oxidation rates at temperatures where condensed oxides form has been made for tungsten (11) and several other metals (12). Similar studies at high temperatures where the oxide products vaporize are rare in general and have not been made for tungsten. The purpose of this study was to determine the reaction probabilities and observe variations in tungsten morphology during oxidation of low index faces.

Experimental

One half inch diameter single crystals of known [hkl] orientation were wafered to produce short cylindrical samples each bound by parallel (hkl) faces. Using a 2% NaOH electrolyte, these surfaces were electropolished, and some were electroetched to develop etch marks and to outline subgrain boundaries. The oxidation procedure is described below. Samples were set on a thin tungsten pedestal located in a vacuum chamber. A stable mounting was accomplished using an insertion hole drilled in the side of the sample. The chamber was evacuated and backfilled with dry oxygen to 1 x 10^{-6} atm. Pressure was maintained by controlling the flow of oxygen through the system. This oxygen pressure was chosen and used exclusively because of several advantages. First, this pressure was high enough to permit removal of considerable tungsten. This allows full development of morphological changes and insures accurate rate measurements. Second, although this pressure is higher than typical condensation-evaporation experiments in metal systems, it is lower than required to form a gas boundary film sufficient to affect the rate of oxidation. Third, at this pressure, there is comparative rate data for polycrystalline tungsten from two sources (4, 7). All samples were oxidized at 2050° ± 50°C using an R.F. induction coil. Temperature was measured with a calibrated disappearing filament pyrometer using corrections for the spectral emissivity of tungsten and calibrated window absorptivity. The oxidation rate was determined by measuring the decrease in distance between opposite (hkl) faces with micrometer calipers accurate to ±0.0001 in. These measurements were made on samples which had been oxidized 420 min, and the decrease in interface distance varied between 0.0195 and 0.045 in.

The tungsten crystals used as samples were grown by the Linde Company using a plasma arc Verneuil technique, Table I. In all cases misorientation of crystal faces with the surface was less than 5°.

Since the orientation and appearance of etch marks generated in aqueous solutions were used to correlate the morphological results of high-temperature oxidation, a brief introductory discussion of wet etch marks on tungsten is necessary. Etch pits in tungsten have been studied extensively by Schadler (13) using a $CuSO_4 \cdot NH_4OH$ solution and by Berlec (14) using both a $CuSO_4 \cdot NH_4OH$ solution and a 2% NaOH solution. The results using either etchant are identical. Square etch pits are developed on (100) surfaces, and elongated triangular pits develop on (112) surfaces of tungsten. In both cases, the defining sides of the etch pits are {110} planes. Plastic deformation experiments and matched etch pit patterns in cleaved surfaces indicate that the etch pits coincide with dislocations intersecting the surface. Berlec (14) has observed small oriented etch hillocks with a triangular outline on heavily etched (111) surfaces of tungsten. Neither etch pits nor hillocks occur on (110) surfaces of tungsten. All of these results were confirmed during the present study. We have also found that the wet etch pyramids on (111) surfaces cluster at subgrain boundaries, suggesting an association with dislocations.

Vicinal surfaces composing the faces of structural anomalies, hillocks and pits, formed on tungsten were identified from (*a*) the height or depth of the structure measured by oil emersion microscopy, (*b*) the projected geometry of the structure, and (c) the orientation of the crystal with respect to the orientation of the hillock or pit. Crystal orientation was determined by x-ray diffraction.

Results

The measured values for reaction probabilities on (100), (110), and (111) faces are shown in Table II. These data are also shown in graphical form and compared with polycrystalline data at the same pressures in Fig. 1. The values for (110) and (111) faces are similar to the polycrystalline values, but the reaction probability on the (100) face was much faster, approaching half of the total collision rate.

The differences in morphology of the tungsten surface were more striking, but the results were equally reproducible. Polished (100) and (111) surfaces tended to remain smooth while (110) surfaces were jagged. Grooving of subgrain boundaries occurs on (100) and (111) surfaces. Etch pits or other indications of accelerated oxidation at dislocations were not observed on any of the crystal faces as a result of oxidation. Wet etch pits introduced before oxidation lost definition as a result of oxidation but did not change otherwise.

(100) Surface.—Examination of the 90-min oxidation micrographs reveals occasional marks similar to the wet etch pits. These hillocks are the initial appearance of growth anomalies on (100) surfaces which remain for extended periods of oxidation and eventually become octahedral pyramids. These growth forms also appear as small rounded craters in their early stages.

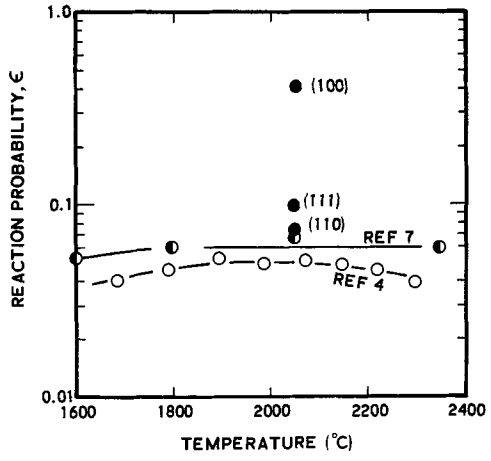

Fig. 1. Reaction probability for polycrystalline tungsten wire (4) and rod (7) and single crystal low index faces at 1 x 10^{-6} atmospheres oxygen pressure.

Fig. 2. Carbon replica of stepped pyramid on (100) tungsten surface. Magnification 1500X.

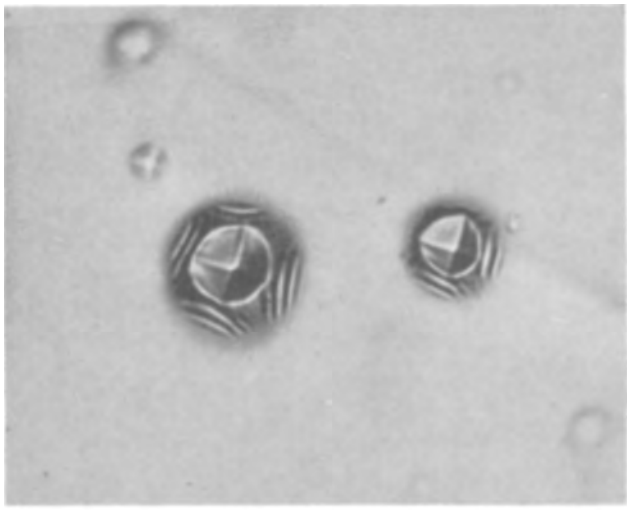

Fig. 3. Octahedral pyramids on (100) surface with cores having the shape of shallow polyps. Small craters slightly out of focus can be seen in the background; oxidation 7 hr at 2070°C. Magnification approximately 500X.

Sometimes they appear as shallow polyp structures containing fourfold symmetry. An electron micrograph replica of a mature octahedral pyramid is shown in Fig. 2. It is considerably larger than a wet etch pit. Its sides are {111} faces rather than the {110} faces observed for wet etch pits. The octahedral faces are stepped to provide for a flatter total pyramid shape without sacrificing the exposure of low index faces at the surface. However, the edges of each pyramid, where the {111} planes intersect, are not stepped. This shape leads to the appearance of fourfold inverted rings in optical micrographs. The center of these pyramids may simply be a continuation of the pyramid structure or contain the shallow polyps. Two examples of the latter are shown in Fig. 3.

The mature stepped pyramid structures are slow to develop. Those shown in Fig. 2 and 3 were formed by an oxidation period of 7 hr. There were comparatively few of these structures on the (100) surface, but they were observed on all samples oxidized more than 3 hr. They have been seen at subgrain boundaries, but there was no preference for this location and little tendency to cluster at any location. Their orientation is fixed by their {111} faces and the orientation of the crystal, Fig. 4. Small misorientations between adjacent subgrains were indicated by small changes in orientation of the stepped pyramids contained within them. As with wet etch pits, slight misorientation of the surface with respect to the (100) plane caused distortions of the symmetrical shape of the pyramids.

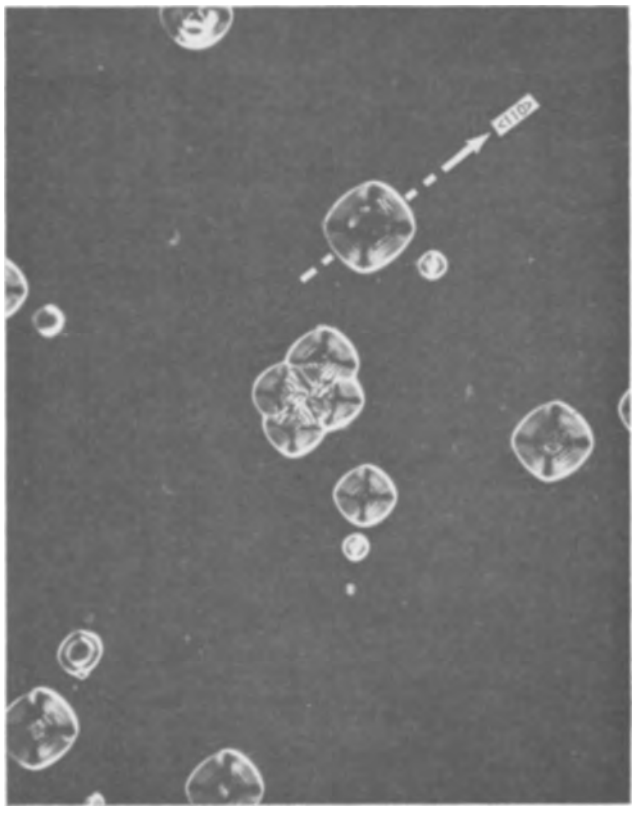

Fig. 4. Orientation of stepped octahedral pyramids on (100) tungsten surface; darkfield illumination. Magnification approximately 130X.

Extensive oxidation after dislocation etching has shown that octahedral pyramids are not initiated at dislocations. However, mature pyramids subsequently act as traps for dislocations. A polished (100) surface was oxidized 7 hr and later marked with a referencing hardness indentation near two octahedral pyramids. The sample was then etched in 2% NaOH to develop wet etch pits. This is shown in the second micrograph of Fig. 5. Dislocations clustered within the strain hardened area around the indentation mark as expected. However, equally dense dislocation clustering has occurred within the octahedral pyramid. Because the wet etch pits are bound by {110} faces their outline is rotated 45° with respect to the square outline of the octahedral pyramids.

Electron microprobe analysis of the tungsten surface at the stepped pyramids was undertaken to determine if impurities were influencing this behavior. Elements other than tungsten were not present in detectable amounts. Furthermore, the tungsten x-ray emission intensity was not diminished at octahedral pyramids relative to the rest of the sample. If tungsten oxides, borides, carbides, or nitrides were present in appreciable quantities, a measurable reduction in tungsten x-ray intensity would have been detected.

(111) Surface.—The morphology development on (111) surfaces was similar to the (100) surfaces. The surface remained smooth; but gradually stepped tetrahedral pyramids matured, Fig. 6. They were more numerous than the octahedral pyramids observed on the (100) surface. Electron micrographs show the steps more clearly than light micrographs. In many instances the hillocks are rounded and only approximate tetrahedral shape. These oxidation pyramids are oriented differently than the wet etch pyramids. This is shown

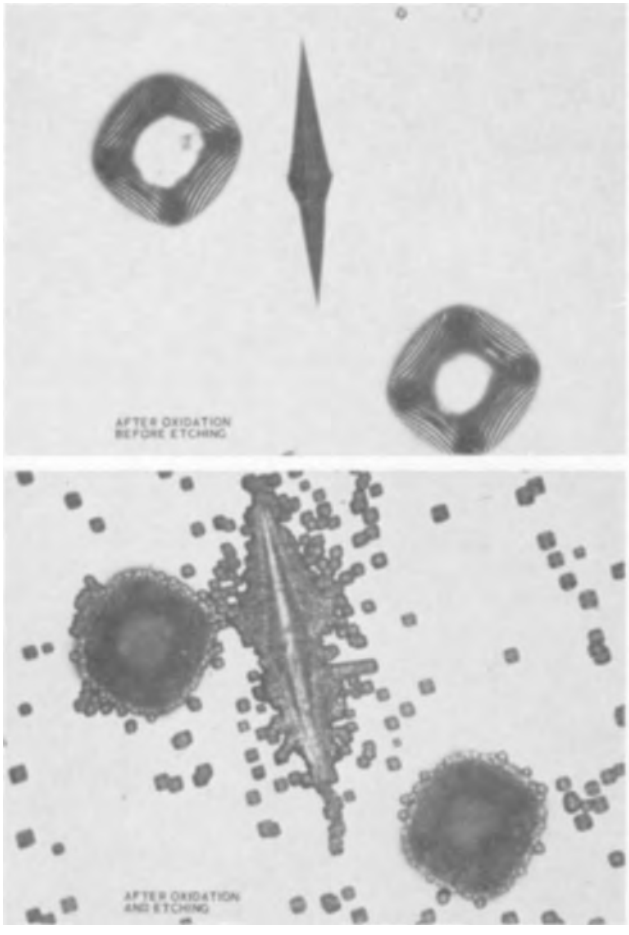

Fig. 5. Post oxidation wet etching treatment shows accumulation of dislocations at stepped pyramids on (100) tungsten surface. Magnification approximately 260X.

in Fig. 7. Both micrographs were taken in the same area and identified by hardness indentations, not shown. The sample was wet etched prior to oxidation, left micrograph. The triangles formed by the intersection of the wet etch pyramids with the (111) surface are pointing down and to the left. The results of a 1-hr oxidation treatment are shown in the right micrograph. A stepped pyramid has formed at the top of the photographed surface, but its triangular outline on the surface is pointing upward and to the right. Oxidation has rounded the wet etch pyramids and is tending to reorient them as triangles pointing in the opposite direction of their original orientation. From a comparison of crystal orientation, as determined from x-ray diffraction studies, with pyramid orientation on the (111) surface we determined that the wet etch pyramids are bound by {110} faces while the stepped oxidation pyramids are bound by {100} faces. The apparent change in orientation of the wet etch pyramids during high temperature oxidation is caused by the preference for {100} faces rather than {110} faces under these conditions. Consequently, the {100} faces advance and the {110} faces recede as defining surfaces for the hillocks.

(110) Surface.—Pyramids or other definite crystallographic shapes do not form on the (110) surface. Grooving of subgrain boundaries also does not occur although these boundaries usually can be detected and followed in a microscope field because of slight differences in shading which occur at the boundaries. The mature morphology developed after a 7-hr oxidation treatment consists of: (*a*) long serrated ridges; (*b*) triangular shapes with saw-tooth edges pointing toward shallow depressed areas and all oriented in a common direction; and (*c*) numerous parallel striations. These are shown in Fig. 8. Rare examples of isolated dodecahedral (110) faces occurred as small

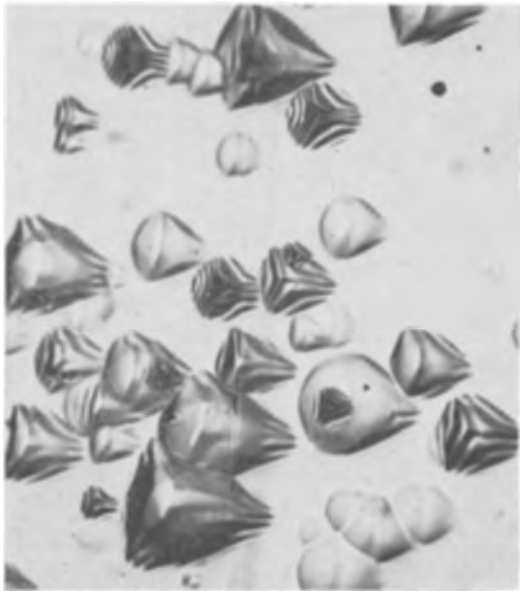

Fig. 6. Mature tetrahedral pyramids on the (111) surface of tungsten oxidized 7 hr at 2050°C. The photograph is bisected by a subgrain boundary.

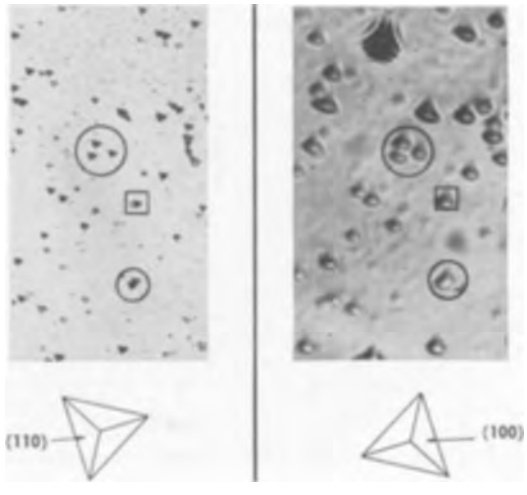

Fig. 7. Orientation of wet etch pyramids on (111) before oxidation, left; reverse orientation of oxidation triangular pyramid developed during a 1-hr oxidation period at 2050°C in the same area, right. Photographs were matched with indentation marks. Magnification approximately 375X.

sections of the tungsten crystal projecting outward from the surface.

Discussion

The results of this study are not easily explained by other published data or models for evaporation and condensation. The order of oxidation rates measured in this study, (100) > (111) > (110>, is different from the rates of formation of thin oxide films on tungsten measured by Metrofanov (11) at 400°-450°C. The order of the latter study was (111) > (100) > (110), and rate increases were correlated with reductions in electronic work functions. The oxidation mechanisms are different, and agreement is not necessarily expected.

Batterman (5) studied faceted hillocks and pits formed during the etching of germanium in a H_2O_2-HF solution. He reasoned that a stable hillock required that the recession rate of the hillock face be less than the product of the recession rate of the base plane and cosine of their angle of intersection. Batterman's results were generally consistent with this rule, but not consistent in all cases. The prevalent formation of

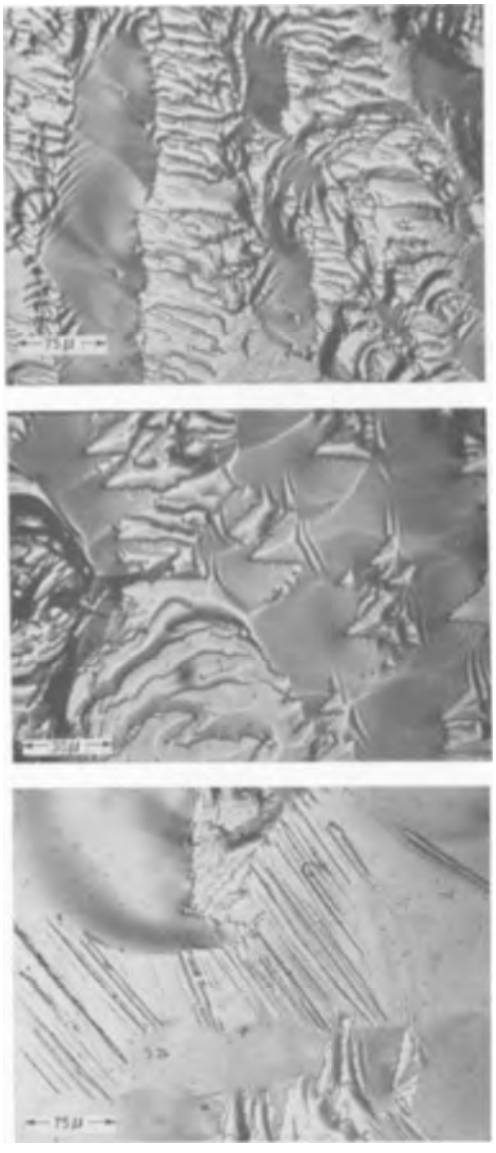

Fig. 8. Characteristic patterns on the (110) tungsten surface resulting from oxidation.

tetrahedral pyramids with {100} faces on a (111) base plane of tungsten does not conform with Batterman's rule.

Sticking coefficients of diatomic molecules have been attributed to entropy decreases involved in transforming from the gas phase to the chemisorbed state. In particular, hindered rotation of the molecule in the chemisorbed state appears to be a plausible cause of a sticking coefficient less than unity (16). On this basis, the sticking coefficient is the ratio of the partition functions for the chemisorbed state and gas state. Since vibration frequencies cannot be evaluated, the approximation that vibrational partition functions have values of unity is taken, and the sticking coefficient is reduced to the reciprocal of the rotational partition function for oxygen

$$\epsilon = \frac{\sigma h^2}{8\pi^2 IkT} \qquad [2]$$

The calculated value for ϵ at 300°K is 0.014. This does not conform with the experimental results, and the model fails to account for the observed rate anisotropy.

When entropy effects are absent, evaporation coefficients are expected to be high and macroscopic ledges absent unless impurities are present (17). Impurities may be contributing to the observed morphologies, but without positive evidence no conclusions can be drawn.

Low-Pressure Oxidation of Niobium at 1200°-1700°C

Per Kofstad and Svein Espevik

Central Institute for Industrial Research, Blindern, Oslo, Norway

ABSTRACT

The oxidation behavior of niobium has been studied at 1200°-1700°C at oxygen pressures ranging from 2×10^{-4} to 0.5 Torr. The oxidation involves dissolution of oxygen in the metal, formation of NbO, NbO_2, and Nb_2O_5. The oxidation may be divided into 3 main stages: (*a*) an initial linear oxidation which is followed by (b) a parabolic oxidation which, in turn, transforms into (c) a final linear oxidation. The initial linear oxidation involves dissolution of oxygen in the metal and the oxidation is governed by the rate of chemisorption on the metal surface. The parabolic oxidation is due to formation of protective NbO_2, which is further oxidized to porous nonprotective Nb_2O_5 at a linear rate. The oxidation is affected by the presence of liquid Nb_2O_5 at and above 1500°C, and at higher temperatures evaporation of Nb_2O_5 becomes an increasingly important part-process.

A major shortcoming of refractory metals is their poor high-temperature oxidation resistance. When considering applications of these metals or their alloys at elevated temperatures, even under "vacuum" conditions, a knowledge of their oxidation behavior is required. Also for applications of these metals in coated condition, such knowledge is desirable as it provides the margin of safety in case of coating failure.

Inouye (1) studied the oxidation of niobium at 850°, 1000°, and 1200°C at oxygen pressures ranging from 3×10^{-5} to 5×10^{-3} Torr. The initial oxidation was found to proceed principally by dissolution of oxygen in the metal, and this was followed subsequently by formation of NbO, NbO_2, and Nb_2O_5. NbO_2 was shown to form a protective scale, which was further oxidized to a nonprotective layer of Nb_2O_5. Other investigators have studied the oxidation behavior of niobium at higher oxygen pressures at temperatures up to 1200°C (2-6). Close to 1 atm O_2 the oxidation has been found to involve primarily the dissolution of oxygen in the metal and the formation of Nb_2O_5. However, on the basis of Inouye's work (1) it seems safe to conclude that NbO and NbO_2 are formed as intermediate reaction products also at higher oxygen pressures, although they may only be present in small amounts.

No detailed studies of oxidation of niobium at temperatures in excess of 1200°C appear to have been reported previously in the literature.

Experimental Methods

Materials.—The niobium metal sheet was obtained from Murex Ltd., England. Estimates of metallic impurities were as follows: Fe and Al, each 0.05%; Si, 0.02%; Cr, Pb, and Hg, each 0.01%, and C_T 0.1%. The hardness of the as-received sheet was VHN 75 (10 kg load).

Prior to oxidation the specimens were polished with alumina, rinsed in distilled water and acetone. The metal was recrystallized in high vacuum ($<10^{-5}$ Torr) in the oxidation apparatus prior to the start of the oxidation run. Commercial tank oxygen dried over phosphorus pentoxide was used.

Methods.—Rates of oxidation were measured thermogravimetrically with a Cahn automatic recording balance. The specimens were suspended in a Pt-13% Rh wire ($d = 0.2$ mm). Above 1600°C the Pt/Rh-wire became alloyed with niobium, probably through the formation of liquid alloy phase, and under these conditions a thin niobium wire was used to suspend the specimen in the hotter part of the furnace. The surface area of the niobium wire was small compared to that of the specimen.

The furnace is shown schematically in Fig. 1. An alumina tube (Morgan recrystallized alumina) served as reaction chamber, and it was mounted directly on the baffle valve of an Edwards F203 oil diffusion pump which has an unbaffled pumping speed of 70-80 liters/sec and a speed through the baffle valve of 50-55 l/sec. The alumina tube had an inner diameter of 33 mm and a length of 50 cm. A small alumina bucket was placed in the lower end of the tube to catch any specimens which might fall down due to breaking of the suspending wire. The reaction temperature was measured with Pt-5% Rh/Pt-20% Rh or Ir/Ir-60% Rh thermocouples located inside the reaction chamber next to the specimen.

The complete furnace system consisted of two separate high-vacuum systems serving, respectively, the reaction chamber and the heating element chamber. The latter contained the molybdenum heating element (wire with a diameter of 1 mm wound directly on the alumina tube and embedded in alundum cement) and three molybdenum and tantalum heat shields. The outer wall of the reaction chamber consisted of a Pyrex tube which was cooled by a tight-fitting, water-cooled copper shell. High vacuum was always maintained in the heating element chamber.

The specimens were introduced at room temperature and the system was evacuated to $<10^{-5}$ Torr. The temperature was subsequently raised and equilibrated. Due to outgassing of the furnace during the heating period, the temperature was slowly increased to the desired level, and 3-4 hr was used to raise the temperature to 1500°C. The outgassing and small unavailable leaks in a furnace system of this type unquestionably cause some contamination in addition to the original impurities in the niobium specimens. On the other

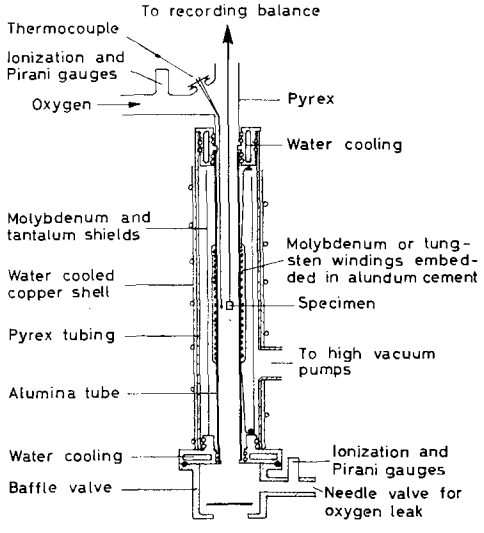

Fig. 1. Schematic illustration of the furnace system

hand oxygen impurities at temperatures above 1600°-1700°C may to some extent be removed through oxide evaporation. In a later improvement of the system a vacuum lock has been incorporated which permits an introduction of the specimens into the furnace after outgassing and temperature equilibration of the system.

The oxidation run was started by introducing oxygen in the system, and up to 1 min was necessary before establishing the correct oxygen pressure. During oxidation at the lower pressures the baffle valve was kept open, and oxygen was continuously pumped through the reaction chamber. The oxygen pressure was monitored at both ends of the reaction chamber by means of calibrated Pirani (LKB) and ionization (Leybold) gauges. Below approximately 0.01 Torr a pressure drop developed along the reaction chamber. Under these conditions the desired pressure was first established at the top of the chamber, and a small oxygen leak was subsequently introduced in the baffle valve to equalize the pressures. During oxidation the same oxygen pressure was maintained at both ends of the reaction chamber.

When the reaction rate measurements were completed, the specimens were cooled slowly in high vacuum in the oxidation apparatus. As this procedure could cause changes in the appearance of the reacted specimens, specimens for metallographic examinations were also oxidized in another furnace system and quenched from the reaction temperature by dropping them onto niobium metal ships in quartz tube beneath the furnace. The quartz tube, which was also part of the high vacuum system, was precooled in liquid nitrogen.

The x-ray diffraction studies were made with a GE-XRD-3 recording x-ray diffractometer. The metallographic studies were performed with a Reichert universal camera microscope (Model MeF).

Experimental Results

Reaction rate measurements.—Rates of oxidation of niobium were measured at temperatures from 1000° to 1700°C at oxygen pressures ranging from 2 x 10^{-4} to 0.5 Torr O_2. The initial studies were made on specimens measuring approximately 11 x 11 x 1.9 mm (total surface area of about 3.3 cm^2), but as will be discussed below, it was also later necessary to study oxidation rates as a function of sample size.

Results of the thermogravimetric studies on 3.3 cm^2 specimens are presented in Fig. 2-5, in which the weight change (in mg/cm^2) is plotted as a function of time (in minutes). The weight change was evaluated using the original geometrical dimensions of the specimens. No attempts were made to study reaction rates at oxygen pressures lower than 2 x 10^{-4} Torr O_2 due to possible effects of degassing of walls, etc., on the oxidation. No measurable weight changes were observed during heating of the specimens provided the pressure in the system was $<10^{-5}$ Torr. If the pressure rose to 10^{-4} Torr during the heating period, small weight gains could result prior to the run, but such contamination (<0.02 mg) were not found to affect the subsequent oxidation within the reproducibility, which could be estimated to be within 15%.

Figures 2 and 3 show the effect of oxygen pressure on the rate of oxidation at 1400° and 1600°C, respectively. In Fig. 4 and 5 is shown the effect of tempera-

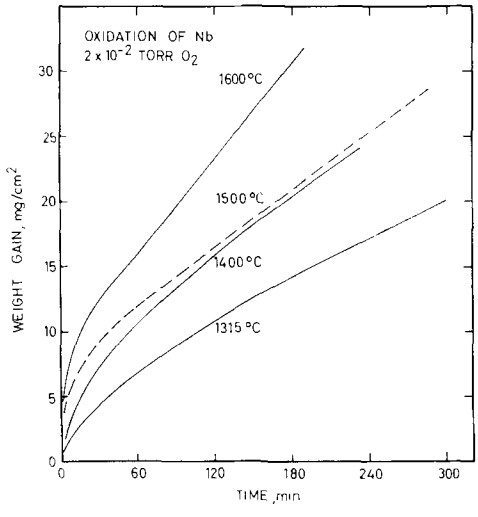

Fig. 5. Effect of temperature on oxidation of niobium at an oxygen pressure of 2 x 10^{-2} Torr.

ture on the rate of oxidation at oxygen pressures of 5×10^{-4} and 2×10^{-2} Torr.

The reaction rate measurements show that the oxidation may be divided into three main stages: (i) an initial linear rate of oxidation which is followed by (ii) a parabolic stage (<1500°C), which in turn after longer periods of oxidation transforms into (iii) a final linear rate of oxidation. The rate of oxidation during all three stages exhibits a large oxygen pressure dependence. The duration of the two first stages is a function of oxygen pressure and becomes shorter the higher the oxygen pressure. At 2×10^{-2} Torr O_2 the duration of the initial linear stage is a few minutes at most.

Between 1400° and 1500°C a change in the temperature dependence of the oxidation during the final linear oxidation is observed (Fig. 5). This change is concluded to be associated with the transition from solid to liquid Nb_2O_5. The melting point of Nb_2O_5 is about 1490°C (7, 8).

Above 1500°C oxide evaporation also becomes an important part-process as evidenced by the weight loss observed during later stages of oxidation at and above 1600°C (Fig. 4). Rates of oxide evaporation into vacuum ($\sim 2 \times 10^{-5}$ Torr) from oxidized specimens were measured at 1550°, 1600°, and 1650°C.

Studies on oxidized specimens.—When oxidation was stopped during the initial linear stage, no visible changes of the specimen could be observed, and no oxide phase could be identified either by x-ray diffraction or metallographic studies. However, x-ray diffraction studies showed that the lattice parameter of the niobium metal had increased during oxidation. From this it is concluded that oxygen dissolves in the metal during the linear stage (9, 13).

X-ray diffraction studies on the surface of specimens oxidized into the parabolic stage only gave reflections due to NbO_2. At 1700°C an additional, unidentified reflection with $d = 2.21$Å was observed. The color of the surface oxide was black, and the oxide adhered extremely well to the substrate. Metallographic cross sections closely resembled those previously published by Inouye (1). The scales were often broken up, but this is concluded to be a result of the cooling of the specimens and the resultant stresses which are built up due to the difference in thermal expansion of the oxide and the substrate. It was also difficult to preserve the scales during polishing.

NbO was present beneath the NbO_2 scales, and the metallographic cross section shows that it is preferentially formed at grain boundaries and that it grows as irregularly shaped crystals in the niobium metal. Examples of cross sections of niobium specimens oxidized at 1500° and 1600°C are shown in Fig. 6a and b. The amount of the NbO phase present in a specimen appeared to be larger the higher the temperature.

The final linear stage of the oxidation was found to be associated with formation of Nb_2O_5 on the NbO_2 scale. After cooling to room temperature, the pentoxide was identified as the high-temperature modification, α-Nb_2O_5. The oxide was in the form of a porous and voluminous scale which easily detached at room temperature. The color was gray.

When liquid Nb_2O_5 was formed, sudden weight losses were observed during the thermogravimetric measurements, and this was probably due to a dripping off of the liquid oxide. After oxidation most of the pentoxide was also found, in one case in the form of a drop, at the lower end of the specimen.

Discussion

The oxidation behavior of niobium at 1200°-1700°C exhibits the same general features as described by Inouye (1) for the temperature range 850°-1200°C. The oxidation involves three main stages: (i) an initial linear oxidation, (ii) a subsequent parabolic stage, and (iii) a final linear oxidation. Above the melting point of Nb_2O_5 the oxidation is affected by the presence of the liquid oxide phase, and above 1500°C evaporation of

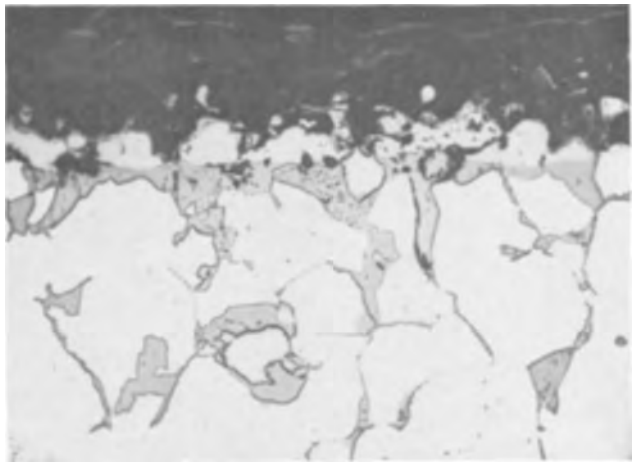

Fig. 6. Metallographic cross section of specimen oxidized for 4100 min at 1500°C and 2×10^{-4} Torr O_2. The gray oxide is NbO. Magnification 80X.

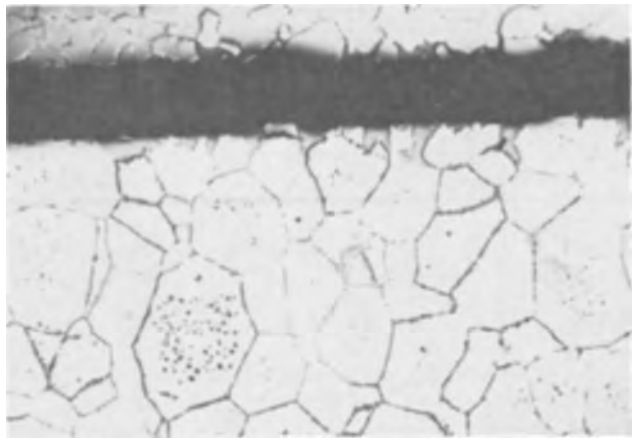

Fig. 6b. Metallographic cross section of specimen oxidized for 60 min at 1600°C and 5×10^{-3} Torr O_2. Magnification 80X.

Nb_2O_5 also becomes important during the later stages of the reaction. In the following the various stages and the associated mechanisms and rate-determining processes will be discussed.

The Initial Linear Oxidation

Oxygen dissolution.—During the initial linear oxidation oxygen dissolves in the metal. During later stages and during the transition to the subsequent parabolic oxidation it is concluded that oxidation also comprises formation of NbO at the metal surface.

The initial linear oxidation shows a large oxygen pressure dependence, and the shorter duration of this stage with increasing oxygen pressure partly reflects that the niobium becomes more rapidly saturated with oxygen. However, at higher oxygen pressures a competing oxide formation on the surface also tends to shorten the linear stage, and above about 10^{-2} Torr O_2 the initial linear oxidation becomes too short to be evaluated accurately from the thermogravimetric studies. Under these conditions a simultaneous oxygen dissolution and oxide formation take place.

At sufficiently low oxygen pressures the duration of the initial linear stage will be determined by the solubility of oxygen in niobium, and thus on the size and thickness of the specimens. In this respect a knowledge of the solubility of oxygen in niobium is important.

The solubility of oxygen in niobium in equilibrium with NbO has been studied by Seybolt (9), Elliot (10), Pemsler (11), Bryant (12), and Gebhardt and Rothenbacher (13). A summary of their results is shown in Fig. 7. Both the heat of solution and the solubilities at 1000° and 1100°C reported by Seybolt may be too high, as an extrapolation leads to unreasonably high solu-

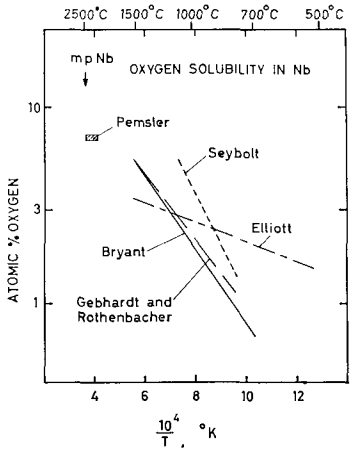

Fig. 7. Solid solubility of oxygen in niobium in equilibrium with NbO as a function of the reciprocal absolute temperature.

bilities at temperatures close to the melting point of niobium. At low temperatures one may fail to reach equilibrium between NbO and the niobium-oxygen solid solution due to slow kinetics. Below 700°C the formation of suboxides of niobium (18-20), which are probably metastable, may also yield too high apparent solubilities. Pemsler reports a solubility of about 7 at. % in the temperature range 2170°-2470°C. There is good agreement between the results of Bryant and of Gebhardt and Rothenbacher, and it is believed that these results represent the better values for the oxygen solubility in niobium.

Using Bryant's values the maximum weight gain due to oxygen dissolution for specimens measuring 11 x 11 x 1.9 mm amounts to about 3.8 mg/cm² at 1300°C, 5.15 mg/cm² at 1500°C, and 6.45 at 1700°C. At the lower oxygen pressures employed in this work (2×10^{-4} and 5×10^{-4} Torr O_2), the initial linear rate persists until the specimens become close to saturated before appreciable oxide formation begins to take place.

Temperature and oxygen pressure dependence.—Figure 8 shows the initial linear rate of oxidation as a function of oxygen pressure. Both the results of this work and those of Inouye are included. The results suggest that the initial linear rate is proportional to the oxygen pressure at low oxygen pressures and that a transition to a gradually smaller pressure dependence occurs with decreasing pressure.

In considering the initial oxidation it is found, as described below, that a large fraction of the impinging oxygen molecules reacts with the metal. Under such conditions the danger exists that the measured rate of reaction may be partially or completely governed by the rate of transport of oxygen through the reaction tube to the specimen. This will be a function of the dimensions of the tube, the reaction rate, and the total

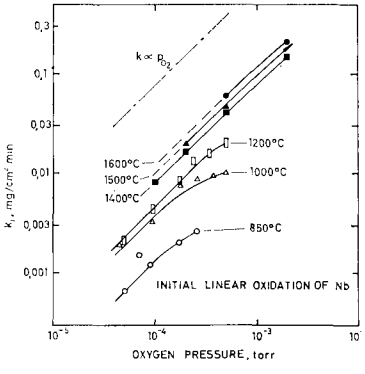

Fig. 8. The rate constant for the observed initial linear oxidation, k_i, as a function of oxygen pressure. The open points show Inouye's results (1) while the filled points represent this work.

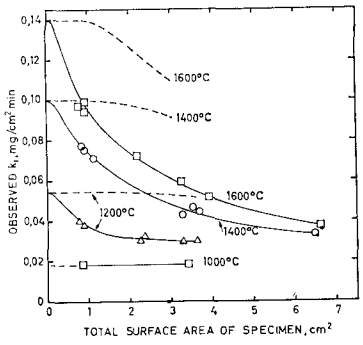

Fig. 9. Observed initial linear rate of oxidation as a function of total surface area of specimen.

surface area of the specimens. In order to test and thus possibly correct for such an effect, the rate of oxidation was measured as a function of specimen size. The results of such measurements are illustrated in Fig. 9, which shows the initial linear rate as a function of the total surface area of the specimen. As seen the observed reaction rate above 1200°C was found to increase markedly with decreasing surface area, thus indicating that the oxidation was in fact partially governed by transport of oxygen in the reaction chamber.

At sufficiently small rates of total oxygen consumption of the specimens the rate should be independent of specimen surface area, and thus an extrapolation of the curves in Fig. 9 to zero surface area should give the rate of reaction of the metal. From the results in Fig. 9 it is seen that an exact extrapolation is difficult to make at the higher temperatures. In the present case the reaction rates at zero surface area was estimated by comparing with rates measured in another apparatus for which a rate-limiting transport of oxygen was not equally critical. The latter values are indicated by the broken lines. Below 1200°C, at which transport limiting effects are not important, both apparatus gave the same rates of oxidation. It may also be noted that during subsequent parabolic oxidation below 1500°C and during the final linear oxidation the reaction rates become slow enough that transport-limiting factors are of no importance.

Although the observed reaction rates above 1200°C are partly limited by transport of oxygen in the reaction chamber, it may still be concluded that the reaction is proportional to the oxygen pressure as the results in Fig. 8 represent relative values at the same surface area. The same pressure dependence is also suggested by Inouye's results below about 2×10^{-4} Torr O_2. This pressure dependence suggests that adsorption of oxygen on the surface is an important rate-limiting factor.

In considering adsorption on metals we shall follow Ehrlich's (14) treatment and assume that oxygen molecules first become physically adsorbed on the surface and that subsequent chemisorption occurs on specific surface sites from the reservoir of physically adsorbed molecules. Accordingly the adsorption is written as

$$O_{2(g)} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} O_2 \text{ phys. ads.} \qquad \text{phys. ads.} \quad [1]$$

$$2 \text{ sites} + O_2 \text{ phys} \xrightarrow{k_2} O_{\text{chem}} + O_{\text{chem}} \quad \text{chemisorption} \quad [2]$$

If adsorption of oxygen limits the rate of oxidation, the subsequent steps in the reaction, which may involve incorporation of the chemisorbed oxygen atoms and subsequent diffusion into the metal, are relatively rapid processes, and the oxidation mechanism is described by Eq. [1] and [2].

$k_1 p_{O_2}$ denotes the rate of adsorption of physically adsorbed molecules. When assuming a condensation coefficient of unity (15), $k_1 p_{O_2}$ is equal to the rate of

impingement of oxygen molecules, which from the kinetic gas theory is given by

$$k_1 p_{O_2} = \frac{p_{O_2}}{(2\pi mkT)^{1/2}} \qquad [3]$$

k_{-1} and k_2 represent the rate constant for desorption and chemisorption of physically adsorbed molecules. The temperature dependence of k_{-1} and k_2 may be given the general formula

$$k_n = \alpha_n \exp(-E_n/RT) \qquad [4]$$

where E_n is the activation energy and α_n accounts for the frequency and probability factors associated with the process.

The above model neglects effects due to interactions of physically adsorbed molecules and desorption of chemisorbed oxygen molecules.

During linear oxidation one may further assume that the concentration of the intermediate species, *i.e*, the physically adsorbed molecules, does not change with time and that the condition of stationary states may be applied. This leads to the following expression for the initial linear rate of oxidation, k_i

$$k_i = k_1 p_{O_2} \frac{k_2(1-\theta)^2}{k_{-1} + k_2(1-\theta)^2} \qquad [5]$$

where θ represents the fraction of chemisorption sites occupied by chemisorbed oxygen.

From Eq. [5] it is seen that $k_i \propto p_{O_2}$ at sufficiently low oxygen pressures, *i.e.*, when $1-\theta \cong 1$, while a transition to a gradually smaller oxygen pressure dependence will be observed with increasing oxygen pressure, *i.e.*, when θ can no longer be neglected. As seen in Fig. 8 this is in agreement with Inouye's results. It should furthermore be noted that the deviation from $k_i \propto p_{O_2}$ probably occurs at lower oxygen pressures the lower the temperature.

When $k_i \propto p_{O_2}$ the temperature dependence is given by

$$k_i = \frac{p_{O_2}}{(2\pi mkT)^{1/2}} \cdot \frac{\alpha_2 \exp(-E_2/RT)}{\alpha_2 \exp(-E_2/RT) + \alpha_{-1}\exp(-E_{-1}/RT)} \qquad [6]$$

and accordingly an Arrhenius plot of k_i should not give a straight line relationship. This is also suggested by the experimental results as shown in Fig. 10, where the logarithm of k_i has been plotted as a function of the reciprocal absolute temperature under conditions where $k_i \propto p_{O_2}$, *e.g.*, at 10^{-4} Torr O_2. The values of k_i represent extrapolated values at zero surface area

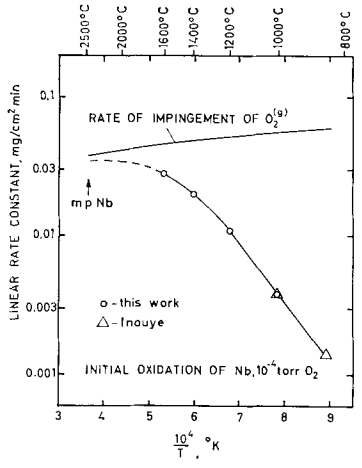

Fig. 10. Logarithm of k_i (extrapolated values at zero surface area of specimen) as a function of the reciprocal absolute temperature.

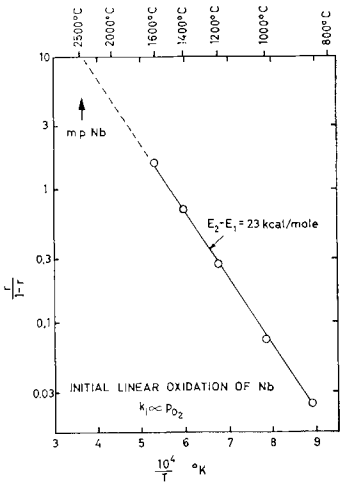

Fig. 11. Logarithm of the quantity $r/1-r$ as a function of the reciprocal absolute temperature; r is the reaction coefficient.

(Fig. 9), and the values have furthermore been extrapolated from 5 x 10^{-4} to 10^{-4} Torr O_2 in order to allow a comparison with Inouye's results under conditions where $k_i \propto p_{O_2}$. Equation [6] does, of course, also apply at other oxygen pressures as long as $k_i \propto p_{O_2}$. The calculated weight gain if all oxygen molecules which impinge at 10^{-4} Torr O_2 were to react with the metal is also shown in Fig. 10.

In order to confirm the above mechanism (Eq. [1] and [2]) one may introduce the term reaction coefficient, $r = k_i/k_1 p_{O_2}$, which denotes the fraction of the impinging molecules that react with the metal. The term $r/1-r$ is given by

$$\frac{r}{1-r} = \frac{k_2}{k_{-1}} = \frac{\alpha_2}{\alpha_{-1}} \exp\{-(E_2 - E_{-1})/RT\} \qquad [7]$$

and a plot of log $r/1-r$ as a function of $1/T$ should thus give a straight line relationship where the slope is determined by the difference in activation energies between that of chemisorption and that of desorption of physically adsorbed molecules. Figure 11 shows that the initial linear oxidation of niobium obeys Eq. [7] under conditions when $k_i \propto p_{O_2}$ and that $E_2 - E_{-1} = 23$ kcal/mole.

It may be noted that the value of r increases from 0.024 to 0.61 from 850° to 1600°C, and at the latter temperature about 60% of the impinging oxygen molecules react with the metal. Tantalum exhibits a closely similar oxidation behavior under corresponding conditions (15), but for this metal the reaction coefficient r is about half of that for niobium. Both metals have therefore excellent gettering properties at high temperatures.

In Fig. 11 the value of $r/1-r$ has been extrapolated to the melting point of niobium. Corresponding values of k_i have been evaluated and these are indicated by the broken part of the curve in Fig. 10, and these thus represent estimated values if the mechanism is valid up to the melting point. It may be possible, however, that a direct desorption of chemisorbed oxygen to the gas phase becomes significant at temperatures near the melting point of niobium, and this could cause a larger decrease in the "apparent" activation energy k_i with increasing temperature than indicated by the extrapolated values in Fig. 10. Depending on the associated activation energies an appreciable desorption of molecules could even cause a reversal in temperature dependence. Niobium metal may also be deoxidized by high-vacuum treatment at very high temperatures, probably through the evaporation of niobium oxides, and such effects would further be expected to influence the oxidation behavior of niobium. At low partial pressures of oxygen near the melting point of niobium the oxygen solubility will also be a function of the

oxygen pressure (11) and the duration of linear stage will be correspondingly limited.

Parabolic Oxidation

During the transition from the initial linear to the parabolic oxidation, it is concluded that the oxidation mainly results in formation of NbO. This does not occur as a plane-parallel film or scale on the metal, but as a growth of NbO crystals into the metal from the surface. The NbO crystals are irregularly shaped and often show large variations in size. It is reasonable to conclude that the growth of NbO depends on the orientation of the individual grains in the metal. The growth and penetration of NbO into the metal is also favored at grain boundaries. Qualitatively it appears that NbO formation is governed by the crystal growth in the solid phase, but from this work it is not possible to evaluate specific details of this process or its temperature dependence. Qualitatively it may, however, be concluded that the amount of NbO becomes relatively larger the higher the temperature.

The parabolic oxidation itself is concluded to be associated with NbO_2 formation. Metallographic examinations after cooling to room temperature show in places a broken-up scale, but this is probably a result of cooling as in the places where the NbO_2 scale is intact, it exhibits excellent adherence to the substrate. NbO_2 probably forms a compact, protective scale during the oxidation, as is also previously found by Inouye (1), and the parabolic rate is concluded to reflect a Wagner-type mechanism with a rate-determining diffusion through NbO_2.

For a further evaluation of the diffusion process associated with the parabolic oxidation the oxygen-pressure dependence of the parabolic rate constant, k_p, has been evaluated, and the results are shown in Fig. 12. In estimating the rate constant it was assumed that the amount of NbO in the metal beneath the scale remained unchanged during the oxidation. Below 1500°C $k_p \propto p^{1/2}{}_{O_2}$, while at 1500°C the results indicate a smaller and also a varying oxygen pressure dependence. At 1600° and 1700°C the reaction rate measurements did not permit an evaluation of the parabolic rate constant. This may possibly be due to an increased importance of NbO formation, to the presence of liquid Nb_2O_5, or to effects of oxide evaporation (see below).

Judging from the growth of the oxide scale on niobium, a rate-determining transport of oxygen in NbO_2 appears probable. If the Wagner mechanism applies, an oxygen pressure dependence of $k_p \propto p^{1/2}{}_{O_2}$ is unusually large. It also rules out a defect structure involving oxygen vacancies. However, a possible explanation could be that the defects in NbO_2 involve interstitial oxygen according to the relationship

$$1/2\ O_2(g) \rightleftharpoons O_i^{z-} + ze^+ \qquad [8]$$

and that diffusion of oxygen takes place through an interstitially mechanism. A pressure dependence of $p^{1/2}{}_{O_2}$ could in principle be obtained either if the electron holes, e^+, are associated with the interstitial oxygen ion or if intrinsic ionization of electrons from the conduction to the valence band ($\text{nil} \overset{K_e}{\rightleftharpoons} e^+ + e^-$) yields an electron hole concentration which is very much larger than that produced from Eq. [8], *i.e.*, if $\{e^+\} = K_e{}^{1/2} >> O_i{}^{z-}$.

According to Eq. [8] NbO_2 is proposed to contain excess oxygen relative to the stoichiometric oxide. NbO_2 has possibly a small homogeneity range (17), but otherwise little is known about its defect structure. The above considerations (Eq. [8]) are therefore at this stage purely speculative and are put forth solely to explain the oxygen pressure dependence of the parabolic oxidation.

In the temperature range 1200°-1400°C the parabolic oxidation has an activation energy of $E = 44$ kcal/mole. In view of the lack of knowledge of the defect structure of NbO_2 a detailed interpretation of this value is not possible.

NbO_2 is further oxidized to Nb_2O_5, and the growth of the latter oxide is, at least during the later stages of the reaction, linear with time. During the parabolic growth of NbO_2 traces of Nb_2O_5 may be present on the surface although it is not detected in the x-ray diffraction studies. The fact that the parabolic oxidation does exhibit an oxygen pressure dependence shows that Nb_2O_5 has no protective properties. This is also suggested by the appearance and by the metallographic cross sections of oxidized specimens which show porous scales of Nb_2O_5. The growth of NbO_2 + solid Nb_2O_5 thus probably involves a Loriers-type mechanism **(17)**.

Final Linear Oxidation

Growth of solid Nb_2O_5.—As mentioned above the solid Nb_2O_5 has no protective properties and forms a voluminous and porous scale. When this stage is reached during the oxidation, the thickness of the NbO_2 scale will, according to a Loriers-type mechanism, approach a limiting thickness, and the final linear rate essentially represent formation of Nb_2O_5.

The rate of formation of Nb_2O_5, k_f, also shows a large oxygen pressure dependence. This is shown in Fig. 13 where log k_f is plotted as a function of log p_{O_2}. Results from ref. (4) are also included, and these are represented by the open points. At 1000°C k_f is proportional to $p^{1/2}{}_{O_2}$ over the whole oxygen pressure range studied. The same applies to the higher oxygen pressure at 1200° and 1300°C.

An oxygen pressure dependence of $k_f \propto p^{1/2}{}_{O_2}$ suggests that a dissociative adsorption equilibrium is established on the surface (14, 15). Following Eq. [1] and [2] the reaction may in this case be written

$$O_2 \overset{K_1}{\leftrightharpoons} O_2 \text{ phys. ads.}$$
$$2 \text{ sites} + O_2 \text{ phys. ads.} \overset{K_2}{\rightleftharpoons} O_{chem} + O_{chem} \qquad [9]$$

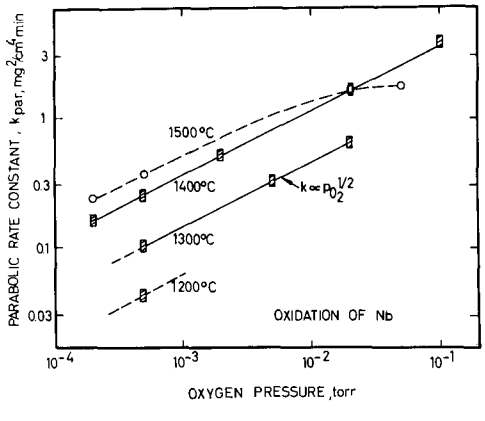

Fig. 12. Parabolic rate constant for formation of NbO_2 as a function of oxygen pressure.

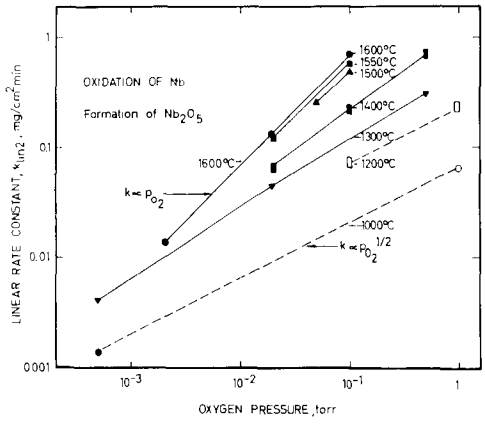

Fig. 13. Rate constant for the final linear oxidation, k_f, as a function of oxygen pressure.

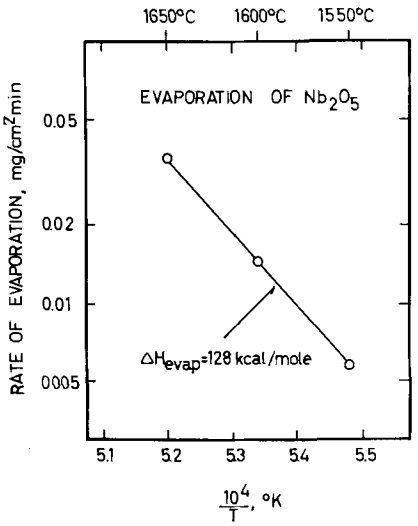

Fig. 14. Logarithm of the rate of evaporation from liquid Nb_2O_5 on oxidized Nb specimens as a function of the reciprocal absolute temperature.

$$O_{chem} \xrightarrow{k_3} \text{products} \qquad [10]$$

where $K_1 = \frac{k_1}{k_1}$ and K_2 represent the equilibrium constants. The rate of oxidation is accordingly given by

$$k_f = k_3 [O_{chem}] = k_3 K^{1/2}_{12} (1-\theta) p^{1/2}_{O_2} \qquad [11]$$

where $K_{12} = K_1 K_2$. At low coverage, *i.e.*, when $1-\theta \cong 1$, the rate of oxidation will be proportional to $p^{1/2}_{O_2}$ as observed for k_f. It should also be noted that at sufficiently high oxygen pressures, the rate of oxidation will as a limit become independent of oxygen pressure.

At very low oxygen pressures the assumption of chemisorption equilibrium will no longer be valid, and at sufficiently low oxygen pressures the rate of adsorption will become rate-determining. As a limit the rate of oxidation will become proportional to p_{O_2} as described above for the initial oxidation. The change to a somewhat larger oxygen pressure dependence at the lower pressures at 1300° and at 1400°C is believed to reflect such a transition in the rate-determining process.

When $k_f \propto p^{1/2}_{O_2}$ the activation energy amounts to about 24 kcal/mole. In this connection it should be noted that the value of k_3 increases while that of K_{12} decreases with increasing temperature, and the activation energy associated with k_f (when proportional to $p^{1/2}_{O_2}$) represents the difference between the activation energy associated with k_3 and the "enthalpy of chemisorption" associated with K_{12} (Eq. [11]).

Formation of liquid Nb_2O_5.—The rate of formation liquid Nb_2O_5 shows a different dependence on oxygen pressure and temperature than that of the growth of solid Nb_2O_5. As seen in Fig. 13 $k_f \propto p_{O_2}$ for the formation of $Nb_2O_{5\,liq}$. At low oxygen pressures this difference in pressure dependence leads to a smaller rate of formation of Nb_2O_5 when it is in liquid form (*e.g.*, 1600°C) than when it is solid (*e.g.*, 1300°C).

From the relationship $k_f \propto p_{O_2}$ it is concluded that the rate of chemisorption is the rate-determining process. When liquid Nb_2O_5 is formed, the whole specimen surface is probably always covered by a continuous layer of liquid oxide. When relatively large amounts are formed the oxide also drips off the specimen. The rate-determining chemisorption takes place on the liquid oxide surface, and the oxygen rapidly diffuses through the liquid phase to the solid oxide phase where it reacts to form Nb_2O_5.

The apparent activation energy for the formation of $Nb_2O_{5\,liq}$ as determined from the results at 1500°, 1550°, 1600°C amounts to 16 kcal/mole. Following the treatment for the initial linear oxidation this value approximately corresponds to the difference in activation for the chemisorption and the desorption of the molecules physically adsorbed on liquid Nb_2O_5.

Oxide evaporation.—Above 1550°C an appreciable evaporation of Nb_2O_5 takes place, and at 1600°C, for instance, a resultant weight loss of the specimen occurs during later stages of the oxidation at the lower oxygen pressure (Fig. 4).

The rates of evaporation in vacuum ($\sim 2 \times 10^{-5}$ Torr) was measured at 1550°, 1600°, and 1650°C and the results are presented in Fig. 14. The evaporation rates per unit surface area were evaluated using the original geometrical dimensions of the unoxidized specimens. Corrections due to the increase in surface area resulting from oxide formation would be small.

The enthalpy of evaporation is 128 kcal/mole. As this value is much larger than the activation energy for the formation of liquid Nb_2O_5 (~ 16 kcal/mole), the oxide evaporation will become increasingly important the higher the temperature. The rate of oxide evaporation may be considered to be approximately independent of oxygen pressure at oxygen pressures employed in this work, while the rate of formation is proportional to p_{O_2}. The amount of liquid Nb_2O_5 on the surface or whether it evaporates as soon as it is formed, will consequently at a specific temperature be determined by the oxygen pressure.

The rate of evaporation from a free surface into a vacuum is related to the pressure of the evaporation species by the Hertz-Langmuir equation

$$z_i = \alpha_i p_i / (2\pi m_i kT)^{1/2} \qquad [12]$$

z_i is the number of molecules evaporating per unit time per unit area, m_i is the molecular weight of the gas molecule, p_i is the equilibrium pressure, and α_i is the evaporation coefficient. When the molecule in the condensed phase is the same as the vapor species, the value of α_i has been found to be close to unity. In this work the liquid Nb_2O_5 may be expected to be deficient in oxygen relative to stoichiometric composition, but the exact composition is not known.

No mass-spectrometric analysis has been made of the evaporating species, but, assuming an evaporation coefficient equal to unity and that the molecules are Nb_2O_5, the observed evaporation rates give (Eq. [12]) the following values for the equilibrium pressure of Nb_2O_5: 4.3×10^{-6} Torr at 1550°C, 9.5×10^{-6} Torr at 1600°C, and 2.8×10^{-5} Torr at 1650°C.

Electrical Behavior of Passive Iron

J. L. Ord[1] and J. H. Bartlett

Department of Physics, University of Illinois, Urbana, Illinois

ABSTRACT

From a study of the steady-state and of galvanostatic transients, it is concluded, in agreement with Vetter and Weil, (i) that there exists a layer on iron when it is passive, (ii) that an electric field drives ions through this layer, and (iii) that the resistance to the flow of these ions is nonohmic. In the steady state, the thickness of this layer varies linearly with passivating potential from about 8Å to about 68Å. Transition from the steady passive state to the active state can occur slowly (probably by uniform thinning) for anodic current constant and less than the steady-state value, or rapidly (probably without thinning) for cathodic currents. The results indicate that, when the system is in a nonsteady state, there is a nonzero charge distribution within the layer. Even if the steady-state current be restored, it may take a long time for this charge distribution to relax back to the neutral steady state.

The nature of passivity, as exemplified by the electrical behavior of a passive iron electrode, has been the subject of much debate. Interest has centered around such questions as: (i) Is there a thin monolayer or a layer of appreciable thickness on the surface? (ii) What are the mechanisms for formation and removal of such layers? (iii) What is responsible for the large (600 mv) overpotential necessary to maintain iron in the passive state?

Previous studies of the electrical properties of passive iron have not been very extensive. Some work has been done in alkaline solutions, but the most information has been obtained with acid solutions. Some early investigations were made using nitric acid (1) but this is a rather complicated system, and later studies (2-4), including those reported here, are all with sulfuric acid. Franck and Weil (2) demonstrated the existence of a nonzero steady current, which is called the corrosion current and which is just sufficient to form new layer at a rate which balances the loss rate due to dissolution by the acid. Vetter (4) recorded galvanostatic transients from the steady state, measuring the rise of potential as a function of net charge added. He suggested the existence of an electrical field across a passive layer of appreciable thickness. His potentiostatic measurements also indicated that current through the layer is an exponential function of this field. Weil (3) repeated these measurements with more refined techniques, and concluded that "it is correct to assume that particle transport through the passive layer occurs by ions moving in an electric field." Vetter later (5) speculated that the layer is a composite oxide, the part nearest the metal being Fe_3O_4 and the outer part being Fe_2O_3.

The present work, using entirely different methods of analysis, confirms the essential ideas of Vetter and of Weil that there is an electric field driving ions through the layer and that the resistance offered to their flow is nonohmic in nature. In addition, it indicates that there is a nonzero charge density within the layer during the course of a galvanostatic charging process. The system is not then in a steady state, and it takes a considerable time, even when the steady-state current has been restored, for the system to relax back to normal. Reliable estimates of the thickness can as yet be made only for the steady state, where the thickness varies linearly with passivating potential from about 8Å to around 68Å.

Activation comes about in two different ways. For large cathodic current, the process is independent of layer thickness, so that activation corresponds to a rapid breakdown of protection at the metal-layer interface. On the other hand, when an anodic current of less than steady-state value flows, activation does depend on the initial thickness, which is taken to mean that the acid must eat away the layer until finally there is a breakthrough with consequent disruption.

Experimental

Transients were recorded by photographing an oscilloscope trace. This technique enables very fast transients to be recorded and is convenient also for transients of several minutes duration. Slow transients were recorded by setting the sweep rate at 5 sec/cm and adjusting the sweep length to 10 cm. The dead time between sweeps is negligible at this setting. An example of a slow transient recorded in this manner is given in Fig. 5.

The circuitry used is shown schematically in Fig. 1. The potentiostat consists of a 10-turn Helipot placed across a bank of 2v batteries. The galvanostat consists of a variable resistor in series with a 180v battery bank. These simple arrangements offer a number of advantages over more sophisticated electronic circuitry. (*A*) The galvanostat and potentiostat can be placed in series, and switching from one to the other can be accomplished by shorting or opening the galvanostat output. (*B*) Complex transients can be applied using a relay bank with calibrated time intervals between the closing of the relays. For example, one can switch in succession from constant potential to one constant current to open circuit to another constant current, with all switching controlled by the relay bank. (*C*) Auxiliary electrodes are not needed in the cell. The galvano-

stat kept the current constant to within 0.5% for all potential transients of interest. When the Helipot was replaced by fixed resistors for potentiostatic transients, the potential stayed constant to within 1 mv for current changes of 100 μa.

The Schering impedance bridge, consisting of R_1, R_2, C_1, and C_2 along with the cell, is shown in Fig. 1 (it does not affect the potentiostatic circuitry). The a-c signal was introduced by connecting a 5-ohm resistor in series with the potentiostat, and connecting a low-frequency oscillator across it. A high-gain null detector allowed the bridge to be operated with 10 mv a-c across the cell.

The measuring and recording circuitry is more critical than the cell supply circuitry. A VTVM with 100 megohm input impedance and a 20 μa panel meter can be used for most simple measurements. For more critical measurements a Keithley d.c. VTVM Model 200B (input impedance greater than 10^{14} ohms) was used to measure potential, and a Keithley Micro-microammeter Model 414 to measure current. A low-noise cathode follower with bandwidth greater than 100 kc is needed to operate the oscilloscope, especially for open-circuit transients. Either a conventional triode (6F5, grid current 6×10^{-9} amp) or a triode-connected electrometer tube (CK 5886, grid current less than 10^{-14} amp) can be used in a battery-operated cathode-follower circuit to achieve this performance.

The electrolyte used for all experiments except those studying the effect of pH was 2*N* H_2SO_4. The behavior of a passive iron electrode in this electrolyte does not appear sensitive to dissolved gases; oxygen-saturated, nitrogen-saturated, and hydrogen-saturated electrolytes yield identical results. Since a platinized-platinum electrode was made the cathode, hydrogen-saturated electrolyte was usually used to stabilize the potential of the cathode. Measurements were normally made at room temperature (22°C). A mercurous sulfate (0.1*N* $K_2SO_4/Hg_2SO_4/Hg$) electrode was used as reference. All potentials are given with respect to this reference. At room temperature in 2*N* H_2SO_4 this electrode has a potential of approximately 0.725v with respect to a reversible hydrogen electrode.

The anodes were prepared from a polycrystalline iron rod of 99.99% purity. An anode consisted of a ½ in. segment of this rod machined to a cross-sectional area of 0.2 cm^2 and mounted on a copper rod covered by glass tubing. The iron was first coated with a compound such as WD-4 shellac or Cenco Sealstix. After the coating had been removed from the end, the rod was mechanically polished. The anode surface was mounted so as to be vertical in the cell. It is usually desirable to work with a mildly etched surface whose roughness factor does not change rapidly. With the anode geometry described above (even after deep etching) a nominally plane surface of 0.2 cm^2 area can be restored by mechanical polishing. To enable data obtained using anodes of different roughness factors to be compared, the assumption has been made here that at

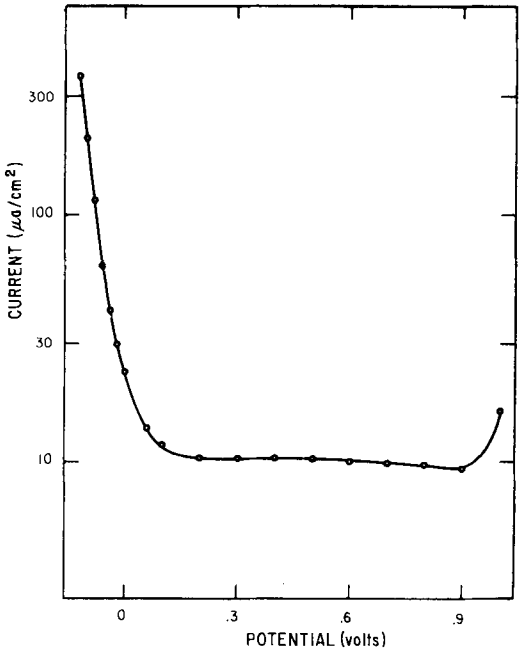

Fig. 2. Steady-state current *vs.* potential

room temperature (22°C) in 2*N* H_2SO_4 the current density at potentials in the middle of the passive region is 10 μa/cm^2. An electrode which exhibits this current density probably has a roughness factor near 1.5. (No measurement of the roughness factor was made.)

Results

Potentiostatic measurements.—If an iron electrode is placed in solution and a constant potential is applied, the current is found to reach a steady state after a certain interval, and the dependence of steady-state current on potential is represented by a so-called current *vs.* potential curve. The shape of this curve in the active region was given by Bartlett and Stephenson (6), and in the passive region by Franck and Weil (2). In the present measurements, where the electrode was passivated at constant potential, the current reached the steady state within 30 min and then stayed constant for at least 10 hr. Figure 2 shows the steady-state current density as a function of potential for the passive region. (The active-state corrosion potential is located at −1.03v on the potential scale, *vs.* mercurous sulfate, used in Fig. 2.) Franck and Weil (2) have reported longer times to reach the steady state, but they passivated at constant current and reached oxygen evolution, where there is presumably a fairly thick oxide layer, before switching to constant potential. (The longer times would be expected because of the fact that the oxide layer must become thinner to correspond to a steady state of a lower potential, and both thinning and readjustment take place slowly.)

As is seen from Fig. 2, the current density is approximately constant in the passive region between about 0.2v and 0.9v. Above 0.9v, it rises steeply with increasing potential due to oxygen evolution, and below 0.2v it also rises rapidly with decreasing potential, which represents an increase in rate of dissolution of the electrode.

The steady-state current density depends strongly on temperature and pH. The temperature dependence[2] is consistent with an activation-controlled process with energy of about 17 kcal/mole, as reported by Vetter (4). The pH range from 0 to 3 was studied using mixtures of H_2SO_4 and K_2SO_4, and it was found that the logarithm of the current density decreases linearly with increasing pH over this range. The current density changes by a factor of 10 for a pH change of 3.

[2] This measurement has been made for the range of 5°-70°C, at a potential of 0.4v, by D. DeSmet (private communication).

Only a limited amount of information about the electrode can be obtained from potentiostatic transients. When the potential is switched from one constant value to a higher one, the current density has an initial (infinite) discontinuous rise, because of the relation $i = C\ dV/dt$, which is followed by a slower decline to its initial value (7). If one measures the value of the current density just subsequent to the above capacitive transient, the indications are that it depends exponentially, not linearly, on the potential. For a quantitative study of this dependence, it is more convenient to use galvanostatic transients.

Measurements of a-c impedance were made in conjunction with the steady-state potentiostatic measurements. The a-c impedance, corrected for electrolyte resistance, may be expressed in terms of an equivalent parallel resistance, R_p, and capacitance, C_p. Both resistance and capacitance decrease with increasing frequency. The capacitance changes by a factor of 2 and the resistance by a factor of 10^3 over the frequency range from 1 to 10^4 cps. The resistance and capacitance are plotted against steady-state potential in Fig. 3 and Fig. 4 for a frequency of 100 cps.

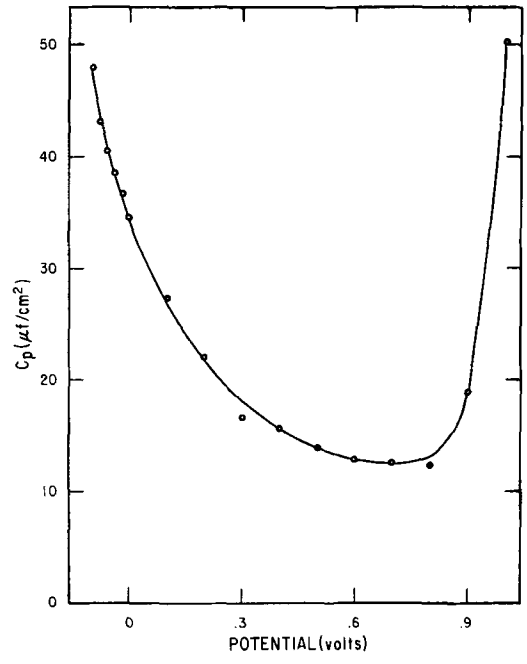

Fig. 4. Parallel capacitance vs. potential; frequency, 100 cps

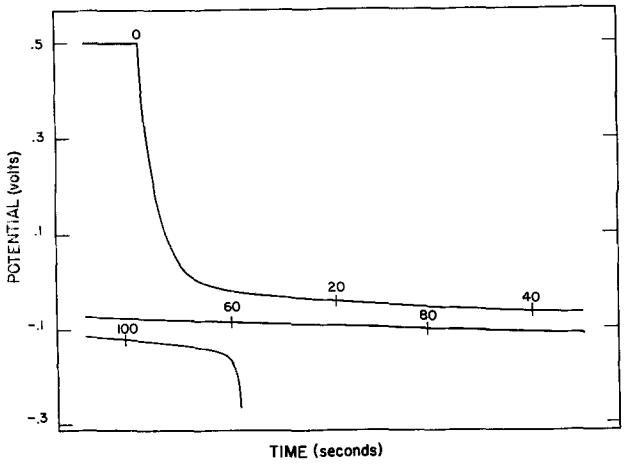

Fig. 5. Open-circuit potential transient. The corrosion potential (—1.03v) is not shown.

Galvanostatic measurements.—Figure 5 shows the potential transient observed when a steady state is interrupted by opening the circuit. This galvanostatic transient can be divided roughly into three parts: an initial capacitive transient, a sloping plateau,[3] and a sharp transition to the corrosion potential (not shown in the figure). Transients starting from different steady-state potentials differ mainly in the height of the capacitive transient.

An examination of the variation with current of the initial slope of a galvanostatic transient shows that the electrode does have a definite capacitance C which is given by the equation

$$i = C\ dV/dt + i_{ss} \qquad [1]$$

where i_{ss} is the steady-state current. The dependence of the reciprocal capacitance on the initial steady-state potential is shown in Fig. 7. Also shown is the reciprocal a-c equivalent capacitance at 100 cps.

In experiments such as the above, the times are so short that the potential V cannot change appreciably. To describe the behavior for longer times, let us assume that the potential is given by

$$i = C\ dv/dt + f(v) \qquad [2]$$

where v is the overpotential measured from a zero to be defined below. Since the observed transient is not a linear function of the time, the quantity $f(v)$ cannot be a constant. Furthermore, although the transient appears roughly exponential, the fit to a single exponential curve is not close, and so we cannot assume $f(v) = v/R$ (equivalent circuit as a resistance in parallel with a capacitance). However, if the parallel leakage current $f(v)$ be assumed to depend exponentially on v (as might be expected if activation processes control), then the transient can be fitted reasonably well. Accordingly, let us assume that

$$f(v) = i_o \exp\ (v/v_o) \qquad [3]$$

where i_o and v_o are constants.

When $i = 0$ (open circuit), the differential equation of the capacitive transient is, from [2] and [3],

$$C\ dv/dt + i_o \exp\ (v/v_o) = 0 \qquad [4]$$

and the solution is

[3] Attempts to define precisely a "Flade potential" at the end of this plateau meet the difficulty that the plateau itself curves downward well before the sudden transition to the active state.

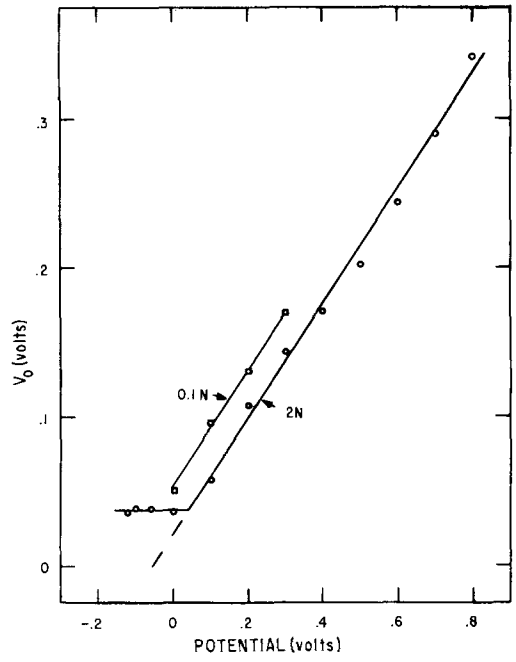

Fig. 6. v_0 vs. potential

$$v = v_o \ln(Cv_o/i_o) - v_o \ln(t + Cv_o/i_I) \quad [5]$$

where i_I is the current prior to opening the circuit. An equation of this form has been derived by Grahame (8), and applied to a study of the anodic oxidation of cadmium (8a). By choosing θ suitably, one can fit the initial two-thirds of the capacitive transient by a straight line

$$v = \text{const} - v_o \ln(t + \theta) \quad [6]$$

The slope of this straight line is v_o, and it is a well-defined experimental parameter.

Figure 6 shows the values of v_o which are obtained when the circuit is opened from a definite steady-state potential, as a function of that potential. This function is linear in the region where the current density is constant, and is constant (and equal to 37 mv) at lower potentials (below about 0.05v for $2N$ H_2SO_4).

In order to calculate the parameter i_o, it is necessary to determine the zero of overpotential. Since the overpotential under consideration is associated with the capacitive transient, it will be zero when that transient has died out. However, there is another much slower process occurring which causes the plateau to slope. Accordingly, it is natural to suppose that the above overpotential is zero on the plateau extrapolated backwards. When this is done, it turns out that i_o is approximately constant over the potential region where the steady-state current i_{ss} is constant. Because the plateau is not exactly linear, this extrapolation is difficult. However, one can obtain a well-defined zero of overpotential by assuming i_o is constant when i_{ss} is, and extrapolating as in Fig. 6. The zero is located at -0.055v, and $i_o = 0.75$ μa/cm^2 when $i_{ss} = 10$ μa/cm^2, and the acid is $2N$ H_2SO_4.

Since the exponential nature of $f(v)$ has been established, and since the steady-state current density has a temperature dependence indicating the existence of an activation energy, it is now in order to discuss the theoretical equation relating current density to overpotential across an activation barrier. This, according to various authors (9), is of the form

$$i/i_o = \exp(\alpha\lambda\eta/kT) - \exp(-(1-\alpha)\lambda\eta/kT) \quad [7]$$

where η is the overpotential measured from the reversible potential, α is the fraction of the overpotential which aids the forward current, λ is the valence of the charge carriers, and i_o is the exchange current at zero overpotential. If η is large, the last term may be neglected and this equation has the same form as Eq. [3]. If η is small, however, Eq. [3] and its consequence Eq. [5] are no longer valid, and this may account in part for the fact that the bottom third of the capacitive transient deviates from the curve of Eq. [6].

Assuming temporarily that η is large, let us try to correlate it with the measured overpotential v. If we should equate v to η, then it folows that $v_o = kT/\alpha\lambda$, a constant independent of v. This result is not consistent with Fig. 6, where v_o depends linearly on v, and hence the entire overpotential cannot appear across the activation barrier.

It seems more reasonable to assume (10) that a layer of thickness D is present at the interface and that only a fraction of the overpotential appears across the activation barrier. In this event, we can relate $\alpha\eta$ to the field E by the equation $\alpha\eta = aE$, where a defines a "jump distance" for forward motion of particles across the activation barrier. Then, from Eq. [7] and [3], we have

$$E = (kT/a\lambda)(v/v_o) \quad [8]$$

for the field across the barrier. If there were no charge within the layer, then (by Gauss' theorem) the field would be constant across the layer, $v = ED$, and the thickness

$$D = (a\lambda/kT)v_o \quad [9]$$

If we assume that in the steady state the layer is neutral, then its thickness will be proportional to v_o, which can be determined experimentally. Figure 6 then indicates that (i) the layer has a limiting thickness below which it does not decrease and (ii) that the thickness increases linearly with steady-state potential up to about ten times this minimum thickness.

As mentioned above, the steady-state current density depends strongly on pH. Comparison of the two curves in Fig. 6, representing $0.1N$ H_2SO_4 and $2N$ H_2SO_4, respectively, shows that v_o depends only on v and not on pH.

In reaching the steady state, for a given overpotential, the system parameter i_o somehow adjusts itself so that the final value is in accordance with Eq. [3], where the current density i is itself equivalent to the rate at which the acid removes the layer, this rate depending on pH and temperature.

A comparison of Fig. 6 with Fig. 7 shows that the reciprocal capacitance is a linear function of v_o in the steady state. Apparently the capacity is related to the

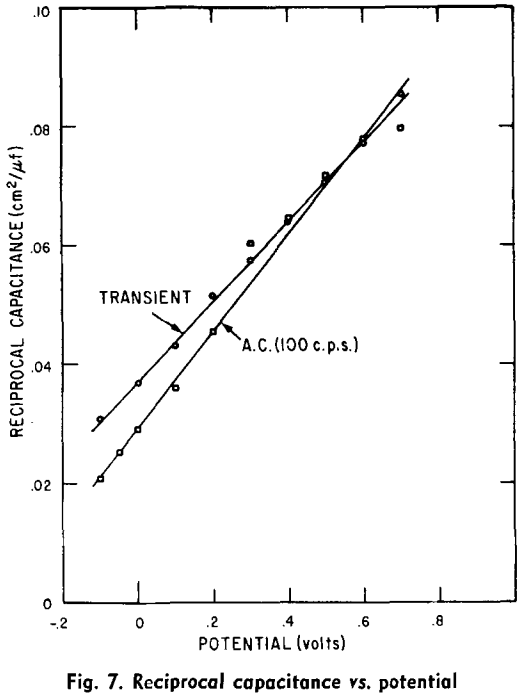

Fig. 7. Reciprocal capacitance vs. potential

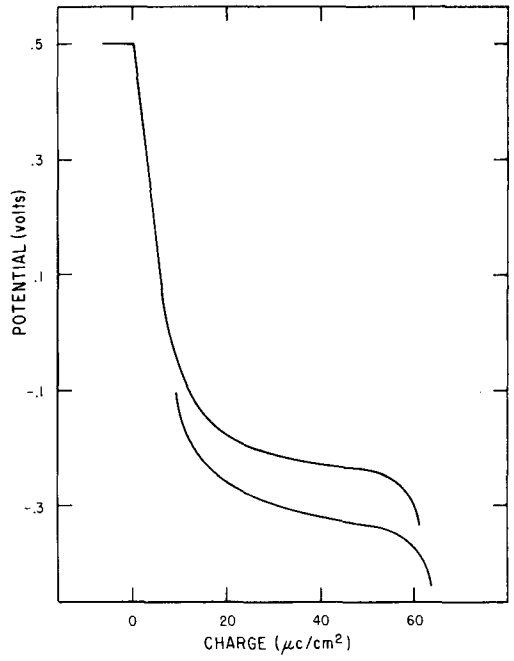

Fig. 8. Cathodic potential transients. Cathodic current: upper curve, 0.256 ma/cm²; lower curve, 2.56 ma/cm².

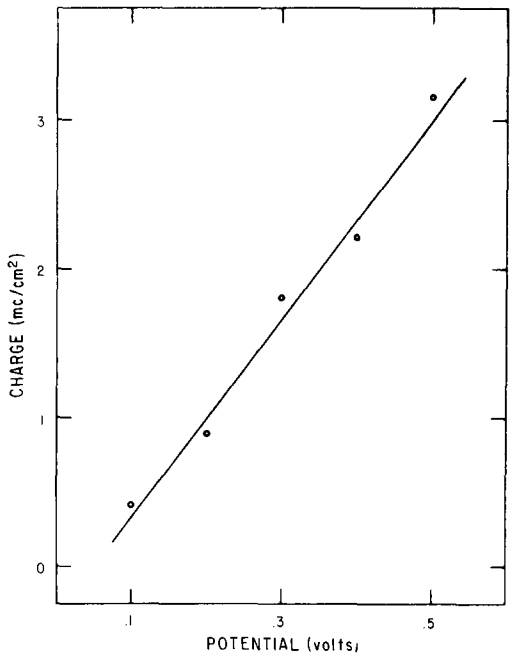

Fig. 9. Charge to activate vs. potential. Anodic current 3μa/cm²

thickness of the layer. The discussion section below shows that this is to be expected if one adopts a rather general model for the layer.

Transition to the Active State

If the electrode is initially passive and in a steady state with anodic current i_{ss}, a transition to the active state may be effected if one applies a constant current $i < i_{ss}$. This current can be anodic or cathodic.

The case where the current is cathodic and large with respect to the corrosion current is illustrated by Fig. 8, where potential has been plotted *vs. it*, with t the time the current i has flowed. The two curves are for two different values of the current, and it is seen that the length of the plateau[4] depends only on the charge and not on the current density. (Strictly speaking, activation might be expected to depend on $(i_{ss} - i)t$, but $|i_{ss}| < i$ and hence one may use it for the charge involved, without causing appreciable error.) The amount of charge required, before the transition to the active state occurs, is equivalent to a fraction of a monolayer. Other authors (3) have observed this, and have suggested that a "hole" is created in the layer. But then the charge to make a hole should depend on the layer thickness (as measured by the initial potential) and this is not found. An alternative explanation is that large cathodic currents cause disruption of a monolayer, followed by a general breakdown and a transition to the active state.

Activation with anodic current $i < i_{ss}$ is different from that with large cathodic current, because the initial thickness is important in the former case. In Fig. 9, for an anodic current density of 3 μa/cm², the activation charge is shown as a function of initial steady-state potential. This charge is greater than that for cathodic activation, and it increases linearly with the thickness of the surface layer. During anodic activation, the erosion of the layer by the acid may be assumed to continue at the rate i_{ss}, while formation occurs at the rate i. As long as there is an anodic current, this will tend to flow where the layer is thinnest and thus automatically keep the thickness of the layer uniform. However, continued erosion will eventually make the layer so thin that disruption must occur. With this picture, the anodic activation charge corresponds to a layer at least several atoms thick, and so will be greater than the cathodic activation charge, which seems to involve less than a monolayer.

If the current is zero or cathodic and small, the transition to the active state is intermediate in behavior between the above types of activation. Presumably the erosion culminates in the formation of a hole through the layer, there being nothing to prevent it. For zero applied current (open circuit) the time to activate is not entirely reproducible, which apparently is due to the thinning being nonuniform, or in other words to the existence of "local action currents."

Layer Growth

To study the increase in thickness of a passive layer, we have recorded galvanostatic transients with anodic currents greater than the steady-state current, and a typical one is shown in Fig. 10. Starting from the steady state, there is at first a capacitive rise in potential, which may be regarded as a rapid adjustment to the increased current. The potential goes through a maximum, decreases slightly to a plateau and then rises linearly with time. (The experiments of Weil (3) were such that the maximum and plateau were not recorded.) At higher passivating potentials, the length of

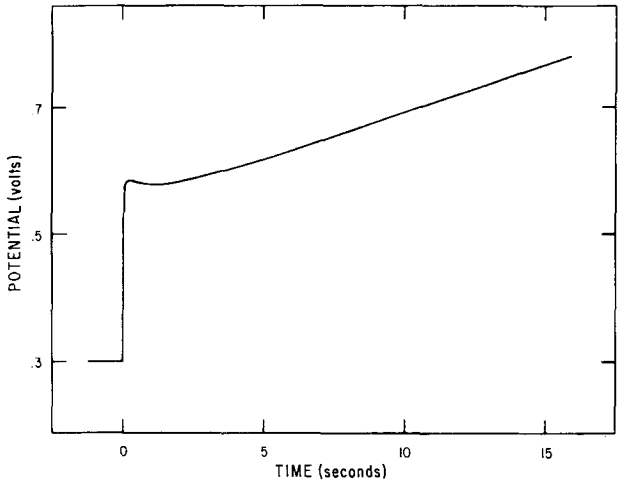

Fig. 10. Galvanostatic potential transient. Anodic current, 183 μa/cm².

[4] The plateau itself shifts to more negative potentials as the cathodic current is increased, according to $\Delta V = 0.04 \ln i$, which relation is practically independent of thickness.

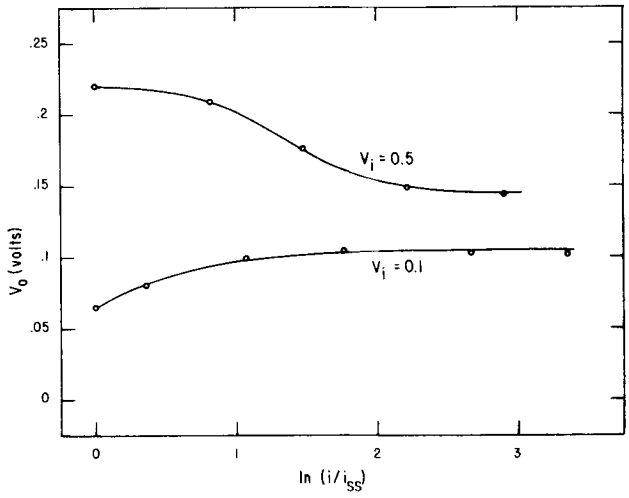

Fig. 11. Dependence of v_o on current. Initial steady-state potential: upper curve, 0.5v; lower curve, 0.1v.

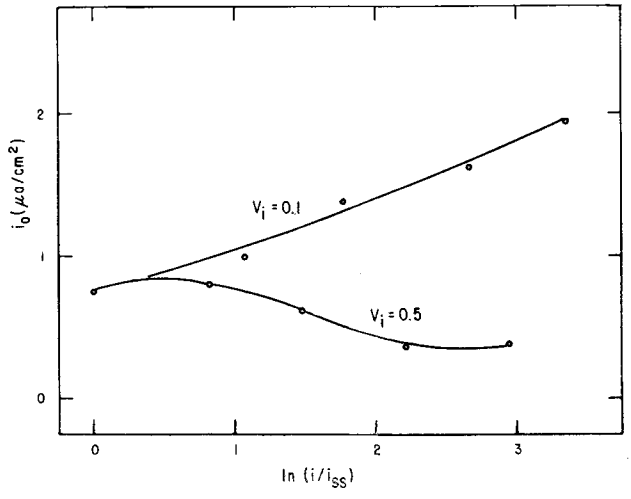

Fig. 12. Dependence of i_o on current. Initial steady-state potential: upper curve, 0.1v; lower curve, 0.5v.

the plateau shows little potential dependence, but does vary approximately inversely with excess current, indicating that a constant amount of charge is required to reach the end of the plateau. The slope of the linear potential rise is approximately proportional to $i - i_{ss}$, as would be expected if the layer is thickening.

Closer investigation reveals that a point on the above linear rise does not correspond to a steady state, for the field is not constant across the layer. If the circuit be opened when an excess charge of 0.05 mc/cm^2 (enough to complete the capacitive transient and arrive on the plateau, without appreciably changing the layer thickness) has passed, then it is found that the field across the activation barrier has changed from its steady-state value. [The open-circuit transient can be fitted by a $\ln(t + \theta)$ function over a wide range of potential, and so one can obtain good parameters v_o and i_o. These are shown in Fig. 11 and 12, for 2 different values of the initial steady-state potential v_i, as a function of the applied current i.] Now with a given potential v and a thickness D, the average field is v/D, which will be the actual field in the steady state. If the field across the activation barrier is different from this average, so must the field in the remainder of the layer be different, and the field cannot be constant. By Gauss' theorem, $\partial E/\partial x = 4\pi\rho$, so the interior of the layer has a nonzero charge density at the end of the plateau (and on the linear rise as well).

Relaxation from the charged condition to the neutral steady state can be followed by switching down to the

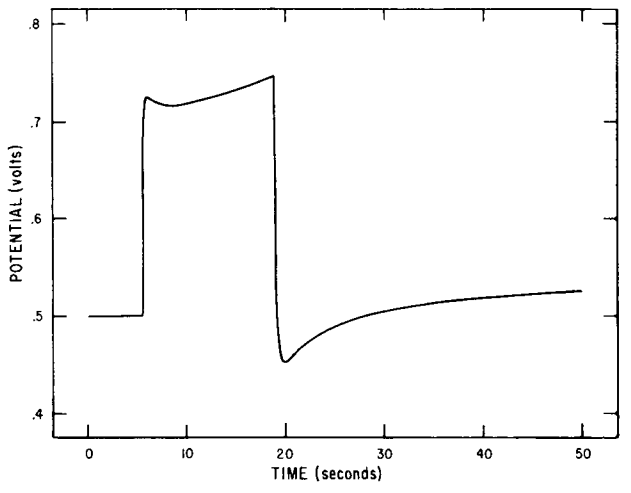

Fig. 13. Galvanostatic potential transient. Current switched from 10 to 73 μa/cm^2, then back to 10 μa/cm^2.

corrosion current, at any point of the linear rise. Figure 13 shows the resulting behavior. The rapid drop of potential (capacitive transient) is followed by a slow rise. After about a half a minute, i_o and v_o return to their steady-state values, which are consistent with the final potential. But an open-circuit transient from the linear rise drops very rapidly, so that i_o and v_o can be expected to be nearly constant during the drop, which is in fact found.

In general, then, i_o and v_o can change rapidly if a large change of current is made, but quite slowly if redistribution of charge over the whole layer is involved. If, for instance, the solution be changed from 0.1N H_2SO_4 to 2N H_2SO_4, keeping the potential constant, the quantity v_o takes about 2.5 min, and i_o as long as 10 min, to reach new steady values (unpublished experiments by D. DeSmet). Apparently i_o and v_o serve to describe local conditions at an activation barrier, which conditions adjust rapidly to electron flow, but only slowly to motion of ions.

The thickness of the layer can be estimated by indirect methods in a manner similar to that used by Vetter and Weil (1), and our results are roughly the same. If excess charge ΔQ is given to the layer, and relaxation at $i = i_{ss}$ is allowed to proceed to completion, then the increase of potential ΔV is related to ΔQ in a linear fashion, as shown in Fig. 14. If this charge ΔQ all goes to build layer, the increase in thickness ΔD is given by the equation $\Delta D = M(\Delta Q/\sigma A)/s\lambda F$, where M is the molecular weight, σ the roughness factor, A area, s specific gravity, and λ the valence of ion. Thus we can relate ΔD to ΔV if we make assumptions about M, σ, s, and λ. But since Fig. 6 shows a linear connection between v_o and V, ΔD will be proportional to Δv_o. This is in agreement with Eq. [9], the factor of proportionality being $a\lambda/kT$. Assuming that the layer is composed of Fe_2O_3, that $\sigma = 1.5$ and $\lambda = 3$, and that $D = (a\lambda/kT)v_o$ from Eq. [9], the minimum thickness is calculated to be 8Å. the thickness at $v = 800$ mv is 68Å, and the jump distance a is 1.9Å. [A somewhat similar dependence of thickness on potential was found in the anodic oxidation of platinum (11, 12)].

Discussion

Now that the evidence indicates the existence of a nonzero charge within the layer, it becomes natural to inquire how this charge builds up, relaxes, and causes the layer to change in thickness. One can obtain at least partial answers by considering the behavior of a layer with an arbitrary distribution of charge.

If the charge density is ρ and the dielectric constant is ϵ, then Gauss' theorem states that

$$\epsilon E = 4\pi \int \rho dx \qquad [10]$$

The drop in potential across the layer is

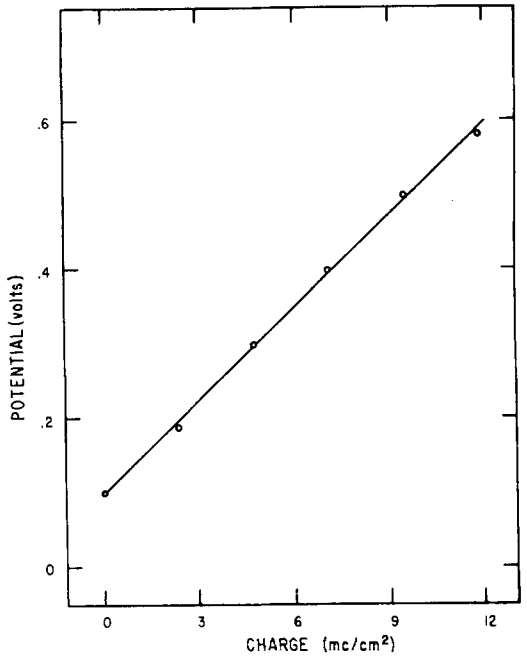

Fig. 14. Steady-state potential *vs.* charge. Potential measured 100 sec after switching down to steady-state current. Charge = $(i - i_{ss})t$.

$$v = -\int_0^D E dx \qquad [11]$$

This may change because the charge density changes, or because the layer increases in thickness. The total amount will be

$$\Delta v = \int_0^D \Delta E\, dx + E\Delta D \qquad [12]$$

Furthermore, by continuity, the time rate of change of charge density is given by

$$\frac{\partial \rho}{\partial t} = -\frac{\partial i}{\partial x} \qquad [13]$$

where i is the current density.

Now let us discuss a galvanostatic charging process, using the above equations. When the current is increased at $t = 0$, electrons flow without delay, leaving ionized iron atoms behind, ready to migrate in the opposite direction under the influence of the field E. Suppose that these ions are contained in a small length Δx. Then, from [13]

$$\Delta\rho\, \Delta x = \Delta i\, \Delta t$$

By [10], $\epsilon\Delta E = 4\pi\, \Delta\rho\, \Delta x = 4\pi\, \Delta i\, \Delta t$.

If the region Δx is at the metal interface and $\Delta x << D$,

$$\Delta v = -D\Delta E = \frac{4\pi}{\epsilon} \Delta i\, \Delta t\, D \qquad [14]$$

Since capacity is defined in general by the equation $C = -i/(dV/dt)$, we see that our system behaves as if there were a capacitative element (in parallel with the normal resistance) through which the current Δi flows. Its capacity is, from [14],

$$C = \epsilon/4\pi D \qquad [15]$$

This equation is consistent with our experimental observations that the reciprocal capacity in the steady state varies linearly with the potential (and thus with the thickness). Since there is nothing in the above derivation which restricts the system to be in the steady state, we should be able to find the thickness by measuring the capacity and applying Eq. [15].

To proceed further, let us attempt to describe the thickening process, making what seem to be natural assumptions. Vetter (4) has suggested that at the layer-electrolyte interface negative oxygen ions are produced and that these can migrate through the layer toward the metal. Exactly where they combine with positive ions to produce added layer has been left open, so let us suppose that this occurs somewhere in the middle of the layer, the position being determined by the relative mobilities of the various types of ion. If, except where the ions are combining, the charge density is steady, then $\Delta E = 0$ and Eq. [12] results in $\Delta v/\Delta t = E_c(\Delta D/\Delta t)$, E_c being the field at the site of combination. If the thickening (thinning) occurs at a constant rate, then the potential will rise (fall) linearly with time. For a galvanostatic transient with $i > i_{ss}$, we do observe a linear rise, and for $i > i_{ss}$ a linear fall, during the latter part of the transient.

More quantitative statements about changes in thickness and about the factors governing the exchange current and electric field seem to demand further experimentation, especially in connection with the relaxation process. Qualitatively, however, the above model does tie together phenomena which are otherwise inexplicable, and thus furnishes guidelines toward further progress in understanding the structure of a passive layer.

Acknowledgment

This work was supported by the U.S. Army Research Office (Durham) under contracts DA-11-022-ORD-2525 and DA-11-022-ORD-3442, and by the University of Illinois Research Board.

Mr. W. P. Perkins rendered invaluable assistance both in performing the experiments and in analyzing the data. Mr. L. D. Ferguson assisted with studies of capacitance and of concentration dependence. Mr. J. E. Orme helped with the a.c. measurements, and Mr. P. O. Schemmel and Mr. W. H. Trester with the data analysis.

For all this support and assistance, we are deeply appreciative.

Manuscript received May 7, 1962; revised manuscript received Oct. 14, 1964. This paper was presented at the 2nd International Passivity Conference, Toronto, September 1962.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

The Structure of Electrodeposited Copper Examined by X-Ray Diffraction Techniques

E. M. Hofer[1] and H. E. Hintermann

Laboratoire Suisse de Recherches Horlogères, Neuchâtel, Switzerland

ABSTRACT

X-ray diffraction line profiles of copper, electrodeposited from an acid plating bath in the presence of thiourea, have been analyzed by Fourier techniques. From the coefficients data on microstrains, crystallite size, twin fault, and stacking fault densities were obtained. The stored energy and the dislocation density have been derived from the value of the rms strains. The sums of the determination of the Fourier coefficients of the various diffraction peaks were calculated with a computer. The particle size as determined by the Fourier analysis varies between 1350 and 180Å. The smallest particle size is obtained in a plating bath with a thiourea concentration of 20 mg/l. The deposits contain no stacking faults; the microtwin density is high. The microstrains are strong, indicating high values for the stored energy, ≈0.25 cal/g, and the dislocation density, ≈2 x 10^{11}/cm^2. A relationship was established between hardness and strain. X-ray results were compared with those obtained from electron microscopical observations on the same specimens.

The mechanical properties of electrodeposits have been the subject of many studies (1). The properties are due to definite microstructural features comparable to those produced by cold-work, such as small grain size and strong internal tensions. Fischer (2) explained that strong inhibition can entirely block a crystal's active growth sites during deposition and thus cause a notable decrease in the grain size with increasing amounts of the additive. Vermilyea and co-workers proved quantitatively that the rate of electrodeposition of metal whiskers is controlled by this mechanism (3), and that the formation of polycrystalline electrodeposits can be explained by the same mechanism (4).

Strains in galvanic deposits are similar to those produced by cold-work. Their presence has been known for almost a century (5, 6). They are the result of distortions in the mosaic structure influenced by the deposition parameters (7, 8). Strain can result from the transformation of atomic hydrogen enclosed in the crystalline body of the metallic deposit into molecular hydrogen (9-11), the retaining and releasing of atomic hydrogen during electrodeposition (10, 11), and the presence of dislocations created by growth accidents (9, 12). Steinemann and Hintermann (13) measured dislocation densities in copper deposits of 10^8 to 10^{11} dislocations/cm^2. Another reason for the presence of strains is the inclusion of the additive or a reaction product thereof in the deposit (13). By electron microscopical techniques an occlusion density of 10^{17}/cm^3 was determined (13). Jan (14) measured the occlusion density by x-ray small angle scattering and obtained similar results. The pinning of dislocations between inclusions, as observed in copper sheets electroplated in the presence of gelatine, is still another cause for the improved mechanical properties of electrodeposited metals (13, 15).

An accurate and extended knowledge of the microstructure of electrodeposits was necessary if a relation between certain deposition parameters and the resulting mechanical properties of the electrodeposits were to be found. One possible and promising method of investigation was a Fourier analysis of the x-ray diffraction peaks obtained from electrodeposits (16, 17). This method renders a better statistical value for the crystallite size than does the electron microscope, since the examined surface of the specimen is much larger. Moreover, from the analysis of the diffraction peaks by Fourier techniques, additional data on the magnitude of microstrains and the density of growth faults can be obtained. This technique has the further advantage of being nondestructive. Its results combined with hardness measurements contribute to a better understanding of the structural defects and their influence on the mechanical properties of electrodeposited metals.

Experimental

Sample preparation.—Copper deposits of 30μ thickness were produced on laminated and annealed copper sheets of 50μ thickness. The electrolytic cell was of cylindrical shape with a rotating cathode and a stable concentric anode of the following dimensions: cathode, diameter 40 mm, height 100 mm, effective height[2] 82 mm; anode, diameter 80 mm, height 100 mm. This cell was constructed for good reproductibility of the following parameters: (*a*) current density *i*, (*b*) temperature *T*, (*c*) geometry *G*, (*d*) agitation *A*. These parameters were kept constant for all depositions.

Seven deposits were made. Analytical grade thiourea[3] was used as an additive. The initial composition of the plating bath was 1*N* $CuSO_4$, 1*N* H_2SO_4, prepared as described by Fischer and co-workers (18, 19). A fresh solution was used for each plating. The thiourea was added in quantities of 5, 10, 15, 20, 25, 40, and 100 mg/l solution immediately before the electrodeposition. The other deposition parameters were: $i = 28$ ma/cm^2 and $T = 22° \pm 1°$C. The samples were chosen from an area exhibiting the least of preferred crystallite orientation, usually from the central region of the cathode. In order to prevent recovery at room temperature, the specimens were held under liquid nitrogen until investigated by x-ray diffraction.

Heat treatments were made for 1 hr at temperatures of 100°, 175°, 250°, 350°, 450°, and 550°C, respectively.

X-ray methods.—The x-ray diffraction patterns were recorded with a Philips proportional counter diffractometer. Filtered Co Kα radiation (voltage 30 kv, current 10 ma, Fe filter) was used, thus eliminating the copper fluorescent radiation from the sample. The width of the divergence slit was 1°, that of the receiving slit 0.2 mm. The scanning speed was ¼ degree 2θ/min, the chart speed 800 mm/hr.

The electrodeposits were mounted in a stainless steel specimen holder in order to provide reproducible experimental conditions during the recording of the various diffraction patterns. The heat-treatment was performed while the specimen was kept in the holder. The background was determined from a sample annealed at 550°C and substracted from each diffraction pattern of the samples to be analyzed.

[2] Height of the sheet on which the copper actually was deposited.

[3] Merck p.a.

If a fcc metal is considered to be composed of a stacking of (111) layers whose normal sequence would be ABCABCABC . . ., a stacking fault is a break in this sequence ABC↓BCABC . . ., whereas a reversal in the sequence ABCACBA represents a twin fault. The probability α of finding a stacking fault between two (111) layers can be determined from the relative positions of the 111 and 200 reflections of the sample as deposited and the annealed standard (20, 21), *i.e.*

$$(2\theta_{200} - 2\theta_{111})_{\text{untreated}} - (2\theta_{200} - 2\theta_{111})_{\text{annealed}} = -\left(\tan\theta_{200} + \frac{1}{2}\tan\theta_{111}\right)\frac{45\sqrt{3}\,\alpha}{\pi^2} \quad [1]$$

The Fourier analysis of the recorded diffraction peaks was carried out with an electronic computer, IBM 1620. The program was established in such a way that, after the function to be analyzed had been introduced in form of discrete values P'_ν spaced in regular intervals θ_ν, the Fourier coefficients and the position of the center of gravity with regard to the peak maximum, ΔCG, of each peak were obtained (17). For the calculation of the Fourier transform and ΔCG, intervals equal to 2 sin θ/λ were used. The ordinates were previously divided by $f^2(1 + \cos^2 2\theta)/\sin^2\theta$, f being the atomic scattering factor. Once the ΔCG value was known, the probability β of finding a twin fault between two (111) layers could be determined by the method of Cohen and Wagner (22)

$$\Delta CG(^\circ 2\theta)_{111} - \Delta CG(^\circ 2\theta)_{200} = \beta\,(11\tan\theta_{111} + 14.6\tan\theta_{200}) \quad [2]$$

The cosine Fourier coefficient A_L, for which the line broadening due to instrumental effects (23) is corrected by the method of Stokes (24), can be considered as the product of two coefficients A_L^S and A_L^D. L is the real distance in the crystal normal to the diffracting planes, equal to na_3; n is the harmonic number, and a_3 is the unit cell dimension in the direction perpendicular to the diffracting planes. A_L^S is due to the particle size, A_L^D to the rms strain averaged over the distance L : $\langle\epsilon_L^2\rangle^{1/2}$

$$\ln A_L = \ln A_L^S - 2\pi^2(L/a_o)^2 h_o^2 \langle\epsilon_L^2\rangle \quad [3]$$

where $h_o^2 = (h^2 + k^2 + l^2)$ is the order of the reflection and a_o is the true lattice parameter. Only the term due to the strain is a function of h_o^2. Thus, if A_L is plotted as a function of different orders of reflection $(h_1^2 + k_1^2 + l_1^2)$ a straight line is obtained, whose intersection with the ordinate furnishes the value of A_L^S. This value, a function of L, renders $\langle D\rangle_{\text{eff }hkl}$, the size of the coherently diffracting domains. This effective dimension of the particles includes the effects of grain boundaries, small angle boundaries, stacking faults, and twin faults

$$\frac{1}{\langle D\rangle_{\text{eff }hkl}} = -\left[\frac{dA_L^S}{dL}\right]_{L\to o} = \frac{1}{\langle D\rangle} + \frac{1.5\alpha + \beta}{a_o} c_{hkl} \quad [4]$$

c_{hkl} is a coefficient which depends on the reflection under study. In this work the orders 111 and 222 have been used for which c_{hkl} is equal to $\sqrt{3}/4$. The expression $[(1.5\alpha + \beta)/a_o]\ 3/4 = \langle D\rangle^{-1}_{F\,111}$. The term $\langle D\rangle_{F\,111}$ is the calculated particle size due to the presence of faults only.

The diffraction peaks of all seven samples with and without heat treatment at different temperatures were analyzed by Fourier techniques. To apply the correction of Stokes for the instrumental line broadening, a sample annealed at 550°C was used as a standard. Moreover, to check if there was any annealing effect on freshly deposited coatings at ambient temperature, these samples were stored after deposition under liquid nitrogen and their x-ray diffraction patterns recorded at a sample temperature of —160°C. For this purpose a low-temperature goniometer head analogous to the one described by Wagner (25) was used. It was experimentally verified that neither the width nor the form of the diffraction peaks were influenced by the use of this goniometer attachment.

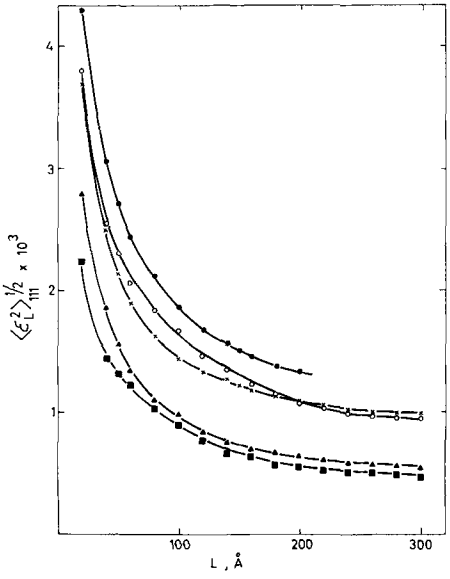

Fig. 1. rms strain $\langle\epsilon^2_L\rangle^{1/2}$ *vs.* the averaging distance normal to the diffracting planes L, for copper deposited from 1*N* H_2SO_4, 1*N* $CuSO_4$ with 40 mg/l thiourea and for different annealing temperatures: •, —160°C; ○, 25°C; X, 100°C; ▲, 175°C; ■, 250°C; 40 mg/l.

Results

Strains.—The rms strains of the seven specimens were calculated as a function of L (example in Fig. 1). If it is assumed that the distribution of the strains within the crystal is random, it is possible to calculate the stored energy due to the elastic distortions in the lattice with the formula of Faulkner (26)

$$V = \frac{15\,E}{2(3 - 4\nu + 8\nu^2)}\langle\epsilon^2\rangle$$

where E is Young's modulus in the direction $[hkl]$ of the deformation and ν is Poisson's ratio.

The rms strain $\langle\epsilon_L^2\rangle^{1/2}$ is a component normal to the reflecting planes, averaged over a column length L, then squared and averaged over all sample regions. According to McKeehan and Warren (27), the true value of the strain is only obtained at small values of L. Therefore V has been chosen to be calculated for $L = 20$Å, a value which seemed sufficiently small to satisfy this condition, yet sufficiently great that $\langle\epsilon_L^2\rangle^{1/2}$ could be determined precisely. Values of V were calculated for each annealing temperature T_a at various thiourea concentrations (Fig. 2 a-g). Also listed in Fig. 2 are the size of coherently diffracting domains, rms strain, and Vickers DPH values. The curves were drawn taking into account for the maximum deviation from V, as indicated in the appendix. The point at —160°C indicates that the sample was actually kept at this temperature during the recording of the diffraction pattern. From the plotted curves it is evident that the release of the stored energy with increasing temperature does not proceed in a parallel manner for the seven specimens. Hence the recovery mechanism depends on the concentration of the additive which itself influences the structure, the number of occluded impurities, and the number of faults in the plate. Several authors (28-30) have studied the recovery of pure copper after irradiation or cold-work and have distinguished five recovery stages. Although the numerous publications on this subject agree on the activation energy of the different stages and also on the

temperature ranges within which the transitions are supposed to occur, they disagree somewhat on the interpretation of the kinetics of these phenomenons.

The first recovery stage, between —240° and —225°C, is attributed to close-pair annihilation by the motion of interstitials immediately adjacent to a vacancy (28-30), or to a local rearrangement process occurring in displacement spikes (29). The second stage, between —160° and —60°C, is associated with di-interstitial (30) or interstitial (28) migration or with the migration of divacancies or "wide" pair recombination (29). The third stage, between —60° and +40°C, is characterized by divacancy migration (28), diffusion of interstitials, and their recombination with vacancies (29), vacancy migration, or the breaking up of interstitial clusters (30). All the authors attribute the fourth stage, from

100° to 200°C, to the migration of isolated vacancies and to their disappearance at grain boundaries or dislocations. The fifth stage, at about 240°C, is unanimously considered as the stage of reorganization of the crystal by self-diffusion and migration of dislocations occurring before the recrystallization or simultaneously with it.

This information is summarized in Table I. An attempt was made to compare the recovery behavior of the copper electrodeposits of this study to samples of pure copper processed in a different manner as described in the literature.

In the case of the electrodeposits only the stages III, IV, and V could be observed, because the bath temperature at the time of the deposition was 22°C. The only purpose of the diffraction under liquid nitrogen was to prevent a recovery of the deposit at ambient temperature. From Fig. 2 it is evident that the three later recovery stages could generally be observed on all deposits. The different stages have been separated by taking into account (i) the limiting temperature as stated in Table I, (ii) the course of the curves as indicated by the measured points, and (iii) for stage V also the onset of the rapid grain growth. The percentages of recovery were calculated from the curves representing V as a function of T_a (Fig. 2), assuming that 50% of the entire stored energy is represented by the latter three recovery stages, as is actually the case for irradiated and cold-worked metals. However, two remarks must be made: (*A*) The presence of a rather high number of impurities occluded in the crystalline structure of the deposits retards the different recovery steps so that the processes succeeding one another become less pronounced and tend to overlap. (*B*) It is more the secondary effects of the recovery stages III and IV which can be observed by x-ray diffraction methods, namely the vacancy migrations. Their occurrence makes a rearrangement of the dislocation network within the crystal lattice possible and thus diminishes the microstrains. Results are reported in Table I. Those obtained from the deposits produced at low and medium thiourea concentrations compare reasonably well with the values given by the literature, those deposits produced at high thiourea concentrations do not. But rather than to look for a good agreement between literature and experimental results this comparison reveals the complexity of the structure and the recovery behavior of these electrodeposits.

Crystallite size and recrystallization.—The crystallite size varies as a function of the additive's concentration in the plating solution. The inverse of the crystallite size, $1/\langle D\rangle_{\text{eff }111}$, was plotted as a function of the initial thiourea concentration in the bath (Fig. 3). As a maximum had previously been found for the strains at 20-25 mg/l thiourea, a minimum of the grain size was observed in the same concentration range.

The average diameter $\overline{D}$ as obtained from an electron microscopical study of these electrodeposits was determined by the method of Braun (31) which relates the average volume $\overline{v}$ of the grains to its average linear dimension $\overline{\mathcal{L}}$ measured on the micrographs,

i.e., $\overline{v} = 2.57\ (\overline{\mathcal{L}})^3$. The values in Table II indicate an excellent concordance between $<D>_{eff\ 111}$ and $\overline{D}$.

The results from the electron microscopical study on the various electrodeposits are summarized in Table III.

A minimum grain size is observed at an original thiourea content of 20-25 mg/l solution.

The growth of the coherently diffracting domains with the annealing time and temperature is different for each specimen (Fig. 2). By observing the curves relating the crystallite growth to the annealing temperature at constant annealing time, a slow increase of the grain size is noticed, previous to the fast raise which gives evidence of the actual recrystallization. This slow grain growth is perhaps induced by the diffusion of vacancies from sites of high local strain toward grain boundaries and dislocations. The absorption of vacancies by dislocations leads to a complete rearrangement of the dislocation network within the lattice, thus causing an increase in crystallite size $<D>_{eff\ 111}$ as measured by Fourier techniques. These mechanisms have been described and discussed by van Bueren and Hornstra (32).

Twin faults.—No shifts of the 111 and 200 reflections were found on the x-ray diffraction patterns of the electrodeposits. This indicates a low stability or a very small number of stacking faults in the plates. The same findings were obtained from the electron microscopical study of these deposits. On the other hand the microtwin faults are numerous and easily detectable. Different interpretations exist concerning their formation in a metal electrodeposited in the presence of an additive. Most theories explain them as caused by a blocking of one of the crystal's growth directions by the additive (9). Hinton, Schwartz, and Cohen (16) explain the formation of the twin faults on the basis of a particular stacking mechanism of the (111) layers. The arrival of an additive molecule or a molecule of a reaction product thereof can have either of two effects on the structure of the crystallite: (*A*) An adsorbed foreign molecule, if similar in size to the metal atom to be deposited, may let pass an advancing growth step and permit the crystal layers to pile up continuously in a correct stacking sequence. The region around the molecule may be strained, causing dislocations, but no faults will be produced. (*B*) If the adsorbed foreign molecule is considerably larger than the metal atoms of the deposit, an advancing growth step is forced by this obstacle to change its growth direction, and the growth layers continue to pile up in a stacking sequence in reverse to the former until the molecule is covered. Thus a fault is created. In most cases the plating solution does not contain the additive dissolved in a simple molecular form but rather in

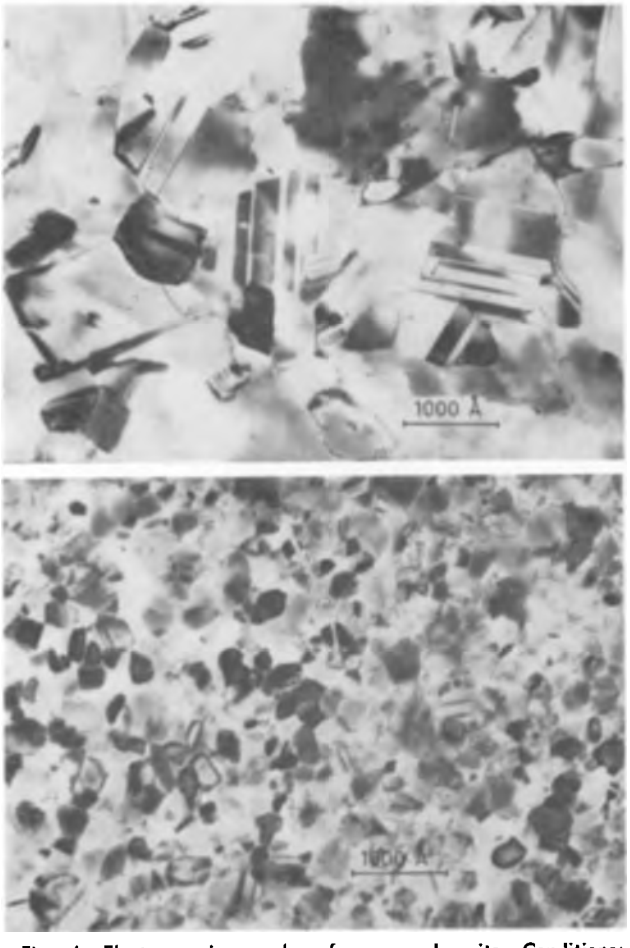

Fig. 4. Electron micrographs of copper deposits. Conditions: 1*N* H_2SO_4, 1*N* $CuSO_4$, 28 ma/cm^2, room temperature. (a) (top) solution containing 10 mg/l thiourea; (b) (bottom) solution containing 20 mg/l thiourea.

Table III. Evaluation of the electron micrographs

Additive conc, mg/l	Average grain size $\overline{D}$, Å	Appearance
5	1500	Large grains, broken up in subgrains by small angle boundaries and microtwins. Occlusions preferentially arranged in chains.
10	620	Grains of rounded shapes; occlusions more numerous and more randomly distributed than in the former deposit (Fig. 4a).
15	990	Structure different from the structure of the other deposits. Elongated grains in preferential directions. Chains of occlusions arranged in the direction of the longer axis of the crystallites. Microtwins not uniformly distributed over the plate.
20	250	Very small grains of rounded shapes and homogeneous in size (Fig. 4b).
25	470	Similar to the preceding deposit but with larger grains.
40	615	Similar to the plating deposited in the presence of 10 mg/l thiourea, but less uniform.
100	350	Needle-like structure. Small grain size. Boundaries faded and difficult to estimate.

complex compounds with the metal ions, the formation parameters and exact stoichiometric composition of which are not yet well understood. It is very possible that these complex compounds present themselves, according to the experimental conditions, in a form more or less favorable for the formation of microtwin faults. However, since these phenomena occur either as chemical or electrochemical reactions in the bulk of the plating solution or in the diffusion and double layer immediately adjacent to the electrode surface during electrodeposition, they do not come within the scope of this paper.

The probability of finding a twin or growth fault, *i.e.*, of finding two or more layers in an incorrect sequence, was calculated by the method of Cohen and Wagner. The influence of the instrumental line broadening and the $K\alpha_1\alpha_2$ doublet was minimized by an appropriate choice of the slits in the pathway of the incident and diffracted beams, respectively. Furthermore, a recent study by Witt and Schoening (33) makes it evident that the $K\alpha_1\alpha_2$ doublet introduces a negligible error in the determination of β, if the asymmetry of the peak is measured over the entire line profile, as is actually done in this study by means of an IBM 1620 electronic computer.

Table II reports the calculated β values of the seven plates as deposited. β varies between 0.005 and 0.021. With these probability values it is possible to calculate $<D>_{F\ 111}$, *i.e.*, the crystallite size due only to the presence of faults. The absolute value for the twin fault density as such is perhaps of little significance. What seems to be more important is the comparison between $<D>_{\text{eff }111}$ and $<D>_{F\ 111}$. There are in fact samples with high β-values for which $<D>_{F\ 111}$ is much larger than $<D>_{\text{eff }111}$ (20 mg/l and 25 mg/l thiourea). This indicates that the relative twin fault density in the deposit is low. Yet, for other samples (5, 10, and 40 mg/l thiourea) this difference between $<D>_{F\ 111}$ and $<D>_{\text{eff }111}$ is small. Hence the grains of the deposit are divided by a great number of twin faults, which is also confirmed by the electron microscopical study. Thus, the investigated samples may be classified in two groups: (*a*) deposits with predominant influence of the twin faults, $<D>_F/<D>_{\text{eff}} < 2$ (5, 10, and 40 mg/l thiourea), and (*b*) deposits for which the smallness of the coherently diffracting domains is due to other causes, $<D>_F/<D>_{\text{eff}} > 2$ (20 and 25 mg/l thiourea).

Dislocations.—Considering the fact that local strains caused by occlusions of impurities fall off with $1/r^3$, and the strains due to dislocations with only $1/r$, it can be concluded that $<\epsilon_{50}^2>^{1/2}$ is mainly due to dislocations. Furthermore, knowing the values for the rms strains and postulating a maximal separation and a minimal interaction of the dislocations as a working hypothesis, it is possible to calculate the dislocation density in the sample with the formula of Williamson and Smallman (34)

$$\rho_{WS} = \frac{16 <\epsilon_{50}^2>}{b^2}$$

where b is the Burgers vector of the dislocation ($a_o/2$ [110]). Admitting moreover the hypothesis that the recovery stages are due only to mechanisms anticipated by the literature, and also assuming that the entire energy remaining in the metal lattice in recovery stage V is the sum of the energies of individual dislocations only, and finally knowing the energy of a simple dislocation, it is possible to calculate the dislocation density. According to Cottrell (35) the energy of a single dislocation is 1.5×10^{-4} erg/cm. The dislocation densities were calculated according to both methods, the results of which are reported and compared in Table II. A good agreement between the results of the two methods was observed, the value ρ_c generally being slightly higher than ρ_{WS}. The accuracy of this method depends on the estimation of the onset of recovery stage V, which is rather hazardous at certain instances. The differences between the two methods are small indeed. In the former, it is postulated that only in the recovery stage V the energy due to dislocations alone is released. Thus it is possible to separate the strains caused by dislocations from those due to other causes. In the latter, the strains due to dislocations are separated from those of other origins, considering that they fall off with $1/r$. In both methods the hypothesis of the maximal separation and the minimal interaction between the dislocations is made. No consideration is given, however, to annexed effects as, *e.g.*, the pinning of dislocations by occlusions.

Hardness.—Microhardness measurements were made on the deposits using a Zeiss D 30 Hardness Tester, type Hanemann. All hardness values reported here, expressed in Vickers hardness number (VHN), were determined using a load of 20g. Test samples were chosen from the same area of the cathode as those used for the x-ray investigation.

Three factors seem to influence the hardness: (i) the fineness of the grain, (ii) the dislocation density, and (iii) the pinning of the dislocations by impurities. The fineness of the grain and a high dislocation density restrict the mobility of the dislocations. For this reason, the Vickers hardness number (VHN) was reported as a function of the annealing temperature T_a, together with the rms strains $<\epsilon_{50}^2>^{1/2}_{111}$ and the crystallite size as determined by the Fourier analysis of the diffraction peaks, $<D>_{\text{eff }111}$. All are variables of the same function (Fig. 2). An excellent agreement is noticed in the behavior of these quantities with the temperature, which proves that the hardness depends on $<D>_{\text{eff }111}$ and $<\epsilon_{50}^2>^{1/2}_{111}$. Furthermore it may be noted (Fig. 3) that the deposits presenting the smallest grain size and the highest strains are also those with the highest hardness number. Thus again one observes a concurrent behavior of the hardness, the inverse of the crystallite size, and the rms strains of the deposits.

Conclusions

Figure 3 could serve as a summary of the structural study carried out on the copper-thiourea system. Based on a least square calculation straight lines have been drawn between the points of measurement of the inverse of the grain size, the microstrains, and the Vickers hardness. These lines show the trend of these parameters to increase with the logarithm of the concentration of thiourea, indicating a direct action of the quantity of the additive on the structure and mechanical properties of the deposit.

The same points[4] have been connected also by curves, all of which indicate a maximum in the region of 20 mg/l thiourea. This may be interpreted as follows:

1. The region between 5 and 10 mg/l thiourea. This could be designated as the "region of normal interaction," meaning that the additive produces the expected effects on the electrodeposits, such as small grain size, strong preferred orientation,[5] and numerous twin faults. These are all effects which can be explained by relatively simple mechanisms, for example the blocking of certain growth layers by the additive.

2. The region between 15 and 30 mg/l thiourea. It could be called the "region of strong interaction." The high number of additive molecules can block all growth directions of the crystallite, thus causing large strains and producing structures of small grain sizes. For the same reason the relative twin fault density decreases and the preferred orientation of the crystallites disappears. The deposit is very homogeneous, the mechanical properties are optimal. It is the region of the additive's highest power.

3. The region between 30 and 100 mg/l thiourea. This region could be designated as the "region of complex interaction" because the effects are diverse. They seem to have a recurrent tendency, the grain size and the

[4] Except those for 15 mg/l thiourea, for which the authors feel that the measurements are not reliable enough to influence the trend of the curve.

[5] This preferred orientation was measured using a Schultz goniometer (36).

relative twin fault density increase, the preferred orientation of the crystallites reappears and the hardness number decreases. The molecules of the additive are too numerous; hence they either disturb one another in their action of blocking the growth centers, or they form less inhibitive complex compounds with the copper ions. These deposits contain within themselves areas which strongly resemble deposits of the first type of this classification (large number of twin faults, preferred crystallite orientation) and areas which resemble deposits of the second type (small grains of homogeneous size and shape).

A more detailed study of the copper-thiourea system is imperative. It should explain which one of the two interpretations: linear increase of the parameters with the logarithm of the thiourea concentration or maximum at a certain well-defined value of the additive's concentration is correct. However, our mastery of certain electrochemical problems is incomplete, and our knowledge of the reciprocal actions between electrolyte and additive in the bulk of the solution and at the electrode-electrolyte interface is fragmentary. A better understanding of these reactions is necessary before the present study can be refined and extended.

Acknowledgments

The authors are grateful to Professors P. Dinichert and J. Rossel for helpful discussions. They thank Ph. Javet for the preparation of the deposits, J. Béguin for taking the electronmicrographs, Dr. A. Braun for the hardness measurements, and E. Saurer for assistance in the numerical computations.

Manuscript received April 30, 1964; revised manuscript received Oct. 8, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

APPENDIX

The limits of reproductibility of the Fourier analytical treatment of the profiles of x-ray diffraction lines have been determined on a coper electrodeposit by performing the following operations five succeeding times: (*a*) mounting the specimen in the specimen holder, performing the diffraction; (*b*) measuring the ordinates P'_ν according to equal intervals with a pantograph; (*c*) calculating the Fourier transforms and applying the correction of Stokes, on an electronic computer IBM 1620; (*d*) separating graphically the grain size effect from the effect of the microstrains; (*e*) calculating the quantities $<D>_{\text{eff }111}$ (size of the coherently diffracting domains), $<\epsilon_L^2>^{1/2}{}_{111}$ (rms strains) and $<D>_{F\,111}$ (crystallite size due only to the presence of faults).

The maximum deviation and the standard deviation have been calculated for these different quantities and are reported in Table IV.

From the maximum deviation on $<\epsilon_{20}^2>^{1/2}{}_{111}$ of $\pm 3\%$ the maximum deviation on V was calculated to be $\pm 6\%$.

In one case it was shown that the results obtained from two different deposits, produced under identical electrochemical conditions, strayed less than 10%. However, further investigations of this sort are needed to assert this value.

Preparation and Properties of Electrodeposited Cylindrical Magnetic Films

M. W. Sagal

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

A process is described for the electrodeposition of cylindrical permalloy films with near zero magnetostriction. The design of a plating cell intended to achieve good uniformity of electrolyte agitation over the plating region is given. The steps used in the preparation of the wire substrate are discussed. Results showing the dependence of average alloy composition on electrolyte flow rate and pH are given, along with typical magnetic characteristics of the plated wire.

Most of the work described in the literature on the preparation and characteristics of magnetic thin films for memory applications has been concerned with films evaporated or electrodeposited on flat insulating or metallic substrates (1, 2). An alternative configuration, an anisotropic film deposited on the surface of a small diameter wire, offers a number of advantages from the device point of view (3). A process for the fabrication of this material by a continuous electrodeposition process using high agitation conditions for achieving high current densities and compositional uniformity has been described previously (4, 5). In this earlier work the importance of proper substrate preparation, including the use of a copper preplate, was pointed out. This paper describes an advanced design of a continuous plating system in some detail, including a sequence of substrate cleaning and preplate steps which has been found to give a satisfactory surface for the subsequent plating of a nickel-iron film with desirable magnetic properties. Further, the degree of composition control that can be routinely achieved by proper regulation of the plating parameters is discussed, along with typical data showing the dependence of average film composition on electrolyte flow rate and pH. Finally, values of magnetic parameters closely related to the ultimate performance of the material as a memory device are given.

The process is shown schematically in Fig. 1. The substrate is a 0.005 in. diameter hardened Be-Cu wire which is carefully drawn in order to minimize scratches caused by dirt particles collecting on the dies. It is pulled through the apparatus at 6 in./min. The wire is protected from the laboratory atmosphere by a nitrogen blanket between each process step. An electrolytic alkaline cleaner removes organic soil and loose dirt, and an acid dip removes surface oxide. The wire surface at this state, although superior to that of ordinary commercially drawn wire, still shows (Fig. 2a) a large number of pits and small scratches under high magnification. In general, 1μ magnetic films plated onto this surface with no further preparation do not have satisfactory properties. The wire is then plated with 1μ of copper from a commercial plating bath.[1] Figure 2b shows the appearance of the wire surface after copper plating. This copper plate may serve to

[1] Unichrome copper plating process of M and T Chemicals, Inc.

smooth the surface although it clearly does not eliminate the surface imperfections completely. The omission of the copper plating step in the process has the effect of raising the values of dispersion and minimum bit writing current (see discussion of magnetic properties for definitions) by a factor of from 2 to 4, depending on the local surface roughness of the substrate. The wire is rinsed in ultrasonically agitated deionized water between each of these preparatory steps.

Electrical contact is made to the wire by means of a gold plated brass wheel following the last rinse tank to permit the introduction of direct current into the wire while the permalloy film is being deposited. The circumferential magnetic field from this current results in a circumferential easy axis in the film where the application requires it. Alternatively, if an easy axis along the wire length is desired, a field is applied by means of Helmholtz coils mounted outside the permalloy plating chamber.

In the high current density-high agitation permalloy plating process used here, the composition of the plated

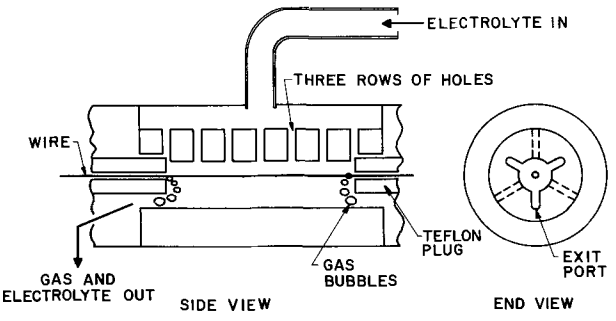

Fig. 3. Plating cell

alloy is a sensitive function of the electrolyte agitation at the wire surface. The permalloy plating chamber is designed to give uniformly high agitation along the entire length of wire being plated in order to reduce the possibility of composition gradients in the film. A centrifugal pump forces the electrolyte through the cell. Provision is made for regulating the electrolyte temperature, pH, and flow rate. The heart of the plating chamber is a Lucite tube with three staggered rows of holes drilled through the wall (shown schematically in Fig. 3). The electrolyte is forced through these holes and impinges on the surface of the moving wire at high velocity. It is removed through low impedance exit ports at both ends of the chamber. The wire passes in and out of this Lucite tube through Teflon plugs which extend into the region of high electrolyte agitation. Nitrogen gas is bubbled through the Teflon plugs to establish a plating region whose length is determined by the maximum penetration of gas bubbles into the Lucite tube. The bubbles penetrate past the Teflon tips by about one bubble diameter, which is approximately equal to the hole diameter of the Teflon plugs. The gas is swept out through the low impedance exit ports at each end by the high velocity electrolyte. This bubble seals serves two purposes. It prevents leakage of the electrolyte from the plating chamber into the rest of the apparatus, and it insures that the electrolyte agitation at the entrance and exit points of the wire is very nearly the same as the agitation in the central portion of the plating cell.

The nitrogen gas swept out from the plating region leaves the system through a tube in the outer part of the plating chamber. Since the electrolyte is not sealed off from air, a gradual drop of Fe^{2+} concentration is observed. This oxidation problem has not been serious since a change in electrolyte composition can be compensated by an adjustment in another process variable.

The importance of a near-zero magnetostriction composition in uniaxial magnetic films has been generally recognized (1). The stresses in evaporated or electrodeposited films cause severe degradation in uniaxial properties if the film is very far from the zero magnetostriction composition. For the plated wire, the composition requirements are even more severe because of the bending and twisting of the small diameter wire substrate which occurs during handling. It has been found that the average composition of the film should be held to within about $\pm$ 0.2% of the zero magnetostriction composition to avoid difficulties from strain-induced skew during memory assembly. In contrast, a detectable increase in dispersion of the film in an unstressed wire (resulting from internal stresses in the film) occurs when the film composition deviates from the zero magnetostriction composition by more than about $\pm$ 1%.

The required control of composition can be obtained by proper control of plating parameters. The composition of the plated alloy depends on bulk bath composition, temperature, pH, agitation, and plating current density. Electrolyte agitation affects the composition of the plated film through its effects on depletion layer

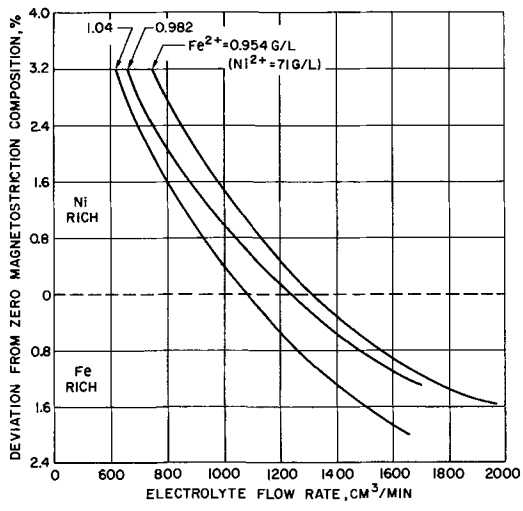

Fig. 4. Dependence of film composition on electrolyte flow rate (sulfamate bath). The zero on the ordinate corresponds to about 20% Fe. A composition "0.8% Fe rich" is therefore 20.8% Fe.

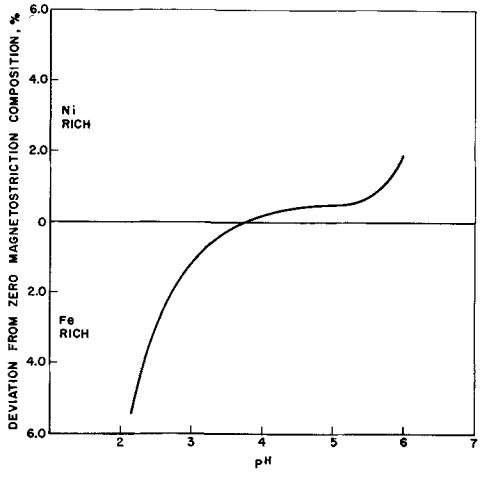

Fig. 5. Dependence of film composition on electrolyte pH (sulfate-chloride bath).

thickness and the composition of the electrolyte next to the substrate (which is in general different from the bulk composition). For a fixed plating cell geometry, agitation is dependent on the electrolyte flow rate. Figure 4 shows how the composition of the film, determined by x-ray fluorescence, depends on electrolyte flow rate with other parameters held constant. The probable effect of a change in plating cell geometry will be to move the curves of Fig. 4 along the flow rate axis. The increase in Fe content of the film with increasing flow rate (*i.e.*, increasing agitation) is in accord with the expected effect of decreased depletion layer thickness on the deposition rate of the more readily deposited metal (6) (Fe in this case).

Figure 5 illustrates the dependence of film composition on bath pH with other parameters held constant. The increase in Fe content below pH = 4 may be associated with a slight drop in cathode efficiency at low pH. This would increase the proportion of the more readily deposited metal in the alloy in a way similar to a decrease in current density (6).

In routine operation, the composition is measured indirectly by a magnetostriction measurement. One end of a plated wire is clamped and the other end twisted through a known angle. The resultant helical stress in the film introduces an easy axis skew, which is measured by the method of Belson (7). The sense and magnitude of the induced skew is a measure of

Table I. Magnetic characteristics

Belson α_{90}	$= 1.2°$	
Belson skew	$= 0.3°$	
H_K (loop tracer)	$= 3$ oe	

the deviation of the average film composition from the zero magnetostriction alloy.[2]

The plating conditions are then adjusted until the magnetostriction is as close to zero as possible (corresponding to a composition of about 20% Fe, balance Ni). For example, the electrolyte flow rate or pH can be changed to modify the alloy composition, as indicated in Figs. 4 and 5. The average film composition can be controlled to ± 0.1%.

X-ray fluorescence composition measurements are based on an average over 3 feet of plated wire. The magnetostriction test provides a measurement of average composition over 1 in. lengths of wire. Measurements of magnetostriction over a series of adjacent 1 in. segments give the same result which shows that any composition variations along the wire length must be on a scale $<<$ 1 in. Further, the absence of bad bits resulting from magnetostriction effects when the wire is incorporated into experimental memory planes with approximately 0.05 in. bit centers (3) indicates that significant compositional variations along the wire are absent. Although the type of plating cell described here is designed to minimize agitation inhomogeneities along the plating length, experiments have not yet been carried out to measure composition gradients through the film thickness. In principle, one source of composition gradient often found in plated films because of the build-up of a depletion layer (8) should be absent here, since wire entering the plating cell encounters a steady state depletion layer.

Both sulfate-chloride (2) and sulfamate (4) baths have been used successfully.

Magnetic Properties

The most significant magnetic characteristics of the plated wire, as determined by an on-line pulse test, are given in Table I. The on-line test permits continuous monitoring of memory characteristics as the wire is produced. Only properties of films with the easy axis around the wire circumference are described here, since this type of film has been most thoroughly studied. Some of the characteristics of these films have been previously given (3).

A ½ in. long coil which supplies a hard direction field is mounted at the end of the plating apparatus. This coil defines the length of wire under test, and is long enough to effectively eliminate the geometry-dependent demagnetizing field in the hard direction. The pulse program is shown in Fig. 6. The parameters of primary interest are:

1. $I_{b_{min}}$, the bit writing current (*i.e.*, the current producing the easy direction field) needed to switch 90% of the available flux at a particular value of hard direction writing field $H_\perp$; and
2. $I_{b_{max}}$, the bit disturb current (with $H_\perp = 0$) which reduces the 90% written-in bit to 81% of full flux on the application of 100 disturbs. (For a 0.005 in. diameter wire, 1 ma ≡ 0.032 oe.)

[2] This technique is due to T. R. Long (to be published).

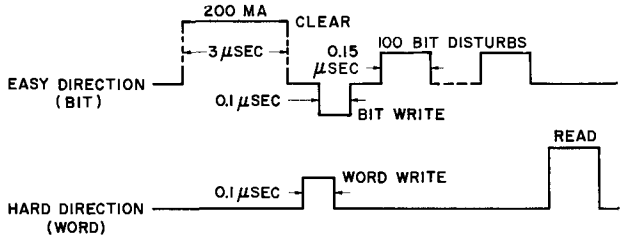

Fig. 6. Pulse program for on-line test of wire with circumferential easy axis.

Values of $I_{b_{min}}$ and $I_{b_{max}}$ for a typical film are given in Table I. Since variations of about ±20% in bit current amplitude and pulse width should be anticipated in actual memory operation, a good criterion for acceptable film quality is $I_{b_{max}} \geqq 1.5\ I_{b_{min}}$. In addition, in order to be conservative, the measurements are made using a disturb pulse width 1.5 times the bit write pulse width since the disturb effect increases with pulse width (3).

The increase of $I_{b_{max}}$ with an increase in $I_{b_{min}}$ is a general phenomenon in these films. This result implies that the specification of an undisturbed read signal equal to 90% of available flux is not a complete description of the state of the film before the application of disturb pulses. The particular combination of $H_{\perp_{WRITE}}$ and bit writing current which is chosen to switch 90% of available flux affects the resistance to domain wall motion when easy axis disturb pulses are subsequently applied.

The effects of a larger number of disturb pulses and the simultaneous application of easy and hard direction disturb pulses are measured off-line, and have been discussed elsewhere (3).

Table I also contains values of α_{90} (dispersion) and skew as measured by the Belson technique (7), as well as the anisotropy field H_K measured by a loop tracer method. These measurements are of some use in qualitatively evaluating film samples, but are a poor means of quantitatively predicting performance under pulse switching conditions.

Acknowledgments

It is a pleasure to acknowledge the contributions of J. T. Chang, I. Danylchuk, U. F. Gianola, C. E. Johnson, T. R. Long, and A. J. Perneski. The author would also like to thank K. M. Olsen and R. F. Jack for samples of Be-Cu wire and Miss S. M. Vincent and J. E. Kessler for x-ray fluorescence analysis of the films.

Manuscript received June 30, 1964; revised manuscript received October 1, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

Fluorescent Emission Spectra in II-VI Compounds

R. E. Halsted, M. Aven, and H. D. Coghill

Research Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

Fluorescent emission spectra in "pure" and variously doped single crystals of CdTe, ZnTe, and to a lesser extent CdSe and ZnSe, have been recorded at temperatures of 25°K or below. These data have been tabulated and graphically presented along with prior low-temperature data on these materials, CdS, and ZnS. The pattern of results provides evidence for the existence of analogous defects throughout the II-VI family of compounds.

The fluorescent emission properties of the large band-gap II-VI compounds, particularly ZnS and CdS, have been investigated extensively in the past. Preparative procedures for maximizing specific emission bands in these materials in powder form have been established. Much attention has been given to models which at least provided a conceptual basis for organizing the results (1). Currently considerable attention is being given to the development of improved techniques for the preparation and purification of single crystals of II-VI compounds (2-4). Much progress has been made. One can therefore anticipate increasing application in the near future of diverse optical and electrical measurements to the determination of the position and nature of defect levels in these materials.

This work should be significantly expedited by making maximum use of evidence that analogous defect levels may exist in the various members of a given class of compounds. Similarities in preparative procedures, experimental behavior, and interpretation of results can thus be exploited. Prior studies of the ZnCdS phosphor system have provided a nice illustration of the utility of fluorescent emission data for establishing such analogs. With improved preparative control, it was established that the emission bands attributable to a given impurity exhibit a systematic shift in wavelength with host lattice variation from ZnS to CdS (5-7). Comparatively limited attention has been given to an extension of this evidence for analogous emission bands from the sulfides into the selenides and tellurides of zinc and cadmium (8-10).

In the course of investigations of II-VI compounds at this Laboratory, we have recorded emission spectra in "pure" and doped single crystals of these materials, generally at ~25°K. Data on the compounds CdTe and ZnTe provide a substantial addition to prior work. Emission due both to near-band-edge radiative recombination processes and deep impurity levels has been observed. Because of the survey nature of this work, these results will eventually be extended and perhaps some cases of inaccurate identification established.

We have noted, however, that the results do indeed provide a rather convincing extension of the evidence for analogous emission processes found in the ZnCdS system. A compilation of these data with prior work has been found to have current value in suggesting probable analogs between the transitions in different compounds. For example, it has provided a basis for appraising the relevance of electrical transport and optical measurements in p-type ZnTe and CdTe to a general understanding of acceptor defects in this class of materials. For this reason we have prepared the following tabulation of our data and selected prior published data on the positions of fluorescent emission bands for impurities from columns I, III, and VII of the periodic table in the sulfides, selenides, and tellurides of zinc and cadmium. Column V and other impurities were not included because of the limited amount of data now available for more than one II-VI compound. The information is also presented graphically. In addition to cataloging the new results, this form of presentation dramatizes the evidence suggested by the order in the data for probable analogs in the fluorescent emission processes in these materials. Some questions arising from these correlations are noted. However, no attempt is made to provide a critical examination of the evidence for the nature of the various recombination processes involved.

Experimental Procedure

Our method for taking fluorescent emission data has been conventional in nature. For data at liquid hydrogen temperature, samples were mounted with an adhesive varnish (G.E. 7031) on a coolable copper substrate in an evacuated housing. They were masked, except for an observation slit, with indium foil. A thermocouple, cemented in pressure contact with the edge of the crystal but shielded from exposure to the excitation radiation by the foil, was generally used to monitor the temperature of the sample. Samples were immersed in liquid helium for 4°K data. A 1000-w filtered high-pressure mercury arc (G.E. AH-6) was used as an excitation source. Both LiF prism and grating spectrometers were employed as dictated by resolution and wavelength range requirements. Spectrometer output was measured with either cooled PbS, infrared sensitive photomultiplier (RCA 7102), or 1P21 photomultiplier detectors. Spectrometer and detector combinations were calibrated in wavelength and response with standard sources.

Our results have been obtained primarily on single crystal material prepared at this Laboratory. Single crystals of all materials except CdTe have been grown from the vapor (11). CdTe crystals were grown from the melt (3). Samples of commercially available vapor-grown CdS and CdSe were also employed (12, 13). Data on material doped both before crystal growth and by diffusion after crystal growth have been recorded. Cleaved surfaces were preferably employed for observations of fluorescence. In order to obtain comparable results on chemically etched surfaces, some experimentation with etching procedures for each material was generally required.

Compilation Procedure

Tables I through VI present a compilation of our emission data and prior published data for the compounds ZnS, CdS, ZnSe, CdSe, ZnTe, and CdTe, respectively. For convenient reference we have also cited the low temperature band gap, E_g; the energy for exciton formation, E_{ex}; and the longitudinal optical phonon energy, $E_p(\mathrm{LO})$. E_g is established by adding to E_{ex} the exciton binding energy determined by observation of both ground and first excited states. Our somewhat arbitrary selection of prior data was prompted by considerations such as the following.

Data taken at 80°K or below have been cited wherever possible for several reasons. The position of low-temperature emission peaks can be related to well-defined band-gap energies for estimates of the binding energy of the defect levels involved. The emis-

sion peaks are also narrower and their maxima better defined. In some cases LO phonon structure can be resolved providing a measure of the transition energy unobscured by LO phonon emission. Between 0° and 80°K the band gap decreases in energy only ~0.01 ev. References were also favored which were concerned with tracing a given emission band through a variation in host lattice composition. Some recent references are cited to supply an entry into the literature concerned with providing a detailed description of specific recombination mechanisms. In some cases our data have been tabulated and prior references also listed. In most such cases we are assuming responsibility for some difference in detail, *e.g.*, temperature, but the results are regarded as being in agreement.

The peak positions given for emission bands with unresolved LO phonon structure are the energy equivalent of the wavelength of maximum emission on an energy per unit wavelength ($E/\Delta\lambda$) *vs.* wavelength plot. Most published data on these compounds are so plotted. The use of the physically more significant photons per unit photon energy ($P/\Delta E_p$) *vs.* photon energy plot would shift the position of broad peaks to somewhat lower energies since $(P/\Delta E_p) \propto \lambda^3(E/\Delta\lambda)$. Widths at half-height of these broad emission peaks are tabulated in parentheses after the peak position to provide an approximate description of the emission band. Evidence for small variations in the position of these spectra with crystal structure and identity of compensating defects have been omitted even though well established (5). However, some cases of extreme variation are noted.

Fluorescent emission of near-band-gap energy in II-VI compounds at low temperatures occurs as resolved sets of equally spaced emission lines formed by the simultaneous emission of photons and 0,1,2,--LO phonons (14). The relative intensities of lines within a set have been described by a relation of the form $I_n = I_o N^n/n'$ (15). I_n is the relative intensity of the $(n+1)$th line involving the emission of a photon plus n LO phonons. N is the mean number of emitted phonons. Although the accuracy of this description appears to be poor when applied to experimental results with sufficiently small N, we have used it as a basis for characterizing spectra with resolved LO phonon structure. We have tabulated the position of

the highest energy peak of the series and identified such energies with an asterisk. $N(\equiv I_1/I_0)$ is given in square brackets for a number of cases where the peaks were reasonably well resolved. We have attempted to select those band-edge spectra which appear to be dominant *in pure materials*. Some variability has been observed in the position of the exciton absorption line, and hence in the band gap in nominally pure materials (30). We have therefore tabulated band-edge emission data from one source for each compound, although citing other references. This procedure should permit a more significant determination of the energy differences between the various transitions listed.

Emission bands are identified with the addition of specific dopants. Generally speaking, there remains uncertainty in II-VI compounds as to the specific nature of the defect at which an emission process originates. Compensating native defects, isolated or associated, may be involved as well as the dopant. The specified impurity addition is therefore indicative of preparative procedure, but cannot be regarded as identifying the origin of the emission in any precise way. In presenting the data some abbreviations were introduced. The symbols for specific elements are generally employed with the exceptions of U and D denoting "undoped" (but not necessarily pure) and "donor" impurity, respectively. The use of D indicates that essentially the same result has been obtained with several impurities from columns III or VII of the periodic table. If D is linked to another element by other than a comma, *e.g.*, Ag > D, Ag ≈ D, Ag — D, the presence of both impurities is believed to be required. In some compounds the results have been shown to be dependent on the relative proportion of impurities; hence, *e.g.*, Ag > D.

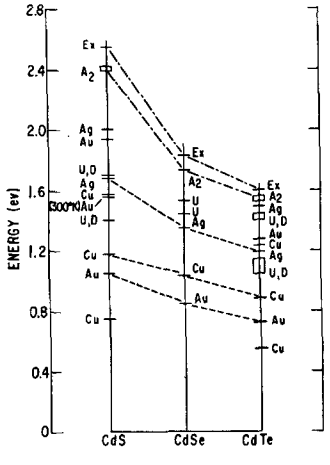

Fig. 5. Fluorescent emission energies in CdSSeTe system

This information is presented graphically in Fig. 1 to 5. The pattern of analogous emission processes suggested by the data is indicated by the connecting lines. Solid lines are employed where correlations have been previously established by a study of the relevant ternary compounds through a range of compositions. A reference is cited for each case of this type. Broken lines are used in two cases where the validity of the correlation appears assured even though their position

in compounds of intermediate composition has not been ascertained. Emission attributed to bound or free excitons is termed "exciton" emission and identified by its proximity in energy with exciton absorption or reflectance data. The energy scale of Fig. 1 to 5 does not permit an indication of the detail observable with high resolution in this region. Analogs of the "green edge emission" or "A_2" emission of CdS are identified by the unique characteristics of their spectra (16). Dashed lines are employed where the correlations are suggested by the pattern of results but have not otherwise been confirmed. If the correlations prove generally valid, one might expect the connecting lines to approximate the positions of emission bands in intermediate compounds. The curvature of these lines can, however, be substantial. It may perhaps be extreme in the case of ZnSeTe compounds where the band gap has been reported to go through a minimum at a composition $ZnSe_{0.35}Te_{0.65}$ (17).

Discussion

The data presented in Fig. 1 through 5 demonstrate that there exists a general regularity in the way the positions of the levels belonging to the different luminescence centers vary from compound to compound. Examination of the data for the more detailed features of such correlative relationships, however, generates many questions which at present have no simple or unambiguous answers. Some examples are illustrative.

Emission attributed to the recombination of excitons bound to various defects gives rise to quite complex spectra at liquid helium temperatures. Some prominent examples are included in Tables I and VI, although not resolved in Fig. 1 to 5. In the case of CdS, Zeeman effect studies of these emission and associated absorption spectra have identified three types of transitions present as: (*a*) exciton bound to a neutral donor defect, (*b*) exciton bound to an ionized donor, and (*c*) exciton bound to a neutral acceptor (27, 42). Free exciton recombination is also observed and identified by its coincidence in energy with exciton absorption. It becomes relatively more prominent at higher temperatures where the binding energy of an exciton to the above defects is small compared to kT. Analogous recombination processes occur in other compounds (43-45). Tentative identification of bound exciton processes in II-VI compounds other than CdS may be feasible by assuming that the energy by which the exciton is bound to a defect, E_{ex}-E_{exd}, is approximately a constant fraction, F, of the defect binding energy, E_d, for a given type of shallow defect. Here E_{exd} is the formation or recombination energy for an exciton bound to the defect. If the nature of a transition becomes known from magneto-optical studies, a knowledge of F should conversely permit an estimate of the position of the defect level involved. In silicon $F \approx 0.1$ for excitons bound to either donors or acceptors with defect binding energies up to 0.15 ev (43). The applicability of this relationship to the II-VI class of compounds requires the approximate validity of the effective mass approximation and a relatively constant ratio of hole-to-electron masses. For an exciton bound to a neutral donor in CdS a value for F of $0.0066/0.033 = 0.20$ was found (27). Comparable ratios for the dominant emission in the exciton region for n-type CdTe and ZnSe are indicated. The magnitude of F for the exciton bound to a neutral acceptor is uncertain in CdS since the depth of the active acceptor level is not known. Since the effective mass of electrons is smaller than the effective mass of holes in II-VI compounds, F may be smaller for acceptor defects than for donor defects (46).

Analogs of the green edge emission in CdS have been identified by their unique doublet structure. Currently two types of defect levels observed in electrical transport measurements could provide recombination transitions of appropriate energy. A correlation has recently been made between these spectra and the presence of double-acceptor levels near the conduction band in II-VI compounds (47). An explanation of the emission energy and structure, the temperature dependent characteristics, and the variability of the spectra with crystal doping appears possible on this basis (16). However, electrical measurements have also shown the presence of acceptor levels approximately 0.05 ev from the valence band in CdTe and ZnTe (48-50). Analogs of these levels in the selenides and sulfides would permit donor-acceptor-pair emission (51) in the energy ranges of interest. It remains to be determined whether one or both of these mechanisms are operative.

Figures 1 to 5 suggest that the pattern of "high" and "low" energy emission bands identified in the literatube for Cu, Ag, Au, and "self-activated" ZnCdS phosphors exists for the entire II-VI family of compounds. Thus the extensive effort which has been devoted to the identification of such emission processes as those occurring at 2.85 and 2.38 ev for ZnS:Cu, 2.7 ev for self-activated ZnS and 2.00 ev for CdS:Ag has immediate relevance in other compounds if the correlations are valid (52). Discrepancies remain to be resolved. For example, the "high energy Ag" band occurring at 2.00 ev in CdS:Ag has been attributed to a transition between a level near the conduction band and the valence band (53). The suggested analog in ZnTe, however, appears to involve a transition between the conduction band and a relatively shallow acceptor level which can be seen electrically (50).

In ZnS and CdS a structured emission band can be observed at ~0.8 ev. The structure is attributed to internal Cu transitions that are relatively uninfluenced by host lattice composition. Other transitions occur in the red and near infrared in ZnS which appear to depend strongly on the identity of both donor and acceptor impurity. ZnSe and ZnTe samples generally are found to exhibit infrared emission at photon energies below those discussed above. Further investigation may establish analogs among these.

Acknowledgments

The authors gratefully acknowledge contributions by their colleagues at the Research Laboratory, both by way of informative discussions and material for spectral analysis. L. H. Esmann provided skillful assistance with much of the experimental work.

This investigation has been supported in part by the U.S. Army Engineer Research and Development Laboratories, Fort Belvoir, Virginia, and in part by the Aerospace Research Laboratory, Office of Aerospace Research, U.S. Air Force.

Manuscript received Sept. 11, 1964. This paper was presented at the Toronto Meeting, May 3-7, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

Luminescence of Europium in the Ternary System: La_2O_3-Gd_2O_3-Y_2O_3

R. C. Ropp[1]

Sylvania Electric Products Inc., Towanda, Pennsylvania

ABSTRACT

A detailed study of a rare-earth oxide ternary system activated by Eu^{+3} has shown that these phosphors are host-sensitized. There are matrix excitation bands present as well as a band attributed to perturbation of excited states of Eu^{+3}. An exciton mechanism is believed responsible for the matrix band and the field perturbation of the excited Eu^{+3} state.

The broad field of phosphors comprising rare-earth oxides activated by rare earths has been neglected in the past, primarily because of availability and purity of rare-earth materials. Recently, however, there has been a renaissance of interest in the fluorescence of rare earths, chiefly because of their applicability to the field of lasers. The earliest work by Urbain (1) stressed the cathodoluminescent properties of Gd_2O_3 and Y_2O_3 activated by small amounts of Eu, Er, Sm, or Tb. Subsequent investigations included description of the ultraviolet properties of La_2O_3:Pr (2), as well as Lu_2O_3, Sc_2O_3, or Y_2O_3, all activated by Sm (3). Later studies concentrated on Y_2O_3. Rosenberger (4) studied Y_2O_3:Er and La_2O_3:Er, and the spectroscopic transitions associated with Er^{+3} luminescence. Chang (5) studied conditions necessary for laser action of Eu^{+3} in Y_2O_3. Wickersheim and Lefever (6) gave general properties of luminescence of phosphors based on Y_2O_3 and La_2O_3, while in the most recent work, Axe and Weller (7) studied the effect of other rare-earth impurities on the luminescence of Eu^{+3} in Y_2O_3.

In an earlier work by the author (8), it was established that only three rare-earth oxides were effective as matrices in promoting rare-earth fluorescence: La_2O_3, Gd_2O_3, and Y_2O_3.[2] Of the rare-earth ions, only Sm^{+3}, Eu^{+3}, Tb^{+3}, and Dy^{+3} gave appreciable room-temperature luminescence. A study of the ternary system was conducted to define some of the mechanisms which produce luminescence in rare-earth oxide phos-

[1] Present address: Westinghouse Electric Corporation, Bloomfield, N. J.

[2] Here we designate Y_2O_3 and La_2O_3 as rare-earth compounds, although they contain no 4f electrons as does Gd_2O_3 [$4f^7$]. They do have similar chemical behavior.

phors, and to determine the energy processes which occur during the luminescent transitions. Compound formation in the ternary system is limited to the monoclinic $LaYO_3$ and to the hexagonal compound La_3YO_6 (9). Presumably, similar gadolinium compounds form.

Experimental Methods

The nitrates (or the oxides dissolved in concentrated nitric acid) of the requisite rare earths were dissolved to form 0.40M solutions. Mixtures of the ions in solution were made so that the required volumes totaled one liter before precipitation. The activator content was maintained at 2.5 mole % of the total cation content. Oxalic acid as a 10% solution was used as the precipitant, knowing the reaction to be quantitative in the presence of 5 mole % excess acid (10).

$$2M^{+3} + 3(C_2O_4) = \rightarrow M_2(C_2O_4)_2 \cdot xH_2O$$

where x = 2 to 6 when the precipitation is carried out at 80°C. The precipitate was dried overnight at 110°C and fired in air at temperatures ranging between 500° and 1100°C to form the phosphor, using open silica crucibles.

La_2O_3 is unstable in air, spontaneously forming the hydroxide $La(OH)_3$ which is nonluminescent. Appropriate precautions to prevent hydrolysis are required prior to measurement of spectral properties.

The optical spectra were obtained with the aid of a commercial instrument (11) having two monochromators. The excitation monochromator provided a constant energy excitation beam over the range of 46,000 to 20,000 cm^{-1}. Either monochromator may be programmed separately to provide excitation or fluorescence spectra. The spectra are automatically compensated for wavelength energy but not for relative intensity. Resolution in the instrument varies from a few angstroms in the ultraviolet to about 10Å in the red region of the spectrum.

Experimental Results

Single-oxide systems.—All three single oxides are activated by Eu^{+3}, as shown in Fig. 1. The excitation properties differ, while the emission occurs in the same spectral region, the strongest line being a red emission line close to 6100Å.

La_2O_3 has the hexagonal A-type structure, while Y_2O_3 and Gd_2O_3 form the cubic C-type structure, both typical of the rare-earth oxides, depending on the atomic number and firing temperature (12). Table I lists published data found for these oxides as well as cell constants determined in this work.

The most intense emission line for Eu^{+3} in La_2O_3 is positioned at 16,100 cm^{-1}, while those for Gd_2O_3 and

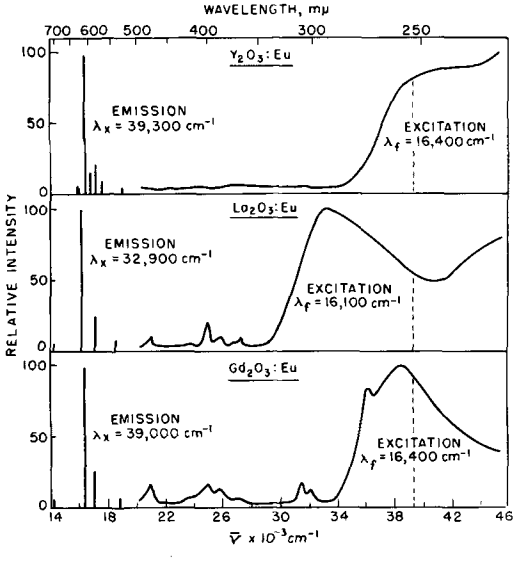

Fig. 1. Excitation-emission of Eu^{+3} in rare-earth oxide matrices

Table I.

Oxide	Firing temp, °C	Structure	a_o	c_o	Cation site symmetry	Number of oxide neighbors
La_2O_3	1000	Hexagonal	3.937Å	6.130Å	Distorted octahedral	7
Y_2O_3	1000	Cubic	10.604	—	Distorted cubic	6
Gd_2O_3	1000	Cubic	10.8	—	Distorted cubic	6
Gd_2O_3	1400	Monoclinic	Not determined		Distorted trigonal	7

Y_2O_3 are positioned at 16,400 cm^{-1}. These differences are attributed to symmetry changes at the cationic site where Eu^{+3} in Gd_2O_3 or Y_2O_3 can substitute in either of two sites having C_{2v} or S_6 symmetry. The site in La_2O_3 involves a peculiar sevenfold coordination having C_3 symmetry (13).

There are three distinct features in the excitation spectra. The low-intensity narrow bands are probably 4f → 4f transitions between levels of the activator atoms. There are two broad, intense excitation bands, one of which always appears at the same wavelength, regardless of activator (8). These are probably matrix excitation bands. The position and intensity of the other broad excitation band (thought to be an activator excitation band) are dependent on both the matrix and the incorporated activator (8).

The matrix excitation band of Y_2O_3:Eu occurs at about 2000Å. Those phosphors based on La_2O_3 all show the same broad matrix excitation band at 2200Å. The rather narrow excitation band in Gd_2O_3:Eu found at 36,000 cm^{-1} (2780Å) is caused by an excitation transition in the Gd^{+3} ion ($^8S_{7/2} \rightarrow {}^6I_J$). There is a broad excitation band peaking at about 47,600 cm^{-1} for Gd_2O_3:Eu because of matrix excitation.

The nature of the activator excitation band is more obscure. The bands might be attributed to 4f → 5d transitions or to a perturbed 4f → 4f transition in the Eu^{+3} activator center. Previous authors have favored the former, primarily because it is difficult to visualize or justify a mechanism involving perturbation of the "shielded" 4f electronic states.

The effect of structure on excitation.—The three matrices, La_2O_3, Y_2O_3, and Gd_2O_3, offer an ideal group for studies of matrix-activator interactions and the effect of site symmetry of fluorescent properties. Referring to Table I, it may be seen that all structures involve sites in which a departure from a regular symmetry is prevalent.

In a phosphor where host sensitization plays a primary role, long-range energy transport mechanisms would be expected to occur only in those matrices having a high degree of lattice-ordering. In noncrystalline materials, host sensitization (matrix excitation) does not generally occur.

Thus, the differences in excitation band position observed for the three systems would lead to the expectation that the matrix bands should be dependent on structure. The fact that Gd_2O_3 is dimorphic offers a method for determining the effect of structure on excitation bands. It would be expected that the intensity of the matrix excitation band would be highly dependent on the crystallinity of the matrix, and its position perhaps dependent on structure. Substantiating experimental data are presented in Fig. 2. Note that the monoclinic form has a broad peak apparent at 42,000 cm^{-1} (as well as the band due to Eu^{+3}). The cubic form, identified by x-ray analysis, also has two peaks whose relative intensities depend on firing temperature. The material fired at 600°C has one main peak at 39,400 cm^{-1}; another band appears at 44,000 cm^{-1}. The difference in intensity of this latter band is due to differences in crystallinity of the materials. Thus, according to x-ray diffraction analysis, the 600°C-fired material is much less crystalline and the matrix excitation band is much less intense than the

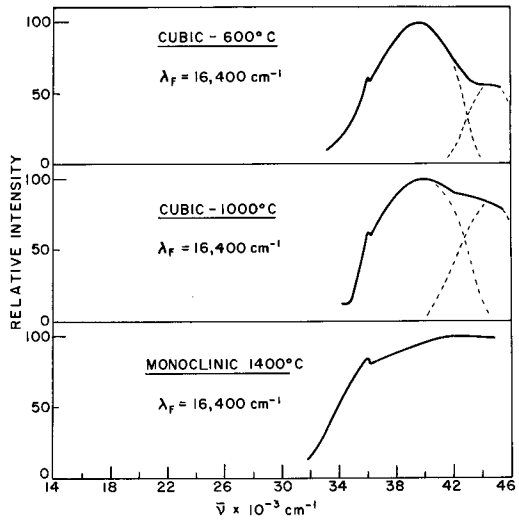

Fig. 2. Effect of structure on Gd_2O_3 : Eu excitation spectra

material fired at 1000°C. A previous paper (14) has shown that decomposition of the oxalates begins at 400°C and is complete at 600°C if given enough time for reaction. The materials were identified, by x-ray analysis, as cubic Gd_2O_3. The chief difference was in crystallite size (*i.e.*, crystallinity). Thus, the matrix excitation band intensity is a function of the degree of lattice-ordering.

There is one energy transfer process which occurs in the Gd_2O_3 phosphor, but not in Y_2O_3 or La_2O_3. This is the excitation transfer process corresponding to absorption within the Gd^{+3} ion (2780Å) by a transition within the 4f shell, with subsequent excitation of Eu^{+3}. This process is a separate excitation mechanism from the activator or matrix excitation processes.

The ternary system.—The ternary system forms only four compounds: $LaYO_3$ is monoclinic (9), and presumably $LaGdO_3$ has the same structure; La_3YO_6 is hexagonal, and likewise its conjugate, La_3GdO_6. No other compounds are known. Figure 3 shows a phase diagram found for the ternary system fired at 1000°C. Three separate single-phase regions were found: cubic, monoclinic, and hexagonal. Two-phase regions connect each with the other. The phase diagram must be regarded as approximate, since no specific effort was made to determine composition after firing. The data represent the initial cation ratios of ions in solution before oxalate precipitation and subsequent firing. Since these steps are essentially quantitative, no serious error is believed to have resulted (7). At 1400°C, the phase diagram changes so that the area of the cubic phase is reduced and the monoclinic region expands to include monoclinic Gd_2O_3.

It was found that the ultraviolet plaque response (2537Å irradiation) was a function of structure and not of composition (see Fig. 4). Thus, the hexagonal and monoclinic regions can produce 65% of standard manganese-activated cadmium-borate phosphor brightness. In the mixture having the cubic structure,

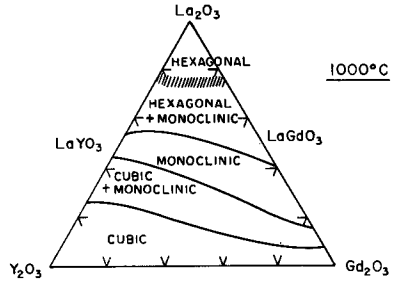

Fig. 3. Phase diagram of the ternary system La_2O_3-Gd_2O_3-Y_2O_3

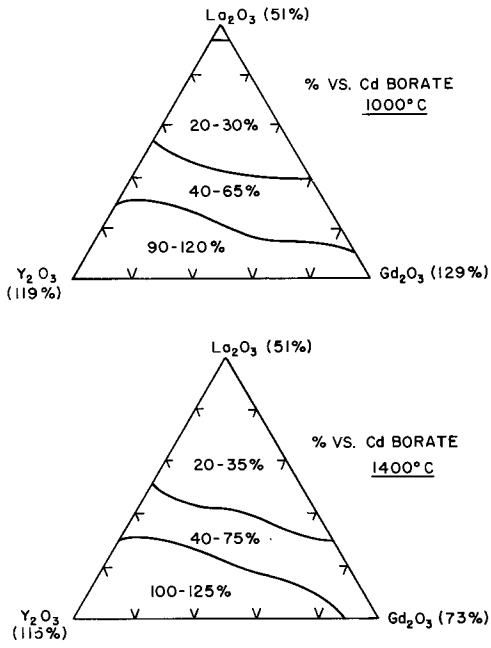

Fig. 4. Plaque brightness as a function of composition

those compositions containing no La have the highest brightness. Of these, the ultraviolet response seems to increase with Gd_2O_3 content, which would be predicted since the excitation-band maximum of Gd_2O_3:Eu is closer to 2537Å than that of Y_2O_3:Eu. The experimental data, accordingly, indicate simple solid-solution formation between Y_2O_3 and Gd_2O_3. However, the systems fired at 1400°C show decreased ultraviolet response as the transition from cubic to monoclinic symmetry occurs. Consequently, high ultraviolet response is found only in compositions having cubic symmetry.

In the ternary system, the differences in the excitation bands attributed to Eu^{+3} were determined as a function of composition. Since these excitation bands appear at widely separated points in the spectra, it is possible to classify the bands as to type. These data are given in Table II. Note that these are the excitation bands attributed to perturbation of excited states of the Eu^{+3} cation incorporated within the matrix.

It is readily seen that the excitation peak observed is not a function of structure but is due to the presence or absence of La. When La is present, the excitation is typical of the La_2O_3 spectrum, regardless of structure.

Discussion of Results

It has been demonstrated that there are two broad, intense excitation bands present in Eu^{+3}-activated rare-earth oxide phosphors. Of these, the band peaking at the higher energies has been shown, by correlation of x-ray and excitation data, to be associated with

Table II. Excitation as a function of composition

Composition La	Y	Gd	Structure	Excitation peak, cm^{-1}	Type of Eu^{+3} band

matrix excitation, at least in Gd_2O_3:Eu. Because the matrix band intensity is dependent on lattice-ordering, one is led to the conclusion that this band is the result of exciton processes (excited states of the lattice). There are at least two possibilities of exciton formation. In one process, the exciton formation involves an oxygen p^6 electron in analogy to the alkali halides (15). In the other, cation exciton states in the lattice are involved. Such behavior has been observed also in the alkali halides, particularly KCl (16). Of the two mechanisms, the latter is preferred because of the behavior of the excitation bands in the ternary system. In the ternary system, the matrix excitation may occur by formation of "bound-states" in which a cation p^6 electron is excited to a p^5d or p^5s state, and the wave is propagated throughout the lattice (17). Such a mechanism gives rise to host sensitization and requires high lattice perfection. Experimental evidence supports these conclusions because of the fact that there are "typical" matrix excitation bands for all three compounds. Such bands are a function of the cation, not of the structure.

As mentioned previously, the nature of the activator excitation band is not at all clear. The broad, intense excitation bands found at lower energies might be attributed to one of three causes: (i) the matrix, (ii) the isolated activator center, or (iii) the interaction of matrix with activator center. Case (i) can be shown to be improbable by consideration of the energy levels of Gd^{+3} and Eu^{+3}, as shown in Fig. 5. The energy levels were determined by absorption measurements (18) of Gd^{+3} and Eu^{+3} in solution. Although the triplet absorption of Gd^{+3} appears shifted in Gd_2O_3:Eu, the main excitation band cannot be attributed to Gd^{+3}, but must be due to Eu^{+3} energy levels perturbed by the crystal field or some other factor.

Case (ii) must be eliminated because only narrow bands would be expected for $f^n \rightarrow f^{n-1}f^*$ transitions (and perturbation of the $f^n \rightarrow f^{n-1}d^*$ excited state would involve the crystal field interaction).

Case (iii) can be subdivided into two possibilities: (a) where the interaction arises between cation pairs M^{+3}-Eu^{+3}, and (b) where the perturbation is due to the interaction of a field on the activator center, *i.e.*, the perturbation of the excited state is dependent on crystal structure. In the ternary system, if (a) proved to be true, we would expect La_2O_3:Eu, which has poor response to 2537Å, to improve in brightness when small amounts of Gd, Y, or both, were present. Experimental results, given previously, eliminate this possibility.

Thus, one is left with the conclusion that the broad excitation band is due to perturbed excited states of the activator, Eu^{+3}. A possible explanation is that perturbation is caused by the exciton field. The exact nature of the perturbation mechanism, whether field-interaction or vibronic coupling, is unknown. However, the experimental evidence shows that the La_2O_3 matrix possesses the lowest energy exciton states, so that even a cubic structure containing but 20% La still possesses an excitation spectrum typical of La_2O_3 containing Eu^{+3}. With this mechanism, one would expect the position of the band (*i.e.*, the minimum energy required for excitation) to be a function of composition, not of structure, as observed.

Correlation (19) of the published values of the energy levels of Eu^{+3} (20) to the emission spectra shows that in La_2O_3 emission occurs from the $^5D_1$ level, whereas in the other cubic oxides, emission occurs from the $^5D_0$ state. This difference is attributed to the local site symmetry of the Eu^{+3} activator in the oxide structures.

It has been observed that a mechanism, in which $4f \rightarrow 4f$ transitions can possess high oscillator strengths with strong transition probabilities, can exist (21) and that such a transition would involve an enforced dipole type of transition at the C_{2v} site in the cubic crystal because of the lack of a center of inversion. Polarization of emission along the $\bar{1}1\bar{1}$ plane would then be expected. It remains for more direct measurements to demonstrate the accuracy of the proposed mechanism.

Acknowledgment

The author is indebted to Dr. C. W. W. Hoffman for the x-ray powder diffraction measurements, to H. D. Layman for preparation of the samples, and to Dr. R. W. Mooney, M. A. Aia, and Dr. H. J. Borchardt for helpful discussions.

Diffusion-Induced Imperfections in Silicon

M. L. Joshi and F. Wilhelm

Components Division, International Business Machines Corporation, Poughkeepsie, New York

ABSTRACT

Diffusion-induced dislocations and precipitates have been studied through electron microscopy as a function of the diffusion depth. High concentrations of phosphorus and arsenic were diffused in (111) Si wafers to a shallow depth under the condition of constant solute surface concentration. Extensive dislocation networks were observed in phosphorus diffused wafers, whereas only a few single dislocations were detected in arsenic-diffused wafers. The results are shown to be in general agreement with Prussin's model of dislocation generation by relief of the stress due to solute lattice contraction of P and As.

The generation of dislocations in crystals by solute concentration gradients is well known (1-3). Such gradients can, for instance, be set up by fluctuations of the freezing rate during solidification. The solute concentration gradients imposed by shallow diffusion of large dopant concentration have been shown to cause the generation of dislocations in silicon (4-6). Queisser (4) found regular arrays of line patterns following crystal symmetry on silicon diffused with a high concentration of boron into a shallow surface layer and etched subsequently. These patterns were interpreted as slip lines due to the stress introduced into silicon lattice by the nonuniformly distributed, undersized, substitutional boron impurity. Prussin (5) produced etch pits marking dislocation sites on cleavage planes normal to the plane of diffusion in (111) silicon wafers symmetrically diffused with boron and phosphorus. It was shown that the stresses introduced by the solute lattice contraction were sufficient to produce dislocations. X-ray microscopy (6) and electron probe analysis (7) using essentially the reverse current of an irradiated diode as a read-out have given support to these findings. Jaccodine (8) reported the observation of individual dislocations forming networks in a phosphorous-diffused (111) silicon slice by transmission electron microscopy.

In this article, we present a study of diffusion induced dislocations as a function of the impurity diffusion depth in a (111) silicon wafer by the technique of transmission electron microscopy. Transmission electron micrographs were also obtained at the surface and near the junction in an arsenic-diffused wafer with surface concentration $\approx 5 \times 10^{20}$ cm^{-3}. This was done to explore the influence of the atomic size factor in the generation of defects by diffusion. On the basis of Pauling's tetrahedral covalent radii, P is undersized in Si, whereas As is almost the same size.

There is a considerable interest in regard to the diffusion-induced imperfections, other than dislocations. The detailed analysis of thin phosphorus-diffused layers in p-type silicon by Tannenbaum (9) has shown that at high concentrations of phosphorus ($>10^{20}$/cm^3) there is a significant difference between the profiles determined by sheet resistivity (corrected for ionization) and by radio tracer measurements. Tannenbaum interpreted this difference by postulating that part of the phosphorus is present not in the substitutional sites, but in the interstices or as precipitates. The detection of phosphorus precipitation by transmission electron microscopy in the diffused profile should be very informative in the light of the above consideration.

Experimental

Diffusion.—Three slices 10-mil thick and ~1 in. in diameter were cut parallel to (111) from a Czochralski-grown boron-doped ($\sim 10^{15}$ cm^{-3}) silicon crystal. The dislocation density of the crystal section from which the slices were cut was found by the etch pit technique to be less than 500/cm^2. The silicon wafers were lapped and chemically polished to remove any surface damage. Two of the wafers were symmetrically diffused on both sides with phosphorus in an open tube configuration at a temperature of 1150°C from a P_2O_5 source that was held at 300°C. The wafers were removed from the diffusion furnace and allowed to cool in room air on the quartz platform.

The third nondiffused wafer annealed at 1150°C served as a control to detect any possible defects introduced during specimen preparation. Both the etch pit technique and the electron microscopy revealed no such defects.

One of the diffused wafers was used for the determination of the solute profile, and the other for the study of the diffusion-induced imperfections. The surface impurity concentration was greater than 10^{21}/cm^3, as determined from the sheet resistance measurements and Irvin's curves (10). The p-n junction depth was about 2μ. The phosphorus-diffusion profile as obtained by the anodization-sectioning technique (9) in conjunction with the sheet resistivity measurements is shown in Fig. 1. This profile represents the ionized phosphorus distribution. The diffusion-induced imperfections were examined at the surface and at the depths 1/4, 1/3, 1/2, 1 and 1 1/2μ in the solute profile, as indicated in Fig. 1.

Specimen preparation.—The diffused wafer was cut by diamond-scribing into strips ⅛ in. wide. These strips were subjected to anodic oxidation, on the side to be studied. By successive removal of the oxide layers with HF, the appropriate depth in the solute profile was reached. The thickness of the removed silicon

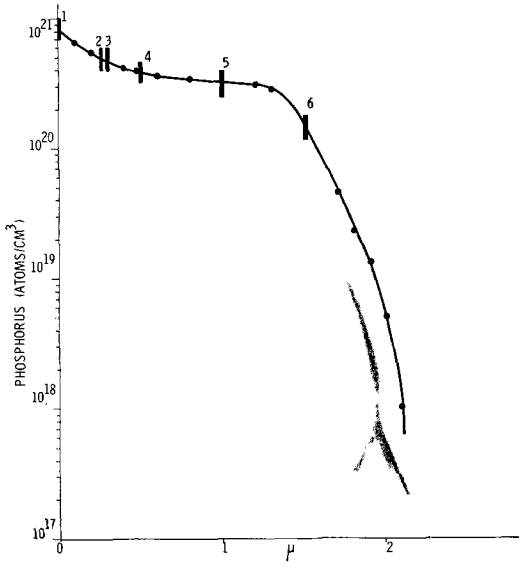

Fig. 1. Diffusion profile indicating levels of depth in the specimen where imperfections were studied; electron micrographs at point 1 to 6; four-point probe profile; diffusion: silicon 1150°C, P_2O_5 300°C.

layer per sectioning strip was determined from a comparison of the silicon oxide color to a standard film thickness gauge. The accuracy of this measurement is about ±50Å in 1000Å. Each strip was cut into ⅛ x ⅛ in. samples.

In order to obtain transparency to the electron beam in the microscope, the specimen had to be thinned to a few thousand angstroms. The samples were chemically polished down from the other side of the diffused surface under study by chemical polishing, using the solution: 300 cc of HNO_3 (70%), 200 cc of CH_3COOH (glacial), 100 cc of HF (47%), and 3g of iodine crystals. The surface to be studied was well protected from the chemical attack. Occasionally, samples were thinned by the electrolytic jet etch technique using a mixture of isopropyl alcohol and HF.

Electron Microscopic Observations

A Philips electron microscope (100B) was used for diffraction electron microscopy of the specimens. Individual dislocations are found in all investigated layers of the P-diffused wafer, down to a depth of 1½μ in the diffusion profile. At the surface (0μ depth) and at the depth of ¼μ (Fig. 2 and 3), rather complete networks were seen. Many threefold nodes are observed, joined by sections of almost straight dislocations. The network cells are of dimensions ½ to 1μ across. Dislocation densities up to 10^9 cm/cm^3 were measured. At the depth of 1/3μ into the diffused layer (Fig. 4), the dislocation networks appeared to be broken into smaller patches, sparingly connected with each other. At still greater depths (½ to 1½μ), the networks have practically disappeared (Fig. 5 and 6) and individual dislocations, some straight and some branched with one or two threefold nodes, are present.

The spreading of the network and the length of the component dislocations indicate that the dislocations lie in the plane of observation, *i.e.*, in the (111) plane. In many cases, where dislocations leave the (111) plane to terminate at the specimen surface, an abrupt change of direction takes place, revealed by the wavy appearance of the dislocations. The waviness [explained by the dynamical theory of diffraction contrast (11)] is due to inclination of the dislocation line with respect to the foil.

No stringent regularity exists in the network studied. Whenever small range regularity is detected, network cells tend to be hexagonal (Fig. 3), with dislocations joining in nodes under angles of 120°. Straight disloca-

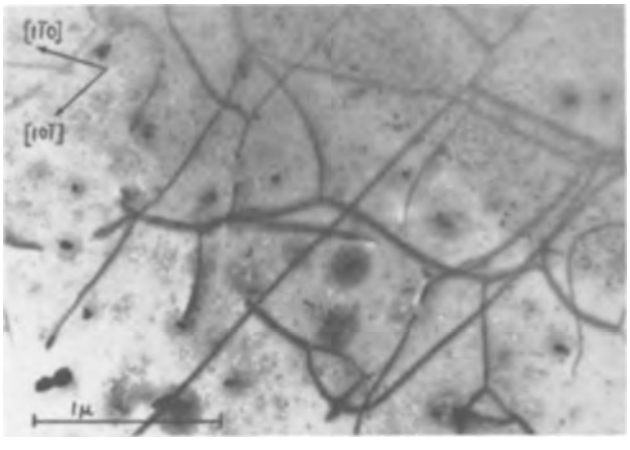

Fig. 2. Dislocation structure near the surface (depth 0μ)

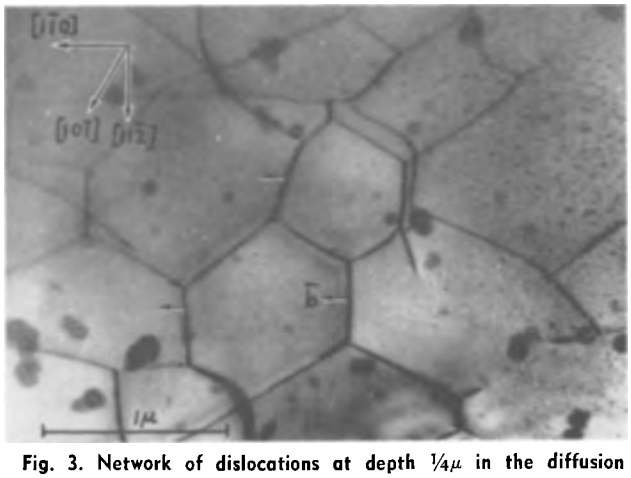

Fig. 3. Network of dislocations at depth ¼μ in the diffusion profile; arrows indicate Burgers vector.

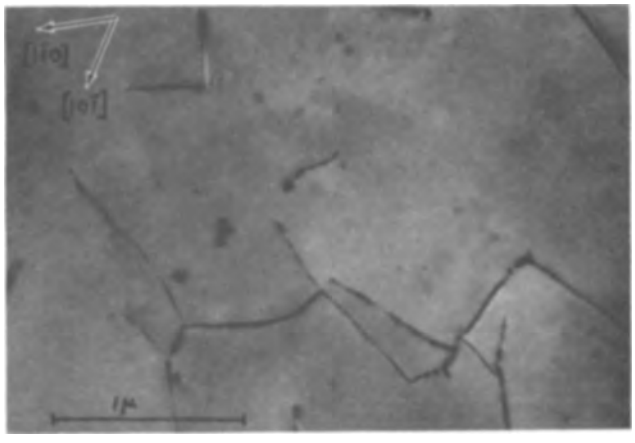

Fig. 4. Breaking-up of dislocation network at depth 1/3μ

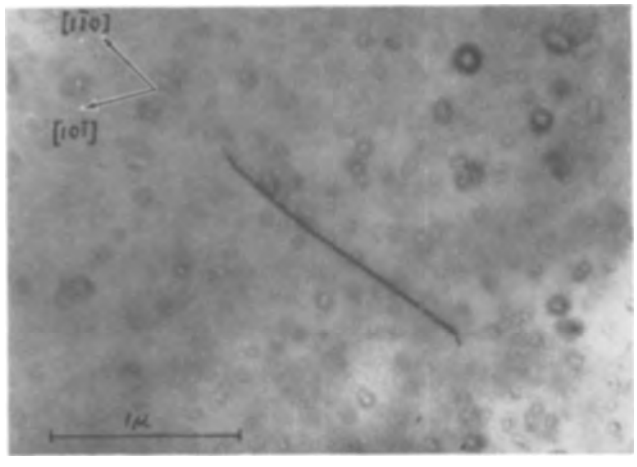

Fig. 5. Single dislocation at depth ½μ; only a few dislocations are found at this and at deeper levels.

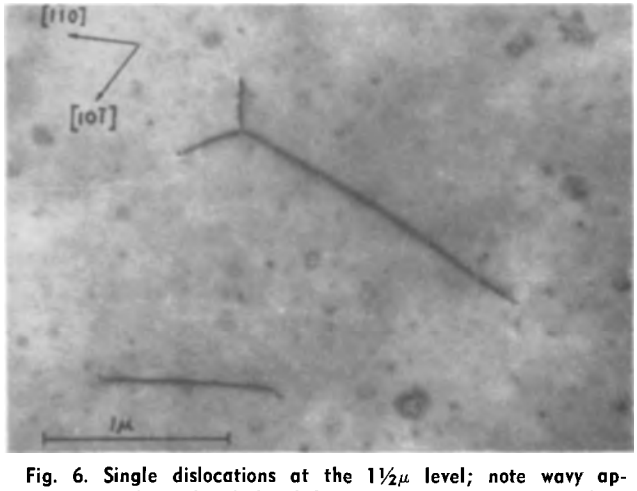

Fig. 6. Single dislocations at the 1½μ level; note wavy appearance at the ends of the dislocations, indicating tilt of these dislocation parts out of the plane of observation.

tions often lie in <112> directions. Isolated nodes, however, are occasionally found with their dislocations lying in a <110> direction.

The Burgers vector was determined on some of the dislocations (Fig. 3) by darkfield observation under illumination from a selected diffracted beam, indicating the edge character of the dislocations. They are of $a/2$ <110> type, in agreement with the findings of other researchers (6, 8).

Tilt of the specimen in the electron microscope revealed no other dislocations other than those shown in Fig. 3. The threefold nodes of the dislocation networks observed were contracted; no indication of extension is present. Figure 7 represents several groups of almost-straight parallel dislocations at $1/3\mu$ depth at the magnification of 12,000X. They seem to form a triangular pattern, with dislocations lying in <110> directions—interpreted as lying on {111} planes other than the plane of the specimen.

Dislocations in the specimen studied are rather immobile. No dislocation motion under the stress of the electron beam was observed in the electron microscope. Occasionally microcracks are observed in the material, created during the specimen preparation.

A (111) silicon wafer from a pulled silicon crystal doped with P ($>5 \times 10^{20}/cm^3$) was investigated for comparison with the diffusion-induced defects. Only very few dislocations inclined to the plane of observation were found in these specimens (Fig. 8). No other defects than dislocations were found.

On the magnification scale employed (30,000X), the dislocation distribution is considerably inhomogeneous.

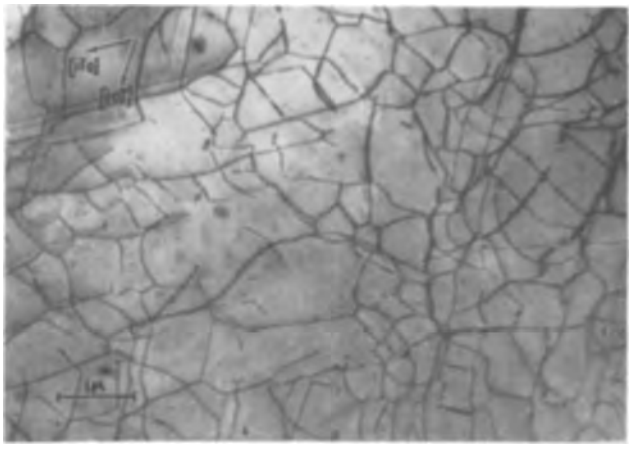

Fig. 7. Low-magnification micrograph reveals traces of dislocations lying in the three {111} planes, projected upon the plane of observation. In this micrograph (taken at a depth of $1/3\mu$), an unusually high dislocation density (for this depth) is found, not characteristic for this level when compared to many other observations.

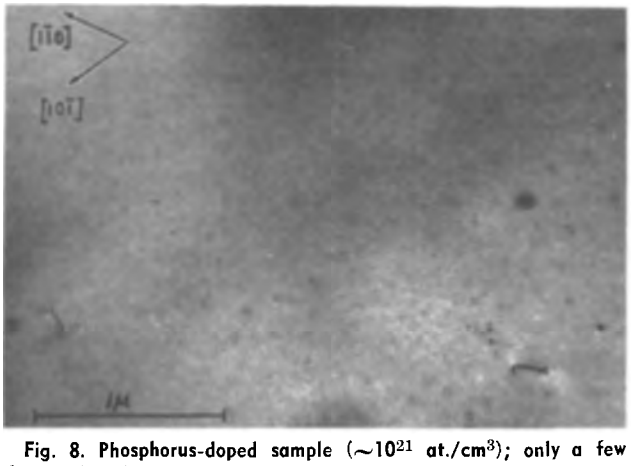

Fig. 8. Phosphorus-doped sample ($\sim 10^{21}$ at./cm^3); only a few short dislocations are present.

Frequently, particles of crystalline shapes (Fig. 9) are found in the diffused specimen throughout the diffusion profile studied herein. Their distribution also varies considerably in the different areas investigated. There are square, hexagonal and elongated particles of various apearances, with sizes ranging from 500Å to about 1μ. It is strongly suspected that these particles are phosphorus precipitates. Dark-field imaging did not give any indication of coherence of these particles with the parent lattice. The particles retain their shapes even in very fine detail when the specimen is washed in concentrated HNO_3 and subsequently in concentrated HF. They appear, however, to be lightened in contrast after the acid treatment.[1]

Arsenic diffused (surface concentration, $5 \times 10^{20}/cm^3$) boron-doped ($\sim 1.5 \times 10^{16}/cm^3$) silicon samples were examined at the surface and near the junction. Only a few single dislocations were observed; they often seem to lie almost perpendicular to the plane of observation (Fig. 10). Needle-type precipitates were observed at some places near the surface. No precipitation was detected near the junction.

Discussion

The electron microscope investigation gives evidence of the presence of dislocations and precipitates in silicon specimens, with a diffusion gradient of a high concentration of phosphorus. The absence of any significant amount of dislocations in the uniformly doped phosphorus ($> 5 \times 10^{20}/cm^3$) specimen should indicate that it is not necessarily the high solute concentration that induces dislocations. The small distribution coefficient ($k_0 = 0.35$) in phosphorus doping of single crystals could cause local concentration fluctuations, giving rise to the few dislocations seen in Fig. 9. The extensive dislocation networks seen in the diffused-phosphorus specimens are the result of relief of the stress gradient introduced by the solute lattice contraction of phosphorus diffused in silicon. Incidentally, the origin of the diffuse regions of extra x-ray scattering power observed on the glide plane traces in the case of silicon grown by floating-zone process has been suggested by other researchers to be these dislocation networks (12, 8). In addition, the regular arrays of the line markings (4) revealed by etching seem to be slip lines caused by glide on {111} planes, which our observations on dislocation networks corroborate.

The determination of the Burgers vectors in some experiments (Fig. 2), indicates that these particular dislocations seem to possess almost-pure edge character. These dislocations are oriented very closely in a <112> direction. The pure-edge dislocation on the (111) plane with a/2 <110> Burgers vector in the case of a diamond lattice is a composite dislocation which

[1] In a similar investigation, Schmidt and Stickler (14) have recently reported the identification of a silicon phosphide phase by transmission electron microscopy.

Fig. 9. Photo shows particles found in many areas throughout the diffused profile.

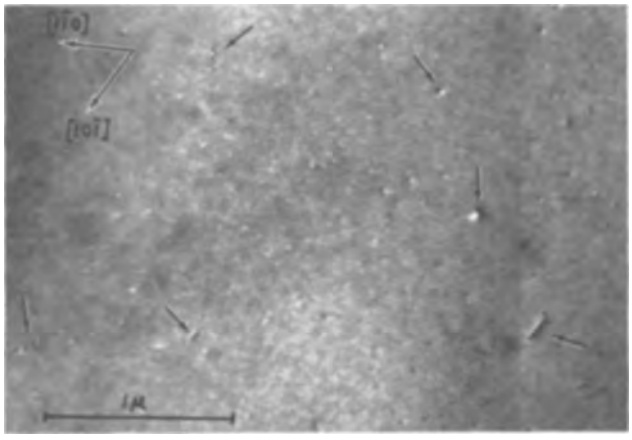

Fig. 10. Small dislocations in an As-diffused specimen; some are pointed out by arrows; micrograph taken near the surface.

occurs when the axis of a simple 60° Read's dislocation (with 1.4 broken bonds per lattice constant) changes alternately from one <110> orientation to another (13). Under the conditions of diffusion and solute lattice contraction such a dislocation (which requires 1.63 broken bonds per lattice constant) could be energetically possible.

The dislocation networks in the (111) plane of observation give credence to Prussin's concept of the stress relief by diffusion-induced dislocations. Since the dislocations must lie in the diffusion plane for the stress relief, only the six {111} slip systems with Burgers vectors a/2 <110> lying in {111} planes other than the plane of diffusion can be activated (according to Prussin). Only the edge components of these Burgers vectors contribute to the strain relief in the diffusion plane. The generation of the dislocations with predominant edge character is also consistent with this model. In the case of diffusion from a constant solute surface concentration (*i.e.*, for a strictly erfc distribution), Prussin derived a Gaussian dislocation distribution from the surface to a point in the diffused layer where the dislocation density drops to zero. The etch-pit density distribution on the cleaved plane extended half way into the diffusion profile in Prussin's own experiment (of deep diffusion of phosphorus in silicon). The significant feature of our study is that a dislocation density of 10^9 cm/cm^3 extends from the surface to about $1/3\mu$ depth and then begins to drop very rapidly and is negligible beyond a quarter of the way into the profile.

The surface dislocation density (according to Prussin's model on the basis of the solute lattice contraction coefficient $\beta \approx 10^{-24}$ cm^3/atom) is $\approx 3 \times 10^8$ cm, which is within one order of magnitude of our experimental observation. However, the dislocation penetration into the interior in our experiment seems shallower than expected. Considering the inhomogeneity of dislocation distribution on the scale of observation, it is not possible to compare the distribution actually obtained by electron microscopy to the expected one. The total number of dislocations created at the beginning of the diffusion process is dispersed into the interior of the sample during transport of the solute. This dispersion is likely to be restricted because of the nodes tending to anchor the dislocation networks.

It is also invariably observed that solute profiles are not erfc-type when high amounts of impurities are diffused into very shallow depths. Both of these considerations (anchoring and solute profiles) may be responsible for the deviations of the dislocation distributions-based strictly on the erfc distribution of the solute. The likely effect of dense dislocation networks in the diffused surface affecting the sheet resistivity measurements should not be neglected in estimating impurity concentration from Irvin's curves.

The absence of dislocation networks in the case of a large amount of arsenic diffusion indicates the importance of the degree of atomic misfit. The misfit ratio r/r_o (where r and r_o are Pauling's tetrahedral covalent radii of the solute and silicon) for P and As is 0.932 and 1.0, respectively. The incorporation of As in Si, consequently, would involve very little strain. The high surface concentration of P ($> 10^{20}$/cm^3) in comparison with that of B ($\approx 3 \times 10^{19}$/cm^3) needed for observation of slip patterns (4) is another example of the solute lattice contraction effect ($r/r_o = 0.746$ for B).

The observation of particles believed to be phosphorus precipitates indicates that the strains introduced into the diffused samples are locally inhomogeneous. The origin of the precipitates lies in the diffusion process, and well-defined shapes imply crystallinity (14). The incorporation of such particles may contribute to the deviation of the diffusion profile from the expected one. It should not be surprising if these precipitates, which extend almost to the p-n junction, affect the electrical behavior of the devices containing large amount of P diffusant.

TriPyramid Growth of Epitaxial Silicon

Morio Inoue

Research Laboratory, Matsushita Electronics Corporation, Takatsuki, Osaka, Japan

ABSTRACT

The tripyramids in vapor grown epitaxial silicon on substrates of (111) orientation were examined by chemical etching and x-ray diffraction techniques. The growth patterns of the tripyramids were brought out clearly by etching the epitaxial layer with the Sailer etch and the iodine etch successively. The tripyramids consist of twinned crystallites of [511] orientations. They originate at the interface between the substrate and the epitaxial layer. The cause of twinning was proved to be the formation of silicon carbide on the surface of the substrate. A crystallographic model was derived from the experimental results.

Epitaxial silicon films grown on single crystal substrates by the vapor decomposition method often contain stacking faults and tripyramids. The stacking faults have been investigated by many authors using chemical etching (1) and electron transmission techniques (2). It has been shown that the number of the stacking faults depends on both the physical perfection and amount of surface contamination of the substrate (3).

In addition to the stacking faults, growth hillocks, called tripyramids (4), have been observed on {111} substrates (5, 6). Batsford *et al.* reported that the residual water and organic solvents during chemical polishing induce the stacking faults and the tripyramids (3). Those were produced during the film growth, and they have been often found to be associated with the stacking faults. The tripyramids seen on epitaxial silicon layers obtained by reduction of silicon halide have also been observed on some germanium layers deposited by cathodic sputtering (7). Miller *et al.* (5) proposed a crystallographic model and a formation mechanism for the pyramids. However their model does not seem satisfactory to explain our geometrical observation by chemical etching and x-ray diffraction. A new model is proposed and the geometry and origin of the tripyramid growth are discussed in this paper.[1]

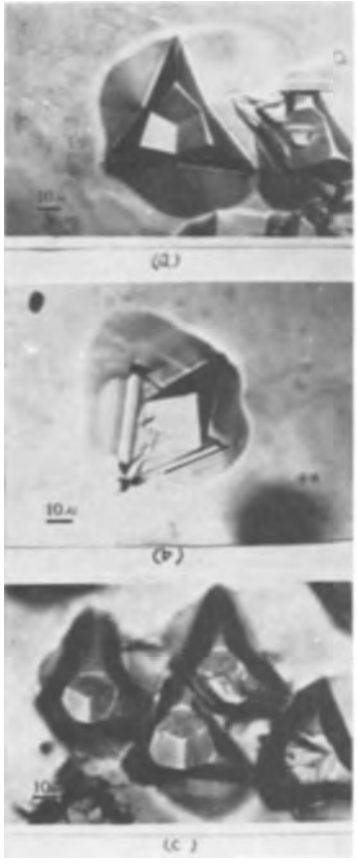

Fig. 1. Microphotographs of tripyramid growth on Si (111): (a) a typical tripyramid, (b) a monopyramid, (c) modified tripyramids.

Experiments

Epitaxial growth.—The epitaxial layers were prepared by silicon tetrachloride vapor decomposition at 1250°C in a hydrogen atmosphere (8). Chemically etched silicon wafers of (111) orientations were used as substrates. A substrate was placed on a graphite susceptor and heated by induction. The final removal of oxide was carried out in a hydrogen stream for 15 min at a temperature of 1260°C. The growth rate was approximately 1μ min^{-1}. The grown layers were usually $10 \sim 1000\mu$ in thickness.

Figure 1 shows a starlike hillock on the epitaxial layer called a tripyramid. The size and height of the tripyramid hillocks vary proportionally to the deposition thickness of the layer. They originate at the interface between the substrate and the epitaxial layer. Usually they exhibit figures similar to the one shown in Fig. 1a, but in a particular case monopyramids (Fig. 1b) and modified tripyramids (Fig. 1c) were observed. The geometry of the tripyramids were clarified by measuring the height and length under the optical microscope (Fig. 7).

Chemical etching study.—The internal crystallographic structure of the growth pyramids has been investigated by chemical etching techniques. The Sailer

[1] After this work was completed, a paper on the tripyramid imperfections was published by T. L. Chu and J. R. Gavaler, *Phil. Mag.*, 9, 993 (1964). They had studied the structure of tripyramids by chemical etching and optical microscope techniques. Their crystallographic analysis is similar to that of this work. However, their work does not contain the nucleation mechanism of the tripyramid.

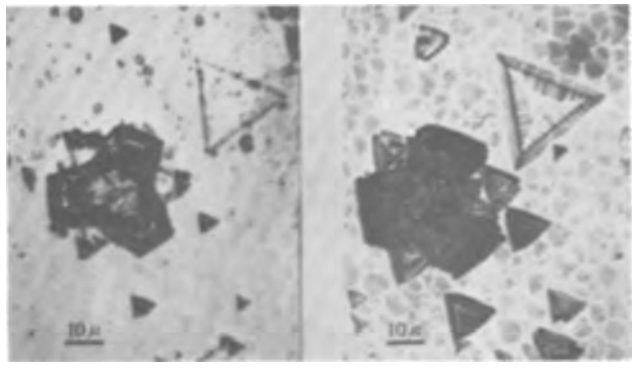

Fig. 2. Etch figure of tripyramid etched with Sailer etch: (a) (left) 2 hr, (b) (right) 3 hr. Dislocation etch pits and triangular etch figures of the stacking faults are revealed simultaneously.

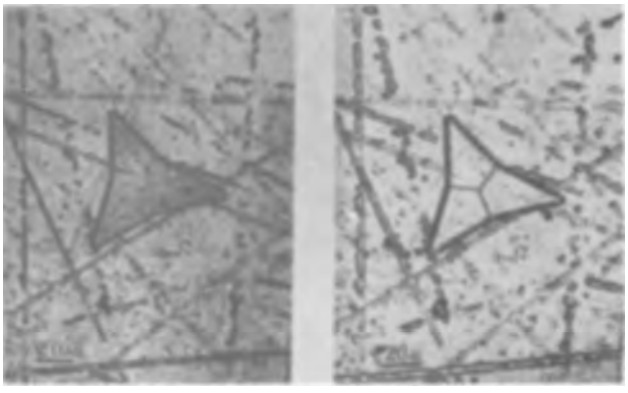

Fig. 3. Etch figure of tripyramids: (a) (left) etched with Sailer etch for 1 hr after partial removing of the hillock; (b) (right) the same samples were etched successively with iodine etch for 10 sec.

etch[2] and the iodine etch[3] were used in this work to bring out clearly the growth pattern of the pyramids. Figure 2 shows an etch figure of a tripyramid etch with the Sailer etch for 2 ~ 3 hr at room temperature. The copper deposited on the surface during Sailer etching was removed with nitric acid. Triangular defect boundaries associated with the tripyramids and isolated stacking faults were definitely revealed. As the Sailer etch shows clearly the area of a tripyramid, but does not reveal its inner structure, a modified etching was tried.

The samples were subjected to the Sailer etch for 1 hr and to the iodine etch for about 10 sec after hillocks were removed by lapping the surface with alundum powder and diamond paste. Whereas etching with the Sailer etch for 1 hr only reveals outlined boundaries (Fig. 3a), a following short period of iodine etching definitely etches the Y-shaped inner boundary between three incoherent crystallites (Fig. 3b). The angle at the tip of the starlike figure is 43°. Surrounding defect boundaries exhibit faster etch rates than inner Y-shaped boundaries. Besides these outer and inner boundaries, stacking faults and twin boundaries are also etched definitely by this technique as shown in Fig. 4. Figure 4 shows the etch figure after the double etching described above. Growth pyramids often associate with stacking faults (Fig. 2a and Fig. 4). It is noted that the stacking faults and the tripyramids are concentric in their configuration and are rotated 60° to each other.

In Fig. 4 the length of an equilateral triangle due to a stacking fault is equal to the distance between two adjacent tips of a starlike tripyramid configuration. This shows that the tripyramids originate at the substrate-epitaxial layer interface and grow in a similar way to the stacking faults. Moreover, it was proved by etching the cross section, that in the presence of stacking faults, the tripyramids originate at the same point as the stacking faults.

[2] 3000 ml NHO_3 + 600 ml HF + 2 ml Br_2 + 23g Cu $(NO_3)_2$ dilute 10:1 with deionized water before use.

[3] 110 ml glacial CH_3COOH + 100 ml HNO_3 + 50 ml HF + 0.3g I_2.

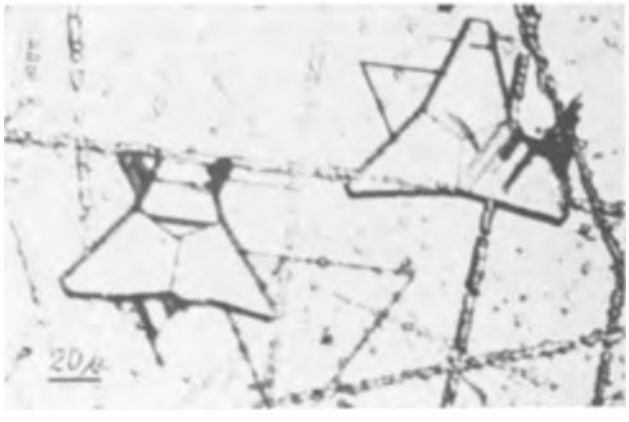

Fig. 4. Etch figure of tripyramids and stacking faults. Etched with Sailer etch for 1 hr and iodine etch for 10 sec.

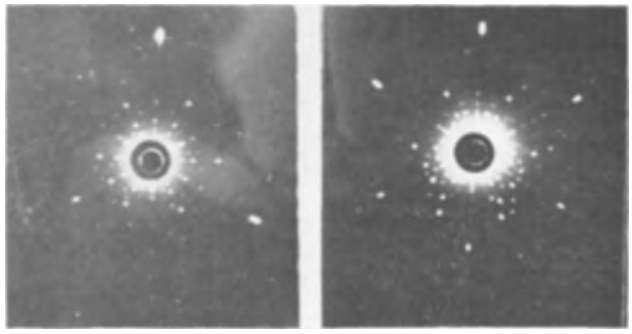

Fig. 5. X-ray back Laue reflection photograph: (a) (left) substrate silicon of [111] orientation; (b) (right) tripyramid hillock region of an epitaxial layer.

However, a tripyramid as shown in Fig. 3b, not associated with the triangular defects of a stacking fault, is often observed. This figure suggests that stacking faults are not essential to the growth of tripyramids.

X-ray back reflection.—The orientation of the crystallite can be shown up by x-ray back reflection. Laue photographs were taken on epitaxial layers with a 80μ growth thickness. A grown layer whose density of tripyramids was more than 5 x 10^4 cm^{-2} showed the following mixed Laue spot pattern (Fig. 5b). (On the sample, whose tripyramid density was less than 1 x 10^3 cm^{-2}, the spot pattern due to only the [111] orientation was observed.)

(I)	[111] substrate
(II)	[111] 180° rotated twin
(III)	[511] due to the rotation about $[\bar{1}11]$ as twin axis.
(IV)	[151] due to the rotation about $[1\bar{1}1]$ as twin axis.
(V)	[115] due to the rotation about $[11\bar{1}]$ as twin axis.

(I) is the substrate orientation and the epitaxial area free from the tripyramids which has substantially a [111] orientation (Fig. 5a). (II) is 180° rotated twins about the [111] substrate orientation. (III), (IV), and (V) are also twin orientations to the substrate crystal, although their axes are not parallel to the substrate [111] direction. Above five axes gave nearly the same intensities, but sometimes one of the intensities of (III), (IV), and (V) became predominantly when one of the three crystallites of the tripyramid grew exclusively as shown in Fig. 1b.

The crystallite orientations of the tripyramids were clarified by the correspondence between the boundary figure of etching and the results of x-ray diffraction (described in detail in the discussion).

Electron diffraction study.—In order to know the origin of four kinds of twins, substrate surfaces were examined by electron diffraction. It was proposed that the overgrowth of SiC on silicon originate twinning of the crystal (5). A silicon wafer of (111) orientation on which carbon of a few angstrom in thickness was deposited in vacuum, was heated at a temperature of 1175°C for 15 min in a hydrogen stream. Electron diffraction showed that the carbon coated silicon surface reacted with the carbon to form silicon carbide (α-SiC). When carbon-coated silicon wafers were used as substrates, the epitaxial layer inevitably produced many tripyramids. Figure 6 shows the effect of carbon deposition on tripyramid nucleation. On the left half

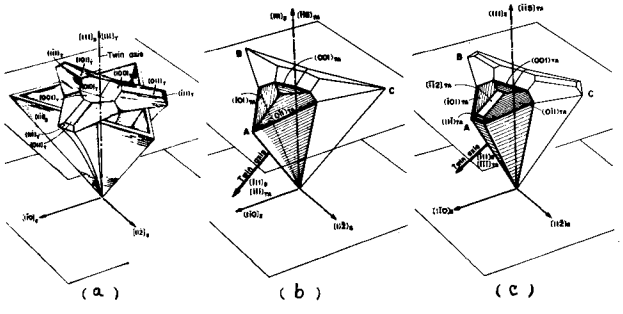

Fig. 7. Three-dimensional diagram illustrating the geometry of the tripyramid: (a) Miller's model, (b) and (c) author's model.

region, a carbon film was deposited before epitaxial growth. In the growth system, a graphite pedestal used as RF heater is the active source of carbon contamination. However in an all silicon-quartz system where no carbon is present, the tripyramid growth was very rare or not observed.

Discussion

Miller *et al.* proposed a crystallographic model and a formation mechanism for the pyramids (5). After their model the tripyramid associates with the twin lamella as shown in Fig. 7a. Tripyramids are 60° twinned to the substrate resulting from overgrowth of the silicon carbide.

From the experimental results of the etching and the x-ray reflection the author derived a model different from that by Miller (5). The schematic diagrams are shown in Fig. 7b and 7c. In the following paragraphs the crystallographic models are discussed in comparison to the Miller model (Fig. 7a).

The orientations of the crystallites in a tripyramid were [511], [151], and [115]. Three crystallites A, B, and C in Fig. 7c are incoherent to each other and were connected through the Y-shaped boundary as shown in Fig. 3b. Since the tripyramids have [511] orientations, they exhibit faster etch rates with the Sailer etch than the surrounding (111) region in Fig. 2. It was shown by partial removing and etching that the tip of the starlike tripyramid grows rectilinearly as shown in Fig. 7b.

The crystallographic indices of the exposed planes of the tripyramid were (110) and (100) (Fig. 7b). The modified form of Fig. 1c exposed (211) and (111) planes too (Fig. 7c). These indices were determined by measuring the height and length under the optical microscope on the basis of the criteria of the [511] and [111] orientations which were established by x-ray diffraction. The results do not agree with the model in Fig. 7a. The interfaces in the layer marked by oblique lines in Fig. 7b were determined in the same way and they appear to be (221) planes to the twinned crystallite.

The tripyramid and the substrate silicon are combined by multiple and complicated twinnings. In a diamond structure 60° twinning axes <111> exist in four ways, [111], [$\bar{1}$11], [1$\bar{1}$1], and [11$\bar{1}$]. All of the twinnings were detected by x-ray diffraction. Twinnings [$\bar{1}$11], [1$\bar{1}$1] and [11$\bar{1}$] correspond to the crystallites A, B, and C, respectively, in Fig. 7b (cf. Fig. 2c).

Although a crystallite A combines with a surrounding (111) layer by twinning about the [$\bar{1}$11] axis, the interfaces between them are not ($\bar{1}$11) plane but have a more complicated boundary. The striped bands in Fig. 4 correspond to the [111] 180° rotation twins. In fact these twins are always present in x-ray diffraction patterns. Because tripyramids without stacking faults are observed (Fig. 3), stacking faults are not essential to growth mechanism.

The cause of twinning was proved to be the formation of silicon carbide by Miller *et al* (5). After their results, the formation of α-SiC (hexagonal) layers on the silicon surface brings forth the twinning by the packing effect. SiC (0001) is parallel to the Si (111). The twin in the diamond lattice is produced when two extra SiC (0001) planes are inserted into a crystal. SiC nucleates at sites along the steps bounded by the (111) planes (5). These steps are produced by the thermal etching or by a reaction of $SiCl_4$ and H_2. Twinning about each of three ($\bar{1}$11) planes of the steps or etch pits on the (111) substrate surface introduces the crystallite of [511] orientation as shown in Fig. 7b. The effect of carbon or silicon carbide on tripyramid nucleation was experimentally proved (Fig. 6). In practical growth conditions, there are some origins which appear to be capable of depositing silicon carbide on the substrate surface beside the carbon pedestal. They are the small quantities of organic solvents such as methane, carbon tetrachloride, etc. (3, 9, 10). Vapor transport reactions of the carbon and silicon have been proposed (5).

It has been concluded that the tripyramid is introduced into the vapor-grown silicon layer through a few atomic layers of silicon carbide formed at the substrate interface. The graphite pedestal and the organic solvents are the active source of carbon contamination. To produce highly perfect epitaxial layers free from the tripyramids, it is necessary to clean the substrate and to remove carbon from the reaction system.

Vapor Phase Transport and Epitaxial Growth of $GaAs_{1-x}P_x$ Using Water Vapor

G. E. Gottlieb

RCA Laboratories, Princeton, New Jersey

ABSTRACT

It was found that $GaAs_{1-x}P_x$:Te doped layers can be homogenously transported by a vapor phase technique using water vapor. Epitaxial layers of the same As-P ratio as the melt-grown source wafers were grown onto [$\bar{1}\bar{1}\bar{1}$] and [100] GaAs substrates. The reaction proceeds via the following equation

$$2GaAs_{1-x}P_x + H_2O \rightleftarrows Ga_2O + (1-x)\ As_2 + (x)\ P_2 + H_2$$

Ga_2O is the actual transporting species. At a water vapor pressure of 0.286 mm (ice at −30°C) an activation energy of 85 kcal/mole was calculated. The amount of material transported was found to be a function of (*a*) $\sqrt{P_{H_2O}}$ entering the system, (*b*) the temperature difference between source and substrate, (*c*) the composition of the source material, and of course (*d*) the absolute source temperature. The transport of GaAs with water vapor was found to have an activation energy that is nonconcentration dependent within the range of water vapor pressures studied. Certain aspects of Te doping were studied; the oxygen content of the epitaxial layers was studied via mass spectrographic techniques.

The useful and interesting electrical characteristics of GaAs and GaP are well known. A logical extension of the work on these compounds is a study of the properties of the alloys $GaAs_{1-x}P_x$. As in the case with the pure compounds (especially GaP) the alloys are difficult to prepare by normal melt growth techniques. The usual problems encountered in the melt-growth of high melting point materials are concerned with purity and crystallinity. The alloys present the additional problem of homogeneity, *i.e.*, a constant ratio of As to P throughout the matrix.

This paper will discuss the growth of $GaAs_{1-x}P_x$:Te doped layers by a vapor phase technique. This work was instituted in order to obtain a compound having a band gap of 1.72 ev, so that by injection luminescence it emits at 7200Å and thereby stimulates a $CaF_2:Dy^{+2}$ laser. This experiment was performed (1), and it was found that the light emitted by the $GaAs_{1-x}P_x$ diodes was sufficient to stimulate the above-mentioned laser. The difficulties inherent in the melt-growth technique, just mentioned, suggested that vapor phase growth should be used as a preparative technique. Schäfer (2) discussed various aspects of vapor phase transport, the preparation of high melting point materials via volatile intermediates. Antell and Effer (3) applied the technique to III-V compounds, using iodine and chlorine as the transporting agent. Pizzarello (4) synthesized large polycrystalline boules of $GaAs_xP_{1-x}$, using GaAs and P or GaAs and GaP as starting materials and iodine as the transporting agent. Holonyak (5) reported the epitaxial growth of GaAs and GaP, using various chlorides as transporting agent. In the present work oxygen transport was utilized, in contrast to the above worker's use of halide transport. Gershenzon and Mikulyak (6) have also reported the growth of GaP, via a Ga_2O transport mechanism. Previous experience (7) with the transport of GaAs via Ga_2O, in a close-spaced system, indicated that Ga compounds can be transported successfully in this manner. Therefore, the close-spaced system with water vapor as the source of oxygen seemed the logical choice of method.

Frosch (8) has reported the growth of GaP and $GaAs_{1-x}P_x$ utilizing a Ga_2O vapor transport mechanism in an open tube apparatus, with the bulk of the paper devoted to GaP. In contrast to the above, the present paper is largely concerned with the growth of $GaAs_{1-x}P_x$ in the close-spaced system, via Ga_2O. Some of the topics discussed in the above paper are common to those reported in the present work, for example, growth rates, doping, crystal morphology, and usable growth parameters. However, the work reported here is devoted solely to $GaAs_{1-x}P_x$, presenting quantitative data on (a) the effects of temperature, (b) the $\sqrt{P_{H_2O}}$ relationship, (c) the homogeneity of the grown layers, and (d) incorporation of the transport agent into the grown layer.

Experimental

The close-spaced system of Nicoll (9) was used. The source and substrate wafer temperatures were each controlled by separate heaters. To insure an equal temperature over the entire wafer heavy molybdenum disks were placed between the wafers and their respective heaters. Temperature measurement and control were achieved by thermocouples placed in small holes in the molybdenum disks. A spacing of 10 mils was used between the source and substrate. Palladium diffused hydrogen, at a flow rate of 6 cc/min, was passed over ice at −20° to −30°C; the ice temperature was maintained by a salt-ice bath, or by an ethylene glycol-water bath. This technique controlled the amount of water vapor admitted to the system. The various growth parameters were studied by observing the weight loss of the source wafer as a function of the parameter of interest. A detailed description of the apparatus and of the experimental procedure has been given previously (7).

The $GaAs_{1-x}P_x$:Te source wafers were cut from melt-grown ingots. These source wafers were polycrystalline, with a varying As-P ratio. Mechanically polished (111) and (100) GaAs wafers, etched in 1:1:10 $H_2O:H_2O_2:H_2SO_4$ prior to growth were used as substrates.

Results and Discussion

The actual transport is assumed to proceed as follows

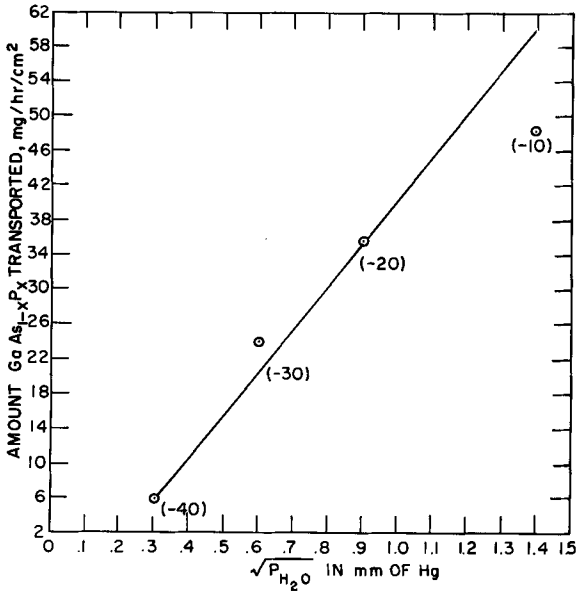

Fig. 1. Amount of $GaAs_{1-x}P_x$ transported as a function of water-vapor pressure. Figures in the parenthesis are the temperatures corresponding to the indicated vapor pressures. T_H, 935°C; T_C, 920°C.

$$2GaAs_{1-x}P_x + H_2O \rightleftarrows Ga_2O + (1-x)\,As_2 + (x)\,P_2 + H_2 \qquad [1]$$

Ga_2O is the transporting species, as demonstrated by several authors (10, 11). It was previously found (7) that the transport of GaAs by H_2O is proportional to $\sqrt{P_{H_2O}}$; this study shows that the amount of $GaAs_{1-x}P_x$ transported (Fig. 1) is also dependent on $\sqrt{P_{H_2O}}$, with some deviation at higher H_2O concentrations. This deviation from the expected relationship could be due to the formation of Ga_2O_3, which was observed in this work at higher water vapor concentrations; (P_{H_2O} above 9 mm). Previous work (12) on the Ga_2O-Ga_2O_3 system is in agreement with the above.

Figure 2 shows a plot of the reciprocal temperature *vs.* the log of the amount of $GaAs_{1-x}P_x$ transported. The activation energy for the reaction, calculated from this graph is 85 kcal/mole, at a water vapor pressure of 0.286 mm (ice at —30°C). Comparative activation energies are 74 kcal/mole, for GaP, at a water vapor pressure of 0.286 mm, and 49 kcal/mole, for GaAs at a water vapor pressure of 4.58 mm (ice at 0°C) (7). The closeness of the activation energies indicates that essentially the reaction is "Ga transport," via Ga_2O.

It was found that the GaAs-H_2O transport reaction has a non-concentration dependent activation energy, within the range of water vapor pressures studied. At 4.58 mm H_2O pressure, the activation energy is 49 kcal/mole and at 0.77 mm the activation energy is 47.4 kcal/mole. This indicates that within the above mentioned limits there are no competing source reactions, ruling out the formation of Ga_2O_3 as represented by the following equation

$$2GaAs + 3H_2O \rightarrow Ga_2O_3 + H_2 + As_2$$

The formation of Ga_2O_3 would also lower the efficiency of the reaction by 1/3 putting an upper limit of 67% on the deposition efficiency. In the present study 80-90% of the weight loss of the source was gained on the substrate.

This lack of dependence of the activation energy on the H_2O concentration is in direct contrast to the GaAs-HCl (13) situation, in which the activation energy is very dependent on the HCl concentration (pressure).

The layers of $GaAs_{1-x}P_x$ obtained in this study were

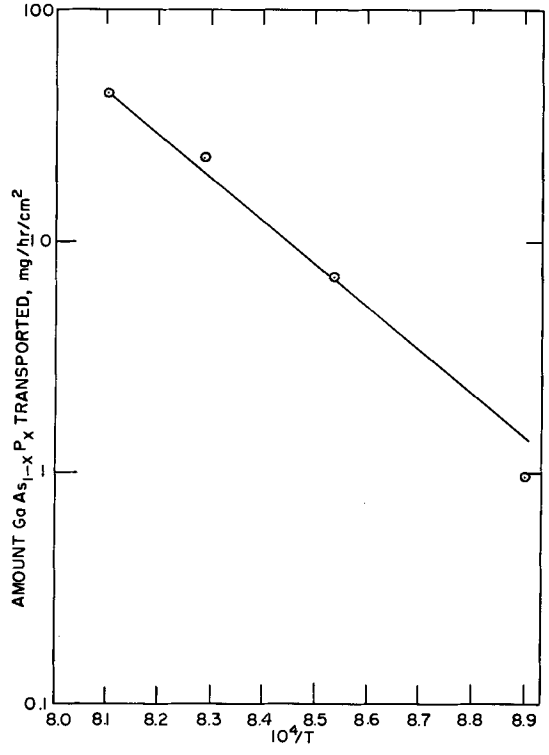

Fig. 2. Temperature dependence of the transport rate plotted as the amount of $GaAs_{1-x}P_x$ transported *vs.* $10^4/T$.

single-phase, single-crystal solid solutions of the above material. A completely mirror-like layer was usually obtained, at a growth rate of one-four mils/hour. Among the factors influencing growth rate are source composition, temperature of source and substrate, temperature difference, and wafer geometry. A good growth rate is not in itself sufficient to produce useful layers. Other factors of importance to be discussed, are substrate perfection, doping and impurities in the films.

It was found that the growth rate varied significantly with the source composition. As shown in Fig. 3, growth rate increased as the percentage of GaP increased. A possible reason for these results is the effect of the reverse reaction. GaAs can be transported at much lower temperatures than GaP. Therefore, at higher temperatures the reverse reaction becomes appreciable, and tends to limit the amount of material transported with a small temperature difference. These results are at temperatures of 935°-920°C (935° hot zone, or source, 920° cold zone, or substrate).

Small changes in the temperature difference have striking effects on the appearance of the grown layers. A $GaAs_{1-x}P_x$ layer grown at 950°-900°C, (900°-cold zone, or substrate), is usually very rough, 940-900 improves the appearance somewhat, but a startling change occurs when 940-920 is used. Under these con-

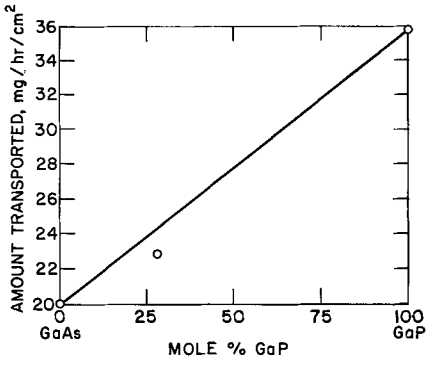

Fig. 3. Dependence of the amount of material transported on source composition. T_H, 935°C; H_2O, at 30°C; flow rate, 6 cc/min.

ditions the layer is mirror-like, with only occasional growth defects. This strong temperature dependence is in direct contrast to the GaAs situation, in which a variation of 50°C in the temperature difference between source and substrate produced hardly discernible changes in the grown layers.

The above facts are partially explained by Fig. 4. This shows that as the temperature difference between source and substrate is decreased, the amount transported also decreases. Although the concentration of Ga_2O in the gas phase is determined by the source temperature, the rate of removal of Ga_2O is determined by the substrate temperature. The same amount of material is therefore arriving at the substrate, but the "sticking probability" is lowered, due to the higher substrate temperature. For this reason, less material is deposited per unit area per unit time. Furthermore, the higher substrate temperature produces an increased surface mobility; this along with the lower deposition rate explains the improved crystallinity observed with small temperature differences. The effect of the temperature difference on the amount of material transported is demonstrated by two experiments performed at a source temperature of 980°C. In the first experiment the substrate temperature was 965°C, and 33 mg/cm²/hr were transported. In the second experiment, all the conditions were the same except that the substrate temperature was decreased to 930°C. In this case 110 mg/cm²/hr were transported.

The dependence of the amount of $GaAs_{1-x}P_x$ transported on the substrate temperature is due to the close-spacing, and the resultant interaction between source and substrate parameters. The close-spaced system approaches the behavior of a sealed system, in which the substrate temperature, by affecting the concentration of Ga_2O in the gas phase, has a profound effect on the amount of $GaAs_{1-x}P_x$ transported, as shown in Fig. 4.

Most of the source wafers were Te doped in the 1-5 x 10^{18} atoms/cm³ range; however, 10^{17} Te/cm³ doping was also studied. Both mass spectroscopic and electrical measurements indicated that in the range 10-100 ppm (2 x 10^{17}-2 x 10^{18}), the Te concentration in the epitaxial layer is the same as that in the source wafer. However, source wafers with up to 300 ppm of Te produced epitaxial layers containing only 100 ppm. This data is shown in Table I. Since the vapor pressure of elemental Te is large, it is not clear whether the Te transports as Te or as TeO_2.

The uniformity of the grown layers was studied by ultrasonically cutting small disks (0.040 in. diameter) from an epitaxial layer and corresponding source wafer, and then analyzing the composition of these disks via lattice constant measurements. The results of one such analysis are shown in Fig. 5. The grown layer had a maximum over-all variation in composition of 2%; the diffraction lines were sharp, indicating a variation within each disk of less than ±0.5%. Both the internal variation, and the over-all variation are much less in the grown layer than in the source. The As-P variation in the source is usually about 15%.

The layer shown in Fig. 5 was grown at a rate of ~12 mils/hr. A similar analysis (not shown) was performed on a layer grown at ~1.6 mils/hr. It was found that the maximum over-all compositional variation was also ~2% in this layer. However, the point to point variation was much less in the layer grown slowly, than in that grown more rapidly. Most of the slowly grown layer was one composition, with a single point deviating from this composition by ~2%. This indicates that the compositional variation within the grown layer is dependent on the growth rate. As would be expected, regrowth of a wafer further reduces compositional variation.

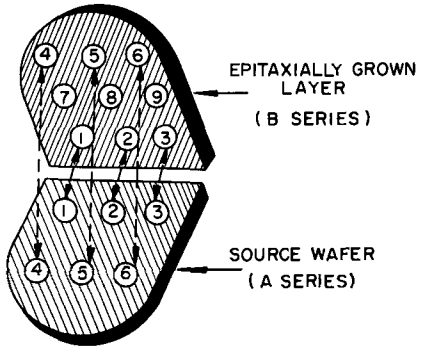

Fig. 5. The relationship between the source composition (A series) and the epitaxial layer composition (B series) is shown. Identical numbers from each series indicate areas adjacent to each other during growth. The substrate in this case was [100] GaAs wafer, grown at 920°C (substrate temperature).

A very few layers had areas of smeared Laue patterns, indicating some type of crystalline imperfection. In order to determine whether these irregularities are already present in the substrate wafers, or whether they are originating in the epitaxial layers, GaAs substrate wafers were etched in 1:1:10 $H_2O:H_2O_2:H_2SO_4$. Of a large number of substrate wafers etched in this manner, only a few showed any type of defect; the majority of the wafers polished in the above etch. The defective wafers were used as substrates, and the layers grown on these wafers had areas of smeared Laue patterns. Correlating these areas with the corresponding substrate areas showed that the substrate irregularity has propagated into the grown layers, manifesting itself as a "smeared" Laue pattern. Microphotographs of this effect are shown in Fig. 6.

Three separate areas on an individual $[\bar{1}\bar{1}\bar{1}]$ GaAs substrate were photographed. Each area is shown prior to growth and after growth of the epitaxial layer; the Laue pattern of the layer in each area is also shown. The substrate and layer photos are magnified 150X. The layer was grown at a substrate temperature of 920°C and a growth rate of 4.6 mg/hr/cm² (0.37 mils or 9 μ/hr). Figure 6(a) shows a severely distorted area. The irregularities are already evident in the substrate and are manifested as a dark area on the deposit photo. The Laue pattern shows broken dots, and the start of ring formation. In Fig. 6(b) the disturbances are less severe. The dots in the Laue pattern are somewhat distorted and broken. Figure 6(c) shows a nondistorted area, with nonbroken dots, essentially defect free single crystal material. Layers grown on the (100) plane were found by visual and microscopic examination to have fewer crystalline defects than (111) growth.

Typical wafer surfaces are shown in Fig. 7. Figure 7(a) exhibits an epitaxial layer grown on a [100] GaAs substrate. The layer was grown at 920°C at a growth rate of 5.4 mg/hr/cm², or 0.43 mil/hr. The mirror-bright surface is manifested by the reflection of the graph paper from the surface. Figure 7(b) depicts a typical epitaxial layer grown on a $[\bar{1}\bar{1}\bar{1}]$ GaAs substrate. The layer was grown at 920°C, at a growth rate of 47 mg/hr/cm², or 3.7 mils/hr.

In a transport reaction the amount of transporting agent incorporated into the grown layer is of interest. For this purpose, mass spectrographic studies were utilized. Table I shows that the source wafers were

reasonably low in oxygen concentration. The oxygen content of the grown layers was found to be 100-1000 ppm, or 0.01-0.1 atomic per cent. This is the same range that previous workers (13, 14) found for the incorporation of halide transporting agents in halide vapor grown III-V compounds. A recent report (15) indicates that molybdenum is attacked by oxygen at 550°C; mass spectrographic analysis did not show the presence of any molybdenum in the epitaxial layers. This indicates that the reaction of water vapor with $GaAs_{1-x}P_x$ is favored over the molybdenum reaction.

Single-crystal, single-phase layers of $GaAs_{1-x}P_x$:Te were also grown using powdered sources. Both powdered $GaAs_{1-x}P_x$, and GaAs plus GaP were used. Preliminary investigations on the uniformity of these layers indicate that they are at least as homogenous as the layers grown from melt-grown source wafers.

Summary and Conclusions

It was found that $GaAs_{1-x}P_x$:Te can be homogenously transported in the close-spaced system. A con-

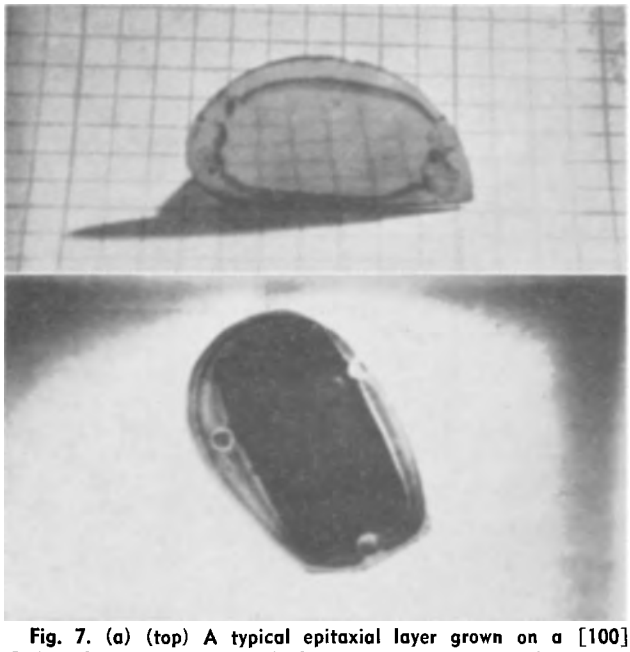

Fig. 7. (a) (top) A typical epitaxial layer grown on a [100] GaAs substrate is shown. (b) (bottom) Depicts a typical epitaxial layer grown on a [$\bar{1}\bar{1}\bar{1}$] GaAs substrate.

trolled amount of water vapor added to the hydrogen stream is the transporting agent. The rate of transport is dependent on $\sqrt{P_{H2O}}$. In the range 2 x 10^{17} — s x 10^{18} Te/cc, the grown layer concentration corresponds to the source concentration in a 1:1 ratio. It was found that the amount of $GaAs_{1-x}P_x$ transported is dependent not only on the source temperature, but also on the temperature difference between source and substrate.

Acknowledgments

It is a pleasure to acknowledge the experimental acumen of J. F. Corboy, Jr. The author is indebted to P. G. Herkart for advice, encouragement, and useful discussions. Thanks are due to R. J. Paff for performing the lattice constant measurements, and to H. H. Whitaker for the mass spectrographic analysis. The author is indebted to P. Robinson for useful discussions and to D. Richman for a critical reading of the manuscript.

Manuscript received April 9, 1964; revised manuscript received Oct. 9, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

Measuring Mobility and Density of Charge Carriers Near a P-N Junction

D. Pomerantz

Laboratory for Physical Science, P. R. Mallory, Burlington, Massachusetts

ABSTRACT

Two types of probe measurement are described which allow the determination of the conductivity mobility and the density of majority carriers in the neighborhood of p-n junctions. The first of these measures the change in sheet conductivity of a layer as a function of the reverse bias applied to a junction bounding the layer. The second measures the capacitance of the junction *vs.* the reverse bias. The techniques are applied to silicon p-n junctions of both the epitaxial and diffused variety. A significant difference is observed in the mobility variation near these two types of junction.

As an aid in the analysis of junction semiconductor devices it is valuable to measure directly the physical properties of the semiconductor in the neighborhood of the junctions. The main properties of interest are the concentration, mobility, and lifetime of charge carriers. This work will describe a method of measuring the first two of these parameters and its application to two widely used silicon junction types; (i) junctions between a lightly doped epitaxial layer grown on a lightly doped substrate of opposite conductivity type and (ii) junctions produced by a heavily doped diffused layer in a lightly doped substrate of opposite conductivity type.

Experimental

Figure 1 illustrates a technique for measuring the differential sheet conductivity of a layer bounded by a junction. The experimental arrangement is similar to a conventional four point resistivity probe (1) except that two additional probes have been added, making contact with the substrate. The current probes, I_1 and I_2, supply a constant current, I, which flows in the n-layer of the sample illustrated, the junction acting as a barrier to current flow in the p-region. The voltage probes, V_1 and V_2, are connected to a high impedance voltmeter so that they do not draw any current and therefore measure the transverse potential drop in the

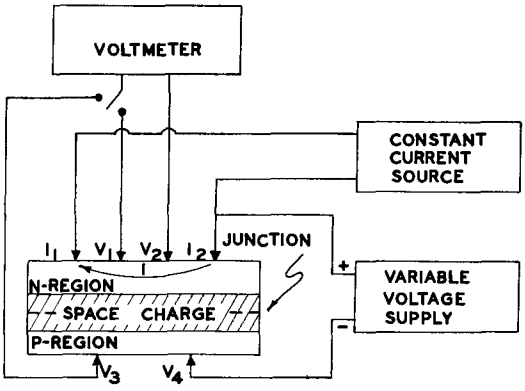

Fig. 1. Experimental arrangement for measurement of differential sheet conductance.

n-layer due to the current I. From this the sheet conductivity may be deduced. The voltage probe, V_4, applies a variable potential to the substrate with respect to the current probe I_2. The sign of this potential is such as to reverse bias the junction. Since the leakage current of the junction flows through probe V_4, it is not suitable for measuring the potential of the p-region. Another probe, V_3, is provided for this purpose which may be connected to the voltmeter through the switch. The voltage applied to the junction is then measured between probes V_2 and V_3. By increasing this applied reverse bias, the junction space charge region is caused to sweep mobile carriers out of the n-layer, decreasing its sheet conductivity. The measurement consists in determining the voltage difference between V_1 and V_2 as a function of the voltage applied to the junction, measured between V_2 and V_3.

The difference between two conductivity measurements at slightly different voltages is a measure of the conductivity of the particular lamina swept out by the space charge when the increment of voltage is applied. The principle of operation is similar to modulation of the channel resistance of a field effect transistor, except that care is taken to operate at sufficiently low currents so that the transverse voltage drop in the layer is small compared to the voltage applied to the junctions, *i.e.*, remote from pinchoff. The measurement may be made with either sign of current flow in the n-region, but more accurate results are obtained if the direction of the current I is such as to forward bias the point contact diode, I_2, through which voltage is applied to the n-layer. When this diode is reverse biased, variations in its reverse characteristic due to noise or surface effects produce variations in the potential of the n-layer. Excess junction leakage current flowing transversely in the n-region will produce an error in the voltage measured between V_1 and V_2. For the polarity of the current, I, shown in Fig. 1, this will increase the measured voltage. The amount of increase may be measured with the current source disconnected. This error voltage is then subtracted from the original reading to obtain the effect of the current I alone. The correction is unmeasurably small for junctions of good quality. The current I is adjusted to be sufficiently large to produce an accurately measurable voltage, but small enough so that injection of minority carriers into the base by the forward biased current probe is negligible. The latter effect is observable as a rapid increase in the current flowing in V_4, as I is increased. This is avoided as it signifies the presence of nonequilibrium carrier concentrations which produce modulation of the n-layer conductivity. Typical values of current lie between 0.2 and 0.5 ma. The measurement of differential sheet conductivity may be made on a whole slice if the junction is sufficiently free of defects. In this way different areas may be measured nondestructively. In practice this situation is rare, and it is convenient to etch onto the slice, through the junction, a pattern of rectangular mesas with dimensions of aproximately 1 by 4 probe spacings. For measuring the properties of both the n- and p-regions, rectangular dice of these dimensions are used.

In addition to the differential sheet conductivity, the carrier density as a function of position must be known in order to determine how the mobility varies in the n-layer. This is determined from capacitance *vs.* voltage measurements as shown in Fig. 2. Here a variable voltage is supplied to the two probes, C_1 and C_2, through a capacitance bridge. Two separate probes, V_2 and V_3, determine the voltage applied to the junction. To avoid errors due to the capacitance of the probes, C_1 and C_2, which are in series with the junction, two additional current supplies are used to forward bias these point contact diodes. The effect is to provide a low resistance in parallel with the capacitance of the contacts. Without this current flowing, the point contacts will be at almost zero bias and can easily have a capacitance which is comparable to the junction. This leads to an erroneously small result. The currents I_1 and I_2 are adjusted so that further increase produces no reduction in capacitance. In practice this leads to values of 20-50 μa.

Theory of Measurement

Figure 3 illustrates the distribution of space charge density near a reverse biased p-n junction. The dotted lines give the net amount of ionized fixed charge. To the right of the origin is plotted the charge density due to ionized donors net of ionized acceptors (N_d) as a function of distance into the n-region which has a thickness, t. To the left is plotted the charge density of ionized acceptors net of ionized donors (N_a) as a function of distance into the p-region.

The solid lines show the total space charge density, $\rho(v,x)$, which is produced when the fixed charge is stripped of its neutralizing mobile carriers by the built-in plus the applied voltage. For the purpose of calculating mobilities, it is not necessary to assume that the charge drops abruptly to zero at the edge of the space charge region. Figure 3 illustrates the more

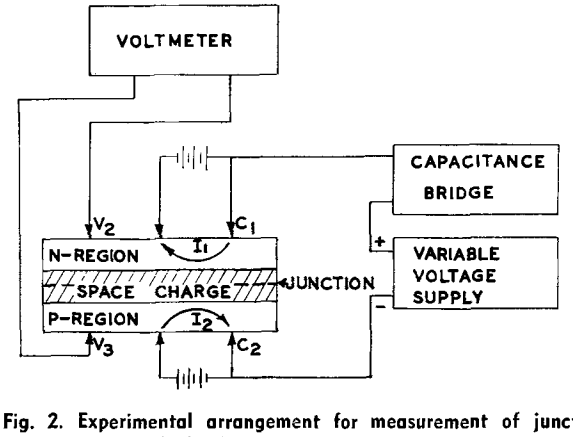

Fig. 2. Experimental arrangement for measurement of junction capacitance *vs.* applied voltage.

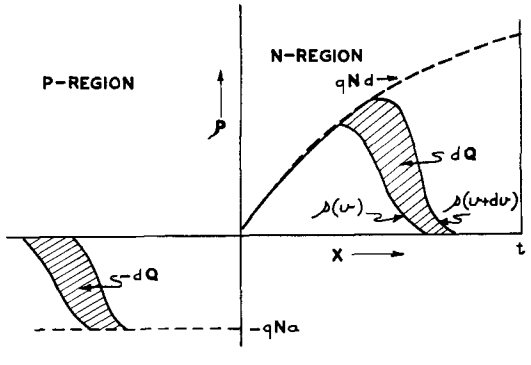

Fig. 3. The net fixed charge density (dashed) and the space charge density (solid) near a p-n junction.

gradual reduction characteristic of small applied voltages. An increase in applied voltage, dv, produces an increase, dQ, in the space charge on the n-side of the junction as shown in the figure. Over-all neutrality requires a space charge, $-dQ$, be produced on the p-side. The small signal capacitance per unit area at this particular voltage is just the ratio of the induced charge per unit area, dQ, to the inducing voltage, dv

$$c(v) = \frac{dQ}{dv} \quad [1]$$

where

$$Q(v) = \int_0^t \rho(v,x)\, dx \quad [2]$$

We now consider the change in sheet conductivity due to the same change, dv, in voltage. It will be seen that to a very good approximation this is attributable to the mobile charge of magnitude $-dQ$ which is removed from the fixed charge dQ in Eq. [1]. The total sheet conductivity of the n-layer is

$$\sigma_s = \int_0^t (nq\mu_n + pq\mu_p)\, dx \quad [3]$$

where n, p, μ_n, μ_p, the electron and hole concentrations and their mobilities are functions of x, the distance from the junction; and q is the electronic charge. The charge density is given by

$$\rho(x) = qp(x) - qn(x) + qN_d(x) \quad [4]$$

Substituting $n(x)$ from Eq. [4] into Eq. [3] gives

$$\sigma_s = -\int_0^t \rho(v,x)\mu_n\, dx + \int_0^t pq(\mu_p + \mu_n)\, dx + \int_0^t N_d(x)\, q\mu_n\, dx \quad [5]$$

In Eq. [5] the second integral is the contribution due to minority carriers plus an equal number of neutralizing majority carriers. This is entirely negligible except for near intrinsic silicon (*i.e.* > 1000 ohm-cm). Since the third integral is not a function of v we have

$$\frac{d\sigma_s}{dv} = -\mu_n \frac{dQ}{dv} \quad [6]$$

The quantity dQ, which is the differential of Eq. [2], is illustrated in Fig. 3. It is equal in magnitude (and opposite in sign) to the area density of mobile charge swept out of the region shown cross hatched in Fig. 3. The average mobility of these charge carriers is μ_n. The expression for the mobility is obtained by eliminating dQ/dv between Eq. [1] and Eq. [6]

$$\mu_n = -\frac{1}{c}\frac{d\sigma_s}{dv} \quad [7]$$

It is to be noted that μ_n is the true conductivity mobility for majority carriers, a quantity normally derived on theoretical considerations from the Hall or drift mobilities. Here it may be determined directly from measurable quantities. The mobility will normally be a function of the applied voltage v, reflecting the variation in crystal properties or impurity concentration at the edge of the space charge region. This voltage will in turn be related to distance from the junction through the capacitance measurement described below. In this way the edge of the space charge, probing into different laminae, determines the variation of mobility within the p- or n-region.

For an infinite sheet, thin compared to the probe spacing, the quantity σ_s in Eq. [7] is given by $\sigma_s = I(\ln 2)/\pi V$ (2) where V is the voltage measured between probes V_1 and V_2, Fig. 1. If the sample area is limited, other correction factors are required. These have been calculated by Smits (2). In the case of a rectangular sample comparable in width or narrower than the probe spacing, some precision is added to the mobility determination by the fact that the width of the sample drops out of Eq. [7]. In this case σ_s is given by (2).

$$\sigma_s = Is/VC'd \quad [8]$$

where s is the probe spacing, d the rectangle width, and C' a numerical factor tabulated in (2) and closely approximating unity for a narrow rectangle. This approximation corresponds to parallel current flow past the voltage probes. If the measurement is made at constant current, the following expression is obtained by differentiation of Eq. [8]

$$\frac{d\sigma_s}{dv} = -\frac{I}{V^2}\frac{dV}{dv}\frac{s}{C'd} \quad [9]$$

The capacitance per unit area c, is determined from the measured capacitance C, by $c = C/da$, where a is the rectangle length. Substituting this expression along with Eq. [9] in Eq. [7] gives

$$\mu_n = \frac{I}{V^2}\frac{dV}{dv}\frac{sa}{C'C} \quad [10]$$

from which d, the sample width, drops out. This expression has been used for obtaining the results described below. The accuracy of the determination is limited mainly by the measurement of the small voltage increment dV. In the measurements described below, dV is of the order of 10 mv and is determined to an accuracy of better than 1% using a precise high impedance differential voltmeter. Such accuracy is necessary to determine the relatively small variation of mobility with doping.

The equations for determining impurity concentration and distance from the junction from the measured values of $c(v)$ are

$$\frac{d}{dv}\left(\frac{1}{c^2}\right) = \frac{2}{qe}\left(\frac{1}{N_d} + \frac{1}{N_a}\right) \quad [11]$$

$$c = \frac{\epsilon}{s_a + s_d} \quad [12]$$

$$N_d\, ds_d = N_a\, ds_a \quad [13]$$

where ϵ is the dielectric constant and s_a, s_d, are the widths of the space charge layer in the p- and n-regions, respectively. Equations [11] and [12] are a generalization of those originally derived by Schottky (3) for the case where either N_d or N_a is large compared to the other. Equation [11] is proved by substituting Eq. [12] and then Eq. [13] into it, remembering that $qN_d\, ds_d = dQ = cdv$.[1] Equation [13] expresses the condition of over-all charge neutrality where ds_d and ds_a are the incremental increases in space charge penetration into n- and p-regions, respectively. In the derivation of these equations it is necessary to assume a sharp edged space charge region, a good assumption for applied voltages large compared to the built-in voltage. For small applied voltages the position coordinates s_a and s_d derived from the above relations must be considered to have an uncertainty of the order of the distance over which the space charge drops from qN_d or qN_a to zero. The mobility and impurity concentration which are determined as a function of s_a and s_d must therefore be considered as averages over this range.

In addition to Eq. [11]-[13] one other relationship is needed to determine the four quantities $N_a(s_a)$ and $N_d(s_d)$, when N_a and N_d are of comparable size. For the case of an epitaxial layer it is reasonable to assume a constant substrate doping, which is then measurable. As will be seen, this assumption may be verified from the results. For the case of a diffused junction there will be a narrow region on both sides of the junction which will be linearly graded, *i.e.*, $N_a = N_d$. As the space charge penetrates into the heavily diffused side of the junction this impurity concentration increases to a large value, eliminating its term from the right side of Eq. [11]. Using each of these assumptions in turn, N_d and N_a, determined from Eq. [11], are plotted as a function of $s_a + s_d$, the total space charge

[1] The author is indebted to E. Pittelli for this result.

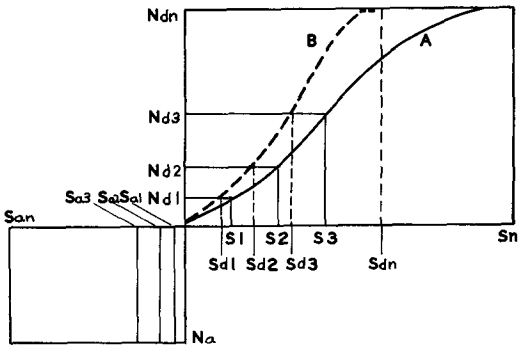

Fig. 4. Method of determining the relative penetration of space charge into the p and n-regions.

width, determined from Eq. [12]. The actual variation of $N_d(s_d)$ is then found by interpolating a curve which approaches the first situation asymptotically for a narrow space charge region and the second situation for a wide space charge region. While this process is not entirely free of ambiguity, a typical example, illustrated in Fig. 6, shows that the error incurred cannot be large.

It is now possible to relate the mobility directly to the net impurity concentration since both have been determined as a function of the total space charge width, $s_a + s_d$, through its dependence, Eq. [12], on the measured value of c. Examples of this result are illustrated by the curves of Fig. 5 and 6. If the differential sheet conductivity measurement is made on both sides of the junction, this relationship can be separately established in the p-and n-regions.

It only remains to separate the space charge into its two components, s_a and s_d. This is especially significant in epitaxial layers on lightly doped substrates since, in this case, a large part of the space charge region may penetrate into the substrate. If, as assumed previously, this region contains a uniform impurity concentration, N_a, the relative penetration of the space charge may be obtained by graphical integration of Eq. [13]. The process is illustrated in Fig. 4, where $s_1, s_2, \ldots s_n$, are successive values of space charge width, increasing incrementally; $N_{d1}, N_{d2}, \ldots N_{dn}$, are the corresponding values of net donor density on the n-edge of the space charge region; $s_{d1}, s_{d2}, \ldots s_{dn}$, are the corresponding penetrations of the space charge into the n-region and $s_{a1}, s_{a2}, \ldots s_n$, the penetrations of space charge into the p-region. The difference equations arising from Eq. [13] are

$$s_{d1} N_{d1} = 2 s_{a1} N_a, \quad s_{d1} + s_{a1} = s_1 \qquad [14]$$

$$(s_{d2} - s_{d1})\ (N_{d2} + N_{d1}) = 2 (s_{a2} - s_{a1}) N_a,$$

$$s_{d2} + s_{a2} = s_2 \qquad [15]$$

etc.

These equations are solved by choosing closely spaced values of s_1, etc., and determining the values of N_{d1}, etc., from the curve derived from Eq. [11], [12], *e.g.*, curve A of Fig. 4. The values of s_1 and N_{d1}, along with the measured N_a, are substituted into Eq. [14] which are solved for the two unknowns: s_{a1}, s_{d1}. These are substituted along with s_2 and N_{d2} into Eq. [15] which are then solved for s_{a2}, s_{d2}. The process continues as far as measurements have been made. The values of s_{d1}, etc., *vs.* N_{d1}, etc., give the actual variation of net donor concentration with distance from the junction, *e.g.*, curve B of Fig. 4. Using this result the position coordinates s_a, s_d, may now be related individually to C and hence to v since $C(v)$ is a measured function. In this way the mobility, previously determined as a function of N_d, is directly related to distance from the junction. For diffused junctions, such as Fig. 6, the penetration on the diffused side is normally quite small and may generally be neglected. When this is not the case it is again possible to use Eq. [13] and through a process of graphical integration determine the quantities s_a, s_d.

It is of interest to determine the range over which the above measurements may be carried out. To do this, we observe from Gauss' electrostatic theorem that the maximum field, which occurs at the junction, $E_{max} = Q/\epsilon \approx 300$ kv/cm. From this we obtain the maximum net area density of donors or acceptors which can be included in the space charge region before breakdown, *i.e.*, $Q/q \approx 3 \times 10^{12}/\text{cm}^2$. Thus, for example, impurities at an average density of $10^{15}/\text{cm}^3$ can be measured out to a distance of 30μ from the junction, a value which is not affected by the distribution of impurities on the other side of the junction. On the other hand, E_{max} may be calculated by integrating the charge due to the measured distribution of net donors or acceptors out to the point of breakdown. This technique is useful for detecting premature breakdown of junctions due to surface effects or field concentrators in the space charge region.

Results

The results of measurements of n-type epitaxial layers on p-substrates and n-type wafers with diffused p-type surface layers are shown in Fig. 5 and 6. For the epitaxial layer of Fig. 5, the solid lines give the net donor concentration, calculated from Eq. [11], and the mobility, calculated from Eq. [10], as a function of total space charge width, calculated from Eq. [12]. The value of N_a used in Eq. [11] was measured as $3.0 \times 10^{15}/\text{cm}^3$. The dashed curves are the result of the graphical integration of the solid curves using Eq.

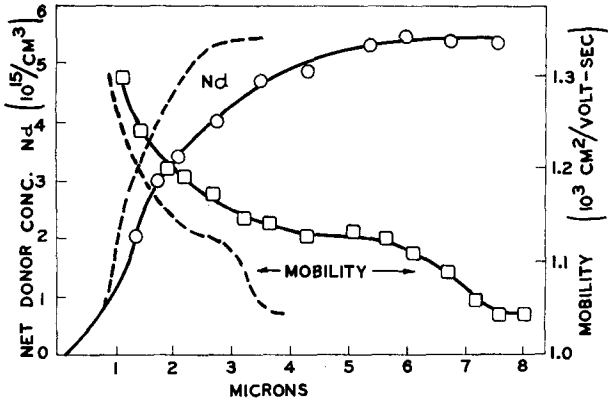

Fig. 5. Variation of mobility and impurity concentration in an n-type epitaxial layer on a p-type substrate. For the solid curves the abscissa is total space charge width. For the dotted curves abscissa is distance into the n-region measured from the junction.

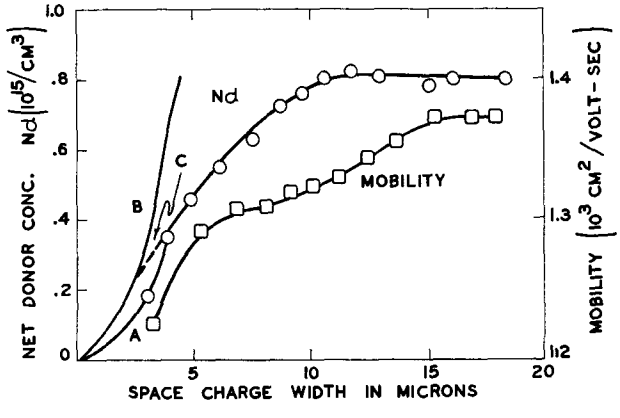

Fig. 6. Variation of mobility and impurity concentration in an n-type substrate with a p-type diffused layer. Curve A is for infinite impurity concentration on p-side of junction. Curve B is for a symmetrical junction. Curve C (dashed) is interpolated between A and B.

[13] as described above. In this case the abscissa is distance from the junction. In the net donor concentration we observe a slow increase in impurity concentration, approaching an asymptote about 3μ from the junction. This increase has been explained (4) as due to etch back of the relatively pure substrate material which dilutes the n-type impurity in the gas phase, so that the first deposited layer is less heavily doped. An alternative explanation is that during the initial growth stage the ratio of n-type impurity to Si deposited is lower than its ratio in the gas phase owing to selective decomposition of $SiCl_4$. This results in a boundary layer next to the growth interface which is enriched in impurities, the process continuing until a steady state is reached. In either case, a reduction in mobility is expected owing to the build-up of impurities in the layer as distance from the junction increases. This is observed as plotted in the two lower curves. The mobility appears to approach an asymptote at about the same position as the impurity concentration asymptote but then suffers another reduction as the surface of the layer is approached. The latter effect is not explained at the present time. As a simultaneous check on this determination of the impurity and mobility profiles it is observed that by integrating the product of these quantities and the electronic charge over the layer, the total sheet conductivity of the layer is obtained, a quantity which can be directly measured by the four probe technique. The limit of integration is determined by a bevel and stain measurement of the layer thickness. The result is expressed by

$$\sigma_s = \int_0^t q\mu_d(s_d)\, N_d(s_d)\, ds_d \qquad [16]$$

Since it is usually necessary to extrapolate μ_d and N_d some distance to the surface of the layer, Eq. [16] is only a rough check. For the specimen of Fig. 5 the difference between the calculated and measured values of σ_s is less than 5%.

In the case of the diffused junction, the mobility variation in the substrate as shown in Fig. 6 is opposite to its variation in the epitaxial layer. The sample is a deep (40μ) gallium diffused p-type region on a 5 ohm-cm n-type substrate. In this case the measured variation in μ_d is due to compensation of the substrate impurities by the tail of the gallium diffusion, so that the total impurity concentration increases as the junction is approached from the n-side, causing a reduction in mobility.

Summary

It has been shown that the conductivity mobility and carrier density may be directly measured in the vicinity of blocking junctions. The probe method of measurement does not require the application of permanent contacts and is therefore useful for characterization of materials to be fabricated into semiconductor devices. In epitaxial layers the mobility is found to increase as the junction is approached. In diffused junctions the mobility is found to decrease as the junction is approached from the substrate side. The difference is attributable to the fact that the diffused junction is produced by compensation, which results in a greater density of scattering centers at the junction than in the substrate, whereas the nature of epitaxial growth is such as to produce a smaller density of scattering centers at the junction than in the layer.

Diffusion of Gold into Silicon Crystals

G. J. Sprokel and J. M. Fairfield

International Business Machines Corporation, Endicott and Poughkeepsie, New York, respectively

ABSTRACT

Profiles are obtained for gold diffusing into silicon wafers of finite thickness. The profiles do not obey Fick's law. The effects of shallow diffusions of phosphorous and boron on the gold concentration are described; gold concentration is higher in areas of high phosphorous concentration.

Gold is used quite extensively to control the charge storage time of high speed diodes and transistors. Therefore, the diffusion of gold into silicon wafers of finite thickness is important in the design and fabrication of these devices. The diffusion of gold into silicon has been discussed by Struthers (1), Boltaks (2), Dash (3), and more recently by Wilcox and LaChapelle (4). It has become apparent from these publications that gold diffuses quite fast (1, 2), probably occupying interstitial positions of the silicon lattice, and that at least part of these interstitial atoms may convert to substitutionals (3).

In the above diffusion studies experimental conditions were such that the diffusing gold never pene-

trated through the whole specimen. If, however, gold is allowed to reach the opposite surface, as it is in practical applications, unexpected effects are observed. The concentration near the opposite surface is higher than expected and is affected by the state of that surface. It is the purpose of this paper to discuss these effects in some detail.

Experimental Procedures

Briefly, the experimental procedure is as follows. Gold labeled with Au 199 is plated on and diffused into silicon wafers in an argon atmosphere. Thin slices are etched off sequentially, starting at the side opposite the plated surface. The amounts of gold and silicon in each etchant sample are determined, and concentration profiles are constructed from these data.

Wafers are cut from pulled silicon crystals, and the surfaces are lapped and etched. The concentration of electrically active impurities is about 10^{13} at./cm^3. The wafers are approximately 25 mil thick.

Some of these wafers were diffused with phosphorus or boron to study the effects of these diffusions on the gold concentration. Planar structures were used, having been prepared in the conventional way. Silicon oxide was grown thermally; windows were etched in using photolithography; phosphorus or boron was diffused in the window areas to a depth of approximately 1μ. Then gold was plated on the opposite side and diffused in.

Detail.—Carrier-free Au 199 obtained as gold chloride[1] is dissolved in HNO_3/HCl and freeze-dried. The residue is taken up in 1 ml of a plating bath containing $KAu(CN)_2$ 0.01*N*; KCN 0.2*N*; Na_2HPO_4 0.03*N* (5). Immediately before plating the surface is "roughed" using 600 grit SiC paper and cleaned ultrasonically. Adhering plates were obtained on all wafers. The plate contains 1.5 x 10^{18} at. of Au, sufficient for an average concentration of 4 x 10^{19} at./cm^3 in the wafer. The ratio of Au 199 to Au 197 is adjusted to about 10^{-4}, sufficient for a detection sensitivity of 5 x 10^9 at. Au/cpm.

The gold is diffused in an argon atmosphere to prevent oxidation of the wafer surface. The argon gas was monitored for Au 199. Evaporation of gold is negligible.

In preparation for the etching sequence, the wafer is cemented to a Teflon[2] rod with the plated side toward the Teflon. The rod is inserted into a polypropylene test tube, containing 5 ml etching solution cooled to about 0°C in melting ice, and rotated to provide gentle agitation. The etching solution used in most of this work is a mixture of 3 parts HNO_3 s.d. 1.4; 2 parts glacial acetic acid; and 1 part HF 48%. Etching times are adjusted to remove the amount desired, then the etching solution is replaced and the process repeated until the wafer is dissolved.

Immediately after etching all samples are assayed for gold by counting the Au 199 gamma peak at 0.158 Mev in a single channel gamma spectrometer. By comparing the count rates of the etchant samples with the count rate of known aliquots of the plating bath, the amount of gold in the etchant is calculated. The amount of silicon in the etchant is determined by neutron activation analysis. The etchant solution, transferred into a suitable polypropylene container, is irradiated with fast neutrons produced by the reaction T(d, n) He 4.[3] The assay of silicon is based on the reaction Si 28 (n, p) Al 28. The only interfering reaction is O 16 (n, p) N 16. Compton scattering from the O 16 gammas causes considerable background at the silicon peak. Therefore the etchant samples are cooled for 2.5 min before they are counted. The O 16 activity has now decayed to 10^{-6} of the original amount, while Al 28 activity has decreased only to 0.46. The neutron flux is not constant enough for quantitative work, therefore each etchant sample is irradiated together with a silicon standard. From this one can calculate the total flux for the particular irradiation period, but since the fast neutron flux is moderated by the etchant solution (essentially water) a correction is necessary. The correction can be obtained by irradiating a silicon standard together with a solution made by dissolving a known amount of silicon in etching solution. The sensitivity of the method for pure silicon, under the experimental conditions of this study, is about 5 μg/cpm at a background of about 4 cpm, and for the etchant solution about 10 μg/cpm at a background of about 10 cpm. This background depends on the chemicals used; in particular HNO_3 contains measurable amounts of silicon. The samples of etchant solution contain 5-20 mg of silicon. Therefore the sensitivity is quite adequate. Since chemical operations are not involved the method of assay is quite fast, about 10 min/sample.

The amount of silicon in the etchant solution determines the thickness of the slice removed from the wafer. The amount of gold in the etchant solution and the volume of the slice determine the local concentration of gold. The sum of the thickness of the slices should add up to the thickness of the wafer. The difference is usually less than 0.001 in., the average for all wafers checks within 0.0002 in. However, the standard deviation for one sample is about 25% of the average. Since this would cause a similar spread in the data for the gold concentration, determination of the actual amount removed greatly improves the accuracy of the data.

Results

Concentration profiles.—Figures 1 and 2 show concentration profiles after diffusion at 1000° and 1100°C, respectively. All profiles are characterized by a nearly horizontal central region. Near the gold side the concentration drops 2 or 3 orders of ten in a distance of 1 or 2 mils. Near the opposite side the concentration tends to increase. The concentration in the central

region increases with diffusion time as indicated in Fig. 3 and 4, but the location of the steep gradient near the gold side is independent of time. Therefore the steep gradient must be considered an artifact of the experiment. At the plated surface gold-silicon eutectic is formed. The eutectic melt does not wet the surface but may well extend, in localized spots, to a depth of a few milli-inches.

Radial homogeneity.—Data in the previous section refer to the average gold concentration in a slice. Autoradiograms of etched wafer surfaces indicate substantial homogeneity across the surface. However, nearly all autoradiograms made in the course of this study show spots of much higher gold concentration. The number of such spots is small except near the original wafer surface. Spots tend to conglomerate at the original surface, but a shallow etch removes most of this activity. The size of single spots on the film is of the order of 10μ. The activity in one spot cannot be measured directly from the optical density because the x-ray film is overexposed at that spot. To make an appreciable contribution to the total, the activity in one spot would have to be 10^6 times larger than the average, which is unreasonable. Therefore, wherever the number of spots is small, the contribution of this localized gold can be neglected.

Often the same configuration of spots appears in autoradiograms from several sequential etches. In such cases gold has clearly accumulated along lines extending into the crystal, probably dislocations. These lines may extend 5 mils or more. Since their number is small, typically less than 1/mm^2 they cannot contribute to a fast transfer of gold through the wafer.

If a wafer which has been shown to contain this type of gold accumulation is heated for a long time (20 hr or more), no appreciable change in the number of spots is found. Under these conditions there is no external supply of gold, and since the lattice is far from saturated one would expect the accumulations to disappear completely if they contributed to the transfer.

Surface effects.—The amount of gold collecting near a wafer surface depends on the surface preparation. It is smaller for etched surfaces than for etched and oxidized surfaces. If a gold diffused wafer is etched and heated again, gold collects near the surface mostly in localized spots which can be removed by a shallow etch in agreement with an earlier observation (7). The increase in the gold concentration under an oxide layer can be used to prepare autoradiograms of oxide-masked wafers. The window areas appear lighter.

Shallow phosphorous diffusions also affect the gold concentration. At high phosphorous concentrations (8 x 10^{20} at. P/cm^3 at the surface) the window areas are darker and have therefore collected more gold (Fig. 5a). However, at low concentrations (2 x 10^{20} at. P/cm^3 or less) the masked areas are darker. Therefore the mask dominates at low concentration (Fig. 5c).

The electrical junctions are about 1-2μ from the surface. If substantially more than this is etched-off, a pattern as in Fig. 5a reverses; the window areas are now lighter. A pattern as in Fig. 5c remains unchanged. Therefore, the effect of the masking still persists 10 or 20μ from the SiO_2/Si interface (Fig. 5b and 5d). The window areas in Fig. 5b and 5d are no longer sharply delineated but appear diffuse. Examining autoradiograms of gold in a phosphorous diffused area under a microscope shows that the gold is not uniformly distributed over the area but tends to build up near the edges (Fig. 6). Boron diffusion does not produce comparable effects but the highest concentration used was only 1 x 10^{20} at. B/cm^3.

Discussion

From Fig. 1-4 it is seen that the concentration of gold in bulk silicon, introduced from an infinitely large source at the surface, increases smoothly with time, rapidly for short diffusion times but only slowly for longer diffusion times. At 1100°C the gold concentration is 2.2 x 10^{16} at./cm^3 after 42 hr diffusion time. At 1000°C the concentration is 9.8 x 10^{15} at./cm^3 after 250 hr. Collins, Carlson, and Gallagher (7) have reported data on the solubility of gold in silicon. Details are not given, but by interpolating the graph in Fig. 1 of their paper, the solubility may be shown to be approximately 3 x 10^{16} at./cm^3 at 1100°C and 9 x 10^{15}

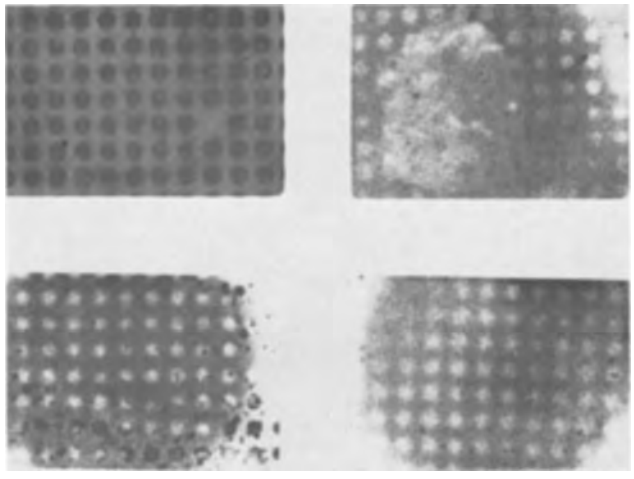

Fig. 5. Au 199 autoradiograms of P diffused wafers. Circular windows (diameter 400μ) etched in oxide mask. P diffused from PH_3. Junction depth 1-2μ. Au 199 diffused from a plate on the opposite surface. Excess removed prior to exposure. (a) (top left) 8 x 10^{20} P/cm^3. After Au diffusion oxide mask removed in HF. Window areas contain more gold than masked areas; (b) (top right) same as 5a but etched to a depth of 10μ. Window areas are now lighter. The area in the center indicates the spot where the oxide mask was removed prior to gold plating (to assure good contact); (c) (bottom left) 2 x 10^{20} P/cm^3. Window areas contain less gold than masked areas. Autoradiogram shows the original surface, before cleaning in HF. Notice spots of high Au concentration in 5c, absent in 5a; (d) (bottom right) Same as c but etched to a depth of 25μ. The pattern remains unchanged.

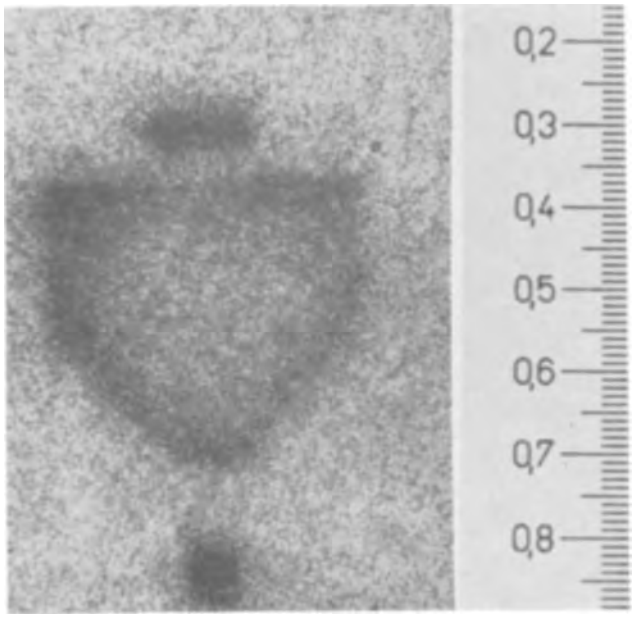

Fig. 6. Accumulation of gold in a phosphorous diffused area, starting at the circumference and proceeding inward. It appears that the intersection of mask and window has a larger effect on the gold concentration than the diffused phosphorous itself. (Scale 10μ/div.).

at./cm^3 at 1000°C. Numerically these data agree well; however from the slope of the curve in Fig. 3 it is doubtful whether solubility has been reached. The true solubility is probably slightly higher. The data in Fig. 3 and 4 will be used in a forthcoming paper (8).

The buildup of gold occurs much faster around areas of lattice imperfections or discontinuities (*e.g.*, surfaces, dislocations, phosphorous diffusion, etc.). This phenomenon can be explained by an interstitial-substitutional model, as discussed by Frank and Turnbull (9) for copper in germanium and used by LaChapelle and Wilcox (4). Gold diffuses rapidly as an interstitial but converts to a relatively immobile substitutional by combining with a lattice vacancy. This conversion occurs more rapidly near sources of vacancies.

Surfaces are sources of vacancies; thus the total concentration builds up near the surface as evidenced by the graphs in Fig. 1 and 2. Thermally oxidized surfaces can produce more vacancies than unoxidized surfaces. Mechanical damage of the surface can produce more vacancies still.

The observed accumulation of gold along lines extending into the crystal may well represent dislocations. A mechanism discussed by Dash (3) in which the collecting gold induces dislocations to climb could well be operative. The stability of these accumulations emphasizes the relative immobility of gold atoms in the substitutional state.

Finally, damage or dislocations from high surface concentrations of phosphorus act as sources of vacancies and thereby collect gold relatively rapidly. This fact is particularly important when high surface concentration phosphorous diffusions are used to make high speed diodes and transistors. In such devices, the amount of gold is intimately related to the charge storage times.

Conclusion

There is qualitative evidence for the interstitial-substitutional mechanism; a gold atom diffuses as an interstitial but is converted to a nearly immobile substitutional. The conversion occurs everywhere but is particularly prominent near sources of vacancies. Gold collects especially fast in areas prediffused with a large concentration of phosphorus.

Gold can be used to study damage done to a lattice by phosphorous diffusion or oxidation.

A Study of the Dissolution of Zinc in Buffered Acetic Acid Solutions

Robert S. Alwitt[1] and Robert S. Kapner

Department of Chemical Engineering, Rensselaer Polytechnic Institute, Troy, New York

ABSTRACT

The kinetics of zinc dissolution in buffered acetic acid solutions are described. The dissolution process occurred along the walls of zinc tubes with acid solutions passing through the tubes in laminar flow. Only a moderate degree of diffusional resistance in transporting reactants to the reaction surface was observed. The data indicate that molecular acetic acid as well as hydrogen ions participate in the cathodic reaction. Possible dissolution mechanisms are proposed based on simultaneous reactions involving hydrogen ion and molecular acid discharge at the metal surface. Only at high acid concentrations does the molecular acetic acid discharge reaction become important.

The purpose of this investigation was to obtain information on the kinetics of the dissolution of zinc by acetic acid. Using buffered acid solutions, in which the *p*H and molecular acid concentration could be varied independently, information was obtained on the role of the weak acid molecule in the dissolution process. There is little information in the literature on this point.

Kilpatrick and Rushton studied the dissolution of rotating zinc and magnesium cylinders in deaerated solutions of HCl, acetic acid (HAc), and other weak acids (1). They found the reaction rate to be dependent on rotational speed and viscosity, both indicative of a significant degree of diffusion control. However, for both HCl and HAc, the activation energy was about 10 kcal/mole, far greater than the 3-4 kcal/mole to be expected for a reaction under complete diffusion control. The reaction rate was first order with respect to total acid concentration, but not to the hydrogen ion concentration alone. They concluded that the surface reaction was due to both ionic and molecular acids, but the results were not clear-cut. Levich (2) reported a study of the dissolution of rotating magnesium disks in 0.1*N* HCl, 0.15*N* HAc, and 0.15*N* HCOOH. The data indicated that in all cases the reaction rate was determined by the diffusion of acid to the surface. Allbutt and Tolley (3) determined the dissolution rate of zinc in dioxan-water solutions of HCl. At sufficiently high dioxan concentrations an appreciable fraction of the HCl was present in molecular form. In these solutions the data indicated the possibility of direct reaction between zinc and covalent HCl.

The dissolution of a metal by an acid can be considered as consisting of simultaneous anodic and cathodic electrochemical processes. According to the Wagner-Traud theory of mixed potentials (4), which has been substantiated for simple systems, each process can be analyzed independently of the other. In this paper only the cathodic processes occurring on the zinc surface are discussed. In a strong acid, the usual cathodic reaction is reduction of hydrogen ions to atomic hydrogen and thence molecular hydrogen. With a weak acid, another possible cathodic reaction is reduction of the molecular acid species.

It was anticipated that dissolution would be under significant diffusion control, which would result in the reactant wall concentration being less than the bulk concentration. In such a situation it is imperative that the experimental reactor be of a design that will permit calculation of wall concentrations from experimentally measurable quantities. The two designs most frequently used for this purpose are the rotating disk and the tubular reactor. The latter was used in this study.

The "quasi-stationary" technique of Frank-Kamenetskii (5) was used to calculate wall concentrations. This method assumes that the conditions of diffusional transport can be considered independent of the course of the surface reaction. The fact that the diffusion and reaction processes are coupled by a surface boundary condition is neglected. This results in consideration only of transport in the direction normal to the surface, neglecting reactant that arrives due to longitudinal convective transport. Any error inherent in this method can be substantially reduced provided longitudinal concentration differences are kept very small. This can be easily accomplished in a differential reactor, one in which reactant conversion is minimized.

With these assumptions, the amount of reactant supplied at steady state to an element of reactor surface is

$$q = \beta (C - C_W) \qquad [1]$$

At steady state, q must equal the surface reaction rate. The definition of β, the diffusion velocity constant (or mass transfer coefficient) is $\beta = N_{Nu}D/d$. Since diffusion is considered to be independent of the surface reaction process, β can be determined from analogous heat transfer data or theory. With q and C determined experimentally it is a simple matter to calculate C_W.

Experimental

The dissolution of zinc by buffered and unbuffered solutions of acetic acid was studied in a tubular reactor. The ranges of the independent variables were: C_{HAc}, 10^{-3} to 10^{-2}M; *p*H, up to 6.0; N_{Re}, 50-1000. Sodium acetate was used as the buffering salt. Except for runs to determine the heat of activation, the temperature of the test section was maintained at 30° ± 1°C. Prepurified nitrogen was bubbled through the acid solution for 4 to 12 hr prior to the start of a run to remove dissolved oxygen. Reagent grade chemicals and distilled water were used throughout. The reactor section was made of 99.999% zinc. As-received zinc billets were pickled, recast in Pyrex tubes, machined to the dimensions of schedule 80 ¼ in. pipe, and chemically polished. These zinc tubes were annealed in an argon atmosphere for 24 hr at 350°C and then repolished. Metallographic examination at 400X showed no evidence of cold-work on the inner surface of a sample.

The test apparatus is pictured in Fig. 1. The test section consisted of three lengths of zinc tube connected by flange and O-ring assemblies to give a total length of 33.3 cm. The dissolution rate was low enough so that the inside diameter of the tubes did not change significantly during these runs. Entrance and exit

sections were schedule 80 ¼ in. PVC pipe of sufficient length to insure well-developed laminar flow in the test section. Acid solution was fed through the reactor by maintaining a constant positive head at the outlet of the acid reservoir with a pressure-regulated source of nitrogen. Flow rate was regulated with the stopcocks after the rotameters. Reaction conditions were such that the hydrogen concentration never exceeded the solubility of hydrogen. The test section and polyethylene acid reservoir were held at constant temperature by a temperature controlled circulating water bath heated by immersion heaters not illustrated in Fig. 1.

Procedure.—When not in use, the test section was filled with distilled water. At the start of a run, 2 x $10^{-3}N$ HAc was run through for 40 min to remove any oxide build-up on the tube surface during storage in water. Acid made up to the desired composition in the reservoir was passed through the reactor at several flow rates. At the slowest flow rate it was found that after running for 20 min steady-state conditions were assured. At all flow rates, 20 min were allowed before collecting effluent samples. The concentration of zinc in the effluent was determined for each flow rate using a modification of the spectrophotometric method of Rush and Yoe (6, 7). At each acid composition 3-6 flow rates were run in random order. Corresponding to each effluent sample the potential of the zinc was determined with reference to a saturated calomel electrode (SCE) kept at 30°C in the same water bath. Potential readings were made with a Beckmann Model G *p*H meter. Further details of the experimental apparatus and procedure can be found elsewhere (8).

Results

From the data of replicate runs it was found that reaction rates were reproducible within ± 15.8% and corrosion potentials were reproducible within ± 6 mv, both at the 95% confidence level.

For each acid composition the least squares line for log C_{Zn} *vs.* log N_{Re} was determined. Some typical results are shown in Fig. 2. The average slope of all runs was —0.930 ± 10.3%. The slope was not a function of HAc concentration or *p*H. In the absence of diffusional effects the slope would be —1 and for complete diffusion control it would be —2/3. There is no theoretical reason for a linear relationship in the region of intermediate control. In the present case the justification is that the residual variance of the least squares lines was not significantly greater than the variance of replicate points.

Since there were some diffusional effects, the concentration of reactants at the wall were less than the bulk concentrations. The wall concentration of HAc was calculated using the approximate method of Frank-Kamenetskii (5) described above. For each acid composition the calculation was made at N_{Re} = 150, using the C_{Zn} from the least squares line to determine the average reaction rate over the reactor. The average Nusselt number for a tube of length L is $1.61(N_{Pe}d/L)^{1/3}$ (9). Over the range of bulk concentration used, the diffusivity of acetic acid varies less than 1% and was calculated to be 1.34 x 10^{-5} cm²/sec at 30°C (10). Using these values and the dimensions of the reactor, the value of β in Eq. [1] was 3.78 x 10^{-4} cm/sec. An experimental determination of β agreed within 5% with the calculated value. The fraction of acid reacted was always less than 3%, so the reactor was considered a differential reactor with bulk acid concentration equal to the inlet value.

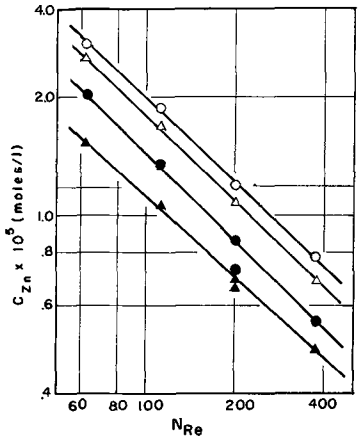

Fig. 2. Typical experimental results. ${}_BC_{HAc} \times 10^3$: ▲, 2.00; •, 3.92; △, 7.76; ○, 10.04.

The average value of the ratio ${}_WC_{HAc}/{}_BC_{HAc}$ calculated from Eq. [1] was 0.895. Ninety-five per cent of the values were greater than 0.75. Assuming no concentration gradient in acetate ion, the gradient in C_{H^+} was proportional to that in C_{HAc}. Figure 3 shows the relationship between C_{Zn} at N_{Re} = 150 (proportional to reaction rate) and wall concentration of HAc at various bulk *p*H values.

The electrode potential of the zinc was independent of flow rate. It was a function of acid concentration

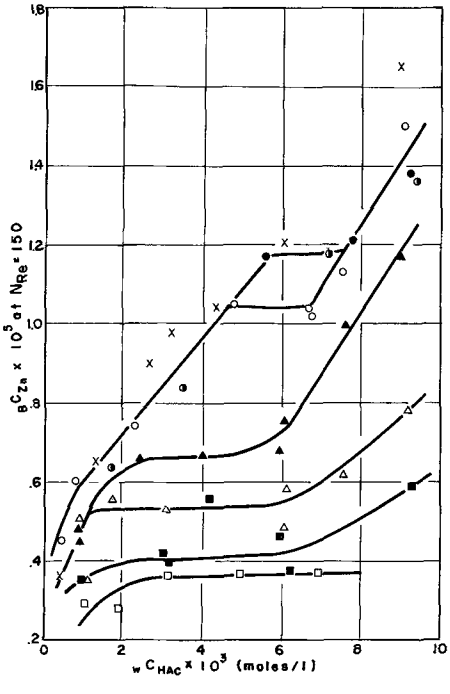

Fig. 3. Reaction rate vs. wall concentration of acetic acid. N_{Re} = 150; *p*H: X, no buffer; •, 3.50; half dark circle, 3.80; ○, 4.10; ▲, 4.50; △, 5.00; ■, 5.50; □, 6.00.

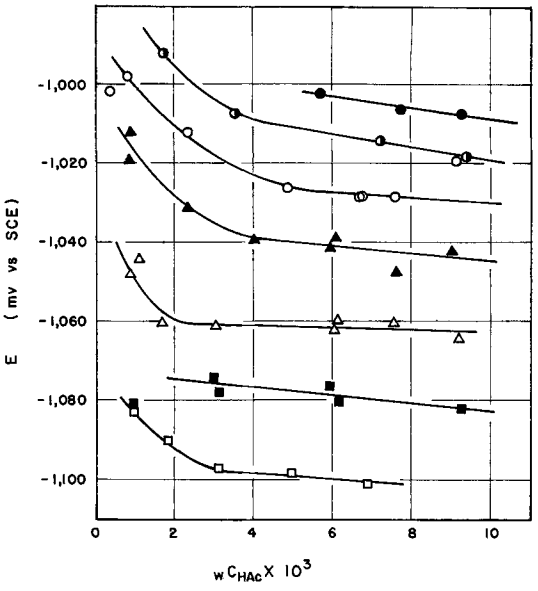

Fig. 4. Zinc potential vs. wall concentration of acetic acid. N_{Re} = 150; pH: ●, 3.50; half dark circle, 3.80; ○, 4.10; ▲, 4.50; △, 5.00; ■, 5.50; □, 6.00.

and pH, as shown in Fig. 4. Values of potential with unbuffered acid are not given since it was very difficult to obtain steady or reproducible results with these solutions. At a concentration of 5 x 10^{-3}M, acetic acid has a conductivity of only 100 μmhos. With this acid the impedance of the solution path between the zinc and the reference electrode was about one megohm. This is high enough to account for the observed erratic potential readings.

The change of reaction rate with temperature was determined for three solution compositions. The apparent energy of activation was determined from the slope of the log rate *vs.* $1/T$ plots shown in Fig. 5. The results were corrected for diffusional effects using a graphical relationship developed by Rosner (11). The results with each solution were as follows:

Solution $C_{HAc} \times 10^3$	pH	Activation energy (kcal/mole) Exptl.	Corr.
1.37	4.08	4.55	5.83
5.23	5.98	4.62	4.87
9.70	4.10	4.90	5.50

An average value of 5.4 kcal/mole would apparently be accurate within ± 10% over the range of experimental conditions.

Discussion

The transport of reactants to the zinc surface played a much smaller role in the over-all reaction rate than had been expected. The use of ultrahigh purity zinc (99.999%) and a reaction surface free of cold work apparently reduced the surface reaction rate sufficiently so that diffusion was not the predominant slow step.

The calculated wall concentrations are those that would exist at the zinc-solution interface in the absence of all other effects except convective forces and concentration gradients. However, at a metal-electrolyte interface there will exist an electric double layer (edl) with its associated electric field. The thickness of the edl varies, but is usually considerably less than 1000Å. Thus, within any reasonable experimental accuracy, the calculated wall concentration can be taken as that existing at the solution boundary of the edl. Uncharged species will be little affected by the edl, so the calculated wall concentration of HAc molecules are representative of the true interfacial concentration. However, ionic concentration in the edl is a function of potential and ionic strength as well as bulk

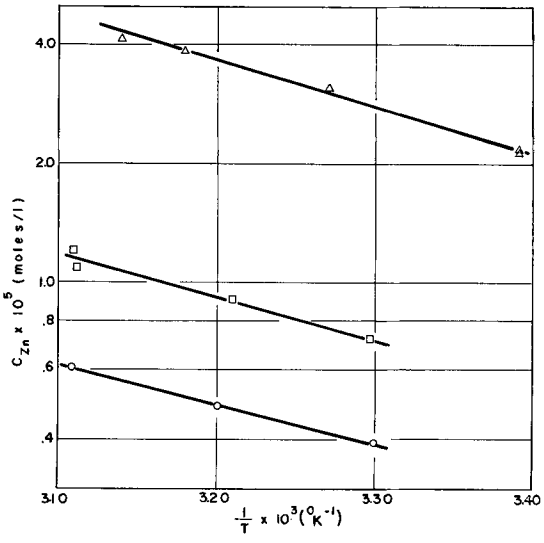

Fig. 5. Arrhenius plot for determination of over-all activation energy:

Symbol	$_BC_{HAc}$	pH	N_{Re}
□	1.37×10^{-3}	4.08	125
○	5.23×10^{-3}	5.98	200
△	9.70×10^{-3}	4.10	100

(wall) concentration.[2] At high ionic strength (> 1M), it can usually be assumed that ionic concentrations within the edl are the same as those outside the edl. In this study ionic strength was determined primarily by the sodium acetate added to adjust pH, and was always less than 1M. Thus, it was not possible to analyze the rate data quantitatively to evaluate possible reaction mechanisms without introducing several assumptions about the properties of the edl. However, qualitative analysis of the data yields some interesting information.

Examination of Fig. 3 shows that at each pH there is a range of C_{HAc} over which rate is independent of C_{HAc}. At lower and higher C_{HAc} the rate depends on C_{HAc}. In Fig. 4 it is seen that at each pH the electrode potential changes rapidly at low C_{HAc} and then changes little with further increase in C_{HAc}. The increasing reaction rate at low C_{HAc} and constant pH could be due to the changing potential rather than to a dependency on C_{HAc}. Since the potential is relatively stable at each pH at high C_{HAc}, the increase in reaction rate in this region appears to be a function of C_{HAc}. It is interesting that the data at high C_{HAc} can be extrapolated linearly to the origin with a slope dependent on pH and/or E. This is indicative of a reaction that is first order with respect to HAc.

The experimental data may be explained by a reaction scheme in which at low C_{HAc} the rate-controlling step of the cathodic reaction is a function of pH and E. At high C_{HAc} the rate-controlling step is a function of pH, E, and C_{HAc}. The simplest way for this to occur would be by means of parallel reaction paths, one path involving a proton and the other an HAc molecule. As the HAc concentration increased, the second reaction would be favored.

It is generally accepted that reduction of H^+ on a metal proceeds in the following sequence

$$H^+ + e \rightarrow H \qquad [2a]$$

followed by either

$$H + H \rightarrow H_2 \qquad [2b]$$

or

$$H + H^+ + e \rightarrow H_2 \qquad [2c]$$

[2] Breiter *et al.* (12) give a brief description of the effect of the edl on surface reactions. More detailed information is in chapters by Parsons and Frumkin in ref. (13).

It is possible that reactions analogous to [2a] and [2c] can occur involving HAc molecules, *e.g.*,

$$HAc + e \rightarrow H + Ac^- \quad [3a]$$

$$H + HAc + e \rightarrow H_2 + Ac^- \quad [3b]$$

At low C_{HAc} the rate-controlling step might be [2a], followed by [3a] at high C_{HAc}. Or, at low C_{HAc} the rate-controlling step might be [2b] or [2c] followed by [3b] at high C_{HAc}. The standard electrode potential is —0.280v for the reaction, $HAc + e = \frac{1}{2} H_2 + Ac^-$. When compared with the standard electrode potential of —0.763v for the reaction, $Zn = Zn^{+2} + 2e$, it is seen that the reduction of molecular acid is quite feasible in this system.

Other reactions first order with respect to C_{HAc} are also possible. For example, reduction to acetaldehyde

$$CH_3COOH + 2H^+ + 2e = CH_3CHO + H_2O \qquad E_o = -0.118v$$

Yakhontov (14) found small amounts of acetaldehyde present after reacting zinc with 40% and 60% acetic acid at 100°C. However, considering the conditions of the present experiment, it is doubtful that this reaction contributed significantly to the observed rate.

For a discharge reaction such as [2a] or [3a] the energy of activation is generally greater than 10 kcal/mole. The observed energy of activation was significantly less than this. If surface coverage with atomic hydrogen was high, a reaction between adsorbed H atoms or between adsorbed H atoms and a species in solution might proceed with a much lower activation energy. Among others, Bockris and Potter (15) reported a study that showed that on tungsten and nickel surfaces the heat of adsorption of H atoms falls considerably at coverages above about 70% until at about 90% coverage the heat of adsorption is about 5 kcal. Thus, the observed heats of activation may be indicative of significant surface coverage. Such coverage could explain the relative constancy of the heat of activation even when measured at conditions at which different reactions might be rate-controlling.

On this basis it does not seem likely that discharge of H^+ or HAc were rate-controlling steps. The data do not permit distinguishing whether reaction [2b] or reaction [2c] was rate-controlling at low C_{HAc}. Whichever one of these was controlling at low C_{HAc}, it appears that a reaction such as [3b] became dominant at high C_{HAc}.

Additional work to confirm these suggested reactions is in progress. Experimental studies are being made using sufficient supporting electrolyte which will permit estimates of wall concentrations of ionic species. With these data a quantitative treatment of the dissolution mechanism can be undertaken. The effect of soluble inhibitors on the kinetics of this dissolution process is also being studied.

Conclusions

1. The dissolution of zinc in acetic acid can proceed under only slight diffusion control.
2. Molecular acetic acid can take part in the cathodic reaction on zinc in acid solution.
3. The dissolution reaction appears to occur through parallel reaction paths, one path involving a proton and the other an HAc molecule. As the HAc concentration increases, the second reaction is favored.

Conductance of Glass Immersed in Molten Salts

Kurt H. Stern

National Bureau of Standards, Washington, D. C.

ABSTRACT

The electrical conductance of high SiO_2 glass was measured when immersed in a number of molten salts and salt mixtures between 800° and 900°C. Sodium and lithium ions diffuse into the glass, both from their own chlorides and from low concentrations in KCl. The glass comes to equilibrium with each melt composition, the time of equilibration depending on the particular ions in the melt. The activation energy of sodium and lithium ion conduction in glass is 75-84 kJ (18-20 kcal), with potassium it is variable between 105 kJ (25 kcal) and 167 kJ (40 kcal). The conductance method is not sufficiently precise to detect silver and cuprous ion diffusion into glass.

In spite of several studies of the behavior of glass in molten salt media the detailed processes involved in the interaction between various glasses and salts are not yet well understood. The present state of knowledge may be summarized as follows: (*A*) Electrical conduction in silica glasses is ionic (1, 2), the magnitude of the current depending on the kinds of ions, their concentration, and the temperature. (*B*) Silica glasses containing alkali metal oxides are cationic conductors, the oxide anions remaining fixed in the glass structure (2). (*C*) Activation energies for conduction are similar to those for diffusion, typically 84-168 kJ (20-40 kcal) (3). (*D*) When a glass initially containing ions is placed into a molten salt, ion exchange may take place, ions from the glass diffusing out and ions from the melt diffusing in (4, 5). Factors determining this exchange are not well known. (*E*) When a high-purity (low ion content) glass, such as fused silica, is placed in a molten salt, ions from the salt diffuse into the glass (7). There is some evidence that the smaller of two ions in a salt mixture will diffuse preferentially into the glass (7), but specific ion-glass interactions may also be significant (6). (*F*) The surface composition of an ion-containing glass may differ from that in the bulk, both in the presence and absence of salt. The equilibrium composition is that giving the minimum surface free energy (8). (*G*) Some glasses, *e.g.*, Vycor, contain bound water as OH groups in the silica structure. In a water vapor environment these OH groups move, leading to net diffusion of H_2O through the glass (9, 10). Nothing is known of the effect of this bound water on the transport of ions through the glass. (*H*) If a glass initially containing no ions, *e.g.*, pure silica, is exposed to a molten salt whose cations diffuse into the glass, electrical neutrality requires that an equivalent amount of anions migrate into the glass also. Information on this point is largely lacking, although there is some evidence that anions migrate through glass under an applied field (11).

The present paper reports a study of the electrical conductance of high-silica glass, mainly Vycor, immersed in various molten salts. Two effects were studied: (i) changes of conductance with time, caused by the immersion of the glass in a salt or salt mixture, (ii) changes of conductance caused by changes in the melt composition and temperature, which are independent of time.

Experimental

The conductance cells consisted of 13 mm O.D. Vycor glass U-tubes ~ 25 cm high, with a 1 mm thick glass partition in the center of each cell separating the legs. The bright platinum electrodes, 1 cm^2 in area, were suspended by sealed-on platinum wires from glass caps which fitted over the ends of the cell. Thus the electrodes could be removed easily for addition of salt to the cell and repositioned. Since the resistance of the salt had been found (in a similar tube without partition) to be negligible compared to that of the partition, the precise position of the electrodes did not affect the measurement.

In each measurement the salt composition in both compartments was the same. 15g of the salt or salt mixture under study was placed in the preheated cell, already positioned in the center of the furnace, melted, the electrodes were introduced, and measurements begun.

Using a Marshall control panel and packing the cell in vermiculite kept the temperature constant to within ± 1°. The temperature was measured by a chromel-alumel thermocouple whose hot junction was positioned just outside the center of the cell. Resistance was measured with a Jones and Josephs-type bridge with Wagner ground at 1 kc. Between 1 and 10 kc resistance was independent of frequency. High resistances were measured in parallel with a high-precision 10^4 ohm resistor. In a typical measurement the cell was filled with one salt and allowed to equilibrate; the resistance was measured as a function of temperature. The desired amount of a second salt was then added and the procedure repeated. Further additions were made until the cell was full. Each new experiment was started with a new cell. In some experiments the conductance was measured as a function of time until equilibrium was reached.

Since it proved impossible to reproduce precisely the cross section and thickness of the glass partitions in the various cells, the actual values of $1/R$ have little significance when comparing measurements made in different cells. Changes occurring with time and melt composition in the same cell and the temperature coefficient of conductance both in the same and different cells are significant, however.

Reagent grade NaCl, KCl, and KBr were dried under vacuum at 500°C; LiCl was vacuum dried above its melting point. Anhydrous CuCl was prepared by reduction of $CuCl_2$ by sulfurous acid (12). Reagent grade AgCl was used without further purification.

Results and Discussion

In many of the experiments the salt initially put in the cell was KCl because it was known that potassium ions diffuse into glass only to a slight extent (7). Thus the addition of a salt whose ions diffuse into glass to a greater extent can be detected by an increase in conductance. Since, in addition to diffusion of ions into the glass, ions may also diffuse out, only relatively large changes in conductance can be considered significant. Thus, although a noticeable change in conductance on addition of salt is evidence for some glass-salt interactions, the absence of such a change does not necessarily imply absence of interaction.

Since most experiments were carried out with Vycor the subsequent results refer to that glass unless otherwise indicated.

General observations.—In the initial experiments, carried out with KCl, the cell was heated to 800°C

and the salt added. Fluctuations in conductance occurred for several hours, both with Vycor and fused silica, the conductance decreasing during this period by as much as a factor of four. If the empty cell was kept at 800°C for several days before introducing the salt, fluctuations were much reduced. A slow decrease in conductance still occurred for several days subsequent to the addition of salt, probably because the diffusion of sodium ions out of the glass is the predominant effect. The removal of fluctuations on heating the empty cell suggests that structural changes or loss of bound water are taking place.

In all experiments the conductance eventually reached a steady value, although this usually required several days. After the first few hours, changes were quite slow. When a steady value had been reached the temperature dependence of the conductance was measured between 800° and 900°C. In virtually all cases the conductance ($1/R$) was a linear function of $1/T$ so that the activation energy (E_a) is independent of temperature in this range. The addition of a second salt to the KCl already in the cell may or may not produce a change in conductance. If the former, the process described above generally repeats, *i.e.*, the conductance changes again, in some cases over a period of several days until another equilibrium value is reached.

Experiments with specific systems are described below.

KCl-NaCl

The addition of either KCl or NaCl to a cell which has only been heated to bring it to the temperature of the experiment (800°-900°C) leads to a fairly rapid decrease of conductance for several hours. Since the effect occurs even with NaCl it cannot be attributed to the diffusion of Na^+ ions out of the glass, (as it can for KCl) but is probably due to structural rearrangements of the glass, *e.g.*, loss of bound water. It appears likely also that Na^+ ions do not diffuse immediately into such a glass.

If the glass has been heated for several days prior to salt addition only a slow decrease of $1/R$ takes place with KCl, as expected for the diffusion of Na^+ out of the glass.

To study the effect of NaCl addition on the equilibrium conductance value the empty cell was first heated at 650°C for three days. After KCl had been added, $1/R$ decreased slowly for three days at 830°C from 1.04×10^{-5} to 0.245×10^{-5} reciprocal ohms after which $1/R$ remained constant. The temperature was then varied randomly for several hours between 800° and 900°. All points fell on the same linear $1/R$ *vs.* $1/T$ plot. A weighed quantity of NaCl was then added. The conductance became steady in a few hours and the temperature coefficient was again determined. The procedure was repeated several times until the cell was full. Results are shown in Fig. 1. The mole fraction of NaCl (X_{NaCl}) is shown to the right of each curve. The conductance increases with increasing X_{NaCl} and the temperature coefficient decreases. Both effects are linear in X_{NaCl} as shown in Fig. 2, where the Arrhenius activation energy has been calculated from the conductances at 814° and 890°C.

If KCl is added to glass originally equilibrated with NaCl the effect is much smaller and in the opposite direction, *i.e.*, the conductance decreases slightly. For example, with NaCl alone $1/R = 10.1 \times 10^{-5}$ reciprocal ohms, with $X_{KCl} = 0.34$, $1/R = 6.4 \times 10^{-5}$ reciprocal ohms. The Arrhenius activation energy E_a remains virtually constant at 77.4 kJ (18.5 kcal). These results indicate that potassium ions replace sodium ions only slightly in the glass, but that because of their larger size they block some of the available conductance paths in the glass structure. The much higher activation energy observed for KCl alone and its decrease with added NaCl are consistent with this view and with recent observations of membrane potential measurements on this system (7).

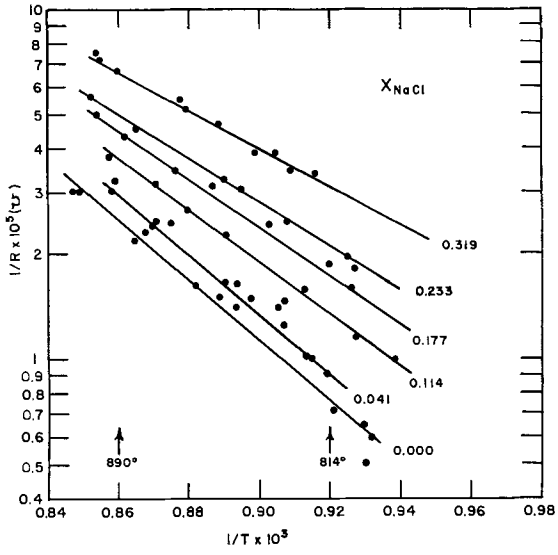

Fig. 1. Equilibrium conductance values of Vycor in various KCl-NaCl mixtures as a function of $1/T$.

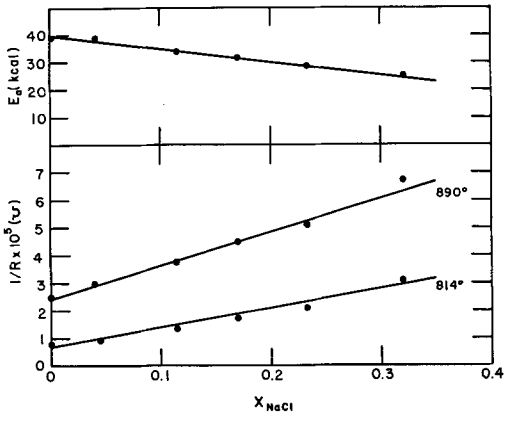

Fig. 2. Change in conductance and activation energy on the addition of NaCl to KCl, data of Fig. 1.

Similar, but less extensive, experiments were also carried out with fused silica (Vitreosil). The results were the same qualitatively, but much longer periods of time were required before constant conductance values were reached, possibly because this glass has less open pores than does Vycor.

KCl-LiCl

When LiCl is added to glass equilibrated with KCl, as described above, the conductance increases linearly with time, showing that lithium ions are diffusing into the glass. Figure 3 shows a typical plot for $X_{LiCl} = 0.055$. Even at this very low concentration lithium ions

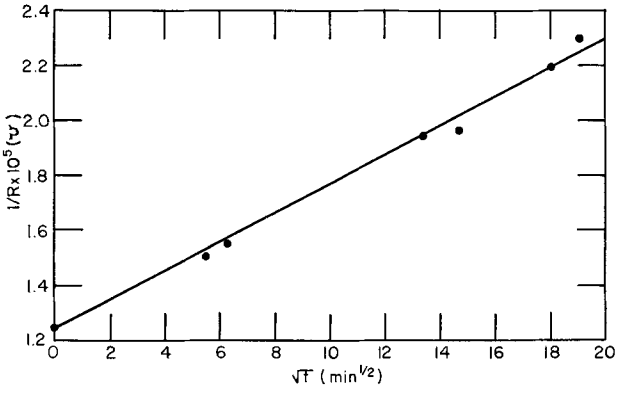

Fig. 3. Change in conductance of Vycor equilibrated with KCl on the addition of 5.5 mole % LiCl, 830°C.

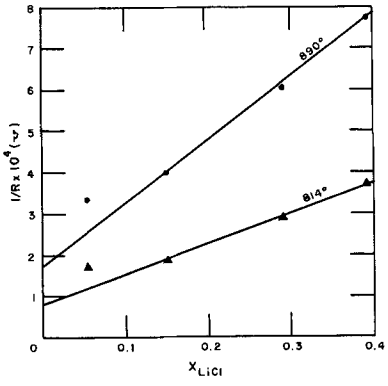

Fig. 4. Change in conductance of Vycor on the addition of LiCl to KCl.

are either displacing the slower potassium ions already in the glass or moving through unoccupied channels in the glass.

As with NaCl, new equilibrium conductance values are reached with successive additions of LiCl. Similarly, the conductance is linear in X_{LiCl} (Fig. 4). The activation energy remains constant as LiCl is added.

KCl-CuCl, KCl-AgCl

The addition of CuCl and AgCl to KCl produces no significant change in glass conductance up to 10 mole % added salt, the highest concentration used. This result does not imply that cuprous and silver ions do not diffuse into glass. That they in fact do so from their own pure molten salts is well known (6). However, when the glass has already been equilibrated with a salt whose ions penetrate the glass preferentially, diffusion of Cu^+ and Ag^+ is greatly reduced. For example, glass membrane potential experiments in the AgCl-NaCl (13) and CuCl-NaCl (14) systems indicate that nearly all of the cationic current is carried through the glass by sodium ions.

NaCl-LiCl

When the glass is initially equilibrated with NaCl instead of KCl the conductance is approximately ten times as great. This large increase indicates that both concentration and mobility of sodium ions in the glass are greater than those of potassium ions since the ionic mobilities probably do not differ by that much. The same conclusion was reached previously from experiments with NaCl additions to KCl.

When even small amounts of LiCl are added to NaCl the conductance rises still further. In contrast to the KCl-LiCl system, however, the increase in conductance occurs so rapidly, within a few minutes, that it cannot be followed accurately. A comparison of the two systems implies that the prior equilibration with NaCl has had a different effect on the glass structure than that with KCl (*cf.* Fig. 3), making it more permeable to Li^+ ions. Successive additions of LiCl cause corresponding increases in the conductance, the equilibrium values being linear functions of X_{LiCl}. Both this dependence and that on temperature are shown in Fig. 5 and 6. It thus appears that sodium ions do not occupy all of the possible conductance paths in the glass, possibly because some of them are too small for Na^+, although they can accommodate Li^+.

The effect of high NaCl concentration on glass can also be seen by comparing the increase in conductance produced by a given amount of salt. The addition of 10 mole % of NaCl and LiCl added to KCl increases the conductance by 8×10^{-7} and 12×10^{-7} reciprocal ohms, respectively; the addition of 10 mole % LiCl added to NaCl gives a change of 475×10^{-6}. This conductance increase is, however, almost entirely due to the very much larger initial conductance with NaCl as compared to KCl. Thus, the conductance increases by 22% when 10% LiCl is added to NaCl and by 15%

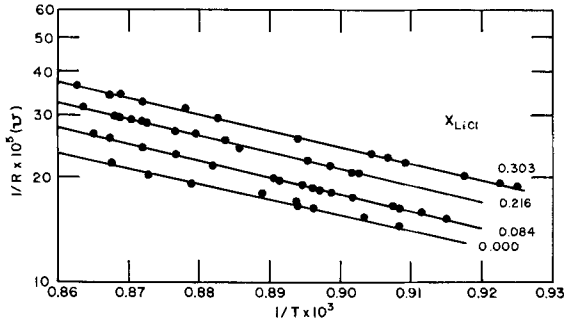

Fig. 5. Equilibrium conductance values of Vycor in various NaCl-LiCl mixtures as a function of $1/T$.

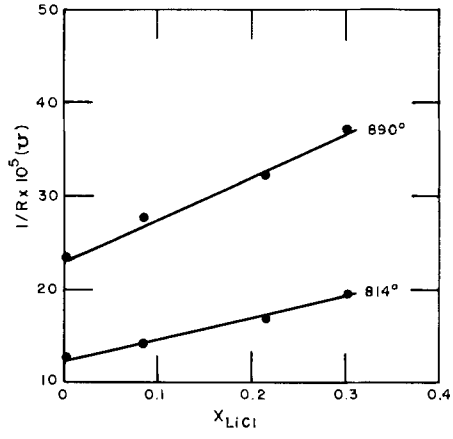

Fig. 6. Change in conductance of Vycor on addition of LiCl to NaCl

when it is added to KCl. These data suggest that the interaction of Na^+ ions with glass differs from that of the other alkali metal cations, but it is not known how.

The activation energy remains virtually constant at 75-84 kJ (18-20 kcal), as LiCl is added to NaCl, but this is not surprising since most of the current is still being carried by sodium.

KBr-KCl-NaBr

To see if a change in anion had any effect on the conductance a cell was initially filled with KBr. The conductance was low, as with KCl, and similarly decreased with time. Over a three-day period $1/R$ decreased from 4.9 to 3.1 x 10^{-6} reciprocal ohms while E_a increased from 26 to 29 kcal. The addition of KCl up to 20 mole % produced no significant change, the

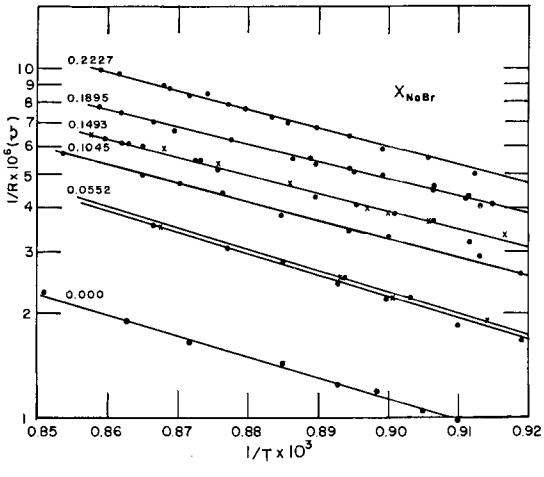

Fig. 7. Equilibrium conductance values of Vycor in NaBr-(76 mole % KBr-24 mole % KCl) as a function of $1/T$.

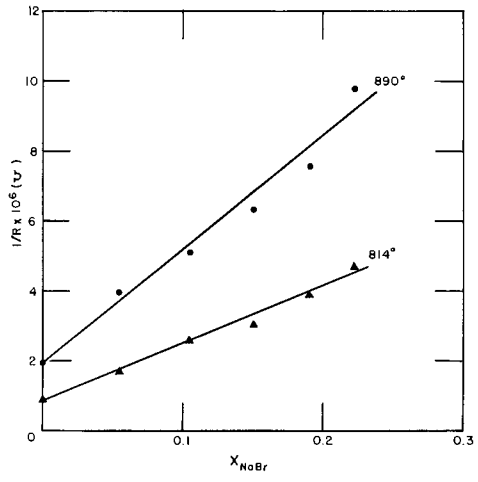

Fig. 8. Change of conductance of Vycor on addition of NaBr to a KBr-KCl melt, data of Fig. 7.

conductance decreasing slowly over a period of weeks. Evidently the effect of adding the smaller Cl^- ion is insignificant compared to the conductance decrease produced by Na^+ diffusion out of the glass.

After two weeks of equilibration with the above KBr-KCl mixture, 24 mole % KCl, NaBr was added. The conductance increased rapidly, the increase being linear in time, as expected. Subsequent additions of NaBr gave the data shown in Fig. 7. The two curves for $X_{NaBr} = 0.0552$ show the change in $1/R$ after one day, the increase with time being clearly much less than that due to a concentration change. As shown in Fig. 8 the increase in conductance is linear in X_{NaBr}, E_a decreasing from 11.2 to 96 kJ (27 to 23 kcal) over the concentration range shown.

Conclusions

The results of the present study are in general agreement with previous work bearing on the behavior of high-purity silica glass in molten salts.

1. The diffusion of potassium ion into glass is very small even when it is the only cation in the melt. In that case the predominant effect appears to be the diffusion of Na^+ out of the glass.

2. From KCl-NaCl and KCl-LiCl melts sodium and lithium ions, respectively diffuse into the glass. The glass comes to equilibrium with a given melt composition fairly rapidly, showing that a uniform ionic composition in the bulk of a $\sim$ 1 mm thick glass is established in a few hours.

3. When LiCl is added to NaCl in equilibrium with glass, Li^+ diffuses rapidly into the glass, showing that not all interstices are filled with Na^+, perhaps because some of them will only accommodate the smaller Li^+.

4. Although Cu^+ and Ag^+ are known to diffuse into glass from their own salts and probably also, although to a much lesser extent, from mixtures with alkali halides, the conductance method is not sufficiently sensitive to detect such diffusion.

5. The present work allows no definite conclusion to be drawn about anion diffusion into glass. Addition of Cl^- to Br^- produces no detectable change in conductivity. However, if the glass is to preserve its electrical neutrality as cations diffuse into it, anions must follow. It is conceivable, however, that partial charge separation in the glass occurs, with anions occupying only the surface layer (adsorption).

6. In general, the activation energy increases with decrease in permeability to a given ion, similar to the behavior with gases (15). The lowest values of E_a, 75 kJ (18 kcal), was observed for NaCl. With KCl E_a fluctuated considerably, probably depending on the residual sodium content of the glass. The highest value obtained was 163 kJ (39 kcal), but an occasional E_a as low as 105 kJ (25 kcal) was obtained with the salt. The addition of NaCl to KCl always lowered E_a.

Manuscript received Sept. 4, 1964. This paper was presented at the Toronto Meeting, May 3-7, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

June 1965 Discussion Section

A Discussion Section, covering papers published in the July-December 1964 JOURNALS, is scheduled for publication in the June 1965 issue. Any discussion which did not reach the Editor in time for the December 1964 Discussion Section will be included in the June 1965 issue.

Those who plan to contribute remarks for this Discussion Section should submit their comments or questions in triplicate to the Managing Editor of the JOURNAL, 30 East 42 St., New York, N. Y., 10017, *not later than March 1, 1965.* All discussion will be forwarded to the author(s) for reply before being printed in the JOURNAL.

Investigations of the Kinetics of Hydrogen and Oxygen Reactions on a Platinum Electrode in Acid Solution Using Pulse and Decay Techniques

Sigmund Schuldiner and Theodore B. Warner[1]

U. S. Naval Research Laboratory, Washington, D. C.

ABSTRACT

The influence of hydrogen partial pressure, current density, and temperature on the anodic oxidation of sorbed H and the anodic generation of sorbed O were determined. Electrode processes were evaluated and separated to give the following quantities: (*a*) the amount of H associated with a Pt surface and its immediate vicinity, (*b*) the extent of reaction of H atoms, absorbed in the metal interior, that migrate to the surface of the metal and are either ionized or react with O atoms, (*c*) the extent of reaction of H_2 from the solution phase, (*d*) the amount of O adsorbed on the Pt surface, and (*e*) the amount of O absorbed in the Pt surface layers (skin).

The kinetics of the open-circuit reaction of galvanostatically determined amounts of sorbed O with H_2 were determined. This investigation showed that absorbed O in Pt significantly affects coulometric measurements at pulse lengths longer than about 1000 μsec. The presence of absorbed O in the Pt can also materially affect the reaction rate of chemisorbed O with H_2. Under the experimental conditions, transport of reactants on the solution side was fast enough so that diffusion did not limit processes in either the H ionization or O sorption regions. The data indicated that migration of adsorbed species on the Pt surface to active sites was rate controlling in the O sorption region, except in the case of reaction of adsorbed O with H_2 when significant amounts of O were absorbed in the skin of the Pt. In this case the chemical reaction rate between adsorbed O and H_2 was retarded so that this chemical step appeared to be rate determining. Reaction rates of the adsorbed O and H_2 reaction under open-circuit conditions were determined at varying temperatures, adsorbed and absorbed O concentrations, and H_2 partial pressures.

This investigation was carried out to determine the influence of hydrogen partial pressure, current density, and temperature on (*a*) the anodic oxidation of adsorbed hydrogen

$$Pt - H \rightarrow H^+ + Pt + e^- \qquad [1]$$

where Pt— indicates a chemisorbed species, and (*b*) the anodic generation of atomic oxygen

$$H_2O + Pt \rightarrow Pt - O + 2H^+ + 2e^- \qquad [2]$$

on a platinum electrode. By use of relatively fast (*i.e.*, high current density) constant current anodic pulses, only that hydrogen already sorbed on the Pt electrode is ionized, and a given number of O atoms are generated and adsorbed on the electrode surface without a significant number of these O atoms absorbing into the outermost layers (skin) of Pt (1—3), or combining to O_2 and diffusing away into solution. By use of longer charging times (*i.e.*, low current densities), some H_2 in solution is ionized in addition to the originally sorbed hydrogen, and a large part of the deposited O atoms may be absorbed into the surface layers of Pt during the time of the applied pulse and more than a monolayer is deposited. Previous work at this Laboratory (1, 3), as well as the work of others, has indicated that O atoms formed during anodic polarization in the O sorption region primarily will either be chemisorbed on the Pt electrode surface or be absorbed in the surface layers of the Pt electrode. In addition, if H atoms are dissolved in the Pt bulk, they may migrate to the surface and either be ionized or react with O atoms.

It has been shown (1, 4) that the rate of reaction of molecular hydrogen in solution with chemisorbed O atoms at potentials above 0.9v (*vs.* NHE) is relatively slow, hence low-current-density-charging pulses were used to determine the combined amount of adsorbed and absorbed O and the reaction of adsorbed O with H_2. The amount of reaction involving H_2 can be determined by comparing such curves with charging curves obtained in hydrogen-free solution. The amount of H_i which migrates to the surface where it is oxidized can be determined in H_2-free solutions by subtracting the number of coulombs required to charge a Pt electrode, free of H_i, to the O_2 evolution potential from the number of coulombs required to charge the same Pt electrodes containing H_i over the same potential range. Thus, the amount of fast-reacting sorbed hydrogen, H_s, the additional hydrogen reacting from solution, H_2, and from the metal interior, H_i, the amount of O atoms adsorbed on the Pt surface, O_{ad}, the amount of O atoms absorbed into the skin of the Pt, O_{ab}, and the amount of reaction of H_2 with adsorbed O atoms can all be determined using the operational definitions of these quantities.

Experiments were conducted to determine the kinetics of the reaction of O_{ad} with H_2 under open-circuit conditions. Here the electrode was coulometrically charged (see Fig. 1b) with a known amount of O_{ad} or O_{ad} plus O_{ab} and the pulse terminated. The potential decay with time was then photographically recorded from an oscilloscope trace (see Fig. 1b) from which the time for reaction of O_{ad} with H_2 in solution plus H_i which migrates to the surface could be measured.

Breiter (5) also used a kinetic technique involving the reduction of chemisorbed oxygen with H_2. However, the method used in this paper varies in several important respects from that of Breiter. In our work we can distinguish between O chemisorbed on the electrode surface and that absorbed into the skin of the metal. Breiter's potentiostatic method (5) undoubtedly included both O_{ad} and O_{ab}. In this paper we shall show that the presence of O_{ab} can materially affect the rate of the reduction of O_{ad} with H_2. Breiter (5) determined the amount of sorbed O at a given anodic potential by using a cathodic sweep which did

[1] National Academy of Sciences Postdoctoral Resident Research Associate.

not clearly separate the oxygen region from the double layer region. In our work we form a given amount of O with an anodic charging pulse where we can separate the amount of O_{ad} present from the amount of O_{ab} dissolved in the Pt electrode. We can also correct for the double layer charge (1). The significance of Breiter's determination of reaction rates at given decay potentials is difficult to assess since his electrode probably contained both O_{ad} and O_{ab}. His reaction rates for different polarization potentials decreased with increased polarization potential, and since potentiostatic charging for 60 sec is adequate time for considerable absorption of O, his decrease in reaction rate can be explained by increased amounts of O_{ab} at higher polarizing potentials.

Our method does suffer in that it does not determine reaction rate as a function of decay potential, but yields the integrated reaction rate over the entire decay potential range. We can, however, limit the potential to which the electrode is anodically charged and thereby successively decrease the amount of O formed. This permits us to show the effects of reduced surface coverage of O on its reaction rate with H_2.

Experimental

The electrochemical system, gas purification trains, and general procedures have been described elsewhere (1-3). True areas (about 0.3 cm^2) of the working Pt bead electrode were defined using the method previously reported (1, 6), and cleanliness of the working electrode and solution was verified by the configuration of the anodic charging curve in the O sorption region (6). The electrolyte was 1M H_2SO_4 solution and was maintained at a constant temperature (±0.5°C) with a water bath. Water bubblers used to saturate the helium or hydrogen going into the cell were kept in the same constant temperature bath to maintain the same partial pressure of water vapor and thereby to keep the electrolyte concentration in the cell constant.

After pre-electrolysis of the solution, the temperature of the water bath was set at a given value and an appropriate mixture of hydrogen and helium (or one of these pure gases) was bubbled through the cell at given rates (0-1300 ml/min) as determined with one or two flowmeters. Zero stirring rate measurements were taken shortly after stopping the flow of a given gas or gas mixture into the cell. The electrometer, pulse generator, and oscilloscope used were the same as previously reported (3), as were the reference (Pt wire and miniature glass) and counter (Pd tube) electrodes. In order to polarize the Pt bead electrode up to the O_2 region with low current density pulses (< 5 ma/cm^2), long duration pulses (> 0.5 sec) were required. These pulses were generated with an Electronic Measurements Solid State (Model C612) Constant Current power supply, using a telegraph key to switch the current on and off. The resulting charging curves were photographed from the oscilloscope screen.

Single-shot, constant-current pulses were used to determine the anodic charging curves. After a current pulse, the electrode was permitted to recover to its normal open-circuit potential before the next pulse was applied. Pulse current densities, known to ±3%, were varied from 780 $\mu a/cm^2$ to about 3 amp/cm^2. The $\mu coul/cm^2$ of hydrogen ionized and oxygen formed were corrected for double layer charging by using a previously determined relationship between double layer capacitance and potential (1).

After anodic charging curves were taken under a variety of conditions, a series of photographs were made showing the polarization decay in H_2-saturated solution (varying H_2 partial pressures and temperatures) at the Pt bead electrode, which was previously charged with a known number of coulombs to a given potential in the O sorption region or somewhat beyond in the O_2 formation region. (Figure 1a delineates the various regions for the charging and decay traces.) In these experiments a charging pulse was set for a given duration and an oscillogram taken (see top charge curve in Fig. 1b). The oscilloscope sweep rate was then considerably slowed and the voltage amplification increased so that the pulse itself was largely off the screen and lasted only a very small fraction of the total time displayed. Then the decay curve (see decay curves in Fig. 1b) following pulse cut off ran for the length of the horizontal sweep until the potential and shape of the decay curve showed complete removal of sorbed oxygen. Thus, with this technique a known number of O atoms could be formed on the surface and the time required for their subsequent open-circuit reaction with molecular hydrogen in solution determined.

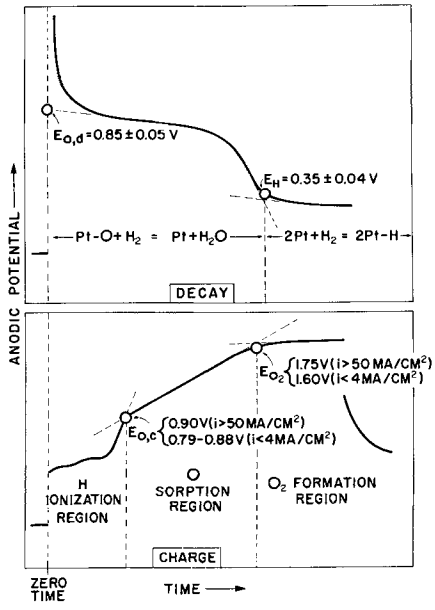

Fig. 1a. Oscilloscope traces: delineation and definition of the major reaction regions and potentials in charge and decay traces.

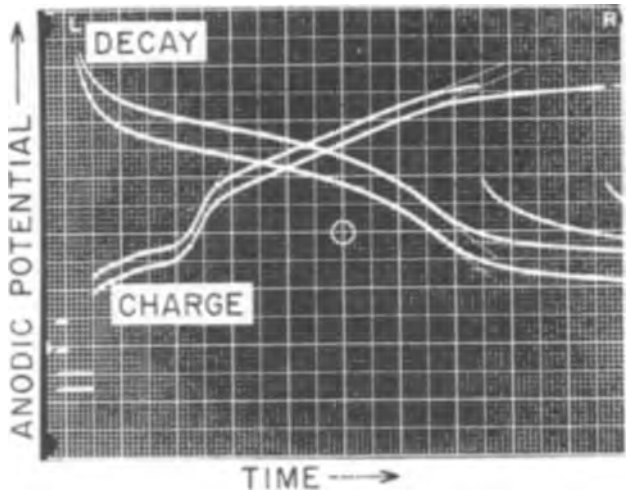

Fig. 1b. Typical anodic charging curves (50 μsec per horizontal division, 0.5v per vertical division, i = 2.61 A/cm^2) and decay curves (2000 μsec per horizontal division, 0.2v per vertical division) at 50°C and p_{H_2} = 0.88 atm.

Anodic Charging Reactions

From the photographed anodic charging traces (Fig. 1b), the number of $\mu coul/cm^2$ of both ionized H and O formed on the Pt bead electrode was determined. These values were corrected for double layer charge. For high-current-density anodic pulses (1-3 amp/cm^2) only O_{ad} is formed and the number of coulombs

used to charge the O sorption region at room temperature was used to define the surface area (1) of the Pt bead. Under these conditions the O sorption region was assumed to require 420 μcoul/cm^2 to charge (equivalent to one monolayer, one-to-one correspondence with surface Pt atoms); the H ionization region was found to require 230 μcoul/cm^2 to charge. The 230 μcoul/cm^2 of H oxidized represents the amount of H (H_s) associated with the Pt surface under open-circuit conditions (p_{H_2} = 1 atm). Experimental evidence (1, 7) indicates that part of this hydrogen is chemisorbed on the Pt surface as atoms and part is absorbed primarily in the outermost layers of the Pt. The experimental data at 23°C showed that within experimental error, this quantity of H, for the higher current density pulses, was virtually independent of the hydrogen partial pressure in the cell (0.02 to 1 atm). This indicated that the amount of chemisorbed hydrogen in rapid equilibrium with H_2 gas above the solution is very small at room temperature and verified previous work from this Laboratory (1, 8).

At lower current densities the amounts of charge consumed in both the H and the O regions exceeded 230 and 420 μcoul/cm^2, respectively. These excesses of charge, q_{ex}, represented: (*a*) the amount of hydrogen in the H ionization region, $q_{H,ex}$, oxidized beyond the amount of hydrogen, H_s, originally associated with the surface before imposition of the anodic pulse, and (*b*) the excess charge in the O sorption region, $q_{O,ex}$, which was due primarily to the oxygen, O_{ab}, formed beyond that needed to form a single monolayer of O atoms, O_{ad}, plus any H_2 and H_i oxidized.

Figure 2 shows both the current density and the hydrogen partial pressure effects on $q_{H,ex}$ and $q_{O,ex}$. The $q_{H,ex}$ can come from two sources, the molecular hydrogen, H_2, bubbled into the cell and the hydrogen dissolved in the interior, H_i, of the Pt bead diffusing out to the surface. Estimations of the amount of H_i which diffused to the surface and then was oxidized were made in pure helium-saturated solutions (the electrode was first saturated with H_2, p_{H_2} = 1 atm, then the H_2 was replaced with He and charging curves were obtained). These experiments showed that with current density pulses of higher than 0.203 amp/cm^2, virtually no hydrogen diffused from the interior of the Pt bead to the surface during the charging pulse. At lower current densities, some hydrogen coming from this source was detected and the p_{H_2} = 0 points in Fig. 2a roughly indicate their values. Interestingly, the amount of H_i (about 300 μcoul/cm^2) diffusing to the surface at current densities of 3.53 ma/cm^2 and lower was essentially independent of current density.

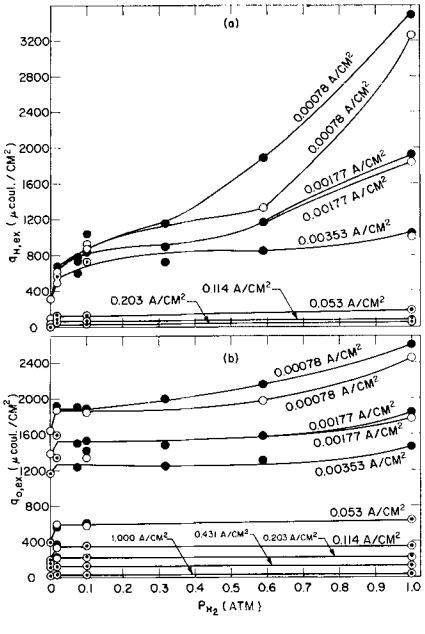

Fig. 2. Data from anodic charging curves at 23°C. Effects of current density, stirring, and hydrogen partial pressure on excess of charge in (a) the H ionization region, $q_{H,ex}$, and (b) the O sorption region, $q_{O,ex}$; ○, quiescent solution; ●, vigorously stirred solution.

The $q_{O,ex}$ appears to represent primarily the amount of O_{ab} in the skin of the Pt bead plus the possible reaction of H_2 and the H_i which diffused to the surface during anodic charging. Lack of stirring effects at current densities above 0.053 amp/cm^2 made it unlikely that a significant amount of oxygen was lost from the surface in the form of O_2 in the O sorption region. Reaction of O_{ad} with H_2 at potentials in the O sorption region has been shown to be slow (1, 4); however, the data in Fig. 2b show that at current densities of 3.5 ma/cm^2 and lower, a significant amount of reaction of O_{ad} with H_2 must occur. Here both stirring and increased hydrogen partial pressure cause an increase in the amount of charge consumed in the O sorption region. However, as the hydrogen partial pressure is decreased, eventually the number of coulombs of charge transferred does not vary even with stirring. But even at these low hydrogen partial pressures there evidently is some reaction of O_{ad} with H_2, because when the hydrogen partial pressure is reduced to zero, the amount of charge expended decreases. In fact, even at current densities as high as 0.203 amp/cm^2 there appears to be a significant amount of reaction of O with H_2. The fact that there are conditions under which hydrogen partial pressure and/or increased stirring does not affect the apparent amount of hydrogen reaction with O_{ad} means that under these conditions the transport of H_2 to the electrode surface by convection and diffusion is faster than the reaction of H_2 with O_{ad}.

At the lowest current density pulse applied (0.78 ma/cm^2), increased stirring rates above those used in the Fig. 2a data considerably lengthened the hydrogen ionization region on the oscilloscope trace. With a small decrease in current it was impossible to polarize the electrode beyond the hydrogen region. This showed that the exchange current density, i_o, for the hydrogen reaction is close to 0.78 ma/cm^2 and that extremely fast stirring is necessary to minimize diffusion polarization. This value checks previous steady-state measurements (9) from this Laboratory when the previous values are adjusted to correspond to the definition of true surface area used here. On the other hand, the length of the O_{ad} region was virtually independent of further increases in the hydrogen stirring rate, beyond the corresponding values shown in Fig. 2b, at 0.78 ma/cm^2. This demonstrated that i_o, for the reaction of H_2 with O_{ad}, is considerably less than 0.78 ma/cm^2, and it also follows that diffusion polarization of H_2 in the vigorously stirred solution was insignificant.

The data shown in Fig. 2b for the helium-stirred solution (p_{H_2} = 0, Pt electrode containing H_i) primarily gives the sum of H_i atoms which diffuse to the surface and are ionized and of O_{ab} generated during the anodic pulse. At the lowest current density this amounts to the equivalent of about four atomic layers of O.

Experiments conducted in helium-saturated solution in which H_i in the Pt bead was completely removed (potential *vs.* NHE was 0.47-0.59v) showed that the amount of O_{ab} in the skin of the metal was 910, 1020, and 1260 μcoul/cm^2 at current densities of 3.53, 1.77, and 0.78 ma/cm^2, respectively. The p_{H_2} = 0 values shown in Fig. 2b, for the same series of current densities, include oxidized H_i and O_{ab} and are 1170, 1400, and 1630 μcoul/cm^2, respectively. The amount of H_i which diffuses to the surface and is oxidized appears to level off at about 400 μcoul/cm^2 at the two lowest current densities, but at all these low current densities the H_i contribution is significant.

The $p_{H_2} = 0$ values shown in Fig. 2b therefore account for both oxidized H_i and O_{ab} and the difference between $q_{O,ex}$ values at $p_{H_2} > 0$ and $p_{H_2} = 0$ represents the amount of H_2 from solution which is ionized. The high $q_{O,ex}$ values for the low current density data indicate that the top layers of Pt atoms in the metal skin may be fairly well saturated with oxygen. As will be shown later this can have a marked effect on the catalytic behavior of Pt.

The data in Fig. 2 show large differences in $q_{H,ex}$ and $q_{O,ex}$ for given current density pulses. Using these curves the amount of H_2 ionized in the H ionization region and H_2 reacting in the O sorption region were separated from the total q_{ex} values and compared. This comparison showed that at current densities of 3.53 ma/cm^2 and lower, the number of equivalents of H_2 reacting in the O sorption region is considerably less than the number of equivalents of H_2 being ionized in the hydrogen region, even though the duration of the O sorption region is about twice as long. At current densities of 0.053 amp/cm^2 and higher the reverse occurs; here considerably more H_2 reacts per unit time in the O sorption region than in the H ionization region. These experimental facts show (*a*) that hydrogen diffusion cannot be rate controlling in both the H ionization and O sorption regions, otherwise the number of coulombs of H_2 per unit time reacting in both regions would be identical, (*b*) at low current densities, H_2 is ionized much faster in the H ionization region than H_2 reacts with O_{ad} in the O sorption region, therefore, H_2 diffusion cannot be rate controlling in the O sorption region, and (*c*) at the higher current densities, H_2 reacts with O_{ad} faster in the O sorption region than these molecules are ionized in the H ionization region; here one concludes that H_2 diffusion cannot be rate controlling in the H ionization region.

The exchange current densities of both the charge transfer and molecular dissociation steps of the hydrogen reaction have been shown (1, 8, 9) to be independent of the charging rate. Hence, the differences in the reaction rates of H_2 at the anodized Pt bead at low and high current densities must be in the O sorption region. We believe that the rate of reaction of H_2 with O_{ad} is faster with high current density pulses because less O is absorbed into the skin of the Pt under these conditions. The work which will be reported in the last section of this paper will further verify that the rate of the reaction between H_2 and O_{ad} is strongly dependent on the amount of O_{ab} in the skin of the Pt electrode.

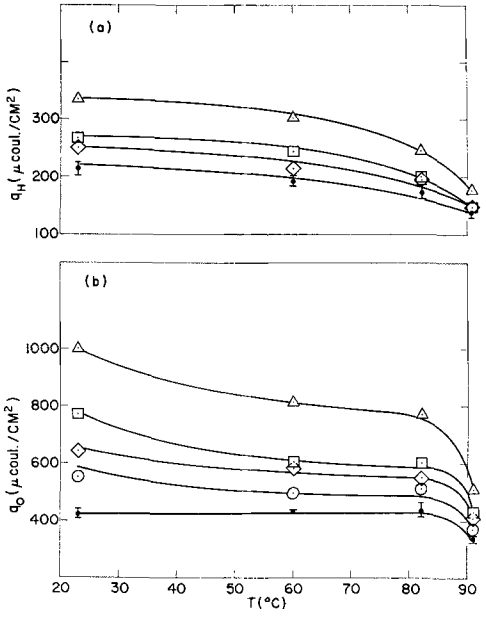

Fig. 3. Temperature effects on anodic charging curves: (a) q_H in hydrogen ionization region [Solid circle with I thru it, 0.43, 1.00, 1.69, 2.52 amp/cm^2; other symbols same as (b)]; (b) q_O in oxygen sorption region; △, 0.053 amp/cm^2; □, 0.114 amp/cm^2; ◇, 0.203 amp/cm^2; ○, 0.43 amp/cm^2; solid circle with I thru it, 1.00, 1.69, 2.52 amp/cm^2.

Temperature effects.—The effects of temperature on both the H ionization and O sorption regions are shown in Fig. 3. Data scatter is indicated for the high current pulses and was approximately the same for the other pulses. The curves in Fig. 3a for the H ionization region indicate that the effect of temperature is essentially the same for all current densities, the lower current density pulses showing additional discharge due to reaction of H_2 that comes from the solution. The fact that there is an inverse temperature effect seems to indicate that the lower H_2 partial pressure at higher temperatures would be an important factor. Nevertheless, the data in Fig. 2a clearly show that at the current densities involved the effect of H_2 partial pressure is essentially negligible at 23°C.

One important factor brought out by these curves (Fig. 3a) is that the amount of H_s decreases as the temperature increases. This can be seen especially for the high current density curve where the ionization of extra H_2 from solution would be unimportant. This decrease in the amount of H_s could be due essentially to the lower H_2 partial pressure at higher temperatures. Thus, even though the 23°C case apparently shows independence of the amount of H_s with p_{H_2}, this may be due to the fact that at this temperature the equilibrium between H_s and H_2 may take a relatively long time to be established. It could also well be that the loss of the bulk of the hydrogen from Pt is not through equilibration with H_2 dissolved in the solution, but is due to reaction with trace amounts of oxygen which leak into the system. Higher temperatures could both increase the amount of the oxygen leak and the rate of reaction of O_2 with H_s.

Because the curves in Fig. 3a are essentially parallel, the effect of temperature on $q_{H,ex}$ can be considered to be constant. Unfortunately, it is not possible with this data to separate H_2 partial pressure effects from temperature effects. Measurements were taken in both quiescent and stirred solution (zero and 1300 ml/min gas flow, respectively). Under both conditions, the numbers of coulombs measured for the data (except at the lowest current densities) shown in Fig. 2a were essentially the same. Where there is no stirring effect, we are led to believe that diffusion of H_2 from the solution was not the controlling factor. Hence, we conclude that the rate-controlling step for the ionization of the molecular hydrogen which comes from solution is the dissociation of H_2 to H.

Temperature effects (Fig. 3) in the O sorption region are quite different from those in the H ionization region. Figure 3b shows that at high current densities, where only surface adsorption of O occurs, q_O is independent of temperature with the exception of the 91°C value. The temperature invariance indicates that a transport or charge transfer step may be rate controlling. Here also diffusion in solution can be ruled out by the lack of stirring effects. The transport here would most likely involve either the migration of a water molecule to a site where it can be oxidized or the migration of an O atom to a suitable site on the electrode surface. The sudden drop in q_O at 91°C is difficult to explain. There are several possibilities: (*a*) the effects of electrode poisons would most likely increase at higher temperatures, and the reproducibility of the data being poorest at this temperature would tend to support this, and (*b*) the bonding of O_{ad} at 91°C may be such that a linear bond with surface Pt atoms no longer predominates and therefore full coverage would be less than 420 μcoul/cm^2. Our cleanliness tests at 91°C and after immediate lowering of temperature did not indicate impurity adsorption; however, we cannot be sure that some self-poisoning process did not occur at this temperature.

The lower current density (0.053-0.43 amp/cm^2) data in Fig. 3b show a definite temperature effect of $q_{O,ex}$ throughout the entire temperature range. The curves are roughly parallel, and here again diffusion control in solution is unlikely due to the absence of stirring effects. The fact that there is an inverse temperature effect may be due to a decrease in the solubility of O in the metal skin as the temperature increases and thereby the rate of absorption which gives $q_{O,ex}$ decreases. Decreased hydrogen partial pressure is probably also a factor.

These temperature effects indicate that important changes are taking place, not only on the surface but in the surface layers of the Pt electrode. More work is contemplated on the absorption of O into the skin and the effects of these absorbed atoms on the surface reaction kinetics.

Chemical Reaction of Molecular Hydrogen with Chemisorbed Oxygen Atoms

The unique feature of the technique used to study the reaction of H_2 with O_{ad} is that electrochemical measurements were used not only to determine the kinetics of a chemical reaction occurring on a metal surface under open-circuit conditions, but the effects of the various sorbed species could be isolated. Accurate control of the amount of O_{ad} was possible by coulometric means. Also, the effects of O_{ab} on the rate of the surface reaction between O_{ad} and H_2 could be determined.

The data in Fig. 4 give the reaction rate

$$i_r = \frac{\text{number of } \mu\text{coul/cm}^2 \text{ of O generated during the anodic phase}}{\mu\text{sec required to reduce O with } H_2 \text{ which migrates to the surface}}$$

where i_r is expressed in amp/cm^2. The chemical reaction involved is

$$Pt - O + H_2 \rightarrow H_2O + Pt \qquad [4]$$

With the high current densities (1.66-3.36 amp/cm^2) used to collect the data shown in Fig. 4, absorption of O during anodic charging was found to be negligible. The data for $q_O > 420$ μcoul/cm^2, $E_{O_2} \approx 1.8$v, also indicate that an excess of adsorbed O can be formed in the O_2 formation region. These excess O atoms are evidently not lost by diffusion into solution as O_2 in the fast pulse times used. This may indicate that initially at E_{O_2} at least as much as about another monolayer of O atoms can be held on the electrode surface. These extra O atoms may easily go into the interstitial holes in the Pt lattice (especially in the 110 plane). The potential may simply be a function of the coverage of surface atoms with O_{ad}. After these surface atoms are saturated, the holes in the lattice are filled without apparently affecting the potential and, as the data in Fig. 4 show, the reaction rate, i_r, of Eq. [4] is independent of the surface coverage from one monolayer up to about two monolayers. It is also possible that the extra oxygen is in the molecular form and is held in position firmly enough so that losses are negligible during both the formation of oxygen and reaction with H_2. A third possibility is that PtO_2 is formed at E_{O_2} before the generation of O_2. Molecular hydrogen then reacts with both PtO_2 and Pt-O at essentially the same rate.

Blank runs were made at 23°C to estimate the effects due to a terminating resistance used to maintain pulse shape. The electrode was first exposed in 1 atm H_2 saturated solution and then the H_2 was replaced with pure He. After sweeping out the solution with He for about 20 minutes, the potential became more anodic by about 60 mv. Decay traces in this solution (p_{H_2} calculated <0.01 atm) gave i_r values equal to a little over one-half of the i_r values found in the H_2 swept solutions. This means that i_r values shown in Figs. 4 and 5 should be reduced by about ½ to give true i_r values for the reaction of O_{ad} with H_2. Check runs were made also with the terminating resistance removed from the pulse output. These runs gave essentially a zero blank showing that the contribution of H_i to i_r was negligible, and the results checked those found using the terminating resistance corrected for its blank.

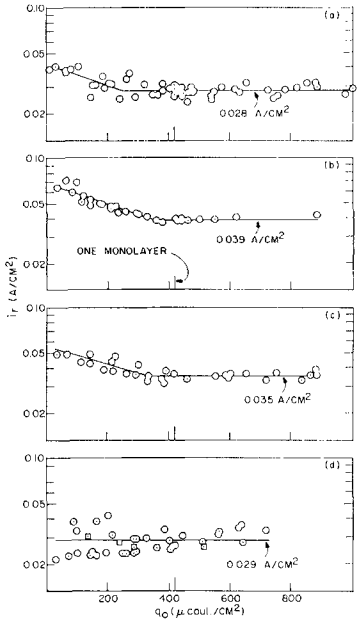

Fig. 4. Rates of reaction, i_r, of O_{ad} with H_2 obtained from decay curves following high current density anodic pulses terminated at various points in the O sorption or O_2 formation regions (no O_{ab} generated). (a) 23°C, 1.0-0.1 atm H_2; (b) 50°C, 0.88 atm H_2; (c) 70°C, 0.69 atm H_2; (d) 90°C, ⊙, 0.31 atm H_2; □, 0.09 atm H_2.

The values of i_r in the plateau regions of Fig. 4 can be considered to be essentially independent of both temperature and hydrogen partial pressure. (The data in Fig. 4a showed a random scatter of points at 0.1, 0.5, and 1 atm H_2 partial pressures.) The values shown in Fig. 4 were taken also at stirring rates beyond which i_r did not increase with increasing stirring. The lack of stirring rate and H_2 partial pressure effects eliminates the diffusion of H_2 from solution as the rate-controlling mechanism. The lack of H_2 partial pressure and temperature effects also eliminates the direct chemical reaction of H_2 with O_{ad} as a possible rate-determining step. A third possible controlling step is one which involves a dissociation of H_2 into atoms and its migration across the surface to active sites bearing O atoms where the reaction in Eq. [4] can occur. It is also possible that the rate-controlling step may be the migration of O_{ad} to the active sites where it can react with either atomic or molecular hydrogen.

The fact that i_r at $p_{H_2} = 1$ atm after subtracting the i_r at $p_{H_2} < 0.01$ atm gives values somewhat higher than 0.01 amp/cm^2, which is about one order of magnitude higher than i_o for the molecular hydrogen ionization reaction (0.00078 amp/cm^2 or 0.0015 amp/cm^2 on an apparent area basis), demonstrates that (*a*) diffusion of H_2 cannot be rate-controlling in the H ionization region because the reaction with H_2 shown in Eq. [4] occurs faster under equal stirring rates, and (*b*) that H_2 does not dissociate into atoms before reacting with O_{ad}, because here again the reaction of

O_{ad} with H_2 is faster than the ionization of H_2 which requires dissociation into atoms. Taking all of these facts into consideration, the most likely rate-controlling step for the reaction between H_2 and O_{ad} is the migration of O_{ad} atoms to active sites where they can directly react with H_2. Hence a reasonable rate-determining step can be postulated, even though the detailed reaction steps which comprise the over-all mechanism are not known.

At lower surface coverages, θ ($\theta < 1$), the data in Fig. 4 show that i_r increased as the surface coverage decreased. This suggested, since the most active sites would be covered with O_{ad} first, that the decrease in the number of inactive sites covered with O_{ad} reduced the amount of necessary migration to active sites and thereby i_r tended to increase. This argument also supports the O_{ad} migration step as the rate-controlling one.

When charging pulses from 0.053 to 1.0 amp/cm^2 were used to form the O sorption region, the rate of charging was slow enough so that some of the O atoms formed absorbed into the skin of the Pt bead and, possibly, some H_i atoms migrated to the surface (as shown in the previous section). Under these conditions, at the end of the charging pulse part of the O atoms formed were adsorbed on the Pt surface and part absorbed in the skin of the electrode. Loss due to reaction with H_i and with H_2 from solution during charging was significant mainly at current densities below 0.2 amp/cm^2, even at the lower current densities used only a fraction of the O_{ad} reacted with H_i or H_2 (see Fig. 2b).

The data in Fig. 5 were obtained with pulses which were terminated just at the end of the O sorption region (see, for instance, upper charge curve in Fig. 1b), but which were of such low current density that additional amounts of oxygen could dissolve in the Pt. This is in contrast to the data in Fig. 4, which were obtained with high current density pulses. Some of these latter pulses were long enough to charge well into the O_2 formation region, some were terminated just at the end of the O sorption region, and some were terminated at various points within the O sorption region.

Figure 5 shows that O_{ab} has a marked effect on i_r. The reaction current density, i_r, of Eq. [4] is sharply diminished as the amount of O_{ab} increases (correction of i_r for any reduction of O_{ad} due to migration of residual H_i to the surface during charging would tend to decrease i_r further). Figure 5a shows that i_r is a direct function of p_{H_2}. Figure 5b shows that although increased temperature tends to increase i_r (see i_r values in Fig. 5a at comparable partial pressures), the lowering of H_2 partial pressure with increasing temperature (owing to increased partial pressure of water vapor) exerts a stronger effect than temperature.

The data in Fig. 5 were also taken under vigorous stirring conditions where increased stirring rates did not change i_r; therefore diffusion control of H_2 was minimized. The results shown in Fig. 5 indicate that the reaction mechanism for Eq. [4] must be quite different than for the case where O_{ab} is insignificant. The dependence on H_2 partial pressure indicates that the reaction is controlled by the chemical reaction of H_2 with O_{ad}. The tendency of a positive temperature dependence also indicates such a reaction control. The increase in i_r as $q_{O,ex}$ decreases shows that the reaction rate increases as the amount of sorbed O decreases, and the change to the higher slope at low $q_{O,ex}$ values indicates that the reaction step is becoming so fast that the over-all rate i_r, approaches the comparable values shown in Fig. 4 where O_{ad} migration is the indicated rate-controlling step. Hence, in the region of the steeper slope (Fig. 5) there appears to be a mixed control of the reaction. This is also verified by the coming together of the curves in Fig. 5 at the lowest $q_{O,ex}$ values. This indicates that H_2 partial pressure and temperature effects become less important as in the data shown in Fig. 4.

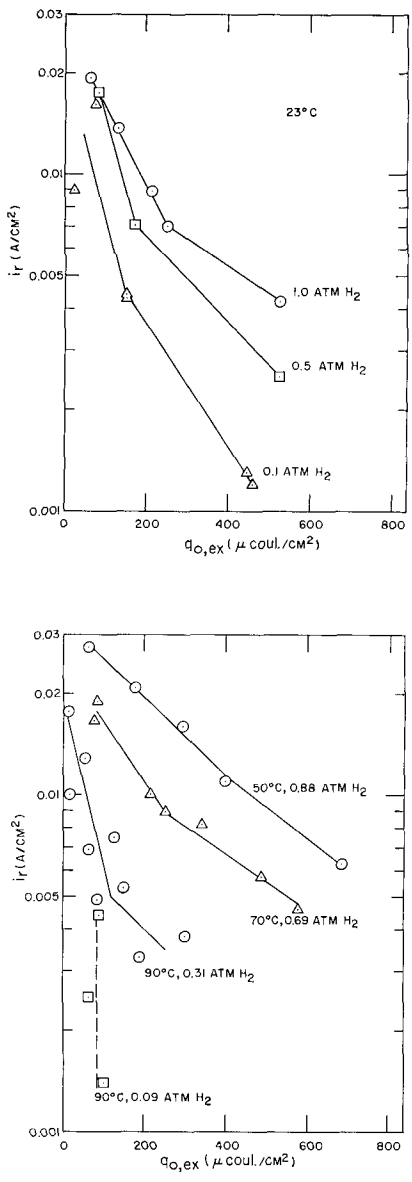

Fig. 5. Rates of reaction, i_r, of O_{ad} with H_2 obtained from decay curves following low current density anodic pulses terminated at end of O sorption region (O_{ab} present).

It is felt that the presence of O_{ab} in the Pt bead markedly lowers the heat of adsorption of O_{ad}. This in turn evidently slows the rate of the chemical combination of O_{ad} and H_2.

One of the most important results of this investigation is considered to be the application of the described technique for separating differently sorbed species associated with a surface and determining their effects on the rates of chemical reactions.

Conclusions

Use of the techniques described here has led us to conclude:

1. That platinum electrodes in sulfuric acid solution can absorb considerable quantities of oxygen and hydrogen in excess of the quantity present on the surface. In this work the oxygen was generated on the electrode surface electrolytically; the hydrogen was present in the solution.

2. That this absorption is fast. Measurable quantities of absorbed oxygen are found after anodic polarizations of 1000 μsec or longer.

3. That multiple monolayers can be absorbed if sufficient time of contact is allowed.

4. That desorption is slow. An effort is necessary to obtain an electrode free of these dissolved species. Coulometric studies involving oxidation or reduction of substances adsorbed on the surface of a platinum electrode can be seriously affected by the presence of these dissolved species as an unrecognized reactant (10).

5. That catalytic behavior of a platinum electrode is drastically affected by such absorbed species.

These conclusions, in turn, lead to the conclusion that the use of anodic pulses to clean an electrode prior to use may create more problems than it solves, and if used, extreme care must be taken to insure that the above processes do not influence the measurements.

Acknowledgments

The authors gratefully acknowledge the help of Professor P. H. Emmett of Johns Hopkins University, especially his suggestion that the surface migration of adsorbed species to active centers may be applicable for the reaction of O_{ad} with H_2.

Manuscript received June 8, 1964; revised manuscript received Sept. 23, 1964. This paper is to be presented at the San Francisco Meeting, May 9-13, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

SYMBOLS

(Figure 1a delineates and defines the major reaction regions and potentials in the charge and decay traces. Wherever a quantity of material was determined coulometrically, double layer capacitance charging was corrected for.)

H_s hydrogen atoms associated with Pt atoms on the surface and immediately below the surface. Operationally, H_s is the time-independent amount of H atoms coulometrically measured with an anodic pulse that polarizes the electrode through the H ionization region in less than 1000 μsec. At a Pt electrode under 1 atm H_2 at 25°C, H_s = 230 μcoul/cm^2.

H_i hydrogen atoms located in the interior of a Pt electrode. Operationally, these H atoms do not migrate to the surface and react under the conditions referred to under H_s. H_i atoms only add to the measured number of coulombs at polarization times longer than 1000 μsec.

H_2 molecular hydrogen in the solution phase.

i_r number of μcoul/cm^2 of O generated during an anodic pulse divided by the time, in μsec, required to reduce this O with H_2 plus H_i which migrates to the surface.

O_{ad} oxygen atoms chemisorbed on the Pt electrode surface. By the definition of area used, these atoms are in a one-to-one correspondence with surface Pt atoms. Operationally, O_{ad} is the time-independent amount of O atoms coulometrically measured with an anodic pulse that polarizes the electrode through the O sorption region in less than 1000 μsec. At 25°C, O_{ad} = 420 μcoul/cm^2.

O_{ab} oxygen atoms absorbed in the skin of the Pt electrode. Operationally, these atoms only add to the measured number of coulombs at polarization times longer than 1000 μsec.

q_H the number of μcoul/cm^2 of reaction in the H ionization region.

q_O the number of μcoul/cm^2 of reaction in the O sorption region.

$q_{H,ex}$ the number of μcoul/cm^2 of hydrogen oxidized in the H ionization region in excess of the amount of hydrogen atoms (H_s) originally associated with the electrode surface before imposition of the anodic pulse. $q_{H,ex}$ is due to oxidation of H_i and H_2.

$q_{O,ex}$ the number of μcoul/cm^2 of charge expended in the O sorption region in excess of the amount required to generate the O atoms (O_{ad}) chemisorbed on the Pt surface. $q_{O,ex}$ is due to the formation of O_{ab} and of the oxidation of H_i and H_2.

fraction of available sites on the surface covered.

Polarography of Lead Complexes in Glycolic Acid and Malonic Acid as Competing Chelating Agents

Tsai-Teh Lai and Ching-Chiang Hsieh

Department of Chemical Engineering, Cheng Kung University, Tainan, Taiwan, China

ABSTRACT

The polarography of lead complexes in glycolic acid, malonic acid, and in a mixture of glycolic acid and malonic acid has been studied in detail. With glycolic acid, $Pb(G)^+$ and $Pb(G)_2$ were identified. With malonic acid, evidence for the existence of $Pb(HA)^+$, $Pb(HA)_2$, and $Pb(A_2)^{-2}$ was obtained. In a mixture of glycolic acid and malonic acid as competing ligands to the lead ion, the complex species of $Pb(G)^+$, $Pb(G)(HA)$, and $[Pb(G)(A)]^-$ were formed. The electrode reactions and concentration dissociation constants of the complexes were given. The coordination ability between the lead ion with the following groups decreased in the order: $-COO^- > -OH > -COOH$.

The polarographic behavior of the complexes of uranium (VI) with glycolic (1) and malonic acid (2) has been investigated. The malonate complexes of iron (3) and chromium (III) (4) have been studied polarographically.

Although the polarography of lead complexes with tartaric acid has ben reported by Iwase (5), it was found that little has been done with other carboxylic or hydroxylic acids. In an attempt to determine what complexes of lead existed in the competing chelating

agents of glycolic acid and malonic acid, and to estimate their concentration dissociation constants, a detailed investigation by polarography was undertaken.

Experimental

Apparatus.—The apparatus and procedure used in this work were described previously (1).

The characteristics of the capillary were 1.10 $mg^{2/3}$ $t^{-1/2}$ at a mercury column height of 61 cm and an applied potential of —0.500v *vs.* SCE.

All polarographic solutions were allowed to stand at least 30 min before measurements were made to assure equilibrium. No maxima were encountered, and no suppressors were added to the solutions.

All experiments were carried out at 30° ± 0.1°C.

Chemicals.—The stock solution of 0.01M lead nitrate was standardized complexometrically with standard EDTA solution (6). A 2M stock solution of malonic acid and 1M stock solution of glycolic acid were prepared, and their exact concentrations were determined with carbonate-free sodium hydroxide solution which was standardized with potassium biphthalate of the National Bureau of Standards.

Results and Discussion

The half-wave potential for the lead complex PbA_x^{2-nx} at the dropping mercury electrode may be represented by

$$(E_{1/2})_c = (E_{1/2})_s + \frac{0.060}{2}\log K_c - \frac{0.060}{2}x \log [A^{-n}] \text{ (at 30°C)} \quad [1]$$

Here K_c is the concentration dissociation constant of the lead complex and $[A^{-n}]$ is the concentration of ligand.

If A^{-n} and B^{-m} represent chelating agents that compete for the electron pair donor groups to the lead ion, the half-wave potential of the resulting complex $PbA_xB_y^{(2-nx-my)}$ is expressible as

$$(E_{1/2})_c = (E_{1/2})_s + \frac{0.060}{2}\log K_c - \frac{0.060}{2}x \log [A^{-n}] - \frac{0.060}{2}y \log [B^{-m}] \quad [2]$$

When the ligand number x of A^{-n} is identical to the ligand number y of B^{-m}, Eq. [2] can be simplified to

$$(E_{1/2})_c = (E_{1/2})_s + \frac{0.060}{2}\log K_c - \frac{0.060}{2}x \log [A^{-n}][B^{-m}] \quad [3]$$

We then obtain

$$\frac{\Delta(E_{1/2})_c}{\Delta \log [A^{-n}][B^{-m}]} = -0.030\,x \quad [4]$$

This equation shows that if the value of the slope of $E_{1/2}$ *vs.* log $[A^{-n}][B^{-m}]$ is an integral multiple of 0.030, the ligand number of A^{-n} and B^{-m} are the same. That is, the ligand A^{-n} and B^{-m} will have identical coordination ability to the lead ion when the solution has the same concentration of A^{-n} and B^{-m}.

Reversible and diffusion controlled reduction.—Figure 1 shows the typical polarograms and the plots of log $i/(i_d - i)$ *vs.* $E_{d.e.}$ for lead ion solutions (curve I), containing glycolic acid (curve II), malonic acid (curve III), and glycolic acid and malonic acid (curve IV). It is obvious from Fig. 1 that the half-wave potential of simple lead ion in 0.1M KNO_3 solution at pH 3.50 is —0.397v *vs.* SCE and the half-wave potentials are all shifted to negative side by chelation with glycolic acid, malonic acid, and a mixture of glycolic acid and malonic acid.

The slopes of the conventional log plots for the polarograms of lead-glycolate, lead-malonate, and lead-glycolate-malonate system at various pH values were rounded up in Table I. The temperature coefficients of

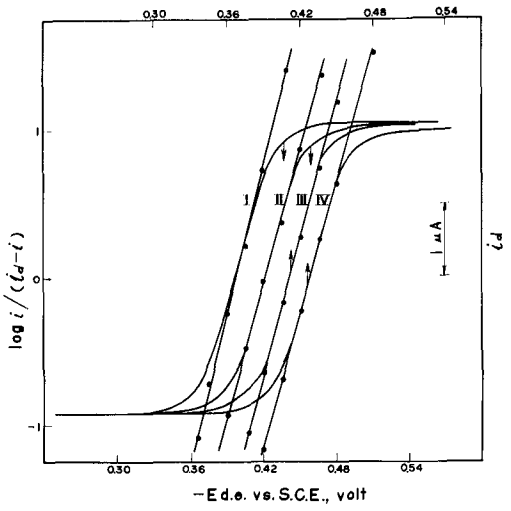

Fig. 1. Typical polarograms and log $i/(i_d-i)$ *vs.* $E_{d.e.}$ Polarograms of solutions containing 1.116 mM $Pb(NO_3)_2$, 0.1M KNO_3, at pH 3.50 with various chelating agents: (I) no chelating agent; (II) 0.1027M glycolic acid; (III) 0.0976M malonic acid; (IV) 0.1027M glycolic acid and 0.0976M malonic acid.

half-wave potential and diffusion current were also determined with the data listed in Table II. From Tables I and II, it is obvious that the three systems are all 2-electron reversible and diffusion-controlled reduction.

Lead-glycolic acid system.—Curve I in Fig. 2 represents the effect of pH on the half-wave potential of a lead-glycolic acid system. At pH < 2.35, the half-wave potentials are independent of pH and remain constant at $(E_{1/2})_s$ value, indicating that no chelation occurred. In the pH range 2.35-4.15, the slope of $E_{1/2}$ *vs.* pH is —0.028 showing that one hydrogen ion was required in releasing the coordinated glycolate anion from one mole of lead-glycolate complex to form glycolic acid. At pH > 4.15, the half-wave potentials became independent of pH value again, showing that no hydrogen ion was involved in the reduction of the complexes.

To determine the ligand number of the lead-glycolate complexes, the variation of half-wave potential with the concentration of glycolate ion was measured (Fig. 3). The concentration of glycolate anion was calculated from the nominal concentration of glycolic acid, the pH of the solution, and the pKa (3.82) (7), for glycolic acid.

In curve I of Fig. 3, the half-wave potentials are essentially independent of glycolic acid concentration

Table I. Slopes of $E_{d.e.}$ *vs.* log $i/(i_d-i)$

Systems	pH range	No. of polarograms	$E_{d.e.}$ *vs.* $-\log i/(i_d - i)$ low val.	high val.	avg.
Pb-Gly.	1.5-7.5	52	0.028	0.031	0.030
Pb-Mal.	1.5-7.5	54	0.028	0.032	0.030
Pb(Mal.)(Gly.)	1.5-7.5	65	0.028	0.031	0.030

Table II. Temperature coefficients of half-wave potential and diffusion current

Systems	pH	Temp range, °C	Temp coefficient of $E_{1/2}$ (mv/°C)	i_d (%/°C)
Pb-Gly.	5.3	13-25	−0.44	+1.7
		25-47	+0.27	
Pb-Mal.	5.3	13-47	−0.13	+1.4
Pb(Gly.)(Mal.)	5.3	13-47	−0.13	+1.6

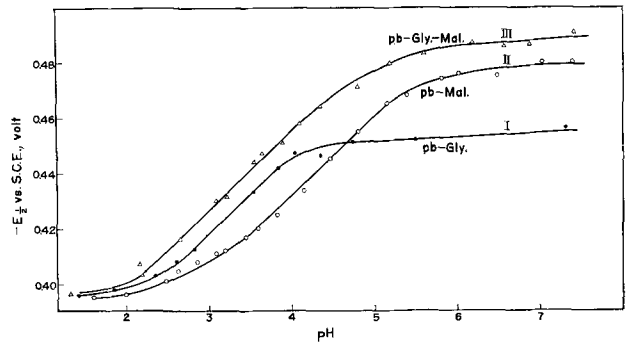

Fig. 2. Effect of pH on half-wave potential. Polarographic solutions containing 1.116 mM $Pb(NO_3)_2$, 0.1M KNO_3, and various chelating agents: (I) 0.205M glycolic acid; (II) 0.218M malonic acid; (III) 0.205M glycolic acid and 0.218M malonic acid.

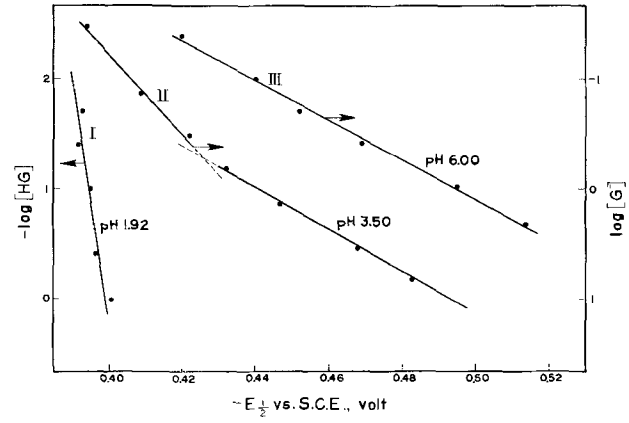

Fig. 3. Variation of half-wave potential of lead-glycolic acid system with ligand concentration: 1.116 mM $Pb(NO_3)_2$, 0.1M KNO_3.

at pH 1.92. This is in good agreement with the fact that no chelation occurred in the low pH region as mentioned above. Curve II in Fig. 3 consists of two straight lines which intersect at glycolate concentration 0.055M. The slopes of the lines are 0.028 and 0.055, corresponding to the ligand number of 0.92 and 1.83, respectively. Thus, the chelate species and electrode reactions in the pH range 2.35-4.15 can be written

$$[G^-] < 0.055M,$$
$$PbG^+ + H^+ + 2e + Hg = Pb(Hg) + HG \qquad (a)$$

$$[G^-] > 0.055M,$$
$$Pb(G)_2 + H^+ + 2e + Hg = Pb(Hg) + HG + G^- \quad (b)$$

The slopes of curve III in Fig. 3 is 0.055, corresponding to the ligand number of 1.83. Thus, the chelate species and electrode reaction at pH > 4.15 may be expressed as

$$Pb(G)_2 + 2e + Hg = Pb(Hg) + 2G^-$$

Lead-malonic acid system.—It is obvious from curve II in Fig. 2, the half-wave potentials are independent of pH at pH < 2.25 and pH > 5.40. However, in the pH range 2.25-5.40, the half-wave potentials are dependent on pH, and the $\Delta E_{1/2}/\Delta pH$ is —0.028, indicating that one hydrogen ion was consumed in the electrode reduction.

As shown in Fig. 4, the diffusion current constants remain constant at 3.12 at pH lower than 5.25 and at 2.88 at pH greater than 5.25, revealing that two kinds of chelate species transform at pH 5.25. This result and the pK_2 value 5.36 (8) of malonic acid, evidenced that the ligand species is hydrogenmalonate ion at pH lower than 5.25, and is malonate ion at pH greater than 5.25.

The ligand number of the chelates were estimated from Fig. 5, in which the concentration of the hydrogenmalonate ion and malonate ion were calculated

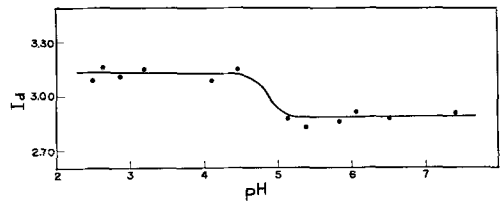

Fig. 4. Effect of pH on diffusion current constant of lead-malonate complexes.

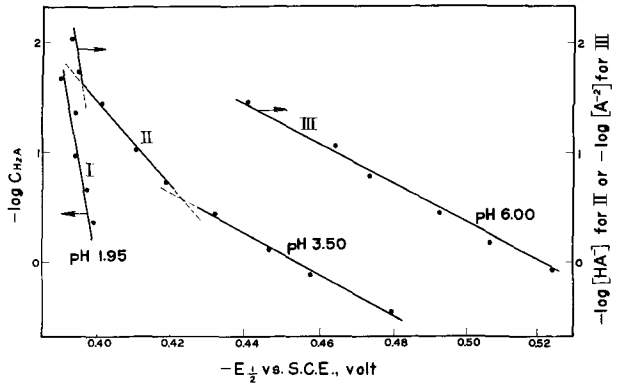

Fig. 5. Variation of half-wave potential of lead-malonic acid system with ligand concentration: 1.116 mM $Pb(NO_3)_2$, 0.1M KNO_3.

from the added concentration of malonic acid, the pH of the solution and using $pK_1 = 2.75$ and $pK_2 = 5.36$ (8).

Curve I in Fig. 5 shows that the ligand number is nearly equal to zero, *i.e.*, essentially no chelation occurred at pH lower than 2.25, which is in good agreement with the result of curve II in Fig. 2.

Curve II in Fig. 5 shows two breaking points at the hydrogenmalonate ion concentration of 0.025 and 0.27M. The first breaking point at 0.025M shows the starting point for chelation, namely, a concentration of hydrogenmalonate ion greater than 0.025M is required to assure the chelation with 1.116 mM lead ion. The ligand number of the lead-hydrogenmalonate chelates were found to be 0.87, and 1.80, as evidenced by the slopes of 0.026, and 0.055, respectively (curve II, Fig. 5).

Based on the forgoing discussion, the chelate species and electrode reactions in the pH range 2.25-5.25 can be expressed as

$$0.025M < [HA^-] < 0.27M,$$
$$Pb(HA)^+ + H^+ + 2e + Hg = Pb(Hg) + H_2A \qquad (a)$$

$$[HA^-] > 0.27M,$$
$$Pb(HA)_2 + H^+ + 2e + Hg = Pb(Hg) + HA^- + H_2A \qquad (b)$$

Above pH 5.40, the malonate ligand took the place of the hydrogenmalonate ligand, as predicted by the sudden drop of the diffusion current constant from 3.12 to 2.88 (Fig. 4). The slope of curve III in Fig. 5 is 0.057 from which the malonate ligand number is 1.90. Thus, above pH 5.40, the formula is $Pb(A)_2^{-2}$ and the electrode reaction will be

$$Pb(A)_2^{-2} + 2e + Hg = Pb(Hg) + 2A^{-2}$$

Lead-glycolic acid-malonic acid system.—Two kinds of chelating agents, glycolic acid and malonic acid, were used in competing for the electron pair donor groups to the lead ion, at the condition of nearly identical concentrations.

The $E_{1/2}$ *vs.* pH plot for this system appears as curve III of Fig. 2. The chelation starts at pH 2.1. The line obtained by varying the pH from 2.1 to 5.3 has a slope of —0.029, indicating that one hydrogen ion was involved in the reduction.

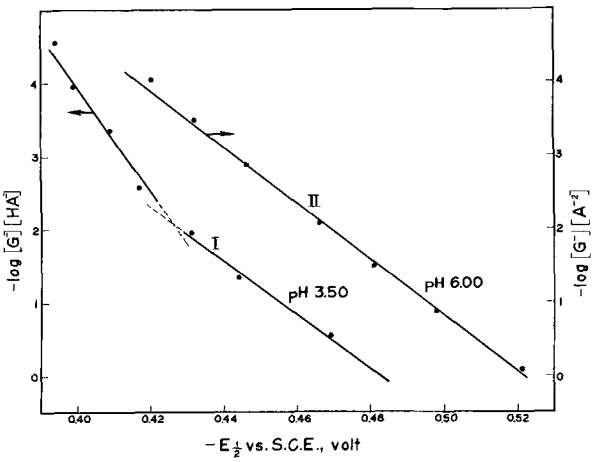

Fig. 6. Variation of half-wave potential of lead-glycolic acid-malonic acid system with ligand concentration: 1.116 mM $Pb(NO_3)_2$, 0.1M KNO_3.

In an attempt to apply Eq. [4], the plots of $E_{1/2}$ *vs.* log $[G^-]$ $[HA^-]$ for *p*H 3.50 and $E_{1/2}$ *vs.* log $[G^-]$ $[A^{-2}]$ for *p*H 6.00 are shown as curves I and II of Fig. 6, in which G^- and A^{-2} denote, respectively, glycolate ion and malonate ion.

In curve I of Fig. 6, the break occurs at $[G^-][HA^-] = 7.9 \times 10^{-3}$ M; the slope is 0.015 for the upper line and is 0.027 for the lower line. Let x and y be the ligand number of G^- and HA^- or A^{-2}. Applying the value of slope, 0.015, in Eq. [4], we get $x \neq y$ when $[G^-]$ $[HA^-] < 7.9 \times 10^{-3}$ M. It was already shown that the glycolate ion can complex with the lead ion only in a 1:1 ratio at lower ligand concentration. The same is true of the hydrogenmalonate ion. Hence $x = 1$ and $y = 0$ or $x = 0$ and $y = 1$ for the case $x \neq y$. This relation indicates that the chelate formed in the competing agents, may be either $Pb(G)^+$ or $Pb(HA)^+$ when $[G^-]$ $[HA^-] < 7.9 \times 10^{-3}$M. However, because of the greater stability of the $Pb(G)^+$ complex (as will be shown in the next section) the $Pb(G)^+$ rather than $Pb(HA)^+$ was considered as the most probable species. On the other hand the slope of the lower line, 0.027, is sufficiently close to 0.030, to yield a value of $x = y = 1$. This shows that the chelate species is Pb(G) (HA) when $[G^-]$ $[HA^-] > 7.9 \times 10^{-3}$M. Thus, the electrode reactions in the *p*H range 2.1-5.3 can be formulated as

$[G^-]$ $[HA^-] < 7.9 \times 10^{-3}$M,

$$Pb(G)^+ + H^+ + 2e + Hg = Pb(Hg) + HG \quad (a)$$

$[G^-]$ $[HA^-] > 7.9 \times 10^{-3}$M,

$$Pb(G)(HA) + H^+ + 2e + Hg = Pb(Hg) + HA^- + HG \quad (b)$$

Similarly, the slope of curve II in Fig. 6 at *p*H 6.0 is 0.026, giving $x \cong y$ and a chelate species of $[Pb(G)(A)]^-$. Thus, the electrode reaction at *p*H greater than 5.3 is

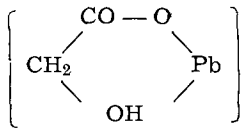
$$[Pb(G)(A)]^- + 2e + Hg = Pb(Hg) + G^- + A^{-2}$$

Concentration dissociation constants of chelates.— The over-all concentration dissociation constants of the chelates were determined by application of Eq. [1] and [2] in which $(E_{1/2})_s$ is —0.397v *vs.* SCE (curve I, Fig. 1). The *p*K values obtained for the chelates are summarized in Table III.

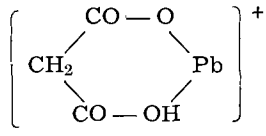
Table III. Concentration dissociation constants of lead complexes

Chelating agents	Ligand number	Chelate species	*p*K
Glycolic acid	0.92	$Pb(G)^+$	2.13 ± 0.03
	1.83	$Pb(G)_2$	3.24 ± 0.05
Malonic acid	0.87	$Pb(HA)^+$	1.37 ± 0.01
	1.80	$Ph(HA)_2$	1.88 ± 0.06
	1.90	$Pb(HA)_2^{-2}$	4.19 ± 0.07
Mix. of glycolic acid and malonic acid	0.90	Pb(G)(HA)	2.89 ± 0.07
	0.87	$[Pb(G)(A)]^-$	4.13 ± 0.06

The $Pb(G)^+$ chelate has the five-membered ring structure



and the $Pb(HA)^+$ has the six-membered ring structure



Pfeiffer (9) has shown that, in general, a five-membered ring is more stable than a six-membered ring when the ring is entirely saturated. This was proved by the *p*K values of 2.13 for $Pb(G)^+$ and 1.37 for $Pb(HA)^+$ as shown in Table III. These facts show that the coordination ability of the lead ion with —OH is stronger than that of the lead ion with —COOH.

As listed in Table III, the *p*K value of $Pb(A_2)^{-2}$ is 4.19 and that of $Pb(G)_2$ is 3.24, indicating that the coordination ability between the lead ion and $—COO^-$ is stronger than that between the lead ion and —OH. Thus, it was concluded that the coordination ability between the lead ion with the following groups decreases in the order $—COO^- > —OH > —COOH$. This order is in excellent agreement with the order of *p*K values (Table III): $Pb(A_2)^{-2}$ (4.19) > $[Pb(A)(G)]^-$ (4.13) > $Pb(G)_2$ (3.24) > Pb(G)(HA) (2.89) > $Pb(HA)_2$ (1.88)

Conductivity through Hydrogen Bonded Organic Compounds and Their Homogeneous Solutions

I. Conductivity of Aliphatic Alcohols and Their Benzene Homogeneous Solutions

M. F. Mayahi and A. E. Habboush

Department of Chemistry, College of Science, University of Baghdad, Iraq

ABSTRACT

The conductivity of methanol, ethanol, n-butanol, n-pentanol, and n-hexanol was measured at 30°C. The effect of an increase of one (—CH_2—) group in the carbon chain was determined by plotting molar conductivities *vs.* molar volumes (ml) of each pure alcohol; the slope of the straight line obtained was —55 units. The conductivity of these alcohols in benzene solution at 30°C was found to show a characteristic rise with concentration; the conductivity rises sharply at about 6M concentration of each alcohol. Such points are referred to as inflection points. The plot of molar conductivities of solutions *vs.* the volume of the solution containing one mole of each alcohol at the inflection point gives a straight line, the slope of which is —38 units.

The effect of the hydrogen bond on the conductivity of alcohols (1), solid organic (2) acids, and acidic solutions of water and alcohols (3) has been investigated previously. Mecke *et al.* (1) studied the conductivities of pure methanol, isopropanol, tertiary butyl alcohol, and benzyl alcohol, and the conductivities of their solutions in CCl_4, chlorobenzene and benzene. They found that conductivity decreased as branching in the carbon chain increases. Ubbelohde *et al.* (2) studied the conductivity of solid organic acids and found that the conductivity of the interhydrogen-bonded acids was a hundred times greater than those with intrahydrogen-bonded acids.

Conway *et al.* (3) worked on proton conductance in water and alcohols and observed the lower mobility of the proton as the alcohol hydrocarbon chain length increases. Our work is concerned with the conductivity of hydrogen-bonded compounds and in this paper we report the conductivities of pure methanol, ethanol, n-butanol, n-pentanol, n-hexanol, and also the conductivities of their solutions in benzene at 30°C.

Experimental

Materials.—Methyl alcohol was supplied by Fisher Scientific Company (certified reagent) containing 0.01 % water and was used without further treatment. Ethyl alcohol and benzene were of Analar grade of the British Drug Houses Company and used without further treatment. Butyl alcohol and hexanol were supplied by B.D.H. and were treated with $MgSO_4$ and distilled. Amyl alcohol was Analar grade of Merck & Company and was treated with $MgSO_4$ and distilled.

Apparatus.—A Wayne Kerr Universal bridge B221 was used with a special cell designed for low conductivity measurement, the distance between the platinized platinum electrodes being 0.35 cm.

Method.—Conductivity measurements were made at 30° ± 0.1°C. 5 ml of benzene or alcohol was transferred to the cell using syringe-type graduated 5-ml pipet. After reaching thermal equilibrium, the alcohol or benzene was added from an automatic 1-ml closed buret, graduated to 0.005 ml, to benzene. The cell was sealed immediately with strong adhesive tape to prevent further contact with air. The cell was stirred and readings were taken immediately until a constant value was obtained, experimentally found to be about 2 min. Separate experiments showed that the readings stay constant for 20 min except for solutions containing very high percentages of methyl or ethyl alcohols. For methanol and ethanol the value changed quickly with time, and the value after 2 min was taken. For further additions of alcohol or benzene the adhesive tape was removed from the buret inlet in the cover of the cell, and the buret tip was inserted in the inlet for quick delivery, and the cell was immediately resealed. Each titration curve was done completely in less than 2 hr.

The buret stopcock was treated with vacuum silicone grease which was soaked for two days in alcohol, boiled, the supernatant alcohol decanted, and the grease dried at 100°C before use.

Results and Discussion

The large increase in the initial values of pure methanol and ethanol are due to absorption of water from the air. The results show decrease in conductivity of the pure alcohols as shown in Fig. 1 and 2, as the carbon chain increases in line with observations made by Conway *et al.* (3) for proton mobility in alcohols. This decrease in conductivity is directly related to the per cent hydrogen bonding in these alcohols, such hydrogen bonding decrease with increasing carbon chain, as reflected from their boiling points, heat of vaporization, and thermal conductivities (4).

The effect of an increase of —CH_2— groups on conductivity can be estimated by plotting molar conduc-

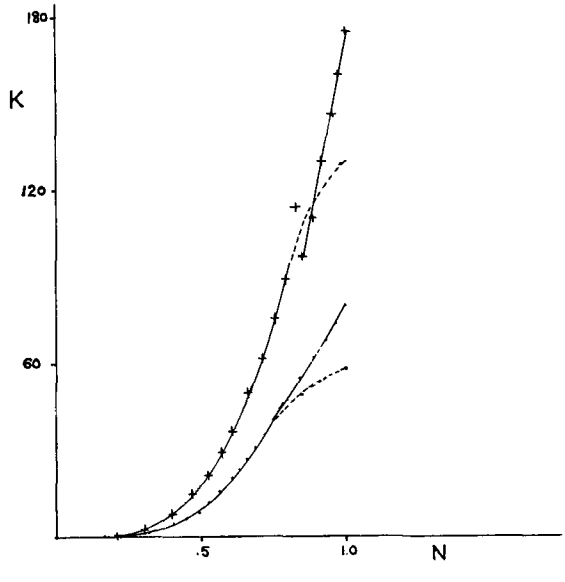

Fig. 1. Specific conductivity (K) x 10^8 ohm^{-1} cm^{1-} *vs.* mole fraction (N) for methyl alcohol (+) and ethyl alcohol (•) in benzene at 30°C. The straight line in each curve shows the effect of water in each system. The dotted parts are the extrapolation to the lowest reading of each alcohol.

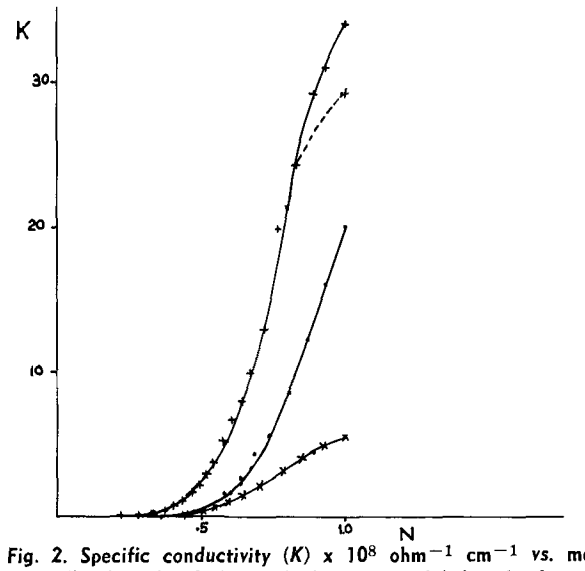

Fig. 2. Specific conductivity (K) x 10^8 ohm^{-1} cm^{-1} vs. mole fraction (N) for n-butyl alcohol (+), n-pentonol (•) and n-hexanol (X) in benzene. The dotted part is the extrapolation to the lowest reading for n-butanol at 30°C.

tivity *vs.* molar volume, Fig. 1. The slope of the straight line is —55 units.

The addition of an inert solvent to these alcohols should affect conductivities in the same manner as increasing the carbon chain in each alcohol. Such an effect is observed in the conductivities of alcohols when diluted with benzene. Plots of specific conductivity against mole fraction are shown in Fig. 1 and 2: for each alcohol there is a particular concentration at which the conductivity rises sharply with increasing concentration. These concentrations will be referred to as inflection points. This inflection indicates that the per cent hydrogen bonding of the alcohol has reached critical value, the meaning of which will be explained later. The inflection points were obtained from each curve by the usual method used to find end points in conductimetric titration; that is by drawing tangents to both ends of the curve, the point on the actual curve which corresponds to the intersection point of the tangents. The conductivity of the solution at that concentration corresponding to the inflection points was read directly from the curve. The inflection points are listed in Table I.

At the inflection points the hydrogen bond formation reaches a critical value, and the conductivity through such hydrogen-bonded chains rises sharply because the effective collisions between these chains is much greater than that between smaller chains present in solutions of lower concentrations. The increase in hydrogen bond formation when the concentration of alcohol is increased is amply verified in the literature by spectral work (4, 5). The inflection point of each alcohol occurs where the same number of moles of the different alcohols are present per unit of solution (*ca.* 6 moles/liter, Fig. 1 and 2, Table I). Table I shows that the conductivity of methanol at its inflection point is higher than that of hexanol at its inflection point, although there is the same number of

Table I. Inflection points taken from Figs. 1 and 2

Alcohol	Mole fraction of alcohol	Specific conductivity ohm^{-1} cm^{-1}, at inflection points	% v/v of alcohol	No. of moles/liter
Methanol	0.43	11.0 × 10^{-8}	26	6.35
Ethanol	0.50	8.0	36	6.18
Butanol	0.61	6.8	58	6.15
Pentanol	0.67	3.6	63	6.52
Hexanol	0.70	2.0	65	6.16

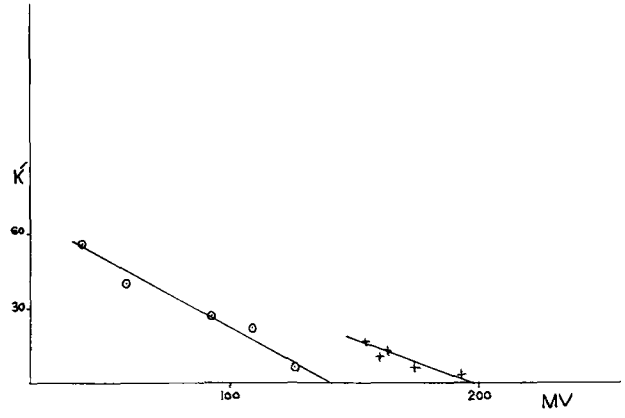

Fig. 3. Molar conductivity (K') x 10^6 ohm^{-1} cm^{-1} vs. molar volume (MV) for pure alcohols (⊙), and for alcohols in benzene at their inflection points (+) at 30°C.

moles/liter involved in each case. This is due to the fact that conductivity can proceed only through hydrogen bonds produced by effective collisions. The increased carbon chain length in the higher alcohols reduces these effective collisions by shielding the (OH) group in the alcohol molecule. This shielding is reduced to some extent in benzene solution but not entirely. The reduced shielding effect of the longer carbon chain is indicated by comparing the slopes obtained by plotting molar conductivities *vs.* molar volumes for the pure alcohols (—55 units) and for the solutions at the inflection points (—38 units) (Fig. 3).

The meaning of the slopes, as indicated earlier, is the decrease in molar conductivity brought about by an increase of one —CH_2— group in the carbon chain of the alcohol. The lower slope obtained for the inflection points in benzene solution indicates a reduction of the steric effect of the longer carbon chain and polymer chains also; the benzene straightens up these chains, thus reducing the shielding of the (OH) group and therefore increasing the effective collisions, which in turn causes the conductivity of the higher alcohols to increase relative to that of methanol. The large increase in conductivity caused by the small amount of absorbed water can be explained by the same reasoning: that is, the small water molecule, when hydrogen bonded between alcohol molecules, reduces the steric effect of the longer carbon chain, thus increasing the extent of hydrogen bonding in the whole system.

Our work, and that of Mecke (1), indicates the necessity of the hydrogen bonds for the conductivity of pure alcohols and their solutions. The solvents used in such systems were benzene, CCl_4, and chlorobenzene. The conductivity of these solvents, although small, is not negligible, especially at higher temperature (1).

It is difficult to explain the conductivity of such inert solvents as CCl_4 by the mechanism proposed by Mecke for the alcohol system, $HROH^+$----------O^-R $\rightleftarrows$HOR--------HOR. A different mechanism involving tunneling of electrons through solvent molecules might explain the conductivity of the inert solvents as that of CCl_4 (6, 7). This mechanism might also be involved in the conductivity of alcohols. The tunneling of electrons is easier through the hydrogen bonds (3) making the conductivity of alcohols higher than those of the inert solvents; accordingly the conductivity of alcohols should decrease with dilution.

Conductivity through Hydrogen Bonded Organic Compounds and Their Homogeneous Solutions

II. Conductivity of Phenol, o- and p-nitrophenol in Benzene and Ether

M. F. Mayahi and A. E. Habboush

College of Science, Baghdad University, Baghdad, Iraq

ABSTRACT

The conductivity of p-nitrophenol is more than that of o-nitrophenol in ether at 21°C. The solvent effect on conductivity is shown by measuring the conductivity of phenol in benzene and in ether at 21°C. The participation of the hydrogen-bonded complex C_6H_5OH-----$O(C_2H_5)_2$ in the conductivity of the system is postulated. Such complexing lowers the rate of increase in conductivity with concentration of phenol in ether compared to that in benzene.

The important influence of the hydrogen bond on conductivity was shown in Part I (1) for methanol, ethanol, butanol, n-pentanol, and n-hexanol. In this part we report the conductivities of phenol and benzoic acid in benzene and in ether, also o- and p-nitrophenol, and o- and p-nitrobenzoic acid in ether, all at 21°C.

Ubbelohde *et al.* (2) had shown that the conductivities of interhydrogen bonded solid organic acids are some hundred times greater than those of intrahydrogen bonded acids. Mecke *et al.* (3) studied the conductivities of o- and p-chlorophenol in CCl_4 at 20°C and found that the conductivities of the p-isomer is some hundred times greater than that of the o-isomer at 0.066 mole fraction.

Our work on the o- and p-nitrophenol and on o- and p-nitrobenzoic acid in ether shows differences similar to those reported by Ubbelhode (2) and Mecke (3).

Experimental

Materials.—o- and p-nitrophenol were commercial products and were twice recrystallized from alcohol before use. Benzoic acid and its o- and p-nitro compounds, phenol, benzene, and ether were of analytical grade and were used without further treatment

The method and apparatus for conductometric titrations were as described in Part I.

Results and Discussion

Figures 1 and 2 are plots of specific conductivity *vs.* molarity for phenol in benzene and in ether at 21°C. As in the case of alcohols (1) the conductivity is lowered as concentration is decreased. This decrease of conductivity is brought about by the decrease in per cent hydrogen bonding with dilution. Spectral evidence shows that phenol is interhydrogen bonded, and such bonds are broken on dilution with inert solvents (4). Thus interhydrogen bonding is important in the conductivity of phenol. Any other process which breaks the hydrogen bonding of phenol should bring about a decrease in conductivity. On this premise, the o-substituted phenol should have much lower conductivity than their p-isomer owing to the formation of the intrahydrogen bonding as indicated by spectral work (5). Such low conductivity was observed in our study of the conductivity of p- and o-nitrophenol in ether at 21°C. Figures 3 and 4 show the plot of specific conductivity *vs.* molarity for each isomer. The highest molarity used in each case was about the saturation point of each isomer. It is evident that the conductivity of p-nitrophenol is about six times more than that of o-nitrophenol in ether, even when the concentration of the latter compound is much higher. This ratio in conductivity would be still higher in noncomplexing solvents. This result is in good agreement with that found by Ubbelohde (2).

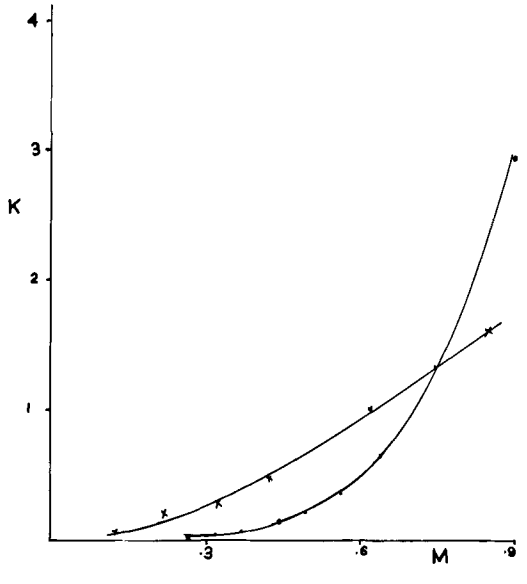

Fig. 1. Specific conductivity (K) x 10^{-8} ohm^{-1} cm^{-1} *vs.* molarity (M) for phenol in benzene (•) and in ether (X) at 21°C.

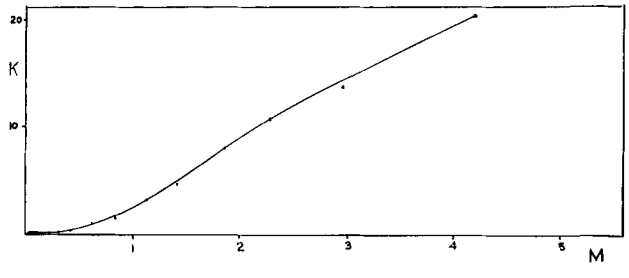

Fig. 2. Specific conductivity (K) x 10^{-8} ohm^{-1} cm^{-1} *vs.* molarity (M) for phenol in ether at 21°C.

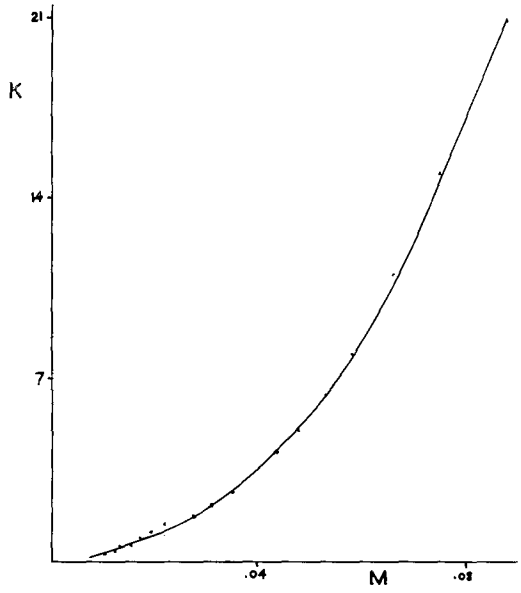

Fig. 3. Specific conductivity (K) x 10^{-8} ohm^{-1} cm^{-1} vs. molarity (M) for p-nitrophenol in ether at 21°C.

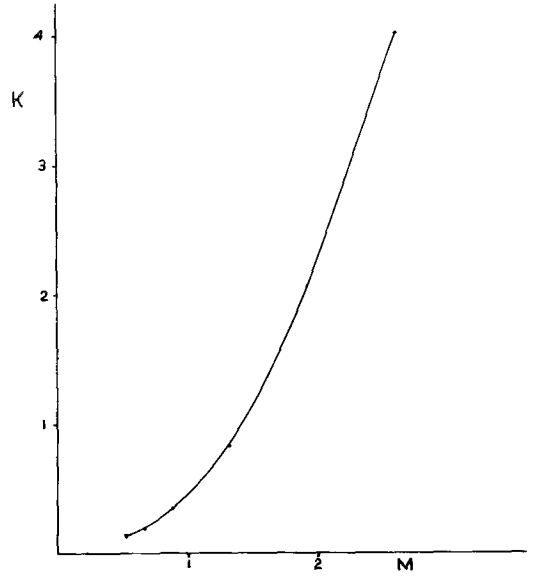

Fig. 4. Specific conductivity (K) x 10^{-8} ohm^{-1} cm^{-1} vs. molarity (M) for o-nitrophenol in ether at 21°C.

Inspection of Fig. 1, 2, and 4 shows that the conductivity of phenol is higher than those of o-nitrophenol in ether, indicating again the effect of intermolecular hydrogen bonding on conductivity. Also, the conductivities of benzoic acid which forms dimers and its o-NO_2 and p-NO_2 derivatives gave very small conductivities compared with that of phenol in ether (1.6M benzoic acid has a conductivity of 0.060 x 10^{-8} ohm^{-1} cm^{-1}).

The effect of solvent on conductivity is shown by comparing the conductivity of phenol in benzene and in ether (see Fig. 1 and 2). The rate of increase of conductivity of phenol is benzene is more than that of phenol in ether, as concentration is increased. This is due to the fact that the interhydrogen bonding of phenol is broken by the ether molecule, since the hydrogen bonding ether and phenol is stronger than between phenol molecules, as indicated by infrared study (6). However, Fig. 1 shows that the conductivity of phenol in ether is higher than that of phenol in benzene at the lower concentrations. Since the conductivity of an organic compound is increased when hydrogen bonding is involved, and (as indicated above) such hydrogen bonding is interrupted by ether molecules, then the higher conductivity of phenol in ether at the lower concentration must indicate that the hydrogen bonded complex between phenol and ether, *i.e.*, C_6H_5OH----$O(C_2H_5)_2$, is participating in the conductivity of the whole system. This involves an equilibrium between the phenol polymers and the indicated complex. After the intersection point of the two lines in Fig. 1 the conductivity of phenol in benzene is higher than that of phenol in ether, where the same concentrations are involved. This can be explained by assuming that there is greater increase in the formation of polymerized phenol in benzene than in ether.

A further example on the effect of solvent on conductivity is that of the difference in conductivity of benzoic acid in benzene (0.8M conductivity 0.0032 x 10^{-8} ohm^{-1} cm^{-1}) and in ether (0.8M conductivity 0.050 x 10^{-8} ohm^{-1} cm^{-1}). This difference is expected because benzoic acid is known to form closed dimers in benzene; these dimers are largely opened by the ether molecules (7).

Hydrogen Evolution at a Solid Indium Electrode

James N. Butler and Manfred Dienst

Tyco Laboratories, Inc., Waltham, Massachusetts

ABSTRACT

Measurements of hydrogen overvoltage on solid indium electrodes were made in 0.1M $HClO_4$ at temperatures from 21° to 59.5°C. The slow step in the hydrogen evolution reaction is probably discharge of a hydrogen ion, as indicated by the exchange current (10^{-11} amp/cm^2), transfer coefficient (0.5), effect of added iodide ion, and effect of acid concentration. The enthalpy of activation is 14.1 ± 0.5 kcal/mole at the reversible hydrogen potential and 10.0 ± 0.2 kcal/mole at the zero-charge point. From these values, an estimate of 50 ± 10 kcal/g atom is obtained for the heat of adsorption of hydrogen atoms on indium. The reaction is very sensitive to traces of oxygen, and the formation and removal of oxide films are discussed.

Indium offers an unusual opportunity for a detailed study of the hydrogen evolution reaction. In dilute acid, hydrogen evolution is the principal reaction over a potential range of more than 0.8v. The variation in reaction rate due to the influence of the double layer is greatest near the zero-charge point, which is known for indium and lies within the accessible range of hydrogen overpotential measurements. Thus indium is a good electrode on which to study how the hydrogen evolution reaction is influenced by the double layer. Indium also provides an interesting comparison with mercury, which has a similar hydrogen overpotential, but quite a different zero-charge point.

Although considerable work has been done on the dissolution of indium and indium amalgams and on the deposition of indium from solutions containing In^{+3} ions, no adequate measurements have been made of hydrogen overpotential on pure indium.

Bockris (1) made a brief survey of hydrogen overvoltage on eight metals in 1*N* HCl in the current density range from 10^{-3} to 10^{-1} amp/cm^2, and among these was indium. The results of this study are included in Fig. 1. Because no attempt was made to exclude oxygen rigorously from the electrolyte or to remove all traces of superficial oxide films from the electrode, the results of this study must be regarded as preliminary.

Hydrogen evolution has been noted by several workers (2-4) when the rate of indium deposition in acid solution becomes limited by diffusion of In^{+3} to the electrode surface. Kangro and Weingärtner (2) made a study of the deposition of indium from acid solutions containing $In_2(SO_4)_3$ and H_2SO_4, on an indium-coated platinum electrode. They noted that at sufficiently high current densities hydrogen evolution, rather than indium deposition, was the primary process. Their current-potential curve obtained in a solution of pH = 0.86, containing 1% of $In_2(SO_4)_3$ is also shown in Fig. 1. Although the results agree roughly with those of Bockris, a large discrepancy exists in the slope of the Tafel line.

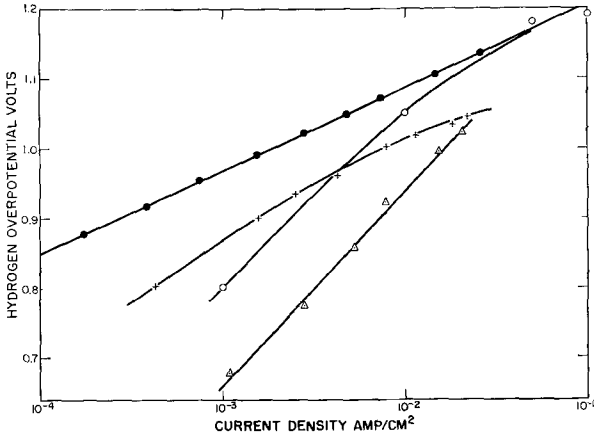

Fig. 1. Comparison of measurements of hydrogen overpotential by various workers: •, this work; ○, Bockris (1); +, Kangro and Weingärtner (2); △, Kochegarov *et al.* (3).

Kochegarov, Zaburdaeva, and Zyablova (3) performed a similar experiment, depositing indium from $In_2(SO_4)_3$-H_2SO_4 solutions onto a copper electrode. Their results, obtained at pH = 2.5 in a solution containing 0.1M $In_2(SO_4)_3$ (Fig. 1), agree with the results of Kangro and Weingärtner (2) at the highest current density, but the overvoltage values are generally much lower and the slope is closer to that of Bockris (1). In neither of these experiments was oxygen excluded from the solution, so that the current observed probably resulted not only from hydrogen evolution, but also from indium deposition and oxygen reduction. It is apparent from the above discussion that no systematic study has been made of In electrodes under conditions where hydrogen evolution is the only process taking place (34).

The necessity for rigorously removing oxygen from the solution when making measurements of hydrogen overvoltage has often been emphasized (5, 6), and the presence of differing amounts of oxygen in the electrolyte and on the electrode surface could account for the disagreement among the results of the three studies mentioned above. Furthermore, the slope of the Tafel lines in Fig. 1 varies between 120 and 280 mv. Although 120 mv is consistent with a slow-discharge mechanism for hydrogen evolution, a higher Tafel slope indicates that an additional process, such as indium deposition or oxygen reduction, is taking place (7, 8).

We have made accurate measurements of the hydrogen overpotential on indium in perchloric acid at several temperatures. These results are reported in this paper and discussed in terms of the transition state theory of reaction rates and the structure of the electrical double layer at the indium-electrolyte interface.

Experimental

A conventional three-compartment cell was used, with platinized platinum counter and reference electrodes. A Luggin capillary was positioned within 4 mm of the working electrode, and under the conditions of measurement, the resistance between the tip of the capillary and the electrode surface was 3-8 ohms. Measurements were made potentiostatically, using a Wenking electronic potentiostat (Brinkmann Instruments) together with a microammeter (Griebach, 0.5% accuracy).

The electrolyte was prepared from triple-distilled conductivity water and reagent grade perchloric acid (Baker). Except where noted, the concentration of perchloric acid was 0.100M. The solution was purified

by pre-electrolysis for 16 hr at a current of 10 ma, using a platinized platinum electrode as cathode. This cathode was removed from the solution before measurements were made. The solution was saturated with purified hydrogen throughout pre-electrolysis and all measurements. An oil-bath thermostat maintained the temperature constant within ±0.2°C from 20° to 60°C.

The cylindrical working electrode was made from 99.999% indium (American Smelting and Refining Company) and had a surface area of approximately 0.5 cm². It was electropolished in a 2:1 mixture of methanol and nitric acid, at an anodic current density of 0.3 amp/cm². After electropolishing, the electrode was thoroughly washed with conductivity water and introduced to the cell. The most reproducible measurements were obtained after the electrode had been polarized overnight in the cell at −1.0v. This effect was related to the removal of an oxide film and will be discussed in detail later.

The capacity of the electrode was measured by suddenly changing the current and observing on an oscilloscope the corresponding change in the potential of the electrode. For this measurement, the electrode was polarized galvanostatically.

From the initial linear increase of potential, the capacity was calculated using the relation

$$C = \Delta i(dt/dV)$$

where Δi is the current increment. If the current was increased by about 1 ma, the electrode potential increased linearly by about 4 mv in 16 μsec, corresponding to a capacity of about 4 μf (8 μf/cm²).

Results

In order to achieve reproducible values for the current-potential curve at low current-densities, it was necessary to prepolarize the indium electrode cathodically (usually at −1.0v with respect to a reversible hydrogen electrode) for an extensive period of time. Apparently the electropolished electrode was covered with a thin film of indium oxide, even though it appeared brightly metallic. At a temperature of 30°C, prepolarization for 16 hr at −1.0v was sufficient to remove the oxide film completely, as indicated by the fact that further prepolarization did not change the current-potential curve. During a typical prepolarization period, approximately 0.3-0.4 coul/cm² were passed in addition to the hydrogen evolution current observed on a clean electrode. If this were due entirely to removal of oxide film, the film on the electrode would have been approximately 0.1-0.2μ in thickness. Such a thick oxide film should have resulted in the appearance of interference colors, which were not observed. More likely, a large part of the additional current passed during prepolarization resulted from reduction of traces of dissolved oxygen in the electrolyte.

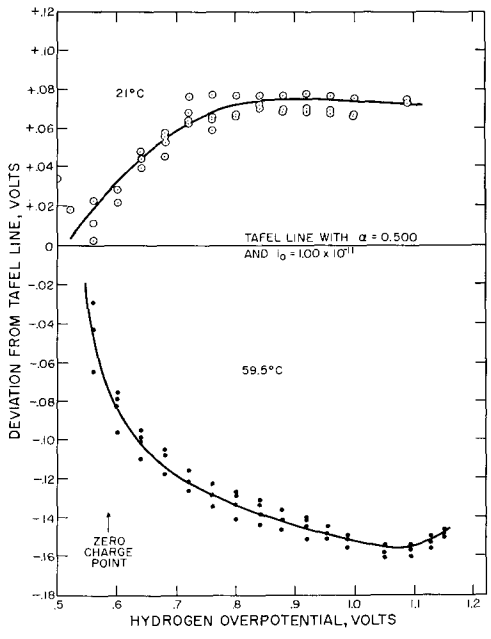

Fig. 2. Deviation of experimental current-potential curve from an arbitrary Tafel line with $\alpha = 0.500$ and $i_0 = 1.00 \times 10^{-11}$.

The measured potential values were corrected for the iR drop to obtain overpotential values, which are listed in Table I. Each set of values is the average of two to four current-potential curves, taken with the potential increasing and with the potential decreasing.

In Fig. 2 are shown two sets of current-potential measurements at 21° and 59.5°C. To show the small differences between the measurements clearly, we have plotted the deviation of the experimental values from a Tafel line

$$\eta = \frac{RT}{\alpha \mathbf{F}} \ln(i/i_0) \qquad [1]$$

with arbitrarily chosen values of exchange current $i_0 = 1.00 \times 10^{-11}$ amp/cm² and cathodic transfer coefficient $\alpha = 0.500$. Although there is a systematic deviation from the arbitrary Tafel line, the average difference between two points taken at a given potential at the same temperature is only about 4 mv. As can

be seen in Fig. 2, at 21°C, the deviations from the Tafel line became more positive at higher overpotentials, and at 59.5°C, the deviations became more negative at higher overpotentials. The data obtained at intermediate temperatures showed current-potential curves which were intermediate in shape bewteen the two extremes shown in Fig. 2.

As we shall explain in the discussion section, it seems likely that the slow step in the hydrogen evolution reaction on indium is the discharge of a hydrogen ion. For a reaction in which discharge of an ion is the rate-determining step, the measured overpotential includes not only the potential drop across the compact (Helmholtz) double layer, which drives the reaction, but also a potential drop across the diffuse (Gouy-Chapman) double layer, which does not influence the reaction rate (9-12). We have therefore used the relations derived by Frumkin (9, 13, 14) to obtain parameters which describe the experimental data. Unlike mercury, indium has a zero-charge point which falls at the lower end of the accessible range of overvoltage measurements: at —0.580v with respect to a reversible hydrogen electrode in 0.1M $HClO_4$ (15). This means that the contribution of the diffuse double layer to the total potential drop will vary appreciably over the range of potentials where we have measured the current-potential curves.

In order to apply Frumkin's equation to correct for the potential drop across the diffuse double layer, it is necessary to obtain ϕ_2, the potential of the outer Helmholtz plane, which is identified with the transition state for the hydrogen discharge reaction in the absence of specific adsorption. This potential is given by the equation (9, 16)

$$K\phi_0 = \left[\frac{2RT\,D\,D_0}{\pi}C_+\right]^{1/2}\sinh\left(\frac{\phi_2\mathbf{F}}{2RT}\right) \quad [2]$$

where R is the gas constant, T is the absolute temperature, D is the dielectric constant of water, $D_0 = 1.128 \times 10^{-12}$ coul volt^{-1} cm^{-1}, C_+ is the concentration of univalent electrolyte, $\mathbf{F}$ is the Faraday constant, K° is the integral capacity of the Helmholtz layer, and ϕ_0 is the rational potential of the electrode [potential with respect to the zero-charge point (16)].

The measured values of capacity are shown in Fig. 3, together with the interpolated curve which was used in the calculations, corresponding to the empirical equation

$$K = 8.9 + 2.75\ \phi_0 + 1.25\,\phi_0^2 \quad [3]$$

The measured capacity was somewhat lower than the 15 to 20 μf/cm^2 obtained with mercury (16), gallium (17), and lead (18), which may result from a thin residual oxide film.

For comparison, an alternative capacity function was obtained by extrapolating results obtained on a series of indium amalgams (19). This function presumably

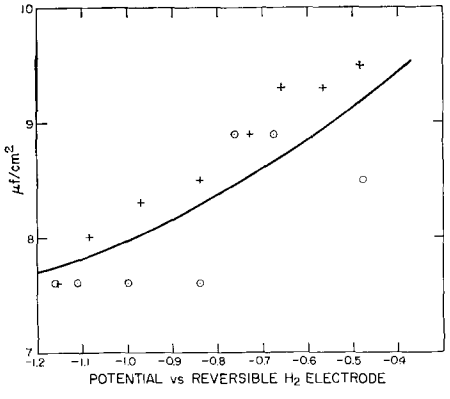

Fig. 3. Experimentally measured capacity values and interpolated curve used for calculations (Eq. [3]). ○, Clean electrode; +, oxidized electrode; ——, interpolated curve Eq. [3].

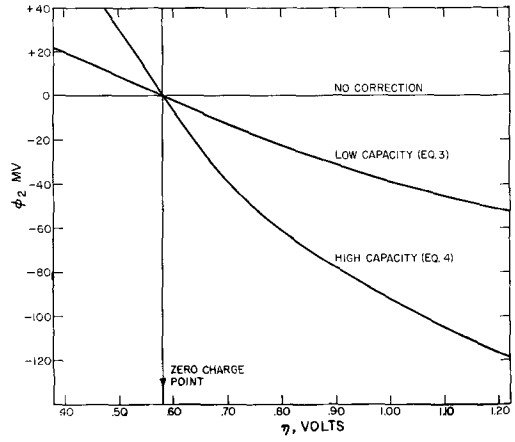

Fig. 4. Calculated values of the potential of the outer Helmholtz plane, ϕ_2, at 32°C.

is a good approximation to the capacity of pure supercooled liquid indium, and was

$$K = 42.0 + 46.6\,\phi_0 + 54.0\,\phi_0^2 \quad [4]$$

Equation [4] gave values in the range from 30 to 40 μf/cm^2.

In Fig. 4 are plotted two typical curves giving ϕ_2, the potential of the outer Helmholtz plane with respect to the bulk of the solution, as a function of the hydrogen overpotential. These were calculated using Eq. [3] and [4] to approximate K° in [2]. Note that when the high-capacity function given by Eq. [4] is used, the values of ϕ_2 obtained are nearly twice as large as when the low-capacity function given by Eq. [3] is used.

The overpotential for a reaction, where discharge of a hydrogen ion is the slow step, is given by the equation (9, 13, 14)

$$\eta = \frac{1-\alpha}{\alpha}\left(\phi_2 - \frac{RT}{\mathbf{F}}\ln[H^+]\right) + \frac{RT}{\alpha\mathbf{F}}\ln i - g_H + \text{const.} \quad [5]$$

where α is the cathodic transfer coefficient, i the current density, g_H the free energy of desorption of a hydrogen atom for the surface of the electrode, and $[H^+]$ the bulk concentration of hydrogen ions. Since we are holding the composition of the electrode and the concentration of hydrogen ion in the electrolyte constant, we can lump the constant terms into a corrected exchange current i_o'

$$\eta = \frac{1-\alpha}{\alpha}\phi_2 + \frac{RT}{\alpha\mathbf{F}}\ln(i/i_o') \quad [6]$$

where

$$\ln i_o' = (1-\alpha)\ln[H^+] + \frac{\alpha\mathbf{F}}{RT}g_H + \text{const.}$$

The corrected exchange current i_o' is different from the exchange current obtained from the simple Tafel Eq. [1] because of the term in ϕ_2, which corrects for the potential drop across the diffuse double layer. If $\phi_2 = 0$, Eq. [6] reduces to the simple Tafel equation.

Equation [5] can be cast into the form of a straight line

$$y = \alpha x + B \quad [7]$$

where

$$y = \frac{RT}{\mathbf{F}}\ln i + \phi_2$$

$$x = \eta + \phi_2 \quad [8]$$

The slope of this line is α and its intercept is

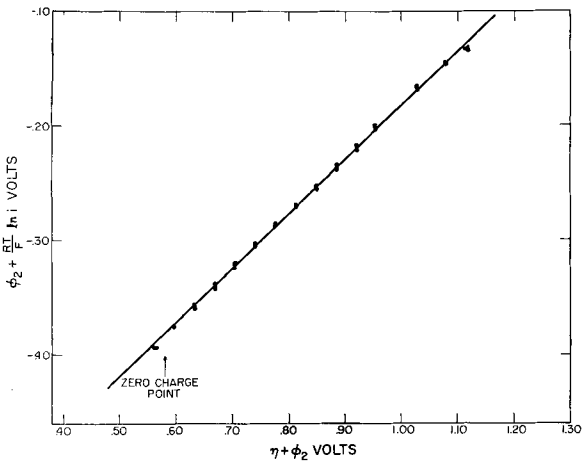

Fig. 5. Fit of experimental data to Eq. [5]. The temperature was 32°C, and the low-capacity function (Eq. [3]) was used to calculate ϕ_2. The correlation coefficient for the least-squares straight line is 0.9995. The best values for the parameters are $\alpha = 0.472 \pm 0.003$ and $-\log i_o' = 10.82 \pm 0.05$.

$$B = \frac{RT}{\mathbf{F}} \ln i_o' \qquad [9]$$

To obtain the parameters for each of the experiments conducted, ϕ_2 was calculated from Eq. [2] using the capacity function defined by either [3] or [4], and for each data point the quantities x and y, given by Eq. [8], were calculated. A least-squares straight line (Fig. 5) was fitted to the function $y(x)$, and from its slope and intercept were obtained the best values for α and $-\log i_o'$. The 95% confidence limits provide an estimate of the probable error in the measurements. These calculations were performed on an IBM 7094 computer.

The values so obtained are listed in Tables II and III, along with the values of α and $-\log i_o$ obtained when no correction is made for the potential drop across the diffuse double layer. From Table II, we can see that the larger the capacity, the smaller is α and the larger is i_o'.

Comparing the confidence limits on the parameters calculated with the high-capacity function, the low-capacity function, and with no correction, we can see that the best over-all fit is obtained with the low-capacity function. The high-capacity function gives a slightly better fit at the high temperatures, and no correction at all gives a slightly better fit at the low temperatures. The results obtained using the low-capacity function are probably the most realistic and will be used in the subsequent discussion.

Discussion

Mechanism.—In our calculations and in the following discussion of the results, we assume that discharge of a hydrogen ion is the rate-determining step in the hydrogen evolution reaction on solid indium. This mechanism is suggested by a number of observations, which we shall discuss here.

Table III. Effect of electrode preparation

Temperature 30°-32°C

History of electrode	Parameters of current-potential curve[a] α	$-\log i_o'$	No. points
1. Electropolished, reduced at −1.0v for 40 hr as 30°C	0.489 ± 0.004	10.83 ± 0.06	35
2. Electropolished, reduced at −1.0v for 16 hr at 25°C	0.472 ± 0.003	10.82 ± 0.04	59
3. Treatment 2, followed by redn. at −1.0v for 16 hr at 60°C	0.482 ± 0.002	10.80 ± 0.04	30
4. Clean electrode, oxidized for 5 min in air at 25°C (only points with $i > 10^{-4}$ amp/cm²)	0.459 ± 0.009	10.36 ± 0.14	16
5. Treatment 4, followed by redn. at −1.0v for 16 hr at 30°C	0.486 ± 0.004	10.84 ± 0.06	23
6. Clean electrode, left on open circuit (−0.4v) for 15 min	0.485 ± 0.006	10.84 ± 0.08	20

[a] Calculated using experimental capacity values given by Eq. [3].

The exchange current on indium is approximately 10^{-11} amp/cm² at 30°C, of the same order of magnitude as the exchange current on lead and mercury, metals for which considerable evidence indicates a slow discharge mechanism (8, 9, 20). As shown in Fig. 5, the data fit Eq. [5] over a wide range of potentials, including the zero-charge point of indium, where the largest deviation from Eq. [5] would be expected if discharge were not the slow step. The observed effect of the diffuse double layer is thus the same as is expected for a slow discharge mechanism. The observed transfer coefficient is very close to 0.50, indicating a symmetrical activation energy barrier. This also implies that discharge is the slow step (21).

One important effect of the slow-discharge mechanism is the extreme sensitivity of the hydrogen overvoltage to adsorbed species on the electrode (9, 20). A specifically adsorbed anionic species on the electrode lowers the overvoltage at small current densities. In a few experiments, we added potassium iodide to the electrolyte and observed that, at current densities below 10^{-4} amp/cm², the overvoltage was approximately 0.1v lower than in the absence of potassium iodide. This agrees qualitatively with the results observed on mercury, lead, and gallium (9, 17, 20). However, the effect observed could have been at least partially due to small amounts of oxygen or free iodine in the electrolyte, since the results were very irreproducible.

A further consequence of the slow-discharge mechanism is that the dependence of overvoltage on pH should be given by Eq. [5]. An experiment with 0.01M $HClO_4$ as electrolyte gave the results summarized in Table IV. According to Eq. [6], the quantity

$$-\log i_o' + (1 - \alpha) \log [H^+]$$

should be independent of the electrolyte composition. In Table IV we see that it is the same within experimental error for both 0.1 and 0.01M $HClO_4$.

In view of the foregoing observations, it seems reasonable to assume that discharge of a hydrogen ion is the slow step of the hydrogen evolution reaction on indium.

Enthalpy of activation.—According to the transition state theory (8, 21, 23), the enthalpy of activation for the discharge reaction is given by

$$\Delta H^{\ddagger} = RT^2 \left(\frac{\partial \ln i}{\partial T} \right)_{\eta} \qquad [10]$$

and depends on the potential at which the temperature coefficient is measured.

The temperature dependence of the corrected exchange current is shown in Fig. 6. These values were obtained using the capacity function given by Eq. [3]; however, the uncorrected values of exchange current, and the values obtained using the capacity function given by Eq. [4] differ only by an additive constant. The best straight line through the points obtained at the three highest temperatures gives $\Delta H^{\ddagger} = 14.1 \pm 0.5$ kcal/mole for the enthalpy of activation at the reversible hydrogen potential. The values obtained at the lower temperatures have been omitted because the effect of adsorbed oxygen or a thin oxide film makes Eq. [10] inapplicable.

Although it is conventional to calculate the enthalpy of activation at the reversible hydrogen potential, it is also significant to look at the enthalpy of activation at the zero charge point of the electrode. In Fig. 7 is plotted the current at the zero charge point [$\eta = 0.58$v (15)] as a function of the reciprocal temperature. The slope of the best line defined by the high temperature points is 10.0 ± 0.2 kcal/mole. In principle, the current at the zero charge point should be independent of the capacity function used to calculate the diffuse double layer correction. The effect of the capacity function on i_z, apparent in Fig. 7, reflects the effect of scatter in the current-potential values on the interpolation at the zero charge point.

In order to compare the enthalpy of activation for indium with that for mercury, it is desirable to refer

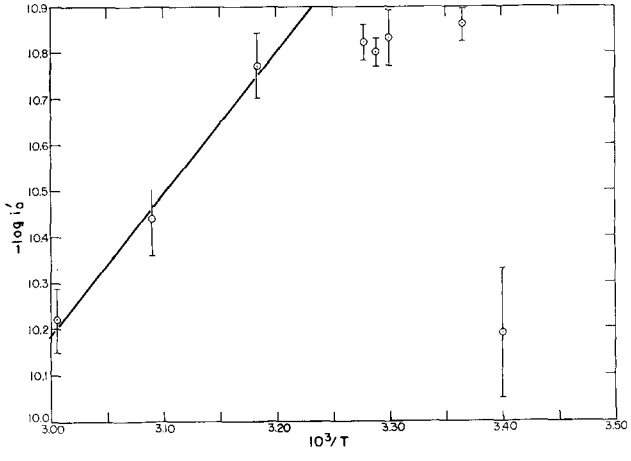

Fig. 6. Temperature dependence of the corrected exchange current. The straight line corresponds to an enthalpy of activation of 14.1 ± 0.5 kcal. The low-capacity function was used in calculating i_o'.

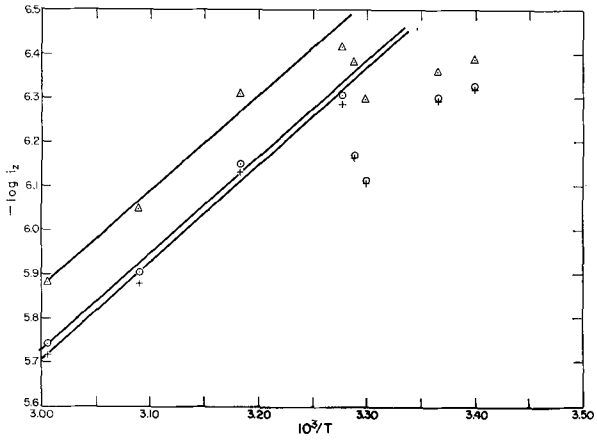

Fig. 7. Temperature dependence of the current at the zero charge point. All three straight lines have a slope corresponding to an enthalpy of activation of 10.0 ± 0.2 kcal. ○, Low capacity; △, high capacity; +, uncorrected.

both to the same potential relative to the zero-charge point. The reversible hydrogen potential in 0.1M $HClO_4$ is 0.165v positive with respect to the zero-charge point of mercury, but is 0.58v positive with respect to the zero-charge point of indium (15). Consequently, a comparison of $\Delta H^{\ddagger}$ at the reversible hydrogen potential will contain contributions from the temperature dependence of the double layer structure.

At the reversible hydrogen potential, $\Delta H^{\ddagger}$ for the hydrogen evolution reaction on mercury was determined by Post and Hiskey (23) to be 21.7 ± 0.2 kcal, and by Iofa and Mikulin (24) to be 21.1 ± 0.5 kcal. The potential dependence of the enthalpy of activation is given approximately by (23)

$$\Delta H^{\ddagger} = \Delta H^{\ddagger}_{rev} - \alpha \mathbf{F} \eta \qquad [11]$$

where $\Delta H^{\ddagger}_{rev}$ is the enthalpy of activation at the reversible hydrogen potential, and η, the cathodic overvoltage, is positive.

Equation [11] does not hold as well for indium as it does for mercury. This can be seen by calculating the difference in the enthalpy of activation on indium between the reversible hydrogen potential and the zero charge point. Using Eq. [11], this difference is calculated to be 6.7 kcal; the experimentally observed difference is only 4.1 kcal. For this reason, we feel it is more accurate to extrapolate the results for mercury than the results for indium.

Thus, at the zero charge point, $\Delta H^{\ddagger}$ for the hydrogen evolution reaction on mercury is 19.8 kcal, which may be compared with 10.0 kcal which we have observed for $\Delta H^{\ddagger}$ at the zero charge point on indium.

Similarly, but with less accuracy, we may compare the enthalpy of activation on mercury at the reversible hydrogen potential (+0.165v with respect to the zero-charge point) with that for indium at a potential of +0.165v with respect to the zero-charge point, an overpotential of 0.415v. For mercury, $\Delta H^{\ddagger}$ is 21.7 kcal; for indium, $\Delta H^{\ddagger}$ is 11.9 kcal.

Parsons and Bockris (22) have estimated, for mercury and nickel, the theoretical dependence of enthalpy of activation on the heat of adsorption of hydrogen atoms. Using a similar method, Rüetschi and Delahay (26) have calculated heats of adsorption for hydrogen atoms and correlated them with experimental values of overvoltage at constant current density.

Because of the similarity in hydrogen overvoltage between mercury and indium, it seems likely that the values of all parameters involved in the dependence of $\Delta H^{\ddagger}$ on heat of adsorption are approximately the same for mercury and indium (15). The curve of this dependence, calculated for mercury by Parsons and Bockris (22), is shown in Fig. 8. To show the uncertainty in such a calculation, two extreme estimates are

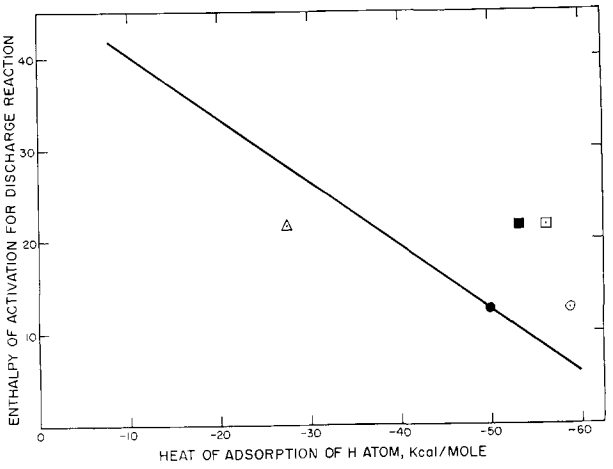

Fig. 8. Relation between enthalpy of activation and heat of adsorption of hydrogen atoms, with estimated values for mercury and indium. ——, Theoretical curve (22); •, indium, this work; △, mercury (24, 25); □, mercury (27); ■, mercury (26); ○, indium (26).

shown for the heat of adsorption of hydrogen atoms on mercury: Frumkin, Iofa, and Bagozky (25) estimated this quantity to be approximately 28 kcal, whereas Conway and Bockris (27) estimated it to be approximately 57 kcal. The theoretical curve calculated by Parsons and Bockris (22) falls between these two extremes. Our value of 11.9 kcal for the enthalpy of activation for the hydrogen evolution reaction on indium (at a potential of +0.165v with respect to the zero-charge point) allows us to estimate that the heat of adsorption of hydrogen atoms on indium is 50 ± 10 kcal. This value is consistent with the value (56.6 kcal) estimated by Rüetschi and Delahay (26).

Effect of oxide film.—We have mentioned that, before reproducible measurements of overpotential could be obtained, it was necessary to remove the oxide film on the electrode by prolonged cathodic polarization. At temperatures below 30°C, this oxide film was not removed even after polarization for 16 hr at — 1.0v.

The oxide film we have observed is probably similar to the film formed on passivation of indium. Popova and Simonova (32) showed that anodic polarization of indium in both acid and alkaline solutions produce a passive oxide layer which corresponded approximately to a monolayer of oxygen. In 0.1M $HClO_4$, this passive oxide layer was apparently stable, even though In_2O_3 is thermodynamically unstable in acid solutions (33). A similar type of oxide film has been observed on solid gallium (18, 28). Indium antimonide is known to form a stable, coherent film of In_2O_3 both on thermal oxidation (29, 30) and on anodic oxidation (31). This film is difficult to reduce, even in acid solution (29).

Our observations on the oxide film formed on indium are in accord with these results. In our experiments, polarization of the indium electrode at — 0.6v for 16 hr failed to remove the oxide film; complete removal required an elevated temperature, as well as prolonged cathodic polarization at — 1.0v (See Table III).

The fact that indium forms such a stable oxide film causes a hysteresis effect in the current-potential curve when traces of oxygen are present. In Fig. 9, we see the current-potential curve observed when a freshly prepared electrode is introduced into the cell. As the cathodic overpotential is increased, the lower curve is obtained; the wave resulting from both the reduction of the oxide film and the diffusion-limited reduction of oxygen in the solution. If the electrode is held for several hours at 1.0v cathodic polarization, the current decreases. If the overpotential is then decreased, the upper curve is obtained. The wave for oxygen reduction is shifted to lower current densities, both because the concentration of oxygen in the solution is smaller and because part of the oxide film has been removed from the electrode.

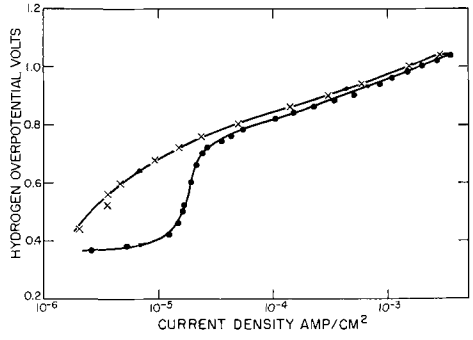

Fig. 9. Current-potential curve taken using a freshly prepared electrode. The lower curve was taken with overpotential increasing; the electrode was held at an overpotential of 1.04v for 2 hr and then the upper curve was taken, with overpotential decreasing.

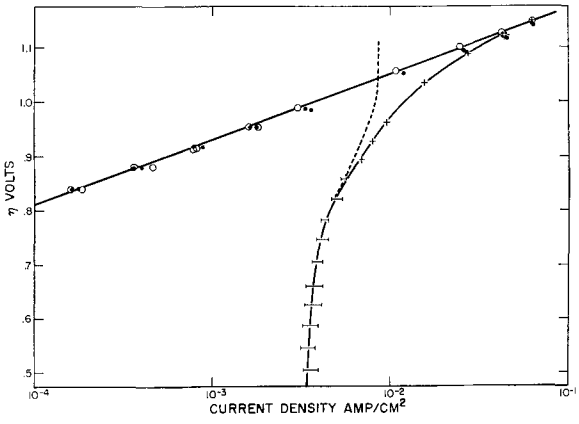

Fig. 10. Current-potential curve taken on a clean and oxidized electrode in the absence of oxygen and on an electrode in a solution saturated with oxygen. The oxygen reduction current was obtained by subtracting the current given by the upper curve from that given by the lower curve. Without oxygen: •, clean; ○, oxidized. With oxygen: ———, total current; — — —, O_2 reduction current.

This wave definitely results from oxygen reduction, and not from In^{+3} reduction. If the electrode is prepolarized until the current-potential curve shows no hysteresis and obeys Eq. [5] over the accessible range of overpotentials, we may assume that the oxide film has been completely removed. If such an electrode is left on open circuit for 15 min, no effect is observed on the current-potential curve (Table III), indicating that no appreciable amount of In^{+3} exists in the solution due to chemical dissolution of the electrode. In contrast, if the electrode is removed from the cell and exposed to the air for only 1½ min, the subsequent polarization curve shows hysteresis and has the shape shown in Fig. 9. In order to restore the electrode to its former condition, it is necessary to polarize it cathodically for 16 hr. During this time, approximately 0.5 coulombs of charge pass through the cell in addition to that required to evolve hydrogen. This additional current is probably due both to reduction of oxide on the electrode and to the reduction of oxygen in the solution. These results are summarized in Table III.

The effect of bubbling oxygen over the electrode is shown in Fig. 10. The oxygen reduction current (dotted line) has been obtained by subtracting, from the total current, the current for hydrogen evolution at the same potential. Note that although the oxygen reduction current appears to be diffusion limited in the range of potentials shown, the limiting current in fact increases by about a factor of two at approximately

0.8v. This effect probably results from stirring by evolved hydrogen. At lower potentials, the limiting current for oxygen reduction is controlled by diffusion of oxygen through a boundary layer at the electrode surface. When the rate of hydrogen evolution becomes large enough, hydrogen bubble formation at the electrode surface disturbs this boundary layer and increases the maximum rate at which oxygen can diffuse to the electrode.

Another possible explanation of this phenomenon can be made in terms of the kinetics of reduction of the oxide film. If the rate of reduction of oxygen on the oxide film is slower than the rate of reduction of oxygen on a clean electrode, then, at potentials between 0.4 and 0.8v, a steady state is set up. The oxide film is reduced, but is regenerated by oxygen diffusing from the solution. However, at potentials above 0.8v, reduction of the oxide film itself is sufficiently fast that the electrode becomes free of oxide and oxygen reduction takes place directly on the surface of the metal. Because this reaction is faster, a higher limiting current controlled by diffusion of oxygen is reached.

An alternative kinetic explanation for the increase in oxygen reduction current at high potentials is that the oxide film catalyzes the hydrogen evolution reaction. This explanation is not correct. In Fig. 10 the data are given for an oxidized electrode and an oxide-free electrode under the same conditions. In the region covered by Fig. 10, the current-potential curves for hydrogen evolution, in the absence of oxygen, are identical on clean and oxidized electrodes. The oxide does not catalyze the hydrogen evolution reaction.

34. Note added in proof: Murtazaev and Nikol'skaya [*Dokl. Akad. Nauk Uz. SSR*, **21**, 31 (1964), *Chem. Abstr.*, **61**, 15661 (1964)] have studied hydrogen evolution on indium in KOH, HCl, and H_2SO_4. At 10^{-3} amp/cm^2 in acid, $\eta \cong 0.85$ volts compared to our value of 1.00 volts. This low overvoltage, together with the high Tafel slope (200-250 mv) indicates considerable oxygen in the electrolyte. Hence their current-potential curves do not correspond to hydrogen evolution alone.

Improved Porous Electrode for Studying Electrocatalytic Reactions of Gases and Vapors

G. Bianchi

Laboratory of Electrochemistry and Metallurgy, University of Milan, Milan, Italy

ABSTRACT

An improved porous electrode is described which is a convenient basis for a comparative study of electrocatalytic activity of noble metals and/or for investigations of electrocatalytic processes on gases. The suggested technique makes use of porous graphite disks having a part of their surface covered with a thin layer of catalyst kept in position by means of a thin network of sintered Teflon drops. Such an electrode is to be disposed horizontally with its upper catalyst side kept in the atmosphere of the concerned gas, the remaining part being immerged in the solution. Solution by capillarity moves upward to moisten catalyst. Teflon prevents solution from reaching a too high level which would submerge the catalyst. This way the triple contact electrode-solution-gas is complete and efficient, and both solution level and graphite porosity are not critical factors. Polarization curves and charge-discharge curves have been determined in order to evaluate performances of that porous electrode in various electrochemical systems and processes.

Investigation of electrochemical processes of gas sparingly soluble in aqueous solutions has its chief obstacle in the set up to be deviced to realize the contact electrode-solution-gas. Such a contact may be obtained by means of a porous electrode wet-proofed so that the contact between the gas and the solution is in the pores of the electrode itself. A similar artifice is applied in the fuel cells where porous electrodes with controlled porosity are used. However this method does not give satisfactory results when applied to draw polarization curves or charge-discharge curves or to make analogous determinations.

The structure of the electrode gives origin to concentration polarization in the gas phase and in the solution inside the pores of the electrode itself. Furthermore it is unavoidable to have incorrect determinations of polarization by ohmic losses taking place inside the porous electrode. On top of that must be put the hindrance offered to the construction of electrodes with reproducible properties, when electrodes activated in different ways are to be used, by the fact that the activation must be realized by deposition of the catalyst inside the pores of the electrode.

A different problem is the perfection of an experimental set up valid for studying and evaluating catalysts as Pt-Pd-Rh, etc., blacks involving electrochemical methods. This problem has been recently considered by Grubb and Michalske (1) who proposed a metal screen as a support for the pasted catalyst. The necessity for a method to evaluate the electrocatalytic activity of noble metals has been outlined recently in the case of ethylene anodic oxidation in acid solutions (2). Such a method can be perfected easily and rapidly as the evaluation of the catalysts may be done only by measuring the current at controlled potential for selected reactions of the electrode.

Suggested Technique

The newly suggested technique makes use of the properties of a porous graphite electrode suggested by Elmore and Tanner (3) having a part of its surface covered with a thin layer of an appropriate catalyst kept in position with Teflon. The electrode is disposed horizontally with the part covered with the catalyst kept in an atmosphere of gas and the remaining part immersed in the aqueous solution. The solution moves upward by capillarity through the pores of the electrode and moistens the catalyst layer. The Teflon wetproof layer also helps to prevent solution from reaching a too high level which would completely submerge the catalyst. On the other hand, this porous Teflon layer is very thin (about 0.2 mm) so that the concentration polarization on the gas side is negligible as long as very high current densities are not reached. This way the contact electrode-solution-gas is complete and satisfactory, and solution level is not a critical factor.

The detailed electrode previously described is shown in Fig. 1 together with the polarization cell used and the correct disposition of the Luggin-Haber's capillary to prevent ohmic losses in the polarization measurements (4).

The electrode is prepared in conformity with the following specifications: a disk of porous graphite 4 mm thick and 25 mm in diameter, pierced in the center to settle a Luggin-Haber's capillary, is covered over by a thick paste of the catalyst finely ground in distilled water, a slight depression being applied

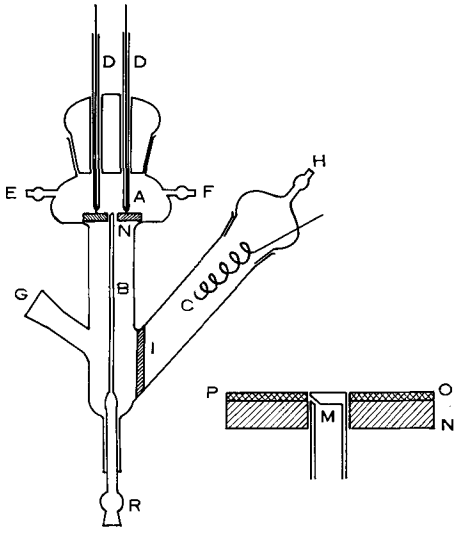

Fig. 1. Complete view of the cell using the porous electrode with capillary imbibition for measures of polarization with detail of the electrode and disposition of the Luggin-Haber's capillary: A, gas chamber; B, solution; C, counterelectrode; D, wires for connection with polarizing circuit and potentiometric circuit; E, inlet of the gas or vapor; F, outlet of the gas or vapor; G, connection with reservoir of solution; H, outlets of gas evolved at counterelectrode; I, sintered glass diaphragm; M, Luggin-Haber capillary with lateral opening positioned in the hole at the center of the electrode; N, porous graphite electrode; P, O, layer of catalyst; R, to reference electrode.

underneath the disk during the process. Both in the case of Pt black and of graphite powder activated with platinum the deposited catalyst amounts to about 5 mg/cm^2. The disk dried in a muffle furnace at 120°C is sprayed with an aqueous suspension of Teflon (du Pont 30) and afterwards heated *in vacuo* at 300°C for 3 hr to sinter the Teflon. The spraying of Teflon suspension should be done so that the Teflon cover results in a net involving 3 or 4 layers of drops, whose mean diameter is about 50μ. This can be achieved by spraying the Teflon, drying with hot air, spraying the Teflon again, drying, and so on. This wetproof Teflon cover protects the catalyst from mechanical damage and prevents the formation, during operation, of a veil of solution over the activated surface of the electrode without screening the catalyst itself.

If the studied catalyst can be damaged during the heating at 300°C necessary to sinter Teflon, the electrode could be used without the Teflon layer, too. In this case, however, the solution level is critical, and the current which the electrode can now supply is reduced to about 25%.

Such an electrode may be used as a research tool for studying electrochemical processes involving gases and vapors. In the latter case the vapors are flushed round the electrode by a stream of inert gas as disturbing phenomena of concentration polarization in the gas phase are unimportant as in the case of porous wet-proofed electrode.

Results

The performances obtained with this electrode are explained in some of the accompanying figures. Figure 2 shows potentiostatic curves of polarization related to the anodic ionization of hydrogen.

Curves A and B are obtained with two electrodes prepared by using graphite at different porosity but according to the same technique. The results are equivalent and prove that the properties of the porous graphite are not critical for the behavior of the electrode. Curves C and D are obtained with a catalyst different from that used for curves A and B and show the anodic ionization of pure hydrogen (curve C) or of a mixture 50% H_2 and 50% N_2 by volume.

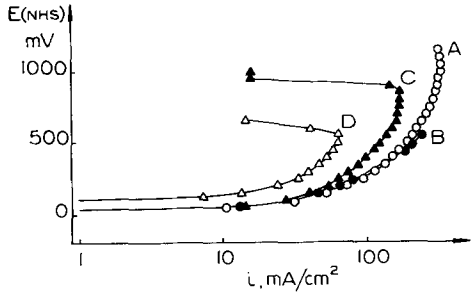

Fig. 2. Potentiostatic polarization curves for the hydrogen anodic ionization in acid solution 0.5M H_2SO_4 at 25°C. A, B, C, pure hydrogen; D, mixture of 50% H_2 and 50% N_2 by volume. For curves A and B the same catalyst is used but the supporting electrode is different: in one case (A) being graphite National S 2368, grade 45, porosity 48%; in the second one (B) being graphite Stackpole Carbon Co. PC 57 H, porosity 68%. For curves C and D the same electrode and the same catalyst is used. The catalyst is different from that used for curves A and B.

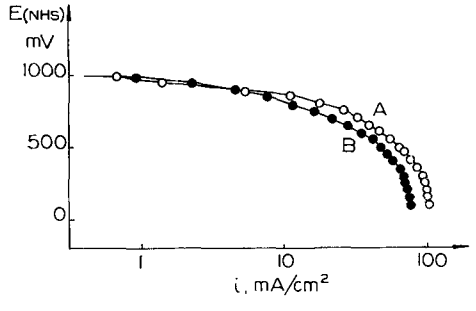

Fig. 3. Cathodic polarization curves for the reduction of O_2 in acid solutions at 50°C: A, electrode cathodically activated at + 200 mv, NHS; B, electrode after functioning for long time at + 700 mv, NHS.

The O_2 cathodic reduction on Pt black in 2.5M H_2SO_4 at 50°C is shown in Fig. 3. Polarization curve A is obtained with an electrode activated by cathodic polarization at + 200 mv (NHS); curve B with an electrode that worked for long time at + 700 mv. The variation of current is immediate when air is substituted for oxygen and *vice-versa* (Fig. 4). This fact, more than the ratio 5:1 between the current verified in the two cases, shows that the concentration polarization on the gas side is so low that no appreciable effect is produced.

Figure 5 illustrates the anodic oxidation of methanol in acid solution at 25°C. Methanol vapors are carried by a nitrogen stream.

Performances of various catalysts (platinum, iridium, rhodium, and ruthenium blacks) in the anodic

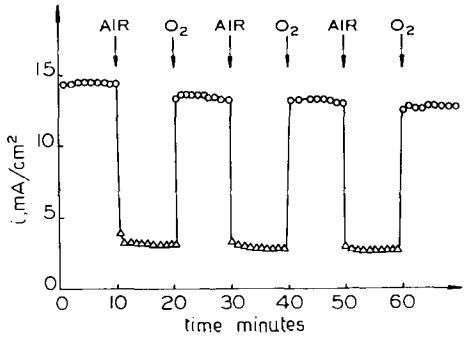

Fig. 4. Current response during cathodic reduction of oxygen at 700 mv, NHS, in acid solutions at 50°C, on alternated substitutions of oxygen for air and *vice versa*.

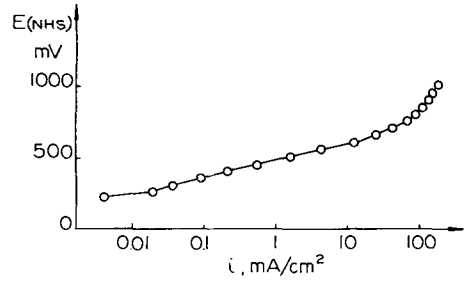

Fig. 5. Polarization curve for the anodic oxidation of methanol vapors carried by a stream of nitrogen in acid solution (0.5M H_2SO_4) at 25°C.

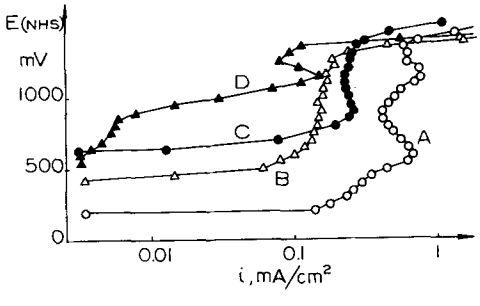

Fig. 6. Polarization curves for the anodic oxidation of propane in acid solution (0.5M H_2SO_4) in the presence of various catalysts at 25°C: A, platinum black (Engelhard); B, iridium black (Johnson and Matthey); C, rhodium black (Engelhard); D, rutenium black (Johnson and Matthey).

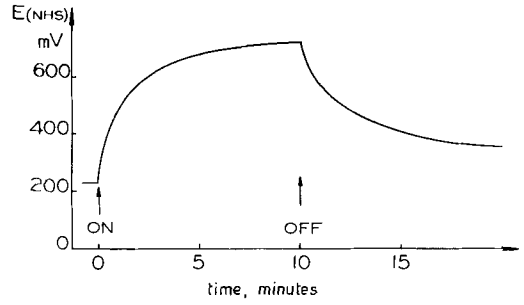

Fig. 7. Anodic charging curves at constant current (i = 0.5 ma/cm^2) and decay curve after anodic polarization for propylene in acid solution (0.5M H_2SO_4) at 25°C; platinum black as catalyst.

oxidation of propane in acid solution at 25°C are compared through the potentiostatic curves in Fig. 6, which confirm that platinum is the best catalyst for propane anodic oxidation (5).

The anodic charging curves related to propylene in acid solution in presence of platinum black are in Fig 7. The electrodes were activated by anodic formation of platinum oxides followed by cathodic reduction at 200 mv (NHS). It is evident that during the anodic oxidation of propylene, the catalyst undergoes a process of slow poisoning.

Discussion

The results quoted in this paper put into evidence that the capillary imbibition porous electrode can be advantageously used as a research tool for studying the electrochemical processes of gases and vapors. It can furthermore be employed as a support for a hydrogen reference electrode, reliable and simple, with exchange currents as high as 10 ma/cm^2. It is also possible to foresee the utilization of such an electrode in fuel cells and industrial plants.

Technical Notes

Oxidation by Transport through Blocking Pores

P. L. Harrison

Central Electricity Research Laboratories, Leatherhead, England

Under certain conditions the oxidation of mild steel in aqueous solutions in the temperature range 250°-400°C produces a double layer magnetite film, the inner layer of which is protective (1). In dilute alkaline solutions, the growth of this inner layer becomes extremely slow at a thickness of a few tens of microns, and there is some indication of a limiting thickness of about 50 μm. Under weakly acidic or strongly alkaline conditions (2, 3) the magnetite does not form as a protective layer and corrosion continues at a rapid rate. The mechanism of the corrosion process and the conditions leading to a nonprotective oxide have been the subject of many recent studies (4-6).

Some of this work (4, 5) has shown that the magnetite layer formed is porous. Measurements of the density of laboratory-grown magnetite (4) indicated a porosity of about 10% volume/volume, and electron microscopy of magnetite films 1000-2000Å thick (5) indicated that pores of 100-500Å are present between the particles of magnetite. Porosimetry studies (7) of an exceptionally thick magnetite deposit from part of a power-station boiler were in agreement with these measurements. Such porosity can be reconciled with a protective oxide layer by assuming that the pores gradually become blocked during the course of oxidation. It is known (1) that during oxidation metal ions pass out through the oxide as oxidant passes in. There is a possibility, therefore, of reaction taking place within the pores.

The growth of a porous oxide under conditions such that the pores become blocked during oxidation has been treated by Evans (8). He considers two cases. One case represents self-blocking in which the pores through which the reactants diffuse become blocked by the reaction taking place within them. If w represents the weight of metal oxidized and n represents the number of pores per unit area, then we have $\frac{dw}{dt} = k_1 n$ and $-dn = k_2 dw$ which give the asymptotic equation

$$w = \frac{n_o}{k_2}(1 - e^{-k_1 k_2 t}) \qquad [1]$$

where n_o is the value of n at $t = 0$.

The other case, termed mutual pore blocking by Evans, is one in which the oxide formed within a pore causes a compressive strain in the surrounding oxide, which closes up neighboring pores. The number of pores so blocked is proportional to the density of pores, so that the equations become

$$\frac{dw}{dt} = k_1 n \text{ and } -dn = k_3 n dw$$

These give the direct logarithmic equation

$$w = \frac{1}{k_3}\log_e (k_1 k_3 n_o t + 1) \qquad [2]$$

It is to be noted that, in the case of self-blocking, the weight of metal oxidized cannot exceed an amount represented by $w = n_o/k_2$. No such limit applies in the case of mutual blocking, so that at large values of t the extent and rate of oxidation is greater for the

mutual blocking case than for the self-blocking case. This arises because implicit in the equation $-dn = k_3\, ndw$ is the assumption that the pores responsible for causing blocking of neighboring pores do not themselves become blocked. Evans (9) suggests that the oxide growing within the pore becomes wedged across the pore in such a way that it fills part only of the cross section. As this oxide continues to grow, compressive strains are set up at the points of contact between it and the pore surface. The transmission of these strains through the bulk oxide causes neighboring pores to become blocked even though the intrapore oxide does not completely block the pore in which it is growing. Evans suggests that the effective resistance of this pore to the passage of reactants is unaltered, because, although the cross section is reduced at the site of the intrapore oxide, the strains this oxide imposes cause the cross section of neighboring lengths of the pore to be increased. He suggests that the two effects can be assumed to cancel each other out.

A further case of pore-blocking which is of interest is one in which the intrapore oxide responsible for the blocking of neighboring pores also causes blocking of the pore in which it is forming. This is a combination of the two cases considered by Evans. The relevant equations are

$$\frac{dw}{dt} = k_1 n \text{ and } -dn = k_2\, dw + k_3\, n\, d\, w$$

which give for the relation between extent of oxidation and time, the equation

$$w = \frac{1}{k_3} \log_e \left[1 + \frac{k_3 n_o}{k_2} (1 - e^{-k_1 k_2 t}) \right] \qquad [3]$$

The curves for this case and for the case of self-blocking pores only are given in Fig. 1. In order to aid comparison, the nondimensional quantities

$$W = \frac{w k_2}{n_o},\ T = k_1 k_2 t \text{ and } G = \frac{k_3 n_o}{k_2}$$

have been used.

Equations [1] and [3] then become

$$W = 1 - e^{-T} \qquad [4]$$

and

$$W = \frac{1}{G} \log_e [1 + G\,(1 - e^{-T})] \qquad [5]$$

respectively.

Curves for $G = 0.0$, 0.1, 1.0, and 10.0 are given in Fig. 1. Putting $G = 0$ reduces Eq. [5] to [4] the equation for self-blocking pores.

At small values of T Eq. [5] approximates

$$W = \frac{1}{G} \log_e (1 + G\,T) \qquad [6]$$

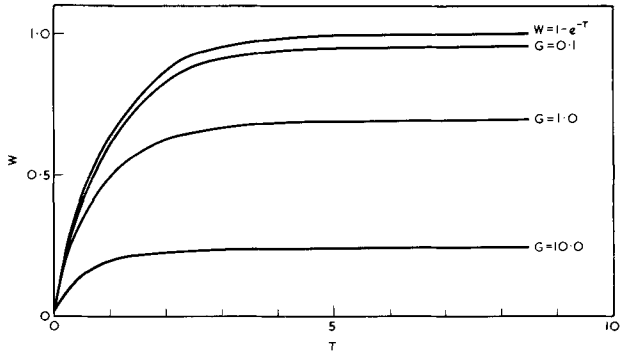

Fig. 1. Oxidation curves for pore blocking mechanism giving protective oxide: ord, W, dimensionless weight gain; abs, T, dimensionless time.

At large values of T, Eq. [5] approximates

$$W = \frac{1}{G} \log_e (1 + G) - \frac{1}{1 + G} e^{-T} \qquad [7]$$

From Eq. [6] and [7] it is seen that Eq. [5] represents a transition from a direct logarithmic growth law to an asymptotic growth law. In the early stages of oxidation when the pore density is relatively high, mutual blocking of pores will have the greatest influence on the growth law giving a direct logarithmic growth law. Measurements on the corrosion of mild steel to magnetite in alkaline solutions have suggested a logarithmic growth law at least in the early stages (4, 10). In the late stages of oxidation, when the pore density is relatively low, mutual blocking of pores will be relatively unimportant and self-blocking will have the greatest influence giving an asymptotic growth law. Such a transition would be consistent with the high degree of protection that magnetite formed during aqueous corrosion is capable of giving.

Under more strongly alkaline or weakly acidic conditions the magnetite formed does not afford protection, and a near linear oxidation rate is observed. There is no reason to assume that pore blocking does not occur under these conditions even though the oxide is nonprotective. However, with the rapid in-filling of pores that can be expected in the more corrosive conditions, the stresses built up within the oxide may become too large to be completely relieved by the blocking of neighboring pores. This excess stress could be relieved by shear strains which would create additional pores or cracks in the neighborhood of the blocked pore. Such a mechanism would introduce a term $-k_4\, dw$ into the expression for $-dn$ so that we have $-dn = (k_2 - k_4)\, dw + k_3 n\, d\, w$. The effect of the production of pores in this way is to reduce the importance of self-blocking of pores in the growth law, that is, to reduce the effective value of k_2. In the particular case of $k_4 = k_2$, the oxide grows wholly according to the direct logarithmic law. If $k_4 > k_2$, then effectively, $k_2 < 0$, and $-W$, $-G$ and $-T > 0$. Equation [5] then becomes

$$(-W) = \frac{1}{(-G)} \log_e [1 + (-G)\,(e^{(-T)} - 1)] \qquad [8]$$

For large $(-T)$ this approximates to the form

$$W = A + BT \qquad [9]$$

representing a linear growth law. This occurs at a time when the pore density approaches a value sufficient to give a balance between the rate of pore blocking and the rate of pore production. Curves of Eq.

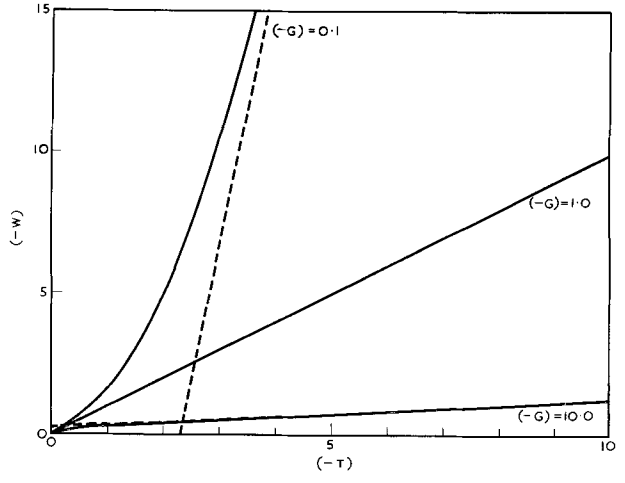

Fig. 2. Oxidation curves for pore blocking mechanism giving nonprotective oxide: ord, $(-W)$ dimensionless weight gain; abs, $(-T)$, dimensionless time.

[8] for values of (—G) of 0.1, 1.0, and 10.0 are given in Fig. 2.

It is seen that a nonprotective oxide is not inconsistent with a pore blocking mechanism. The situation that is most likely to occur is that the stresses produced in the oxide do not become fully relieved in the early stages of oxidation, but slowly increase as the oxide thickens. This would have the effect of slowly increasing the value of k_4, perhaps to a limiting value, as the oxidation proceeded. If this limiting value of k_4 is greater than the value of k_2, the effective value of k_2, positive at the beginning of the oxidation, would eventually become negative. This would give the sequence, with increasing time of logarithmic, asymptotic, accelerating to linear for the oxide growth law, representing a transition from a protective to a nonprotective oxide layer.

Both protective and nonprotective magnetite layers have been produced on mild steel oxidized in aqueous solutions at high temperature. A simple extension of the theory of pore blocking by Evans can explain the appearance of these two oxide forms, and suggests that their appearance may depend on the same basic mechanism.

Synthesis of GaAs by Vapor Transport Reaction

H. R. Leonhardt

IBM Watson Research Center, Yorktown Heights, New York

Within the last few years vapor growth processes have become a common method to prepare single crystalline GaAs (1-6). In most cases the following reaction is used

$$3\,GaX + \frac{1}{2}\,As_4 \rightarrow 2\,GaAs + GaX_3 \qquad [1]$$

where X = Cl or I. The iodide disproportionation reaction is usually employed in closed tubes because iodine is a solid which makes the loading procedure of the ampoules fairly simple. For most purposes, however, flow systems are more attractive. Therefore, an iodide process suitable for such an open tube apparatus has been developed.

Elemental gallium and arsenic were used as the source materials, H_2-HI being the transporting agent. The hydrogen iodide was prepared *in situ* from hydrogen and iodine to insure sufficiently high purity of the carrier gas (7). There were mainly two reasons for combining synthesis and epitaxial growth of GaAs: (i) Since gallium and arsenic are available in high purity, one can expect that such a system has the potential to produce high-purity GaAs, especially since the low-temperature iodide process is utilized. (ii) Separate sources for the two components permit a wide variation in the composition of the reactive gas.

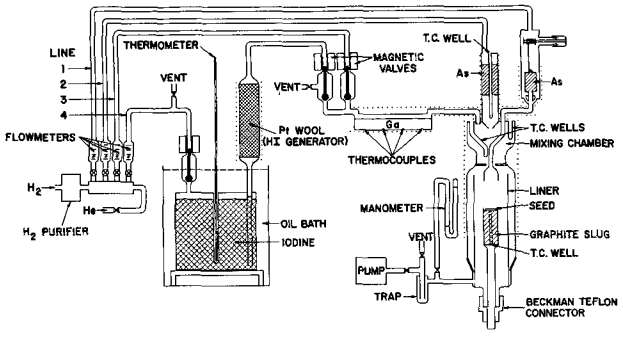

Fig. 1. Flow chart of GaAs vapor growth system

Figure 1 shows the basic features of the apparatus. Purified hydrogen can be fed into the system through four input lines. During the initial heat up period, the GaAs substrate is placed in a bell shaped shelter into which line 1 terminates, and hydrogen containing some arsenic is passed over it. The purpose of the arsenic is to prevent decomposition of the seed. Therefore, its pressure which is controlled by the temperature of the arsenic source in line 1 has to be kept above the dissociation pressure of the seed crystal. Assuming solid-vapor equilibrium for the arsenic, thermodynamic calculations show that the arsenic temperature has to be $\geq$ 190°C for a substrate preheating temperature of 750°C which was generally used. Data for the calculations were taken from the literature (8-10). For the actual decomposition process, lines No. 2 and 4 are used. The arsenic in line 2 is transported in elemental form. In 4, iodine is evaporated and converted to hydrogen iodide which reacts subsequently with gallium to form gallium iodides. The arsenic and gallium source are heated by multizone furnaces which provide a constant temperature over the entire length of the two zones. The gas streams from lines 2 and 4 are mixed in a chamber which is kept sufficiently hot so that no GaAs can form in it, the appropriate temperature being determined by calculations which will be described in the next section. In the deposition chamber the gases are cooled down so that GaAs precipitates.

Such a two-line system brings some complications with it since the conditions in the different zones have to be adjusted to each other. The best theoretical approach to this problem possible at the present time is a thermodynamic analysis which has been made with the following assumptions: (A) Thermodynamic

equilibrium is achieved in each part of the system. (B) All important vapor phase species are known. (C) The partial pressures of the various species follow the ideal gas law. (D) The total pressure p_t equals 1 atm throughout the entire system. (E) All solids and liquids are pure phases. (F) The conditions are chosen so that the gas streams from line 2 and 4 in Fig. 1 yield a mixture in the mixing chamber which is in equilibrium with solid GaAs.

The first assumption has been checked for the three most critical zones: the iodine, the gallium, and the arsenic source. Studies on the evaporation rate of iodine by Reisman, Berkenblit, and Alyanakyan (11), and on the rate for the Hi-Ga reaction by Silvestri (12) have been used to demonstrate the validity of the assumption for the iodine and the gallium source. For the arsenic source kinetic calculations were made based on data given by Brewer and Kane (13). Under all conditions the relaxation time of the solid-vapor equilibrium for the arsenic was found to be orders of magnitude shorter than the residence time of the transporting hydrogen gas in the source chamber, which means that also at the arsenic source equilibrium obtained. In order to check the assumption on the total pressure, p_t has been measured at the input side of the system. It was found to be only a few Torr above atmospheric pressure, *i.e.*, $p_t = 1$ atm is a good approximation.

Table I. Vapor phase species in the system

Abbreviations: A, arsenic source; G, gallium source; D, deposition chamber; M, mixing chamber; I, iodine source; p_t, total pressure; f_n, flow rate in line n, c, $\left(\frac{\text{gallium content}}{\text{arsenic content}}\right)_M$

Zone	Vapor phase species
A	As_2, As_4, H_2
I	I_2, H_2
G	GaI, GaI_3, HI, I_2, I, H_2
M, D	GaI, GaI_3, HI, I_2, I, H_2, As_2, As_4

It can be readily demonstrated that the system is defined thermodynamically by specifying the following experimental parameters: 1, the ratio of the flow rates; 2, the temperature T_A of the arsenic source; 3, the temperature T_M and the ratio c between the gallium and arsenic content of the vapor phase of the mixing chamber; and 4, the temperature T_D in the deposition chamber. These specifications and a series of independent equilibria provide a sufficient number of equations, shown in Table II, to calculate the partial pressures of the various vapor phase species (Table I) and the appropriate temperatures at the iodine and the gallium source.

From the partial pressures in the mixing and deposition chamber one can determine the gallium to

Table II.

iodine ratio y_M and y_D in the two zones. The difference Δy between these quantities is the amount of gallium which should precipitate as GaAs according to thermodynamics in the deposition chamber per equivalent of iodine:

$$\Delta y = y_M - y_D$$

$$= \left(\frac{p_{GaI} + p_{GaI_3}}{p_{GaI} + 3p_{GaI_3} + 2p_{I_2} + p_I + p_{HI}} \right)_M - \left(\frac{p_{GaI} + p_{GaI_3}}{p_{GaI} + 3p_{GaI_3} + 2p_{I_2} + p_I + p_{HI}} \right)_D$$

Δy represents the maximum value for the experimental growth rate which one can expect in the system for a given set of conditions.

A large number of cases with different values for the parameters was calculated on an IBM 7090 computer. For practical use, a few were selected on the basis of high Δy values and reasonable temperatures for the gallium and iodine source.

Epitaxial GaAs has been grown successfully in this open tube iodide system using gallium[1] of 99.9999% and arsenic[2] of 99.999% purity. The substrate surfaces were prepared by means of a chemical polishing technique which has been developed recently by Reisman *et al.* (19).

Some of the results are shown in Table III and Fig. 2. Under the conditions indicated in Table III the effective deposition rates (*i.e.*, only the growth on the seed crystal is taken into account) were appreciably smaller than the calculated values. This is at least partly due to the fact that GaAs precipitated not only on the substrate but also on the walls of the reaction tube and on the seed holder.

Figure 2 shows the effect of deposition temperature on the surface perfection. Deposits grown at 620°C on substrates oriented in the <111> A direction (which is the gallium terminated side) developed many pyramids within a short time (Fig. 2a), and as the growth continued a few big pyramids took over (Fig. 2b). Better results in terms of surface smoothness were obtained at higher deposition temperatures (Fig. 2c). Above 650°C, however, the deposition rate started to decrease appreciably. The rates between 620° and 650°C were in the order of 20 μ/hr. Runs were also made with substrates oriented in the <111> B and the <100> direction. In agreement with results reported for the closed tube iodine process (1) only polycrystalline growth could be obtained on <111> B substrates. Deposits grown in the <100> direction were epitaxial, but the surfaces showed a very dense pattern of pyramids.

The electrical properties of the vapor grown material summarized in Table III were determined from

Fig. 2. Deposits grown for different lengths of time t and at different deposition temperatures T: (left) t_a = 45 min, T_a = 620°C; (center) t_b = 4 hr 30 min, T_b = 620°C; (right) t_c = 45 min, T_c = 650°C.

Hall and resistivity measurements. All deposits were n-type. The results were obtained from samples which had been grown thick enough so that the original substrate could be removed. Two series of experiments were made under different conditions. Between the first and the second one the arsenic source had to be replenished. Aside from that the various source materials were not changed between runs. In Table III the runs are listed in chronological order. The increase in mobility and the decrease of the carrier concentration in the course of the first series shows that the system became cleaner from run to run. The abrupt deterioration of the vapor grown material after the arsenic source had been reloaded indicates that a substantial fraction of the impurities came either from the arsenic or was introduced during the loading procedure (*e.g.*, the system might have become contaminated with silicon when the arsenic container was sealed).

In the two series of runs the deposits were grown under different arsenic pressures. Theoretically one would expect that with increasing arsenic pressure the concentration of free electrons in the grown GaAs would decrease and the hole concentration increase due to a decrease in arsenic and an increase in gallium vacancies.[3] However, this effect was apparently much smaller than the effect of contaminants on the electrical properties so that it could not be observed.

In Table III the best values for the mobilities are appreciably higher than what has been found normally in vapor grown GaAs (22). Together with their strong temperature dependence this might be an indication that the material was not severely compensated.

Acknowledgments

The author would like to thank Mr. J. V. Lyons for participating in the initial part of this work, Dr. A. Reisman for helpful discussions, and Mr. E. Baran for his assistance in the experimental work. He also wants to acknowledge the support which he received from Miss A. Kuhlke and Dr. R. Kelisky by making the computer calculations, from Dr. S. E. Blum by supplying the GaAs substrates, and from Dr. J. F. Woods and Mr. S. Baliozian by making the electrical measurements.

A Chemical Polish for Lead Telluride

M. R. Lorenz

IBM Watson Research Center, Yorktown Heights, New York

The preparation of PbTe surfaces free of damage has been investigated by several workers using various techniques. The results of these studies have recently been tested and summarized (1). Briefly there exists a satisfactory electrochemical polish (2). A chemical polish (3) which can produce film (1) and damage free flat surfaces (3) is also known. Although the reported chemical polish may be ideal for flat surface preparation, it has the disadvantage of requiring a mounted sample. The purpose of this communication is to describe a new and simple chemical polish for PbTe which does not have any limitation with regard to geometry. The polished surfaces are indistinguishable from those obtained by use of the electrochemical polish (2).

Test samples consisted of both single and polycrystalline wafers as well as irregular shaped PbTe crystals. The polishing solution was composed of saturated aqueous $K_2Cr_2O_7$ and concentrated nitric acid. The volume ratio of the two components is fairly limited and is between 4.2 and 5.0 with the optimum at about 4.5. A typical polishing solution would consist of 40 cc saturated $K_2Cr_2O_7$ solution and 9 cc concentrated HNO_3. For large crystal charges or dissolution of thick layers the solution volume would of course require a corresponding increase to avoid rapid dilution of the polish strength. The PbTe samples were placed in a Pyrex basket which was fused to a Pyrex rod. By rotating the basket while suspending it in the solution, at room temperature, the test samples were subjected to a good polishing action. Similarly good action was achieved by placing samples directly into a solution beaker and stirring the solution vigorously with a magnetic stirrer. When surfaces appeared satisfactory the samples were well rinsed in H_2O and dried. The rate of material removed for the above conditions was measured on a number of samples for various periods of time. The results show a dissolution rate which varied between 20 and 40 μ/min. Temperature control during polishing appears not extremely critical. However, tests at 45°C indicate a dissolution rate nearly double that at 25°C without any appreciable change in the surface finish.

Sometimes a smooth polished crystal may have a barely perceptible golden colored film on the surface. The occasional appearance of the film is not understood but is no cause for concern since it can be readily removed. Film covered samples were placed in 50% NaOH solution. The solution was heated to 100°-120°C and then left to cool back to room temperature. The samples were rinsed in dilute HCl solution and then thoroughly rinsed in distilled water and dried. The above treatment removed any visible surface film but does not lead to cracking of samples due to thermal shock as had been noted earlier (3, 1).

The procedure described here is simple and quick. It suffers no restriction with regard to geometry. However, as any chemical polish it requires slight variations on the part of the experimentalist to achieve the desired results.

The application of the PbTe polishing solution to GeTe, SnTe, and SnSe was attempted with little success. Variations of the $K_2Cr_2O_7$ to HNO_3 ratio did not lead to any improvement. A mixture of 20 parts of saturated $K_2Cr_2O_7$, 11 parts of HCl, and 1 part of HNO_3 gave visibly smooth shiny surfaces on SnTe. After a few minutes, the shiny surfaces showed slight discoloration which was easily removable by dipping into 20% NaOH solution. Microscopic investigation, however, indicated that the SnTe surfaces were in general ripply and pitted. Similar surfaces could be obtained on GeTe when a mixture of 20 parts of saturated $K_2Cr_2O_7$ and 1 part of HNO_3 was used.

Transpiration Studies of the Ge-I_2-Inert Gas System

A. Reisman, M. Berkenblit, and S. A. Alyanakyan

IBM Watson Research Center, Yorktown Heights, New York

Recently, the results of thermodynamic analyses of the Ge-I_2 solid-vapor system in the presence of inert and/or reactive gases at constant total pressure were presented (1, 2). The data derived from these analyses were intended as guides in designing and operating an open tube disproportionation system for growing Ge single crystals epitaxially via reaction [1]

$$GeI_4 + Ge \rightleftarrows 2GeI_2 \qquad [1]$$

Use of the data in an experimental system, however, depends on the degree of equilibrium that is achieved in equilibrating a carrier gas with solid phases at certain critical points in the open tube flow train. In the Ge-He-I_2 system these points are; the halogen source, the germanium source, and the deposition region.

The present report describes studies of transpiration phenomena in the above system. In essence these studies involved determining the flow conditions at different temperatures which were necessary for a He stream to equilibrate physically with an iodine source, and for an I_2-He mixture to equilibrate chemically and physically with a Ge bed. Because of the results obtained, it will be seen that there are interesting aspects in the flow rate ranges in which the I_2-He gas is not in equilibrium with the Ge. Studies of the deposition region have not been conducted pending the construction of a complete vapor transport train.

Experimental Procedure

Figure 1 is a schematic representation of the iodine bed employed. The design of this bed enables passing of the incoming gas stream through either the iodine source or a bypass. Both the source and bypass chambers contain glass beads to increase the heat capacity of the bed to offset cooling effects due to gas flow and evaporation. Figure 2 is a schematic representation of the train used in the experimental evaluation of the iodine bed efficiency. The He carrier gas was purified in a John Mickel Associates purifier, which in turn is followed by a flow meter, the iodine source, thiosulfate absorption traps, and a wet test meter. Without prepurification of the carrier gas, the thiosulfate solutions, maintained at a starting pH of 7, invariably decomposed with the liberation of sulfur due to the presence of CO_2 as an impurity in the He.

All experiments were conducted on as-received semiconductor grade iodine. Before using this material, the packed bed was flushed for several hours with the carrier gas.

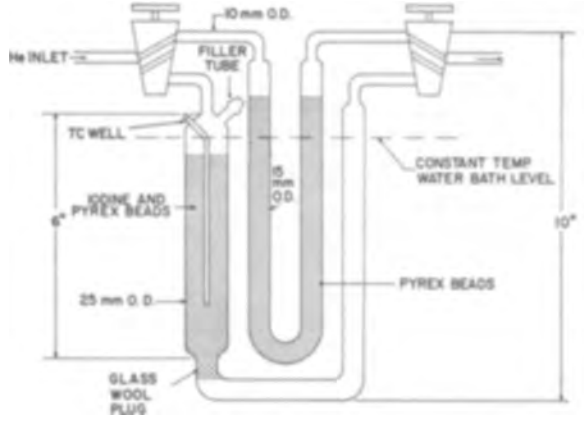

Fig. 1. Iodine source bed design

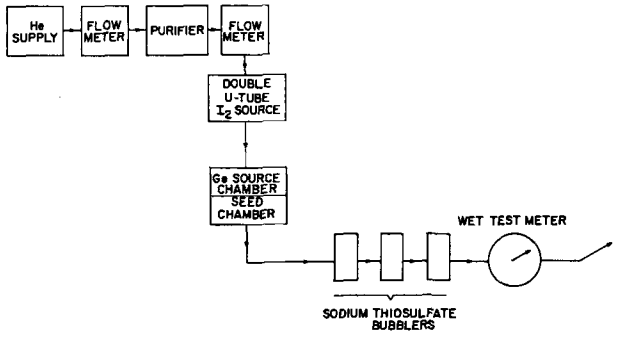

Fig. 2. Schematic representation of I_2 transpiration train

Since no convenient method analogous to that employed for the iodine analysis suggested itself for the Ge system, it was decided to determine the Ge quantity removed from the source bed by a weight loss method. Figure 3 shows the experimental arrangement used to obtain data at 400°, 450°, and 620°C. The design employed facilitates disassembly of the reaction train to enable weighing the Ge bed.

Results and Discussion

Iodine transpiration studies.—Although the equilibrium flow rate range can be evaluated by plotting iodine gas phase concentration *vs.* flow rate for each of the iodine source temperatures investigated, values of the halogen source vapor pressure were also computed. Comparison of these values with those in the literature insure against the possibility of a systematic error in our method of evaluating iodine gas phase concentration leading to incorrect absolute values. These values are important in comparing the Ge-I_2 reaction data with the thermodynamic results mentioned previously. Two series of transpiration experiments were conducted, one with an iodine source at 50.5°C, the other with the iodine source at 61.8°C. At all flow rates up to approximately 0.9 l/min, the systems appeared to be in equilibrium.[1] The calculated vapor pressures for the two temperatures were 2.14 ± 0.06 mm and 4.79 ± 0.07 mm, respectively. Comparison of these approximate values with those of Baxter and Grosse (3) who used a more sophisticated transpiration technique indicates that no major systematic errors

[1] Vapor pressures were calculated with the aid of the equation below. Assuming ideal gas behavior and a constant value of atmospheric pressure (1 atm), the partial pressure of iodine in atm is given by

$$p_{I_2} = n_{I_2}/[n_{I_2} + \frac{V}{RT_M}(1 - p_{H_2O})]$$

where n_{I_2} is the number of moles of iodine, determined by titration of the thiosulfate solutions, that are carried in the volume V measured at a wet test meter whose temperature is T_M and where p_{H_2O} is the vapor pressure of water at T_M.

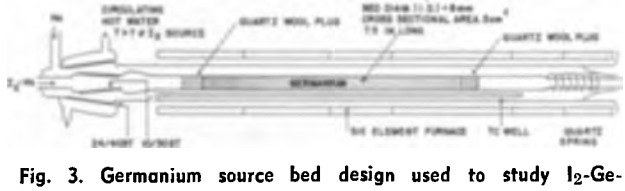

Fig. 3. Germanium source bed design used to study I_2-Ge-He system.

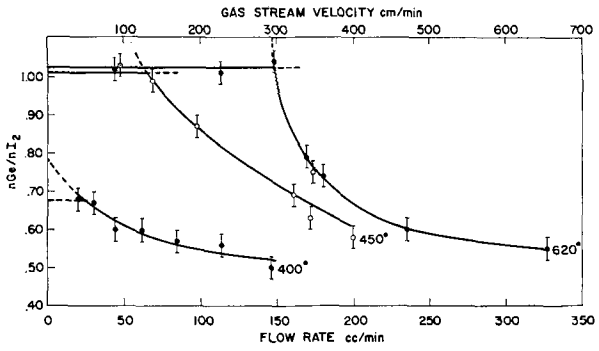

Fig. 4. Transpiration data for the Ge-I_2-He system

were involved in the iodine analysis. The values obtained by them were 2.24 and 4.83 mm, respectively.

Ge-I_2 *transpiration studies.*—On the basis of the thermodynamic analyses (1, 2) in the temperature interval 350°-650°C, the value of the vapor phase component mole ratio Ge/I_2 as a function of temperature is limited at the lower temperature by a value of 0.5 coinciding with the semiconductor-halogen species stoichiometry GeI_4. At the higher temperature, the limiting value of this ratio is 1.0 coinciding with the semiconductor-halogen species stoichiometry GeI_2. Consequently, it was expected that for the three temperatures studied, 400°, 450°, and 620°C, the flow rates at which solid-gas phase equilibrium are attained would lead to values of the Ge/I_2 ratio within the limits defined by the thermodynamic analyses. Again, as with the studies involving iodine equilibrium, the equilibrium flow rate region for Ge can be evaluated by plotting Ge vapor phase concentration *vs.* flow rate. As a check to insure against some systematic error leading to incorrect absolute Ge transport values, the I_2 and Ge transpiration data were used to calculate Ge/I_2 component mole ratios in both the equilibrium and nonequilibrium flow rate regions.

In measurements of the type under consideration linear gas stream velocities are more significant than gas flow rates since the latter are independent of equipment geometry. As no simple means of establishing the linear gas stream velocities in the packed Ge bed could be evolved, a reference velocity scale based on the hypothetical velocities that would have obtained in an unpacked bed of the dimensions shown in Fig. 3 was calculated for the flow rates employed. This velocity scale is meant only to provide some feeling for the gas residency time in the Ge bed. The arbitrary Ge particle size distribution used in this investigation was 52.2% retained on No. 8 U.S. Standard Sieve Series, 18.2% retained on No. 12, 16.3% retained on No. 20, 8.6% retained on No. 40, 2.7% retained on No. 60, and 2.0% passing hrough No. 60. Repeated bed packing of newly crushed, sieved, and "white etched" Ge provided reasonably reproducible data. It is to be noted that the use of any other arbitrary particle size distribution would merely have shifted the flow rate at which the gas effluent from the Ge bed became saturated, but would not have altered the equilibrium Ge/I_2 ratio obtained at a given temperature.

Figure 4 presents the Ge/I_2 mole ratios derived from both the iodine and Ge measurements as a function of flow rate (also in terms of the hypothetical linear gas stream velocity mentioned above).

The significant features of this figure may be summarized as follows:

1. At 400°C, it could not be established whether equilibrium was achieved at the lowest measurable flow rate. The smooth curve can be extrapolated to zero flow in two ways, one assuming that equilibrium has been achieved at finite flows, the other assuming equilibrium is achieved only at zero flow. In the latter instance, the zero flow intersection provides an equilibrium Ge/I_2 ratio in reasonable agreement with that predicted thermodynamically, *i.e.*, 0.78 and 0.83, respectively.
2. At higher temperatures, equilibrium appears to have been achieved within the limits of experimental uncertainty, the equilibrium flow rate range increasing with increasing temperature. Thus at 450°C, a theoretical value of 0.95 is predicted and 1.01 ± 0.04 is obtained experimentally. At 620°C, a theoretical value of 0.99 is predicted and 1.03 ± 0.03 is obtained experimentally.
3. Most significant, however, are the implications concerning the reaction mechanism between Ge and I_2 that may be drawn from the data in the nonequilibrium regions of the three curves. In each instance it is observed that with increasing flow rate the curves tend toward a limiting value of 0.5. This implies that the reaction of Ge with iodine proceeds via the two step mechanism

$$Ge_{(s)} + 2I_{2(v)} \rightleftarrows GeI_{4(v)} \quad [2]$$

$$GeI_{4(v)} + Ge_{(s)} \rightleftarrows 2GeI_{2(v)} \quad [3]$$

The first of these reactions appears to be rapid since even at the fast flow rates we have never observed free iodine passing through the Ge source bed (the asymptotic approach of the curves to a value of 0.5 supports this visual observation). The second reaction is markedly slower than the first. As the latter is the desired one in this vapor transport reaction, it represents a serious experimental limitation in the design of an efficient, reproducible germanium-iodine disproportionation open tube scheme. Thus, if one operates within the nonequilibrium linear gas stream velocity range, the tendency to form GeI_4 increases with increasing flow rate, resulting ultimately in a readily achievable worst case of zero transport efficiency (4).

Brief Communications

An A-C Conductive Adhesive for Testing Electroluminescent Devices

Alexander Baczewski

General Telephone & Electronics Laboratories, Inc., Bayside, New York

This communication deals with the compounding of an inexpensive material which allows temporary adhesion of the conductor to an electroluminescent device.

Many electroluminescent devices consist of a conductive transparent material, an electroluminescent layer and an aluminum back electrode prepared by high-vacuum evaporation. It is very difficult to repair pinholes and small blemishes in the electroluminescent layer once the aluminum back electrode has been applied. A temporary electrode that would make it possible to find such defects before the aluminizing step would allow the preparation of defect-free devices. Such an electrode must provide good electrical contact to the sometimes very rough electroluminescent layer, and it should be easy to apply and remove. Although water dispersions of graphite can be used for this purpose, the water is deleterious for most devices and may magnify or even cause defects. In addition, the black color of the conductor will detract from the brightness of a device. Alloys of mercury, indium, and thallium can be used for this purpose since they have very low melting points and wet almost any surface; these alloys, however, are extremely toxic and quite expensive (1).

It is well known that the reaction products of boric acid and aliphatic polyhydroxy compounds and their ammonium salts are good conductors of electricity (2). Some of these compounds dissolve in ethylene glycol; such solutions are also good conductors and are colorless, water-free liquids. They have been used formerly in the manufacture of capacitors (3). A solid polyhydric alcohol increases the viscosity without decreasing the conductivity; hence, it is possible to mix ethylene glycol, mannitol, boric acid, and ammonia in such a way that a very viscous, clear mass results which may be used as an adhesive; the amounts are not critical. Table I gives a few examples.

Table I. Polyol-ammonia-boric acid combinations

Constituent	% by weight			
Ethylene glycol	44	44	44	23
Mannitol	7	7	28	28
Boric acid	35	28	21	42
Ammonia	14	21	7	7

The solutions were prepared in the following manner. Various amounts of ethylene glycol, mannitol, and boric acid were mixed and aqueous ammonia was added while the temperature was slowly raised to 125°C with vigorous stirring. The temperature was maintained at 125°C for 5 min and then at 100°C for 2 hr without stirring. The resulting adhesive was kept in a desiccator.

One of these compounds was spread on paperbacked aluminum foil and the coated foil pressed onto a non-aluminized electroluminescent lamp. When the lamp voltage was increased slowly, thin spots lit up, and pinholes could be found before shorting occurred. The foil was removed and the adhesive was washed off with methanol. After elimination of the defects, and subsequent application of the evaporated electrode, the lamp brightness was equivalent to that of defect-free lamps that had not undergone this treatment.

The Formation of $FeSn_2$ during the Electrodeposition of Tin on Iron

W. Roger Buck, III, and Henry Leidheiser, Jr.

Virginia Institute for Scientific Research, Richmond, Virginia

The resistance to corrosion of commercial tinplate in some environments appears to be related to the characteristics of the iron-tin alloy $FeSn_2$ which is formed at the interface between the two metals during heat-treatment following the electrodeposition step (1). The purpose of this communication is to point out that fine-grained $FeSn_2$ is formed during electrolysis of iron in an alkaline bath but is not formed during electrolysis in an acid bath. This experimental result may have important consequences in focusing attention on a variable which appears to be subject to control.

Tin was electroplated on ⅜ in. iron cylinders (both Ferrovac-E and type-L steel) with a hemispherical end from the following two baths: acid bath: $SnSO_4$ 100 g/l, H_2SO_4 30 g/l, tartaric acid 30 g/l; alkaline bath: $Na_2SnO_3 \cdot 3H_2O$ 90 g/l, NaOH 7.5 g/l, NaOAc 15 g/l, 30% H_2O_2 0.5 ml/l. Both baths were operated

at 70°. The majority of the experiments were carried out at a current density of 3 amp/dm^2 and a plating time of 30 sec. These conditions are equivalent to an average deposit thickness of approximately 6000Å in the acid bath assuming 100% current efficiency, and to an average deposit thickness of approximately 2300Å in the alkaline bath assuming deposition from the Sn(IV) state and a current efficiency of 75%. The iron samples were polished in a commercial chemical polishing reagent, MirroFe, and were abraded with levigated alumina immediately before plating. The grain size of the deposit from the acid bath was of the order of 10^{-2} mm in diameter and of the order of 10^{-4} mm in diameter in the alkaline bath as indicated by x-ray diffraction analysis. Grain-size modifiers were not added to the acid bath as is the commercial practice.

The deposits were examined by x-ray diffraction using unfiltered iron radiation and grazing incidence on the hemispherical surface. This technique is remarkably sensitive to small amounts of crystalline material when the strong diffraction line occurs at planar spacings above 2.5Å. The diffraction line of iron at 2.03Å and the diffraction lines of tin at 2.92 and 2.79Å were clearly visible in all experiments. The strongest diffraction line of $FeSn_2$ at 2.56Å was used to determine its presence.

A faint line due to $FeSn_2$ was occasionally visible when the sample was x-rayed immediately after deposition of tin from the alkaline bath: it was always visible when the sample was annealed at 100° in boiling water for 10 min or more after deposition. $FeSn_2$ was not detected when deposition was carried out from the acid bath. Annealing the sample for as long as 60 hr at 100° in boiling water did not result in the formation of $FeSn_2$ identifiable by x-ray diffraction techniques.

The alkaline bath differs from the acid bath in many respects but particularly in the fact that hydrogen is codeposited with tin in the alkaline bath. The importance of hydrogen was examined by several methods: (*A*) the sample was electrolytically precharged with hydrogen immediately before electrodeposition of tin from the acid bath; (*B*) the tin concentration in the acid bath was lowered to 0.001 of its ordinary value (0.1 g/l $SnSO_4$) and deposition was carried out at 8 amp/dm^2 and low current efficiency; (*C*) tin was electrodeposited from solutions containing 0.002-0.010 g/l of dissolved tin at 100°. $FeSn_2$ was occasionally detected in (*A*), it was detected in (*B*) after annealing at 100° for 10 hr, and it was always detected in (*C*). These experiments suggest that the codeposition of hydrogen favors the formation of $FeSn_2$.

The $FeSn_2$ diffraction line was very clear on samples in which iron was subjected to electrolysis at 1 amp/dm^2 for 6 hr in boiling 0.1M Na_2CO_3 solutions containing 0.002 g/l dissolved tin. Based on prior studies with radioactive tin (2) the rate constant for the pickup of tin by metallographically polished iron at 100° is 2×10^{-8} g/cm^2-sec$^{1/2}$. If the tin forms $FeSn_2$ as a continuous film, this rate constant indicates that a film 30Å thick should be formed in 6 hr. The clear diffraction line suggests that appreciably more $FeSn_2$ is present at the interface than is expected on the basis of thermal diffusion only. These experiments agree with experiments in the indium-antimony system (3) in which it was found that electrolysis increased the rate of formation of InSb.

The Platinum-on-Carbon Catalyst System for Hydrogen Anodes

I. Characterization of the Catalyst and Support

L. J. Hillenbrand and J. W. Lacksonen

Battelle Memorial Institute, Columbus, Ohio

ABSTRACT

A high degree of hydrogen electrode activity in alkaline media can be achieved with less than 1 mg Pt/cm^2 of electrode, if a properly chosen carbon support is used. For a complete description of the platinum-on-carbon catalyst systems, the physical and chemical states of both platinum and carbon must be considered. In this paper the measurements of total electrode area, metal area and dispersion, pore size distribution, and the location of the Pt within the carbon structure are considered, and the importance of the choice of carbon is illustrated. The control of the chemical interactions between the platinum and the carbon is essential if high activity per unit weight of platinum is to be obtained.

Despite the large amount of work that has been done on platinized carbon electrodes for fuel cells, little information has been published on the choice of materials and methods for construction of a hydrogen anode. This situation is due to the extremely complicated surface chemistry of carbon and the many important variations that are possible in its production.

In the present work on catalytic electrodes for fuel cells, means were sought to characterize the catalyst and its support. Out of this work arose the realization that the possible chemical variations of the carbon surface had large effects on the activity of the platinum catalyst. This and the following paper, Part II, describe the observations that were made of the platinum-on-carbon catalyst system.

Platinized platinum electrodes are commonly recognized to have much better activity for hydrogen than those made from bright platinum. Similarly, a dispersion of platinum on carbon can show a much better performance as a hydrogen anode than that obtainable from an equivalent area of bright platinum, and with the use of substantially less platinum than required for either bright or platinized electrode structures. The complications that arise in the interpretation of such results stem from the fact that the different activities may result either from difference in surface area or from altered chemical states of the surfaces, or both. For the platinized carbon electrodes, the situation is especially complicated since there is the question of the role of the carbon. In the present work, a study was made of the changes in activity produced by the platinum-carbon interactions, and an attempt was made to differentiate these from the changes resulting from physical differences. The platinum-carbon interactions have proved to be of primary importance to the activity of the platinum catalyst.

One of the most important needs was a means to measure the metal area of the electrode. This need extends even to electrodes made from bright foil or wire because they have true areas considerably greater than the geometric area. Measurements (1) of the surface roughness, that is the ratio of true to geometric area, for commercial platinum foil or wire give values somewhat greater than 2, and the redox or etching treatments usually required to activate such electrodes can be expected to increase the roughness. At the other extreme, platinized platinum was found by Bowden and Rideal (1) to have a surface roughness in excess of 1800. Almost certainly this variation in surface roughness is accompanied by changes in surface chemical heterogeneity. The variations in the chemical state of the surface that can accompany these physical changes might be expected to lead to marked changes in electrode activity. A number of theories have been suggested for platinum catalysts as hydrogen electrodes in which the surface heterogeneity is the controlling feature: see for example Hill and Ives (2) and Davtyan (3).

The variations in surface roughness and surface heterogeneity that are possible for the platinum-on-carbon system are much more complicated because of the influences of the carbon surface. For this case, the total surface area can be measured by BET physical gas adsorption, and active metal areas can be differentiated from the remainder of the surface by hydrogen chemisorption. The information gained by these methods is described in the following sections.

The description of a platinized-carbon electrode includes three types of information: (i) the amount of carbon surface and the distribution of the pore diameters present; (ii) the amount and distribution of platinum surface; and (iii) the chemical conditions of the platinum and carbon surfaces and their interactions.

The first of these can be obtained by conventional BET gas-adsorption methods and by mercury-intrusion measurements. The third item is discussed in a separate paper (4). The second can be obtained by hydrogen-chemisorption measurements on appropriate portions of the electrode. However, some improvements in available hydrogen-chemisorption techniques have been necessary.

Measurement of the Surface Area of Platinum on Carbon

In recent years, hydrogen-chemisorption methods have been developed for measurement of platinum-metal areas of platinum-on-alumina catalysts. In these techniques, the samples are reduced in hydrogen and evacuated at 300°-500°C for prolonged periods to provide the required clean metal surface prior to the chemisorption measurement. Unfortunately, this heat treatment is unsuitable for unsupported platinum or for platinum on carbon. The thermal instability of platinum black has been reported by a number of workers, Benton (5) for example. Some of the recent data that show this thermal instability are summarized in Table I, where methods using nitrogen and krypton are based on physical adsorption and for hydrogen on chemisorption.

The data of Table I for the several samples of platinum black clearly show the sintering of unsupported platinum at 500°C. Battelle data shown for Baker Black were assembled from a variety of measurements made at different times and on two different lots of platinum black from the same supplier. There is little doubt that, in the absence of air, sintering of platinum black above 200°C caused noticeable reduction of the

surface area. Recently, Fisher (6) showed that this sintering occurred more readily with clean platinum black than it did with platinum covered by a monolayer of oxygen. Because of the sintering, hydrogen-chemisorption measurements could not be used for any platinum-catalyst preparation in which the platinum might be suspected to show thermal sensitivity similar to that shown for unsupported platinum.

In the case of platinum black, the distinction between the total area by nitrogen adsorption and the metal area by hydrogen chemisorption has not been of major concern for properly cleaned samples, although it may be important if partial poisoning of the platinum surface is suspected. On the other hand, supported platinum such as platinized carbon cannot be properly investigated unless a distinction can be made between the active platinum-metal area and the remainder of the surface. To develop a method for hydrogen chemisorption that was suitable for platinum-on-carbon catalysts, a suitable treatment of the platinum at temperatures no higher than about 200°-250°C was needed. Experiments made to examine the effects of heat treatments on the chemisorption of hydrogen by platinum on carbon are illustrated in Table II.

Table II shows that conventional high temperature (300°-500°C) treatments of experimental samples yield platinum-metal areas of 20 to 30 m^2/g of platinum. The platinum was applied by preparing a slurry of carbon in the appropriate amount of chloroplatinic acid, dried, and heated to 165°C in an air oven over night. This platinum is located on the carbon support originally having a surface area of over 400 m^2/g. If the platinum that was used had been dispersed as a molecular layer, it should have had an area of about 276 m^2/g of platinum. Hence, the values in Table II amount to about 10% of that which could be obtained with a good dispersion. The crystallite sizes shown are calculated values based on this surface-area measurement, assuming that the platinum is dispersed as a regular shape such as a cube. They are not experimental measurements of actual platinum particle sizes.

[a] Platinum area calculated assuming 0.208 cc H_2 (STP) adsorbed per square meter of metal area. See for example L. Spenadel and M. Budart, *J. Phys. Chem.*, 64, 204 (1960).
[b] Calculated assuming the platinum area is distributed as the surface area of cubic crystallites of uniform size.
[c] This shorthand notation should be read: heat at 300°C in flowing H_2 for 1 hr, then at 500°C in vacuum for 17 hr.
[d] This shorthand notation should be read: heat at 250°C in flowing H_2 for 1 hr, then evacuate and purge with He occasionally at 26°C for 48 hr.

When a sample of platinum on carbon with this 300°-500°C treatment was examined for electrode activity, it was found that the heat treatment had destroyed most of the activity that was originally present.[1] Similar samples examined by x-ray line broadening revealed that the crystallites had grown appreciably during the treatment as compared with the crystallite sizes in the original preparations.

Subsequently, it was found that, since degassing could be accomplished in a flowing stream, the sample for chemisorption could be prepared by heat treating to temperatures not above about 200°-250°C for only 1 hr. The table shows that twice as much platinum area was found in this way as compared with that obtained by the old technique. Furthermore, there appeared to be no change when the treatment was repeated on the same samples. Material treated by this technique showed good electrode activity. Some of the differences in platinum dispersion that could be noted by such measurements are suggested by the values given in the remaining entries of the table. As shown in the final two entries, well-dispersed platinum was measurable by this technique. Since the Baker catalysts shown in Table II gave the same surface area by both methods and the treatment could be repeated on Battelle samples without change in area, the procedure appeared to be valid for the measurement of the dispersion of platinum. This conclusion was further supported by the observation that samples treated in this way remained active as hydrogen electrodes.

Amount and Distribution of Platinum

The platinized carbon was used to prepare dual-porosity carbon structures in which the platinum was located only in the outer layer. The general construction of these electrodes is shown in Fig. 1. The inner layer was made from a macroporous carbon which served as a support for the outer or catalytic layer and which also distributed the gas to the outer layer. The outer layer was microporous and contained the catalyst. When the electrode had become thoroughly wetted by the electrolyte, the gas pressure used was sufficient to hold the liquid interface out of the inner layer but permitted the electrolye to penetrate the

[a] With the exception of samples O and P, all samples were dual-layer electrodes and were activated by heating in air at 165°C. The support is NC-60 carbon and the outer layer is made of Darco S-51 carbon, except as noted. The binder used was gum rubber.
[b] Listed as weight per cent of the outer layer, except as noted.
[c] The electrodes were loaded as hydrogen anodes initially, then cycled cathodically and anodically two times. The polarizations are not corrected for IR drop from ohmic resistance in the cell. The limiting current represents polarization down to zero volts *vs.* SCE.
[d] The value of 110 ma/cm² was obtained at the end of the normal cycling. However, an increase in electrode back pressure occurred suddenly, and the subsequent performance was improved as shown.

micropores of the outer layer. The three-phase contact between solid electrode, liquid electrolyte, and gaseous fuel occurred in this layer. The two layers were bound together by a minor amount of gum rubber binder incorporated into the powdered carbon used to form the outer layer. The outer layer could be applied by painting or spraying techniques. Because of the low degree of wettability of the carbon itself and because of the binder used to form the dual-layer structure, even the outer layer was not completely wetted by the aqueous electrolyte. This means that, although the electrolyte generally penetrates the outer layer of the electrode, it probably does not enter any of the finer pore areas of that layer.

With this electrode construction a series of experiments was made to determine the requirements for the amount and distribution of platinum catalyst needed for hydrogen anode service.

For the electrodes described in this paper, the inner layer was generally National Carbon NC-60 carbon cut from a cylinder about 0.5 x 1.0 in. The outer layer was powdered carbon chosen from one of several sources but frequently was Darco S-51. Unless otherwise noted, the platinum was applied to the powdered carbon of the outer layer as chloroplatinic acid and then, after drying, the platinum compound was decomposed by heating the carbon to 165°C overnight in air. A comparison of several conditions for pretreatment is shown in Table III. For each of these electrodes the active geometric area of the electrode was about 15 cm². The electrodes were tested as hydrogen anodes in 30 w/o (weight per cent) KOH electrolyte using a half-cell apparatus. All performances are listed with correction for IR drop in the electrolyte.

The half-cell apparatus consisted of a saturated calomel reference electrode, a platinum foil counter-electrode and the test electrode. A constant and known current was impressed between the test and counter-electrodes with a 6-v battery. The current was adjusted with a potentiometer, and the voltage of the test electrode was compared with the calomel reference electrode. In this work the reference electrode was located in the same position with regard to the other electrodes in all experiments. The IR drop in this arrangement was not measured, but in cells of comparable geometry an IR drop of 300 mv was estimated at 100 ma/cm² for a 20 cm² electrode.

Table III shows effects of variation in the amount and distribution of platinum in this dual-layer electrode structure. The activities listed were obtained from the current needed to polarize the electrode to 0v *vs.* a saturated calomel electrode. This was not a diffusion-limited current, but rather an arbitrary stopping point for these electrode structures. The data are not corrected for IR drop in the electrolyte.

In each case the electrode was activated by cycling the electrode between anodic and cathodic polarizations. In Table III, the results of the first and the third, or final anodic polarization are shown. It is clear that the electrode activity is markedly improved by this cycling and in most cases, at least for electrodes of good activity, the slope of the curve became nearly constant throughout the complete anodic and cathodic cycle so that the electrode system is approximately reversible.

In Table III, it appears that the maximum final activity was approached by platinum concentrations in the outer layer of about 3%; an increase of platinum content up to 7% had only a small additional effect on the final activity. However, improvement in current-voltage characteristics was more pronounced with cycling when the electrodes contained less platinum.

For Electrode 18978-87, the weight of the outer layer was decreased to 0.25g of platinized carbon so that the platinum amounted to about 1 mg/cm² of geometric area. Tests of this and similar electrodes indicated that this amount of platinum was sufficient for good activity.

The role played by the carbon used in the outer layer is illustrated in Table III by electrodes P and O, in which the electrodes had an outer layer of platinum black rather than chemically deposited platinum on carbon. The physical mixture of platinum black and Darco S-51, electrode P, is obviously a poor electrode structure. Electrode O, made using all platinum for the outer layer, had good activity, but the amount of platinum used was about 20 times that for the platinum-on-carbon preparations.

Large differences in activity were observed with changes in the location of the platinum. Electrodes W, Z, X, and I show that platinum located between the two layers of the dual-layer electrode was quite ineffective, whereas platinum located on the outside of the dual-layer structure had quite good activity. Elec-

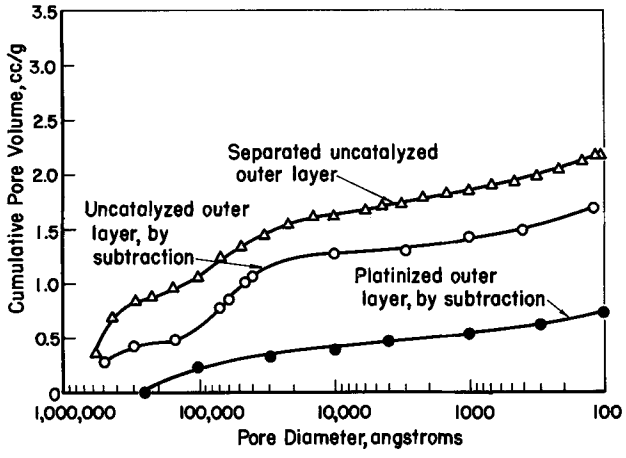

Fig. 2. Mercury-porosimeter measurements of pore distribution for microporous activated Darco S-51 carbon plus gum-rubber binding.

trode Y indicated that platinum black painted on the outside of the dual-layer structure did nothing to further the activity of previously catalyzed dual-layer structure.

Thus, the highest activity for platinum on a weight basis was obtained by chemical deposition of the platinum on a suitable carbon used as the outer layer of the electrode. The platinum had little effectiveness when located btween the electrode layers, but was quite active if located in or near the outer surfaces of the outer layer.

The importance of the choice of carbon is illustrated by the last two entries in Table II. Although the highest dispersions of platinum were obtained with these two carbons, the electrode made using the mineral carbon was almost totally inactive, whereas that made using the Barnebey-Cheney K2046 carbon showed good activity. Thus, it appears that the achievement of a good dispersion of platinum does not insure good activity. The importance of the chemical state of the carbon surfaces is discussed in a second paper (4).

Pore Structure of the Catalyzed Outer Layer

Further information on the location of the platinum in the catalyzed dual-layer structure, and also on the exact nature of the porosity of the completely fabricated electrode, was obtained by examining the pore-size distribution and surface areas for a variety of samples. In each of these structures, gum rubber was the binder.

The results of examining one dual-layer electrode for distribution of macropores by mercury-porosimetry measurements are shown in Fig. 2. To get the proper pore distribution for the outer layer, a method had to be devised to measure the porosities of the two layers separately. In one experiment, the porosity of the NC-60 substructure was measured and subtracted from the porosity shown for an uncatalyzed dual layer structure. The middle curve shown in Fig. 2 gives the pore-size distribution for the uncatalyzed outer layer obtained in this way. A similar curve is shown for the outer layer measured after it had been physically removed from the NC-60 substructure. Some cracking and pulverizing of the outer layer occurred during this separation, and the increase in large pores shown by the top curve of Fig. 2 is a reflection of this crumbling. Otherwise, the two curves referred to in Fig. 2 are quite similar. When the carbon was platinized and then applied to the NC-60 substructure in the normal way, the large reduction in macropores occurred as shown by the lowest curve in Fig. 2. This indicated that the platinum had plugged some of the pores of the carbon.

The micropore distribution below 100Å pore diameter was not obtained for platinum on carbon, but was measured for silver-catalyzed samples. The silver catalyst did not markedly enter the micropores of the carbon. Since the carbon was not readily wetted by water, entry of the aqueous impregnating solution into the micropores of the carbon was not expected, so the conclusions appeared reasonable.

Additional information about the effects of catalyst impregnation and application of the binder on the final pore structure of the outer layer of the electrode was obtained by measuring the total surface area of samples in various stages of preparation. The surface areas were measured by N_2 adsorption in a flow method using the Brenauer-Emmett-Teller technique and were degassed in a stream of helium at 25°C to avoid changes in the gum rubber binder present in one of the samples. The surface area of the Darco S-51 was 463 m^2/g. After deposition of 5 w/o Pt by impregnation with chloroplatinic acid and heat treatment at 165°C, the surface area dropped to 290 m^2/g. This reduction of the total surface area could be explained only by a removal of a large part of the microporosity below 100Å pore diameter, perhaps as a result of plugging by the deposits in the larger pores.

After the gum rubber solution was added, the slurry was used to form a dual-layer electrode. The outer layer then was removed and its surface area was found to be 107 m^2/g. The additional plugging produced by the gum rubber raised the question of the compatibility of the platinum and the gum-rubber binder and of the possible coverage of platinum surface by the binder. Hydrogen chemisorption measurements made on one gum-rubber-treated sample indicated that the platinum area was still totally available after the application of the rubber binder. It appears probable that the binder can be pictured as a porous network which, although it adheres to and bonds the carbon particles together, does not interact strongly with the platinum catalyst and remains porous to hydrogen.

Viton A, a copolymer of vinylidene fluoride and perfluoropropylene, has been used in recent electrodes to replace the gum rubber used as a binder in earlier work. Electrodes prepared with Viton A, cured at 200°C for 24 hr, have good activity and are physically much stronger than those made by using gum rubber.

Conclusions

Based on the observations presented, a few of the details of the structure of the active electrodes can be described. Thus, for the electrodes used in this work, platinum dispersions of about 50 m^2/g on carbon were effective as hydrogen electrodes. This platinum was most effective if located in or near the outer surfaces of the outer layers. The degree of dispersion indicated corresponded to crystallites on the order of 40-50Å size, and these seemed to be located in the macropore portion of the outer layer. Indeed, since the carbons used were all poorly wet by aqueous solutions, it is doubtful if the micropore portion of the carbon ever became wetted by either the platinum solution or the alkaline electrolyte. It is conceivable that these micropores served as gas passages for supply to the active centers of the electrode. In this connection it was of interest to note that the physical mixtures of Pt and C used for one electrode had extremely poor activity.

With proper choice of carbon and control of the electrode preparation, as little as 3 w/o platinum on carbon was sufficient to generate an electrode of high activity. Good hydrogen anodes were made with 1 mg Pt per cm^2 (geometric) or electrode area. There was no evidence that this was the lower limit of the useful range of platinum contents.

Although these measurements served to describe in some detail the microstructure for an active electrode, the achievement of a good dispersion of platinum catalyst did not assure good activity. To complete the picture, a knowledge was required of the chemical

limitations posed by the carbon surfaces present. Thus, although the highest dispersions of platinum were achieved with the last two carbons listed in Table II, the platinum on K2046 carbon showed good activity and the sample made using the mineral carbon was almost totally inactive. The chemical requirements for the carbon surfaces used is the subject of another paper (4).

As a result of these observations, it became apparent that the most efficient use of platinum catalyst for hydrogen anode service could be obtained only if many factors, both physical and chemical, were taken into account. One of the most important of these factors is the chemical interaction between platinum and carbon which must be controlled if high activity per unit weight of platinum is to be obtained.

The Platinum-on-Carbon Catalyst System for Hydrogen Anodes

II. Chemical Requirements of the Carbon Surface

L. J. Hillenbrand and J. W. Lacksonen

Battelle Memorial Institute, Columbus, Ohio

ABSTRACT

The large differences in the activity of platinum-on-carbon anodes that could be produced by the choice of carbon indicated that an important chemical interaction existed between the platinum and the carbon surface. A chemical interaction was also indicated by electron-spin-resonance measurements on plain and platinized carbon. Subsequently it was found that the activity of the platinum anode was reduced to negligible values if the carbon surface was cleaned in N_2 at 1000°C before application of the platinum. If the carbon was reoxidized using CO_2 at 1000°C before application of the platinum, full activity of the platinum deposit was obtained. The effect of N_2 and CO_2 was reversible. Graphitic carbons were unsuitable for this work and did not respond greatly to these treatments. These effects do not seem to be explainable by the surface area changes that are produced. The effect appears to be explainable by adapting the catalyst poisoning theory of Maxted.

In the earlier paper, Part I (1), a dual-layer hydrogen anode was described which used less than 1 mg of platinum per square centimeter on a suitable carbon. The choice of the carbon was found to be important. The highest temperature to which the electrode was exposed was the 165°C heat treatment in air used to decompose the chloroplatinic acid and to activate the electrode. In this heat treatment, the carbon support apparently participated as a reducing agent for the deposition of platinum. Since it was not known whether this reduction provided a clean catalyst of maximum activity, other heat treatments were checked, especially in the presence of hydrogen. This work was part of an investigation of the optimum conditions for activation of the platinum catalyst and led to the experiments that showed the importance of the chemical state of the carbon surface.

Heat Treatments of the Platinized Carbon

The results of the various heat treatments in vacuum, air, and hydrogen presented in Table I show that the treatments at 300°C or above usually were detrimental to the platinum on carbon catalyst. On the other hand, completely fabricated dual-layer electrodes that had been heated in hydrogen at 200°C for several hours had good activity. Also, the hydrogen chemisorption measurements previously reported (1) were made on samples activated at 250°C and were known to remain active as hydrogen anodes following this treatment. On occasion, electrodes of moderate activity appeared to be somewhat improved by the 200°C treatment in hydrogen, so it was concluded that some residual contamination of the platinum surface was removed in this way.

The detrimental effects of heat treatments above 300°C were at least partially explained by the sintering of the platinum catalyst. The x-ray line-broadening examinations (1) showed that the platinum crystallites grew considerably when samples were heat treated at 500°C. However, the large differences in activity related to the type of carbon (1) also suggested that an important chemical interaction existed between the platinum and the carbon surface. Therefore, that part of the effects of heat treatment conceivably was produced by chemical changes that occurred at the platinum-carbon interface.

Investigation of the Carbon Support

The suspicion that platinum-carbon interactions were influencing the activity of the final electrode was strongly supported by the failure of some carbons to yield an active electrode preparation regardless of how the platinum was deposited. Thus, Table II shows that poor activity might be obtained even though the dis-

[b] Sample could not be run because its electrical conductivity was too high.

persion of the platinum, as measured by hydrogen chemisorption, appeared good. The data for the mineral carbon are a good example of this. Further evidence for a platinum-carbon interaction that controls catalytic activity was obtained from chemical treatment of the carbon surface and by the use of electron-spin resonance (ESR) for samples of plain and platinized carbon.

Electron-spin-resonance measurements.—Essentially, ESR is a means for estimating the number of unpaired electrons in a structure. The unpaired electrons represent single electrons that are not involved in chemical-bond formation and are considered to be a measure of the number of free-radical structures trapped in the material. At least two types of interaction can be observed by changes in ESR. One is a physical and the other a chemical interaction. If two electrons interacted magnetically without actually becoming paired, this physical interaction would result in a broadening of the ESR signal and an apparent decrease in the observed intensity. If the unpaired electrons of the free-radical structures are brought together to form a chemical bond, the resulting electron pair formation also results in a decrease in the ESR signal. Where the interaction is chemical, the unpaired electrons involved in the bond formed are totally removed from the resonance, and the signal received is not broadened in spectral width. The interesting differences that appear in ESR among many carbons have been discussed by a number of workers; for example, Kraus and Collins (2), and Collins, Bell, and Kraus (3). The formation and removal of unpaired electrons by direct oxidation of the carbon surface have been discussed by Antonowicz (4), who also indicated the participation of these unpaired electrons in the conduction band for carbon. The relationship of ESR to charge carriers in carbon was discussed by Singer and Wagoner (5).

A relationship between ESR for platinum on carbon and its catalytic activity was the subject of papers by Nicolau and co-workers (6). Nicolau believed that a laminar sandwich-type complex formed between the metal and the graphite crystallites in which a partial sharing of the electrons occurred between these two phases. This appeared to be his explanation for the relationship which he found between the ESR for the material and its catalytic activity in organic hydrogenation reactions. Unfortunately, Nicolau worked with only one particular carbon, and the generality of this relationship is not indicated by his work. In the current studies, it was decided to determine whether the ESR for platinum on carbon could be used as an indicator of electrode catalytic activity.

Because of the relatively high electrical conductivity of carbon, ESR could be obtained for this material only if it was finely divided. Following Collins (3), pulverized carbon samples were contained in melting-point tubes and sealed in ampoules for the control of the sample environment. In each case, the carbon was pulverized to obtain a mixture that was 1/3 (−100 + 325) sieve size and 2/3 (−325). This amount of grinding is considered insufficient to affect markedly the resonance obtained. The samples were usually evacuated at room temperature for several hours and then heated and evacuated at 100°C. Helium was used as a purge gas to sweep the vapors out of the sample tube at various stages during this evacuation. Table II shows some comparative data for the ESR of several carbons before and after application of platinum.

Table III shows that preliminary heat treatments of several carbons in air up to 165°C had no appreciable effect on the resonance for Darco S-51 or Barnebey-Cheney carbons. The mineral carbon appeared to give some signal as received, but after the heat treatment at 165°C, it showed no resonance whatsoever. Pretreatment of the carbon at 165°C was adopted as standard treatment prior to its use in electrode preparations for the ESR studies.

Figure 1 and Table IV show the effects of heat treatment of the carbon at temperatures up to 500°C in air and the effects of the application of platinum to these

carbons. The number of unpaired electrons was obtained from the ESR measurements. There also appeared to be a large decrease in the number of unpaired electrons after the application of platinum to the carbon. These decreases in ESR occurred without line broadening, which was strongly suggestive of a chemical interaction of the platinum with the substrate carbon. Barnebey-Cheney carbon K2046 showed a large decrease in resonance after application of the platinum. These formulations had good electrode activity so that the decrease in resonance in this case did not appear to indicate any appreciable deactivation. Since chemical interactions between the two phases were indicated, it may be assumed that these interactions led to the various degrees of electrode catalytic activity that were observed for these carbons. If some of these interactions were particularly detrimental to the catalytic activity while others were not, the chemical distinction between these two types of interactions would help to define the required properties of the platinum-on-carbon catalyst system. The chemical interactions discussed in the next section were investigated for this purpose.

Chemical alteration of the carbon surface.—The chemical changes induced by heating in air and in hydrogen, as shown in Table IV and Fig. 1, led to a study of the activity changes that could be produced by heating the carbon in various oxidizing and reducing environments. Darco S-51 samples shown in Fig. 1 that had been heated in hydrogen showed poor electrode activity, and a sample of the Barnebey-Cheney carbon which was ground while immersed in

chloroplatinic acid was equally poor. In both cases, the suggestion seems to be that the stronger interactions which were possible with clean or fresh carbon surfaces deactivated the platinum catalyst.

It was realized that the carbon surfaces could contain considerable oxygen. Also, chlorine remained from the decomposition of the chloroplatinic acid. There were also ash constituents in these carbons that could have responded to the oxidizing and reducing environments used to treat the carbon. For this reason, the carbons of interest were analyzed for chlorine and ash. The results are shown in Tables V and VI. From these data it appears that the active samples prepared in this work had relatively high ash content and high chlorine content. The importance of these two variations was not investigated further at this time because large and reproducible activity differences resulted from variations which seemed to be dependent only on changes in the oxygen content of the surface, see for example Table VII.

To vary the surface state of the carbon, samples were treated in hydrogen, nitrogen, air, CO_2, and SO_2. The results obtained from these treatments are illustrated in Tables IV and VII. In each case, the treatment was applied to the carbon alone, and then the platinum was deposited by impregnation with chloroplatinic acid followed by heat treatment overnight at 165°C. The data of Table IV illustrate the loss in ESR with high-temperature treatment either in air or in nitrogen. In Table IV, the large reduction in ESR that accompanied application of the platinum, and the regular decrease in hydrogen-anode activity with increasing carbon treatment temperature, indicated a chemical reaction between the carbon and the platinum. Heating in nitrogen at 1038°C produced a very large reduction in activity, which suggested that the carbon surface treated in this way had a detrimental effect on activity. The SO_2 treatments seem to have had a beneficial effect on carbons that had been partially deactivated by heating.

Cleaning and reoxidation of the surface produced by these treatments led to the experiments summarized in Table VII, which clearly illustrates the large changes in activity produced by cleaning the carbon surface and then reoxidizing the surface using carbon dioxide. The data in Table VIII show that the deactivation produced by nitrogen treatment cannot be

[d] Samples other than those for which values are given were degassed at 150°C for comparison. No significant differences in the area were noted.

explained by changes in surface area. Similarly, the activation produced by CO_2 is not believed to be related to the change in surface area.

Conclusions

The experimental data presented in this paper show that the activity of the catalytic-platinum anode is strongly influenced by the surface state of the platinum catalyst. Further, the effects produced by chemical alteration of the carbon surface indicate that the platinum catalyst is deactivated by a reaction between platinum and a cleaned carbon surface. Oxidation of the surface of the carbon support appears to protect the platinum from this deactivation and perhaps contributes further to the activity of the platinum by effecting changes in the heterogeneity of the surface.

The platinum-carbon interactions described in this research are thought to be altering the catalytic activity of the platinum through the electronic interactions that occur between the two components. The ESR data show some evidence for this interaction. The oxidation of the carbon surface, with the formation of carbon-oxygen structures, presumably leads to an entirely different electronic interaction between the small platinum crystallites and the carbon substrate than occurs with cleaned carbon surfaces. The evidence indicates that the interactions that occur on the oxidized surface are much more desirable for catalysis of the hydrogen anode.

The beneficial effect of the oxidation of the carbon surface seems to be in accord with the theory of catalyst poisoning discussed by Maxted (7). In the present work, the toxic carbon atom is assumed to provide a strong dative bond to the platinum atoms in the Pt-C interface, thereby poisoning the entire crystallite when it is small. Hypothetically, oxidation of the carbon surface shields the platinum from this reaction and provides a readily reducible surface interaction with the platinum crystallite.

In the present study, the catalytic electrodes were intended to use a minimum amount of platinum dispersed as small crystallites on a large amount of carbon surface. For these preparations, the platinum-carbon interactions may be expected to have the maximum influence on activity. Alternatively, in preparations where the platinum crystallites are agglomerated as a platinum black deposit on a small amount of carbon surface, the influence of the Pt-C interface may not be observable.

Design of Primary and Secondary Cells

I. Effect of Polarization and Resistance on Cell Characteristics

Clarence M. Shepherd

U. S. Naval Research Laboratory, Washington, D. C.

ABSTRACT

The current density distribution in a battery is a function of electrode height, electrode resistance, electrolyte resistance, and polarization. Mathematical solutions have been obtained for those cases where the polarization curves are either linear, logarithmic, or cubic. A numerical method is indicated for finding a general solution. In the case of linear polarization, the results are presented in graphs which show the current density distribution and other cell characteristics over a wide range of operating conditions. The determination of these cell characteristics can be of considerable importance in cell design. For practical applications, the complex mathematical calculations involved in the cases of logarithmic and cubic polarization can be eliminated by the use of transformations which convert them to the linear case.

This is the first of a projected series of papers whose main purpose is to determine and describe a theoretical approach to the problem of designing batteries having optimum characteristics such as maximum output. Particular emphasis will be placed on the minimization of battery weight or volume. The effect of polarization and internal resistance on the current density distribution and other battery characteristics will be discussed in this paper.

In most commercial batteries the I-R drop down the grid or electrode is negligible. The term "I-R drop" refers here to the potential drop that occurs when a

current flows through a resistance and is not related to the separate terms I and R as defined later. Thin grids are often used in low weight batteries and in batteries that are to be discharged at high rates. Thus the I-R drop down the electrode may be appreciable. In such a case, consider the paths of two hypothetical units of current, one of which travels a short distance down the anode before it crosses over to the cathode, and the other which travels much farther down the anode before crossing over. In both paths the total potential drop inside the cell, due to I-R drops and polarization, must be the same. In the first path, the I-R drop down the grid is much smaller than it is in the second path, and as a result, the potential drop due to polarization and I-R drop in the electrolyte must be much higher. Consequently, the current density in the upper part of the battery must be greater than it is in the lower part. This variation in current density over the face of the electrode can be quite large and may cause serious overheating at the top of the cell. In any case, the discharge potential and the efficiency will be lower, the capacity at a given discharge rate will be lower, and the maximum discharge rate will be less. Such conditions are undesirable, particularly in a cell that is being designed for optimum characteristics such as minimization of weight. These factors place a limit on how thin a battery grid may be. Consequently, in optimum cell design, it is necessary to determine quantitatively the effects of internal resistance and polarization on the current density distribution.

Tobias and Wijsman (1) have solved the theoretical case for linear polarization. The results are mathematically complex and difficult to evaluate numerically. Moreover, they are limited to the case where the polarization is linear. It can be shown from their work that it is safe to assume in conventional types of batteries that the current flow in the electrolyte is perpendicular to the electrodes whenever the distance between the electrodes is less than approximately one-tenth of their height. This assumption greatly simplifies the mathematical analysis and makes it possible to include the cases where the polarization is logarithmic, cubic, and inverse cubic. The latter case will not be discussed here since it has no practical value.

Mathematical Discussion

The mathematical derivations that follow are obtained by using a model based on the following assumptions:

1. The electrodes are flat, parallel, rectangular, and of uniform width and the spacing between electrodes is less than one-tenth of the electrode height.
2. The path of the current is perpendicular to the electrodes.
3. The grids are uniformly thin sheets of negligible thickness.
4. The current enters and leaves the system uniformly along the tops of the electrodes.
5. The electrode assembly fits snugly in the cell case on both sides and the bottom and the electrolyte level coincides with the top of the electrodes. This assembly eliminates boundary effects and makes the problem two-dimensional.
6. The electrodes and electrolyte are homogeneous and isotropic conductors at uniform temperature.
7. The discharge current is constant.

In actual battery construction, variations from the first five assumptions are generally small and their effect will be negligible. In almost all batteries, assumption six will be true at the beginning of the discharge. In the case of a large current density variation, the electrolyte will be heated unevenly. Also, the active material at the top of the cell will be consumed more rapidly than at the bottom, thus causing an uneven distribution of unused active material which results in the current density distribution changing appreciably throughout discharge. In this case, the mathematical equations that follow will hold true only at the beginning of the discharge. In a cell having optimum characteristics, the current density distribution will be fairly even and consequently the results that follow will be approximately true throughout a major portion of the discharge.

There are other factors that may affect these results during the course of a discharge, the most important of which is change in composition of electrolyte due to its reaction with the active materials. This causes the cell potential and the electrolyte resistance to vary and often results in stratification of the electrolyte. However, it seems highly probable that most batteries designed for minimum weight or volume will use a system in which the electrolyte composition does not change appreciably during discharge.

A base cell is shown in Fig. 1. N of these base cells can be assembled together, anode to anode and cathode to cathode to give a multiplate cell having $N + 1$ electrodes and N electrolyte compartments. It is important to note that each electrode separating a compartment in this multiplate cell is twice the thickness of the electrode in the base cell and will carry twice the current.

In the discussion that follows, lower case letters usually denote variables and capital letters usually indicate factors that are constant for a particular battery:

h, the height of a particular point above the bottom of the electrode, cm. It is the major independent variable.

H, total electrode height, cm.

i, the current density and is the amount of current flowing between the electrodes per unit area of apparent electrode surface at a point that is height h above the bottom of the electrode, amp cm^{-2}.

i_H and i_o are the values of i at the top and the bottom of the electrode, respectively, amp cm^{-2}.

I, the discharge current per unit width of the base cell, amp cm^{-1}. The total discharge current equals $N\,I$ times the width of the electrode.

x, the current per unit width of base cell, flowing vertically past a point on the electrode that is a height, h, above the bottom of the electrode, amp cm^{-1}.

e, the sum of the potential drop in the anode and cathode measured from the top of the electrode to a point that is height, h, above the bottom of the electrodes, volts.

R, the sum of the resistances, measured vertically, of the anode and cathode unit electrodes in the base cell, ohms. Each unit electrode is one unit wide, one unit deep, and one-half the thickness of the actual electrode that is separating compartments in a multiplate cell. In most cases, the resistance of the active material is comparatively high and consequently, the resistance of the pasted electrode is approximately equal to the grid resistance.

L, the actual resistance of a parallelogram one square unit in cross section extending from grid to grid and

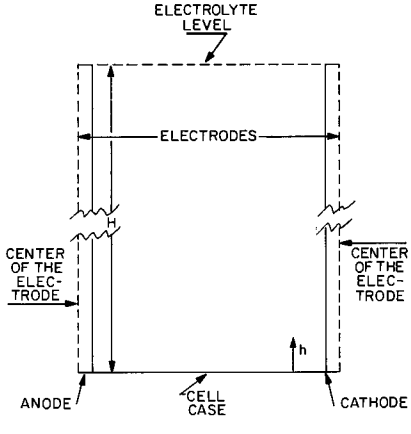

Fig. 1. Base cell

including any spacers or separators, ohm-cm^2. If no spacers or separators are present, L equals the electrolyte resistivity times the distance between the plates.

E_d, a potential drop in the cell that is equal to the difference between the open circuit potential and the discharge potential when the cell is being discharged at a current density equal to i, volts.

$F(i)$, the voltage drop due to polarization, volts. It is defined for the purposes of this paper as follows: E_d equals the sum of the I-R drop in the electrodes, the I-R drop in the electrolyte and the polarization, $F(i)$. In the case of linear polarization, $F(i)$ is defined as being equal to $Ki + K_1$.

K, a constant, the slope of the linear term in the polarization curve, ohm-cm^2.

K_1, the value of the constant term in the polarization curve, volts.

$E^\circ = E_d - K_1$, volts. Since K_1 is usually small in value, E° is generally a good approximation of E_d. If an error were made in determining the value of the open-circuit potential, the same error would be present by definition in E_d and K_1. Such an error would not affect the value of E° nor would it affect any of the derivations and results that follow in this paper. Consequently the open-circuit potential could be redefined or replaced by a new potential such that K_1 would equal zero, $F(i)$ would equal Ki, and E° would equal E_d without affecting any subsequent results.

$$S = L + K, \text{ ohm-cm}^2$$

$$V = (R/S)^{1/2}, \text{ cm}^{-1}$$

$$\Psi = VH = (R/S)^{1/2} H, \text{ dimensionless} \quad [1]$$

If a mathematical equation is to be determined for $F(i)$, it needs to apply only in the range of current densities, i, in which the battery is operating. Since our ultimate goal is an optimum battery in which the range of current densities is usually narrow, it should be fairly easy to find simple equations that will describe the polarization curve adequately.

From the definitions of e, h, R, x, i, and E_d, it can be seen that

$$\frac{de}{dh} = -Rx \quad [2]$$

$$\frac{dx}{dh} = i \quad [3]$$

$$\frac{di}{dh} = \frac{dx}{dh} \cdot \frac{di}{dx} = i\frac{di}{dx} \quad [4]$$

$$E_d = e + Li + F(i) \quad [5]$$

Differentiating Eq. [5] and substituting Eq. [2] and [4] give

$$Rx = Li\frac{di}{dx} + iF'(i)\frac{di}{dx} \quad [6]$$

On integrating

$$Rx^2 = B + Li^2 + 2\int iF'(i)\,di \quad [7]$$

If $iF'(i)$ can be integrated, an equation involving i, x, and the integration constant, B, is obtained, which can be solved for i as a function of x.

$$i = \frac{dx}{dh} = f(x,B) \quad [8]$$

Solving for dh and integrating gives

$$h = f_1(x,B) + C \quad [9]$$

B and C are determined from the boundary conditions, and Eq. [9] is solved for x to give

$$x = f_2(h) \quad [10]$$

which is differentiated to obtain the current density distribution

$$i = f_2'(h) \quad [11]$$

There are a very limited number of mathematical equations for $F(i)$ which will allow a mathematical completion of the analyses in Eq. [5] to [11]. If the steps cannot be completed or if $F(i)$ is available only as a graph, the solution can be achieved by graphical, numerical, or computer methods. In most cases, the simplest practical solution for the general case described by Eq. [5] utilizes a transformation which enables the results to be described as if the polarization were linear.

Linear polarization.—In the case of linear polarization, $F(i)$ is represented by the equation

$$F(i) = Ki + K_1 \quad [12]$$

Substituting Eq. [12] in Eq. [5] gives

$$E_d = e + Si + K_1 \quad [13]$$

Differentiating, substituting Eq. [2] and [4], and integrating gives

$$\frac{S}{2} i^2 = \frac{R}{2} x^2 + C_1 \quad [14]$$

Solving for the current density

$$i = \frac{dx}{dh} = \left(V^2x^2 + 2\frac{C_1}{S}\right)^{1/2} \quad [15]$$

which gives on integration

$$h = \frac{1}{V}\sinh^{-1}\frac{R^{1/2}x}{(2C_1)^{1/2}} + C_2 \quad [16]$$

The integration constants, C_1 and C_2, are determined from the boundary conditions ($h = 0$, $x = 0$), ($h = H$, $x = I$), and substituted in Eq. [16] to give

$$Vh = \sinh^{-1}[(x/I)\sinh(VH)] \quad [17]$$

The following four equations are easily derived from Eq. [17], [2], [3], and [13].

$$\frac{x}{I} = \frac{\sinh[(VH)(h/H)]}{\sinh VH} = \frac{\sinh[\Psi(h/H)]}{\sinh\Psi} \quad [18]$$

$$\frac{iH}{I} = (VH)\frac{\cosh[(VH)(h/H)]}{\sinh VH} = \Psi\frac{\cosh[\Psi(h/H)]}{\sinh\Psi} \quad [19]$$

$$\frac{e}{HIR} = \frac{\coth(VH)}{(VH)} - \frac{\cosh[(VH)(h/H)]}{(VH)\sinh(VH)} = \frac{\coth\Psi}{\Psi} - \frac{\cosh[\Psi(h/H)]}{\Psi\sinh\Psi} \quad [20]$$

$$\frac{E^\circ}{HIR} = \frac{\coth(VH)}{(VH)} = \frac{\coth\Psi}{\Psi} \quad [21]$$

The quantities (x/I), (Ψ), (h/H), (iH/I), (e/HIR), and (E°/HIR) are dimensionless. If K_1 is small compared to E_d, E° will be the approximate potential drop in the cell. Equations [18] to [21] are plotted in Fig. 2 through 5. These equations have also been confirmed experimentally.

The ratio of the current density, i, to the average current density has been plotted as a function of the fractional electrode height, h/H, in Fig. 3. The ideal distribution, obtained at $\Psi = 0$, is a horizontal line. At Ψ equals 5, the ratio of the current density at the top of the battery, i_H, to the current density at the bottom of the battery, i_o, is theoretically more than seventy. It is unlikely that the polarization curve would be linear over this wide a range of current densities. In addition, there are other factors present which will cause the ratio of i_H to i_o to vary from the theoretical value when it is high. At lower values of Ψ, where the batteries are more efficient, the theoretical value of

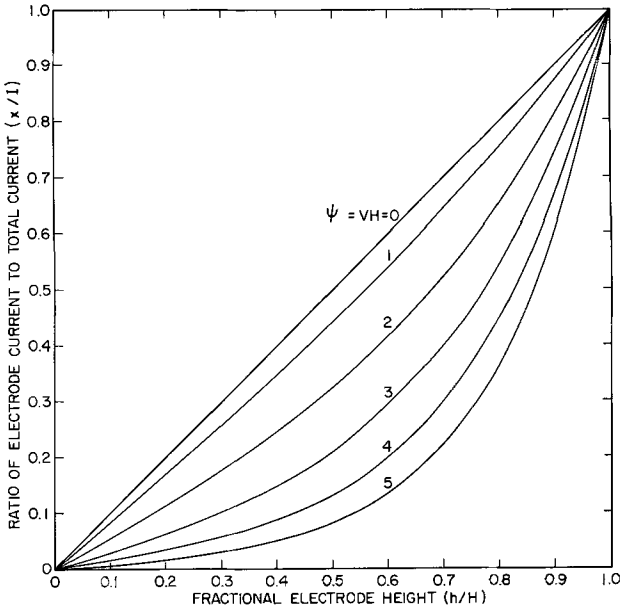

Fig. 2. Variation of current flowing in electrode with electrode height and Ψ for linear polarization.

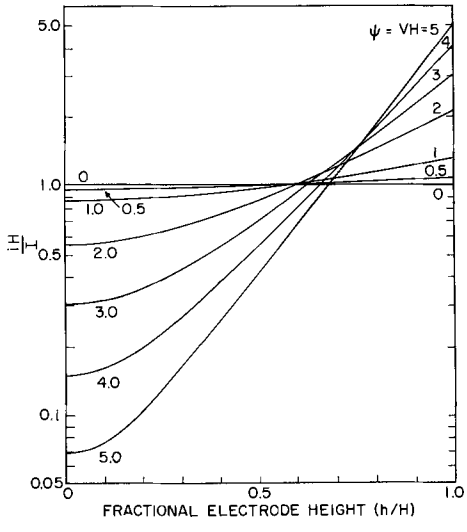

Fig. 3. Effect of electrode height and Ψ on current density distribution for linear polarization.

i_H/i_o will be more accurate. At Ψ equal to one, i_H/i_o equals 1.54. This is fairly close to the level at which an optimum cell will operate. Fortunately, most commercial cells have low values of Ψ.

There are a large number of other equations that can be derived for the linear polarization case. For example

$$i/i_o = \cosh Vh, = \cosh [\Psi(h/H)] \qquad [22]$$

$$i_H H/I = \Psi \coth \Psi \qquad [23]$$

and

$$\frac{eH}{SI} = \frac{H}{I}(i_H - i) = \frac{E^\circ H}{SI} - \frac{iH}{I} \qquad [24]$$

Cubic polarization.—With cubic polarization, $F(i) = K_2 i^3 + Ki + K_1$, and Eq. [5] becomes

$$E_d = e + Si + K_2 i^3 + K_1 \qquad [25]$$

where K_2 is positive in value.

Differentiate Eq. [25], substitute Eq. [2] and [4], and integrate.

$$\frac{R}{2}x^2 = \frac{S}{2}i^2 + \frac{3}{4}K_2 i^4 - C_1 \qquad [26]$$

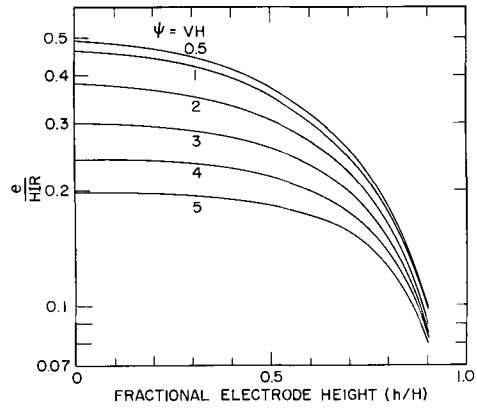

Fig. 4. Effect of electrode height and Ψ on potential drop in electrode for linear polarization.

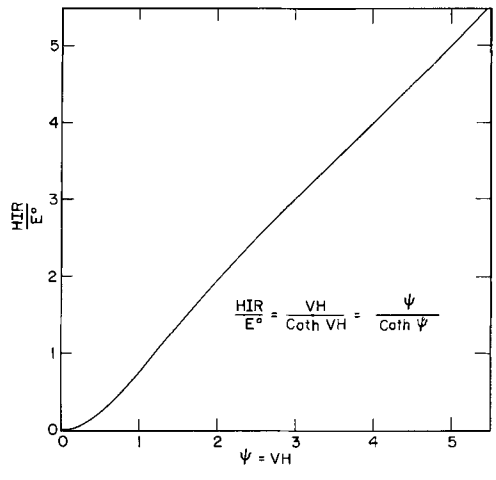

Fig. 5. Effect of Ψ on the approximate potential drop in cell for linear polarization.

$$i = \frac{dx}{dh} = \left[(B + Dx^2)^{1/2} - \frac{1}{2}F \right]^{1/2} \qquad [27]$$

where $F = \frac{2S}{3K_2}$, $B = \frac{S^2 + 12K_2C_1}{9K_2^2}$, and $D = \frac{2R}{3K_2}$.

Equation [27] is not readily integrable. It can be expanded in a Maclaurins series to give

$$h = i_o^{-1}x - \frac{1}{12}i_o^{-3}DB^{-1/2}x^3 + \frac{3}{160}i_o^{-5}(DB^{-1/2})^2x^5 - \frac{5}{896}i_o^{-7}(DB^{-1/2})^3x^7 + \ldots.$$

$$+ \frac{1}{80}i_o^{-3}B^{-1/2}(DB^{-1/2})^2x^5 - \frac{3}{448}i_o^{-5}B^{-1/2}(DB^{-1/2})^3x^7$$

$$- \frac{13}{3360}i_o^{-3}B^{-1}(DB^{-1/2})^3x^7 + \ldots \qquad [28]$$

where $i_o = \left(B^{1/2} - \frac{1}{2}F \right)^{1/2}$.

By the use of dimensional analysis, it can be shown that the coefficient of x^n in any term in Eq. [28] is equal to a constant times the quantity,

$$V_1^{n-1} i_o^{-n} (i_o^2 B^{-1/2})^\Phi \qquad [29]$$

where Φ is some positive integer, including zero, and

$$V_1^2 = \frac{1}{2} DB^{-1/2} = R(S^2 + 12K_2C_1)^{-1/2} \quad [30]$$

When Eq. [29] and [30] are substituted in Eq. [28], it becomes

$$V_1 h = \left[\Psi_1 \frac{x}{Hi_o} - \frac{1}{6}\Psi_1^3 \left(\frac{x}{Hi_o}\right)^3 + \frac{3}{40}\Psi_1^5 \left(\frac{x}{Hi_o}\right)^5 - \frac{5}{112}\Psi_1^7 \left(\frac{x}{Hi_o}\right)^7 + \dots \right] + g \quad [31]$$

where

$$g = \frac{1}{20} i_o^2 B^{-1/2} \Psi_1^5 \left(\frac{x}{Hi_o}\right)^5 - \frac{3}{56}(i_o^2 B^{-1/2})\Psi_1^7 \left(\frac{x}{Hi_o}\right)^7 - \frac{13}{420}(i_o^2 B^{-1/2})^2 \Psi_1^7 \left(\frac{x}{Hi_o}\right)^7 + \dots \quad [32]$$

and $\Psi_1 = V_1 H$.

By definition

$$i_o^2 B^{-1/2} = \left(B^{1/2} - \frac{1}{2}F\right) B^{-1/2} = 1 - \frac{S}{(S^2 + 12K_2C_1)^{1/2}} \quad [33]$$

Since i must have a positive value at the boundary condition, $(h = 0,\ x = 0)$, it can be seen from Eq. [26] that the integration constant C_1 must be positive in value. Consequently, Eq. [33] shows that $i_o^2 B^{-1/2}$ varies in value between one and zero. Therefore, g will become small in value whenever $\Psi_1(x/Hi_o)$ is less than one. Under these conditions, Eq. [31] can be seen by inspection to be approximately

$$V_1 h = \sinh^{-1}[\Psi_1(x/Hi_o)] \quad [34]$$

When $h = H$, $x = I$ and Eq. [34] becomes

$$V_1 H = \Psi_1 = \sinh^{-1}[\Psi_1(I/Hi_o)] \quad [35]$$

When Ψ_1 is less than 0.88, $\Psi_1(I/Hi_o)$ is less than one, g is small in value, and Eq. [34] and [35] are approximate solutions. If Eq. [34] is divided by Eq. [35], the following equation is obtained.

$$\frac{x}{I} = \frac{\sinh[\Psi_1(h/H)]}{\sinh \Psi_1} \quad [36]$$

Equation [36] can also be obtained by substituting Ψ_1 for Ψ in Eq. [18]. An accurate description of the cell characteristics can be obtained by substituting Ψ_1 for Ψ in Eq. [18], [19], and [20]. Cell characteristics can be predicted over a much wider range of conditions by the use of an empirical method which can also be applied to other types of polarization. If there were no polarization during a constant current discharge, Eq. [5] would be

$$E_d = e + Li \quad [37]$$

L would equal S, and the cell characteristics would be described perfectly by the equations for linear polarization. The potential drop due to polarization, $F(i)$, would be in all cases a monotonic increasing function of i containing no sharp breaks, as long as the value of $VH = \Psi$ was under 2 or 3 and the current density variation over the face of the electrode was not large, a condition that would be true in a well-designed battery. Under these conditions, the introduction of the polarization term, $F(i)$, would convert Eq. [37] to Eq. [5] and would cause the existing current density distribution curve to be flattened while retaining much the same shape. If $F(i)$ is linear, the new current density distribution curve is described by Eq. [19]. Since the current density variation is small for low values of VH and since the summation of the current density over the face of the electrode equals I, the new current density distribution curve that results by the introduction of a nonlinear polarization term, $F(i)$, into Eq. [37], should be described approximately by Eq. [19] if Ψ in this equation is replaced by $\Psi_k = V_k H$ where Ψ_k is a suitable function of Ψ and $F(i)$. Ψ_k can be calculated from the numerical value of a single point such as i_H on the true current density distribution curve through the use of Eq. [23]. The approximation curve and the true current density curve both pass through the same point i_H, both have the same integral and have much the same shape. Consequently any difference between the two curves would be expected to be small for low values of Ψ.

Assume a theoretical case where there is no polarization and Eq. 37 applies. Let the value of L be such that $\Psi = 3$. Then the current density distribution over the face of the electrode is completely described by the curve for $\Psi = 3$ in Fig. 3. The introduction of any polarization would flatten this curve toward the limit where $\Psi = 0$ and the current density distribution is uniform. If a linear polarization term as described in Eq. [12] is introduced such that $K = 1.25L$ then Ψ would be reduced in value from 3 to 2 and the current density distribution over the face of the electrode would be completely described by the curve for $\Psi = 2$ in Fig. 3. If a nonlinear polarization term of a suitable size had been introduced instead of the linear term, a flattening of the $\Psi = 3$ curve could be obtained which would be fairly well approximated by the $\Psi = 2$ curve and it could be assigned a value of $\Psi_k = 2$. Under normal conditions such approximation should be accurate enough for use in Eq. [18], [19], and [20] but definitely not in [21].

$\Psi_k = \Psi_2$ has been determined for the case of cubic polarization and its applicable range is shown in Fig. 6 where it is plotted as a function of Ψ and the dimensionless factor F_1.

$$F_1 = \left(\frac{2S}{3K_2}\right)\left(\frac{H}{I}\right)^2 = \frac{FH^2}{I_2}$$

Accurate values of the current flowing in the electrodes, the current density distribution and the potential drop in the electrodes can be obtained by substituting Ψ_2 for Ψ in Eq. [18], [19], and [20], respectively, or in Fig. 2, 3, and 4, respectively. Satisfactory values of $E°/HIR$ cannot be obtained by substituting Ψ_2 in Eq. [21]. Accurate values of $E°/HIR$ can be determined from Fig. 7.

Logarithmic polarization.—In the case of logarithmic polarization, $F(i) = K_3 \ln i + Ki + K_1$ and Eq. [5] becomes

$$E = e + Si + K_3 \ln i + K_1 \quad [38]$$

Differentiate Eq. [38], substitute Eq. [2] and [4] and integrate

$$\frac{R}{2}x^2 + C_1 = \frac{S}{2}i^2 + K_3 i$$

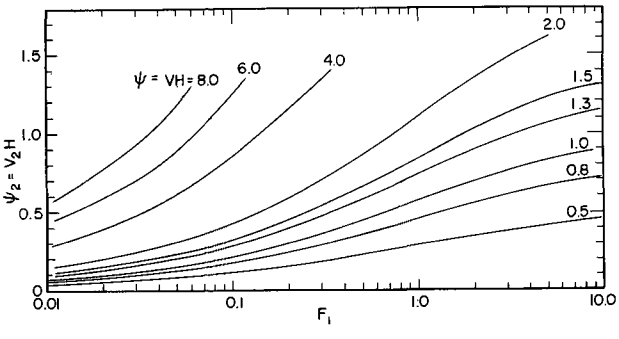

Figure 6. Plot showing Ψ_2 as a function of Ψ and F_1

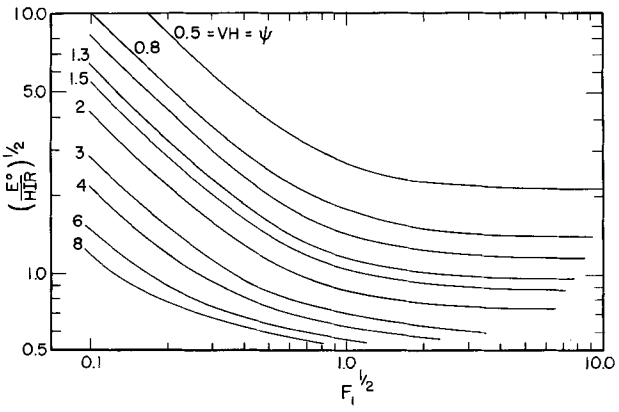

Fig. 7. Approximate potential drop in cell for cubic polarization

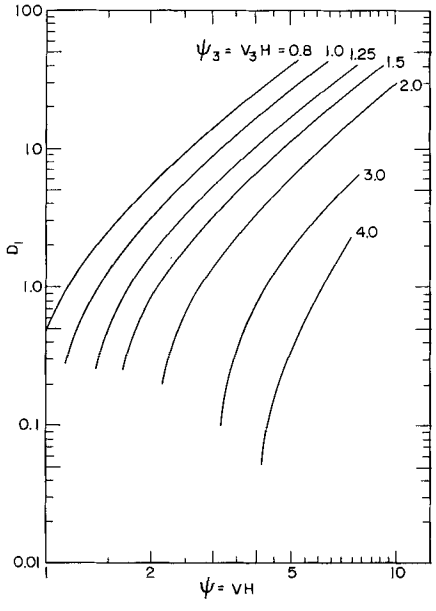

Fig. 8. Plot showing Ψ_3 as a function of Ψ and D_1

Solving for i and x gives

$$i = (V^2x^2 + A)^{1/2} - D \quad [39]$$

and

$$x = \frac{1}{V}(i^2 + 2iD + D^2 - A)^{1/2} \quad [40]$$

where $A = \frac{2C_1}{S} + \frac{K_3^2}{S^2}$ and $D = \frac{K_3}{S}$

$$dx = i\,dh = \frac{(i + D)\,di}{V(i^2 + 2iD + D^2 - A)^{1/2}} \quad [41]$$

which gives on integration

$$h = \frac{1}{V}\ln\left[2(i^2 + 2iD + D^2 - A)^{1/2} + 2i + 2D\right] + \frac{D}{V}\frac{1}{(A - D^2)^{1/2}}\sin^{-1}\left[\frac{2Di + 2D^2 - 2A}{2iA^{1/2}}\right] + C_7 \quad [42]$$

Substituting Eq. [39] and [40] in Eq. [42] gives

$$h = \frac{1}{V}\ln\left[2Vx + 2(V^2x^2 + A)^{1/2}\right] + \frac{1}{V}\frac{D}{(A - D^2)^{1/2}}\sin^{-1}\left[\frac{D(V^2x^2 + A)^{1/2} - A}{A^{1/2}\{(V^2x^2 + A)^{1/2} - D\}}\right] + C_7 \quad [43]$$

When $h = 0$, $x = 0$, and

$$C_7 = -\frac{1}{V}\ln 2A^{1/2} - \frac{1}{V}\frac{D}{(A - D^2)^{1/2}}\sin^{-1}(-1) \quad [44]$$

Equation [44] is substituted in Eq. [42] and [43] to give

$$Vh = \Psi\left(\frac{h}{H}\right) = \cosh^{-1}\left[\frac{(iH/I) + D_1}{A_1^{1/2}}\right] + \frac{D_1}{(A_1 - D_1^2)^{1/2}}\sin^{-1}\left[1 - \frac{\{D_1(iH/I) + D_1^2 - A_1\}^2}{A_1(iH/I)^2}\right]^{1/2} \quad [45]$$

and

$$\Psi\left(\frac{h}{H}\right) = \sinh^{-1}\left[\frac{\Psi(x/I)}{A_1^{1/2}}\right] + \frac{D_1}{(A_1 - D_1^2)^{1/2}}\sin^{-1}\left[\frac{\Psi(x/I)\,(A_1 - D_1^2)^{1/2}}{A_1^{1/2}\{\Psi^2(x/I)^2 + A_1\}^{1/2} - A_1^{1/2}D_1}\right] \quad [46]$$

where $A_1 = AH^2I^{-2}$ and $D_1 = DHI^{-1}$. A_1, D_1, Ψ, (x/I), (h/H), and (iH/I) are dimensionless. When D_1 is negative in value and D_1^2 is larger than A_1, Eq. [45] and [46] become

$$\Psi\left(\frac{h}{H}\right) = \cosh^{-1}\left[\frac{(iH/I) + D_1}{A_1^{1/2}}\right] + \frac{D_1}{(D_1^2 - A_1)^{1/2}}\sinh^{-1}\left[\frac{\{D_1(iH/I) + D_1^2 - A_1\}^2}{A_1(iH/I)^2} - 1\right]^{1/2} \quad [47]$$

and

$$\Psi\left(\frac{h}{H}\right) = \sinh^{-1}\left[\frac{\Psi(x/I)}{A_1^{1/2}}\right] + \frac{D_1}{(D_1^2 - A_1)^{1/2}}\sinh^{-1}\left[\frac{\Psi(x/I)\,(D_1^2 - A_1)^{1/2}}{A_1^{1/2}\{\Psi^2(x/I)^2 + A_1\}^{1/2} - A_1^{1/2}D_1}\right] \quad [48]$$

The function, $\sin^{-1}$, is multivalued. The $\sin^{-1}$ in Eq. [46] is a monotonic function starting at zero for $h/H = 0$ and continuously increasing in value up to h/H = one.

When h/H equals 1, $x/I = 1$, and Eq. [46] and [48] each becomes an equation which gives A_1 as a function of the two known variables D_1 and Ψ and can be solved for A_1 numerically. When these numerical values of A_1 are substituted in Eq. [45], [46], [47], and [48], numerical values are obtained of x/I and iH/I as functions of h/H, D_1, and Ψ. These calculations are quite lengthy. It was found that the numerical work could be greatly reduced by transforming to the linear case through the use of Ψ_k as previously described. The empirical term $\Psi_k = \Psi_3 = V_3H$ has been plotted in Fig. 8 as a function of D_1 and Ψ.

The solutions for the current and potential distributions for logarithmic polarization can be calculated with a high degree of accuracy from the linear polarization equations by substituting Ψ_3 wherever Ψ occurs, in Eq. [18], [19], and [20], or in Fig. 2, 3, and 4. Ψ_3 may not be substituted in Eq. [21]. Ψ_3 can be calculated over the range covered in Fig. 8 from the equation

$$\log(\Psi/\Psi_3) = 0.1520 + 0.2452\log D_1 + 0.12226(\log D_1)^2 - 0.01676(\log D_1)^3 \quad [49]$$

Conclusion

It seems highly likely that the current density distribution and other cell characteristics discussed here can be described fairly accurately for low values of Ψ in any ordinary battery where the polarization is nonlinear, by substituting properly calculated values of Ψ_k for Ψ in Eq. [18], [19], and [20], or in Fig. 2, 3, and 4, thus eliminating most of the mathematics and greatly simplifying the calculation of the cell characteristics. However, values of E° cannot be determined in this manner by substituting Ψ_k for Ψ in any of the linear polarization equations involving E° such as Eq. [21]. In such cases, E_d, the potential drop in the cell, can be calculated by the use of Eq. [5].

A Bacterial Methane Fuel Cell

Willem van Hees

Baltimore Gas and Electric Company, Baltimore, Maryland

ABSTRACT

Fuel cells with a *Pseudomonas methanica* suspension at the anode and sterile medium at the cathode developed 0.5-0.6v on open circuit, methane and air being used. Maximum power density was 2.8 $\mu w/cm^2$ (2.6 mw/ft^2) at 0.35v. Hydroxyl ions are the source of oxygen at the anode. The immediate fuel is hydrogen, probably supplied by a flavoprotein. The free energy efficiency of the fuel cell is 14.2% at very low drain and 8.2% at the maximum power point. Its improvement depends on finding energetically more advantageous ways of interfering electrochemically in the natural respiratory sequence. Current density can be improved, possibly by one order of magnitude.

The problem of cheaply and simply catalyzing the electrochemical oxidation of methane under ambient conditions has been approached but not solved (1). Certain micro-organisms are capable of producing and maintaining a system of organic catalysis and energy transfer by which methane can be oxidized at a rate of about 4×10^{-12} ml/hr/organism at 30°C. Part of the ingested carbon is yielded as carbon dioxide; the remainder is used for bacterial substance. It was not known at which point in the metabolic sequence electrochemistry could take over from nature or whether a soluble intermediate useful in a fuel cell is excreted. Similarly, although on general biochemical grounds the free energy conversion efficiency was expected to be low, no estimations involving electrochemistry had been attempted (2). If 100 ml of a vigorous culture with an organism count of 0.5×10^9/ml use methane at the quoted rate, and if one half of the chemical energy of the methane were convertible in a biofuel cell, a current of 1.0 ma could be expected. These, and other considerations motivated an investigation of some of the properties of a methane bio-anode using a strain of *Pseudomonas methanica* (Söhngen).[1] This organism obligately depends on methane (or methanol) for growth (3).

Apparatus and Experimental Procedures

Electrode potentials were determined at 30°C with a saturated calomel electrode as reference. They are given below in terms of the potential of the normal hydrogen electrode.[2] A Hildebrand type gas electrode was used in 50 ml fluid, while carbon dioxide free gas was bubbled through at a rate of 5 l/hr such that stirring was vigorous. When anode potentials were measured, special care was taken to prevent diffusion of air to this electrode. Bridges were made with the fluid used at the electrode with 2% agar and saturated with potassium chloride.

For fuel cell studies a bio-anode was coupled with an air (oxygen) cathode in a three-compartment device made of a transparent polymer material.

It is similar to a cell described by Davis and Yarbrough (4). Figure 1 shows a schematic longitudinal cross section of three compartments formed by three cylindrical pieces and two membranes. The cylinder wall thickness is 9 mm. The ends of the middle cylinder were machined to mate with the open ends of the two other cylinders. When aligned, and after placing the membranes, the three parts could be tightly pressed together with auxiliary equipment (not shown). Thus, three compartments would be formed. The membranes, made of a regenerated cellulose[3] were then clamped between the cylinder edges. The cellulosic material was permeable to inorganic ions and to dyes but not to protein molecules or bacteria.

The end compartments had electrodes placed close to the membranes and made of helically wound platinized platinum wire with a nominal surface of 12.6 cm^2 each. This material had been selected for the anode because it was expected that hydrogen would be the anode reactant. Furthermore, it was used for the cathode because it had a more negative potential than smooth platinum and several forms of silver,[4] gold or nickel in the medium employed (see below). The bacterial medium was used as electrolyte.

The electrode compartments each had a wide opening facing upward, into which a short access tube was fitted. This permitted the existence of a meniscus of 45 mm diameter, and it prevented the loss of bacteria through froth flotation. The gases were introduced at points directly under the electrodes through polyethylene tubes. Gas inlet and outlet tubes passed through rubber stoppers closing off the short wide access tubes.

The compartment that was supplied with methane (left-hand side, Fig. 1) contained the bacterial suspension and the anode. The other two compartments were filled with sterile medium. Oxygen was bubbled through the cathode half-cell in the form of air. When the fuel cell was in operation, electrons could pass through the external circuit from anode to cathode.

The purpose of the two-membrane arrangement, in preference to a one-membrane two-compartment cell, was to restrict severely the diffusion of dissolved oxygen from cathode to anode. The central compartment had inlet and outlet tubes for purging the fluid in it with oxygen-free nitrogen.

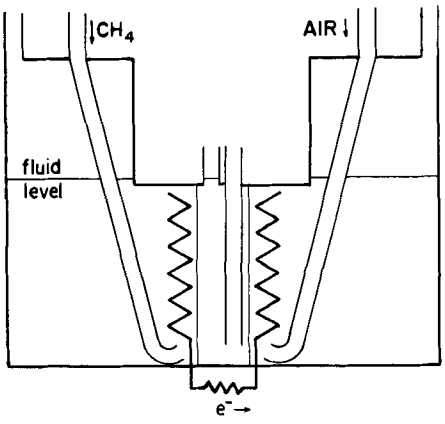

Fig. 1. Schematic diagram of the fuel cell

[1] Received from J. W. Foster, University of Texas, Austin, Texas.

[2] The American convention regarding the sign of electrode potentials is followed. The oxygen electrode potential is negative.

[3] Supplied by A. H. Thomas Co. The average pore diameter is 4.8 $m\mu$, the wall thickness is 0.04 mm. The dialysis bag later referred to is of the same material, but with a wall thickness of 0.02 mm.

[4] Contrary to expectation, *P. meth.* was found to grow well in the presence of pure metallic silver.

The membranes had an area of 25.5 cm^2 each; the electrode compartments had volumes of 153 ml. the middle compartment volume was 41 ml. The inner diameter of the compartments was 57 mm, the over-all inside length after assembly about 136 mm, the distance between the membranes 16 mm.

Carefully purified methane or nitrogen was used in the anode half-cell. These gases were prepared from technical grades by passing them through a purification train to remove thoroughly any electrochemically active impurities, such as hydrogen, oxygen, nitrogen oxides, or unsaturated hydrocarbons, if present. The methane initially was of 95-96% purity, the remainder consisting of saturated hydrocarbons, mainly ethane. These hydrocarbons constitute an insignificant admixture. This is because *P. meth.* is an obligate methane oxidizer, as stated. Furthermore, the nonbacteriological electrochemical reactivities of methane and its C_2 to C_4 homologs are fully expected to be extremely small and virtually the same under the given conditions.[5]

When carbon dioxide was used, a concentration of 8.0% (beverage grade, purified as described above) was maintained in both anode and cathode gases. All gases or gas mixtures were saturated with water vapor at 30°C prior to their entry into the fuel cell, which was operated at that temperature in all experiments. Gas flow to each half-cell was at the rate of 5.0 l/hr.

Emf measurements were made with a sensitive potentiometer preset before circuit closure to a value taken from the chart of a recording potentiometer with a very high off balance input impedance. Thus emf "seeking" and concomitant current drains were avoided. Fuel cell load current was calculated from the voltage drop across known resistances, measured with a recording millivolt meter (0-10 mv scale).

Equilibrium was assumed to exist if a recorded value was maintained without significant fluctuation for at least 30 min. Polarization curves, involving six to eight data points taken over as many or more hours, were obtained after open-circuit equilibrium had been reached overnight.

Pseudomonas methanica was propagated in a completely inorganic medium with methane as the sole source of carbon. The gas over the fluid had the following initial composition by volume: methane 50%, carbon dioxide[6] 10%, oxygen 40%. These culture conditions are highly selective, minimizing the danger of contamination. Frequent tests for invading species always gave negative results. In bulk, the mature culture has a pink color. Unless stated otherwise, an organism count of 0.5 x 10^9/ml obtained at the start of each experiment.

The composition of the medium was: $MgSO_47H_2O$ 0.40g; $CaCl_2$ 0.02g; K_2HPO_4 0.67g; KNO_3 1.00g; NaCl 0.50g; H_2O 1000g.

Results and Discussion

When an electrode is immersed in a suspension of *P. meth.* newly taken from a culture flask, an emf of about —0.6v, mainly due to dissolved oxygen and carbon dioxide, may be observed. The obligately aerobic *P. meth.* will gradually remove the oxygen, a process that may be hastened by scrubbing the fluid with methane or nitrogen. Without scrubbing carbon dioxide will not be fully removed. Equilibrium was found at various emf values between —0.10v and 0v and occasionally above 0v, with a culture that initially had a *p*H of 6.5. A value of about —0.05v represents a majority of cases. In these, the final *p*H was below 8. In the cases that were excluded, bacterial decay had caused a *p*H value above 8 and sometimes above 9. Maintaining bacterial vigor is not compatible with establishing a bacterial electrode potential equilibrium, which requires zero current. When neither gaseous nor dissolved oxygen can reach the bacteria, they depend on ions capable of releasing oxygen upon their discharge at the electrode. At zero current there is no net discharge. Eventually the bacteria will perish. Reaching a potential plateau generally took over one day.

The carbon dioxide free air (oxygen) electrode potential in the medium at *p*H 7.0 usually was quite close to —0.58v. An open-circuit fuel cell emf of approximately 0.53v was thus to be expected. An actual value of about 0.50v was found with the three compartment cell at *p*H 6.0-6.5 (initial). This illustrates that diffusion of dissolved oxygen from cathode half-cell to anode half-cell was indeed very slight.[7]

In order to give the bacteria as natural a set of conditions as possible under the circumstances, carbon dioxide was always used in both halves of the fuel cell. Oxygen, except for apparently negligible diffusion, could only reach the bacteria after discharge of oxygen carrying ions at the anode. Thus the withdrawal of electric power is the only (relatively) substantial means of providing the bacteria with oxygen. This must be true for any obligate aerobe functioning in an anode half-cell. (Facultative anaerobes seem more suited for such a role. When no current is being taken, they can continue producing an electrochemically usable material.)

Methane is not an electrochemically active species at the anode. This may be shown by replacing it by nitrogen, which causes little change in emf as long as the bacteria remain vigorous. In the prolonged absence of methane the organism count dwindles. The cell emf also decreases.

The maximum current in the cell described was of the order of 1μa/cm^2 of electrode area.[8] However, the use of a hydrogen transfer (redox) intermediate enhanced the current density. 1-naphthol 2-sulfonate indo 2, 6-dichlorophenol was found to be suitable under the anode half-cell conditions. At *p*H 7 and 30°C this indicator has a redox potential of —0.119v (5). Its blue (oxidized) form became decolorized when the bacteria had raised the (negative) emf sufficiently through oxygen scavenging and subsequent addition of hydrogen to the dye molecules, and the light pink bacterial color than would prevail. The dye concentration was 0.0028M. The polarization curve obtained with this dye present is shown in Fig. 2 (curve D). The open-circuit fuel cell emf was the same whether the dye was present or not. This suggests that the dye functions as a transfer agent rather than as an electrochemical species.

The dye is decolorized by hydrogen addition, not by oxygen removal. This occurs in the anode half-cell, as well as in an oxygen starved culture, indicating that a naturally occurring dehydrogenation of some substrate molecule also occurs in the fuel cell.

Organisms from a culture with a count of 0.9 x 10^9/ml were centrifuged and washed, then resuspended in a small volume of medium and sonically destroyed at a temperature between 0° and 5°C. The insoluble debris was removed by centrifuging and the pink supernatant solution diluted with medium to the original culture volume. The fluid thus obtained was used in an anode half-cell potential determination with methane as the scrubbing gas. A potential of —0.120v

[5] It would be very difficult to obtain relative reactivity data at ordinary temperatures using a dilute neutral electrolyte. For comparative data obtained under conditions much more conducive to electrochemical oxidation of saturated hydrocarbons, see "Fuel Cells," W. Mitchell, Editor, pp. 285-6, 373-4, New York (1963).

[6] Growth in a newly inoculated medium is extremely slow if this gas is absent. Although methane is the original carbon source, carbon dioxide apparently is both made and used by this species, its presence ensuring rapid growth. This has been observed by others. See C. E. Zobell, *Bacteriol. Revs.*, **10**, 1 (1959), and *Advances in Enzymol.*, **10**, 443 (1950).

[7] Without bacteria, but under otherwise similar conditions, an open-circuit emf of about 0.3v was extremely slowly approached.

[8] Replacement of methane by hydrogen gas under otherwise unchanged conditions, causes a current increase of more than two orders of magnitude, showing that the bacterial anode process severely limits the over-all process rate. The cell geometry, furthermore, was not optimal for power production.

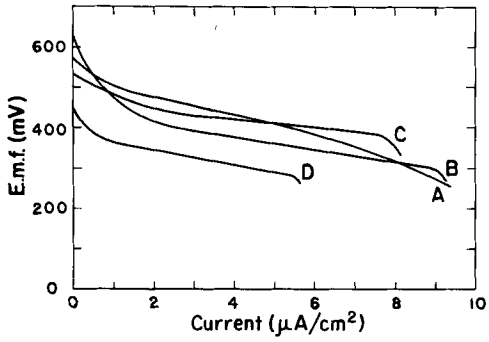

Fig. 2. Polarization curves obtained under different conditions

established itself slowly. This is somewhat below but fairly close to the values usually obtained with live material of "equivalent strength." This shows that the contents of the bacteria play a role in the events taking place in the fuel cell, and that the open-circuit fuel cell emf can be established substantially without involving substances excreted by the bacteria. In order to ascertain whether such substances, if present, have an electrochemical function, physical contact between the bacteria and the anode was prevented in another experiment. This was effected by enclosing this electrode in a slender dialysis bag[3] filled with medium. Under these circumstances, open-circuit emf was established extremely slowly even though the indophenol dye was present; the current at any emf was insignificant. This shows that physical contact between electrode and the bacteria is necessary for charge transfer. The hydrogen used for the anodic formation of water is thus not available from a water-soluble substance excreted by the bacteria, nor from the reduced form of the dye. The latter conclusion further implies that this dye is not a true electrode reactant in this cell. Although *P. meth.* can grow in very dilute methyl alcohol, which probably is an intermediary in the methane oxidation sequence, it is not the immediate fuel. Prior to its removal hydrogen is attached to a substance inside (or on) the bacteria.

The dye, in either form, is easily taken up by or removed from the bacteria, as was shown by dialysis and other experiments. Bacterial contact with the anode is necessary nonetheless. This is due to the fixed ratio maintained between the concentrations of oxidized and reduced dye molecules at any given anode potential and *p*H of the electrolyte. Reduction of dye molecules in (or on) a bacterium required simultaneous oxidation of as many leuco molecules, with the aid of ubiquitous hydroxyl ions and removal of an even number of electrons from the bacterium. The bacteria briefly function as macro-ions on impact with the anode.

By adjusting the fluid *p*H to 7.5 with potassium carbonate prior to start-up of a newly assembled fuel cell, higher open-circuit emf and higher current densities may be obtained. The former varies according to

$$E = 0.753 - 0.03 \log ([HO_2^-]/[OH^-])$$

This relation (6) represents the cell's emf as a function of cathodic peroxide concentration. Higher current densities stem from a lower cathode emf, from the higher redox potential of the dye at higher *p*H (at *p*H 6.5, redox potential $E_o' = -158$ mv; at *p*H 7.5, $E_o' = -80$ mv) and to a minor degree from the added potassium carbonate.[9] Under otherwise equal conditions a higher concentration of the oxidized form of the dye will be available at higher *p*H, which permits an increased rate of reaction with the hydrogen donor substance of the bacteria. Curves obtained after an initial *p*H adjustment to 7.5 are shown in Fig. 2. Curve A represents results after *p*H adjustment only. Curve B was obtained with a strain of *P. meth.* grown in the same medium, but with potassium nitrate replaced by ammonium sulphate on a weight for weight basis. In the case of curve C, the strain was grown in a medium with four times the usual amount of potassium nitrate. *p*H adjustments were also made in these two cases.

Adustment of *p*H has a greater effect than the changes in medium (electrolyte) composition. From the fact that cell performance in the presence of nitrate is not poorer than in its absence, it may be concluded that nitrate is not involved in supplying oxygen to the bacteria at the anode (a nitrate-nitrite mechanism would not involve charge transfer across the cell). This is not surprising; *P. meth.* is a true aerobe incapable of utilizing nitrate oxygen.[10]

Hydroxyl ions are the only ions present that are, under the existing conditions, capable of supplying oxygen at an anode. Whether these ions originate from water molecules at the anode or whether they are formed at the cathode cannot now be stated. For the first case, a mechanism can be written involving a net positive ion (hydrogen ion) transport from anode to cathode, where these ions then are bound. In the second possible mechanism, a net negative ion (hydroxyl ion) transport occurs in the opposite direction. Which mechanism prevails is expected to depend on *p*H and on ion transport rates.

In order to decide approximately where the respiratory chain is interrupted and provided with an electrochemical termination, the anode potential should be compared with known redox potential (E_o') values of the oxidative enzymes.

It is current understanding that bacterial substrate (in this case methane or its derivatives) yields hydrogen which is transferred via a sequence of complex substances, eventually to reach a terminal acceptor (7). This sequence consists of two parts. In each dehydrogenation event, in the first part, two atoms are enzymatically removed from the substrate and bound to an intermediate transfer substance which, in turn, passes two electrons and two protons to the next species in the sequence. At the end of the first part of the sequence hydrogen ions enter into the surrounding fluid and electrons pass on to the next transfer substance. The second or terminal part of the sequence of transfer agents consists of cytochromes. These only transfer electrons, one at a time, until at the last cytochrome step oxygen is reduced and free hydrogen ions from the surroundings are also bound. In each transfer event some energy is used, representing a fraction of the original bonding energy of the hydrogen.

In general, the steps in the dehydrogenation sequence may be formulated as (8)

$$AH_2 + B \rightleftarrows BH_2 + A$$

In the case of aerobic bacteria, the over-all process then becomes

$$AH_2 + \frac{1}{2} O_2 \rightarrow A + H_2O$$

Redox potentials of five intermediates (or types of intermediates) have been determined (9).

The anode potential, measured with a "bridge cell" is 0.05v as stated. The uncertainty in this value is very likely to be within ±0.05v. This potential may be represented by

$$E = E_o' - RT/2f \ln ([AH_2]/[A])$$
$$= E_o' - 0.03 \log 10c = E_o' - 0.03c$$

in which E_o' is the redox potential of the electrochemically active hydrogen transfer substance involved and E the measured culture (anode) potential. E varies very little whether the indophenol dye is used or not. Under the existing conditions the dye is de-

[9] The use of oxygen instead of air results in an approximate doubling of the current density in the middle part of the emf range, other experimental conditions being the same.

[10] Cultures of *P. meth.* die if no O_2 is present, even if extra nitrate used (medium C). Nitrate cannot act here as oxygen donor.

colorized (visually observed). The reduced (hydrogenated) form is present in a relatively high concentration at the anode. This means that the dehydrogenated form (A) of the transfer substance may well be present in a relatively high concentration, so that exponent c will have a fairly small (positive) value. E and E_o' will not be greatly different, and electrochemical interference with the natural metabolic sequence may then be said to occur at the flavoprotein or at the cytochrome b level. These substances have redox potentials of 0.08v and —0.08v, respectively. It appears to be less likely that transfer agents immediately prior to or following those mentioned, are involved. These would be a pyridine nucleotide (E_o' = 0.32v) and a cytochrome c (E_o' = —0.27v) (9).

The fuel then is constituted by hydrogen ions and electrons, produced in equal numbers. Either both are removed from a flavoprotein, or the hydrogen ions come from a flavoprotein and the electrons from a cytochrome b.

It is of interest to note that in an ordinary culture of *P. meth.* "almost certainly the oxygenation step(s) takes place at the stage prior to the conversion of methane to methanol" (10). In the fuel cell this does not hold true if the foregoing considerations are valid.

The cell emf may be used to estimate the efficiency of the conversion of free energy into electrical energy. Free energy conversion efficiency equals the product of current efficiency (observed current/current equivalent of gas consumed) and voltage efficiency (observed voltage/theoretical voltage). If there is no interelectrode diffusion and no internal electrical leakage, the free energy conversion efficiency will be approximately equal to the voltage efficiency (11).

In the present case hydrogen is oxidized electrochemically, but this hydrogen stems from the methane used by the bacteria. To calculate a realistic free energy conversion efficiency, the voltage efficiency value must be multiplied by $\Delta F(H_2)/\Delta F(CH_4)$.

$$\text{Eff.} = E_{\text{obs.}}/E_{\text{theor.}} \times \Delta F(H_2)/\Delta F(CH_4)$$

$\Delta F(H_2)$ represents the free energy change accompanying the oxidation of a mole of hydrogen; $\Delta F(CH_4)$ indicates the same for methane. As was seen (Fig. 2) under certain conditions an open circuit of about 0.6v was reached.

$$\text{Eff.} = 0.60/1.23 \times (-56.7)/(-195.5) \times 100 = 14.2\%$$

This efficiency value, which is quite low for a fuel cell, may be looked on as the maximum so far attainable.[11] Based on current draw at 0.35v (the maximum power point on curve C in Fig. 2) a more realistic value of 8.2% may be found. The current density at this maximum power point is 2.8 μw/cm^2 (2.6 mw/ft^2). Until a means can be devised to interfere electrochemically at an earlier stage in the oxidative chain, efficiencies substantially in excess of some 14% cannot be expected. It is assumed that each pair of hydrogen atoms originates from one methane molecule or its equivalent derivative. The use of inorganics by the bacteria is ignored in this calculation.

The experimental device used was not designed to yield maximal power. However, even with a design perfect for this purpose, power density has to be low because it is geared to bacterial metabolism. It has not been investigated what fraction of the available energy may be removed from the fuel cell over a longer period of time without harming the culture. As was seen, too long a period of lack of oxygen (no power being taken) causes a decrease in bacterial count. But also, it was often noticed when determining polarization curves, that the cell emf should not be taken below a certain value other than briefly. Doing this would result in extremely slow recuperation of the emf on load decrease and frequent inability to regain or even to approach the original open-circuit value.

The persistence of this polarization cannot be satisfactorily explained by assuming the presence of chemisorbed oxygen on the anode. Such an oxide layer could impede the oxidation of fuel at the anode, but only temporarily. The bacteria normally are capable of yielding hydrogen ions (and electrons), and no reason is apparent why this hydrogen would not after load decrease or removal, sooner or later react with the chemisorbed oxygen. The bacterial inability to overcome this polarization, once a relatively substantial amount of energy has been removed to the external circuit in a short time, must be sought in the bacterial physiology.

The bacteria will grow very slowly if carbon dioxide is absent, and only methane and oxygen are available.[6] If only carbon dioxide and oxygen are present but not methane, growth will not be observed. If all three gases are present, growth is rapid, under comparable conditions. It is then concluded that methane is the original carbon source, and it is surmized that carbon dioxide is needed for the synthesis of bacterial substance via a partial reduction. The energy needed for this reduction is less than that obtained from the complete oxidation of methane. An actively multiplying culture of *P. meth.* keeps on producing carbon dioxide (3), however. This means that more energy is liberated in oxidizing methane than is used in reducing carbon dioxide. The difference, it is further assumed, is available for electrochemical conversion. If these considerations have merit, it may then be said that if energy removal from the bacterial system takes place at a rate substantially higher than the rate at which the energy difference referred to is generated, the bacterial metabolism cannot function normally. If this condition is maintained too long, damage occurs, and the organisms lose the ability to recuperate fully and to re-establish the usual open circuit emf. A "physiological polarization" has set in. Although this phenomenon has not been systematically investigated, there is no doubt that determining the high current density end of the polarization curve is detrimental to the bacterial culture. A bacteriological fuel cell with *P. meth.* in the anode half-cell can neither sustain prolonged periods at open circuit, nor under high current drain. It is expected that this will be true for other obligate aerobes.

Under moderate current drain (3μa/cm^2) no deterioration was observed during a period of over 24 hr.

On the basis of a normal methane consumption rate in an active culture (outside of the fuel cell), an estimate of the order of magnitude of the attainable may be formed.

About 15 ml of methane may be used in 24 hr by 153 ml of suspension, under ordinary culture conditions.[12] If it could be arranged that 14% of the chemical energy of this volume of methane were converted electrochemically in the fuel cell described in 24 hr, a current of 0.75 ma should be expected. In actuality, a current of slightly more than 0.1 ma was recorded (Fig. 2).

There is little doubt that improved cell geometry and the use of coarsely porous electrodes would lead to higher current values. Forced bacterial suspension circulation may again improve these, but the net effect might well be smaller due to auxiliary power consumption. A current density, higher than reported by more than one order of magnitude cannot be expected unless a more advantageous access to the metabolic pathways and thus a higher efficiency becomes available. It may serve a purpose to try to adapt strains of *P. meth.* or other methane oxidizing organisms, to a medium with higher conductivity and higher *p*H than used in this work.

[11] The free energy change and the enthalpy change accompanying the oxidation of methane are virtually equal. All stated free energy efficiency values are therefore also thermal efficiency values.

[12] The volume of the anode half-cell; 1.0 × 10^9 organisms/ml. Meniscus area 25 cm^2; culture was briefly shaken twice a day.

Conclusions

1. The potential measured on a platinum electrode immersed in a de-aerated culture of *Pseudomonas methanica* is near —0.05v. (*P. meth.* uses only methane as its source of carbon).

2. A methane and air fuel cell utilizing *P. meth.* in the anode half-cell has an open-circuit emf of 0.5-0.6v near neutrality.

3. Physical contact between bacteria and anode is necessary for the removal of electrons into the external circuit. The electrochemistry takes place in or on the bacteria, not via an excreted (direct) fuel.

4. If methane is replaced by nitrogen the anode potential is not changed at first. However, the bacteria begin to die out. The ability of a fuel cell, of the type described, to produce electrical energy decreases slowly but continuously after methane is replaced by nitrogen. Methane is the original source of the electrochemically active species.

5. The actual fuel species is hydrogen removed from a flavoprotein, and possibly involving a cytochrome b. Hydroxyl ions are the immediate source of oxygen at the anode.

6. Prolonged periods of open-circuit condition and also a very high current drain should be avoided. Both are detrimental to the bacteria. An obligate aerobe, such as *P. meth.* is best suited to functioning under moderate current drain.

7. The free energy conversion efficiency is maximally 14% if methane is considered to be the indirect fuel. At 0.35v, the maximum power point, this efficiency is 8.2%. These values were calculated after the assumption was made that each pair of hydrogen (fuel) atoms oxidized stems from one molecule of bacterial substrate (methane).

8. Current density, in the presence of an indophenol redox intermediate is of the order of milliamperes per square foot in the simple device used. The normal metabolic rate of *P. meth.* in a culture contains no promise that improved cell geometry will result in a current density improvement greater than about one order of magnitude.

Electrochemical Behavior of TiO_x Solid Solutions in Aqueous HF and HF-HCl Mixtures

M. E. Straumanis, K. C. Chuang,[1] J. L. Ratliff,[2] and W. J. James

Departments of Metallurgical Engineering and of Chemistry, University of Missouri at Rolla, Missouri

ABSTRACT

TiO_x electrodes coupled to platinum exhibited very low hydrogen evolution rates, V_2, during anodic polarization in aqueous hydrofluoric acid as compared with V_1, the open circuit rates. The difference, V_1-V_2, was independent of the HF concentration and of the composition of the TiO_x electrodes within the compositional range 0-5% b.w. oxygen. Therefore, these TiO_x alloys are polarizable to the same extent (polarizability about 81%) by equivalent current densities in hydrofluoric acid. A more pronounced effect (polarizability 82 to 138%) was observed for TiO_x dissolving in HF-HCl mixtures. The difference, V_1-V_2, increased with both the oxygen content of the solid solution electrodes and the HCl concentration.

In the search for the reasons of such a pronounced decrease in hydrogen evolution rates of the electrodes during passage of an anodic current, it was found that the dissolution potential, ϵ', of TiO_x electrodes in HF became more noble with time, with the increase of oxygen content of the alloys, and with the increasing concentration of HCl in the HF-HCl mixtures as electrolytes. The ϵ' became more active with increasing concentration of HF. In all cases, increasing anodic current density shifted ϵ' strongly toward positive values. Interpretations of the various ϵ'-changes are given in terms of protective layer formation. These layers formed during anodic dissolution as well as the potential changes (polarization) cause the pronounced decrease in hydrogen evolution at the anodes. Ti-O solid solutions exhibit, because of thermodynamical reasons, a more noble potential than the pure metal.

The kinetics of dissolution of TiO_x alloys in HF was explored previously (1). Simultaneously it was found that these alloys, containing about 5-10% oxygen by weight, when coupled to platinum, were so strongly polarized that the hydrogen evolution or open circuit rate, V_1, was reduced by 9.5 $mm^3\ cm^{-2}\ min^{-1}\ ma^{-1}$ (2, 3). This indicated TiO_x electrodes to be more strongly polarizable than pure titanium dissolving in HF, for which a reduction of 5.7 $mm^3\ cm^{-2}\ min^{-1}\ ma^{-1}$

10.84	$TiO_{0.305}$	0.1-0.75	1.0	9.3

was found (4). Thus it was decided to study the effect of alloy composition on the rate of anodic dissolution and to try and explain the results by appropriate potential measurement.

Experimental

The TiO_x *samples.*—Ten specimens of the alpha solid solution of oxygen in titanium were prepared ranging in composition from 0.785 to 10.84% b.w. oxygen (see Tables I and II). Calculated amounts of Ti and TiO_2 powders, excepting the samples of smallest oxygen content where titanium hydride was also added to reduce the oxygen content, were mixed and compacted at 50 tsi. Each compact was placed in an alumina crucible and presintered for 1 hr *in vacuo* at 500°C. Titanium hydride in the sample of lowest oxygen content decomposed at this temperature. The samples were then heated at 1350°C for 4 hr. Following furnace cooling, the surface layer of each sample was removed and the specimen finished for accurate measurement of surface area. Trimmings were retained for chemical analysis. Samples were examined optically and by x-rays to determine porosity and homogeneity. Each sample was then mounted in Lucite so as to expose a known surface area to the acid.

Chemical analysis of each sample was made using the hydrogen evolution method (5).

Apparatus and procedure.—The apparatus and procedure used have been thoroughly described previously (4). The dissolution flask of recent construction is shown in Fig. 1.

The cell, TiO_x-Pt, was immersed (external circuit switch open) into the acid (300 ml at 25° ± 0.1°C) the stirring mechanism turned on, and the constant hydrogen evolution rate, V_1, recorded. Then the circuit was closed, the current I in ma registered, and the total rate, V_t, with hydrogen evolving from both electrodes was determined.

The difference Δ in the open and closed circuit rates, $V_1 - V_2$, was calculated from the equation

$$\Delta = V_1 - V_2 = V_1 - V_t + 6.97I \qquad [1]$$

As all the H_2 evolution rates are in $mm^3\ cm^{-2}\ min^{-1}$ at STP, V_2, the closed circuit rate at the TiO_x electrode could be calculated from $V_2 = V_t - 6.97\ I$, where $6.97\ I$ is the faradaic rate equivalent of H_2 evolution in $mm^3\ ma^{-1}\ min^{-1}$ at the Pt cathode (assuming this reaction to be the entire cathodic process there). Thus

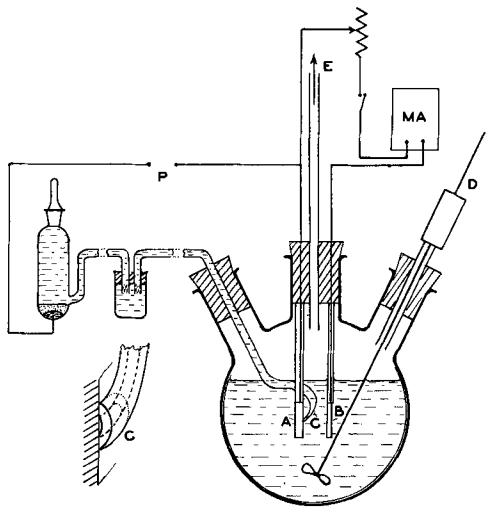

Fig. 1. Apparatus for measurement of anodic potentials during determinations. A, TiO_x electrode mounted in Lucite; B, Pt electrode; C, capillary tube to the salt bridge and calomel electrode; D, stirrer with Hg seal; E, tube to gas buret; P, potentiometer; M.A., milliameter.

Δ (in $mm^3\ cm^{-2}\ min^{-1}$) is the reduction in the rate of hydrogen liberation at titanium caused by the current due to coupling with platinum. In all experiments, a stirring speed of close to 300 rpm was maintained. A simple model illustrating the significance of Δ has been published previously (6).

Dissolution potentials.—The dissolution potentials of four specimens in the absence of an anodic current were determined, measuring the emf of the cell

$$TiO_x/HF, \text{ or } HF + HCl, KCl\ (1N), Hg_2Cl_2/Hg$$

The potential of the anode was reduced to the hydrogen scale. The electrolyte was agitated by a magnetic stirrer at approximately 300 rpm. Potential readings were taken as soon as possible after the electrodes were immersed and then at 5-min intervals.

As Δ is proportional to the anodic current density, the effect of the latter on the potential of the TiO_x electrode was found by coupling it to a platinized Pt cathode at a distance of 10 mm to accommodate the capillary tube, the tip of which was in the TiO_x-acid interface. ϵ' determinations were also carried out during the measurement of the anodic hydrogen evolution rates.

Starting with the highest current density delivered by the cell (no external current was used), each measurement was made 5 min after the change in current density. Three readings were recorded for each current density at 1-min intervals. Two potential readings were taken at each time interval, and the current was adjusted to every other potential reading. A schematic diagram of the apparatus is shown in Fig. 1.

Results

Changes in anodic dissolution rates.—The Δ values (Eq. [1]) were plotted *vs.* current density I. There is a straight line relationship (Eq. [1] and Fig. 2)

$$\Delta = KI \qquad [2]$$

The slope constant K has the units $mm^3ma^{-1}min^{-1}$, meaning that the hydrogen evolution rate of 1 cm^2 of anode surface is reduced by the value of K. Similar straight lines were obtained with the other alloys of Table I, revealing the independence of Δ with regard to both composition and acid concentration.

However, it was found that K did not remain constant when mixtures of HF and HCl were used as solvents. Although the addition of HCl does not alter the diffusion controlled mechanism of dissolution, it

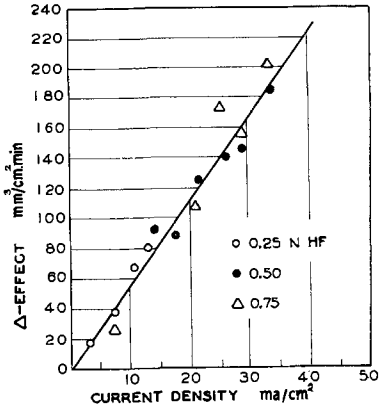

Fig. 2. Effect of current density on Δ for $TiO_{0.102}$ dissolving in HF at 25°C; slope $K = 5.61$.

undoubtedly influences the nature of the metal surface and the composition of the interfacial layers thus altering the K values. Because of this, measurements in HF-HCl mixtures were made, and the results are summarized in Table II.

Although the values obtained with HCl added to the HF, fluctuate to some extent, the increase of K with the increase in HCl concentration and also with the oxygen content can be easily seen. To show the latter increase more clearly, the K values are plotted *vs.* the O/Ti ratio in Fig. 3. At compositions above the dashed line, the total rate of H_2-evolution decreases if an anodic current is applied to the TiO_x electrode. In terms of polarizability, P, (2) for pure Ti, $P = 81.8\%$, and for $TiO_{0.36}$, $P = 138\%$. At the composition of $TiO_{0.07}$, the decrease in H_2-evolution rate at the anode due to the anodic current is exactly balanced by that of the increase at the cathode.

The following phenomena were also observed during these experiments: (*a*) the lower the circuit resistance, the greater were the current fluctuations; severe fluctuations occurred (± 15 ma) at zero ohm box resistance; (*b*) current readings at 0 resistance were less than those at 1 ohm, and sometimes less than 2 ohms box resistance; (c) highest K values were found in most cases from the measurement at 0 ohm box resistance.

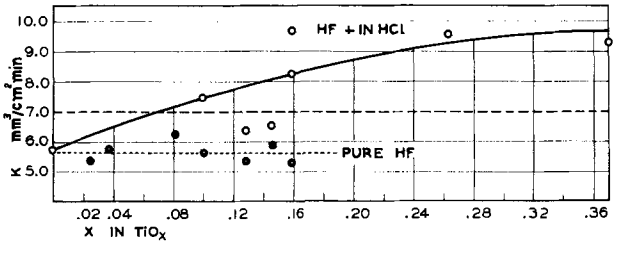

Fig. 3. K values, Eq. [1], obtained in pure HF and in mixtures of HF + HCl (1N) *vs.* x of TiO_x; dashed line: $K = 6.97$ mm³/min at the cathode.

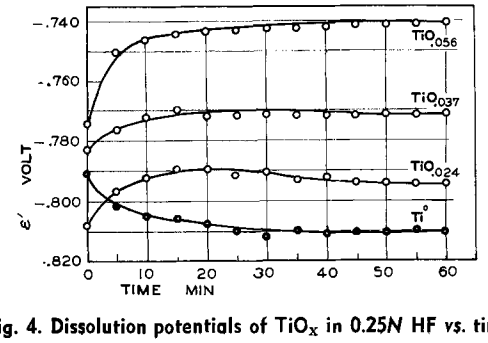

Fig. 4. Dissolution potentials of TiO_x in 0.25N HF *vs.* time

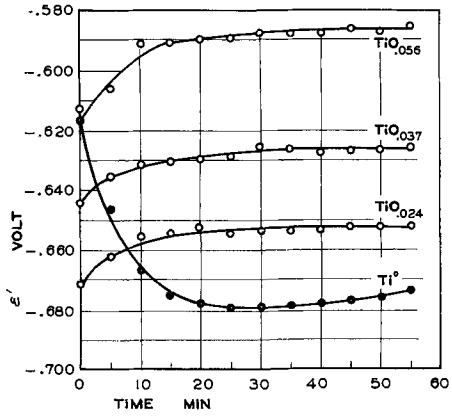

Fig. 5. Dissolution potentials of TiO_x in 0.105N HF-1.0N HCl *vs.* time.

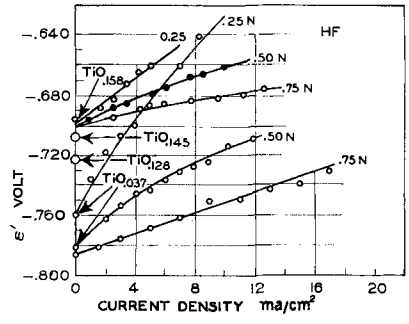

Fig. 6. Effect of current density on the dissolution potential of $TiO_{0.037}$ and $TiO_{0.158}$; ϵ' of $TiO_{0.128}$ and $TiO_{0.145}$ is in between (curves omitted).

Dissolution potentials.—Figure 4 represents the time-potential plots for TiO_x in 0.25N HF and Fig. 5 the same for TiO_x in 0.105N HF-1.0N HCl mixture (hydrogen scale).

From the graphs we note that (*a*) the higher the oxygen content, the more noble is ϵ' for the same acid concentration, (*b*) for the same alloy, ϵ' is more noble in the lower acid concentration, (c) for a given HF concentration, the addition of HCl shifts ϵ' to more noble values, and (*d*) pure Ti becomes less noble with time (except after 30 min in mixed acid).

The effect of current density on ϵ' was studied for $TiO_{0.037}$, $TiO_{0.128}$, $TiO_{0.145}$, and $TiO_{0.158}$ dissolving in 0.25, 0.50, and 0.75N HF. The ϵ' of pure Ti was determined in 0.1, 0.25, 0.50, and 1.0N HF. Plots of ϵ' *vs.* current density are shown in Fig. 6.

It can be seen that an increase in current density is associated with a shift of ϵ' to more noble values. The increase in ϵ' is greater, the lower the acid concentration, and the larger the O-content of the alloy.

Similar data were obtained using a closed cell during the anodic rate measurements (Fig. 1). Apparently, dissolved oxygen in solution had little if any effect on the results.

Discussion and Conclusions

Explanations have to be found (*a*) for the ϵ'-time curves of TiO_x; (*b*) for the ϵ'-current density curves; and (*c*) for the large Δ value in both pure HF and in mixtures of HF and HCl.

It is already known that the potential of pure Ti in aqueous HF becomes more negative with increasing concentration of the acid, approaching a limiting value at about 0.3-0.4N (7). However, in HCl no similar active potential could be observed (8). The most negative value in 10N HCl was —0.37v. Accordingly, it was assumed that HCl, unlike HF, is incapable of dissolving the protective oxide layer on the surface of Ti, which shifts the dissolution potential ϵ' toward

noble values. This hypothesis could now be confirmed using oxygen-containing alloys for potential measurements.

The ϵ'-time curves.—The alpha solid solution has the h.c.p. structure of titanium with interstitial oxygen bonded to a limited number of titanium atoms. Dissolution experiments reveal two Ti associated with three O. Accordingly, the alpha phase may be viewed as a solution of Ti_2O_3 in Ti (5).

The stoichiometry of the dissolution reactions is, for the parts of the alloy containing an excess of Ti, as follows

$$Ti + 3HF = TiF_3 + 1.5H_2 \quad [3]$$

The oxygen present in the metal accumulates on the surface possibly as Ti_2O_3, and since the latter is soluble in HF, it dissolves (chemical reaction)

$$Ti_2O_3 + 6HF = 2TiF_3 + 3H_2O \quad [4]$$

A third equation of verified stoichiometry (5) expressing the dissolution of TiO_x is obtained from [3] and [4]

$$TiO_x + 3HF = TiF_3 + xH_2O + 0.5(3 - 2x)H_2 \quad [5]$$

The electrochemical reaction due to the action of local elements as applied to the Ti in the solid solution is

$$Ti + 3H^+ = Ti^{+3} + 1.5H_2 \quad [6]$$

In the above cases, the Ti ion is, of course, complexed with fluoride ions.

The interpretation of the ϵ'-time curves is as follows: as HF attacks the oxide on the Ti surface, the acid comes in direct contact with the metal, and a very negative potential is measured; since dissolution requires time, the drop in potential occurs along a curve shown in Fig. 4 and 5 for pure Ti. The more concentrated the HF, the faster the drop. As HCl does not dissolve the surface oxide, the ϵ' of Ti remains comparatively noble.

If the metal contains oxygen in solid solution, its dissolution potential will be more noble, the higher the oxygen content (Fig. 4 and 5). This can be explained in terms of the decrease of the free energy of the alloy (9). The further change of the dissolution potential will depend on the solubility of the oxide in the acid. Since in HF the domains rich in Ti° dissolve rapidly according to Eq. [3], the oxide of the alloy slowly accumulates to a certain degree and the excess spalls from the surface and dissolves, Eq. [4]. Thus a nearly constant thickness of film is maintained. Formation of more dense oxide layers, although not perceptible, will cause more noble potentials. Dilution of HF shifts the potentials to more noble values (decrease of oxide layer solubility in HF), as do additions of HCl to the HF. ZrO_x alloys behave similarly (10). Be metal behaves slightly differently (9).

The ϵ'-current density curves.—It is now possible to interpret these curves. When an anodic current is flowing through a TiO_x electrode, at first, the metallic Ti atoms will go into solution according to Eq. [6] and an oxide (probably Ti_2O_3) will accumulate on the surface, causing a rise in anodic potential (Fig. 6). Of course, the potential will also increase as a function of anodic current density.

Since at high concentrations of HF (0.75*N*) the oxide dissolves more rapidly in the acid, the *K* values (Tables I and II) and the inclination of the curves will be lowest. The inclination as well as the starting points of the curves will increase with decreasing HF concentration and increasing concentration of oxygen in the TiO_x electrodes (Fig. 6).

The large Δ values.—A possible explanation is that during self-dissolution reactions [3], [4], and [5] contribute. When anodic current is applied, the rate increase of reaction [6] increases the accumulation of Ti_2O_3 on the electrode surface as Ti° passes into solution. Since reaction rate [4] is slow, the oxide layer reduces the rate of reaction between molecular HF and the domains rich in Ti by increasing the diffusion barrier and probably by covering a portion of the local elements. Thus, as is seen in Fig. 2, the decrease in rate of H_2 evolution at the anode during closed circuit is manifested by the more noble potential of the coupled titanium resulting in a large positive Δ. The constancy of *K* (Fig. 3) in pure HF can then be explained on the basis that variation in oxygen content is insufficient to change the dissolution rate of the oxide layer. In fact, it has been reported that the rate of H_2 evolution from TiO_x alloys is nearly independent of the oxygen content (1).

On the other hand (Table II), the *K* values are much higher in HF-HCl mixtures and dependent upon the HCl concentration and the content of O in Ti. The increase in electrical conductivity as well as the increase in molecular HF concentration speeds up reactions [3] and [6] as shown by the higher dissolution rates (1). Therefore, on application of anodic current, the oxide layer grows more rapidly than in HF alone but the dissolution rate of Ti_2O_3 is affected only slightly. Therefore, at high current densities, the rate of oxide accumulation approaches its dissolution rate. Only a few spots of Ti° remain on the anode and hence, the H_2 development drastically decreases. When the oxide layer exceeds an optimum thickness, breakdown begins and results in current fluctuations. The fact that the current measured at 0 ohm box resistance is less than the current at 1 ohm lends support to the presence of a thick protective film on the electrode surface. The possibility also exists that the oxide film contains less metal than corresponds to the formula thus making it more resistant to acid attack as is the case for NiO (11).

The increase in *K* with increasing HCl concentration is more difficult to explain. In some way, this acid must affect the thickness, porosity, solubility, or adherability of the oxide layer. This is confirmed to some degree by the strong increase in ϵ' with increasing current density (Fig. 6). Therefore, not only the emf of the local circuits causing the self-dissolution of the anode (12) decreases (during the passage of the anodic current), but also the thickness of the oxide layer increases by accumulation (low solubility in HF in presence of HCl), even faster than in pure HF. The consequence is that the drop in rate of anodic hydrogen evolution cannot be compensated any further by the H_2 evolution on the cathode by the current. The *K* constant in such cases becomes larger than 6.97, suggestive of passivation phenomena.

All these experiments show in a direct manner that the presence of oxide layers or even of dissolved oxygen in a metal causes an increase in potential towards noble values with increasing oxygen content.

Electrodeposition of Coherent Deposits of Refractory Metals

I. Niobium

G. W. Mellors and S. Senderoff

Development Department, Parma Research Laboratory, Union Carbide Corporation, Parma, Ohio

ABSTRACT

A general method has been found for the electrodeposition of coherent, dense deposits of refractory metals by electrolysis of molten salts. By dissolving the refractory metal fluoride in mixtures of alkali metal fluorides, one may deposit coherent thick coatings of chromium, hafnium, molybdenum, niobium, tantalum, tungsten, vanadium, and zirconium. Not only do the deposits in all cases have the theoretical density, but in most cases are extremely pure and equal to or better in mechanical properties than electron beam melted material available commercially. While differences exist from metal to metal in the details of the compositions of the electrolyte and the valence state of the refractory metal, the general process can be described in terms of one of the first metals studied, niobium. Niobium metal is electrodeposited from a solution about 10 w/o NbF_5 in a mixture of alkali fluorides at a temperature of about 775°C and a current density of about 50 ma/cm^2 with commercially pure niobium as anode material. Anode and cathode efficiencies are close to 100% and deposits with hardness of 85-100 DPH are obtained regularly. Deposits with densities of 99.8% of theoretical and higher are obtained and the throwing power of the bath is better than that usually associated with commercial nickel plating. There is no major restriction on substrates, since steel, stainless steel, graphite, copper, Hastelloy alloys, and others have been used. Thicknesses up to ¼ in. have been electrodeposited with a surprisingly smooth surface. The microstructures of the deposits are the typical columnar grain structure usually observed in electrodeposits without addition agents and their soundness has been confirmed by mechanical testing. Also, successful electrorefining has been accomplished.

The metals of Group IV-B, V-B, and VI-B have long been a challenge to electrochemists because their compounds cannot be reduced electrolytically to metal in either aqueous or organic media (except for Cr). Alloys of some of them in which the major ingredient is Fe, Ni, or Co have been electrodeposited from aqueous media (1), but all attempts to increase the refractory metal content to that of a useful high temperature alloy have failed. It has been known for many years that compounds of most, if not all, of these metals can be reduced to metal in molten salts but only in the form of powder or dendrites (2, 3, 4). With the exception of Balke's (5) tantalum process, these have not proved to be commercially acceptable because the working up of the mixture of metal crystals and salts which constitutes the cathode product is expensive and results in a comparatively impure product in most cases.

The exceptional cases in which coherent deposits were obtained on a laboratory scale involved highly specific electrolytes. The all-chloride (2) electrolyte from which coherent molybdenum may be deposited is unsuitable for titanium (6). Borate or phosphate melts used successfully with tungsten (3), are completely unsuitable for coherent Ti or Mo deposition. In this series of papers we shall describe a general method for the electrodeposition of coherent deposits of eight of the nine metals of Groups IV-B, V-B, and VI-B (the inapplicability to titanium will be discussed below), their alloys and compounds with each other, and with other elements. In this first paper the electrodeposition of coherent deposits of niobium will be considered.

Despite the considerable body of literature on the electrodeposition of niobium, this metal has not been electrodeposited previously in coherent sheets and its electrodeposition even as powder has been unsuccessful commercially. Niobium as powders or dendrites can be electrodeposited from oxide-fluoride melts (7, 8) but only as a brittle rather impure material (9). Only NbP can be obtained from oxide-phosphate melts (10). Comparatively pure powders have been obtained from mixed chloride-fluoride systems (9, 11) but when they contained oxyfluoride as in one process (12) the powder obtained was impure (9). A process described in two patents (13) claiming the "Method of cladding a base metal with a corrosion resistant metal of the group Ti, Zr, Hf, V, Ta, Nb, Cr, Mo, and W . . . . ." actually produces diffusion alloys of some of these refractory metals with the substrate, and build-up stops when the outer layer of the coating becomes too highly concentrated with respect to the refractory metal. At this point deposition of dendrites of the refractory metal begins.

The solution from which coherent deposits of niobium are electrodeposited in a mixture of the fluorides of niobium and alkali metals, the detailed formulation of which is described below.

Operating Procedures

The mixture of alkali fluorides[1] was melted in a graphite crucible in air in order to expel most of the moisture in the salts and allowed to cool. The slug so obtained was transferred to a nickel crucible, K_2NbF_7[2] was added and the crucible placed in the bottom of the Hastelloy X[3] can be shown in Fig. 1. The Hastelloy can was 4½ in. in diameter and 15 in. from the bottom to the flange. A sheet of niobium for use as anode had

been bent into a cylinder and previously inserted into the crucible in contact with its wall.

An inert atmosphere was maintained within the Hastelloy can by flowing Linde cylinder argon through the system. The bronze gate valve was used as a gas lock during insertion and removal of cathode.

The Hastelloy can containing the crucible with the plating solution was placed in a Hoskins furnace (Type FD104) which was controlled by a chromel-alumel thermocouple and Wheelco controller.

A new electrolyte was electrolyzed for a short while to eliminate residual impurities and to establish the correct valence state for satisfactory deposition.

Plating Range and Effects of Operating Variables

A typical formula for a niobium plating solution is shown in Table I. This corresponds to 10 w/o (weight per cent) NbF_5 dissolved in the ternary eutectic of LiF, NaF, KF. The eutectic composition melts at 454°C. Coherent niobium plates and electroforms of the type shown in Fig. 2 are produced between 700° and 825°C at current densities from 5 to 125 ma/cm². The cell voltage is between 0.1 and 0.25v.

Electrolyte composition.—The composition of the electrolyte is, in general, not critical. Lower concentrations of NbF_5 reduce the limiting current density so that at about 5 w/o the limiting current density is below 20 ma/cm². High concentrations raise the liquidus temperature so that at about 30 w/o CbF_5, the necessary operating temperature (approximately 825°C) approaches a level at which the coherence of the plate begins to deteriorate. The composition of the solvent may be varied widely. The eutectic compositions of KF-LiF and KF-NaF have been used instead of the ternary eutectic with equally good results. A higher operating temperature (minimum 775°C) is required when KF-NaF is used as solvent because of the higher liquidus in this system, but in general the composition of the solvents is largely determined by its effect on the melting point of the solution.

Valence state.—The mean valence[4] of the niobium in the electrolyte must be close to four, the steady state valence in baths operated over long periods of time usually is between 4.1 and 4.2 and under these conditions the cathode and anode current efficiencies are essentially 100% based on the reaction $Nb^{4+} + 4e \rightleftharpoons Nb^0$. This high efficiency is maintained until the mean valency of the bath exceeds about 4.5 when the cathode current efficiency falls rapidly. Although the efficiencies are very irreproducible when the valence of the niobium increases, the values given in Table II, observed in isolated runs, give an indication of the sensitivity of the cathode current efficiency to valence state.

Simple immersion of niobium metal in the solution of KF-LiF-NaF and NbF_5 results in the reaction

$$Nb + 4NbF_5 \xrightarrow[810°C]{KF\text{-}LiF\text{-}NaF} 5NbF_4$$

which proceeds until a mean valence of about 4.5 has been reached. It is for this reason that the anode current efficiency exceeds 100% when the valence of the electrolyte exceeds 4.5. Experiments performed when the bath was stirred either mechanically or by bubbling argon showed that it was possible to reduce the mean valence to about 4.1 (90% as Nb^{IV}) by reaction with Nb metal, but that on standing this reverted to about 4.5. The most desirable lower valency state, that below about 4.3, can only be maintained by electrolysis and the reaction responsible for reduced efficiency of metal deposition at higher valencies is $Nb^{5+} + e^- \rightarrow Nb^{4+}$.

Since not only is the efficiency reduced but impurities in the plate are increased when the valence rises, it is necessary to avoid oxidizing conditions of all types. The valence is increased by oxygen and moisture contamination, and by insufficient anode area. In the latter case, however, anode current densities in excess of 100 ma/cm² did not appreciably oxidize the solution even after long periods of electrolysis. In the case of oxygen or dry air contamination or electrolytic oxidation at the anode, the process may be reversed by correcting the condition and electrolyzing. Hydrolytic

[4] The mean valence is determined by dissolving the frozen electrolyte in the presence of excess $FeCl_3$ and titrating with $K_2Cr_2O_7$ to determine the reducing power. This result is then compared with the value for total Nb obtained by the usual gravimetric procedure.

Table I. Typical formula for niobium plating solution

	w/o	Mole %
LiF	26.2	47.6
NaF	10.5	11.8
KF	47.0	38.2
K_2NBF_7	16.2	2.50

Table II. Sensitivity of cathode current efficiency to valence state

Valence	Cathode current efficiency, %
4.1	100
4.2	98
4.3	85
4.5	35
4.6	~0

oxidation, however, is irreversible. Material balance studies have shown that a solution which has been hydrolytically oxidized has a permanent increase in its valence state. Addition of fresh, pure K_2NbF_7 results in complete reduction of the added Nb^{5+} to Nb^{4+}. The resultant steady state mean valence of the solution is what one would expect on adding the same amount of Nb^{4+} to a bath with Nb content and valence state of the solution prior to the addition.

Temperature.—The lower limit of operation is determined by the liquidus of the plating bath. It has been found that poorer deposits are obtained as one approaches to within 25° or 35° of the liquidus. This may be the result of the increased viscosity and decreased diffusion coefficients combining to reduce the limiting current density to a very small value. The upper limit is established by the gradual loss of coherence of the deposit, proceeding with increasing temperature through a pseudo-plate state to the deposition of powder and dendrites. This probably results from the dissociation of the complex ionic species that is normally reduced at the cathode. This will be discussed below.

Current density.—The lower limit is controlled by the concentration of noble impurities such as iron whose deposition becomes appreciable compared to that of niobium at low current densities. Extremely pure baths have no lower limit to the current density. The upper limit increases with temperature and concentration of Nb^{4+} to the value of the diffusion limited current. Above this current alkali metal is deposited with disastrous effects on the deposits, producing first powders and dendrites, and finally slimes.

Impurities.—The harmful effects of moisture, oxygen, and more noble metal ions have already been indicated. Anions such as oxide, hydroxide, chloride, bromide, and iodide have been found undesirable in varying degrees. The presence of oxide and hydroxide results in hard and brittle metal deposits while the halogen ions reduce the operating range within which coherent deposits are obtainable. Replacement of KF-LiF-NaF with KCl-NaCl as the solvent for NbF_5 results in deposits of dendrites and powders under all conditions. However, as is frequently the case in electrodeposition, trace quantities of some of these impurities have shown addition agent action; for example, by reduction of the grain size of the deposited metal.

In this connection the deposits obtained at 775°C and a cathode current density of 30 ma/cm² of Fig. 3 are of interest. The melt from which these deposits were made was contaminated with moisture or oxygen and it proved impossible to obtain dense coherent deposits from this system, although all efforts were made to "work-in" and electrolytically purify the electrolyte. The five deposits (a to e), run in the indi-

cated order, represent a total electrolysis time of over 100 hr. In Fig. 4a and b are seen the dendrites deposited on the surface of the first two cathodes of Fig. 3. The disappearance of the dendrites and conversion of the deposit to a "pseudo-plate" consisting of coarse-grained niobium powders compacted by some finer grain material is seen in the photomicrographs (Fig. 4c, d, e) of the surfaces of the deposits shown in Fig. 3. In Fig. 4c there still remains some of the salts which fill the large number of voids of the typical compacted powder deposit. The uselessness of this deposit is recognized when one realizes that to obtain metal of even moderate purity it is necessary to pulverize the deposit finely and leach the impurities out of it. Nevertheless, "pseudo-plates" such as this have been the basis of innumerable patents. In Fig. 5d and e, cross sections of the deposits of Fig. 3d and e show that even the initial "plate" is particulate and, in fact, already a powder, though not as easily discernible if the plating is terminated when the deposit is very thin. It is interesting to note that some of the dendrites taken from the Fig. 3a and b cathodes may be single crystals of niobium.

Characteristics of Deposits

Purity.—In Fig. 6 is shown a typical niobium deposit 20 mils thick, on a copper substrate produced from the standard composition electrolyte described above. The usual columnar structure of electrodeposits without addition agents is observed. The good bond to the base metal, the absence of inclusions and grain boundary precipitates is evident. The hardness of the plate is 93 ± 3 DPH and its impurity content is as follows: Fe 0.029%, Cr <0.01, Cu <0.01, Ni 0.022, Ta <0.01, N 0.001, H 0.003, and O 0.039.

Another deposit from an electrolyte using the same concentration of NbF_5 in the NaF-KF eutectic solvent had a DPH hardness value of 70 and an interstitial content as follows: O 0.021%, H 0.0005, N <0.0005, and C ~0.0001. It is not yet established that the indicated change in electrolyte is directly responsible for the difference in purity of the deposit.

Comparatively high oxygen contents have been consistently noted in spite of very low hardness values. It is possible that the most critical contribution to hardness from interstitials comes from the nitrogen and hydrogen content which tend to be very low in the electrodeposited niobium. Plates have been produced with oxygen content as low as 0.007%, but work is still in progress on the reduction of oxygen content to values consistently below 0.01%.

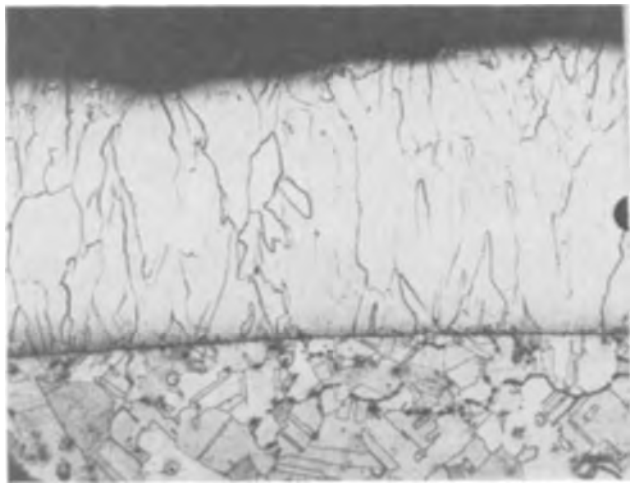

Fig. 6. Cross section of niobium plate on copper (copper at bottom). Magnification approximately 100X.

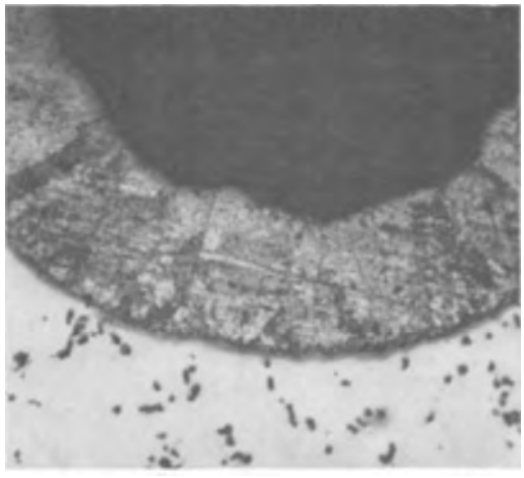

Fig. 7. Cross section of niobium deposit in a recess of a mat of a turbine blade. Magnification approximately 150X.

It is noteworthy that the oxygen content of the cathode in all cases is less than that of the anode. With niobium roundels containing 0.12% oxygen as anode material[5] the plate stabilized at 0.04% oxygen; with roundels containing 0.018% oxygen; 0.006% oxygen was found in the plate, but air contamination of the electrolyte increased the oxygen content of the plate to 0.045% in the next two-day run. Carbon in niobium roundel anodes is also refined out; with 0.037% C in the anodes, the plates stabilized at about 0.0006% C. Nitrogen likewise is reduced from 0.035% in the anodes to 0.0009% in the cathodes in steady state. Iron and nickel impurities in the anodes are concentrated in the cathode and chromium is transferred with only slight refining. With 2% tantalum in the anodes, cathodes are obtained in which tantalum is not detected by emission spectroscopy. The ultimate steady state impurity content of the cathodes must be equal to or less than that of the anode. It is lower in the cases of carbon and oxygen because these elements are apparently lost by precipitation from the melt.

Properties.—The deposits are produced at 100% of the theoretical density of niobium and behave in all matters as arc-melted or electron beam-melted niobium. The columnar structure causes the tensile strength normal to the columns to be a little lower than that of annealed niobium, *i.e.*, 42 to 47 ksi compared to 56 to 57 for electron beam-melted material. The ductility of the plated material is excellent showing an elongation of 25-30% compared to 26-28% for EBM material. The electrodeposited niobium may be directly rolled, a 39 mil plate having been rolled to 9 mils with no intervening annealing.

The resistance ratio[6] has been measured for a representative sample and found to be 30 ± 10. Undoubtedly reduction of the oxygen from the value of 290 ppm in this sample will improve this value.

The properties of electrodeposited niobium as a capacitor were determined by anodizing a plated coating and determining the leakage current at the forming voltage (100v) and at 50v. This was found to be 138 μa and 4.6 μa compared to values for tantalum of the same size and shape of 190 and 50 μa.

Coating properties.—Niobium deposits with exceptional throwing power. While none of the standard boxes or cells were used to measure this property, deposits inside of tubes and in recessed areas of irregular objects showed greater uniformity than is normally encountered with Watts nickel plating. In Fig. 7 is shown a niobium deposit in the recess between the teeth in the root of a turbine blade, where 5.8 mils was deposited in the recess.

Pore-free deposits on reasonably smooth surfaces can be made with certainty in moderate thicknesses. Three to five mil plates on silver are routinely tested by immersion overnight in 1:1 HNO_3. Where the substrate is extremely smooth, as in the case of an optically flat surface of copper, a 1 μin. plate of niobium prevented attack during overnight immersion in nitric acid.

Excellent adhesion is obtained on iron, stainless steel, nickel, copper, and graphite. Uranium and other active metals must be protected before plating with a strike coat, and certain alloys such as Hastelloy C and cupronickel alloys form brittle diffusion layers which impair adhesion. When substrates are cleaned and prepared for plating according to the appropriate ASTM recommended practices with little or no modification, satisfactory adherence is usually obtained.

Discussion

Perhaps the most surprising feature of the study was the importance of essentially pure fluoride melts. While chloride and mixed chloride-fluoride systems have been studied for years and found to produce only dendrites, powders, or sometimes diffusion alloy layers covered with powder, the fluoride melt in the absence of chlorides consistently produces coherent deposits. In the case of zirconium and zirconium diboride the tolerance for chlorides in the electrolyte is very low. Niobium and tantalum have somewhat greater tolerance for chlorides; but even in the latter case, a chloride content in excess of about 10 w/o causes serious deterioration of the coherence of the deposit.

The specific effect of anions can be understood at least qualitatively if one assumes that deposition of coherent deposits from molten salts requires that a complex anion of the correct thermodynamic stability be available in the electrolyte for reduction at the cathode. One must postulate that if the complex anion is insufficiently stable (*i.e.*, has too large a dissociation constant), dendrites and powders will deposit by reduction of the free metal cation available in high concentration from the dissociation of the complex. If on the other hand the complex is too stable (too small a dissociation constant), its reduction potential will reach that of the alkali metals and the codeposition of liquid or gaseous alkali metals with the refractory metal can lead only to particulate cathode deposits or even cathode slimes. In the range of complex compound stability between these two extremes it is probably the direct reduction of the complex anion which produces coherent metal deposits. In the absence of

[5] When niobium roundels were used as anode material they were contained in a nickel screen basket. The nickel was unattacked so long as niobium remained in contact with it.

[6] The ratio of the electrical resistance at 300°K to that at 4.2°K with a sufficiently large magnetic field applied to keep the sample in the normal conducting state.

more quantitative information at present we can only say that the importance of fluoride ion in these systems arises from its effect on the strength of the anionic complexes formed by the transition metals in these molten systems.

There is no doubt that anionic fluoro complexes are more tightly bound than anionic chloro complexes so that since chloro complex systems produce powder deposits with no evidence of alkali metal production, the use of fluoride melts should tend to improve coherence according to the above reasoning.

It was shown in previous publications (15, 16) that the stability of a chloro complex was strongly affected by differing solvent cations. For example, changing from potassium chloride to sodium chloride as solvent for cerium chloride increases the activity of cerium ion by a factor of about 20 (15) and changing sodium to calcium chloride increases the cerium ion activity by an additional factor of about 100. It was also noted (16, 17) that a correlation existed between the quantity Z/r^3 (Z = valence, r = crystal ionic radius) for the solvent cation and strength of the chloro-cerium complex in the system. It appeared that the smaller the "charge density" (Z/r^3) of the solvent cation the stronger was the bonding of the chloro cerium complex. Semiquantitative relationships of this type involving the charge and radius of the ion have been found by many others (18, 19). That this exists in fluoride systems has been shown by surface tension measurements (20, 21) from which it is clear that fluorozirconate complexes are considerably stronger in a KF-LiF solvent than in a NaF-LiF solvent, which again demonstrates that substitution of potassium ion for sodium ion, in this case in a ternary melt, increased the stability of the anionic transition metal complex.

While it is clear that the predominant effect on the strength of the anionic complex is that of the anion, within a given anion series an effect of the solvent cation on the stability of the anion complex can be discerned.

In order to extend this concept to ternary and multicomponent systems it is convenient to define a "molar dissociation coefficient" M, for the solvent such that $M = \sum n_i \frac{Z_i}{r_i^3}$ (where n_i = mole fraction of cation i in the solvent), for the solvent and correlating this with the Z/r^3 for the solute transition metal ion in the valence state from which it is reduced to metal at the cathode. As M for the mixed solvent increases, or Z/r^3 for the transition metal ion decreases, the dissociation of the fluoride complexes of the transition metal ion would increase. Several examples involving Zr, Nb, Ti, and Ta will be used to demonstrate this concept of the solvent effect on coherence of deposits.

Flinak	LiF	NaF	KF	
Mole fraction	0.465	0.115	0.42	
Pauling cation radius	0.60	0.95	1.33	
Z/r^3	4.63	1.17	0.426	$M = \sum n_i \frac{Z_i}{r_i^3} = 2.47$
$n_i \frac{Z_i}{r_i^3}$	2.15	0.135	0.179	

The value of M for the KF (0.50)-LiF (0.50) eutectic is 2.53, that for the NaF-LiF eutectic is 3.246, while for the KF (0.60)-NaF (0.40) eutectic it is 0.724. Thus, the "molar dissociation coefficients" for the lithium-containing solvents have about the same values while that for NaF-KF is much smaller. However, the specific steric effects of Li^+ cannot be ignored. It has been shown (22), for instance, that in the molten alkali nitrates, the Li^+ effectively restricts the rotation of the nitrate ion, while the other alkali ions do not. Therefore, it is likely that the desirable value of the molar dissociation coefficient would be different for Li^+-containing solvents than for others.

It is possible to calculate $\left[\frac{Z}{r^3}\right]$ values for the refractory metal ions, again using the radii of Pauling. No value for Ta^0, Ta^{1+} or Ta^{5+} is given by Pauling, but since $r_{Ta0} \approx r_{Nb0}$ it would be reasonable to assume that the pentavalent ions are approximately the same size. One may further assume that there is little difference, at the most 0.03Å, between the radius of Nb^{4+} and that of Nb^{5+}. No value is given for the radius of Ti^{2+}, but Ti^{4+} is 0.68. Ti^{3+} has been reported as 0.68 ~ 0.69Å, not very different from Ti^{4+}, so it may be reasonable, as a first approximation, to say that Ti^{2+} is of the same order, *i.e.*, 0.67Å. The values of Z/r^3 in Table III are calculated in which Z is the valence state of the ion in the species which is reduced at the cathode.

Table III. Values of Z/r^3

	Valence	Radius	Z/r^3
Ti	2	0.67	6.65
Zr	4	0.80	7.81
Nb	4	0.73	10.3
Ta	5	0.70	14.7

Table IV. Arithmetic product, $M\frac{Z}{r^3}$

	NaF-KF-LiF eutectic	KF-LiF eutectic
Ti	16.4	16.8
Zr	19.3	19.7
Nb	25.4	26.0
Ta	35.9	36.8

Consider now the arithmetic product, $M\frac{Z}{r^3}$, for the four metals and the two-lithium-containing solvents, Table IV.

It is significant that in these two solvents (and also in the NaF-KF solvent) the deposition of coherent zirconium is difficult, though successful, and that of titanium unsuccessful. In the case of zirconium slight departures from the desired composition resulted in the production of potassium vapor probably from a reaction of the type

$$Zr + 4KF \rightarrow ZrF_4 + 4K$$

and in the case of titanium large amounts of potassium vapor were liberated. Since it previously had been established that titanium cannot be deposited coherently at all in the absence of KF, an attempt was made to formulate a ternary solvent for titanium deposition such that $M\frac{Z}{r^3} > 19.3$, that is one with an M of about 2.90. Such a solvent, given that it must contain KF, might be the composition 0.36NaF, 0.54LiF and 0.10KF $\left(\sum n_i \frac{Z_i}{r_i^3} = 2.96\right)$ and experiments carried out in this laboratory indicate that Ti plates of limited thickness may be obtained from this solution provided the KF/TiF_4 ratio is approximately four. The thickness limitation and other difficulties probably caused by the incomplete suppression of potassium deposition, have thus far prevented the application of this general process to titanium deposition as successfully as in the case of the other refractory metals, but the usefulness of this concept of the solvent effect is definitely indicated.

Summary

The electrodeposition of coherent deposits of the refractory metals, Cr, Mo, W, V, Nb, Ta, Zr, Hf and some of their alloys and compounds can be accomplished by electrolysis of molten fluoride systems. In this paper the deposition of niobium from a solution consisting of KF 26.2 w/o, LiF 10.5, NaF 47.0, and K_2NbF_7 16.2 at 775°C, and a current density of 50 ma/cm² has been described. The major variables have proved to be tem-

perature, valence state, and impurity level. The composition is not critical but the presence of a substantially pure fluoride system is required and a tentative explanation based on the maintenance in the solution of a complex anion of appropriate stability for reduction at the cathode to form coherent deposits is advanced. The properties of the deposited niobium are identical in most respects to metallurgically produced metal of equivalent purity and structure. While there are differences among the refractory metals in detail which require specific accommodations in the plating system, niobium may be considered, in general, an example of the group. Additional papers on the other metals are in preparation. These processes are the subjects of patent applications in the United States and foreign countries (23).

Acknowledgments

The authors wish to express their thanks to their colleagues in Union Carbide Corporation for assistance, including B. H. Eckstein, R. B. Puyear, and R. F. Ashton, who performed many of the electrorefining experiments; W. D. Forgeng and J. D. Ruggiero for metallography, W. E. Chambers and I. H. S. Fraser for analyses and R. W. Meyerhoff and F. E. Cariou for the determination of the electrical properties of the deposits. They would also like to acknowledge the interest and encouragement of Dr. R. G. Breckenridge throughout the course of the work.

Electrolytic Capacitor Anodes Derived from Tantalum-Titanium and Niobium-Titanium Alloys

Thaddeus L. Kolski

Pigments Department, Experimental Station, E. I. du Pont de Nemours & Company, Inc., Wilmington, Delaware

ABSTRACT

Porous sheets of tantalum or niobium can be prepared by volatilization of titanium from sheets of tantalum-titanium or niobium-titanium alloys at high temperatures in vacuum. Removal of titanium from the initial alloy results in significantly increased surface area, nearly all of which is available for anodic film formation. Conventional anodization of material prepared in this manner produces anode-dielectric systems of excellent quality. Pore dimensions within the porous anodes are large with respect to anodic film thickness, and formation to 600v can be achieved with only minor loss of effective anode area.

The fundamental relationship determining the capacitance of a parallel plate capacitor is

$$C = 8.85 \times 10^{-14} \epsilon A/d$$

where C is capacitance, f; ϵ, dielectric constant of medium separating plates; A, plate area, cm^2; d, plate separation, cm. In an electrolytic capacitor, the dielectric separating the "plates" is the oxide layer formed on the anode by electrolytic oxidation; therefore d refers to the thickness of this layer and ϵ to its dielectric constant. For a given anode material and set of formation conditions, which determine the nature and thickness of the anodic layer, and assuming perfect contiguity with the counterelectrode, the remaining variable which can influence capacitance is the available surface area of the anodized substrate. In the case of a foil anode, available surface area may be increased by any process which increases the ratio of true area to apparent geometric area, that is, increases the surface enhancement factor. A widely used method of achieving this effect is electrochemical etching. In order to maximize the benefits accruing from increased surface area, however, it is important that the dimensional magnitude of the irregularities be large with respect to thickness of the anodic oxide film to be formed thereon in order that effective area of

the counterelectrode-oxide layer interface conform closely with that of the anode-oxide layer interface.

In addition to high capacitance, good anodic oxide quality is imperative in electrolytic capacitors to be used in applications requiring reliability. By the term "anodic oxide quality," reference is directed toward desirable characteristics such as good barrier properties, resistance to nucleation and crystallization under conditions of elevated temperature or field stress, resistance to damage during counterelectrode application (as in solid electrolyte devices) or other fabrication steps, and resistance to any change over long time periods under conditions of both use and disuse. Obviously, anodic oxide quality cannot be fully assessed without fabrication of statistically significant quantities of finished capacitors and subjecting these to appropriate tests. However, "wet-cell tests" involving metal substrates covered by anodic oxide layers are helpful in providing information which may be used to estimate the potential value of anode materials.

It is the purpose of this paper to describe the properties of two new electrolytic capacitor anode materials which are characterized by high surface enhancement factors and, on the basis of initial evaluation, excellent electrical quality of surface oxide layers which are formed by the process of anodization. These materials are superficially tantalum and niobium; therefore the high dielectric constants and low thicknesses of anodically formed layers of the corresponding oxides are utilized in application of the materials as capacitor anodes.

Preparation and Composition

The preparation of the new materials involves the high-temperature vacuum heating of tantalum-titanium and niobium-titanium binary alloys. Under these conditions, prolific pore formation occurs in the metal bodies as a result of titanium volatilization, with the extensive creation of new surface. Figures 1 and 2 are photomicrographs showing polished sections of typical products prepared in this manner. The total area generated is dependent on several parameters involving the initial alloy body and conditions of vacuum heating; this will be discussed in subsequent publications. The present paper is concerned only with properties of the porous valve metal resulting from this process. It should be kept in mind, however, that although excellent reproducibility of product characteristics is obtained under constant preparation conditions, the nature of the resultant porous body may be varied as a result of changing preparation parameters.

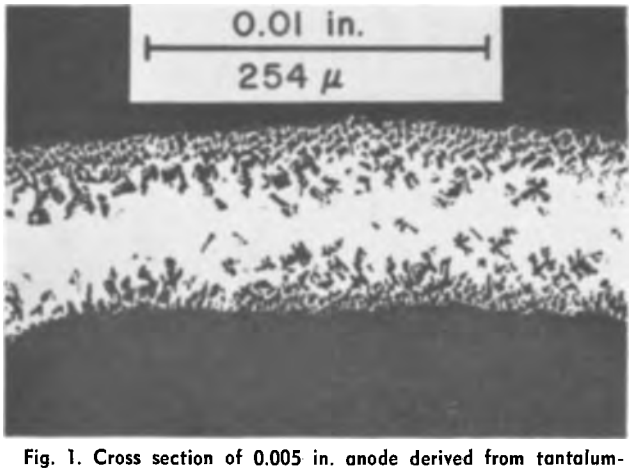

Fig. 1. Cross section of 0.005 in. anode derived from tantalum-titanium alloy sheet. Surface enhancement ratio 14.2.

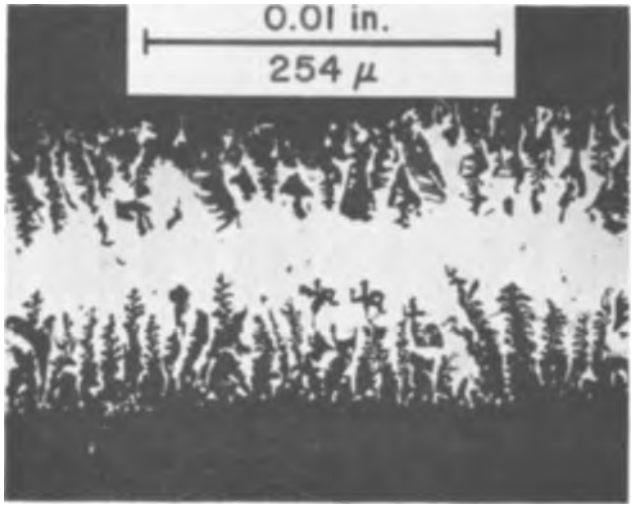

Fig. 2. Cross section of 0.009 in. anode derived from niobium-titanium alloy sheet. Surface enhancement ratio 17.6.

Most of the original titanium content is removed from the alloy as a result of the volatilization process. It would be expected that significant amounts of residual titanium are to be found only deep within the nonporous portion of the anode, *i.e.*, that the anode surface after the vacuum heating step may be considered, to a first approximation, essentially tantalum or niobium. This was confirmed by comparison of x-ray fluorescence from the surfaces of a sheet specimen of niobium-titanium alloy and the product obtained by heating the same material in vacuum. An x-ray probe of sufficient energy to penetrate to an effective depth of about 5μ produced radiation completely devoid of titanium peaks from the vacuum heated specimen; the unheated specimen was characterized by very strong titanium peaks. The limit of titanium detection in this case was below 0.1%.

To characterize further the surface of anodes prepared by vacuum heating tantalum-titanium sheet, the anodic oxide layers formed to different voltages on this substrate were isolated and analyzed by emission spectrography. General aspects of anodization, which in this case was carried out in aqueous 0.01% propionic acid, have been described previously (1). Anodic film isolation was effected by leaching away metal from the anodized specimens with a solution of 10% (by volume) bromine in anhydrous methanol. As shown in column 6 of Table IV, titanium values in the isolated anodic films are independent of film thickness for anodized layers formed from 50 to 500v at room temperature. These analyses confirm that titanium concentration in the superficial regions of alloy-derived tantalum anodes prepared in this manner is no greater than about 0.07% (by weight) to a depth of at least 0.36μ, which is the approximate tantalum thickness required to generate a 500v anodic layer (2).

Surface Enhancement

The highly developed surface of the alloy-derived anodes, as evident from optical microscopy, is manifest in high capacitance values after formation and testing in suitable electrolyte systems. For example, these materials may be anodized conveniently in aqueous 0.01% H_3PO_4 at 25°C and tested in aqueous 10% H_3PO_4 at 25°C using the methods described earlier (1). Formation to 200v with a 1-hr current decay period results in wet-cell test capacitance values such as those shown in Tables I and II. The capacitance per area values are based on apparent, or geometric, area. Upon comparison with the capacitance values obtained using 0.0005 in. foil specimens of tantalum and niobium anodized under identical conditions, it is evident that the true area of the alloy-derived anodes which is effectively available for anodic oxide film formation to 200v is much greater than the geometric area. Other things being equal, the surface enhancement ratio increases with increasing thickness of the anode, because of increasing pore depth.

The high capacitance level of the alloy-derived anodes is entirely accounted for by available surface area, as demonstrated by comparison of surface area values deduced from capacitance measurements after anodization, with those from determination of absolute

surface area by means of BET krypton sorption. To illustrate, six specimens were prepared from niobium-titanium alloy sheet by vacuum heating. The value for charge per unit apparent area for two specimens, after formation to 100 and 200v in aqueous 0.01% H_3PO_4, was 1220 μfv/in.^{2}; this value corresponds to a surface enhancement ratio of 12.2 as compared to 100 μfv/in.^{2} obtained with plain niobium foil vacuum heated and formed under identical conditions. Measurement of absolute surface area of the four unanodized samples of the same alloy-derived material resulted in the data summarized in Table III, from which it is clear that the true area of these specimens is an average of 14.2 times the geometric area. A somewhat higher value is to be expected from gas adsorption measurements than from capacitance determinations, since a portion of the surface reached by krypton atoms is inaccessible to anodizing electrolyte. That some 85% of the anode surface area is reproduced by a 200-v anodic layer, which is about 0.44μ thick (3, 4, 1), attests to the high degree of smoothness in the pore walls and absence of very small pores in these anodes. Further discussion of pore sizes is found below.

Much of the over-all volume of the alloy-derived anodes is essentially a network of pores, resulting in excellent anode material utilization values. It is evident from Tables I and II that gravimetric capacitance efficiencies of the alloy-derived anodes are from 2 to 2½ times those of 0.0005 in. foil specimens of pure tantalum or niobium. The alloy-derived anodes are more efficient on a weight basis than sintered compacts made of tantalum and niobium powders, as well. The advantage is more striking in the case of niobium than tantalum; this is related to the lower melting point of niobium and the excessive surface loss which occurs on sintering niobium powder compacts at temperatures sufficiently high to produce pellets which display low leakage current on anodization (1). Volumetric capacitance efficiencies of alloy-derived anodes also are higher than those of anodes prepared from plain 0.0005 in. foil or sintered powder compacts of pure tantalum or niobium, as based on physical dimensions of anode specimens. However, the volumetric capacitance efficiencies can be misleading unless interpretation in terms of anode configuration for insertion into a specific case size is possible.

Surface enhancement ratio*	14.6	13.8	14.6	14.0

* Compare with 12.2 from capacitance measurements.

Capacitance data listed in Tables I and II are close to the optimum values which have been achieved for anodes of the respective thicknesses. These data were determined early in this research, using small specimens (approx. 1 x ½ in.) which were vacuum heated only a few at one time. Later during the investigation it was found that the simultaneous vacuum heating of many and/or larger specimens in a single batch resulted in anodes which displayed considerably lower d-c leakage levels after formation than the values shown in Tables I and II. With large furnace loads, d-c leakage values as low or lower than those obtained with plain foil vacuum annealed at 2100°C are readily attained. This fact indicates that an important role might be played by titanium vapor which evolves from the alloy sheet under heat-treatment. There seems good reason to speculate that presence of titanium vapor in the furnace hot zone serves to getter the residual atmosphere, and thus decrease or prevent the absorption and accumulation of interstitial impurities in the titanium-containing alloy undergoing vacuum heating.

Conservation of Effective Anode Area to High Formation Voltages

Visual examination of sectioned specimens of the alloy-derived anodes indicates that the pores are smooth-walled and predominantly greater than 5μ in diameter. Since this dimension is large as compared to the thickness of anodic layers, reported to be about 15 Å/v for tantalum (2, 5) and 22 Å/v for niobium (3, 4, 1) in the case of films formed at room temper-

ature, little effective anode surface loss should occur as a result of anodic film growth. This is verified experimentally and is evident from the nearly constant charge values shown in Table IV for anodes derived from tantalum-titanium sheet which were formed to voltages from 50 to 500v.

A plot of reciprocal capacitance *vs.* formation voltage is linear if effective anode surface is constant. Such a plot for anodes derived from niobium-titanium sheet is shown in Fig. 3. Formation in this case was carried out at 25°C in aqueous 0.01% H_3PO_4. The fact that essentially no deviation from linearity is evident up to 500v formation constitutes a demonstration that effective anode surface is not detectably dependent on anodic oxide thickness up to this level, assuming that dielectric constant and field strength within the anodic layer also are independent of thickness.

A definite limit on the thickness of anodic layers which may be formed in dilute aqueous acid electrolytes is imposed by scintillation phenomena which occur at potentials near 500v at room temperature. The use of certain essentially nonaqueous electrolytes allows formation to potentials well in excess of 500v. An electrolyte which has proven particularly suitable for anodization of alloy-derived tantalum is made by dissolving 125g boric acid in a solvent consisting of 250g ethylene glycol and 250g diethylene glycol, and adding concentrated ammonium hydroxide dropwise to a resistivity of 2000 ohm-cm at 125°C. In the following discussion, this electrolyte is referred to as EDBA-2000. Formation may be carried out conveniently at temperatures considerably above room temperature in this electrolyte, thus serving to form thicker oxide layers as a result of the increased temperature as well as higher potentials.

Alloy-derived tantalum anodes surface-enhanced 30.5-fold were used to study the effect of forming to high voltages in the EDBA-2000 electrolyte. These anodes contain more internal surface than those which

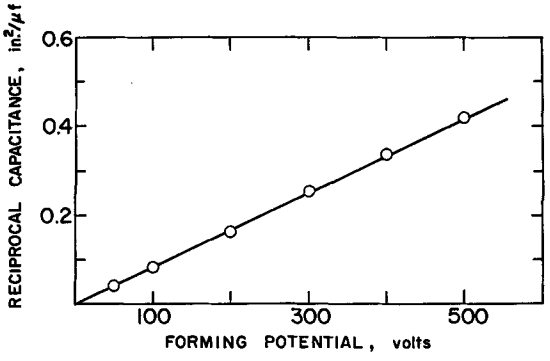

Fig. 3. Reciprocal capacitance vs. formation voltage for 0.0055 in. anodes derived from niobium-titanium alloy sheet. Surface enhancement ratio 12.2.

Fig. 4. Cross section of 0.014 in. anode derived from tantalum-titanium alloy sheet. Surface enhancement ratio 30.5.

are characterized by Table IV and Fig. 3 because of greater anode thickness, 0.014 in., and consequently deeper pores. The specimen shown in Fig. 4 has been formed to 600v at 125°C in EDBA-2000, and the anodic oxide layer, estimated to be 1.2μ in thickness, is visible in the photomicrograph. It appears that some of the smaller pores may be filled with oxide, but the photomicrograph is deceptive because any significant offsetting of the plane of section from the center of a pore gives the illusion of a filled or partially filled pore. Further, the apparent thickening of oxide layer in certain regions is due to large deviations from normality in the angle between the plane of section and the surface of a pore wall.

To measure quantitatively the extent of surface loss at high formation voltages in EDBA-2000 at 125°C, and to compare the capacitance of anodes formed in EDBA-2000 at 125°C and in aqueous 0.01% propionic acid at 25°C, specimens of the 0.014 in. thick, 30.5-fold surface-enhanced alloy-derived tantalum were formed to various voltages in both electrolytes. A summary of capacitance and dissipation factor values for these specimens, measured at 25°C in 10% H_3PO_4, is tabulated in Table V. The decrease in CV product with increasing formation voltage reflects the loss in effective anode area at high formation voltages. The

loss is moderate. Formation to 500v in aqueous 0.01% propionic acid at 25°C results in an effective loss of about 15% of the anode area available at formation up to 200v. Similarly, formation to 600v in EDBA-2000 at 125°C results in an effective anode area about 22% lower than that obtained as a result of formation up to 200v.

Constancy of the product of capacitance, formation voltage, and formation temperature (CVT product) has been demonstrated by Torrisi in the case of plain tantalum foil (6). Comparison of the CVT products shown in Table V for the 30.5-fold surface-enhanced alloy-derived tantalum specimens formed under the two different conditions shows that at low formation voltages, corresponding to negligible area loss due to oxide film growth, both formation conditions yield values near 800,000 μfv°K/in.^{2}. Thus the CVT product appears to be a constant, within experimental error, for the alloy-derived tantalum anodes as well. Plots of reciprocal capacitance as a function of formation voltage are exactly superimposable, as shown in Fig. 5, if formation voltages under the two temperature conditions are reduced to equivalent film thicknesses by the use of the CVT relation. Constancy of the CVT product strongly indicates that the dielectric constant of the anodic layer formed at 125°C in EDBA-2000 is the same as that formed at 25°C in aqueous 0.01% propionic acid.

The slight concavity of the plot in Fig. 5 is due, of course, to filling in of minor pores with anodic oxide, and the 22% area loss as a result of formation to 600v at 125°C may be considered slight indeed in view of the fact that the resultant film thickness is equivalent to that of an hypothetical room temperature film formed to 802v. Even this moderate loss would be lowered in the case of thinner alloy-derived tantalum anodes or those prepared under conditions such that the lower pore size limit in the final product be larger.

The conservation of anode area to high forming voltages shown by the alloy-derived materials is in marked contrast to the case of electrochemically etched foils. The latter materials are characterized by a surface enhancement factor, commonly referred to as the etch ratio, which decreases rapidly with increasing formation voltage. For this reason, as well as the excellent quality of the anodic film, the alloy derivatives are of particular interest for application in high voltage devices.

The large pore size characteristic of these anodes is a major factor contributing to the low dissipation factors shown upon formation and testing in a suitable electrolyte. Typical values are listed in Tables I and II. Access to all anodized internal surfaces through low resistance paths results in a low equivalent series resistance component of the total electrical loss.

High Electrical Quality of Anodic Oxide Layer

Choice of a criterion by which anodic oxide quality may be assessed is not obvious. For example, measurement of d-c leakage at a given voltage level is open to question because the voltage level is in itself arbitrary, and also because the leakage value obtained may be influenced by anodization kinetics during initial film formation if an electrolyte of high resistivity is used. To avoid scintillation at relatively low voltages, it is not unusual to employ electrolytes of high resistivity for investigations at high voltages. Also, spuriously high d-c leakage values may result from capillary rise of test electrolyte past the limit of anodized area on the test specimen. Similarly, mere formation to high voltages is not a definitive test because many substances can be formed to levels well beyond those at which irreparable damage to the anodic layer is done in the form of field-induced crystallization.

Because of these objections, an attempt has been made to design an evaluation procedure which yields information concerning the barrier oxide film quality at several voltages up to the ultimate formation voltage. The technique used involves slow formation at constant current density with intermittent pauses at various voltage levels to note current decay at derated voltages. In effect this corresponds to the measurement of leakage current at many voltages over a wide range, although without holding time at formation voltage. The advantage of this technique lies in permitting definition of a formation level above which an increased rate of change of terminal current during the decay period with formation voltage is observed. Such an increase is interpreted as corresponding to a degradative change in the nature of the barrier oxide film, or what is often called "incipient crystallization." Using an abrupt change in the decay current-formation voltage relationship, rather than the absolute magnitude of the decay current, as the significant response of the quality test reduces objections centered on capillary rise of electrolyte past the anodized area of the specimen as well as slow anodization rate. Interference from the latter factor is further decreased by employing low current densities in the test.

The quality tests were conducted using a current density of 1 ma/in.^{2}, anode area being taken as the total area exposed to anodizing electrolyte. Area was deduced from capacitance measurements on similarly prepared samples, after 200-v formation. Except in the case of the 0.014 in. anodes, no lead wires were attached to the specimens used in these experiments; connection to the power supply circuit was made directly through a narrow tab of the anode which intersected the electrolyte level. Current decay readings were taken at 50-v or shorter intervals. On reaching

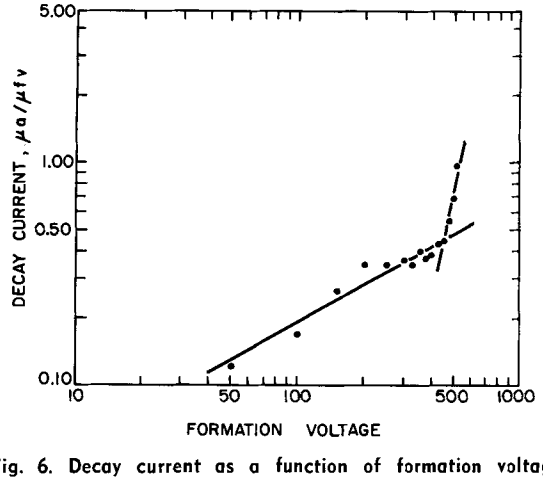

Fig. 6. Decay current as a function of formation voltage in aqueous 0.01% H_3PO_4 at 25°C for 0.006 in. anodes derived from niobium-titanium alloy sheet. Surface enhancement ratio 13.5. Scintillation at 510v.

the formation voltage at which a value for decay current was desired, the potential was dropped back to 70% of forming voltage over a period of 1 min and current allowed to decay at this potential for 3 min. The value used as the decay current was that after 3 min at 70% of forming voltage, or after a total of 4 min under derated voltage. Voltage was then increased back to formation voltage over the period of 1 min, and formation at 1 ma/in.^{2} was resumed. Testing was extended to the highest voltage attainable before anodization rate became seriously slowed or severe scintillation limited higher formation. The values for observed scintillation voltages which are reported in the subsequent discussion are those at which visible sparking is first seen in a darkened room. Scintillation voltages defined in this way were reproducible within a range of 5-10v.

A logarithmic plot of decay current as a function of formation voltage in aqueous 0.01% H_3PO_4 (2950 ohm-cm) at 25°C is shown in Fig. 6, for anodes derived from niobium-titanium alloy sheet. The break in the curve indicates that anodic oxide film degradation sets in at about 450v under these formation conditions. Visible scintillation is observed slightly above 500v.

A similar test in aqueous 0.01% propionic acid (approximately 19,000 ohm-cm) at 25°C for anodes derived from tantalum-titanium alloy sheet is summarized in Fig. 7. Remarkably, at no voltage level does the plot show an upward trend; decay current decreases with increasing voltage past 500v, at which point visible scintillation is first noticeable, to 565v, a level at which scintillation is so extensive that further potential increase across the anodization cell is not possible without increasing current density. The high decay current values at low voltages shown in Fig. 7 are a result of the high electrolyte resistivity. A significant voltage drop across the electrolyte results in a lag in anodic film growth and continued film growth occurs at derated voltages. The relative effect is much greater at low voltages than high voltages, in agreement with the downward trend of the plot. With electrolytes of higher conductivity, delay of anodic film growth is greatly lessened. For example, using aqueous 1% propionic acid electrolyte (1950 ohm-cm) at 25°C, decay current is independent of formation voltage up to the scintillation potential (500v), as shown in Fig. 8. The higher conductivity of this electrolyte, however, allows greater current flow in the event of a triggering mechanism at the oxide-electrolyte interface, and degenerative changes in the anodic film occur shortly beyond the scintillation voltage.

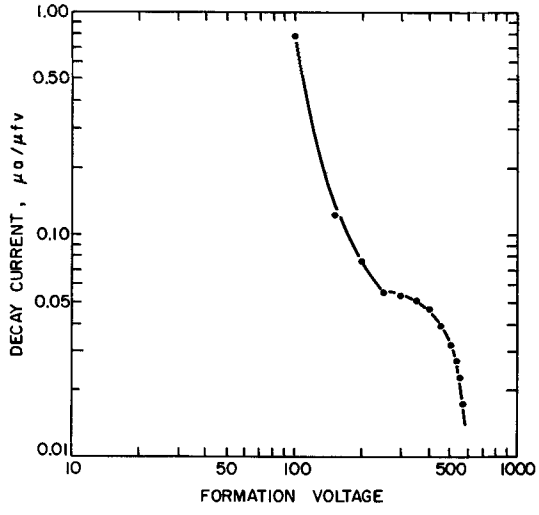

Fig. 7. Decay current as a function of formation voltage in aqueous 0.01% propionic acid at 25°C for 0.005 in. anodes derived from tantalum-titanium alloy sheet. Surface enhancement ratio 14.2. Scintillation at 500v.

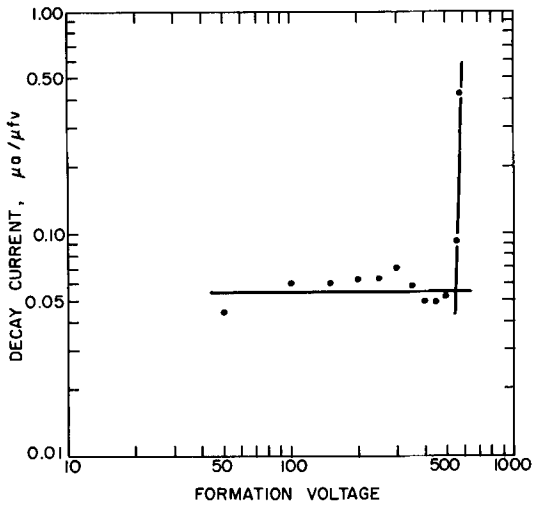

Fig. 8. Decay current as a function of formation voltage in aqueous 1% propionic acid at 25°C for 0.005 in. anodes derived from tantalum-titanium alloy sheet. Surface enhancement ratio 14.2. Scintillation at 500v.

Because the theoretical implications of the anodic oxide quality test, as described above, are subject to further clarification, it is important to use the same test with anodes of well-characterized properties; when used on a comparative basis, the quality test is shown to be significant as a purely operational tool. For comparison, a logarithmic plot of decay current at derated voltage *vs.* formation voltage in aqueous 0.01% propionic acid at 25°C for 0.0005 in. commercial tantalum foil ("high reliability" capacitor grade) is shown in Fig. 9. Formation of foil which is cleaned only by washing and degreasing can be carried to 440v at which level scintillation occurs, but evidence for incipient crystallization as defined above, appears at about 250v. A vacuum purification-anneal heat treatment of such foil at 2100°C for 2 hr, however, results in markedly improved anodization behavior. After such treatment, formation can be continued to 480v without evidence of incipient crystallization.

The excellent quality of the anodic layer formed on an alloy-derived porous tantalum body in EDBA-2000 at 125°C, using as a criterion the change in decay current at 70% of forming voltage as a function of forming voltage, is demonstrated by the logarithmic current-voltage relationship shown in Fig. 10. These data were observed during formation of a 0.014 in. thick, 30.5-fold surface-enhanced anode. Visible scintillation occurs at 640v and evidence of anodic film

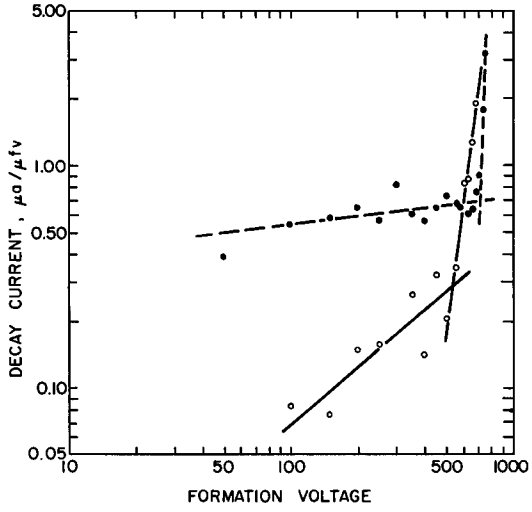

Fig. 11. Decay current as a function of formation voltage in EDBA-2000 at 125°C for 0.0005 in. plain tantalum foil. ● - - - ●, 2100°C for 2 hr, scintillation at 650v; ○ — ○, washed only, scintillation at 625v.

degradation at about 680v is indicated by the sharp increase in decay current. The decreasing tendency of decay current with increasing formation voltage is similar to that observed in Fig. 7 for anodization in aqueous 0.01% propionic acid. From the similarity in electrolyte resistivities, it might be expected that formation in EDBA-2000 would yield a decay current-voltage relationship more like that observed with aqueous 1% propionic acid, as shown in Fig. 8. However, the deeper pores in the 0.014 in. thick specimen contribute significantly to a lag in anodic film growth, the effect of which is pronounced at low formation voltages. In this respect, anodes derived from thick alloy sheet resemble conventional porous pellets made from pure metal powder compacts.

For comparison, the evaluation of 0.0005 in. commercial tantalum foil in EDBA-2000 at 125°C is summarized by the logarithmic plots of decay current *vs.* formation voltage for vacuum heated and unheated foil, shown in Fig. 11. Quality degradation begins near 500v for the unheated foil and near 680v for the foil heated in vacuum at 2100°C for 2 hr. The high decay current levels observed on vacuum heated tantalum foil prior to reaching voltage levels at which oxide degradation occurs are caused by enhanced wetting of the specimen tab by the electrolyte, with the result that oxidation is not limited at a sharp boundary just above the electrolyte-air interface during the test. For an unknown reason, the unheated specimen does not exhibit the same wetting characteristics, as indicated by the generally lower decay current levels below the breakdown voltage.

Another method of comparing the anodic characteristics of the alloy-derived tantalum with those of commercial tantalum foil is to measure current decay as a function of time at some arbitrary voltage level. Current decay curves at 600v in EDBA-2000 at 125°C after slow formation to this voltage at 1 ma/in.^{2} (based on absolute anode area) are shown in Fig. 12. The alloy-derived anode in this case is the same high surface enhancement material as that used in the quality test summarized in Fig. 10. In spite of the higher surface area of the alloy-derived anode, its anodic layer heals more rapidly at 600v in EDBA-2000 at 125°C, as compared to commercial tantalum foil. Both the alloy-derived tantalum material and vacuum heated commercial tantalum foil exhibit decay currents which still diminish after 6 hr, whereas the commercial tantalum foil not heated in vacuum shows a reversal after about 2½ hr.

Resistivity of EDBA-2000 electrolyte increases from 2000 to 2350 ohm-cm over a 6-hr period at 125°C,

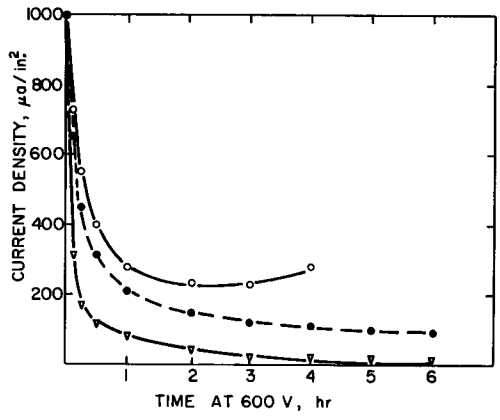

Fig. 12. Current decay at 600v in EDBA-2000 at 125°C for 0.0005 in. plain tantalum foil and for 0.014 in. anodes derived from tantalum-titanium alloy sheet, surface enhancement ratio 30.5. ○ — ○, Ta foil, washed only; ● — ●, Ta foil, 2100°C for 2 hr; ▽ — ▽, alloy-derived Ta anode.

primarily as a result of ammonia evaporation. Although this has the effect of depressing decay current slightly during anodic evaluation in this electrolyte, intercomparison of alloy-derived tantalum and commercial tantalum foil is justified because the test was carried out in the same manner for each sample.

Among the factors leading to the good anodic quality apparent in the alloy-derived anodes, several would appear to be of primary importance. The possible effect of gettering the furnace hot zone with evolved titanium already has been mentioned. Certainly the fact that essentially all of the anode surface is newly created during the vacuum heating step, and in no way mechanically handled prior to anodization, represents a degree of surface cleanliness unmatched in conventional foil or sintered powder compacts. During the vacuum heating step, which is carried out at temperatures near the melting point of the initial alloy, diffusion of impurities is more rapid than in pure tantalum or niobium; this can be expected to result in a more efficient operation of the various physical and chemical processes which serve to produce and remove volatile impurities. Removal of the volatile impurities is further facilitated by the *in situ* development of pores in the metal body. Not to be disregarded is the surface smoothness inside the pores formed during titanium volatilization. The smooth contours presented by the inner pore walls are conducive to the formation of

anodic layers of uniform thickness and freedom from defects induced by sharp field gradients.

Conclusions

The new forms of porous tantalum and niobium, which result from high-temperature vacuum removal of titanium from binary alloys of tantalum and niobium with titanium, appear highly suitable for use as electrolytic capacitor anode materials. Two outstanding advantages inherent in these materials are high surface enhancement ratios which are diminished only slightly by formation to voltages up to 600v and excellent anodic oxide quality. These characteristics indicate that anodes made from the alloy-derived materials will be especially useful for application in high voltage capacitors.

Publications to follow describe capacitors (7) made using anodes such as those described above.

Acknowledgment

The author wishes to express grateful appreciation to Mr. Charles E. Perry, who performed much of the experimental work, to Mr. Karl Moeglich for valuable discussion of anodic oxide quality which led to the quality evaluation test employed in this investigation, and to Dr. Kurt F. J. Heinrich for the surface x-ray fluorescence examination.

Manuscript received May 21, 1964. This paper was presented at the Toronto Meeting, May 3-7, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

Dielectric Films in Titanium Electrolytic Capacitors

Akio Yamashita and Hiroshi Hagiwara

Research Laboratory, Industrial Apparatus Division,
Matsushita Electric Industrial Company, Ltd., Toyonaka, Osaka, Japan

ABSTRACT

The effects of pretreatment and various formation parameters on the properties of anodic films produced on titanium were investigated. It was found that the anodic film on titanium could be improved by a pretreatment of the titanium in nitric acid. Titanium oxide films were formed anodically in a molten salt electrolyte at constant potential, and the leakage current at room temperature showed a v-type curve for the forming time. Physical and electrical properties of the anodic films to obtain minimum leakage current are discussed. The thickness of anodic film was determined and a dielectric constant of about 107 was obtained.

Aluminum and tantalum are commonly used as the base metals for electrolytic capacitors (1, 2). In the case of titanium, relatively little conclusive information is available, and it is still difficult to form a suitable dielectric film for electrolytic capacitors.

It was the purpose of this investigation to study the effects of pretreatment of the anode and various formation parameters on the character of the anodic films produced. The formation parameters include the molten salt electrolyte composition, forming time, potential, and temperature.

In the study of anodic films on metals, factors of significance in evaluation of films include thickness, porosity, density, and electrical properties. Films prepared in this study were evaluated through measurements of thickness, dielectric constant, and electrical properties.

Many studies on the anodic formation of certain metals have been reported. These include common metals such as tantalum. Titanium, about which little is known with respect to its anodizing characteristics, might be expected to have a high capacitance per unit area, if the oxide film formed is the rutile modification, with a bulk dielectric constant on the order of 100. In most cases, however, the oxide films formed have been neither a pure rutile structure nor insulating in nature. Most researchers (3-5) employed various acids or aqueous solutions of common salts as formation electrolytes. Sibert (3) employed various acid electrolytes. Of the basic electrolytes he tried, the phosphate-based materials gave by far the best results. Huber and Bloxson (4) employed a mixed aqueous solution of weak organic acid and alcohol. McLean *et al.* (5) utilized hydrochloric-nitric-sulfuric acid baths for polishing the surface followed by anodizing in a buffered borate solution. They could not obtain, however, satisfactorily low leakage currents for titanium oxide dielectrics anodically formed in these electrolytes.

The leakage current of an electrolytic capacitor presumably depends on the presence of impurities in titanium (1, 6, 7). Major impurities in commercial titanium are iron and oxygen. It is known that the presence of iron generally causes an increase in the leakage current. Oxygen will be in the form of titanium oxide.

Experimental

Preparation of specimens.—Specimens of 99.7% purity titanium foil were employed as strips 0.5 x 5 cm in a thickness of 0.05 mm. The specimens were cleaned by washing in reagent grade toluene and by polishing the metal surfaces in hydrofluoric and nitric acid to remove surface impurities. The acids and reaction products were removed by pure water rinses lasting several hours. Moreover, specimens were immersed in an appropriate pretreatment solution before anodic formation.

Anodization.—Specimens were centered in cylindrical titanium cathodes 80 mm in diameter. Molten salt electrolytes containing different mixtures of sodium nitrate and calcium nitrate were employed, and films were anodized by the instantaneous application of constant voltage utilizing a battery source. Effects of such parameters as type of electrolyte, forming time, and forming voltage on the properties of the dielectric are shown in the following section.

After removal from the cell, specimens were rinsed in pure water and allowed to dry in air. In most cases, electrical testing was done in 10% nitric acid at room

temperatures with a titanium cathode. Leakage current was noted 5 min after a test potential of 10v was applied across the cell. The capacitance and dissipation factor were determined at 120 or 1000-cps using a bias of 3v d.c. and a signal voltage of 1.5v a.c.

Results

Pretreatment.—It was found that the anodic film could be improved by immersing the anode material in various concentrations of nitric acid which nominally is noncorrosive to titanium. The specimens subjected to the immersion treatment were anodically formed at constant formation voltage of 40v in a mixed molten salt electrolyte of 300°C. Table I illustrates the effects of the immersion time on the electrical properties of anodic films of titanium. The leakage current decreases with the increase in immersion time in every concentration of nitric acid over the range studied. Values of the leakage current after 400-hr immersion are about 1/10 as large as the values obtained with no immersion.

Dissipation factor also decreases with the increase in immersion time. Capacitance remains virtually unchanged (Table I, p. 283).

We think that the effect of pretreatment is as follows: an oxide film of the anatase type was formed on the titanium surface by immersion in nitric acid (8) and was left intact prior to anodic oxidation. That is, we presumed from our investigation that this oxide film greatly influenced the later anodic oxidation. Since titanium is very active, it is easily oxidized in comparison with iron. As a result, after all of the titanium surface is oxidized in a dilute acid, iron will be gradually dissolved away from the surface, and the leakage current will be reduced as the immersion time is extended.

Anodization.—Electrolyte.—The effect of forming conditions on the electrical properties of capacitors is illustrated in Table II, p. 283.

Since a molten salt electrolyte consisting of 25 w/o (weight per cent) sodium nitrate and 75 w/o calcium nitrate has a higher melting point than other combinations, the forming temperature is higher. The composition of the molten salt electrolyte, in which the following data for Fig. 1, 2, 3, 4, 5, and 6 were obtained, consists of 75% w/o sodium nitrate and 25 w/o calcium nitrate.

Forming time.—In the case of titanium the leakage current is largely affected by the forming time.

Figure 1 illustrates the relationship between the forming current and the forming time in a molten salt electrolyte of 320°C. The formation was carried out at constant potential. The forming current decreases with the increase of forming time. It is commonly considered that the forming current decreases with an increase of insulation properties of anodic films. However, the leakage current in $\mu a/(\mu f\text{-}v)$ of an electrolytic capacitor at room temperature does not decrease with the increase of forming time. The relationship between the leakage current in $\mu a/(\mu f\text{-}v)$ at a test potential of 10v and the forming time in minutes for various forming potentials in volts are illustrated in Fig. 2. The leakage current shows a v-type curve for the forming time: that is, a time shorter than that necessary to diminish substantially the forming current gives the smallest leakage current. It is presumed that the decrease in current with forming time does occur in a molten salt electrolyte indicating an increase in insulation character. In an aqueous electrolyte at room temperature a new electrochemical mechanism appears which gives higher leakage for longer formation times.

Figure 3 illustrates the relationship between capacitance, dissipation factor and the forming time. Except in the case where specimens were anodically formed at 10v, capacitance decreased slightly with the increase

Fig. 5. Electron micrograph of the etched surface formed for a time longer than that necessary to obtain the minimum leakage current. Magnification 10,000X.

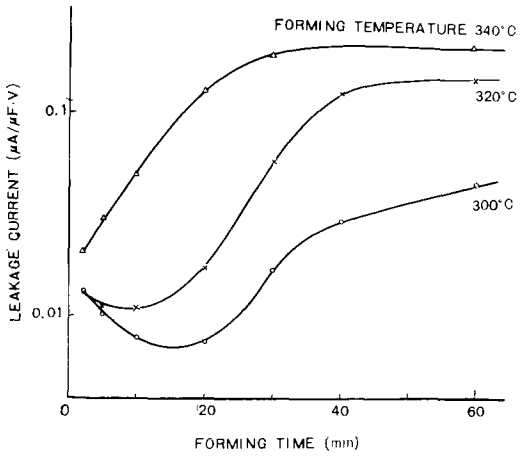

Fig. 6. Relationship between leakage current and forming time for various forming temperatures at the forming potential of 30v.

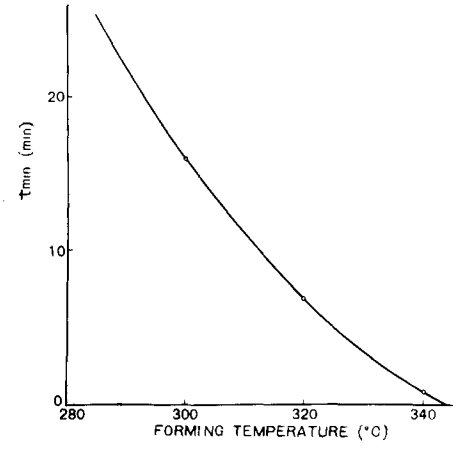

Fig. 7. Relationship between forming time to obtain minimum leakage current and forming temperature.

of the forming time. The capacitance decrease is caused by an increase in the thickness of the anodic oxide film, and very little additional film is formed after 5 min. The dissipation factor decreased with the time except for specimens anodically formed at 10v. It was found that the etching solution CP-4 easily removed the anodic film formed at 10v, and so this film was presumed to be very porous or have a different structure.

Figure 4 is the electron micrograph replica of the surface formed for 10 min at the formation voltage of 10v, which is shorter than the time required to reach the minimum leakage current, and subsequently etched in CP-4. Figure 5 is the electron micrograph of a similar surface but originally formed for 120 min at 30v which is longer than the time required to reach the minimum leakage current. Part I of these photographs shows the titanium surface from which the anodic oxide film has been removed by the etchant, and Part II shows the surface of the anodic film. Since the lattice structure of the titanium molecule is that of a densely packed hexagon, the hexagonal crystal structure is observed in the central part of Fig. 4. The surface of the 10v anodic film (Fig. 4) is rather rough compared with the 30v film (Fig. 5), indicating that the anodic film of the former is etched easier than the latter. The reason is presumably due to insufficient crystallization of the anodic film of the former.

Forming potential.—As shown in Fig. 2, the length of the forming time which gives the smallest leakage current value changes according to various forming potentials. The forming time necessary to obtain the smallest leakage current is less at a high potential (40v) than at a low potential (10v). The minimum in leakage current at 50v is presumed to occur at such a short formation time that it cannot be experimentally detected. Generally the forming time necessary to obtain the minimum leakage current decreases with increasing forming potential. This relationship may be empirically fitted to the data in Fig. 2, using one point at 10v, by the following equation:

$$t_{\min} = 314/v_f - 0.14\,v_f \qquad [1]$$

where $t_{\min}$ is the forming time to obtain minimum leakage current at a 10v test potential, and v_f is the forming potential. This equation indicates that when a lower forming potential is used, a longer forming time will be necessary to obtain the smallest leakage current value. Moreover, it predicts that a minimum leakage current does not exist if specimens are formed at potentials higher than 47.5v. In the capacitor formed at 50v, the leakage current increases as the forming time increases. We think that this increase results from crystallization of the anodic film. Since it is known that the rate of crystallization increases with formation voltage in the case of tantalum (9), it is assumed that the minima of the other formation voltages are also caused by the onset of crystallization.

Forming temperature.—Figure 6 illustrates the relationship between the leakage current and the forming time obtained for various forming temperatures at a forming potential of 30v. The forming time to obtain the minimum leakage current decreases with an increase in the forming temperature. The relationship between the forming time to reach minimum leakage current and the forming temperature is shown in Fig. 7. The curve crosses the x-axis at 343°C. At higher forming temperatures, the leakage current increases with the increase of forming time.

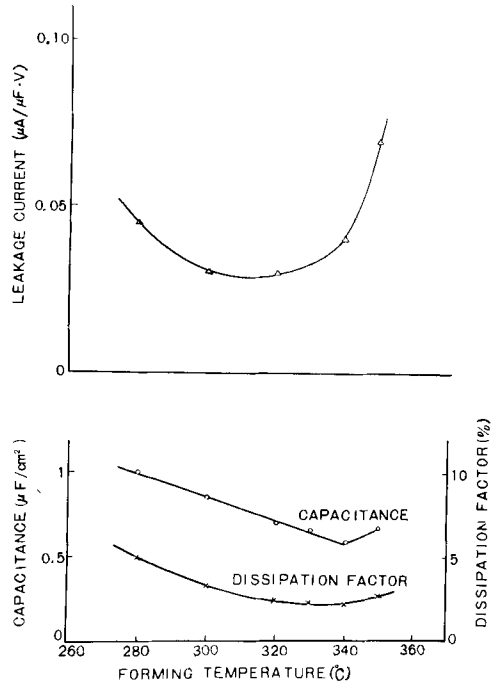

Fig. 8. Variation of capacitance, dissipation factor, and leakage current with forming temperature.

Furthermore the relationship between the electrical characteristics of the film and the forming temperature is shown in Fig. 8. Capacitance decreases linearly with an increase in forming temperature up to about 340°C. At 350°C the capacitance increases somewhat: leakage current increases rapidly between 340°C and 350°C, and the dissipation factor increases slightly at 350°C.

We will attempt to explain the critical temperature in the growth of film due to the theory of Cabrera and Mott (10). When the growth of one layer of atoms takes 10^5-sec[10], it is assumed that the growth of the film is infinitely slow. The thickness of film at that time is X_L

$$X_L = (va'q)/(w - 39kT) \qquad [2]$$

where v is the potential difference across the oxide, a' is the distance from the minimum to maximum potential energy during a jump into oxide, q is the charge on the metal ion entering the oxide, w is the activation energy to enter the oxide in the absence of a field, k is the Boltzmann constant, and T is the absolute temperature. Thus, for temperatures below the critical temperature, $T_c = w/39k$, a stable film is formed: for temperatures above this, the growth continues indefinitely. For titanium at 310°C, the activation energy, w, is 2.09v (11), so the critical temperature T_c should be 348°C. Above 348°C no limiting film will be formed, and the growth will proceed according to the parabolic law. As mentioned above, electrical characteristics show considerable variation between 340° and 350°C, presumably due to the critical temperature of 348°C.

Film Characteristics.—The v-type curve was obtained in the relationship between the leakage current and forming time. The determination of the dielectric constant of the anodic film formed to a minimum leakage current is described in the following sections. The specimens were formed at 40v for 10 min in a molten salt electrolyte whose temperature was 285°C.

Film Thickness.—The thickness of film was ascertained by three methods: measurement of the total amount of charge passed across film during formation, measurement of the interference color, and measurement with an electron microscope. An equation for the total amount of charge passed across the film is $i = A \exp$

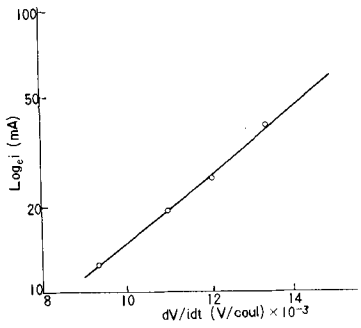

Fig. 9. Relationship between $\log_e i$ and $dv/(idt)$

(BE) according to Cabrera and Mott (10) (A, B = constant). This equation is rewritten as follows

$$\log_e i = \log_e \{SA/\eta\} + 0.4343B \{(S\rho F/M\eta)\, dv/(idt)\} \qquad [3]$$

where i is the circuit current, S the anode surface area, η the current efficiency, ρ the density of oxide film, F the Faraday constant, M the molecular weight of oxide film. The relationship between $\log_e i$ and dv/idt is shown in Fig. 9. The formation was carried out at constant current density at a potential increasing up to 40v. Comparing B (11) obtained directly from the relationship between $\log_e i$ and field F with B obtained from the slope of the line in Fig. 9, the current efficiency should be 0.0208.

By using this current efficiency, the thickness of film is obtained by Faraday's law as follows

$$d_1 = 1830 \text{ (Å)} \qquad [4]$$

This thickness of film was formed with a constant current density at a potential increasing up to 40v, but it is distinct in Eq. [2] that the thickness of film is determined by formation potential. Accordingly the thickness of film formed with constant potential of 40v is approximately equal to the former.

Measurement of the film thickness formed at 40v can also be obtained from the interference color (12, 13). By dividing the thickness of air film giving the same color in transmitted light by the refractive index of bulk rutile (2.62), the thickness of the oxide film is obtained as follows

$$d_2 = 1900 \text{ (Å)} \qquad [5]$$

Furthermore the film thickness is obtained by measurement with an electron microscope. After casting specimens in epoxy resin containing titanium dioxide powder, the oxide film is cut perpendicularly. Figure 10 shows an electron micrograph replica of the cross section of the oxide film. The black line in the center of the graph is the cross section of the oxide film, Part I is titanium, and Part II is the epoxy casting resin. Measuring the film thickness from this photograph results in an average value as follows

$$d_3 \simeq 2000 \text{ (Å)} \qquad [6]$$

The value of film thickness shown in Fig. 11 has been obtained by these methods.

Dielectric constant.—Using the mean value of film thickness formed at 40v, the dielectric constant is obtained as follows

$$\epsilon = (3.6 \times 10^6 \pi C d)/S = 107 \qquad [7]$$

where C is the capacitance, S the anode surface area, $C/S = 0.50 \mu f/cm^2$, d the film thickness of 1900Å. Considering the dielectric constant of the film, the crystal structure is presumed to be a rutile type of titanium dioxide.

Conclusions

It was found that the anodic film could be improved by immersing the anode material in various concen-

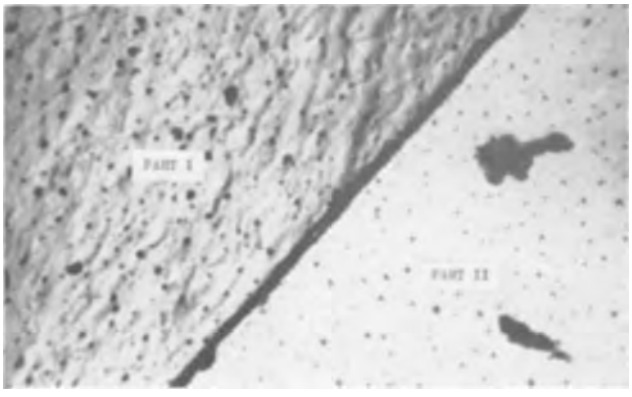

Fig. 10. Micrograph of cross section of oxide film

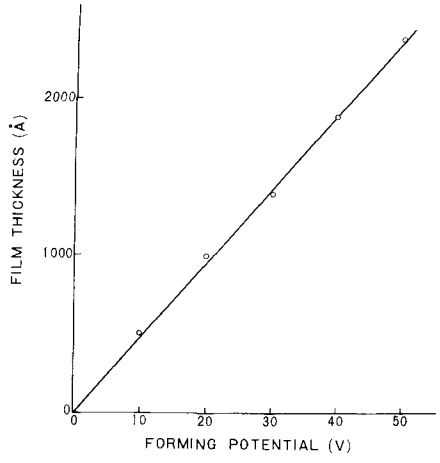

Fig. 11. Relationship between film thickness and forming potential

trations of acid. The leakage current decreases with the increase in immersion time in every concentration of nitric acid.

The leakage current of titanium electrolytic capacitors shows a v-type curve for the forming time, that is, a time shorter than that necessary to substantially diminish the forming current gives the smallest leakage current. The effects of molten salt electrolytes, formation potential, and forming temperature were investigated by a measurement of electrical and chemical properties of anodic oxide films. A critical temperature of 348°C for titanium anodization was obtained and compared with a change of electrical properties.

The measurement of anodic oxide film thickness was obtained by three methods: measurement of the total amount of charge passed across the film, measurement of the interference color, and measurement with an electron microscope. A dielectric constant of 107 was obtained for film formed at 40v. Considering the dielectric constant of the film, the crystal structure is presumed to be rutile type of titanium dioxide.

Glow Discharge Formation of Silicon Oxide and The Deposition of Silicon Oxide Thin Film Capacitors by Glow Discharge Techniques

S. W. Ing, Jr.,[1] and W. Davern

Electronics Laboratory, General Electric Company, Syracuse, New York

ABSTRACT

A process is described for the formation of silicon oxide thin films by the low-temperature decomposition of tetraethoxysilane in an a-c glow discharge. The effects of various process parameters on the film deposition rate and the resultant film characteristics have been studied and are described. It has been shown that thin silicon oxide films prepared by glow discharge techniques can be used effectively as the dielectric in thin film capacitors. The resultant capacitors have low dielectric losses and are very stable under various life test conditions.

A number of techniques have been developed for forming thin amorphous films (less than 1μ) of SiO_2 on various substrates. The most commonly used methods include: (*a*) oxidation (thermal or electrolytic) of silicon (1); (*b*) sputtering of silicon in oxygen (2, 3); (c) evaporation of silicon suboxide in oxygen (4); (*d*) pyrolytic decomposition of organic silicate compounds (5).

The oxidation process is not versatile enough; only silicon substrates can be used. Some success has been achieved with sputtering and evaporation techniques; these can be used in conjunction with a variety of substrate materials. However, the sputtered films that have thicknesses of the order of 1000Å or less usually contain a certain amount of pinholes (2), and show occlusion of large grains with sizes up to 500Å in diameter (3). The evaporated SiO_2 films have ben reported to be hygroscopic (4). The pyrolysis of organic-silicate compounds yields high quality SiO_2 films but only at temperatures greater than 700°C (5); this high-temperature requirement restricts the method to the use of substrate materials that are inert under the conditions of deposition.

A new method based upon a glow discharge has recently been developed (6). Tetraethoxysilane is used, but instead of pyrolyzing at high temperatures, an a-c induced glow discharge is employed to supply the necessary energy for decomposing the tetraethoxysilane and producing silicon oxide. The exact chemical composition of the oxide has not been determined. However, the oxide is amorphous and shows an infrared absorption peak at around 9.4μ, which is characteristic of Si-O bond. Its chemical inertness and its stability at high temperatures are not unlike fused silica.

Previous work in related areas include the electron bombardment formation of thin organic and metallic films (7), the d-c glow discharge deposition of thin films (8), and the d-c gaseous anodization of aluminum (9).

The substrate during the glow discharge deposition of silicon oxide is at near room temperature; thus the technique offers the possibility of depositing films on a wide variety of substrate materials. Furthermore, the oxide films formed by the glow discharge method are quite pin-hole free (6). Consequently, these films have enjoyed a wide range of application. For example, the films have been used effectively as masks against certain impurity diffusions in silicon (6) and GaAs (10) at elevated temperatures.

This paper describes in more detail the glow discharge process that has been developed for depositing thin silicon oxide films. In addition, the paper describes the effects of various process parameters on the film deposition rate and the characteristics of the resultant films. The utilization of glow discharge deposited silicon oxide films as dielectrics in thin film capacitors has been explored and is also reported.

Apparatus and Procedure

The main purpose of the glow discharge apparatus is to expose the substrate to a controlled atmosphere in a partial vacuum. In the present case, the controlled atmosphere consists of a background gas, usually oxygen, and the organic-silicate vapor. A plasma is then formed in the gas which surrounds the substrate where the chemical reactions take place. A flow system is used to feed continuously the background gas (such as argon or oxygen) and the tetraethoxysilane vapor to the reaction chamber; the reaction products are then pumped out. The flow system is shown in Fig. 1. Oxygen is introduced through a leak valve and its flow rate is measured with a rotameter. Tetraethoxysilane is introduced into the chamber through a capillary tube under its own vapor pressure; the vapor pressure is regulated by controlling the source temperature. It has been found that it is necessary to cool the source. In our work this has been accomplished by employing a thermoelectric cooler. The pressure inside the chamber is monitored continuously by a McCleod gauge and controlled by regulating the pumping speed. An adjustable valve is placed in the line leading from the cold trap to the vacuum pump for performing this function.

A schematic of the reaction chamber is shown in Fig. 2. Oxygen is fed into the reaction chamber through the narrow section where the plasma is generated. The

* Substrate was heated to 200°C.

ionized and the disassociated species have a long enough lifetime, so that glow follows the gas stream and extends itself into the region where the substrate is located. Tetraethoxysilane vapor is introduced into the plasma downstream of the narrow section. This step accomplishes the important function of confining the reaction (as much as possible) to the vicinity of the substrate. Using this arrangement, the plasma color intensity is uniform in the region of the substrate.

High-frequency power is applied to the gas through two copper electrodes strapped to the outside wall of the narrow section of the chamber. A half-megacycle, 1-kw induction generator is used as the power source. Electrical coupling between the electrodes and the gas is good in the gas pressure range of several hundredth to several tenths of mm of Hg.

The substrate is placed on a quartz pedestal and floats electrically when surrounded by the plasma. A heater is available for use with an aluminum pedestal when substrate heating is required. The substrate would be in direct contact with the aluminum. A thermocouple, imbedded in the aluminum pedestal, monitors its temperature.

At the start of a run, the source reservoir is cooled to the desired temperature, and the oxygen flow rate and the reaction chamber pressure are adjusted to the desired conditions. The oxygen flow rate, once set, is not affected significantly by the pressure inside the chamber because of a high-pressure drop across the oxygen leak valve. Next, the power is turned on, and a plasma is generated to outgas the chamber and clean the substrate. After a few minutes, the valve leading from the source reservoir to the chamber is opened and the silicon oxide deposition is started. Due to the large volume of reaction products, the pressure inside the reaction chamber begins to increase and a steady state is soon reached. This steady-state pressure has been found to be reproducible from one run to the next.

The vapor pressure of the tetraethoxysilane, (manufacturer specification, 99.9% pure), as a function of temperature was extrapolated based on the original data of Stull (11). The source temperatures employed ranged from 7.22° to 15.55°C, corresponding to a vapor pressure range of 0.52 to 0.92 mm Hg, and were controlled to ±0.5°C.

Fabrication and measurement techniques.—Thin film silicon oxide capacitors were deposited on 1 x ½ in. glass slides. An aluminum electrode was first evaporated lengthwise on one surface of the slide. The silicon oxide film was then deposited over the aluminum strip. A second evaporation of aluminum was then carried out to form the counterelectrode strips, oriented perpendicular to the first aluminum strip. The thickness of the aluminum electrodes is approximately 2000Å. Six capacitors are formed on a single slide, each having an area of 0.097 cm^2.

A piece of polished silicon located adjacent to the substrate was used to determine the thickness of the silicon oxide layer and its refractive index. The measurement was made by first masking half of the silicon surface and then etching the oxide away from the unmasked half with hydrofluoric acid, thus forming a step. A portion of this step was covered with a film of evaporated aluminum to form a reflecting surface. The wafer surface was then examined with an interference microscope using light of a known wavelength. The fringe shifts at the step, with and without the evaporated aluminum, were photographed and measured. The oxide thickness was then calculated from the number of fringe shifts which appeared on the reflecting side of the step. The uncertainties in the thickness measurements are estimated to be ±150Å. Next, the refractive index of the oxide film was calculated from the ratio of the fringe shifts between the aluminum coated and uncoated regions of the step.

Capacitance and loss tangent measurements at 1 k-c were made on each of the capacitors using a bridge circuit. Some of the capacitors were measured at frequencies from 0.1 kc to 3 Mc.

A number of the thin-film silicon oxide capacitors were also subjected to a variety of life test conditions. Their capacitances and loss tangents were measured as a function of the time duration of the tests. Other tests, such as the dielectric strength and the ability to withstand thermal stresses, were also carried out.

Results and Discussion

Deposition of silicon oxide thin films.—The conditions of deposition and the results are presented in Table I. The oxygen pressure shown in the first column refers to the initial pressure within the reaction chamber prior to the introduction of the organic vapor. Parameters that have been investigated include initial oxygen pressure, source temperature, time length of deposition, and substrate temperature. The power input, the chamber and the electrode geometry, and the pumping speed were fixed.

The substrate temperature rise due to the plasma bombardment has been estimated by exposing the aluminum pedestal, which is well insulated from heat sinks, to the plasma under the deposition conditions, using an O_2 pressure of 0.09 mm Hg and a source temperature of 12.78°C. The steady-state temperature of the aluminum was measured to be 75°C. This temperature should be reasonably close to the steady-state bulk substrate temperature during deposition since the plasma is quite uniform in the aluminum pedestal region.

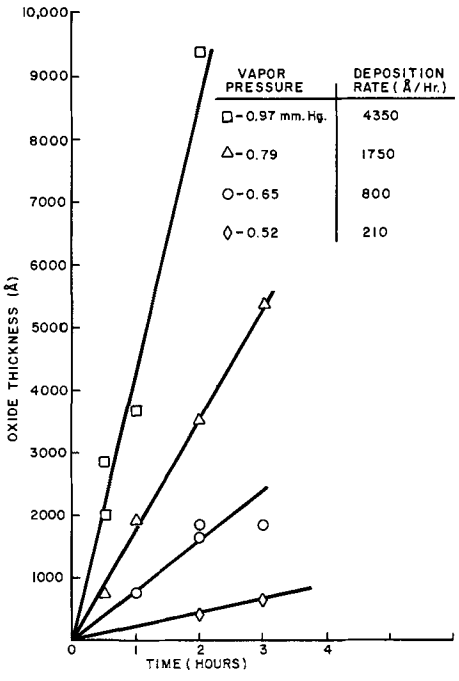

Fig. 3. Deposited oxide thickness *vs.* deposition time

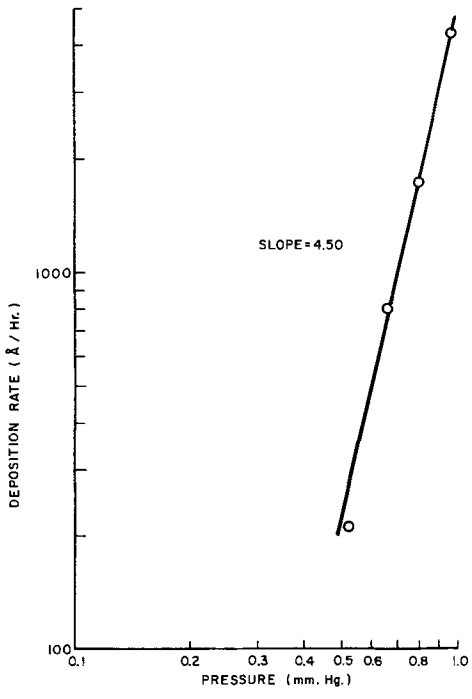

Fig. 4. Oxide deposition rate *vs.* vapor pressure of tetraethoxysilane in reservoir.

In Fig. 3, the oxide thickness is shown as a function of the deposition time for a constant oxygen feed rate, at various partial pressures of tetraethoxysilane in the reservoir. A family of straight lines was obtained, indicating a constant growth rate of the oxide. No initiation periods were observed.

The effect of the source temperature, which is a direct function of the concentration of the source in the reaction chamber, is extremely pronounced. The flow rate of the tetraethoxysilane vapor into the reaction chamber is controlled primarily by the capillary tube (1 mm ID, 2 cm long), as shown in Fig. 1. The capillary tube assures that the source flow rate will not be a function of the geometry of the reservoir. At the capillary inlet the partial pressure of the tetraethoxysilane can be assumed to be in equilibrium with the liquid source. However, the organic flow rate itself is difficult to estimate because the diffusivity of the tetraethoxysilane through the stagnant gas layer in the capillary is not known. In addition, any calculation based on the source depletion rate would be inaccurate, since for each run, the amount of the source consumed is small.

The deposition rate, when plotted as a function of the partial pressure of tetraethoxysilane at the source, yields the straight line shown in Fig. 4. From this line it can be established that R is proportional to p raised to the 4.5 power, where R is the deposition rate and p is the vapor pressure of the source. This relationship is not a universal one and is only applicable under the present set of conditions. However, it does indicate the extent of the deposition rate dependence on the source feed rate.

When the initial oxygen pressure was increased to 0.18 mm Hg (see Table I), a substantial decrease in the deposition rate was observed. The source flow rate into the chamber should not be significantly affected by the increase in the total pressure since the rate of flow across the capillary is governed mainly by the concentration gradient of the source material, assuming that there is no appreciable change in the diffusivity. The explanation may lie in the fact that there is a thick layer of plasma separating the source inlet into the chamber from the substrate. An appreciable portion of the tetraethoxysilane must have decomposed and deposited on the chamber wall before it could reach the substrate. Under higher oxygen partial pressures, a larger portion of the source material can be expected to react in the vicinity of the source inlet; hence, there is a larger amount of material deposited on the wall and a smaller amount on the substrate.

When the substrate is heated to 200°C at an oxygen pressure of 0.09 mm Hg, the deposition rate again decreases. This may be due to a slight upward convection current around the substrate caused by the temperature gradient between the substrate heater and the air-cooled chamber wall. Such a current would tend to lower the concentration of the reactants in the substrate region.

In Fig. 3 the deviations of the data points from straight lines can be attributed to variations in the source temperature (±0.5°C). The deposition rate can more precisely be reproduced when the source temperature is more carefully maintained at a constant value.

The variation in the thickness of the oxide film across a 1-in. diameter substrate can generally be held to ±5% of the total film thickness. The uniformity of the film seems to be a function of the ratio of the substrate area to the cross-sectional area of the reaction chamber. The lower this ratio is, the more uniform is the film thickness.

The product gas has been analyzed using a mass spectrometer. The detectability of the short chain hydrocarbons, alcohols, and other organic species is of the order of 1% minimum concentration in the gas sample. Water vapor could not be analyzed due to the interfering background water content of the apparatus. The species detected were CO, CO_2, O_2, and N_2 indicating that the oxidation of the organic silicate was quite complete within the reaction chamber.

Effect of deposition rate on silicon oxide film characteristics.—The influence of the deposition rate on the characteristics of the thin film silicon oxide capacitors is shown in Table I. The loss tangents of the capacitors made at the higher source temperatures and lower oxygen concentrations (where the oxide growth rates are faster), are generally higher than those made with a lower source temperature and a higher oxygen concentration (where the oxide growth rates are slower).

A few of the capacitors, grown at different rates, were measured for their capacitances and loss tangents as a function of frequency, from 0.1 kc to 3 Mc. Two sets of data were plotted and are shown in Fig. 5 and 6.

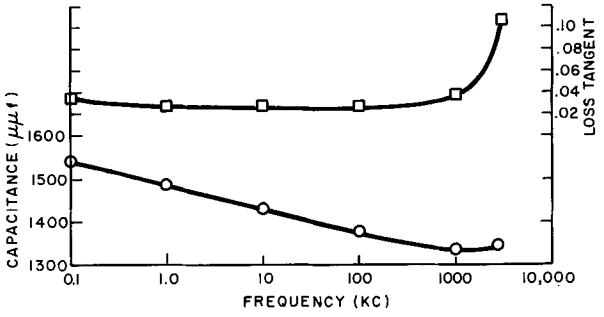

Fig. 5. Capacitance (lower curve) and loss tangent (upper curve) vs. applied frequency; oxide film deposited at a rate of 3700 Å/hr, oxide film thickness, 2800Å.

The curves of Fig. 5 are for films which were grown at rates of 3500-5000 Å/hr; the curves in Fig. 6 are for films grown at rates below 2000 Å/hr. The capacitors formed at the faster growth rates show a consistent decrease of capacitance as the applied frequency increases; the capacitors formed at the lower growth rates remain unchanged in their capacitances as the applied frequency is increased. The slight upturn in capacitance at frequencies greater than 1 Mc is most likely due to series resistances and inductances. The loss tangents of both types of capacitors remain essentially constant up to 100 kc and then begin to increase. Most of the increased losses can be attributed to series resistances in the thin film electrodes. The effect of growth rate can again be observed when the films are etched in hydrofluoric acid. Films that were grown at rates above 3500 Å/hr always yield a brownish residue when rinsed in HF; the films grown at slower rates dissolved completely. The brownish residue is probably organic material that has been occluded in the oxide structure during the deposition process, indicating an incomplete decomposition of the organic-silicate when the growth rate is too high. These entrapped organic functional groups could give rise to a dipolar contribution to the capacitance of the film. The decrease of capacitance with increasing frequency occurring at relatively low frequencies in these high-growth-rate deposited films indicate that these polar molecular segments have long dielectric relaxation times.

Properties of silicon oxide films prepared by glow discharge techniques.—The dielectric constant values of the films lie mostly in the range of 4.5-5.5 as shown in Table I. It is not possible to ascertain the effect of the deposition rate on the film dielectric constant since the variations in the dielectric constants between the films are within the uncertainty limits of the measurements. The refractive index obtained from the interferometer measurements, using 5460Å light, is 1.5 ± 0.1. No density measurements have yet been made. Electron diffraction measurements show that the films are amorphous.

Capacitor Testing

Capacitor life test results are shown in Fig. 7 to 9. The high humidity (with and without applied bias)

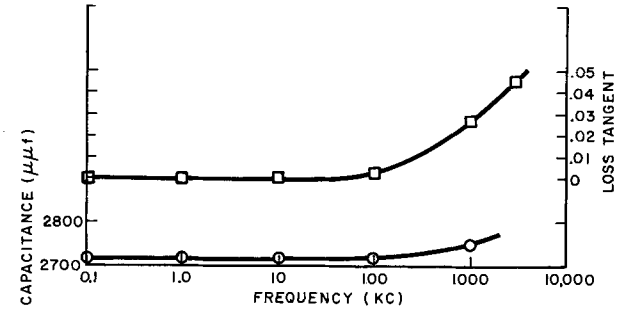

Fig. 6. Capacitance (lower curve) and loss tangent (upper curve) vs. applied frequency; oxide film deposited at a rate of 825 Å/hr; oxide film thickness, 1500Å.

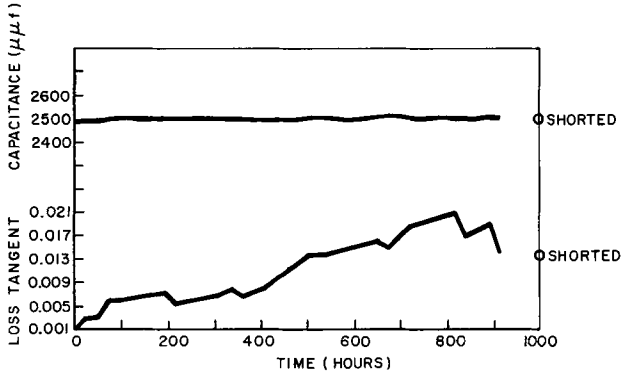

Fig. 7. Capacitance and loss tangent measured at 1 kc vs. test time; test condition: 100% relative humidity at 23°C; deposition rate of the oxide film, 1900 Å/hr; oxide film thickness, 1700Å.

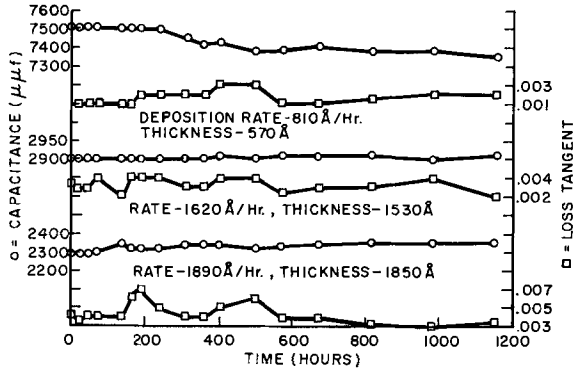

Fig. 8. Capacitance and loss tangent measured at 1 kc vs. test time; test condition: 70% relative humidity at 23°C with 10½v bias.

tests were conducted on capacitors that were formed at slow deposition rates (less than 2000 Å/hr) and without substrate heating. Figure 7 shows the test results of a capacitor exposed to a 100% relative humidity ambience at 23°C with no applied bias. The capacitance and the loss tangent were measured at approximately 50-hr intervals. The capacitance remained essentially constant, but the loss tangent tended to increase with time. A short did develop after 900 hr of testing. Figure 8 shows plots of capacitance and loss tangent *vs.* time of three capacitors that were tested in a 70% relative humidity ambience at 23°C with 10.5v bias applied across the capacitor. Both the capacitance and the loss tangent of these samples remained quite constant over a period of 1150 hr.

Thin film capacitors formed without substrate heating were tested at 100°C and 10.5v applied bias at room ambience. Results are shown in Fig. 9. The initial capacitances and loss tangents were measured at 23°C. The capacitor formed at a slower rate exhibits a very slight decrease in capacitance in the first 50 hr of test with no significant change in loss tangent. However, the capacitor grown at a higher rate exhibits an appreciable decrease in capacitance with time at the start of the test; it then levels off and the capacitance remains constant. The loss tangent seems to maintain its value with time. These changes in capacitances due to heating are irreversible. However, once stabilized, these capacitors show very low thermal coefficient of capacitance; generally less than 20 ppm/°C in the temperature range 23°-100°C.

The dielectric strengths of these films, calculated on the basis of the bulk breakdown voltages, are in the range 5 x 10^6 to 10^7 v/cm. These values compare closely to the dielectric strength of fused quartz, which is reported to be around 10^7 v/cm.

The capacitors were also tested for their ability to withstand thermal stresses. The sandwich assembly was cooled very rapidly from room temperature by

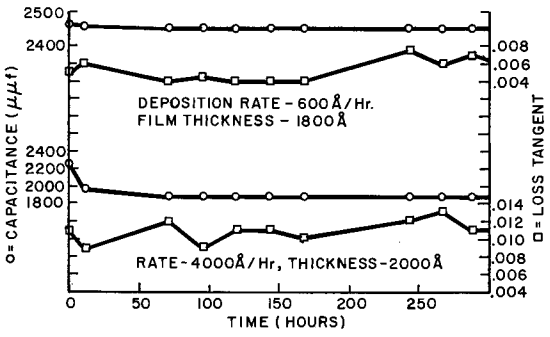

Fig. 9. Capacitance and loss tangent measured at 1 kc vs. test time; test condition: 100° in room ambient with 10½v bias.

immersing it quickly into liquid nitrogen, where it remained for 10 to 15 min. The assembly was then quickly withdrawn and warmed in the room ambient. The cycle was repeated three times. Two capacitors, of film thicknesses 1800 and 2000Å, respectively, were used for the test. The capacitances and the loss tangents were measured before and after the test and no significant changes were observed. Microscopic examinations of these capacitors revealed no cracking or peeling.

Effect of Background Gas

The effect of the background gas on the deposited film was briefly investigated. Both argon and hydrogen plasmas were used. A much slower deposition rate (less than 1000 Å/hr) was required to ensure that the deposited films yield no organic residue when etched with HF. It can therefore be surmised that, although the source itself has a high oxygen content, an oxidizing plasma is still needed to assist in the completion of the decomposition reaction and to provide an ample supply of oxygen for the formation of the silicon-oxygen network.

Proposed Mechanism for Glow Discharge Deposition

A reaction mechanism has been postulated. The mechanism is based on a high energy particle bombardment decomposition of the organic-silicate source in the gas phase, followed by a polymerization of the free radicals into silicon oxide clusters. The clusters are then deposited onto the substrate surface and bonded to the surface atoms. Any attached organic functional groups could also be dissociated from the deposited layer by a subsequent bombardment step.

During deposition the mobility of the clusters on the solid surface must be quite high, since the films as deposited are coherent even when they are very thin (on the order of a few hundred Angstroms). The film adherence to the glass substrate surface is good. For example, the oxide film could not be lifted off by using a "Scotch" tape indicating that strong bonds have been formed between the substrate surface and the first layer of the deposited oxide film.

Conclusions

The glow discharge formation of silicon oxide in an oxygen plasma, using tetraethoxysilane as a source material, has been studied. The resultant silicon oxide films are amorphous, coherent, and exhibit good adherence characteristics. The parameters investigated included oxygen pressure, source material feed rate, and substrate temperature. The oxide film deposition rate has been shown to be a strong function of the source feed rate. The deposition rate is slowed as the oxygen pressure or the substrate temperature is increased, probably due to a lower mass transport rate of the source to the substrate.

The quality of the deposited oxide films, as indicated by their electrical stability and low dielectric loss, is dependent on the deposition rate. At rates below 2000 Å/hr, the films are generally of high quality. The films formed at rates above 3000 Å/hr seem to have a substantial amount of organic material occluded in their structure and are less stable electrically. They also have higher dielectric losses. The dielectric constant of the films are in the range of 4.5-5.5.

The thickness of the film has been controlled so that variations of less than ±5%, across a 1-in. square substrate area, has been achieved. In addition, the deposition rate has been controlled to within ±10%.

Capacitors have been made from the glow discharge deposited films that have specific capacitances in the range of 4,800-110,000 $\mu\mu f/cm^2$. These capacitors have shown good stability in high humidity tests and in room ambient 100°C tests with or without applied bias. The capacitors have low temperature coefficients of capacitance and are able to withstand extreme thermal shocks. The bulk breakdown strengths of the films lie in the range 5 x 10^6 to 10^7 v/cm.

Manuscript received March 6, 1964; revised manuscript received Nov. 6, 1964. This paper was presented in part at the New York Meeting, Sept. 29-Oct. 3, 1963.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

The Infrared Spectra of the Adsorbed Phase on Tantalum Oxide Films

F. Vratny

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

An investigation of the adsorbed phase on anodic and thermally grown tantalum oxide on sputtered tantalum has been carried out using infrared reflectance and transmission spectral techniques. After exposure to air (50% RH), it was possible to identify water, carbon dioxide, and hydrocarbon residues. Both the water and carbon dioxide were removed on evacuation and heating while the hydrocarbon residues were retained by the sample. It is proposed that the hydrocarbon residues occur as a result of gettering processes in the residual gases during sputtering of the original tantalum film, or by incorporation of the organic electrolyte used for anodizing.

The infrared spectrum of a solid can be a very helpful tool in characterizing the nature and existence of adsorbed phases on solids (1). Under appropriate conditions it has been used to determine adsorption isotherms (1-4), and to establish the nature of an adsorbent (5, 6) and the type of interaction between adsorbent-adsorbate (3, 4). Further, it is known that the presence of an adsorbed phase on a solid can have a pronounced effect on the electrical properties of both the bulk and the surface of a solid (7-14). As a particular example, it is known that the presence of an adsorbed layer of water can have a decided effect on the dielectric properties of many oxides (15, 16) as anodic aluminum oxide (17) and anodic tantalum oxide (18). Further, based on charge storage data for tantalum oxide it may be possible that the presence of a second adsorbate may be necessary to explain the pronounced effect at present attributed only to water (18). In order to characterize the various species on tantalum oxide the infrared spectrum of the adsorbate phase was obtained.

It was possible to obtain the spectrum of the adsorbed phase in the 2.5-13μ range without undue complications due to the fact that tantalum oxide presents no interfering band in this region of the spectrum (19). Although techniques are directly available for observing the spectrum of an adsorbed phase on a solid, the particular case of tantalum oxide offers a number of singular peculiarities which required an evaluation of preparative and observational techniques. These factors were evaluated by preparing tantalum oxide by both thermal oxidation and anodization on several different kinds of substrates. Further, spectra were observed by more than one method, including specular reflectance, multiple reflectance, and direct transmission. In this way it was possible to rule out spurious results and to make definite assignments to adsorbate materials. Of the techniques employed it is felt that the method of direct transmission proved the more useful and flexible.

Experimental

Tantalum oxide films were used to evaluate the reflectance method. These samples were prepared by deposition of tantalum on 1 x 3 in. quartz microscope slides. The slides were first cleaned in detergent and rinsed in distilled water and isopropyl alcohol. Tantalum was then deposited by cathodic sputtering at 4 kv and 3 ma/cm^2 from an arc melted tantalum plate. The metallic film had a total thickness of $\sim$ 5000Å and a specific resistivity of $\sim$ 100 μohm-cm. The film was anodized to an appropriate voltage in an electrolyte of 1:2:3 water, oxalic acid, ethylene glycol at 105°C to obtain the desired thickness of oxide.

The samples used for the transmission experiments were deposited as above; however, the substrate was either sapphire or barium fluoride. Anodization was carried out in an identical fashion. The metallic base was removed by anodic etching in a lithium chloride-alcohol electrolyte. This technique made it possible to obtain metal-free areas of at least 2 mm^2 which were suitable for direct transmission experiments (18).

It was not possible to oxidize tantalum thermally at 400°-600°C on potassium chloride or barium fluoride without affecting the substrate. The potassium chloride substrates became opaque while the barium fluoride substrates showed definite carbonate bands. The infrared spectra of samples produced in this way indicated the presence of large amounts of oxide and carbonates from the substrate as well as metallic fluorides arising from the firing process. Consequently, the thermal oxidation was performed only on sapphire substrates at 800°C, where these interferences were controlled by the greater stability of the sapphire. It was possible, however, to obtain a slight trace of an oxide band due to the presence of a metal-metal oxide (M-O-M') stretching frequency arising as a result of the possible interfacial diffusion between tantalum oxide and sapphire.

The specular reflectance spectrum was obtained by means of a Perkin Elmer specular reflectance attachment. In this method light is reflected specularly from the sample surface, collected by a spherical mirror, and focused onto the slit of the spectrometer. In all cases a gold or tantalum surface of high specular reflectance was used in the reference beam.

It was found that if the spectrometer was used at a scale expansion of (1X) the specular reflectance of tantalum oxide was nearly constant and structureless in the 4.5-12μ region of the spectrum. At a scale expansion of (10X) it was possible to identify the presence of adsorbed water ($\sim$ 3600 cm^{-1}) and carbon dioxide ($\sim$ 2350 cm^{-1}). An indication of adsorbed aliphatics or carboxalate OH ($\sim$ 2700 cm^{-1}) was also noted. Possible metal-oxide bands occurred at $\sim$ 1925 and 925 cm^{-1}.

For a further discussion of assignment of absorption bands, see the Discussion.

Multiple Reflectance Spectra (Oblique Incidence)

Although it was possible to obtain a significant picture of the adsorption species on tantalum oxide by the specular reflectance methods, the intensities were marginal due to a single reflection from the sample surface. By the use of a method of multiple reflection from the surface it was possible to intensify the characteristics found by the single reflectance method. Thus, the above samples were investigated by the method of multiple reflectance.

The multiple reflectance spectrum was obtained by means of a special reflectance attachment. The optical system (Fig. 1 and 1b) relies upon polychromatic

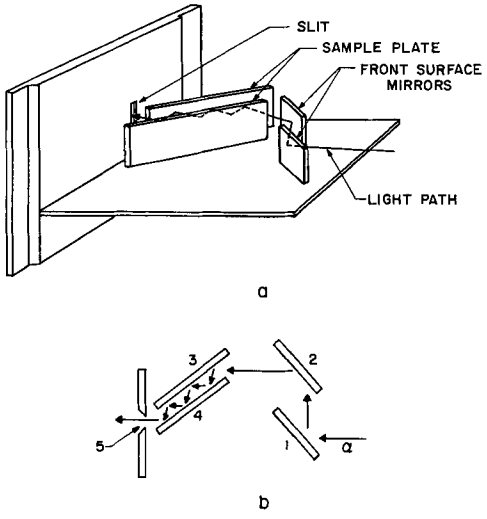

Fig. 1. Optical system for multiple reflection spectroscopy. A, Pictorial view; B, Schematic view, 1,2, front surface mirror, 3,4 sample, 5, slit, α, angle of incidence.

infrared radiation which is reflected from mirrors 1 and 2 onto the sample plates 3 and 4 where multiple reflection occurs between the two parallel sample surfaces. This configuration permits the absorption spectra of an adsorbed specie on a surface to be obtained without interference from the body of the sample. It is quite flexible in that it may be used in oblique or grazing incidence to obtain respectively simple multiple reflection from the sample surfaces or internal reflection in the oxide. This difference results from reflected radiation at angles greater than Brewster's angle ($\tan \theta = \mu$) and internal reflection to a greater extent as this angle is approached, *i.e.*, internal reflection occurs at an angle θ greater than θ' where $1/\sin \theta = n$ (20). At less than the Brewster angle the radiation is totally internally reflected. This is a technique perfected by Harrick (21) and Francis and Ellison (22).

Due to loss of intensity from reducing the effective size of the beam and due to energy losses through scattering and unusual optical densities it was found necessary to compensate the reference beam. A comb attenuator was designed for this purpose. This device has the particular utility of being easily and precisely adjusted to any desired optical density.

Employing the first technique of oblique reflection (surface reflection), with a sample separation of 0.070 in. and an angle of 30° incidence to the light source, it was possible to identify infrared absorption bands (Fig. 2) for carbon dioxide at D (about 2350 to 2500 cm^{-1}), hydrocarbon C-H or carboxalate OH vibrations at C (2600 to about 2800 cm^{-1}), physically adsorbed water evident by the band at B from about 3200 to about 3400 cm^{-1}, and finally chemisorbed water at A at 3580 cm^{-1} and 3630 cm^{-1}. These bands do not have the same appearance as they would have in transmission due to the fact that for a given band the transmission of the samples register changes proportional to k, the absorption coefficient, while in reflection they register changes which are proportional to both n and k, the index of refraction and the absorption coefficient, respectively. Thus, bands will be found to move from their established position to a different frequency (23-26), dependent on the change of n with frequency.

From an estimate of absorption coefficients it is estimated that the band due to chemisorbed water corresponds to about four to eight molecular layers while the physically adsorbed water corresponds to about two monolayers. Correspondingly the CH residues and CO_2 occur at about two to four molecular layers. These estimates represent upper limits to the concentration and are probably too large by an order of magnitude

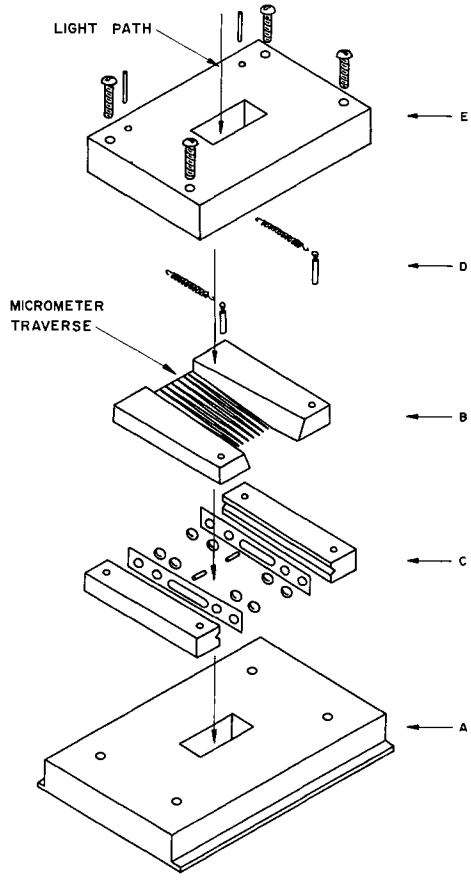

Fig. 1a. Light attenuator, exploded view

in light of comparisons to known surface coverages, see general reference (27).

Multiple Reflectance (Grazing Incidence)

Using the technique of grazing incidence multiple reflectance it was possible to delineate and expand on the features obtained by the oblique incidence method. The same procedure was followed as in the preceding section with the exception that the angle of incidence between the light beam and the sample was ~ 10° and the data were recorded at a scale expansion of (20X). A large number of absorption bands were noted in the 5-7μ region of the spectrum. These are due to atmospheric water vapor (28).

In addition, it was possible to establish the presence of many adsorbed species. In Fig. 3 and 4 the spectrum obtained from an anodic tantalum oxide sample which had been dried for 24 hr at 110°C is compared with the spectrum from a sample which had been held at 100% humidity for 4 hr. In this set of figures as well as following figures, the breaks in the spectra represent experimental translations along the re-

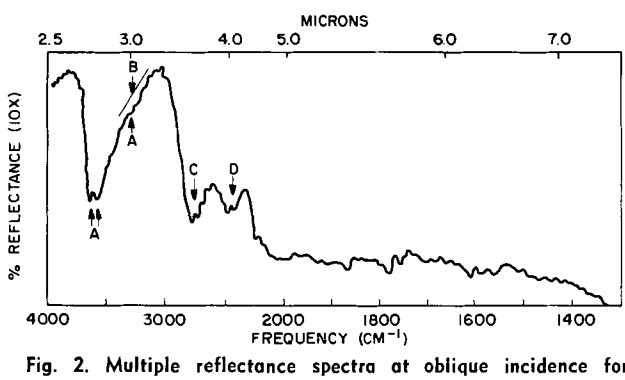

Fig. 2. Multiple reflectance spectra at oblique incidence for anodic tantalum oxide. A, Chemisorbed water; B, physisorbed water; C, CH-residues, D-CO_2. The ordinate is zero to 10% reflectance.

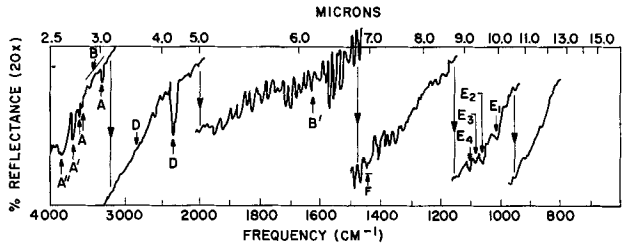

Fig. 3. Multiple reflectance spectra at grazing incidence for dry anodic tantalum oxide. A, Chemisorbed water (OH^-); A', chemisorbed water or CO_2; A", chemisorbed water; B, physisorbed water; C, CH-residue; D, CO_2. The ordinate is zero to 5% reflectance with roughly a 5% increase in base line at each discontinuity.

flectance axis. This was caused by the lack of adequate compensation in the reference beam and the rapidly changing intensity level which occurs with decreasing frequency. Since the spectra were taken with overlapping regions it may be seen that in general this adjustment corresponds to an axis translation of at most a change of 5% reflectance.

The major difference is the large background slope in the 3μ region found in the wet sample. This is quite characteristic of extreme surface coverage by water. This characteristic also masks many of the bands found in this region which are seen in the dry sample. There is also a pronounced water band in the 6.1μ region in the wet sample which is greatly reduced in intensity in the dry sample. In addition, there are indications of CH residues (C), C' is carboxalate OH, CO_2 (D), metallic oxide bands (E), and carbonate or chemisorbed CO_2 (F). Fairly predominant CH Bands are observed, which are comparable to aliphatic CH_{2n+2} and aromatic phthalate configurations. Bands were also observed in the 4-7.0μ region which are due to the carboxylate group.

From an estimate of intensities the chemisorbed water bands may be due to 1-3 monolayers of water while the physisorbed water bands cannot be suitably resolved. The CO_2 band represents about four molecular layers. This is in distinct contrast to the results obtained from oblique reflectance and represents the distinction between internal and oblique reflection.

Transmission Spectra of Thermally Produced Tantalum Oxide

The transmission spectrum of thermally oxidized tantalum on sapphire was obtained by direct transmission at (5X) scale expansion.

The spectrum (Fig. 5) indicated a large amount of carbon dioxide (D) and possibly carbonate ion or chemisorbed CO_2 (F) ($\sim$ 1430 and 2350 cm^{-1}) as well as substantial amounts of adsorbed water (band at $\sim$ 3300 cm^{-1}) (B). Quite distinct to this sample were the intense bands at 1180, 1120, and 1090 cm^{-1} which are suggestive of metal-oxide bands (E). The physisorbed water band corresponds to about 50-150 molecular layers of water while the CO_2 band is due to about

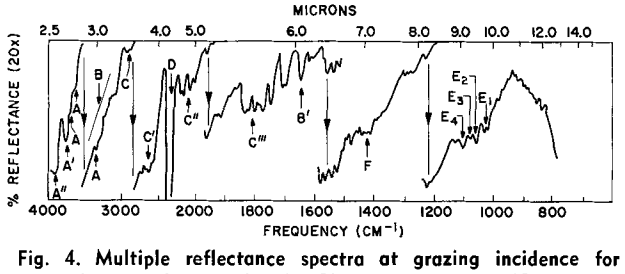

Fig. 4. Multiple reflectance spectra at grazing incidence for wet anodic tantalum oxide. The ordinate is zero to 20% with roughly a 10% increase in base line at each discontinuity.

10-50 molecular layers. The unusually large amount of water and CO_2 is probably due to the thermal nature of the sample which is highly porous.

Transmission Spectra of Anodically Produced Tantalum Oxide

The transmission spectrum was obtained for anodic tantalum oxide on barium fluoride. It was found that the transmission was relatively constant out to the cutoff of the barium fluoride windows. At a scale expansion of 10X (Fig. 6) it was possible to identify both CO_2 (D) and H_2O (A, B). Physically adsorbed water may be identified at $\sim$ 3300 cm^{-1} while chemisorbed water is indicated by the bands at $\sim$ 3700 cm^{-1}. On heating the anodic oxide sample, the 3300 cm^{-1} band diminished in intensity while the 3700 cm^{-1} band increased in intensity due to a reduction in the background as a result of the decrease in hydrogen bonded surface water (29, 30). The presence of physically adsorbed CO_2 (D) is established by the band at $\sim$ 2350 cm^{-1} which corresponds to the ν_3 vibration of CO_2. Chemisorbed CO_2 (F) or carbonate is also suggested by the bands at $\sim$ 1500 cm^{-1} and 1410 cm^{-1}; however, it is recognized that fluorite windows are prone to this type of interference. A further adsorbed specie is indicated by the band at $\sim$ 2950 cm^{-1}. This is due to a CH vibrational mode from adsorbed hydrocarbons (C). The concentration of chemisorbed water has only slightly altered from the thermally produced sample while the physisorbed water has decreased by at least a decade, *i.e.*, 5-15 monolayers of water.

As an extension of the above investigation, an anodic tantalum oxide film on barium fluoride was mounted in a special infrared cell (31), and spectra were obtained as a function of cell pressure and temperature. The results are classified according to active functional groups. Attention is directed to two regions of the spectrum from 4000 to 2700 cm^{-1} (Fig. 7) and 2700 to 1950 cm^{-1} (Fig. 8). In both cases a number of spectra are superimposed at a common origin in order that the results of the pressure-temperature treatment may be seen readily. The sample was first equilibrated at normal atmospheric conditions (O) *i.e.*, 25°C and $\sim$ 50% RH. On reducing the pressure over the sample to 10^{-3} Torr, (O'), a substantial amount of physically adsorbed water ($\sim$ 3250 cm^{-1} corresponding to OH with hydrogen bonding) was lost. The

A, Chemisorbed water; A_1, ω_0 for $VO(OH)_2$; A_2, ω_0 for $SiO_2 \cdot xH_2O$; A_3, ω_0 for $Mg(OH)_2$, $Co(OH)_2$; A_4, γ for Mica (OH), γ for $VO(OH)_2$; A_5, γ for $VO(OH)_2$, B-physisorbed; B, physisorbed water; B_1, $\theta \simeq 1.0$ (150 monolayers); B_2, $\theta \simeq 0.6$ (60 monolayers); B_4, $\theta \simeq 0.3$ (30 monolayers); B_7, $\theta \simeq 0.1$ surface coverage, (1-5 monolayers), C, CH-residues.

sample was then heated in a sequential fashion to ~200°C. The progression 1 to 6 is representative of this temperature cycle, *i.e.*, about 30°C intervals (coverage approximated from ref. (12), molecular layer coverage estimated from intensities). It may be noted that two bands due to chemisorbed water persist at ~ 3520, 3680, and 3800 cm^{-1} due to free hydroxyl while greater and greater amounts of physically adsorbed water are lost. The band at ~2950 cm^{-1} seems to grow in intensity due to a decrease in the magnitude of the water band. This band is due to organic C-H vibrational states. Due to its persistence the associated CH is equally or more strongly held (bonded) than the chemisorbed water. The source of this hydrocarbon contaminant is hydrocarbon cracking during the deposition of the film or incorporation of the organic electrolyte during anodization. Liquid nitrogen trapping of the pumping system during observation of the spectra mitigate the possibility of contamination from this source. The band at ~ 2300 cm^{-1} is assigned to the ν_3 band of CO_2. It appears as a reversal in intensity due to the lack of compensation in the reference beam. With this in mind it may be seen that on heating there is an apparent increase in the amount of CO_2, up to ~ 100°C, followed by a very rapid loss of CO_2 as a temperature of 200°C is approached. This increase occurs as a result of the rapid change in background due to the rapid loss of water from the sample. Although the loss of CO_2 in the region of 200°C is real the loss in the 100°C region can only be inferred.

Discussion

The assignment of infrared bands to adsorbed water or associated hydroxyl groups is primarily a process of correlation with information obtained from assignments made upon bulk materials. In this regard it may be seen from Fig. 9 that water of crystallization ordinarily leads to bands in the 3400 cm^{-1} region. As the degree of association becomes greater, as in the highly complexed water in the chlorates and perchlorates, the bands move to higher energies to ~ 3500 cm^{-1}. Finally, in the case of free hydroxyl groups, as in hydroxides (see Fig. 10) the bands move to ~ 3600 cm^{-1} and even 4000 cm^{-1}. In gas absorption studies, it has been noted that the band associated with water adsorbed on synthetic Zeolite (6) tends to assume a shape dependent upon the degree of surface coverage, Fig. 11. The 3μ band of water is associated with the stretching frequency of the O-H band in water. In

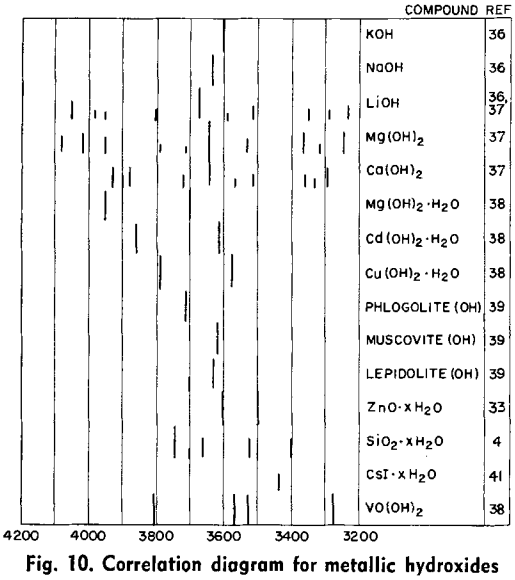

Fig. 10. Correlation diagram for metallic hydroxides

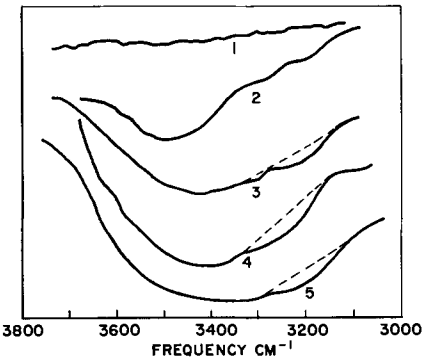

Fig. 11. Spectra of water absorbed on Zeolite. 1, Dehydrated on zeolite; 2, $\theta \simeq 0.34$ surface coverage; 3, $\theta \simeq 0.69$, 4 — $\theta \simeq 1.0$, 5 — liquid water, (6).

this regard it was observed that on increasing surface coverage the band broadened and moved from ~ 3486 to 3377 cm^{-1} with structure at 3200 cm^{-1}. This has been interpreted in terms of the polarity of the water molecule which will tend to orient its hydrogen atoms toward oxygen in the substrate. Since the observed value of the O-H stretching frequency was always found to be less than that for the vapor, its association is probably due to "hydrogen bonding." The broadening is assumed to be due to clustering, mutual interaction between water molecules, rather than further substrate association. This has been substantiated further by Cross, Burnham, and Leighton (43) who predicted that a di-coordinated water molecule, bonded through its hydrogen atoms, should have a stretching frequency of ~ 3500 cm^{-1}. Thus, the highly ionic materials, as potassium hydroxide, sodium hydroxide, etc., have a fundamental closer to that of the free water vapor than can be expected from materials having a high degree of hydrogen bonding.

A second means of assignment is by correlation based on similarity of structure. It may be noted that there is a pronounced mass effect in the alkali metal hydroxides which produce a shift in the fundamental stretching mode. Thus, one may expect a correlation between tantalum oxide and say vanadium oxide. The spectrum for this material has been obtained (38) and contains a fundamental frequency at 3804 cm^{-1} and bands at 3529 and 3566 cm^{-1} which are due to the independent or "free" OH stretching frequency. Further, the 3276 cm^{-1} band is due to an associated or hydrogen bonded mode. In this manner, it is seen that the simple picture of $VO(OH)_2$ is inadequate in that it does not encompass the complexities of this material which is more likely pictured as an interhydrogen bonded hydroxide. Passing on now to the case of tantalum oxide, a certain degree of similarity to vanadium oxide may be assumed, dependent on mass and bonding effects. The degree of similarity is pointed out in Fig. 7.

Finally, a third mode or approach is considered in assignment of water bands associated as an adsorbed phase. It has been proven in numerous structures that the degree of association of water to a substrate is a direct indication of the bonding strength. Thus, on heating the substrate, it is possible to distinguish the bands that leave or diminish in intensity, indicating a physically adsorbed phase in contrast to bands that remain, indicating a chemisorbed or tightly bonded phase. This may be seen in Fig. 7 by direct comparison to Fig. 11. At total surface coverage ($\theta = 1$) there is a large band centered at 3200 cm^{-1}. As the physically adsorbed layer is decreased (approximated at $\theta = 0.6$, 0.3, 0.1) the band decreases in intensity and moves to a higher frequency, indicating a greater degree of surface association (30).

Moving now to the case of the adsorption of carbon dioxide, it is fully documented that CO_2 will give bands at 2.688, 2.765, and 4.225μ (42). However, its effect in the adsorbed state is less understood. In work carried out on zinc oxide, it was found that the prime process was physical adsorption as indicated by the 4.225μ band. It should be pointed out that this is immediately in accord with the present observations, indicating also a prime process of physical adsorption of CO_2, followed by desorption on evacuation and heating.

Finally the identification of hydrocarbon residues must be considered. The fact that hydrocarbons, in general, give bands in the 3.5μ region is fully documented in ref. (41). It has also been shown that hydrocarbons produce essentially the same bands in the normal process of adsorption. This may be seen in the work of Eischens and Pliskins (1, 34) and many others (23, 44-47).

From the present study of the vibrational spectra of the adsorbed phase on tantalum oxide, it is evident that this oxide is prone to adsorption of substantial amounts of water and carbon dioxide. Further, a substantial portion of these adsorbed gases are removed under modest vacuum conditions (10^{-2}-10^{-3} Torr), while a further quantity of gas is removed only on heating. Carbon dioxide is removed at these pressures at ~ 100°C, while removal of strongly adsorbed water requires temperatures as high as 200°C. Two distinct types of adsorbed water were observed; physically adsorbed, and chemisorbed (3, 4, 5, 33, 34). A similar assignment can be made for carbon dioxide (1). In this regard it was noted in the thermal study of these samples that temperature cycling tended to accentuate the formation of chemisorbed water. It would be of interest to determine whether this will have a long term effect on the structure of the oxide as well as an effect on the dielectric properties.

An additional point was raised in this phase of the investigation with regard to the origin of the CH vibrational modes. Their position and band shape is strongly suggestive of chemisorbed CH residues (1, 34, 35). The fact that the residues were not removed on heating suggests a strongly bonded-heavy residue, yet does not preclude the possibility of actual structural incorporation. A possible source of such strongly adsorbed residues is the plasma used to prepare these films. Tantalum is deposited in an argon sputtering plasma at about 20μ pressure. However, it is known that the hydrocarbon background pressure can rise at least as high as 10^{-7} Torr. This will result in incorporation in the deposited film as cracked fractions. A further source of hydrocarbons occurs during the anodization of the tantalum film. Ethylene glycol and organic acids are employed as electrolytes. These will be adsorbed during the anodization and may account for the existence of carboxalate lines found in Fig. 3 and 4.

Without further information on the electrical properties of tantalum oxide during the adsorption, it is impossible to arrive at a definite statement regarding the electronic effects suggested by this information. However, it is known that adsorption of gases on a material having a measurable band gap will result in a process of charge compensation between the adsorbate and adsorbent. There is some physical evidence to indicate that these compensation processes are quite complex (48, 49). On the other hand, Sasaki (50) and others (51-56) have postulated the existence of a p-type layer on n-type or intrinsic Ta_2O_5. A possible source of this is the production of a high density of charged sites. Due to the localized nature of the compensation process in an insulator it seems evident that significant deviations from the average net charge may occur at selected regions of probable charge transfer. This will cause a material which may have been slightly extrinsic to become highly conductive through an accumulation layer or an inversion layer. Such layers may have characteristically large charge storage and transient decay as well as the unusually large rectification characteristics.

Manuscript received May 18, 1964; revised manuscript received Nov. 11, 1964. This paper was presented at the Pittsburgh Meeting, April 15-18, 1963.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

Effect of Ambients and Contact Area on the Asymmetric Conduction of Anodic Tantalum Oxide Films

N. Schwartz and M. Gresh

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

The effect of moisture and metallic contact area has been investigated on the asymmetry properties of anodic tantalum oxide films, approximately 2400Å thick. Moisture has been reversibly desorbed and adsorbed by vacuum baking followed by exposure at 50-85% RH. The cathodic currents are not affected significantly by this cycle, while the anodic leakage and charging current can be changed by factors of 10^6 and 10^2, respectively. The contact area experiment confirm previous results that the asymmetry is due to local inhomogeneities in the oxide film, since nonpolar characteristics, in the absence or presence of moisture, can be obtained with a contact area less than 0.01 mm^2. This result indicates that the moisture effect is associated with defects in the oxide film. The oxide film can thus be considered as a normal dielectric with high symmetrical anodic and cathodic breakdown voltages. Distributed on the average 0.1 mm apart throughout the film are heterogeneities of an unknown nature which cause a symmetrical but lower breakdown than the rest of the oxide. The asymmetry results from an increase in the anodic breakdown at these distinct sites due to the presence of water.

Many investigations have been make on the current transport properties of anodic oxide films. These films when measured in an aqueous electrolyte are capable of passing large currents when the parent metal is cathodic compared to the blocking features when it is anodic. The mechanisms that have been proposed for this effect (1,2) may be arbitrarily classified as heterogeneous or homogeneous phenomena. The first of these depends on local inhomogeneities in the oxide film which are responsible for the asymmetric current flow, with the rest of the oxide film having normal insulating dielectric properties. Evidence for this mechanism is based on the varying resistivity of an anodic tantalum oxide film determined by probe measurements (3), on deductions based on measurements with anodized tantalum rods (4), and on experiments with electrodes evaporated at different angles (5). The homogeneous mechanisms depend on detailed proposals concerning the electronic band structure of the oxide (6) on interactions with the aqueous electrolyte contact (1), and on transport of protons through the film (7).

Studies have been made on the differences between aqueous and nonaqueous electrolytes, the effect of salts in nonaqueous solvents, and the comparison between solvent or metallic contacts in attempts to evaluate the contribution of the counterelectrode to the asymmetry (1). In all of this work, however, there has been no definitive investigation of the effect of water on the conduction properties. The results in liquid sulfur dioxide indicate that the cathodic currents are considerably lower than those in aqueous solution (1), but it is difficult to determine to what extent moisture was excluded. In the normal aqueous electrolyte measurement, of course, the concentration of water cannot be readily varied. The printed tantalum oxide capacitor (8) is an excellent example of the characteristics obtained with uniform anodic oxide films with evaporated metallic contacts. With this capacitor the measurement of asymmetry does not depend on an electrolyte contact, and moisture can be reversibly desorbed or adsorbed. The present work is a preliminary one to phenomenologically define the effects of water on the conduction properties of anodic tantalum oxide films, using the printed capacitor as the vehicle. Moreover, since the counterelectrode contact area can be easily varied with this capacitor, it should be possible to distinguish between the heterogeneous and homogeneous mechanisms without confusion with respect to the variable pressure of a metallic probe (1).

The conduction properties of the printed capacitor do not exactly correlate with those of conventional capacitors, since the cathodic breakdown voltages are much larger than observed for either wet or solid electrolytic types. A strong similarity does exist, however, since there are asymmetric cathodic and anodic breakdown voltages (8). Moreover, anodic tantalum oxide formed on sputtered tantalum films demonstrates a cathodic current characteristic similar to the normal types when measured in aqueous electrolytes (1).[1] These features indicate that information gained by this study will be applicable to anodic oxide films in general.

Experimental Methods

Tantalum films were sputtered from high-purity tantalum cathodes through masks on cleaned soft glass microscope slides to a thickness of about 4500Å. The films were anodized to 100v at 105°C in an oxalic acid-ethylene glycol-water bath resulting in oxide films about 2400Å thick (8). In all cases, the anodization was interrupted to etch electrochemically the tantalum films in lithium chloride in methanol which has been proven beneficial in reducing anodic leakage or shorts (9), but by repeated experiments has been shown not to affect the asymmetry characteristics. The last step in the fabrication was the evaporation of a gold counterelectrode by tungsten filament evaporation techniques at pressures of 1×10^{-4} to 1×10^{-6} Torr.

Two forms of finished capacitor structures are shown in Fig. 1. By limiting the depth of immersion of the tantalum coated slide in the anodization electrolyte the upper contact area (marked Ta in Fig. 1) is not oxidized. Type 1C was used primarily in these studies with capacitors of about 0.035 μF. Type 1A permitted an anode area variation of about 3×10^{-2} to 10 mm^2 with corresponding capacitance values from 50 to 10,000 picofarads for 100v anodization at 105°C. The results reported in general represent the average of four or more capacitors.

Measurements of current-voltage characteristics were performed in two ways: (*a*) a normal current measurement after 1 min at a given voltage; and (*b*) an almost transient value. For this latter measurement,

[1] More detailed measurements with aqueous electrolytes indicate a higher complexity than originally reported (1) and these will be discussed in a later communication.

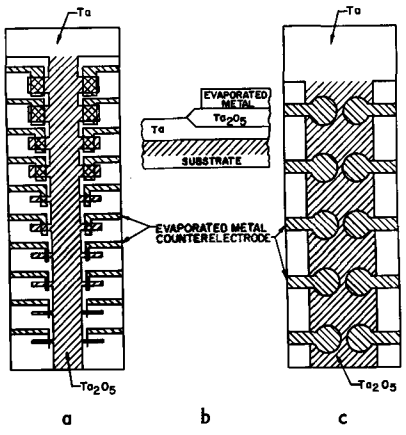

Fig. 1. Structures for the evaluation of printed tantalum oxide capacitors: (a) tantalum anode area variation; (b) schematic capacitor structure; (c) normal capacitor sample.

a motor driven potentiometer generated a single triangular wave at about ±1 v/sec or about 0.002 cps. The micromicroammeter is a direct current amplifier, and the output of the amplifier and the voltage from the potentiometer are displayed on an X-Y recorder. The voltage drop across the micromicroammeter is small compared to that of the test capacitor. A schematic diagram for the output of the measurement is shown in Fig. 2. The voltages are shown as anodic or cathodic with respect to the tantalum electrode of the capacitor. I_C, the ideal charging current generated by the constant increase or decrease in voltage, is given by Eq. [1]

$$I_C = C\frac{dV}{dt} \qquad [1]$$

and is directly proportional to the capacitance in farads and the rate of voltage rise in volts per second. $I_L{}^V$ is the usual leakage current, and $I_P{}^V$ is a polarization current, both of which are voltage dependent. This measurement does not separate the leakage current from the polarization current. No attempts have been made to fit the current-voltage curves analytically, and therefore arbitrary anodic, $V_A{}^B$, and cathodic, $V_C{}^B$, breakdown voltages have been defined as the voltages at which the currents (*i.e.*, ~ 0.1 μa) are three times the charging currents. This dynamic technique allows a rapid evaluation of the d-c properties of many capacitors and their "breakdown" voltages.

The effect of moisture on the properties of the capacitors was determined by baking at pressures from 1 x 10^{-5} to 1 x 10^{-6} Torr at 85° to 125°C for periods of 3 to 4 hr. The capacitors were then cooled to room temperature, and their a-c or d-c properties measured while they were still in the vacuum system through a multiheaded wire seal. Subsequently, moisture or air was admitted to the system and the properties of the films measured.

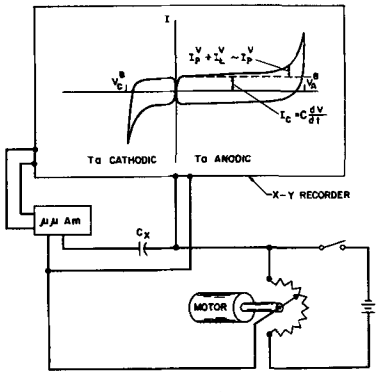

Fig. 2. Schematic output of the dynamic method for determining I-V characteristics.

The structural investigation of the anodic oxide films was performed in a Siemens Elmiskop electron microscope. The oxide films were anodized to 10-20v, since greater thicknesses do not allow sufficient electron transmission. The oxide films were stripped from the metal film by an electrochemical tantalum etching technique. A V-shaped pattern with about 0.25 in. legs and a 30° angle was scratched through the oxide being careful not to penetrate the glass. The tantalum film was etched anodically in a solution of 0.01 w/o (weight per cent) lithium chloride in methanol at room temperature at a potential of 10-20v. For a 3000-4000Å tantalum film, 0.5 cm^2/hr of tantalum was removed. The slide was washed and stored in methanol. When desired, the excess methanol was removed by a nitrogen gas stream, and a 0.25 mm layer of collodion was applied to the exposed tantalum oxide film. After drying overnight, the collodion was cut into convenient sections, and the sections were manually transferred to a screen and the collodion dissolved in butyl acetate.

Results

Effect of Moisture

Effect of moisture on the current-voltage characteristics.—A typical curve for a change in current characteristic after baking in vacuum at 125°C for 3 hr is shown in the upper part of Fig. 3. The anodic breakdown voltage has decreased by approximately 60v, while there has been little change in the cathodic breakdown voltage. In all cases studied, the vacuum baking cycle effected the cathodic current only negligibly, but increased the anodic current profoundly. Moreover, the decrease in anodic breakdown voltage is completely irreversible if the desiccated sample is exposed to dry air, but completely reversible when exposed to moist air. The rate of return to a high anodic breakdown voltage at 50% relative humidity in

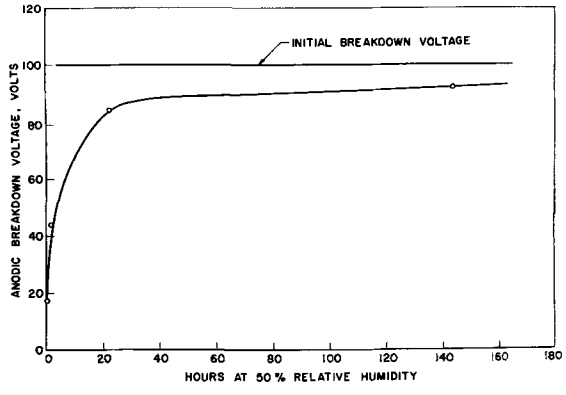

Fig. 4. Anodic breakdown voltage of a printed tantalum oxide capacitor at 50% relative humidity in air as a function of time after vacuum baking.

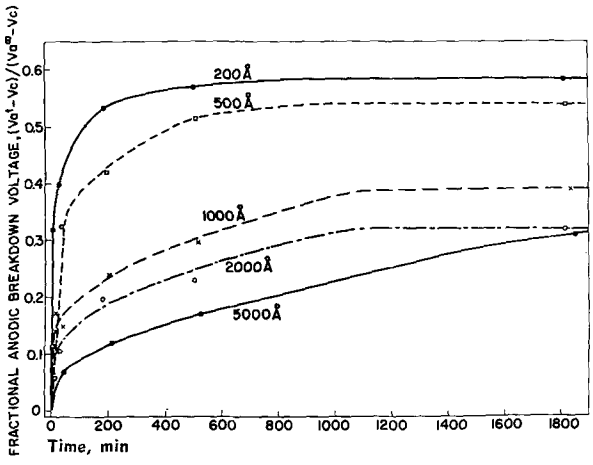

Fig. 5. Fractional anodic breakdown voltage at 45% relative humidity as a function of time after vacuum baking for capacitors with varying thickness of the gold counterelectrode. ($V_a{}^t$ is the anodic breakdown voltage at time t, $V_a{}^\infty$ is the maximum anodic breakdown voltage at infinite time at 85% RH, and V_c is the cathodic breakdown voltage).

air is demonstrated in Fig. 4 for a sample originally desiccated in vacuum at 125°C.

Figure 5 indicates the dependence of the rate of return on the thickness of the gold counterelectrode layer. Since the rate of return depends on the gold thickness it implies that the moisture must be diffusing through the metal electrode. Transmission electron micrographs of stripped gold films indicate that there are many cracks between islands for the thinnest films, which gradually decrease in number for the thicker films. This figure also demonstrates that the anodic breakdown voltage depends on the relative humidity, since for 85% RH the fractional anodic breakdown voltage is 1, rather than 0.3-0.6 illustrated for 45% RH.

When the moisture is removed from the dielectric by vacuum baking, there is only a 3% loss in capacitance over the entire frequency range of 0.1-5 kc, while the dielectric loss decreases by approximately 40%. Depending on the specific model assumed, this loss in capacitance may be associated with a 2-50Å layer in the surface, or a 0.1 μg/cm^2 of bulk water in the oxide film. Both of these values are approximate since a 1.5% loss in capacitance occurs where there is no large change in the d-c characteristics. This background change in capacitance may result from the annealing of the oxide film (6).

The influence of moisture is not specific to tantalum oxide films made from sputtered or evaporated tantalum metal anodes. A similar drying treatment has

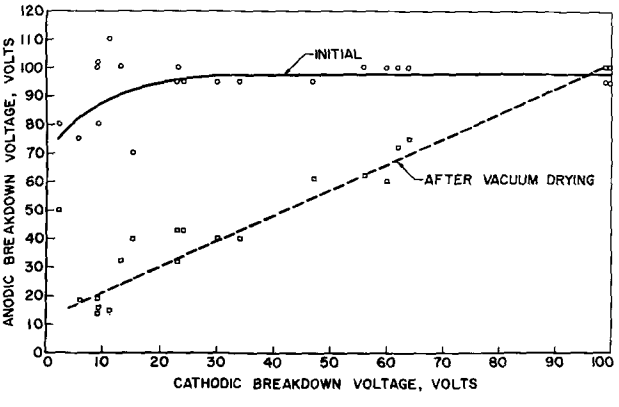

Fig. 6. Dependence of the anodic breakdown voltage of printed tantalum oxide capacitors on the initial cathodic breakdown voltage.

been applied to tantalum solid electrolyte capacitors where the anode is a sintered pellet of tantalum powder and the cathode is a porous layer of manganese dioxide (10). Baking a 1.0 μf capacitor at 125°C for 4 hr at 10^{-6} Torr, caused the anodic breakdown voltage[2] (Fig. 3) to decrease from 67 to 39v. As observed with the printed capacitor the presence or absence of moisture in the oxide has negligible effects on the cathodic characteristic. When this sample was exposed to 50% relative humidity, the anodic voltage characteristic was identical to the value before bake out within 30 min. This fast recovery for such a large area confirms that the slow rate of return for the printed capacitor may be limited by the penetration of the moisture through the gold counterelectrode. In the solid electrolytic capacitor, the manganese dioxide layer is porous enough to allow moisture to be adsorbed rapidly on the tantalum oxide layer.

During the course of this work, many capacitors have been investigated where the cathodic breakdown voltage had a range from 7 to 100v. The top curve in Fig. 6 indicates the anodic breakdown voltages before vacuum baking, and it is apparent that the initial values have no strong dependence on the original cathodic voltage. The lower curve illustrates the anodic breakdown voltages after the vacuum baking. A linear relationship exists between the final anodic breakdown voltage after baking and the original cathodic breakdown voltage. When the cathodic breakdown is in the range of 80-100v there is little change during the baking procedure.

Comparison of dynamic and static leakage measurements.—The data have been presented only when determined by the dynamic method described in the experimental section. For anodic oxide films a long polarization process occurs during current measurements. The dynamic method may tend to emphasize the polarization effect since the transit time is only of the order of 1 sec/v. Many different kinds of comparisons were made between the "static" and dynamic methods, which indicated that, although the latter did measure a high fraction of the polarization current, qualitatively it was a direct measure of the change in anodic characteristics due to the removal of moisture.

This conclusion was best illus rated by experiments on the effect of moisture on the charging rate and terminal leakage current, evaluated by current measurements as a function of time after the instantaneous ap-

[2] The breakdown voltage in this case is defined as for the printed capacitor type in the section on experimental methods.

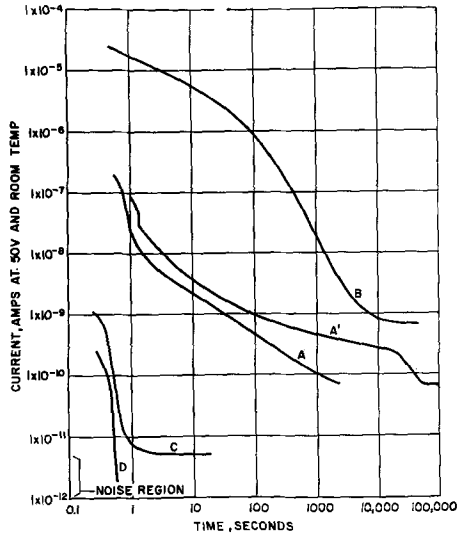

Fig. 7. 50V charging current measured at 25°C as a function of drying. a. In room ambient. b. In vacuum after bake out. c. In 17 Torr of water. a'. After return to room ambient. d. Polystyrene capacitor.

plication of 50v. The capacitors chosen for this study had a cathodic breakdown voltage of 10v in order to obtain a maximum sensitivity of electrical properties to moisture. Curve A (Fig. 7) is the result in a normal room ambient (*i.e.*, ~ 50% RH) and consists of a fast initial charging process followed by a slow step which approaches an analytical form given by Eq. [2].

$$I = At^{-n} \qquad [2]$$

The terminal leakage value appears to be about 5 x 10^{-11} amp for a time approaching 10,000 sec. This two-stage process is quite similar to the results reported for tantalum oxide films in aqueous electrolytes (11), where the first stage was attributed to a RC charging process, but with calculated R values considerably higher than that anticipated from the external circuit resistance. The second stage had the same analytical form of Eq. [2], and this process was presumed to be determined by trapping levels in the dielectric. These charging curves correspond to times beyond the normal expected dielectric charge and represent residual polarization of relatively large relaxation time.

Curve B (Fig. 7) is the result of measurement in vacuum after baking at 125°C at a pressure of 1 x 10^{-3} Torr for 3 hr. The fast initial charging process has disappeared, and the terminal leakage value is 7 x 10^{-10} amp. Curve C is the result of subsequently introducing into the vacuum system water vapor to a pressure of 17 Torr at room temperature (~ 70% humidity). The initial process has reappeared, and is now many times faster than that of curve A. The terminal leakage value is less than 5 x 10^{-12} amp, and could not be determined precisely because of background noise in the measuring circuit. This entire series of steps is essentially reversible, because the successive step of equilibrating the sample in a room ambient resulted in curve A'. Curve D is for a polystyrene capacitor of equivalent capacitance, and indicates the expected result for a low residual charge dielectric film.

Superficially these results confirm the interpretation that the presence of water in or on the oxide film determines both the charging rate and terminal leakage current. Depending on the moisture level, the initial charging rate varies by a factor of 10^6, while the terminal leakage value varies by a factor of 10^2.

There is a serious objection to concluding that the removal of moisture affects the initial charging rate by altering the parameter of a single mechanism. For the condition illustrated by curve B, the vacuum dried condition, the total charge passed in the first 100 sec is approximately 250 times larger than expected on the basis of the initial capacitance and charging voltage. This excess charge can arise in two possible ways: (*A*) The high initial current is truly a value associated with a dielectric breakdown process, but the dielectric can be "reformed" with continued application of a potential. This "reforming" designation does not imply only ionic transfer and may be related to the slow build up of an electronic barrier in some portion of the oxide. (*B*) An improbable large voltage dependent capacitance may arise from the removal of moisture, and its charging process may be exceptionally slow.

This latter possibility could be eliminated by capacitance measurements as a function of bias, and preliminary measurements indicate no large changes in capacitance with bias. For the purposes of this paper, therefore, it will be assumed that the dynamic technique gives a true measure of the breakdown voltage on drying the sample.

Cathodic Breakdown Voltage and Area Dependence

Vermilyea (3) has demonstrated by probe measurements on tantalum oxide prepared on bulk anodes that an area effect exists with respect to the cathodic currents. Despite the large cathodic currents that can be passed through these films in aqueous electrolytes, very small metallic probe measurements indicated that different areas were either highly insulating or conducting. This would imply that the rectification phenomenon observed in electrolytic solutions is related to discrete points in the oxide films rather than being a homogeneous effect associated with the entire film. These experiments have been criticized in several ways, but perhaps the most valid one is that it is difficult to use metal probes and to know conclusively whether the probe is puncturing the oxide films due to point pressures in some cases, and not making contact in other cases. It has been confirmed in this study that it is quite easy to puncture the oxide films even when lightly touching it with a metallic probe. For the tantalum oxide printed capacitor, however, small area evaporated counterelectrodes are easily attained, and this type of contact avoids the ambiguity associated with variable pressure of probes. Moreover, the area of the contact is easily determined by capacitance measurements. The structure used for these experiments is illustrated in Fig. 1a. These slides were prepared by the usual procedure utilizing gold counterelectrodes, and the important variable for study was the cathodic breakdown voltage. These results are plotted in Fig. 8 for two different sputtering runs.

The results demonstrate that down to about 300 picofarads (or 0.3 mm^2) the cathodic breakdown voltage is fairly constant. The voltage rises sharply as the capacitance decreases to the order of 50 picofarads. The shape of the curve depends to some extent on the sputtering run. An interpretation of these curves is that the cathodic breakdown voltage depends on discrete inhomogeneities in the oxide films. The probability of making contact to such a local defect becomes much smaller as the area of the capacitor is decreased. In some of these curves, at about 50 picofarads the full expected cathodic breakdown voltage of tantalum oxide is realized. These data, therefore, entirely confirm Vermilyea's experiments with respect to local defects determining the cathodic characteristics of anodic oxide films.

There is a surprising feature about these data. For each capacitance value, four individual capacitors were tested, and at each capacitance value there is very little spread for the breakdown voltage. If a local inhomogeneity mechanism was of importance, a much broader distribution at high cathodic breakdown voltages would be expected. This feature has not been entirely resolved, but similar measurements have been obtained for a large number of capacitors with values of the order of 50-100 picofarads. For these data (Fig. 9), slides from three different runs were used. One of these slides had capacitors with very low breakdown voltage, and high breakdown voltages could not be obtained at all. For the other two slides, there is a distribution of cathodic breakdown voltages as would

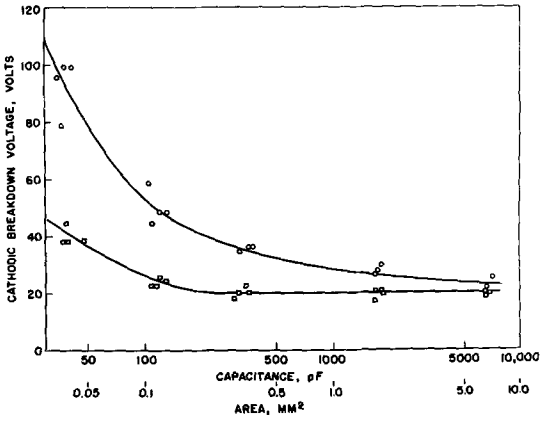

Fig. 8. Cathodic breakdown voltage as a function of the capacitance of printed tantalum oxide capacitors. All formations at 100v at 110°C.

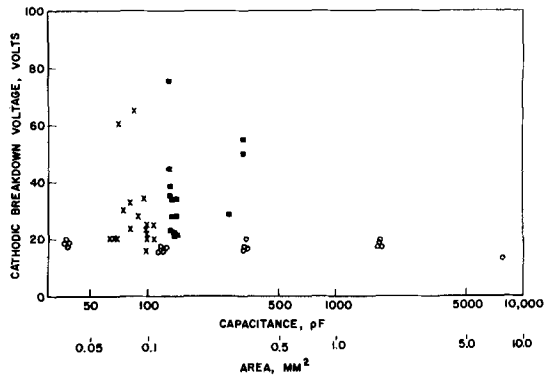

Fig. 9. Distribution of cathodic breakdown voltages for small area capacitors. Each symbol represents an individual sputtering run.

be expected from a local defect mechanism. The tight distribution of the initial data of Fig. 8 may only be due to the small sample size. In attempting to quantitatively fit these data to a model based on localized defects (12) some anomalies have appeared with respect to the exact shape of the curve, and further work is required on this problem. However, in general, it may be concluded that a localized defect mechanism is responsible for the change in breakdown voltage with the variation of area.

As has been indicated previously, the moisture effect for the anodic characteristics depends on the cathodic breakdown voltage. As the cathodic breakdown value approaches 70- 80v the humidity dependence essentially disappears. In fact, the data presented in Fig. 6 is a representation of capacitors of different areas.

Electron Microscope Investigations

Since the previous experiments indicate that local defects exist in the oxide films, some initial electron microscope investigations have been made in an effort to confirm their presence. When the stripped oxide films were investigated by electron transmission, a variety of defect types could be found. They consisted of small crystallized areas, pores which did not completely penetrate the films, and long cracks. Generally, the major fraction of the oxide film was homogeneous and consisted of amorphous tantalum oxide. The defects when they were observed were generally localized in an area of 100 μ^2, but at least one defect was always observed on every specimen screen which has an area of 1 mm^2. At present, it is not clear whether these defects were present originally or were introduced during the stripping of the film. More extensive work is required with respect to the stripping process, the type of defects, their incidence, and their relation to electrical properties and variation of process techniques.

Discussion

The results presented in the previous sections can be summarized in the following conclusions with respect to the conduction properties of anodic tantalum oxide:

(*A*) The anodic currents are decreased by a specific interaction with water, but not with oxygen or nitrogen. However, a possible interaction with a mixture of water and oxygen has not been completely excluded.

(*B*) The interaction with water involves the mechanism of the anodic leakage and capacitive decay currents, but not the cathodic currents.

(*C*) The cathodic currents are related to a local defect, or heterogeneous mechanism, in the oxide film.

(*D*) Since the interaction with moisture described in (*B*) disappears when high cathodic breakdown voltages are obtained by area variation, the moisture effect as well must depend on a local defect mechanism.

The implication of these results is that at defect sites there is a nonpolar oxide film with an anodic breakdown strength roughly equivalent to the cathodic breakdown value. At these sites, however, there is an anodic barrier to current flow caused by the presence of moisture, resulting in high anodic breakdown voltages. Over the remaining area of the oxide, the moisture effect is not important, and the film is nonpolar with cathodic and anodic breakdown strengths approximating the original anodization voltage. Unfortunately, most of these conclusions depend on an interaction with local defects, and no specific mechanism can be proposed until more information is gained about their nature, incidence, and origin. The initial electron microscope studies have revealed physical defects in the oxide film, but they have not been reported in detail since it is not completely certain that they were present in the unstripped oxide films. Compositional defects caused by deviations of stoichiometry or impurities are other possible suspects.

This conclusion of the importance of water in determining the anodic characteristics is sharply different than other interpretations of the asymmetry which emphasize an abnormal cathodic current relative to the expected properties of a normal dielectric. The present interpretation indicates that the cathodic currents are normal, while the anodic breakdown is unusually high due to the presence of moisture.[3]

The two unusual features of these results are the sensitivity to moisture of the anodic leakage and charging currents. In an effort to establish a single mechanism to explain these results, it is tempting to resort to a local defect mechanism proposed by Young (4). The local defect is specifically a microfissure (*i.e.*, a crack or hole) in the oxide. When the tantalum is the cathode in an aqueous solution, large currents can flow because hydrogen is liberated, which because of size and tantalum embrittlement considerations, would not be trapped in the microfissure. When the tantalum is anodic, oxygen would be liberated which would be trapped as bubbles and thus maintain the full dielectric strength of the oxide. To adapt this proposal to the present results, it is conceivable that the vacuum bake out would remove both moisture and oxygen from the microfissures. This would imply that the cathodic characteristics would greatly improve, while the anodic characteristics would not change essentially. It is difficult to rationalize the increase in anodic leakage, unless due to the vacuum treatment the oxide essentially collapsed around the fissure resulting in more intimate contact of the gold to a thinner portion of the oxide film. Of greater consequence, however, is the difficulty in relating the charges in the capacitor current decay process to a microfissure mechanism. Recent studies (11) have indicated that this process is determined by electron traps in the oxide film, which if true, indicates that water is intimately involved in the dissociation and recombination of traps and electrons. In general, the microfissure mechanism, though having interesting features, fails to correlate the general conclusions in detail.

Further studies are required in order to obtain a more detailed understanding of this problem, with an investigation of the defect type perhaps being the most important. One of the interesting questions is whether the presence of moisture affects the oxide as a whole as well as being important in local areas. This is of importance in understanding the influence of moisture on the capacitor charging mechanism. Studies on the charging and discharging process with ultraviolet illumination and varying amounts of moisture as variables might be quite fruitful. An associated study (13) on the infrared spectra of the surface adsorbed species has already indicated the presence of water, carbon dioxide, and hydrocarbons, whose concentration change with temperature and pressure. Experiments with tritiated water have also indicated the

[3] This conclusion holds only within the evaporated electrode configuration. As has been indicated earlier, an aqueous electrolyte contact does cause a change in the cathodic breakdown voltage.

presence of water in or on the oxide film (14). Further studies are required to relate these changes in concentration with electrical properties of the tantalum oxide film.

Acknowledgments

The authors wish to express their appreciation to M. Urban for designing the switching circuits for the dynamic method for determining I-V characteristics, and to C. J. Calbick for his electron microscope studies of thin tantalum oxide films.

The Preparation and Properties of GaAs-InAs Mixed Crystals

Henry T. Minden

Sperry Rand Research Center, Sudbury, Massachusetts

ABSTRACT

Mixed crystals of $Ga_xIn_{1-x}As$ have been prepared by a halogen vapor transport method. The entire composition range was covered and electroluminescent diodes were made. The dependence of emission energy at 77°K on composition was determined. Conditions were determined for the epitaxial deposition of GaAs-InAs mixed crystal layers on pure GaAs needs. A halogen-flow system was used, and liquid Ga-In solutions were used in the source. It was discovered that considerable fractionation occurred in the deposition reaction.

Both GaAs and InAs are direct band-gap semiconductors. P-N junctions in single crystals show strong injection electroluminescence, especially at low temperatures. Stimulated emission has been observed in GaAs and InAs junction diodes which were made in the form of optically resonant cavities (1, 2). At 77°K the emission peak in GaAs is at .8400μ, while for InAs the emission is at 3.5μ. Electroluminescence and stimulated emission have also been observed in diodes which were made from quasi-binary mixed crystals of GaAs and InAs (3). The optical emission fell at wavelengths between the extremes represented by the two pure materials. It remains to determine the dependence of emission wavelength on composition, much as has been done with GaAs-GaP mixed crystals (4).

The electroluminescent emission in direct III-V compounds occurs at energies which are about 0.02 ev lower than the band gap, and the emission energy varies with temperature much as does the gap. The variation with composition of the energy gap at room temperature has been determined for the GaAs-InAs system by optical absorption measurements (5). The mixed crystals were prepared from the melt, however, and there was considerable uncertainty in the measurement of both the composition and the band gap.

It has been found, however, that homogeneous mixed crystals of controllable composition can be grown by halogen vapor transport techniques (6, 7). This technique was used to prepare mixed crystals of GaAs-InAs throughout the whole composition range. Electroluminescent diodes were prepared and the peak emission wavelength was determined as a function of composition. Mixed crystal epitaxial layers were also prepared by deposition on pure GaAs in a halogen-flow system.

Material Preparation

Closed-tube transport.—To prepare bulk crystals of InAs-GaAs we used a slight modification of the so-called closed-tube technique (7). Weighed amounts of powdered GaAs and InAs were sealed in a small, evacuated quartz tube along with some Cl_2 gas. The Cl_2 reacted with the arsenides at room temperature, and all of the material was at one end of the tube. The tube was put in a furnace which had a large temperature gradient. The reactants were at the hot end of the tube (at about 700°C). Complete transport occurred in about ½ hr, and the deposit was generally in the form of small flakes. The tube was then placed in a close-fitting Inconel bomb which had thermocouples placed at either end. The bomb was centered in a cylindrical furnace in such a way that the temperature difference across the quartz tube was roughly 10°C. As before, the source was at the hot end. A mean temperature of 850° was used for low GaAs concentrations, while for GaAs concentrations of greater than about 50% temperatures up to 950° were needed for large crystal growth. The runs were generally made overnight, although longer times were used. Usually the transport was incomplete. As might be expected, the larger the temperature gradient, the faster the transport, and the smaller the crystallite size.

Typical crystals are shown in Fig. 1. They generally had a lamellar structure with well-developed tetrahedral sides. The sides were {111} facets, as determined by x-ray diffraction and by the way the crystallites cleaved. The polarity of the facets was not determined.

Open-tube deposition.—The flow system which was used to deposit epitaxial layers on seed crystals has been described elsewhere (8). A mixture of H_2 and HCl was passed over arsenic metal at 500° and then over a boat filled with a Ga-In solution which was at 850°-900°. Downstream there was a seed crystal of GaAs which was held at temperatures ranging from 650°-750°. Both the H_2 and HCl flow rates were 2-4 x 10^{-3} mole/min, and the indications were that the transport and deposition were almost quantitative in the amount of HCl. Of course, most of the actual deposi-

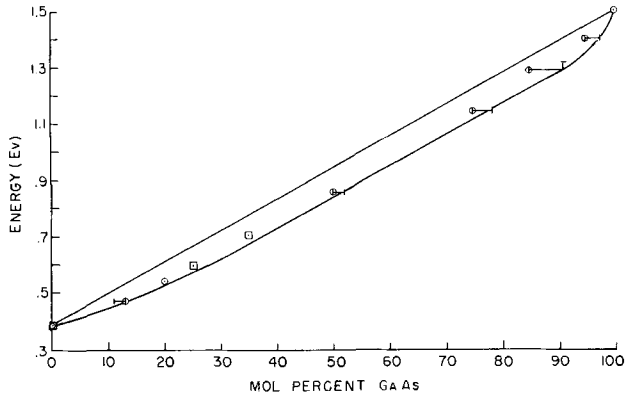

Fig. 2. Dependence of electroluminescence energy on composition for InAs-GaAs mixed crystal diodes. The peak emission wavelength was measured at 77°K. Squares are data of Strauss *et al.* (3) taken at 2°K.

tion occurred on the walls of the tubes and on the seed holder. The deposition rates on the seed were about 15-40 μ/hr; layer thicknesses of 20-50μ were used.

Diode Fabrication

All the material we prepared for this study was unintentionally doped n-type. The crystallites which were obtained from the closed-tube transport were lapped flat on one side. The other side was a naturally formed specular facet. Several such crystallites were sealed in an evacuated tube along with a few mg each of Zn and As. The diffusion runs lasted 2 hr, and temperatures from 650° to 700° were used, depending on the GaAs concentration. The junctions so formed were about 30μ deep.

The crystallites were cleaved or ultrasonically cut into pellets, and the lapped side was alloyed to a conventional transistor header which was In-Au plated. The contact to the specular p-side was made by alloying an In sphere. Occasionally, the n-side of the pellet was alloyed across a hole in the header in order that the radiation could be viewed from the broad area of the junction rather than edge-on.

The epitaxial material was treated in a similar fashion, except that the diffusion times were shorter to prevent the diffusion from penetrating to the GaAs substrate.

Measurements

The closed-tube technique gave compositions which were definitive and reproducible. The initial measurement was the proportion of InAs and GaAs which was weighed out at the start of the preparation. The lattice constant of the synthesized crystals was then measured for several samples by means of x-ray powder patterns.[1] The diffraction lines were sharp and well-defined, and they corresponded to known reflections. From the lattice constants and Vegard's law (9) the composition was determined.

The electroluminescent spectra of diodes made from these crystals were measured at 77°K. The I-V characteristics were measured as a matter of course. Quite naturally, there was a good correlation between the energy of the emission peak and the voltage at which the forward-current break occurred. For a given composition, the maximum variation of the emission peak was about $\pm$ 2%.

The composition which was obtained in the flow system was not so well-defined as for the closed-tube technique. In particular, the composition of the deposit was not simply related to the composition of the source. Therefore, in order to determine the relationship between the source and deposit compositions, several techniques were used to determine the nature of the epitaxial layer. Lattice constants were measured with an x-ray diffractometer. For some samples the optical absorption edge was measured at room temperature.

[1] These measurements were done by W. Croft and R. Carter.

As with the lattice constant, a linear interpolation was made on an energy scale to determine the composition. Although this is not strictly justified, it is sufficiently accurate considering the scatter of our results in these experiments. Finally, on some samples diodes were made and the electroluminescent emission peak was determined at 77°K. Again, a linear interpolation to determine the composition was deemed sufficient for our purpose.

Results

Figure 2 shows the variation of electroluminescence energy with composition. Where a composition range is indicated, the left-hand end of the line represents the composition as determined by the starting proportions, while the right-hand end gives the x-ray composition. There was obviously a slight fractionation which favored GaAs in the deposit. We believe that this can be minimized by repeated grinding and retransport of the deposit. Table I shows the starting compositions which were used and the actual lattice constants which were measured for the transported material. (Note that at around 10% GaAs the deposit was richer in In than the source.)

The peak of the emission spectrum was measured at 77°K. The lines were about 0.02 ev wide, and there was no detectable shift of the peak or line narrowing with increasing diode current. No attempts were made to observe stimulated emission. The emission energy was consistently below the value calculated for a given composition by a linear interpolation between the terminal energies. This is in agreement with work done on the variation of band gap with composition (5) except that our deviations from linearity were not so great.

As mentioned above, the composition of the epitaxial layers which were deposited in the flow system could not be predicted from the proportions of Ga and In in the source. Figure 3 shows the relationship between the source composition and the composition of the deposit. GaAs definitely tended to deposit more readily than InAs. Moreover, between source compositions of 5% and 10% Ga the concentration of GaAs in the deposit varied between 15% and 60%. This made it diffi-

Table I. Starting compositions

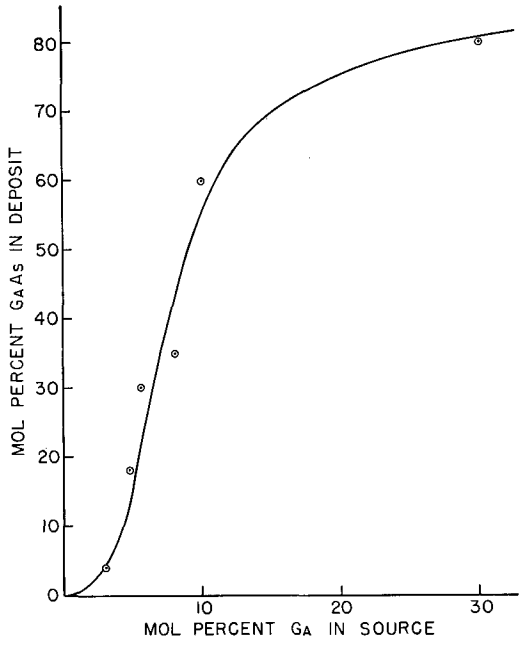

Fig. 3. Fractionation in the epitaxial deposition of InAs-GaAs by an open-tube flow system. The source was a In-Ga liquid metal solution; GaAs seed crystals were used.

cult, but not impossible, to control the deposit concentration in this range. On the other hand, above deposit concentrations of 80% GaAs the composition of the source had little effect on the deposit. Other factors, such as the seed temperatures and the flow rates, were relatively more important. For instance, we observed that higher seed temperatures favored the deposition of GaAs. We have not investigated this region of compositions in detail, but there were indications that when there was as much as 10% In in the source, the amount of In which appeared in the deposit was negligible. In any case, deposit concentrations having less than 10% InAs would be quite difficult to control in the flow system.

The deposition temperatures for InAs and its alloys with GaAs were substantially below those required for GaAs. At these temperatures no observable etching of the GaAs seed occurred. Deposits on polished seeds were sectioned and the interfaces were flat and also abrupt compared to the layer thickness. When pure In was used as the source, x-ray diffraction analysis showed that even thin layers were indeed composed of pure InAs. These results seem to preclude the possibility that the excess GaAs content in the layers came from an etching and redeposition of the seed as has been observed for Si and GaAs-GaP.

As a given boatful of source material was used up during the course of a series of runs, the composition of the deposited layers remained essentially constant. The halogen take-up reactions appeared to follow a Raoult's law type of behavior, while the fractionation took place on deposition. Although the source composition was the principal factor which affected the deposit composition, the deposition temperature played a role. Higher temperatures favored the deposition of GaAs. In fact, efficient deposition of pure InAs took place only at temperatures below about 700°, whereas GaAs deposition was readily possible up to about 780°. This result is to be contrasted with the observation that GaAs and GaP deposit at the same temperature (8). Quite obviously, the deposition reaction is dependent on the group III halide rather than the group V element. No inference can be drawn from our experiments, however, as to whether there was any interaction between the indium and gallium chlorides during the deposition process.

Conclusion

The closed-tube halide transport process is a very good method for obtaining homogeneous mixed crystals of III-V compounds. This has now been shown in the cases of GaAs-GaP and InAs-GaAs, but there is no reason why it should not work for such systems as InAs-InP (10) and possibly GaAs-AlAs (11). The closed-tube method for InAs-GaAs is superior to the flow system for composition control. On the other hand, if epitaxial layers are desired, the advantages of the closed-tube technique are not so clear. Unless extreme care is taken, etching of the GaAs seed takes place, and the deposited composition will be markedly and uncontrollably different from that determined by the proportion of the reactants which are initially used. Similar effects have been noted for GaAs-GaP layers which were deposited in a closed tube.

There is one final disadvantage to layers which were deposited in the flow system. The electroluminescent emission from junctions made in our epitaxial material was relatively weak. Also, the reverse leakage in the diode I-V characteristics was large even at 77°K. We concluded that our layers had a high electron concentration in spite of the fact that they were not intentionally doped. From past experience we suspect that the contaminant was Si. The Si could have readily been picked up from the quartz boat in which the In-Ga liquid source was contained. This contamination might be overcome by using other boat materials, such as high purity graphite or boron nitride. Also, the finely divided, meltgrown mixed crystal could be used as a source.

Acknowledgment

The author wishes to thank Dr. R. Sirrine for communicating the results of his closed-tube experiments which were done at the MIT Lincoln Laboratory. Mr. A. Sears did most of the material preparation and made most of the diodes. Mr. J. Donahue assisted in the measurements.

Manuscript received Sept. 30, 1964. This work was supported by the U.S. Air Force Avionics Laboratory, Wright-Patterson AFB, under Contract No. AF33 (615)-1120.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

Calcium Orthovanadate $Ca_3(VO_4)_2$–A New Laser Host Crystal

L. H. Brixner and P. A. Flournoy

Pigments Department and Engineering Physics Laboratory, respectively,

Experimental Station, E. I. du Pont de Nemours & Co., Inc., Wilmington, Delaware

ABSTRACT

The fluorescent emission of Nd^{+3}, Sm^{+3}, Eu^{+3}, Tb^{+3}, and Dy^{+3} in a $Ca_3(VO_4)_2$ host were determined as functions of rare earth concentrations, and the optimum rare earth concentration for maximum fluorescence was established for each case. Single crystals containing these elements as active ions were grown by the Czochralski technique, and fluorescent lifetime and linewidth were determined for some. Excitation spectra for $Eu_{0.3}Na_{0.3}Ca_{2.4}(VO_4)_2$ indicate energy exchange between VO_4^{-3} and Eu^{+3}. A comparison of absorption spectra for $Ca_3(VO_4)_2$:Nd and $CaMoO_4$:Nd shows the considerably stronger absorption of the vanadate host especially in the 5800Å region. A single crystal of the specific composition $Nd_{0.08}Ca_{2.88}\phi_{0.04}(VO_4)_2$ was machined into a Fabry-Perot resonator and stimulated emission was observed at 300°K with a threshold of 3000 joules.

Many hosts for rare earth ions comprising ternary calcium-oxo-metallates have been studied, with $CaWO_4$ (1) receiving the most intensive investigation. Recently calcium niobate [$Ca(NbO_3)_2$] (2) was added, and now we can also include $Ca_3(VO_4)_2$ in this group. In a previous note (3), the growing of single crystal $Ca_3(VO_4)_2$, as well as its structure and some other properties, were described. This paper deals with fluorescent emission studies of various rare earths substituted in the $Ca_3(VO_4)_2$ lattice as a host. Since a trivalent rare earth ion is introduced into the cation site of divalent calcium, some valence compensating scheme has to be applied to restore electroneutrality. In the absence of any other ions, the simplest balancing occurs according to the vacancy mechanism given in Eq. [1]

$$(1-x)\ Ca_3^{+2}(VO_4)_2 + 2x\ Ln^{+3}VO_4 \rightarrow Ca_{3-3x}^{+2}Ln_{2x}^{+3}\phi_x(VO_4)_2 \quad [1]$$

One can see that for each three calcium ions, only two rare earth ions are substituted and the third site is left vacant, as indicated by the symbol ϕ. In the case of $Ca_3(VO_4)_2$, this deficiency apparently does not create any particular stress or strain in the lattice, since crystals of these compositions can be grown quite readily. A second mechanism involves univalent sodium and compensation occurs in the cation sites according to Eq. [2]

$$(3-2x)\ Ca_3^{+2}(VO_4)_2 + 2x\ Na_{1.5}^{+1}Ln_{1.5}^{+3}(VO_4)_2 \rightarrow 3Ca_{3-2x}^{+2}Na_x^{+1}Ln_x^{+3}(VO_4)_2 \quad [2]$$

Obviously each Na^{+1}/Ln^{+3} pair replaces two divalent calcium ions in this case and, due to the rather good match of ionic radii, solid solubility of $Na_{1.5}Ln_{1.5}(VO_4)_2$ in the $Ca_3(VO_4)_2$ is rather high (up to about $x = 0.6$). The $Na_{1.5}Ln_{1.5}(VO_4)_2$ structure, at least for the case where Ln is Nd, however, is different from that of $Ca_3(VO_4)_2$; it is tetragonal with $a_t = 7.338$Å, $c_t = 5.456$Å.

A third valence compensation mechanism involves compensation in the anion site and is represented by Eq. [3].

$$(1-x)Ca_3^{+2}(V^{+5}O_4)_2 + xCa^{+2}Ln_2^{+3}(Ti^{+4}O_4)_2 \rightarrow Ca_{3-2x}^{+2}Ln_{2x}^{+3}(V_{1-x}^{+5}Ti_x^{+4}O_4)_2 \quad [3]$$

Electroneutrality in this scheme is restored by replacing a pentavalent vanadium ion by tetravalent titanium for each neodymium introduced in the calcium site. Here again the structure of $CaNd(TiO_4)_2$ is different from that of $Ca_3(VO_4)_2$ but has not yet been determined. Similar compensation techniques for other hosts have been used by Nassau (4) and Ballman (2).

Fluorescent emission studies were carried out on samples prepared according to all three schemes. Laser action was observed on a Nd-doped crystal compensated according to scheme [1]. In growing single crystals this mechanism gave the best quality. Scheme [2] was next best, and scheme [3] posed the greatest problem. Ti^{+4} compensated single crystals invariably turned deep brown and opaque on growing, and even subsequent annealing under oxygen failed to yield optically clear crystals.

Fluorescence Studies

All samples for these studies were in polycrystalline form, prepared from the best commercially available chemicals. The rare earth oxides were from the Lindsay Chemical Division, V_2O_5 from the Vanadium Corporation of America, and $CaCO_3$ as well as Na_2CO_3 were standard Baker and Adamson analytical grade chemicals. The preparation was done in two steps: first the constituent components, weighed to the nearest 1/10 mg, were carefully mixed and heated in platinum containers to 650°C (just under the melting point of V_2O_5) for 10 to 14 hr. Homogenization was then achieved by ballmilling under acetone in a mechanical agate ballmill. The dried powders were subsequently compacted into 1 in. diameter pellets and refired at 1200°C for another 10 to 14 hr. Coarse fluorescent scans of the samples emitting in the visible were obtained with a Beckman DK2 recording spectrometer with a mercury lamp F4T5/BL (GE designation) through a Schott UG-11 filter which cuts off above 4000Å. The detector used was a photomultiplier tube 1P28 (RCA). More refined spectra were taken from samples excited by a filtered AH-3 mercury discharge lamp (primarily 3660Å radiation) and a L&N 0.5 meter Ebert mount grating spec-

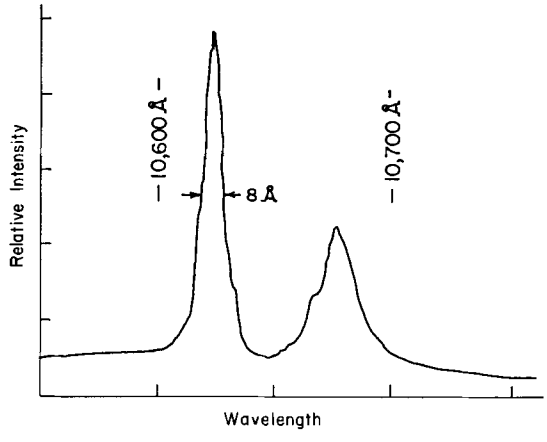

Fig. 1. Fluorescent emission spectrum of $Nd_{0.08}Na_{0.08}Ca_{2.84}(VO_4)_2$ at 77°K.

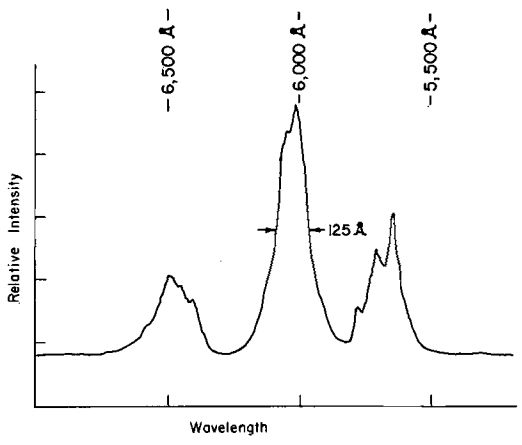

Fig. 2. Fluorescent emission spectrum of $Sm_{0.08}Na_{0.08}Ca_{2.84}(VO_4)_2$ at 300°K.

trometer using again a 1P28 photomultiplier detector. For the infrared spectra a Bausch and Lomb 2-meter grating spectrograph was used in conjunction with Kodak 1-Z infrared sensitive spectroscopic plates. Typical spectra for some characteristic compositions are given in Fig. 1-4. Figure 1 shows emission from a sodium compensated Nd sample where the main fluorescence peak at 1.063μ clearly dominates the other weak emission lines at 77°K. The linewidth is 8 cm^{-1} at 77°K and 40 cm^{-1} at 300°K. In Fig. 10 we will show the fluorescent emission of Nd from a vacancy compensated single crystal, where the lines are considerably broader with width of 180Å at 300°K and 90Å at 77°K. Figure 2 represents the room temperature spectrum of the most intensely fluorescing Sm-composition, and one can see that it consists of essentially three very broad lines centered around 5635, 6010, and 6490Å. The halfwidth of the predominant center line is about 120Å. Surprisingly, this line narrowed only slightly

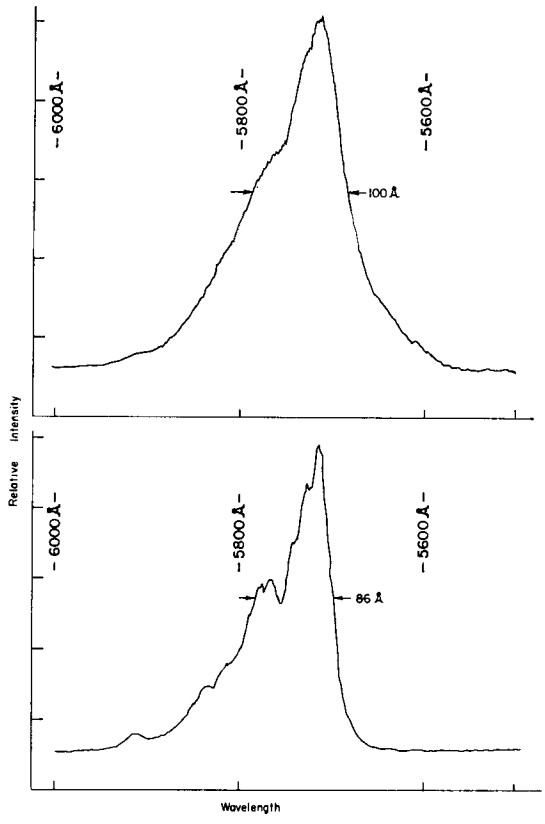

Fig. 4. Fluorescent emission spectrum of $Dy_{0.10}Na_{0.10}Ca_{2.80}(VO_4)_2$ at 300°K (top) and 77°K (bottom).

in going to liquid nitrogen temperature. This indicates that the broadening might be due to crystal imperfections and strain, since the first spectra in the visible were run with very fine powders exhibiting relatively large surface to volume ratios. However subsequent fluorescent emission studies of a single crystal of the composition $Sm_{0.08}\phi_{0.04}Ca_{2.88}(VO_4)_2$ again showed only rather insignificant line narrowing in going from 300° to 77°K. This small spectral difference between room temperature and liquid nitrogen temperature was also observed for the europium case and is best demonstrated in Fig. 3 by giving the spectra for both temperatures. One can see that the spectra are essentially identical with the most intense line at 6137Å. Another series of four weak lines is centered around 5935Å, and there is a weak line at 6075Å. Here again a single crystal of the composition $Eu_{0.3}\phi_{0.15}Ca_{2.55}(VO_4)_2$ gave an essentially identical spectrum with a halfwidth of 19.2Å at 77°K and 16.8Å at 300°K, indicating that the nonnarrowing of lines is not associated only with the powders.

The emission spectrum for the terbium doped sample is extremely weak and almost completely quenched due to the fact that the host absorbs in this region. The spectrum consists essentially of one very broad line centered around 5380Å with a halfwidth of some 125Å. Finally in Fig. 4 the room temperature as well as the liquid nitrogen spectrum of Na-compensated Dy-doped $Ca_3(VO_4)_2$ is given. Here again only insignificant line narrowing occurs, for the powder as well as a single crystal of the composition $Dy_{0.03}\phi_{0.015}Ca_{2.955}(VO_4)_2$. The predominant emission is centered around 5715Å. This band of lines of about 100Å halfwidth narrows to some 80Å at liquid nitrogen and begins to get resolved into a number of individual lines. However, even at 77°K line splitting is not very sharp. Another weaker emission band not represented in Fig. 4 is centered around 4800Å and a somewhat sharper line occurs at 4915Å.

The optimum doping concentration yielding maximum intensity of fluorescence for Nd^{+3} in Nd_xNa_x-

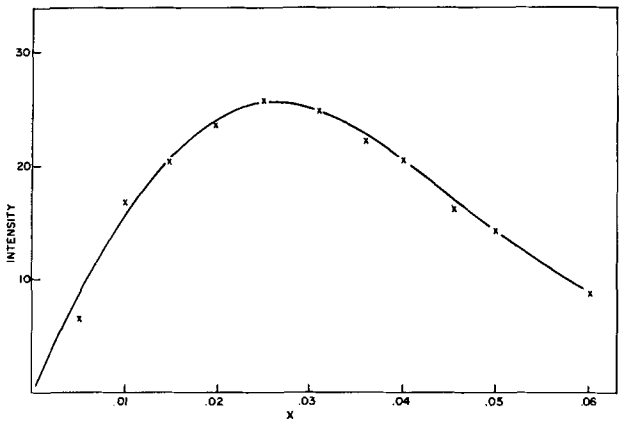

Fig. 5. Fluorescent emission as a function of X for the $Nd_{2x}\phi_xCa_{3-3x}(VO_4)_2$ system.

$Ca_{3-2x}(VO_4)_2$ was found to be at $x = 0.1$. In the case of the Nd compositions, the Ti^{+4} as well as the vacancy compensating mechanism was also applied, and it was of interest to see that the location of this optimum shifted to the considerably lower Nd^{+3} concentrations of $x = 0.02$ for the Ti^{+4} compensation. The optimum x for Nd^{+3} in $Nd_{2x}\phi_xCa_{3-3x}(VO_4)_2$ was found to be 0.025, and the rather typical plot for intensity of fluorescent emission as a function of the Nd concentration is given in Fig. 5. Starting from $x = 0$, one can see the rather steep increase to the optimum and then gradual intensity decrease until eventually complete concentration quenching occurs. The shape of the curve for fluorescence *vs.* concentration for the other rare earths studied was very similar, and for the purpose of a comparison the peak intensities of the strongest line are summarized in Table I for those rare earths emitting in the visible. Fluorescent lifetime for a number of vacancy compensated $Ca_3(VO_4)$:Nd crystals is given in Fig. 6 as a function of Nd concentration.

The predominant excitation wavelength was 3660Å, and since this comparison is not corrected for monochromator dispersion and photomultiplier sensitivity differences, we can only state qualitatively that in this particular host europium is the best emitter in the visible. A direct comparison with the Nd intensities was not possible, since they were not measured under identical conditions.

The outstanding intensity of the europium emission makes one suspect that some form of energy exchange between the host and the Eu^{+3} ion occurs, particularly in view of the fact that such an exchange had been demonstrated for the similar YVO_4:Eu (5) and $Eu_xGd_{1-x}(VO_4)$ (6) systems. We therefore ran an excitation spectrum for $Ca_3(VO_4)_2$:Eu and compared it to Eu^{+3} in $CaWO_4$ in Fig. 7. The data were obtained with monochromatic excitation which was accomplished by using a 1000-watt xenon source and a ½ meter Jarrell-Ash monochromator with a 16Å band pass. A fraction of the excitation energy was monitored with a Perkin-Elmer model 12 spectrometer stripped of all active elements except the thermocouple. Emission at 6150Å at room temperature was detected with an S-11 type photomultiplier through a multilayer dielectric filter optimized for 6150Å. The photomultiplier and thermocouple signal were monitored on a two-channel ratio recording strip-chart recorder presenting a normalized excitation spectrum. A comparison of the two spectra shows evidence for energy transfer from vanadate to europium ions since the excitation of the vanadate host is at least twice as efficient and the wavelength dependence is radically different in the region of vanadate absorption. In a separately run spectrum for the 3000-4000Å region with ½ the gain setting for vanadate, its emission was still considerably more intense than that from the tungstate sample so that the high intensity observed with excitation below 3700Å for the vanadate can only be explained by assuming energy exchange between the VO_4^{-3} and Eu^{+3} ion. Another interesting comparison is made in Fig. 8, where the absorption spectra are compared for Nd^{+3} in a scheelite host, such as $CaMoO_4$ and in $Ca_3(VO_4)_2$. These data were obtained with the Cary spectrophotometer set for approximately 2Å resolution. The

wavelength was scanned from 3000 to 10,000Å. The infrared and visible regions were scanned separately using a PbS and an S-11 type photomultiplier, respectively, and the charts were then joined at 6300Å before reproduction. Comparison of the spectra shows that the vanadate absorption is an order of magnitude stronger than that of $CaMoO_4$:Nd. There are several qualitative differences in the spectra in addition to the obvious intensity changes. Particularly interesting is the difference in the 8800Å region where injection laser pumping is used. This region is reproduced in Fig. 9. Unfortunately in addition to the intensity reversal the shift for the vanadate is toward the higher rather than the desired (8400Å) shorter wavelength region. Generally the absorption bands for the vanadate are broader and consequently exhibit less detail. The vanadate host should be particularly good for pumping with a tungsten source in continuous wave experiments since the absorption is so strong in the near infrared region.

Crystal Growing

The predominant feed starting material was $Ca_3(VO_4)_2$. It was prepared in two steps: by first precipitating $Ca_2V_2O_7$ from purified solutions of $Ca(NO_3)_2 \cdot 4H_2O$ and NH_4VO_3. $Ca_2V_2O_7$ was obtained as a microcrystalline lemon-yellow powder with the typical analysis: CaO, 37.77%; V_2O_5, 61.53%; calc. CaO, 38.14%; V_2O_5, 61.86%. In a second step, $Ca_3(VO_4)_2$ was prepared by interacting $Ca_2V_2O_7$ with the stoichiometric amount of reagent grade $CaCO_3$. Polycrystalline $Ca_3(VO_4)_2$ is practically white; large single crystals, however, do have a distinct light yellow-to-orange color, due to absorption in the blue region of the visible spectrum. The rare earth oxides as well as the other constituents were added to the $Ca_3(VO_4)_2$ powder and melted in Ir crucibles from which crystals were grown. As a rf power source a 25 kw/450 kc/sec Westinghouse generator was used in conjunction with an automatic voltage regulator keeping the current steady to within 2½%. Crystals were grown in air at speeds between ½-¾ in./hr. The crystal cross section was invariably circular with three distinct growth lines along the sides indicating that the principle growth axis has threefold symmetry. Optically this axis corresponds to the a-axis of a scheelite-type oxide, such as $CaMoO_4$, and thus exhibits the expected optical birefringence. Crystals up to 6 in. in length can be grown readily. In comparison with Nd in $CaMoO_4$ (7), they are deeper in color due to the intrinsically colored host. Since considerable difficulty was encountered in growing clear crystals of the titanium compensated compositions, all crystals were grown from either sodium or vacancy-compensated compositions. It was particularly interesting that contrary to experience with the sodium-compensated tungstate case (1), excess sodium was quite detrimental to the quality of the crystals and segregation coefficients even at the 1:1 Na:Nd level were exceptionally close to 1. The calculation of segregation coefficients ($K = c_s/c_l$ where c_s is the concentration in solid, c_l the concentration in liquid) was done by Pfann's (8) method, based on analytical information obtained by x-ray fluorescence analysis of the top and bottom of a crystal. Table II summarizes some typical results for Na as well as vacancy-compensated crystals. Segregation coefficients for the corresponding rare earth vanadates were also determined for single crystals of $Eu_{0.20}\phi_{0.10}Ca_{2.7}(VO_4)_2$, $Sm_{0.08}\phi_{0.04}Ca_{2.88}(VO_4)_2$, and $Dy_{0.03}\phi_{0.015}Ca_{2.955}(VO_4)_2$. They were found to be 0.98, 0.98, and 0.99, respectively.

Since the Na content of the compounds listed in Table II could not be determined by the x-ray fluorescence techniques, we had to estimate it by difference; indications were that hardly any sodium entered the single crystals. It was this result which prompted us to synthesize and study the properties of the vacancy-compensated systems.

Table II. Some typical analyses of doped and undoped calcium vanadates

Nominal composition	CaO%	V_2O_5%	Nd_2O_3%	Total %	Segregation coefficient K for Nd_2O_3	CaO: V_2O_5 ratio
$Ca_2V_2O_7$	37.8	61.5	—	99.3	—	1:0.50
$Ca_3(VO_4)_2$	47.8	51.6	—	99.4	—	1:0.33
$(NaNd)_{0.04}Ca_{2.92}(VO_4)_2$	45.7	51.5	2.4	99.6	1.1	—
$(NaNd)_{0.10}Ca_{2.80}(VO_4)_2$	42.8	51.0	6.1	99.9	1.2	—
$Nd_{0.025}\phi_{0.0125}Ca_{2.9625}(VO_4)_2$	46.9	51.5	1.5	99.9	1.1	—
$Nd_{0.08}\phi_{0.04}Ca_{2.88}(VO_4)_2$	44.5	50.9	4.8	100.2	1.1	—
$Nd_{0.10}\phi_{0.05}Ca_{2.85}(VO_4)_2$	43.4	50.9	6.0	100.3	1.0	—

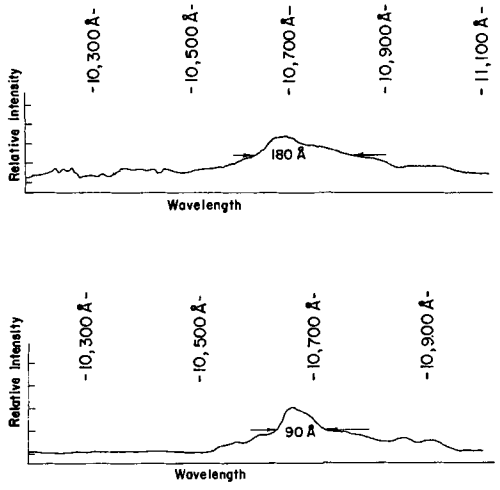

Fig. 10. Fluorescent emission spectrum of single crystalline $Nd_{0.05}\phi_{0.025}Ca_{2.925}(VO_4)_2$ at 300°K (top) and 77°K (bottom).

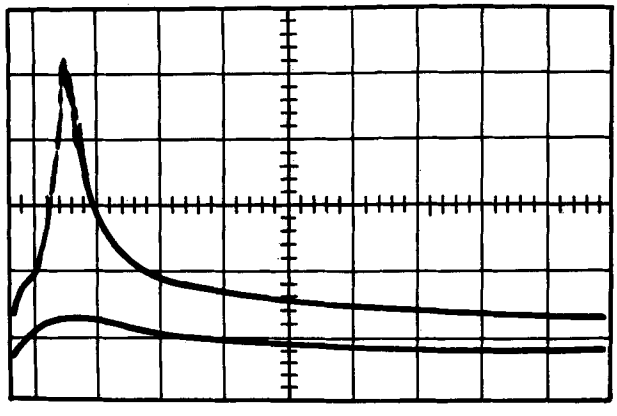

Fig. 11. Stimulated emission of $Nd_{0.08}\phi_{0.04}Ca_{2.88}(VO_4)_2$ at 300°F (lower trace below, upper trace above threshold).

The fact that even without Na compensation we obtained such favorable segregation coefficients is very interesting and particularly useful in single crystals where the Nd^{+3} distribution is nearly homogeneous from top to bottom.

Laser Experiments

Single crystal boules were cut and ground into cylindrical rods 6.3 mm, 4.8 mm, and 3.2 mm diameter and 2 in. long. The cylindrical surfaces were left rough and the ends polished to form a Fabry-Perot resonator. Silver was evaporated onto the end surfaces; one end was 5% transmissive and the other completely opaque. Laser characteristics at 300°K were measured under pulsed illumination in a Lear-Siegler LS-3 laser head with a Kemlite FT100B helical xenon flash lamp. The stimulated emission was detected with a Dumont K1485 photomultiplier through a 3 mm silicon filter. Figure 11 shows typical laser emission just above threshold. Thresholds are typically 3000 joules under these conditions. The spectral output above threshold was determined by focusing the emitted radiation on the entrance slit of a Bausch and Lomb 2-meter grating spectrograph and recording the output on hypersensitized Kodak 1-Z spectroscopic plates. Stimulated emission was observed at 1.067μ with the line width narrowing to 20Å from the normal spontaneous emission linewidth of 180Å at room temperature, as seen in Fig. 10.

Discussion and Miscellaneous Data

Since $Ca_3(VO_4)_2$ constitutes another laser host, it appeared desirable at this point to measure as many pertinent parameters as possible and also to compare the influence of the host on the fluorescent emission of the active ion in it.

In Table III, a summary of the fluorescent emission output of Eu^{+3} under comparable conditions is given for a number of different hosts. It is quite obvious that not only the intensity, the optimum doping level but even the spectral characteristics themselves change significantly as a function of the host.

Eu^{+3} shows relatively narrow line emission in a $Ca_3(VO_4)_2$ host, and the excitation spectrum clearly indicates that some energy exchange occurs between VO_4^{3-} and Eu^{+3}. Therefore this system shows potential as a good laser material, particularly in view of a recent publication by Chang (9) who reported stimulated emission from trivalent europium in yttrium oxide. Furthermore, as can be seen from Table II at least among the cited examples for 3660Å excitation, Eu^{+3} shows the strongest emission in the $Ca_3(VO_4)_2$ host with quantum efficiencies approaching 100% for several lines. It is also interesting to note that the three strongest emitters all contain the VO_4^{-3} ion.

In Table IV we summarize some of the other parameters. In order to put these data in perspective with another laser host we compare them to $CaMoO_4$. In view of this comparison, one would say that $Ca_3(VO_4)_2$ has little to offer as a laser host and merely adds another member to the ever increasing list of established laser hosts. The fact that it is the first intrinsically colored and piezoelectric laser host plus the energy exchange still makes it an interesting candidate, and

Table IV. Comparison of some properties of two laser hosts

	$Ca_3(VO_4)_2$	$CaMoO_4$

Observation of Impurity Redistribution During Thermal Oxidation of Silicon Using the MOS Structure

B. E. Deal, A. S. Grove, E. H. Snow, and C. T. Sah

Fairchild Semiconductor, Division of Fairchild Camera & Instrument Corporation, Palo Alto, California

ABSTRACT

The redistribution of impurities during thermal oxidation of silicon has been investigated using the metal-oxide-semiconductor (MOS) system. It has been demonstrated that the MOS technique permits a semiquantitative observation of both n- and p-type impurity profiles in the silicon surface region. Results are presented for redistribution of aluminum, boron, gallium, indium, antimony, arsenic, and phosphorus. In addition, the effects of oxidation variables (oxidation time, temperature, rate, and ambient) on redistribution, predicted by previous work in these laboratories, have been studied in detail for boron-doped silicon.

The formation of a silicon dioxide layer is an important step in the fabrication of "planar" silicon transistors and other devices. Such oxide layers are used to mask portions of the silicon surface from impurity diffusion as well as for passivation of the surface (1A). In addition, surface-controlled silicon devices, which employ the oxide layer as the dielectric of a capacitor, have become increasingly important in recent years (1B).

Because of these important practical applications considerable effort has been directed to the study of the properties of the silicon dioxide-silicon system. One particularly useful tool that emerged in such investigations is the metal-oxide-semiconductor (MOS) capacitor structure (2, 3) which has been employed in extensive studies of the electrical properties of the oxide-silicon interface (4-8).

It has been shown (9, 10) that thermal oxidation of silicon brings about a redistribution of the doping impurity near the silicon surface. It is clear that those characteristics of semiconductor devices which are dependent on the impurity concentration near the surface will be affected by this redistribution process. Accordingly, the MOS capacitance method might be expected to yield a means of observing the impurity redistribution phenomenon through the influence of this phenomenon on the capacitance-voltage characteristics of MOS structures.

The present work presents the results of such an investigation. We shall begin by describing the principles on which the method is based. Next we shall consider the factors which affect the impurity redistribution profile as well as the relationship between the impurity redistribution in the semiconductor and the electrical characteristics. Experimental results obtained with seven different acceptor- and donor-type impurities are presented and discussed in light of the theory of the redistribution process and of the MOS structure. Finally, the redistribution of boron is studied in detail under a variety of conditions.

Basic Considerations

Principles of the MOS method.—The MOS structure is illustrated schematically in Fig. 1. In essence, it consists of an evaporated aluminum field plate (referred to as the "gate"), the oxide dielectric, and the silicon substrate. Contact to the silicon is through an evaporated aluminum back contact.

The theory of the MOS structure has been developed in detail elsewhere [see for instance ref. (7), (8)], and therefore only a brief qualitative description is given here for the case of a p-type semiconductor. If the voltage applied to the field plate, V_G, is negative, holes are attracted to the vicinity of the interface so that the semiconductor is much like a metal and the capacitance of the MOS structure is approximately the same as the capacitance of the oxide layer alone. On the other hand, if the applied voltage is made positive, holes are repelled from the vicinity of the interface, leaving behind a region from which the majority carriers are depleted so that their concentration in this region is much smaller than the ionized acceptor ion concentration. We shall refer to this as the electrical depletion region. Because the depletion region in effect adds to the thickness of the dielectric, the capacitance decreases. Upon further increase in the applied voltage, electrons are attracted to the vicinity of the interface and form an extremely narrow inversion region. Additional charge induced in the semiconductor

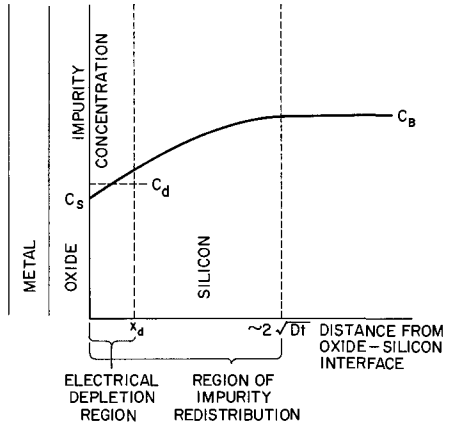

Fig. 4. Relationship of effective surface concentration C_d to impurity redistribution profile.

by further increase in the applied voltage will almost entirely appear in the inversion region and therefore the depletion region stops increasing in size. Correspondingly, the capacitance reaches a minimum value. In the case when the measurement frequency is low enough in comparison with the generation rate of minority carriers, the electrons in the inversion region will be able to follow the variation of the a-c measurement signal, and the capacitance will rise again to the value of the oxide capacitance. The maximum width of the depletion region, however, is independent of frequency (7).

Figure 2 shows the capacitance-voltage characteristics of a MOS structure calculated on the basis of both the high- and the low-frequency theories (8) as a function of the impurity concentration within the semiconductor. Here C and C_o denote the capacitance per unit area of the MOS structure and of the oxide layer, respectively; ϕ'_{MS} is the metal-semiconductor work function difference, and Q_{SS} is the surface state charge density. It is evident that the value of the minimum capacitance, in both theories, is a sensitive function of the impurity concentration. This is further illustrated in Fig. 3 where the ratio of the minimum capacitance to the capacitance of the oxide layer is plotted as a function of the impurity concentration in the semiconductor for the case of 0.2μ oxide thickness.[1]

The analysis on which the theoretical curves shown in Fig. 2 and 3 are based assumes a uniform impurity distribution in the silicon. If the impurity concentration at the surface is different from that in the bulk, this effect might be observed through the minimum value of the MOS capacitance. Impurities are, in fact, known to redistribute near the silicon surface during thermal oxidation (9, 10) so that the situation corresponding to an inverted MOS device might be as depicted in Fig. 4 for the case of impurity depletion from the silicon. It is reasonable to expect that the concentration which affects the MOS characteristics will be some effective concentration, C_d, across the electrical depletion region x_d.

Thus, the experimentally determined minimum MOS capacitance should provide a measure of the effective impurity concentration in the vicinity of the surface. Admittedly, the method is at best an approximate one since it applies a theory which is based on the assumption of a uniform impurity concentration in the semiconductor to the determination of a deviation from this condition. More exact, and much more complicated, approaches are possible through calculating the MOS characteristics based on a nonuniform impurity distribution (11). However, the present method is simple, easy to use and interpret, and, as detailed comparison of the results with those obtained in an earlier more accurate investigation (10) shows, it gives consistently very good results.

Impurity redistribution.—The theory of the impurity redistribution process which takes place upon thermal oxidation of silicon has been presented elsewhere (10). A general equation is derived there which gives the surface or interfacial concentration in the silicon resulting after oxidation as a function of the parameters of the system. This equation is

$$\frac{C_S}{C_B} = \frac{1 + (C_o/C_B)\lambda}{1 + (1/m - \alpha)\sqrt{\pi}\exp(\alpha^2A^2/4D_2)\operatorname{erfc}(\alpha A/2\sqrt{D_2})\,A/2\sqrt{D_2} + \lambda/m} \quad [1]$$

where C_S is the impurity concentration in the silicon, near the oxide-silicon interface; C_B the impurity concentration in silicon bulk; C_o the impurity concentration at outer surface of the oxide during oxidation; $\lambda \equiv r \exp[(\alpha^2r^2-1)A^2/4D_2r^2]\operatorname{erfc}(\alpha A/2\sqrt{D_2})/\operatorname{erf}(A/2\sqrt{D_1})$; $r \equiv \sqrt{D_1/D_2}$; D_1 is the diffusion coefficient

[1] Approximate formulas for the minimum capacitance ratio are given in the Appendix. However, minimum capacitance ratios for other oxide thicknesses can also be readily obtained from Fig. 3 using the series capacitance formula, Eq. [4A].

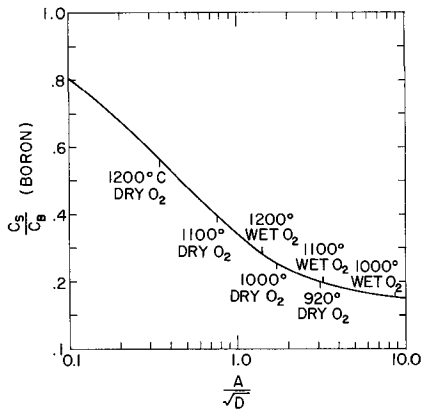

Fig. 5. Redistribution of boron at the silicon surface due to thermal oxidation as a function of the ratio of oxidation rate, A, to square root of diffusivity, $\sqrt{D}$.

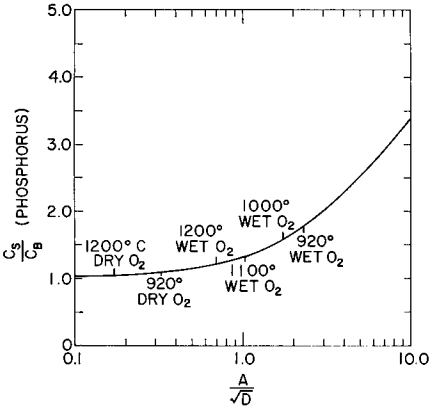

Fig. 6. Redistribution of phosphorus at the silicon surface due to thermal oxidation as a function of the ratio of oxidation rate, A, to square root of diffusivity, $\sqrt{D}$.

of impurity in the oxide; D_2 the diffusion coefficient of impurity in the silicon;

$$\alpha = \frac{\text{Thickness of silicon oxidized}}{\text{Thickness of silicon dioxide produced}} = 0.44;$$

m = (segregation coefficient at Si-SiO_2 interface)

$$\equiv \frac{\text{Equilibrium impurity concentration in silicon}}{\text{Equilibrium impurity concentration in oxide}};$$

A is the oxidation parabolic rate constant, $x_o/\sqrt{t}$; and x_o the oxide thickness.

For boron and phosphorus, we can consider the diffusion in the oxide to be negligible, since r is small (12, 13). As a result, the term λ drops out of Eq. [1]. The values of the segregation coefficient m for boron and phosphorus are taken to be 0.3 and 10, respectively (10). Plots of C_S/C_B *vs.* $A/\sqrt{D}$ are presented in Fig. 5 and 6 for thermal oxidation of boron- and phosphorus-doped silicon based on the above values and Eq. [1]. As mentioned above, A is the parabolic rate constant for thermal oxidation and D (= D_2) is the diffusivity of the impurity in silicon, so that the dimensionless quantity $A/\sqrt{D}$ represents the relative rates of oxidation and diffusion in the silicon. Indicated on the two curves are various oxidation conditions corresponding to oxidation rates and diffusivities at various temperatures in wet and dry oxygen. Diffusivity values for boron are taken from Kurtz and Yee (14) while those used for phosphorus are from Fuller and Ditzenberger (15). The oxidation rate constants used were based on previous work by one of the authors (16). [Wet O_2 indicates oxygen bubbled through water at 95°C. This is referred to as "steam" oxidation in (10).] It should be noted that thermal oxidation of silicon below 1000°C is no longer controlled by diffusion but rather by a surface reaction. Hence the oxidation rate will not be strictly parabolic at 920°C. Nevertheless, data for this temperature, based on an effective parabolic rate constant, are still included in Fig. 5 and 6 as approximations.

Figures 5 and 6 indicate that boron depletes from the silicon surface region during thermal oxidation while phosphorus piles up. It is apparent that the value of $A/\sqrt{D}$ increases with decreasing temperature owing to the fact that diffusivity values decrease more rapidly with temperature than oxidation rate constants. Also, at any particular temperature, the value of $A/\sqrt{D}$ is higher for oxidation in a wet atmosphere than in a dry atmosphere due to the higher oxidation rate of the former (16).

As the $A/\sqrt{D}$ ratio decreases in Fig. 5 and 6, C_S/C_B approaches unity corresponding to no redistribution. On the other hand C_S/C_B decreases for large values of $A/\sqrt{D}$ in the case of boron and increases in the case of phosphorus. This, of course, can be expected on intuitive grounds. Thus it is apparent from these curves that minimum redistribution of both phosphorus and boron occurs at high oxidation temperatures (1200°C) and at a low rate of oxidation (dry O_2).

The actual impurity distribution after oxidation is error-function type (10), so that the extent of the region of redistribution may be approximated by $2\sqrt{Dt}$ where D is the impurity diffusion coefficient in silicon and t is the oxidation time. For a 0.2μ dry oxide $2\sqrt{Dt}$ will vary from 0.12μ at 920° to 1.2μ at 1200°C for boron-doped silicon, and from 1.1μ at 920° to 2.4μ at 1200° for phosphorus doped silicon.

Relationship between the electrical depletion region and the extent of the region of impurity redistribution. —The relative size of the electrical depletion region compared to the region of impurity redistribution is a very important consideration in the MOS method. It has been mentioned above that the impurity concentration which affects the MOS device characteristics is an effective concentration C_d over the width of the electrical depletion region. This width, designated by x_d, is in turn a function of the impurity concentration and the bias voltage. In this work we are interested only in the minimum MOS capacitance which occurs at a sufficiently high bias voltage that x_d has reached its maximum size. A plot of maximum x_d *vs.* impurity concentration,[2] based on the calculations in ref. (8), is shown in Fig. 7. This graph is based on the results of calculations given in ref. (8) which assumed a uniform impurity concentration within the silicon. It is evident from Fig. 7 that, as the impurity concentration increases, the maximum electrical depletion region width decreases.

In the case of impurity redistribution it is necessary to know both x_d and $2\sqrt{Dt}$ in order to determine what portion of the redistribution profile is influencing the MOS characteristics. For instance, let us assume that an impurity depletes at the silicon surface with a redistribution length, $2\sqrt{Dt}$, of 1.0μ and that the interfacial concentration C_S is equal to 0.5 C_B. This example is shown in Fig. 8. In Fig. 8A, an electrical depletion width, x_d, of 0.1μ is shown. Since the minimum MOS capacitance will be determined by the impurity concentration over the region x_d, the resulting value of the effective concentration, C_d, will be fairly close to the concentration at the surface, *i.e.*, C_d will equal say, 0.55 C_B. Figure 8B shows a second possibility where conditions result in an electrical depletion width of 1.0μ. Now the minimum MOS capacitance will correspond to some average concentration over the region between the silicon surface and 1.0μ from the surface,

[2] The maximum of x_d will be referred to simply as x_d in the rest of this work.

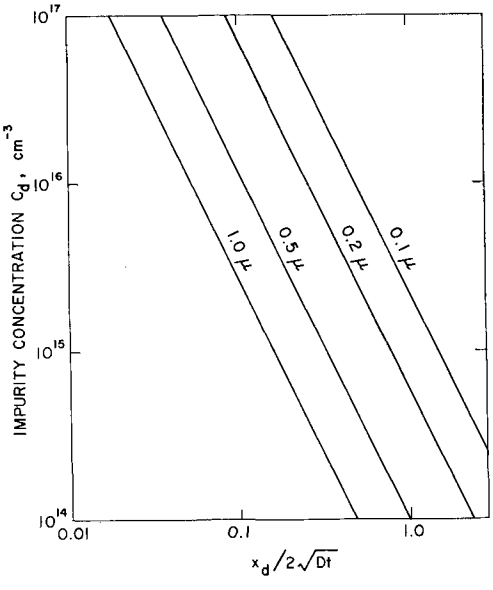

Fig. 10. Dependence of effective surface concentration, C_d, on the ratio $x_d/2\sqrt{Dt}$ for different oxide thicknesses (dry oxygen, 1200°C).

and the value of C_d will be about 0.8 C_B. Finally, in Fig. 8C, an electrical depletion region of 3.0μ is depicted, with a corresponding effective concentration of about 0.95 C_B. It can therefore be noted that while the impurity redistribution remains the same, the C_d value changes considerably depending on the ratio of x_d to $2\sqrt{Dt}$.

The ratio, $x_d/2\sqrt{Dt}$, is thus a significant quantity in the analysis of impurity redistribution. As discussed above, the value of x_d depends only on the impurity concentration over the electrical depletion region, while the quantity $2\sqrt{Dt}$ will be dependent on impurity type, oxidation temperature, and time. Plots of $x_d/2\sqrt{Dt}$ *vs.* impurity concentration are presented in Fig. 9 and 10 for various oxidation temperatures and oxide thicknesses. Both figures represent dry oxygen ambient. If it is desired to know the silicon impurity concentration very near the oxide-silicon interface, a low value of $x_d/2\sqrt{Dt}$ is required. From Fig. 9, for instance, it can be observed that a highly doped substrate oxidized at 1200°C will give the lowest $x_d/2\sqrt{Dt}$ ratio. Similarly, a low ratio is obtained for a 1.0μ oxide on a highly doped substrate as seen in Fig. 10. Other conditions can be selected using these relationships to determine the redistribution profile from the surface into the bulk.

On the other hand, if conditions are fixed, then the ratio $x_d/2\sqrt{Dt}$ will determine what portion of the impurity profile will have a part in determining C_d. In presenting the results for cases where $x_d \gtrless 2\sqrt{Dt}$, C_d will be taken to correspond to the impurity concentration at a point halfway between the silicon surface and x_d, *i.e.*, at distance $x_d/2$.

Experimental

Silicon used in this investigation was single crystal Czochralski type, (111) surface oriented with an initial dislocation count of less than 100 cm^{-2}. After slicing and lapping to 250μ thickness, the bulk impurity concentration was determined using a four-point probe

and a precision micrometer. The slices were cleaned and chemically polished to 150μ thickness in a 4 HF: 10 HNO_3 solution immediately prior to oxidation. Oxidizing ambients included both dry and wet oxygen (oxygen bubbled through water at 95°C). A description of the oxidation apparatus and procedure is given in ref. (16). P-type and n-type silicon slices were oxidized in separate furnaces. Oxide was removed from the back, and aluminum deposited on the top oxide and the back silicon by conventional evaporation techniques (1A). Dots, 250μ in diameter, were prepared from the aluminum over the oxide using photoresist techniques. The sample was then alloyed at 550°C to insure good ohmic contact to the back side. Good ohmic contact to both the field plate metal and the silicon during MOS measurements is important since any oxide in series affects capacitance values and causes erroneous measurements. Oxide thicknesses were determined for each oxidation using multiple-beam interferometry techniques on a mechanically polished test slice.

MOS capacitance-voltage characteristics were determined for several devices on each slice using an automatic recording system. The resulting curve for each unit was analyzed by comparison to the corresponding high frequency or low-frequency MOS theory (8). In most cases the curves followed the high-frequency theory at a 100 kc test frequency. Such samples were selected for more precise measurements on a Boonton capacitance bridge. The ratio of minimum capacitance to oxide capacitance was obtained for each device. Oxide capacitance values used were those measured at large negative bias in the case of p-type silicon and at large positive bias for n-type silicon. (Comparison of measured oxide capacitances with oxide thickness gave the value of the dielectric constant, $K_o = 3.9$). Using a curve of the type shown in Fig. 3, the value of the effective impurity concentration near the silicon surface, C_d, was determined. A specific example is illustrated in Fig. 11.

Results

General survey.—A survey involving several different dopants, both acceptors and donors, was conducted to determine redistribution characteristics caused by thermal oxidation. All oxidations were carried out at 1200°C in dry oxygen. Oxide thickness was 0.20μ in all cases. MOS devices were prepared, C-V plots obtained, and effective surface concentrations determined from capacitance minima. A value of x_d was determined from the effective surface concentration using Fig. 7. Values of $2\sqrt{Dt}$ were calculated based on the conditions of oxidation. The results consisting of the ratio of the effective impurity concentration across the electrical depletion region to the bulk doping, C_d/C_B, are tabulated in Table I. Also shown are values of the ratio $(x_d/2)/2\sqrt{Dt}$ which indicate the position along the impurity profile to which C_d is assigned. The corresponding redistribution values reported in ref. (10) are given for comparison. Following is a short summary of the results.

Antimony and Arsenic.—In ref. (10), these two donor impurities are reported to pile-up slightly under the above oxidation conditions. The present results indicate a small pile-up, of the same order as obtained in the previous study.

Phosphorus.—Figure 6 predicts that phosphorus will pile-up to the extent of $C_S/C_B = 1.1$ at all dry oxidation temperatures. This has been found to be the case for a number of MOS devices, with the exact value varying from 1.1 to 1.2.

Aluminum and indium.—Indium was found in ref. (10) to deplete to a very low value at the oxide-silicon interface. This was found to be the case also in the present experiments. Aluminum behaves in a similar manner. The results indicate that the concentrations of these two impurities right at the silicon surface are much smaller than in the bulk, *i.e.*, $C_S/C_B \ll 1$.

Gallium.—This p-type impurity was the subject of a detailed study described in ref. (10). It was shown that even though its segregation coefficient favors pile-up, the rapid diffusion of gallium through the oxide (17) results in considerable depletion. Results of three separate gallium concentrations are given in Table I. The results indicate, as with aluminum and indium, that the gallium concentration at the surface is near zero.

Boron.—Boron is predicted from Fig. 5 to deplete to $C_S/C_B = 0.6$ under the above oxidation conditions. For $(x_d/2)/2\sqrt{Dt}$ values of 0.1 to 0.2, the observed values of C_d/C_B range from 0.7 to 0.8. A more detailed investigation of boron redistribution is discussed in the next section

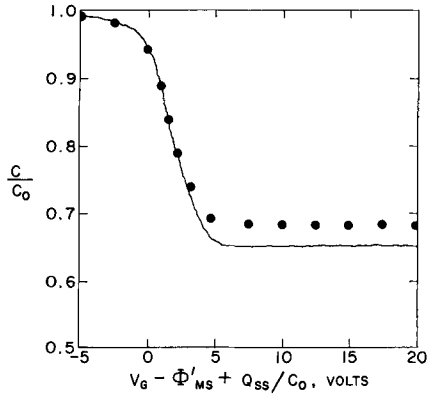

Fig. 11. An example showing comparison between theoretical (solid circles) and experimental (solid line) MOS C-V characteristics. Calculations correspond to the bulk doping, $C_B = 1.45 \times 10^{16}$ cm^{-3} and $x_o = 0.20\mu$. Minimum capacitance ratio of experimental curve, $C_M/C_o = 0.65$, corresponds to an effective surface concentration $C_d = 1.10 \times 10^{16}$ cm^{-3} from Fig. 3. Oxidation was in dry O_2 at 1200°C for 60 min. Value of $x_d/2\sqrt{Dt}$ is 0.24.

Boron redistribution.—Redistribution of boron in silicon due to thermal oxidation was investigated over the temperature range 920°-1200°C. Two main effects were considered in this investigation: (*a*) factors influencing the relationship of x_d, (the width of the electrical depletion region), to $2\sqrt{Dt}$, (the length of the redistribution region); (*b*) factors influencing the impurity redistribution itself.

Results are reported in terms of oxidation type and oxide thickness (Table II); and oxidation temperature and boron concentration, (Table III). The quantity, $(x_d/2)/2\sqrt{Dt}$ to which the effective concentration, C_d, corresponds, is given in both tables.

Oxidation type and oxide thickness.—MOS devices were prepared using four different types of oxidation. Bulk concentration of the boron in the silicon slice was the same in all cases: 1.4×10^{16} cm^{-3}. The value of x_d (the maximum width of the electrical depletion region) corresponding to the bulk impurity concentration was 0.28μ.

From Table II, the differences in boron redistribution caused by various types of oxidations can be noted. For instance, when $(x_d/2)/2\sqrt{Dt} = 0.25$, wet oxygen results in a C_d/C_B value of 0.65 compared to 0.83 for dry oxygen. This trend agrees with predictions based on Fig. 5. In the case of pyrolytic and anodic oxides, where the low oxidation temperatures (hence very low diffusivities) result in very high $(x_d/2)/2\sqrt{Dt}$ ratios, no redistribution can be observed.

It can be noted in the case of both dry and wet oxidation that, as the oxidation time increases and hence the $(x_d/2)/2\sqrt{Dt}$ ratio decreases, the C_d values obtained represent concentrations nearer to the surface.

Oxidation temperature and boron concentration.—Let us first consider the effect of oxidation temperature on boron redistribution. Table III includes results of dry oxygen oxidation of boron-doped silicon at four different temperatures. All oxides are 0.20μ thick. The predicted effect of temperature on the boron surface concentration was presented in Fig. 5. Thus, while at 1200° the boron concentration at the silicon surface was predicted to be 0.6 C_B, at 920° it should be only about 0.2 C_B. If the lowest concentration at each temperature listed in Table III is considered, a uniform decrease in C_d/C_B can be noted going from 1200° down to 920°C. Furthermore the values agree quite closely with predictions based on Fig. 5. Values at 920°C are in parenthesis since oxidation no longer is parabolic at this temperature and the redistribution theory (10) can only be applied as an approximation. The value of $(x_d/2)/2\sqrt{Dt}$ at 920° seems to be too high, perhaps reflecting an uncertainty in $\sqrt{D}$.

At any particular temperature, the variation of boron bulk concentration should affect only the maximum width of the electrical depletion region x_d. As an increasing x_d value causes the $(x_d/2)/2\sqrt{Dt}$ ratio to approach unity, C_d should approach C_B. This is indeed the case at 1000°, 1100° and 1200°. As mentioned above, the $\sqrt{D}$ value of 920° is in question and should apparently be about twice the value listed, i.e., $\sqrt{D}$ at 920° should be 0.03 $\mu/\sqrt{hr}$ according to these results.

The results of Table III are more clearly understood if redistribution profiles based on the theory given in ref. (10) and a segregation coefficient $m = 0.3$ are plotted in Fig. 12. It can be noted that, as the oxidation temperature is lowered, the interfacial concentration of boron and the redistribution length (approximated by $2\sqrt{Dt}$) both decrease. Also included on the graph are x_d distances for several impurity concentrations. It is evident that the higher the boron concentration, the closer C_d will be to the actual interfacial concentration, C_s. At low boron concentrations, the MOS device will merely "observe" the bulk concentration, even for oxides grown at 1200°C.

All dry oxygen boron data from Tables II and III are also shown in Fig. 13 where C_d/C_B is plotted *vs.* $(x_d/2)/2\sqrt{Dt}$. This results in an approximate impurity distribution profile. The predicted distributions are shown by the solid lines. Reasonable agreement is obtained between experimental results and the theoretical profiles, especially in the light of the fact that the MOS method described here is only semiquantitative. The 920°C data are not shown due to the considerations discussed above.

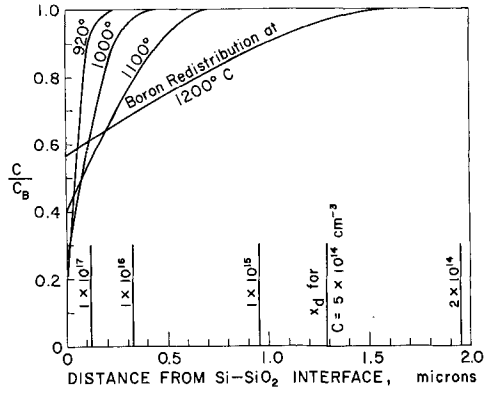

Fig. 12. Predicted redistribution profiles for boron in silicon due to dry oxygen oxidation at various temperatures. The electrical depletion region width, x_d, is also shown for various impurity concentrations.

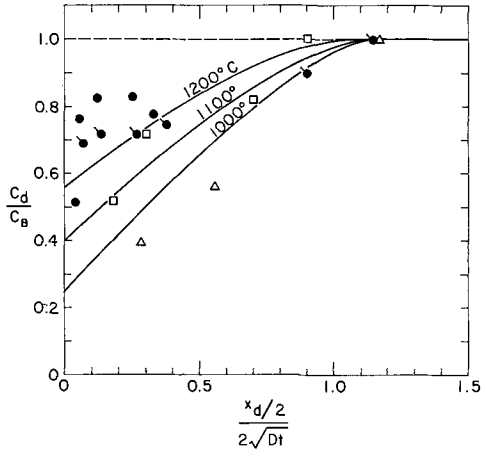

Fig. 13. Experimental results of boron redistribution due to oxidation in dry oxygen. Predicted profiles are also shown. Solid circle 1200°, $C_B = 1.4 \times 10^{16}$ cm^{-3}, varying t ($\rightarrow x_o$); solid circle with line to the left 1200°, open square 1100°, open triangle 1000°, $x_o = 0.2\mu$ varying C_B ($\rightarrow x_d$).

Conclusions

The MOS field-effect capacitance method has proven satisfactory as a semiquantitative method for observing the impurity redistribution in silicon due to thermal oxidation. Concentration values obtained by this method represent effective average values across the electrical depletion region. By a careful choice of conditions this method can even yield the actual impurity redistribution profile.

The results obtained in this study for seven different acceptor and donor-type impurities were found to be in complete agreement with the results of the earlier investigation (10). In addition the effects of oxidation temperature and ambient, not covered experimentally in ref. (10), were investigated in detail for boron. The MOS results agree with the theoretical predictions of ref. (10).

In conclusion, it should be pointed out that the MOS method is relatively nondestructive and can be used with regular device processing by placing MOS field plates over an oxide either at the edge of a wafer or in between conventional devices.

Acknowledgment

The authors wish to thank Mrs. D. S. Sklar for her assistance in the experimental portion of this program.

Manuscript received Aug. 17, 1964. This paper was presented at the Washington Meeting, Oct. 11-15, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

APPENDIX

Approximate Formulas for the Calculation of the Minimum Capacitance Ratio

In the present work, values of the minimum capacitance of the MOS structure as a function of the impurity concentration were based on exact calculations. However, approximate expressions have also been derived which enable their rapid estimation.

The maximum width of the electrical depletion region can be estimated on the basis of the simple model presented in ref. (7).[3] If, in the case of a p-type semiconductor, the maximum depletion region width, $x_{d\max}$, is assumed to be reached when the electron surface concentration in the inversion region equals the concentration of holes in the bulk of the semiconductor, *i.e.*, $n_s = N_A$, this width will be given by

$$2\phi_F = \frac{q\,N_A\,x_{d\,\max}^2}{2K_s\,\epsilon_o} \qquad [1A]$$

where the notation is the same as in ref. (7) and (8). This formula yields values in good agreement with Fig. 7.

The minimum high-frequency space charge capacitance per unit area of the semiconductor will then be given approximately by

$$C_{s\,\min} = \frac{K_s\,\epsilon_o}{x_{d\,\max}} = \frac{K_s\,\epsilon_o}{L_D}\sqrt{\frac{N_A}{2n_i}}\,[4\ln(N_A/n_i)]^{-1/2} \qquad [2A]$$

where

$$L_D \equiv \left[\frac{kT}{q}\,\frac{K_s\,\epsilon_o}{2\,q\,n_i}\right]^{1/2}$$

The minimum low-frequency space charge capacitance can be obtained by setting $dC/dV_G = 0$ since in the low-frequency case the characteristics exhibit a true minimum. This was done by Frankl (19) whose calculations lead to the approximate result

$$C_{s\,\min} = \frac{K_s\,\epsilon_o}{L_D}\sqrt{\frac{N_A}{2n_i}}\,[1 + 0.542u_F - 0.0115u_F^2 + 1.25\times10^{-4}\,u_F^3]^{-1} \qquad [3A]$$

where $u_F = \ln(N_A/n_i)$.

The minimum capacitance ratio of the MOS structure is then given for either case by

$$\frac{C_M}{C_o} = \left[1 + \frac{C_o}{C_{s\,\min}}\right]^{-1} \qquad [4A]$$

where $C_o = K_o\,\epsilon_0/x_o$ is the capacitance per unit area of the oxide layer.

[3] Similar considerations have been advanced by Lehovec and Slobodsky (18).

Substrate Orientation Effects and Germanium Epitaxy in an Open Tube HI Transport System

A. Reisman and M. Berkenblit

Thomas J. Watson Research Center, International Business Machines Corporation, Yorktown Heights, New York

ABSTRACT

The results of the thermodynamic analysis of the system Ge-I_2-H_2-He was used as a guide in designing a germanium epitaxial reactor. The equipment incorporates an instantaneous demand HI generator and is free of lubricated joints and valves. Cleaning of the apparatus is effected by the use of liner tubes and the system operates semiautomatically. Vapor growth studies were conducted to determine the effects on the surface morphology of grown layers caused by substrate parameters such as crystal orientation, resistivity, and conductivity type. It was found that the latter two parameters did not affect surface morphology, but that small crystal misorientations off of <111> surfaces had pronounced effects. Growth rates in the system were of the order of 0.7 μ/hr under the conditions used, and values of N_D-N_A of 10^{15} electrons/cm^3 were obtained routinely using undoped sources. Mobilities for the deposits were in the 14,000 cm^2/v sec range at liquid nitrogen temperature.

The low temperatures associated with Ge epitaxial growth in an iodine process offer some distinct advantages when diffusion processes must be minimized. On the other hand, surface morphology obtainable with this growth procedure is generally inferior to that obtained in a high temperature reduction process. An additional disadvantage in such a disproportionation growth scheme is the low growth rate obtained, necessitating extended time periods during which experimental parameters must be controlled. The recent thermodynamic analysis of the system Ge-I_2-H_2-He (1) indicated that regions of temperature insensitivity for source and seed sites could be used to advantage in achieving long term stability of an open tube Ge-HI disproportionation train in which Ge transport occurs via reactions [1] and [2]. This provided the impetus for designing

$$Ge_{(s)} + 2HI_{(v)} \rightleftarrows GeI_{2(v)} + H_{2(v)} \quad \text{(at source)} \quad [1]$$

$$2GeI_{2(v)} \rightleftarrows Ge_{(s)} + GeI_{4(v)} \quad \text{(at seed)} \quad [2]$$

an apparatus to study possible parameters effecting surface morphology at the temperatures in which Ge epitaxy occurs in an HI transport system.

Experimental Procedure

HI *transport system.*—Examination of the curves of Fig. 1 (1) indicate that for F values [$H_2/(H_2 + He)$ mole fraction] of 0.1, and 0.2, the mole ratio nGe/nI_2 at potential source and seed sites is relatively temperature insensitive. Thus, a plateau is generated at 600°C which is a useful source temperature, and a minimum occurs at around 350°C which represents a useful seed temperature. Using this information as a guide, an apparatus was designed for effecting Ge epitaxy. As a matter of convenience, and in order to assure more rapid attainment of equilibrium, the iodine emanating from the source bed was converted to HI since preliminary experiments had revealed that the conversion $I_2 + H_2$ to HI in the Ge source does not go to completion.

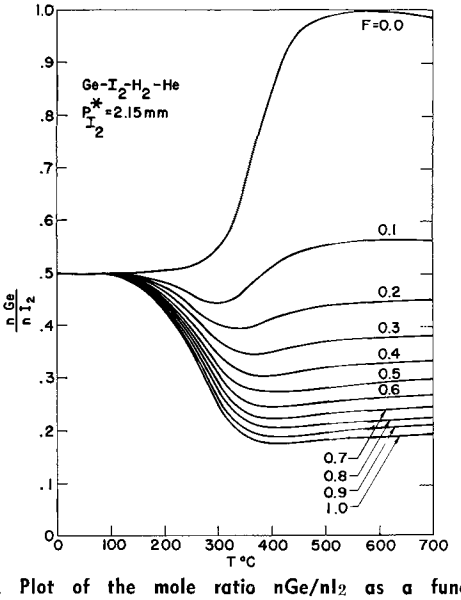

Fig. 1. Plot of the mole ratio nGe/nI_2 as a function of temperature.

HI *generator.*—A problem that existed in the use of HI as a transporting agent was the unavailability of a high purity commercial source. The available HI was found to be contaminated with phosphorus, due probably to the use of phosphoric acid lubricated joints in the synthesis of the reagent. In addition, the available regulators corroded badly in operation making flow control difficult to achieve. It was decided to explore the possibility of developing an *in situ* controlled source of HI free of corrodible or lubricated valves. The apparatus shown in Fig. 2 was evolved and is based on the work of Caley and Burford (2). In place of the catalyst suggested by the authors, platinum wool was used (1 mil crumpled Pt wire). Instead of the "red heat" used by them a temperature of 350°-450°C

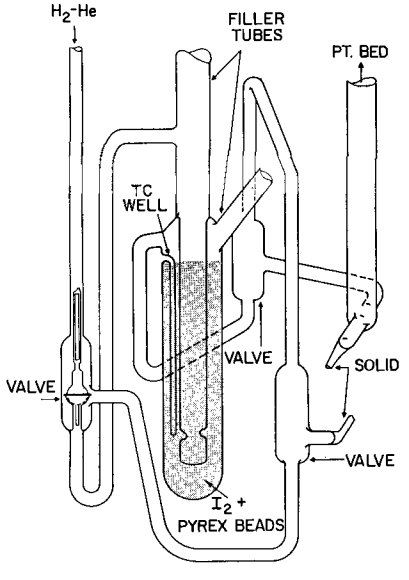

Fig. 2. HI generator

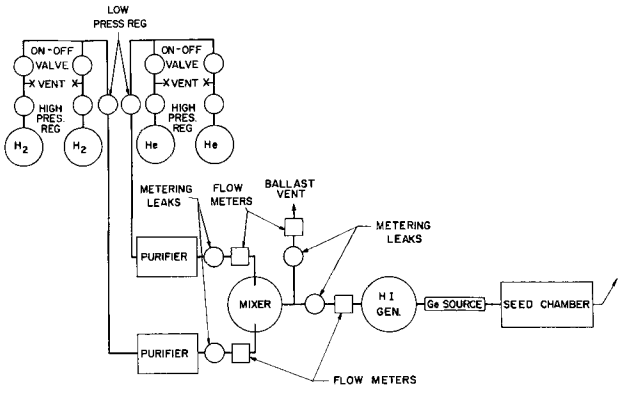

Fig. 3. Schematic representation of deposition reaction train

Fig. 4. Detail of gas entry nozzles into deposition chamber

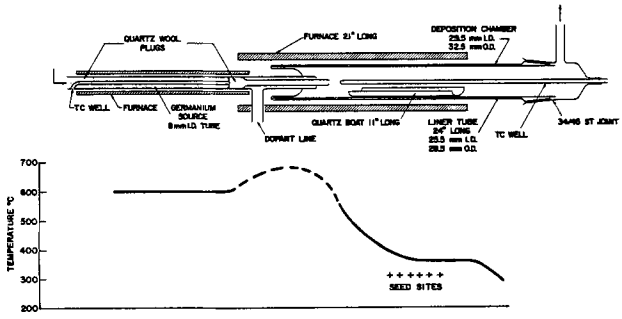

Fig. 5. Germanium source bed and deposition chamber

was found to be adequate. The need for joints and stopcocks was eliminated by using magnetically operated ball joints and a by-pass arrangement as shown in Fig. 2. To obtain more positive valve seating, each magnet assembly is comprised of two coils so that both opening and closing are effected magnetically. The iodine path lengths necessary for equilibrium to obtain between the carrier gas and the bed have been discussed in a paper dealing with transpiration studies in the system Ge-I_2-He (3). For a Pt bed 10 in. long and 20 mm ID heated to 420°C, complete reaction is achieved with linear gas velocities to 1000 cm/min (input flow rate of 1400 cm^3/min) at iodine pressures to 35 mm. If greater flow rates and/or higher iodine pressures are necessary, longer or greater diameter Pt columns and/or higher temperatures may be required. In operation, the efficiency of the synthesis is readily discernible by observing the disappearance of the iodine color at some point in the Pt wool packing. At flows of 75-150 cm^3/min, the iodine color disappears almost immediately within the Pt bed. The glass assembly, up to the Pt bed, is kept in a constant temperature oil bath. Condensation of the effluent HI from the generator and analysis of the condensate failed to reveal any traces of platinum.

The reaction train.—Figure 3 schematically depicts the entire reaction train. H_2 (Matheson, Ultra Pure Hydrogen, 10 ppm impurities) and He (Matheson Helium, 100 ppm impurities) are mixed and purified in a molecular sieve type purifier (J. Mickel Associates). The purifier has a rated capacity of 3 liters/min and provides an output in the 10 ppB impurity range. Flows for the entire system are controlled by Granville-Phillips metering leaks and are monitored by flow meters (Predictability Flowmeters from the Manostat Corp.).

The remaining portions of the system were designed in accord with results obtained in a study of Ge-I_2 transpiration phenomena previously reported (3). Thus, the Ge source was contained in a quartz tube 8 mm ID and 12 in. long heated by a 6 element furnace. The deposition chamber was 24 in. long with an ID of 35 mm again heated by a 6 element furnace.

Since the entire glass portion of the system is constructed free of joints, it was necessary to incorporate a simple clean up procedure which did not require disassembly of the glassware after each deposition. This was achieved by the use of a removable liner in the deposition chamber. Figure 4 shows the construction of the gas entry nozzles into the deposition chamber[1] and the recess surrounding these nozzles into which the liner tube fits, and Fig. 5 shows the design of the Ge source bed and deposition chamber. In order to minimize diffusion between the liner tube and wall of the reactor, the liners were chosen so as to provide a close fit with the wall of the deposition chamber. The use of removable liners has enabled operation without shutdown for cleaning for months at a time.

Temperature and flow conditions.—All of the epitaxial growth experiments were conducted in a carrier gas containing a $H_2/(H_2 + He)$ ratio of 0.2 and an input iodine partial pressure of 2.5 mm. The Ge source was maintained at 600° ± 10°C and the seeds at 365°-405°C. From Fig. 1 it is seen that the equilibrium Ge/I_2 ratio decreases from 0.443 to 0.394 in the temperature interval 600°-365°C. This corresponds to a theoretical dropout of 0.049 moles Ge/mole input iodine.

Figure 5 also shows the temperature profile of the HI reaction train. Following the Ge bed, the temperature was raised to >600°C to prevent premature deposition of Ge, and to increase the temperature gradient past the nozzle. The gradient terminates in a 4 in. long flat deposition region at 360°-365°C. Flow rates were 75 cc/min. At this flow rate the theoretical dropout of Ge in the deposition chamber is 1.8 mg/hr.

Substrate preparation.—Substrate wafers were saw cut from preoriented single crystals. Both Czochralski pulled and zone leveled germanium crystals were used as noted below, although most depositions were conducted on pulled material. The wafers were lapped to uniform thickness with a succession of Al_2O_3 grit sizes of 9.5, 5, and 3μ and then mechanically polished with 0.3μ Al_2O_3 (Linde A) followed by a 0.05μ (Linde B) final polish. These finished substrates exhibit a high polish but are surface damaged.

After mechanical polishing, the wafers were ultrasonically cleaned in deionized water. Then in order to remove surface damage they were etched in a 5:1 HNO_3/HF solution for 30 sec, rinsed in deionized water, ethyl alcohol, and dried in a stream of warm N_2 immediately prior to use. They were then placed in the

[1] The apparatus contains two gas lines into the deposition region, one for Ge and the other potentially for a dopant. The latter was not used in these studies and the gas flowing through the second leg served as a diluent in the deposition chamber. The effect of dilution on growth rate will be described in a later report.

apparatus and given a 15 min HI cleaning etch at 365°C in order to remove surface oxides. This etching did not result in a measurable weight loss (±0.1 mg) nor in a change in surface appearance, but etch products were observed at the outlet portion of the reactor.

Results

Characteristics of deposits and growth rates.—Under the conditions of the experiment as outlined above, growth rates have been of the order of 0.7 μ/hr at 365°C, and approximately half this rate for a seed temperature of approximately 400°C, with depositions conducted for periods up to 96 hr. Most of the deposits have been x-ray analyzed, and generally exhibit crystal perfections which may be termed perfect within the limits of conventional x-ray detectability (4).

Thermoelectric probing showed all deposits to be n-type although the Ge source was 40 ohm cm p-type material. Van der Pauw samples were prepared and net carrier concentrations, N_D-N_A, were determined to be in the range 1-4 x 10^{15} electrons/cm^3. Hall mobilities at liquid N_2 temperature ranged around 14,000 cm^2/v sec. Attempts were made to determine the nature of the impurities present in the system, *i.e.*, such impurities might arise from leaching of the quartz ware, gaseous impurities not trapped by the gas purification system, or impurities in the I_2 source. None of these, however, at the present time can be traced as the source of impurities.

Substrate orientation effects.—Initial deposits were obtained on substrates cut from a p-type, 30 ohm-cm pulled crystal, nominally oriented perpendicular to the <111> direction. The surfaces of these deposits did not show the gross pyramidal overgrowths normally associated with low temperature disproportionation growth (5). Instead, a relatively smooth, matte finish was obtained. Subsequently layers grown on substrates cut from at 1.2 ohm-cm, p-type zone leveled crystal, yielded the more characteristic <111> pyramidal growths. Figure 6 shows both types of surfaces as they were obtained in a single growth experiment using wafers from the two crystals as substrates. This experiment demonstrated that the observed surface morphology differences were not due to system variations, but in some way were related to differences between the substrates.

The differences that were considered included the following: (*a*) The substrate source in one case was a pulled crystal and in the other a zone leveled crystal. Imperfections might have been significantly different in both due to the method of single crystal preparation, and their number and type might influence growth morphology. (*b*) The doping levels of the two crystals were different and might influence surface morphology. (*c*) Though the wafers were all nominally oriented perpendicular to the <111>, the slices from the pulled crystal were found to be approximately 4° off the <111> orientation.

In order to test (*a*) and (*b*) it was felt that the orientation parameter would have to be evaluated first. Consequently, a series of wafers was prepared from a new p-type 30 ohm-cm pulled crsytal. These wafers were cut in three different orientations, all nominally perpendicular to the <111>. The directions of misorientation intentionally introduced are best seen with reference to Fig. 7 which is a simplified stereographic projection perpendicular to the <111>. Because of the three-fold symmetry present, two major misorientations are possible, toward the closest <211>, and toward the closest <110>. It should be noted that in addition to the misorientations described, there are intermediate misorientations possible; namely, those in which the misorientation vector lies in between the two possible major misorientation directions. This gives rise to a misorientation involving two coordinate specifications, a ρ value indicative of the angular misorientation from the <111>, and a ϕ value which locates the intersection of a perpendicular from the surface studied to the stereographic plane within the directions bounded by the <111>-<211> and <111>-<110> vectors. The three types of wafers studied are denoted by <111>, <111> → <211> and <111> → <110>, where the angle off the <111> toward either the <211> or <110> was 3°-5°. After polishing, each wafer was x-ray analyzed to determine its precise orientation.

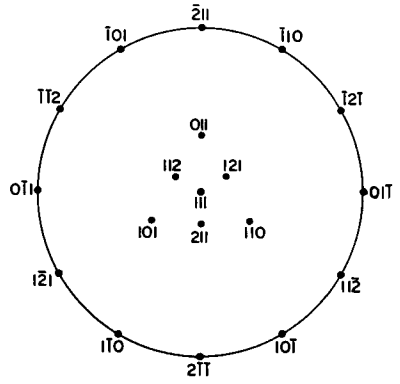

Fig. 7. Simplified stereographic projection perpendicular to the <111>. Angles: ∢ 111-211 = 19°28′; ∢ 111-110 = 35°16′.

The three types of wafers were included in each experiment, their positions in the reactor being randomly changed from run to run. On the basis of a series of such experiments, the following results were obtained reproducibly. Wafers oriented with $\rho \leq 1°$ and ϕ varying from 0 to 60° always developed pyramidal overgrowths. The density of pyramids was dependent on the seed position in the furnace. Thus, <111> wafers first encountering the gas stream developed

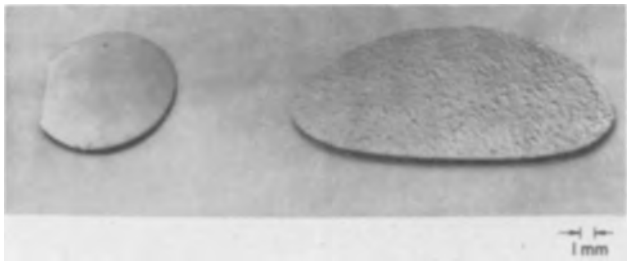

Fig. 6. Simultaneous growth on pulled and zone leveled wafers

Fig. 8. Deposit on substrate with orientation <111>.

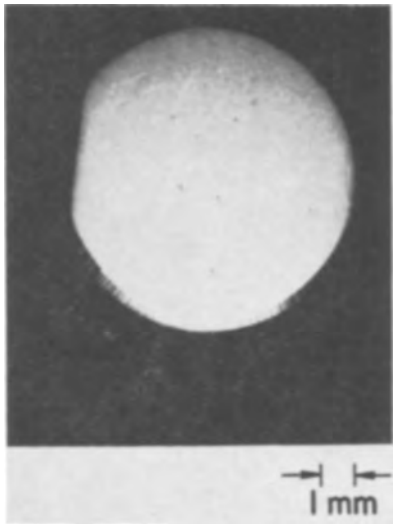

Fig. 9. Deposit on substrate with orientation <111> → <110>.

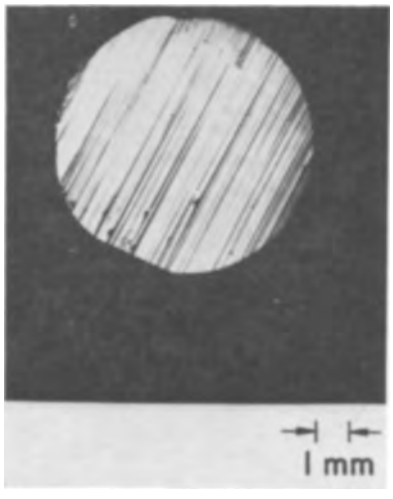

Fig. 10. Deposit on substrate with orientation <111> → <211>.

numerous pyramidal overgrowths, but did not show the greatest weight gain. The <111> wafers further down stream developed fewer, but larger pyramids. Figure 8 shows a typical deposit obtained on a <111> wafer. Wafers misoriented toward the <110> with $\rho = 3°\text{-}5°$ and a ϕ angle of 0-15° from the <111>-<110> vector were free of pyramidal overgrowths, exhibiting the structure shown in Fig. 9. Wafers misoriented 3°-5° toward the <211> with a low ϕ angle yielded shiny deposits which were, however, striated. These are shown in Fig. 10.

While the effects of ρ angle with small ϕ angle in either of the major misorientation directions was predictable, the effects of variation in ϕ angle with $\rho = 3°\text{-}5°$ were not as definable. Thus, when the major misorientation direction was toward the nearest <110> a measurable ϕ angle was always attended by the formation of a bevel around a portion of the wafer edge. This bevel was striated. No definitive, simple way of determining the directions of the striae could be found, although they appeared to be <110> directions. The edge of the wafer on which the bevel formed did not relate to the direction of the gas stream relative to the wafer in the deposition chamber. At higher ϕ angles, 20°-30°, hybrid surfaces developed which did not resemble too closely the surfaces obtained with $\rho = 3°\text{-}5°$ toward either of the two major misorientations. Thus, the surfaces were partially striated and shiny like those obtained on the <111> → <211> and partially matte finish similar to that obtained on the <111> → <110>. Because measurement of the ϕ angle is subject to more error than measurement of the ρ angle, the exact ϕ values at which these hybrids were observed cannot be stated precisely. Less extensive studies with zone leveled wafers gave similar results to those described above.

Studies of substrates with resistivities between 1 and 40 ohm-cm both n and p type from either pulled or zone leveled crystals, showed no further effects on the growth characteristics other than those derived by appropriate misorientation of the wafers. Thus, it may be concluded that the variation in growth characteristics observed is attributable to orientation effects. It is of further interest to note that aside from the furnace position effect observed in <111> oriented wafers, neither position nor temperature effects were observed on the growth habit of the misoriented substrates.

Although detailed studies of other orientations have not been conducted, preliminary studies of growth on <211> and <110> surfaces qualitatively show similar misorientation effects. <211> surfaces were found to be free of striae, <110> surfaces grew nonuniformly and both appeared extremely sensitive to surface condition.

Kinetics of the Silicon-Silicontetrachloride Reaction in a Flow System

Ole Alstrup and Carl O. Thomas[1]

Physics Department, Section III, Technical University of Denmark, Lyngby, Denmark

ABSTRACT

The kinetics of the heterogeneous reaction

$$Si + SiCl_4 = 2SiCl_2$$

have been studied in a flow system with helium as the carrier gas. For this reaction the postulated rate expression

$$\frac{d\,Si}{dt} = -1.0 \times 10^6 \exp\left(-\frac{67000}{RT}\right) P_4^{1/2} + 9 \exp\left(-\frac{29000}{RT}\right) P_2$$

$$g\ Si\ cm^{-2}\ sec^{-1}$$

was shown to describe the experimental results. The flow system data has been analyzed in terms of quantitatively measurable system parameters. Consequently true rather than apparent constants are found.

The reduction of silicon and germanium tetrahalides in a hydrogen atmosphere is widely used as a method for preparing epitaxial films of these materials. The type reaction is written usually as

$$MX_4 + 2H_2 = M + 4HX \qquad [1]$$

where M is the group-IV element and X is the halogen. This form is not even an accurate indication of the material balance. For example, a variety of other products occurs in the silicon-chlorine process including $SiHCl_3$ and miscellaneous polymeric forms. In spite of the large amount of experimental work in this field, a high level of uncertainty remains as to the mechanism by which hydrogen is involved in the over-all process. However, there is a general consensus in the literature [silicon (1-5) and germanium (6-7)] that the type disproportionation

$$M + MX_4 = 2MX_2 \qquad [2]$$

is one of the reactions in the over-all process. The equilibrium for the Si-$SiCl_4$ reaction following Eq. [2] has been studied quantitatively by Schäfer and Nickl (8-9). They concluded that no other molecular species were present to any significant degree. Bylander (2) and Monchamp, McAleer, and Pollack (5) have studied the disproportionation reaction in a flow system, but no quantitative kinetic data were obtained in either case. Monchamp *et al.* then used a low-pressure closed system, somewhat similar to that used by Heinecke and Ing (10) in germanium studies, for the investigation of the kinetics of the disproportionation reaction. They found that

$$\frac{dN_o}{dt} = -8.23 \times 10^{24} \exp\left(-\frac{49100}{RT}\right) P_4^{1/2}$$

$$atoms\ Si\ cm^{-2}\ sec^{-1} \qquad [3]$$

where N_o is the number of atoms in the silicon sample divided by its surface area, and P_4 the $SiCl_4$ pressure. A rate expression of this form indicates that the reaction must go to completion, and that the equilibrium constant must be either zero or infinite. The equilibrium constant is known to have a finite value (8), and consequently the rate expression of Monchamp *et al.* cannot be strictly valid. We postulate, subject to subsequent experimental verification, that the complete rate expression is of the following form

$$\frac{dN_o}{dt} = -k'_1 P_4^n + k'_2 P_2^{2n} \qquad [4]$$

where P_2 is the $SiCl_2$ pressure (P_{SiCl_2}) in the reaction zone, and k'_1 and k'_2 are rate constants. In Eq. [4] the factor-of-two relationship between the exponents is a requirement imposed by the form of the equilibrium constant, since this is found to be equal to P_2^2/P_4. At high flow rates, *i.e.*, not near equilibrium, $|k'_2 P_2^{2n}| << |k'_1 P_4^n|$ and Eq. [3] and [4] become similar in form. As one approaches equilibrium at low flow rates, the right-hand term becomes increasingly significant. We have determined the numerical values of k'_1 and k'_2 and n. The data, when extrapolated to zero flow rate, yield an equilibrium constant in reasonable agreement with that reported earlier by Schäfer and Nickl (8).

Experimental

The reaction chamber is shown in Fig. 1. The normal flow direction was in through the larger tube and out through the smaller central tube. The lower linear velocity through the external tube provided better temperature equilibration for the incoming gases. The influence of the flow direction was only detectable for flow rates above about 1 cc sec^{-1}. The close annular fit between the two concentric pieces and the capillary tip on the inner piece was intended to minimize back-streaming of gases. The volume of the reaction zone could be changed by changing the distance which the central piece was inserted into the larger tube.

At the highest flow rates used, the input pressure was less than 10 mm (Hg) above atmospheric pressure. Since the pressure terms enter to the one-half power and to the first power, the error in neglecting this pressure increment was considered to be negligible.

The flow rate was measured by means of a soap-film flow meter (11). A cold trap and a short capillary were placed between the exit of the reaction chamber and the flow meter to prevent halide products from getting into the flow meter. The flow rate data were

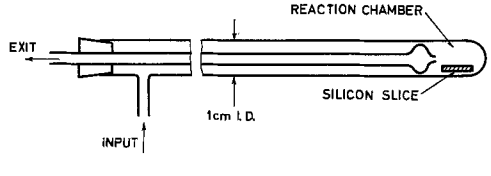

Fig. 1. Quartz reaction chamber

[1] Present address: Department of Physics, University of Tennessee, Knoxville, Tennessee.

corrected to standard conditions (cc sec^{-1} at 25°C and 760 mm Hg).

In the range of about 0.2 cc sec^{-1} to several cc sec^{-1} the flow control and reproducibility were better than ±5%. At flow rates below about 0.2 cc sec^{-1} the reproducibility degenerated rapidly. Therefore, at very low flow rates a motor-driven oil piston pump was used. In this way, a known volume of helium was pumped through the reaction chamber in a given time. The flow rate reproducibility was about ±10%.

A platinum-wound Heraeus furnace was used for heating. The furnace profile was flat to ±2°C for more than the length of the reaction zone. The temperature was stable to about ±2°C for the duration of the runs, usually about ½ hr. The control thermocouple was mounted adjacent to the furnace windings, and the measurement thermocouple was in contact with the end of the reaction chamber. A rather high activation energy was found for the reaction. Consequently the rate will be quite sensitive to the temperature variations, and this may be one of the sources of the scatter in the data.

The silicon slices were cut to a (111) orientation (±0.5°). They were then mechanically polished on both sides to a final thickness of about 0.5 mm. The final polish was with 1μ aluminum oxide. The slices were then waxed down and sawed to specified dimensions. The area figures used in subsequent calculations include both faces and the total edge area of these slices.

The etch rate of the reaction was determined by weight loss measurements on a microbalance. Blank weight loss runs were made with helium alone. The blank weight losses were consistently lower than 3% of the smallest weight losses produced by the reaction, so this correction was disregarded.

The downstream deposit in the cooler portion of the system was silicon, with no evidence of polymeric formation.

Mathematical Analysis

We assume complete mixing in the reactor volume. For this condition, where mixing is very rapid compared to the rate, the composition will be uniform throughout the reaction volume and equal to the output composition. This is of course a limiting condition, but it is apparently fulfilled in the reaction chamber used here as is later shown in the discussion of the results. For this condition the depletion rate of $SiCl_4$ in the reaction chamber is

$$-\frac{dm_4}{dt} = v_o\,(\rho_4^o - \alpha\rho_4) \qquad [5]$$

where m_4 is the weight of the incoming $SiCl_4$ vapor, ρ_4^o the density of $SiCl_4$ in the incoming gas, ρ_4 the density of $SiCl_4$ in the reaction chamber, and v_o the flow-rate of the unreacted gas mixture. α is a correction for gas expansion produced by the chemical reaction and is equal to $(1 + P_4^o)/(1 + P_4)$, where P_4^o is the $SiCl_4$ pressure in the incoming gas and P_4 the $SiCl_4$ pressure in the reaction chamber. Equation [5] may be rewritten as

$$-\frac{dm_o}{dt} = -\frac{M_0}{M_4}\frac{dm_4}{dt} = \frac{M_0}{M_4}v_o\,(\rho_4^o - \alpha\rho_4) \qquad [6]$$

where m_o is the weight of the silicon sample, M_0 the atomic weight of Si, and M_4 the molecular weight of $SiCl_4$. Combined with the postulated rate expression which may be written

$$\frac{1}{A}\frac{dm_o}{dt} = -k_1P_4^n + k_2P_2^{2n} \qquad [7]$$

where A is the total surface area of the sample we get

$$\frac{1}{A}\frac{M_0}{M_4}v_o\,(\rho_4^o - \alpha\rho_4) = k_1P_4^n - k_2P_2^{2n} \qquad [8]$$

For $P_4^o = 0.1$ atm and P_4 equal to the equilibrium value at 1170°C α is equal to 1.023. This is larger than any value applicable to our experimental conditions and consequently we drop the α term at this point. At larger values of P_4, the α term can of course become significant. For $\alpha = 1$ we have

$$P_2 = 2(P_4^o - P_4) = 2\,\Delta P_4$$

Inserting this in Eq. [8] and converting the ρ_4 term to P_4 dimensions by multiplication with M_4/RT we get

$$\frac{v_o}{A}\frac{M_0}{M_4}\frac{M_4}{RT}\Delta P_4 = k_1P_4^n - k_2(2\,\Delta P_4)^{2n}$$

or

$$\frac{v_o}{A}\frac{M_0}{RTk_1} + \left(\frac{4}{K}\right)^n(\Delta P_4)^{2n-1} = \frac{P_4^n}{\Delta P_4} \qquad [9]$$

where K is the equilibrium constant $= P_2^2/P_4 = (k_1/k_2)^{1/n}$. It is significant that for conditions where complete mixing obtains the reactor volume is not one of the system variable or constants.

The derivation ignores the "back-streaming" effect which often can introduce an error at low flow rates. The form of this correction was derived by Merten (12) and used by Thurmond and Frosch (13). We have checked the weight loss from the reaction in our system at zero flow and found it to be about the same magnitude as the blank weight loss. This was done by first blowing $SiCl_4$ through the system for 3 min to insure that a steady-state condition was established. Then the system was closed and allowed to stand at the reaction temperature for 1 hr. The system was then quickly purged with helium and the weight loss measured. After subtracting the calculated weight loss for the first 3 min (obtained from data in other runs) the difference is then due to back-streaming.

Results and Discussion

Evaluation of n.—P_4, the ambient $SiCl_4$ pressure in the reaction chamber, can be determined from the flow rate, the initial $SiCl_4$ pressure P_4^o, and the silicon weight loss by using the equation for the material balance

$$\Delta P_4 = -\frac{1}{v_o}\frac{dm_o}{dt}\frac{RT}{M_0} \qquad [10]$$

where $-dm_o/dt$ is set equal to the weight loss of the sample divided by the time for the experiment. We use these values to construct Fig. 2, which is a log-log plot of etch rate *vs.* P_4. This neglects the second right hand term of Eq. [7]. A straight line can be drawn through the high flow rate points, with a slope of $n = 0.49 \pm 0.01$ in agreement with Monchamp *et al.* Figure 2 is based on nine runs made at a reaction temperature of 1170°C and $v_o/A \geq 3$ cm/sec. The straight

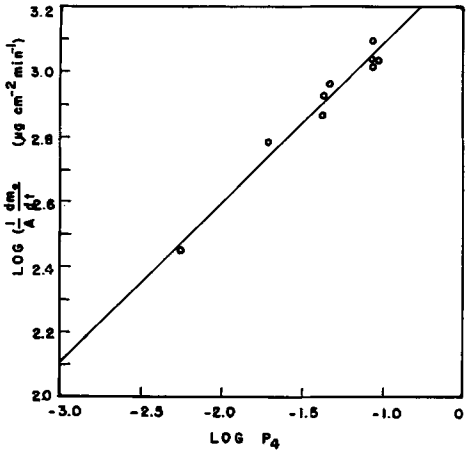

Fig. 2. Etch rate in g Si per cm^2 per min *vs.* the $SiCl_4$ pressure. In log-log plot the slope is equal to the exponent *n*.

line shows that one can neglect the second term in Eq. [7] for the high flow rate experiments. The low flow rate data points can lie far from the line. The validity of the above procedure is further supported by Fig. 5 which will be discussed later.

Evaluation of k_1.—For the special case on $n = 0.5$ Eq. [9] simplifies

$$\frac{v_o}{A}\frac{M_0}{RT}\frac{1}{k_1} + \left(\frac{4}{K}\right)^{1/2} = \frac{P_4^{1/2}}{\Delta P_4} \qquad [11]$$

In Fig. 3 we have plotted $P_4^{1/2}/\Delta P_4$ *vs.* v_o/A for the 1170°C data. The slope of the line is M_0/RTk_1 and the intercept at $v_o/A = 0$ is $2K^{-1/2}$, so that we can determine both the rate constant k_1 and the equilibrium constant K. (k_1 can also be determined from Fig. 2 and checks within 3%). The lower curve is a least-squares fit to 39 runs. The reaction chamber volume was from 1.5 to 4 cc for this group. The upper curve is for three additional runs at 6 cc volume. For these runs the volume was large enough to invalidate the complete mixing assumption, and to produce an apparently lower rate constant. For the remainder of the runs at other temperatures the reactor volume was kept small enough to be in the complete mixing range and no dependency on the volume was observed.

Schäfer and Nickl (8) give 0.050 (in atm) for the 1170°C equilibrium constant. From Fig. 3 we find a value of 0.035 ± 0.015 which is in tolerably good agreement with Schäfer and Nickl's result.

The slope of the lower curve in Fig. 3 yields a value of $k_1 = 79 \times 10^{-6}$ g Si cm^{-2} sec^{-1} $atm^{-1/2}$ which is about five times as large as the k_1 value calculated at 1170°C from Monchamp's rate expression.

Runs similar to those previously described were made at reaction temperatures of 1000° and 1080°C. For each reaction temperature a least squares plot as shown in Fig. 3 was made. Since the slope is M_0/RTk_1, the rate constant k_1 at each temperature can be determined. The intercept in each case was again $2K^{-1/2}$. For these temperatures, K was in closer agreement with Schäfer and Nickl's result.

The three values of k_1 are plotted *vs.* reciprocal temperatures in Fig. 4. The activation energy is found to be 67 ± 7 kcal $mole^{-1}$, which gives

$$k_1 = 1.0 \times 10^6 \exp\left(-\frac{67000}{RT}\right) \text{ g Si } cm^{-2}\ sec^{-1}\ atm^{-1/2} \qquad [12]$$

This activation energy is even higher than that reported by Monchamp *et al.* Both Monchamp and Heinecke have indicated that for flow system measurements they found a very low apparent activation energy, about 5 kcal in the case of silicon (5). We are unable to account for the great difference between their flow system data and ours. We would expect the apparent activation energy to be lower in the closed system where the mass transport is limited in part by diffusion and convection currents in the gas phase. This could account in part for the difference between 49 kcal reported for a closed system by Monchamp and the 67 kcal found in the present work for an open flow system.

Calculation of k_2.—One cannot, of course, derive the rate expression from the equilibrium constant directly. However, if the rate expression is correctly formulated in Eq. [4], we can calculate k_2 and its activation energy from the data available at this point. At equilibrium

$$k_1 P_4^{1/2} = k_2 P_2 \qquad [13]$$

and $k_2 = k_1 K^{-1/2}$. We have found both k_1 and K as functions of temperature, but since our value of the equilibrium constant is in agreement with Schäfer and Nickl's and the latter is determined with more accuracy we have used their value for calculating k_2, *i.e.*, we use

$$K = 1.21 \times 10^{10} \exp\left(-\frac{75000}{RT}\right) \text{ atm}$$

Therefore by use of Eq. [12] we can go directly to

$$k_2 = 9.0 \exp\left(-\frac{29000}{RT}\right) \text{ g Si } cm^{-2}\ sec^{-1}\ atm^{-1} \qquad [14]$$

and the complete rate expression

$$\frac{1}{A}\frac{dm_o}{dt} = -1.0 \times 10^6 \exp\left(-\frac{67000}{RT}\right) P_4^{1/2} + 9 \exp\left(-\frac{29000}{RT}\right) P_2 \text{ g Si } cm^{-2}\ sec^{-1} \qquad [15]$$

The two activation energies are consistent with the H value for the reaction as calculated from the heats of formation of the dichloride and of the tetrachloride.

Flow rate dependency.—Rearrangement of Eq. [11] gives

$$\Delta P_4 = \frac{k_1 P_4^{1/2}}{2k_2 + v_o M_0/ART} \qquad [6]$$

Figure 5 illustrates the etch rate, stated as weight loss per cc of gas, as a function of the v_o/A parameter. The solid line is calculated from Eq. [16] (Recall that $1/v_o \times dm_o/dt$ is proportional to ΔP_4, Eq. [10]) for a reaction temperature of 1170°C and P_4^o equal to 0.045 atm. The broken line is calculated using only the $k_1 P_4^{1/2}$ term from Eq. [7]. For low flow rates the curve is too high and approaches complete reaction rather than the equilibrium value. For $v_o/A \geq 3$ cm/sec one is allowed to disregard the second term in Eq. [15].

By inserting Eq. [10] in Eq. [16] we get

$$-\frac{dm_o}{dt} = \frac{k_1 P_4^{1/2}}{\frac{1}{A} + 2k_2\frac{RT}{M_0}\frac{1}{v_o}} \qquad [17]$$

or

$$-\frac{1}{A}\frac{dm_o}{dt} = \frac{k_1 P_4^{1/2}}{1 + 2k_2\frac{RT}{M_0}\frac{A}{v_o}} \qquad [18]$$

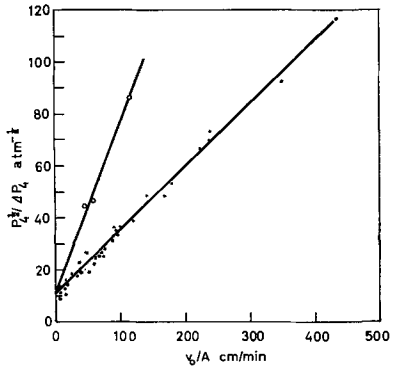

Fig. 3. Data plot based on Eq. [11] for determination of k_1

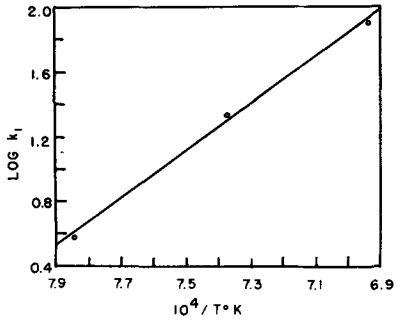

Fig. 4. Temperature dependence of k_1

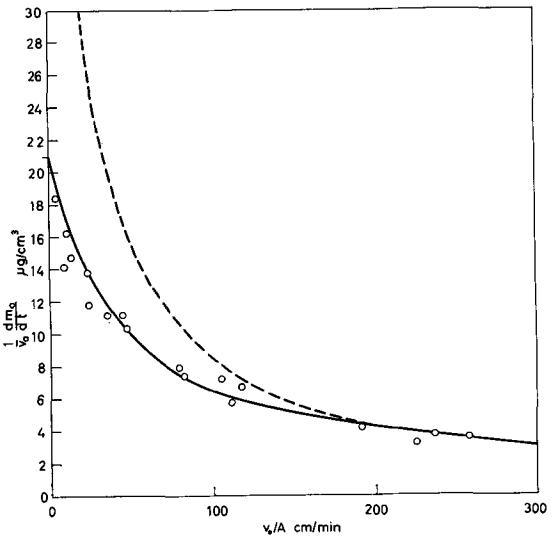

Fig. 5. Etch rate in g Si per cc of the gas *vs.* the flow rate divided by the sample area.

At sufficiently low flow rates Eq. [18] gives

$$-\frac{1}{A}\frac{dm_o}{dt} \cong \frac{M_0}{RT}\frac{k_1}{2k_2}\frac{v_o}{A}P_4^{1/2} = \frac{M_0}{RT}\left(\frac{K}{4}\right)^{1/2}\frac{v_o}{A}P_4^{1/2} \quad [19]$$

At high flow rates

$$-\frac{1}{A}\frac{dm_o}{dt} \cong k_1P_4^{1/2} \cong k_1P_4^{o1/2} \quad [20]$$

By plotting $1/A$ x dm_o/dt *vs.* v_o/A as with Eq. [19] and [20] one gets a curve with asymptotes in 'both ends.' From the asymptotes one can calculate k_1 and K. However the low flow rate region often is so small that the asymptote is determined with a high uncertainty.

Equation [17] and Eq. [18] are consistent as to asymptotes. However if one uses samples of different area, it is seen from Eq. [17] that one cannot get a curve in the intermediate region by plotting dm_o/dt *vs.* v_o. We see that the flow dependency is expressed by the ratio v_o/A rather than by v_o.

The dimensions of v_o/A are cm/sec, a linear velocity, but should not be construed as being the actual linear velocity of the gas in the system, since the area is that of the sample and not the cross section of the reactor. Mathematical normalization to unit area, introduced in Eq. [7] leads to the v_o/A form.

General comments.—The temperature measurement of the reaction chamber is done with a thermocouple placed outside the reaction chamber. Because of the possibility of a temperature difference between the outside and inside of the reaction chamber there may be a systematic error in the temperature measurement. There are different sources of error. The incoming gas may not be sufficiently warm. As mentioned previously this was the case when the gas was let in through the narrow inner tube. When we use the outer tube the temperature profile in the furnace is so flat that the gas obtained the right temperature at all flow rates. This can be seen by the following argument. If the gas temperature is lower than the stated reaction temperature, the temperature difference will increase with increasing flow rate as the time of heat transfer per cc of gas from the wall will decrease. Consequently for two "identical" experiments, where v_o/A is the same but v_o is different, we should get a lower etch rate for the experiment at higher flow rate. This is not observed within the experimental uncertainty. Another source of error could be the heat of the reaction. Also, an error may appear since there may be a temperature difference between the gas and the furnace walls. In fact some later experiments carried out in a quite different system gave etch rates that all were 10% higher than those given here. It may be explained by the two last sources of error. Including these experiments in the calculations would change k_1 about 15% and K about 40%, whereas n would be unchanged. These figures may indicate the uncertainty of the experiments.

Comparing our results with those of Monchamp *et al.* we see that the n-value is the same whereas we get different values for the activation energy of k_1. The difference is so large that it cannot be explained by an error in our temperature measurement. We believe it more likely that Monchamp's etching is partly diffusion limited. This is the case for our experiments with the large reaction chamber as shown in Fig. 3 (upper line). The value of k_1 is lower but the value of n is still 0.5.

Another difference between Monchamp's and our results is that we in the rate expression use the actual pressures of $SiCl_4$ and $SiCl_2$ in the reaction chamber, whereas Monchamp apparently uses the initial pressure P_4^o or an over-all pressure $P_4 + P_2$. However this cannot explain the difference in our k_1 values.

The high activation energy for the etching reaction and the fractional order of the reaction imply that the rate limiting step is surface adsorption or desorption as suggested by Monchamp *et al.* In this case we would expect to see a relationship to the surface roughness factor. However no difference in etch rate was observed on chemically polished and on lapped samples. In most of the runs, the total thickness reduction was about 250μ. Consequently the initial roughness produced by different surface treatments would be smoothed out early in the runs, and the roughness variation could be hidden, along with other experimental variables, in the standard deviation. There was no detectable rate difference between the (111), (110), and (100) planes. Also, there was no noticeable preferential development of crystal faces near the edges or corners of the samples. On the other hand if the rate-limiting step is surface adsorption or desorption, one would expect n to vary with pressure, which is not found in the pressure region used.

Acknowledgments

The authors wish to thank Mrs. I. Lund and Mr. S. Mathiesen for preparing the samples and assisting with the runs; C. D. Thurmond and N. I. Meyer for helpful discussion: the Bell Telephone Laboratories and Haldor Topsøe for contributing the materials used in the work.

Manuscript received July 27, 1964; revised manuscript received Oct. 28, 1964. This paper was abstracted in part from one submitted in partial fulfillment of the requirements for the Lic. Techn. degree by one of the authors (O.A.) and the work was supported in part by grants from the United States Educational Foundation in Denmark and from the American Scandinavian Foundation in New York.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

LIST OF SYMBOLS

A surface area of the sample.
α correction factor to account for the volume expansion in the reaction chamber.
K equilibrium constant $= P_2^2/P_4$.
k_1,k_2 rate constants, associated with P_4 and P_2, respectively.
M_0 atomic weight of Si.
M_4 molecular weight of $SiCl_4$.
m_o weight of Si sample.
N_o number of Si atoms in the sample per unit surface area.
P_4^o $= P^o_{SiCl4} = SiCl_4$ pressure in the incoming gas.
P_4 $= P_{SiCl4} = SiCl_4$ pressure in the reaction zone.
P_2 $= P_{SiCl2} = SiCl_2$ pressure in the reaction zone.
ΔP_4 $= P_4^o - P_4$.
R gas constant.
ρ_4^o density of the incoming $SiCl_4$.
ρ_4 density of $SiCl_4$ in the reaction chamber.
T absolute temperature.
t time (sec).
v_o flowrate of the incoming gas mixture (cc/sec) corrected to 298°K and 1 atm.

Localized Enhanced Diffusion in NPN Silicon Structures

R. Gereth, P. G. G. van Loon, and V. Williams

ITT Semiconductor, Shockley Laboratory, Palo Alto, California

ABSTRACT

Extensive studies of the Emitter Dip Effect (EDE) in npn silicon structures are reported. Typically, 1 ohm-cm n-type silicon starting material was used. Boron diffusion into this material resulted in a 0.7μ base depth and surface concentrations of 1.8 x 10^{20} cm^{-3}. The emitter regions had surface concentrations of 3 x 10^{20} cm^{-3} and 0.4μ junction depths. The dip was typically 0.3μ, *i.e.*, the base penetrated 0.3μ deeper under the emitter than elsewhere. Important experimental findings are: (*A*) Crucible grown, zone refined, and epitaxial silicon give the same results. (*B*) The EDE occurs only if phosphorus doping is sufficient to overcompensate the base doping. (*C*) Multiple emitter diffusion causes multiple dips. (*D*) Slow cooling from diffusion temperature enhances the dip. (*E*) An enhanced boron diffusion constant in the base layer apparently causes the dip rather than the rejection of boron by the region of high phosphorus concentration. (*F*) The dip is not present for lightly doped (10^{17} cm^{-3}) base layers.

Localized enhanced diffusion of the base collector junction underneath the emitter regions has been observed in double diffused high-frequency transistors (1-3). This phenomenon is often referred to as Emitter Dip Effect (EDE). Not very much attention has been given to the EDE in the relevant literature during recent years. This was mainly due to lack of reproducibility complicating the study of the EDE and its theoretical explanation. The EDE was first reported by Miller (1), who described the phenomenon and suggested the possibility that the effect was caused by impurity interactions such as published by Reiss *et al.* (4) for lithium in germanium. Later, the EDE was discussed by Baruch and co-workers (2). Based on a vacancy enhanced diffusion mechanism they developed an hypothesis which partially explained the EDE observed in a npn structure made with gallium base diffusion.

The earliest work which was done in the course of the investigation reported here was concerned with the reproducibility of the effect. Previously, the EDE had been observed only sporadically and was found to be connected in some way with the time and temperature of predeposit of both the base and the emitter dopants, subsequent diffusion and oxidation steps, and operator technique, as well as general cleanliness of the furnaces. After a schedule had been found which gave reproducible results from run to run, intensive studies were made to establish the experimental conditions for the creation of the EDE. Most emphasis was put on a shallow diffused silicon npn transistor. The experiments were extended later to pnp structures.

Experimental Results

Starting material and standard diffusion schedule.— The starting material used in the majority of the experiments was n^-n^+ epitaxial material obtained from Merck, Monsanto, Allegheny, and Texas Instruments. The vapor grown n^- silicon film was about 10μ thick and had a resistivity of 1 ohm-cm, corresponding to a carrier concentration of 5 x 10^{15} cm^{-3}. The resistivity of the n^+ substrate ranged from 0.002 to 0.04 ohm-cm. The same results were obtained when experiments were carried out using crucible grown silicon material of equivalent doping level. The schedule which was followed in most of the work is described below and illustrated in Fig. 1.

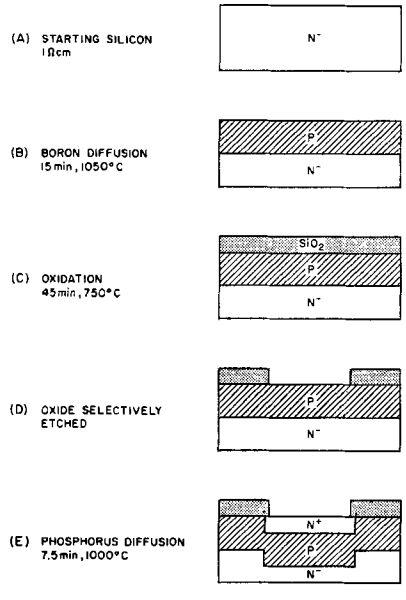

Fig. 1. Processing steps for fabrication of shallow diffused npn silicon structures.

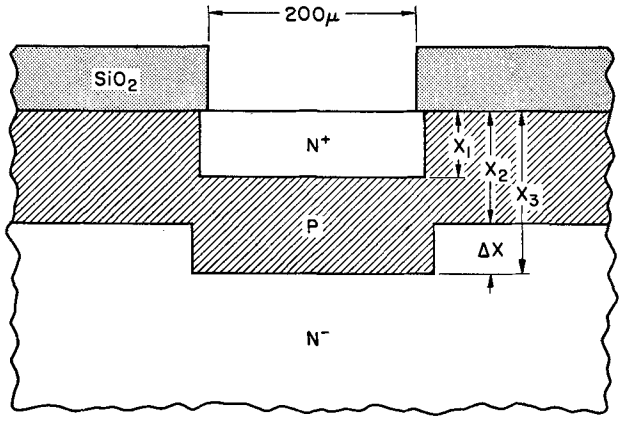

Fig. 2. Schematic drawing of a beveled cross section through npn structure exhibiting the EDE (note the different scale in horizontal and vertical direction). Standard npn structure: $X_1 = 0.4\mu$; $X_2 = 0.7\mu$; $X_3 = 1.0\mu$; $\Delta X = 0.3\mu$.

After standard cleaning steps, the base was diffused in at 1050°C for 15 min using 1% diborane in hydrogen as the dopant source and dry nitrogen as the carrier. This procedure gave a junction depth of 0.7μ and a surface concentration of 1.8×10^{20} cm^{-3}. Following the base diffusion a surface layer of silicon dioxide was grown by means of the thermal decomposition of ethyl silicate (5) in vacuum at 750°C for 45 min. Emitter windows were then opened in this oxide layer. The emitter regions were produced by diffusion of phosphorus at 1000°C for 7.5 min. The diffusion source was P_2O_5 at a temperature of 240°C; the ambient was dry nitrogen.

Beveling and staining the slice following the emitter diffusion revealed the "standard" EDE. An enlarged illustration of the EDE is shown in Fig. 2. For the purpose of this paper, certain distances have been defined as noted in Fig. 2. The emitter base junction depth is defined as X_1, the base collector junction under the oxide as X_2, and the base collector junction under the emitter as X_3. It can be seen that the magnitude of the dip is equal to $X_3 - X_2 = \Delta X$. The distances X_3, X_2, and ΔX are independently measurable and since $X_3 - X_2 = \Delta X$, a check is provided for the value of ΔX. Another advantage of the schedule is that comparatively low temperatures are involved. At temperatures in the range of 1000-1050°C, complicating factors such as thermal diffusion, outdiffusion through the open windows, and diffusion into the oxide mask during the time involved are minimized.

Influence of emitter diffusion on EDE.—Having established a schedule which reliably produced the EDE,

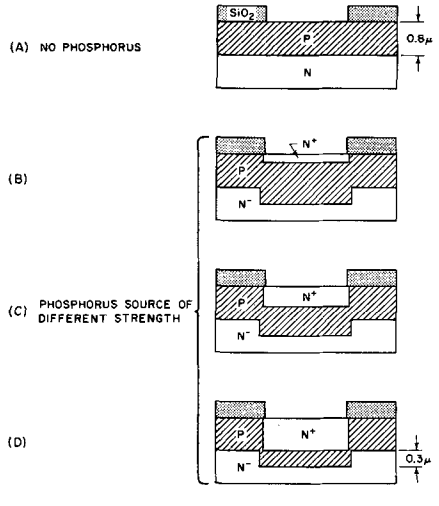

Fig. 3. Emitter dip as a function of emitter junction depth; heat treatment, 15 min, 1000°C.

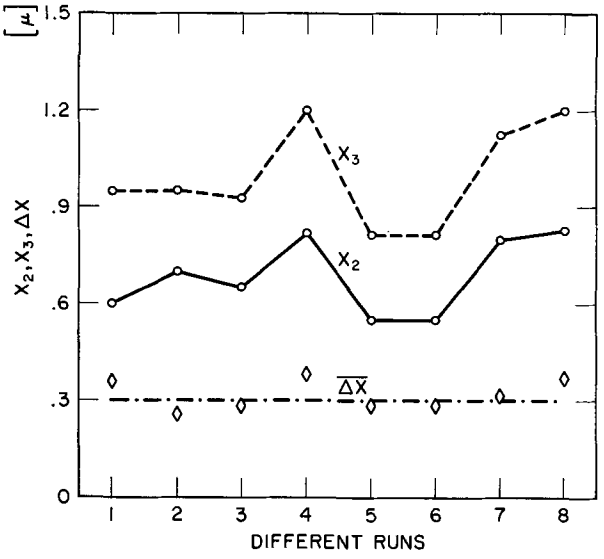

Fig. 4. Observed scatter of X_2, X_3, and ΔX over eight repeated experiments. Emitter diffusion time was 7.5 min. ◇, $\Delta X = X_3 - X_2$.

the influence of the emitter diffusion on the EDE was investigated. It was shown that the presence of a phosphorus doped emitter was necessary to produce the EDE. A dip was never observed unless staining revealed n-type doping in the emitter window. The magnitude of the EDE, however, was independent of the phosphorus concentration above that necessary to produce an emitter. If windows were opened in the oxide over the base layer and the slice diffused for periods of time up to 15 min at 1000°C in a clean tube, no dip was observed. In contrast to this observation, it was found that appreciable outdiffusion of boron occurred if material with opened windows was diffused at 1100°C for 20 min in a clean tube. This outdiffusion resulted in a reverse dip. The experiment also showed that diffusion of boron into the oxide which could result in the EDE did not play an appreciable role at 1000°C.

Deliberate variation in the emitter concentration was obtained by aging a P_2O_5 source for 15 min and then removing it. Doping of the silicon material was then a result of residual P_2O_5 in the tube. In all cases the extent of the dip was 0.3μ, within the limits of experimental error. This observation is in contradiction to earlier findings (1). Figure 3 illustrates our observations. In all cases, the base was the result of the standard diffusion, and the heat treatment thereafter

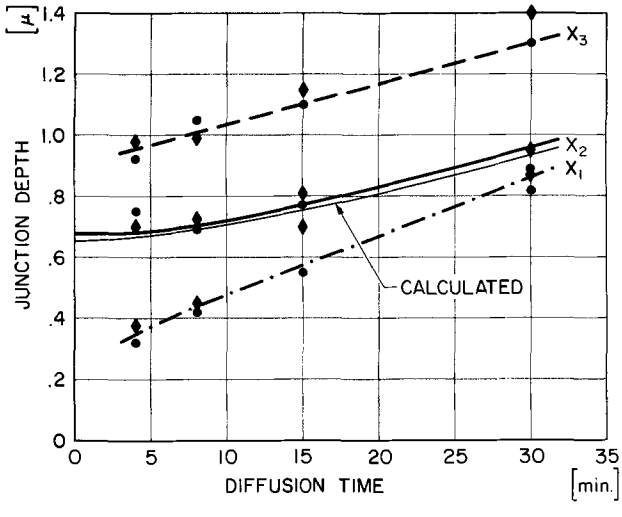

Fig. 5. Junction depths X_j ($j = 1, 2, 3$) as a function of emitter diffusion time. X_j's are defined in Fig. 2; ●, operator A; ◆, operator B.

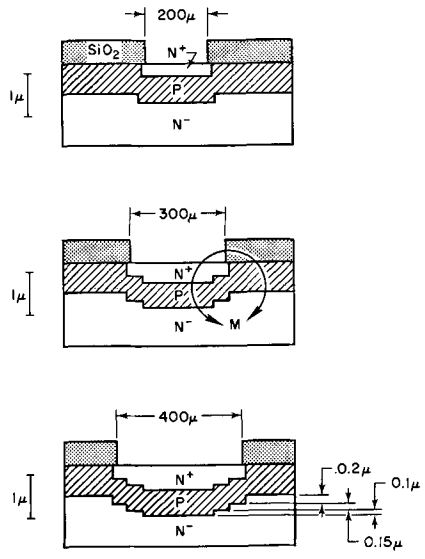

Fig. 6. Multiple EDE caused by multiple emitter predeposition steps.

was for 15 min at 1000°C in a nitrogen ambient. The magnitude of the EDE is seen to remain constant although the emitter junction depth increases with source strength.

Additional studies of the effect of the phosphorus emitter doping level on the EDE are plotted in Fig. 4 and 5. The scatter of X_2, X_3, and ΔX observed over eight repeated experiments are presented in Fig. 4. The emitter diffusion time was 7.5 min, all other parameters were maintained constant. Although the magnitude of X_2 varies, ΔX stays nearly constant with an average value of 0.3μ. Figure 5 shows the junction depths as a function of phosphorus emitter diffusion time. The data represent average values obtained by operators A and B. The average value of ΔX is again 0.3μ. The diffusion of the base collector junction under the oxide X_2 is in good agreement with the calculated values using the boron diffusion constant as published by Fuller and Ditzenberger (6). Of interest is the finding that the dip seems to be produced almost instantaneously. Only in phosphorus diffusion times of less than 2 min was the dip found to decrease in magnitude. This decrease can be attributed, however, to insufficient time for the slice to reach the temperature of the furnace. Further evidence for the observation that the dip is formed in time intervals which are short compared to the over-all diffusion times at 1000°C was provided by an experiment illustrated in Fig. 6. A 200μ wide window was opened in the oxide coating of a slice which contained the standard base. An emitter was then predeposited for 4 min at 1000°C. Following this treatment, the window was widened. The slice was returned to the diffusion furnace for another 4 min. The window was again widened, and the slice was predeposited for a final 4 min. Beveling and staining the material revealed a dip after each diffusion. The initial dip was 0.2μ in this particular slice, and each successive predeposit produced a dip although it became smaller. It should be pointed out that the total EDE produced by the triple phosphorus predeposition steps of 4 min each is 50% larger than that found as a result of a single 12 min emitter diffusion. The base under the oxide remained constant at 0.7μ throughout the experiment. Figure 7 is a microphotograph revealing the "true structure" of a small section labeled "M" in Fig. 6.

Variation of base layer.—Most of the work discussed above was done on material containing a 0.6-0.7μ deep base layer. The surface concentration of acceptors in this material as determined by four-point probe measurements was 1.8×10^{20} cm^{-3}.

An obvious experiment was the determination of the effect of a thicker base layer. The standard silicon epitaxial material was diffused in diborane at 1050°C for 2, 16, and 64 hr. The base collector junction in this material was 2.5, 3.9, and 6μ, respectively. After oxide growth and 7.5 min of phosphorus diffusion at 1000°C an EDE of approximately 0.3μ was visible in the material containing the 2.5μ base. A slight rounding was visible under the emitter of the material containing the 3.9μ base. No EDE was visible in the 6.0μ base layer. The dip in the 3.9μ base material was not reproducible.

Figure 8 is an illustration of another experiment done to determine what influence the base concentration has on the EDE. As described above, a pyrolytic oxide (5) was grown on material which had been diffused in diborane at 1050°C for 2 hr. After opening emitter windows, part of the base layer was etched away in the emitter windows. Subsequently, the slice was predeposited in the P_2O_5 furnace at 1000°C for 4 and 8 min, respectively. No dip was visible. Details of this experiment are illustrated in Fig. 8. From this experiment it was concluded that the EDE occurred only when phosphorus was predeposited in material containing relatively high acceptor concentration levels. The concentration of the boron acceptors in the "tail end of the diffusion" is apparently too low to produce a dip.

Using a series of epitaxially deposited base layers (7) of different doping concentrations, the influence of the base doping level on the EDE was investigated. The substrate was 1 ohm-cm n-type silicon in all cases. The results are summarized in Table I. Only the heavily doped epitaxial layers show the EDE. Run 1 was re-

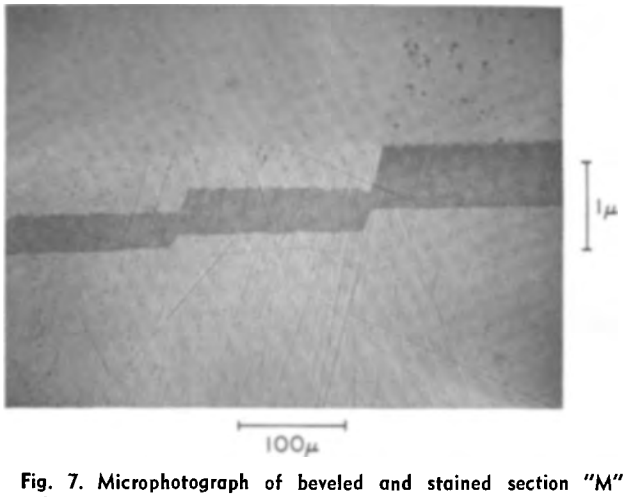

Fig. 7. Microphotograph of beveled and stained section "M" as schematically illustrated in Fig. 6.

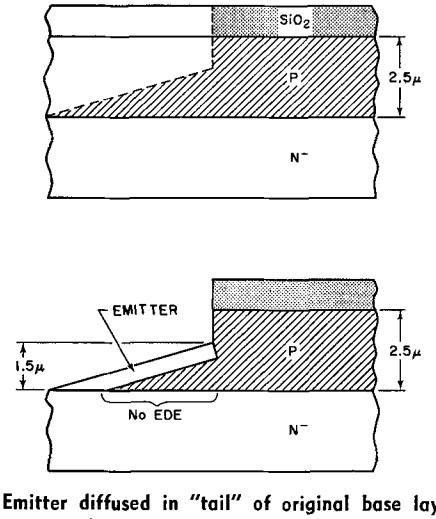

Fig. 8. Emitter diffused in "tail" of original base layer. Dotted line in the upper drawing indicates how the structure was etched prior to emitter diffusion.

Table I. EDE experiments performed with epitaxial base layers. The phosphorus emitter diffusion was carried out at 1000°C for 7.5 min. X_2 and ΔX are defined as shown in Fig. 2

Run	Boron concentration, cm^{-3}	X_2, μ	ΔX, μ
1	1.3×10^{17}	0.6	0
2	1.0×10^{18}	0.9	0
3	3.0×10^{18}	0.9	0.1
4	1.2×10^{19}	0.9	0.15

peated with a silicon slice which had the identical starting epitaxial base layer. Prior to the emitter diffusion, however, a shallow p^+ layer (approximately 0.3-0.4μ deep) was formed in the regions of the emitter windows by exposing the slice at 1050°C for 4 min to a diborane nitrogen gas stream as described earlier. No EDE was found in this slice after the subsequent emitter diffusion (7.5 min at 1000°C). This last experiment clearly demonstrates that it is the magnitude of the base concentration in the region of the base collector junction as opposed to the surface concentration which is important for the formation of the EDE. The influence of the base surface concentration is only indirect since it obviously determines the impurity profile in the diffused base layer and thus the concentration in the vicinity of the base collector junction.

Cooling rate and EDE.—Baruch (2) observed a drastic influence of the cooling rate on the EDE. He reported an increase of the magnitude of the dip by a factor of 2 in a silicon slice containing a gallium doped base and phosphorus doped emitter when the slice was cooled at the rate of 5°C/min and not quenched. With this idea in mind, the following experiment was carried out. Two slices containing the standard base were diffused at 1000° in a phosphorus predeposit furnace. After 7.5 min, one slice and the P_2O_5 source were removed from the furnace. The other slice remained in the furnace. On removal of the phosphorus source, the furnace temperature was allowed to drop at an average rate of 3°C/min from 1000 to 680°C; the slice was then taken out of the furnace and quenched to room temperature. It was found that the EDE in the material which served as the reference slice was the standard one ($\Delta X = 0.3\mu$). On the other hand, the EDE in the slowly cooled material was 0.5μ. The depth of the base under the oxide was exactly the same in both slices. The experiment was done several times and close agreement between runs was found. Part I of Fig. 9 illustrates the effect.

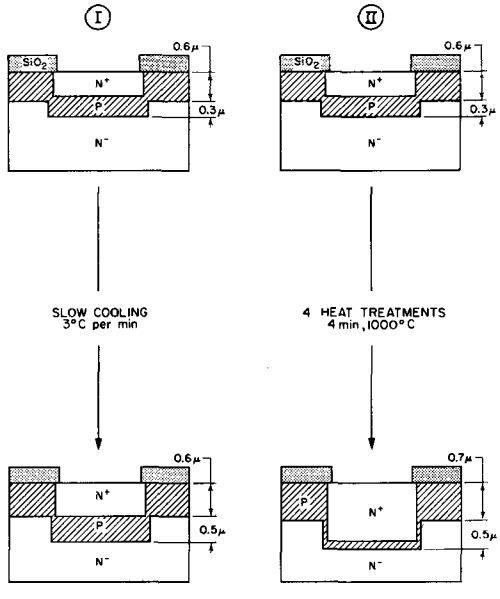

Fig. 9. Influence of heat treatments on standard EDE

Another interesting result was obtained when a slice exhibiting the standard EDE ($\Delta X = 0.3\mu$) was given 4 heat treatments at 1000°C. Each heat treatment was of 4 min duration and was done in a clean furnace without phosphorus source present. After each heating step the slice was rapidly taken out of the diffusion furnace and quenched to room temperature. The time required for removal and cooling was 10-11 sec. Part II of Fig. 9 shows the influence of the heat treatments on the EDE. The total heating time of 16 min during which the slice had been in the hot zone of the furnace, caused a slight movement of the base collector junction underneath the oxide (X_2 changed from 0.6 to 0.7μ) and a strong inward diffusion of the phosphorus atoms forming the emitter region. The dip in the base collector junction was also increased. However, after the four heat treatments it approached the same value of 0.5μ as was found in the "slow cooling" process described above. This observation shows for the first time that the EDE can be influenced by a simple heat treatment without an external phosphorus source.

In the subsequent experiment the function of the emitter in producing the EDE was explored. The EDE was produced following the standard procedure. One half of the slice was treated for 45 sec in an etch which removed the emitter region while leaving the oxide and base layer intact. Both halves were then cooled from 1000 to 700°C over a period of 2 hr in a clean tube without source. It was found that the dip had increased from about 0.2 to 0.4μ in the slice containing the emitter whereas the EDE remained constant at about 0.2μ in the slice from which the emitter region had been removed.

After it was found that the rate of cooling was important in the formation of the EDE, an attempt was made to determine the effect of rapid cooling. The average time required to remove a slice from the phosphorus diffusion furnace was 11 sec. A modification in procedure resulted in decreasing this time to about 1 sec. Phosphorus diffusion for 4 min at 1050°C into silicon containing the standard base followed by this rapid cooling resulted in a 27% decrease in the dip as compared to a slice cooled at the ordinary rate.

Determination of concentration profiles[1].—All results on the EDE described thus far were obtained from cross section evaluation of diffused npn structures. In

[1] This Section was partly supported by Contract No. AF 33(657)-11403.

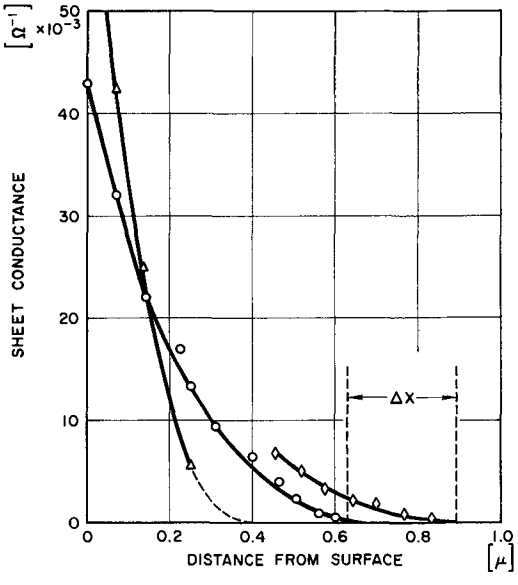

Fig. 10. Sheet conductance measurements as a function of distance from surface, ○, Base only; ◇, base under emitter; △, emitter.

order to gain more information on the EDE, the concentration profile in the standard test structure was determined using the technique of anodic sectioning (8). Two epitaxial silicon slices (n-type, 1 ohm-cm resistivity) were prepared. The first slice referred to as the "base only slice" contained the standard diffused base layer formed at 1050°C for 15 min as described in Fig. 1. The second slice referred to as the "base under emitter slice" contained the standard base plus a shallow phosphorus layer over the entire slice which was produced by a 4 min phosphorus diffusion step at 1000°C. This additional 4 min heat treatment at 1000°C was also applied to the first slice after the actual base diffusion; however, in this case no phosphorus source was present.

Each slice was anodically sectioned separately. The silicon was removed in increments of 0.05-0.06μ as determined by microbalance weighings. Sheet conductance calculations were made using the results of four point probe measurements (9). For further details of the method see paper by Tannenbaum (8). Figure 10 reproduces the experimental results. The sheet conductance is plotted as a function of distance from the surface. The "circles" correspond to the data obtained from the slice which contained only the base layer. In the second slice, the sheet conductance of the base (denoted by "diamonds" in Fig. 10) could be measured only after the emitter was removed. Since the emitter junction depth was 0.4μ, the first reliable sheet conductance measurement of the base underneath the emitter could be performed at a depth of 0.46μ. The emitter dip effect is clearly visible in Fig. 10 as the difference between the extrapolated base collector junction depths of the two slices. The junction depths as revealed by the sectioning procedure were in good agreement with those determined by staining.

The concentration profiles of the diffused boron base layers are plotted in the upper part of Fig. 11. These curves were prepared from Fig. 10 by determining the conductivity from the derivative of sheet resistance in respect to sectioning depth. The concentration of the boron atoms was then found by referring to Irvin's paper (10). The notation of Fig. 11 is the same as that of Fig. 10. The boron concentration as a function of distance from surface was calculated in steps of 0.05μ. At the surface, the boron impurities reach a concentration of 1.8×10^{20} cm^{-3}.

In addition to the measured profiles of the diffused boron layers in the two slices, the profile observed in a

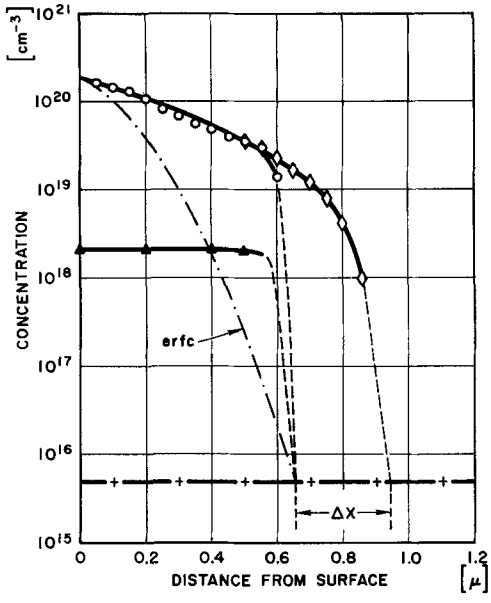

Fig. 11. Concentration profiles of diffused and epitaxial base layers: ○, base only; ◇, base under emitter; ▲, epitaxial base; +, collector (1 ohm-cm, n-type).

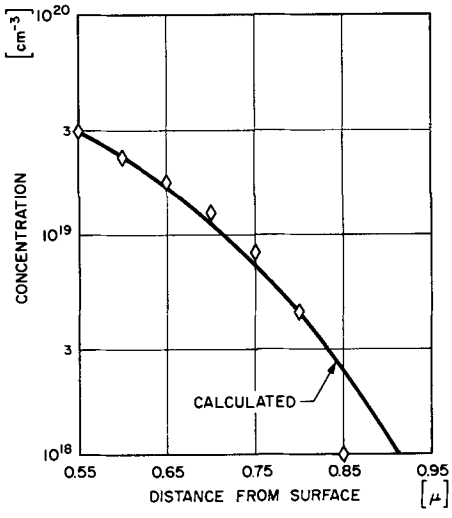

Fig. 12. Concentration profile in base layer of three layer npn structure. The emitter junction depth was 0.4μ deep. The calculated curve corresponds to an erfc distribution. ◇, Base under emitter.

control test specimen in an epitaxially grown base layer is shown; this indicates the precision of the technique. A theoretical erfc distribution for a diffused layer with a surface concentration of 1.8×10^{20} cm^{-3} and a junction depth of 0.65μ is shown for comparison with the two diffused slices.

The results of the concentration profile measurements illustrated in Fig. 11 suggest that (*a*) there is no pile up of boron impurities in the "base under emitter" slice directly in front of the phosphorus emitter (no "snowplow effect") and (*b*) the EDE is not caused by a normal thermal diffusion process. The fact that the snow plow effect is not operative is indicated by the identical curvature which both base layer sheet conductance curves (Fig. 10) exhibit at distances between 0.45 and 0.55μ.

At a depth of 0.6μ the concentration of the base in the "base only" slice drops off rapidly (see Fig. 11) while the profile of the "base under emitter" shows a more gradual decrease. This section of Fig. 11 is redrawn in Fig. 12. The experimentally obtained points are shown together with a calculated curve representing an ideal erfc distribution. This distribution is based on a model which is equivalent to the assumption that the flat concentration profile below 0.55μ in Fig. 11 acts as a constant concentration source leading to an erfc distribution as a function of depth beyond 0.55μ. This curve is shown in Fig. 11 with a "surface concentration" of 3×10^{19} cm^{-3} and $\sqrt{Dt} = (0.12 \pm 0.01) \times 10^{-4}$ cm, where D is the effective diffusion constant and t the time interval for the diffusion. The data of Fig. 12 allow the estimation of a minimum value for the effective D necessary to produce the EDE of Fig. 10. Earlier it was reported that the EDE is created during emitter predeposition steps as short as 3 min. Therefore from this maximum possible time a minimum value for D is given by

$$D_{\min} = \frac{1.44 \times 10^{-10}}{1.8 \times 10^{2}} = 8 \times 10^{-13}\ \text{cm}^2\ \text{sec}^{-1} \quad [1]$$

This value is 30 times larger than that published for normal boron diffusion at 1000°C by Fuller and Ditzenberger (6). The actual effective D may be much greater: The "slow cooling studies" reported earlier actually indicate that the EDE is formed while the slice is taken out of the diffusion furnace. This step normally requires from 10 to 11 sec. For this time which is about 18 times less than 3 min, the apparent diffusion constant which would govern the dip formation must then be at least 500 times larger than normal (6). These estimates clearly show that the EDE can-

not be explained by a normal thermal diffusion process.

Another interesting feature of the data plotted in Fig. 11 is the fact that the profiles of the two diffused base layers coincide at a distance of 0.5μ from the surface. This observation, together with results of spreading resistance measurements (3) underneath the emitter, seems to indicate that the EDE is caused by an enhanced diffusion only of the boron impurities present in the vicinity of the base collector junction prior to the emitter predeposition step. Since the concentration profile of the three layer npn structure could not be measured at distances smaller than 0.5μ from the surface, one might question the conclusion that both profiles coincide. This statement is based only on two measured values (at $x = 0.5\mu$ and $x = 0.55\mu$) and the over-all shape of the concentration curves. However, the following calculation shows that an enhanced movement of the boron atoms occurring throughout the entire base layer would have resulted in a profile differing so drastically from that observed, that it would not have been masked by lack of accuracy in the sheet conductance measurements.

The concentration $C(x)$ of the diffused base profiles of Fig. 11 can be represented in the range between $x_1 = 0.15\mu$ and $x_2 = 0.55\mu$ (x is distance from surface) by the following relation

$$C(x,t) = C(x_1) \exp \{-\alpha(x - x_1) + \beta t\} \quad [2]$$

α is the decay constant and is obtained from Fig. 10 as

$$1/\alpha = 0.28\mu \quad [3]$$

Since Eq. [2] is a solution of Fick's law, one finds that

$$\beta = \alpha^2 D \quad [4]$$

where D is the diffusion constant. During a time interval Δt the exponential concentration profile would move by a distance $\Delta x = x - x_1$ which is given by

$$\Delta x = \alpha D \, \Delta t \quad [5]$$

Assuming the value of $\sqrt{Dt}$ to be $(0.12 \pm 0.01) \times 10^{-4}$ cm, as found for the enhanced diffusion of the boron atoms in the region $x > 0.55\mu$, one can calculate a value of Δx as

$$\Delta x = 0.05\mu \quad [6]$$

A shift of the concentration profile of 0.05μ was not observed for $x < 0.55\mu$ thus suggesting that the enhanced diffusion of the boron atoms forming the EDE takes place only in regions underneath the emitter layer.

EDE in pnp structures.—To our knowledge, the EDE in pnp structures has never been reported. Attempts were therefore made to produce an EDE in this type of structure. It was felt that concentrations and junction depths should be as nearly the same as in the npn structure as possible.

A slice of boron doped silicon ($C_B = 1.5 \times 10^{15}$ cm^{-3}) was diffused for 15 min at 800°C with a P_2O_5 source followed by diffusion in a clean tube for 15 min at 950°C. This treatment resulted in a junction depth of 0.6μ and a surface concentration of about 2×10^{20} cm^{-3} which is in agreement with the junction depth and surface concentration of the base in the npn structure. After pyrolytic oxide growth (5), boron was diffused into the opened windows using a platinum box and B_2O_3 as the source for 5 min at 1100°C. Beveling and staining did not reveal a dip in the pnp structure.

Summary and Discussion

Experimental evidence for the EDE has been collected. The main results of the investigations described in preceding sections can be summarized as follows:

1. The EDE has been observed only in npn structures.

2. The EDE is not caused simply by the presence of phosphorus in the emitter oxide windows. EDE occurs only if the phosphorus doping is so high that it compensates the base doping.

3. The EDE is only observable in npn transistors with sufficiently high phosphorus surface concentration N_D so that at the diffusion temperature $N_D > n_i$, n_i being the intrinsic carrier concentration at this temperature ($n_i = 7 \times 10^{18}$ cm^{-3} for $T = 1000$°C).

4. The EDE does not depend on the diffusion time used to form the emitter. Therefore, multiple emitter predepositions cause multiple dip formation.

5. The dip can be enhanced by slow cooling and reduced by quenching. This suggests that the dip is created during the time the slice is being removed from the diffusion furnace.

6. The EDE is not the result of rejection of boron by the region of high phosphorus concentration, but is rather the result of an increased diffusion constant for boron near the collector junction.

7. The EDE is not caused by the oxide mask since no dip is observed if a slice having open windows in its oxide mask is heat-treated in the absence of phosphorus in a nonoxidizing atmosphere.

8. The base concentration but not the concentration gradient in the vicinity of the collector junction prior to the emitter diffusion determines the magnitude of the EDE.

At this time no hypothesis can be presented which can consistently explain the results of the EDE studies. All features listed above are in qualitative agreement with Baruch's model.

Baruch *et al.* (2) observed the EDE while studying vacancy enhanced diffusion in silicon under high-energy proton bombardment. They found that in the irradiated regions the depth of a diffused layer increased. Such effects had been predicted by Shockley (11-13) who suggested that thin irradiated layers close to the crystal surface may act as a source of vacancies which can diffuse in part toward the interior of the crystal causing an enhanced diffusion of substitutional impurities. Strack (14-15) bombarded silicon samples with low-energy ions in a d-c glow discharge and simultaneously doped the samples with phosphorus and boron. The results are consistent with Shockley's vacancy model. A direct connection between vacancy enhanced diffusion and EDE became obvious when Amadei (16) observed the EDE in an npn transistor which had phosphorus emitters produced by selectively ion bombarding (17) a silicon slice containing a boron diffused base layer. In this case, the EDE could be explained by excess vacancies created while forming the n-type emitter which diffused toward the base collector junction. There they enhanced the diffusion constant of the boron atoms which were already present and produced the EDE.

From the foregoing it becomes apparent that an explanation for the EDE in regular double diffused structures assuming vacancy enhanced diffusion must first of all explain the mechanism which can cause the emitter to act as a source of vacancies. Baruch (2) employed the following model: the introduction of donors to form the emitter increases the local concentration of charged vacancies. His approach is based on the fact that heavy donor doping increased the vacancy concentration (18-22) assuming that vacancies act like acceptors. The emitter could thus be a reservoir for a large number of vacancies which might produce the EDE. Baruch proposed that a fraction of these excess vacancies diffuse toward the base collector junction while the slice cools after being taken out of the diffusion furnace. However, Shockley (23) pointed out that this process is unlikely because the potential barrier for escape of negative charges from emitter to base becomes larger with decreasing slice temperature. The excess amount of negatively charged vacancies will therefore prefer to diffuse toward the surface of the

silicon slice. On the other hand, the results of heat treatments described earlier strongly support the idea that whatever mechanism governs the EDE, the driving force can be "frozen in" by quenching the slice or can come to full development if enough time is allowed in a slow cooling process. The observation that the EDE present in a quenched sample can be influenced by simple heat treatments without the presence of phosphorus is also interesting. This is a completely new aspect which will be pursued in more detail in future experiments. It is hoped that the experimental data reported in this paper may stimulate further investigations.

Acknowledgment

The authors are very grateful to Dr. W. Shockley for his interest in this work, for many stimulating discussions, and for his critical revision of the manuscript.

Manuscript received Aug. 10, 1964; revised manuscript received Oct. 23, 1964. This work was supported by U.S. Army Research Office, Durham, N. C., Contract No. DA-04-200 ORD-1166(X).

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

Vapor Deposition of Germanium on Molybdenum

I. L. Kalnin and J. Rosenstock

American-Standard Research Division, New Brunswick, New Jersey

ABSTRACT

The vapor deposition of germanium on single and polycrystalline molybdenum substrates by hydrogen reduction of $GeCl_4$ vapor has been studied as a function of deposition temperature (600°-950°C), $GeCl_4$ concentration (0.2-4 mole %) and total gas flow (200-600 Std. cc/min). The activation energy of this process was 12 kcal/mole. A multiphase intermediate region containing several molybdenum germanides was found between the Mo and the polycrystalline Ge deposit. The molybdenum germanide phases were identified by x-ray diffraction and delineated by sectioning and selective etching. Their microhardness, electrical resistivity, and adherence were investigated.

The metal-semiconductor system Mo-Ge has received little attention in comparison to other neighboring systems, such as the Mo-Si, for example. Even the phase diagram has not been available (1) until recently (2).[1] Searcy and Peavler *et al.* have reported the preparation of some molybdenum germanides and their x-ray diffraction patterns (3,4). Since the Mo in a nonoxidizing ambient is an excellent material for high-temperature electrical and thermal contacts, it was of interest to examine the extent of interaction between the Ge and the Mo at elevated temperatures as well as the composition and structure of their interface. Preliminary experiments using diffusion couples indicated that the Ge diffusion into Mo was noticeable at 700°C. Satisfactory bonding of the Ge to the Mo was prevented, however, by the α-$MoGe_2$ which was invariably present next to the Ge. The vapor deposition of Ge on the Mo was then resorted to as a possible means of providing a stronger bonding, either because of a cleaner, oxide-free Mo substrate or a molybdenum germanide, other than $MoGe_2$, more adherent to the substrate. Since the effects of epitaxy might be important, the deposition was done on both single-crystal and polycrystalline Mo slices.

[1] The Mo-Ge phase diagram, ref. (2), was published after most of our experimental work was completed.

Experimental

The Mo was obtained commercially either as circular single-crystal slices, 0.5-1.0 mm thick, deposited area 1 cm^2, oriented 2° off the [100] direction or as polycrystalline rod, > 99.95% pure, which was cut into slices of similar size. These slices were mechanically polished with alumina powder of successively smaller grit to a bright finish of approximately 0.2μ peak-to-peak roughness, then etched for 2 min prior to deposition with a boiling concentrated formic acid-hydrogen peroxide mixture, 7:3 vol ratio, to remove about 4μ from the surface. After etching, the single-crystal Mo slices often showed clusters of large pores, probably gas inclusions, up to 0.1 mm in diameter, distributed irregularly over the otherwise smooth surface. These pores were filled with Ge during the deposition and became additional reactive diffusion sources creating pipes of Mo_xGe_y which were sometimes visible in the sectioned substrate (cf. Fig. 8). The $GeCl_4$ was made at our Research Laboratories and was quite pure, since the spectrographic analysis of Ge prepared from it

showed less than 25 ppm of any of the customary impurities, including Si, in it. The cylinder H_2 (> 99.5% pure) was further purified by passage through a commercial deoxydizer-dehydrator assembly.

The deposition apparatus was a conventional flow system made up of a set of gas sources, H_2 and N_2, a set of flow meters, a saturator trap filled with liquid $GeCl_4$ and a vertical, R. F. heated quartz reaction tube, 45 mm OD and 30 cm long. The tube was capped on both ends by brass couplings using neoprene O-ring compression seals and brass flanges. The top flange contained a quartz sighting window, the bottom one a sheathed chromel-alumel thermocouple which also supported a cylindrical graphite susceptor. A cold trap at the outlet end was used to collect the condensable waste products.

Briefly, the deposition was as follows: The Mo slice was introduced onto a quartz slide on top of the susceptor. The apparatus was evacuated and any leakage was eliminated. After the Mo had been preheated in H_2 for 15 to 30 min at 1000°C, the deposition temperature was set and the $GeCl_4$ vapor was introduced by bubbling the H_2 through the saturator trap. The $GeCl_4$ concentration was calculated from the measured weight loss of the trap. It was adjusted by means of a constant temperature cold bath around the trap. After the deposition the specimen was cooled to room temperature at a rate of about 100°C/min.

The specimen evaluation generally involved the following steps: determination of the weight gain and calculation of the average deposit thickness assuming bulk density and geometrical surface area; visual and microscopic inspection of the surface; measurement of the electrical resistance across the interface; identification of the surface phases by means of Laue backreflection photographs; low angle (5°) bevel lapping with alumina abrasives to expand the interface region by a factor of approximately 11; examination of the microstructure of the sectioned region by means of selective etching techniques, microhardness indentations, photomicrography, etc.; and selective removal of portions of the deposit by scratching or grinding for x-ray studies or chemical analysis.

Results and Discussions

Kinetics of the deposition.—The weight gain of the Mo was reasonably linear with time up to our longest deposition time, 90 min. The deposition rate was determined as a function of temperature (600°-950°C), $GeCl_4$ concentration in the H_2 (0.2- 4.0 mole %) and the total gas flow (200-600 Std. cc/min). Figure 1 shows the deposition rate *vs.* reciprocal temperature at the flow rate, F = 550 cc/min and the $GeCl_4$ vapor concentration, C = 0.2 and 1.0 mole %, respectively.

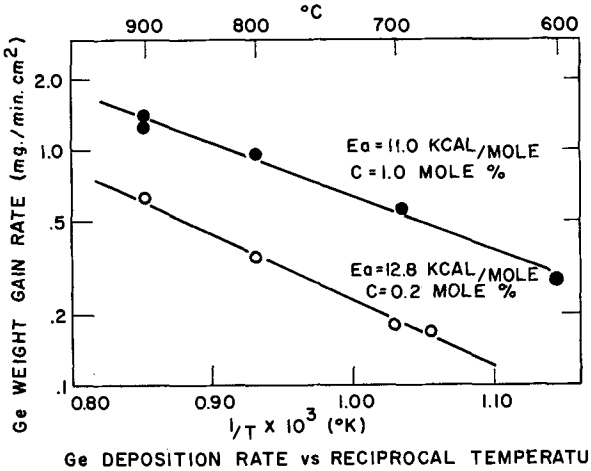

Fig. 1. Ge deposition rate *vs.* reciprocal temperature (F = 550 cc/min).

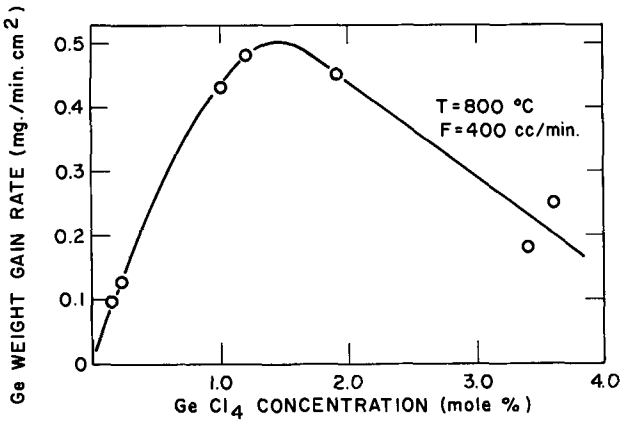

Fig. 2. Ge deposition rate *vs.* $GeCl_4$ concentration (F = 400 cc/min, T = 800°C).

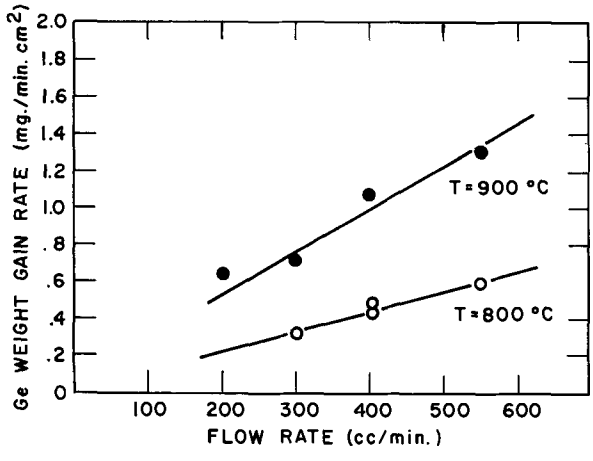

Fig. 3. Ge deposition rate vs. flow velocity (C = 1.0 mole %)

The calculated activation energies for the two concentrations are fairly close, 11.0 and 12.8 kcal/mole, confirming the linearity of the deposition process. The finally estimated activation energy was 12 ± 2 kcal/mole. To convert the weight gain rate to thickness gain rate for Ge (μ/min) one would multiply the ordinate by 1.9. Since the Ge, however, has partially reacted to form molybdenum germanides, Mo_xGe_y, the true thickness would certainly differ from the calculated one. Figure 2 gives the deposition rate as a function of the $GeCl_4$ concentration at 800°C and F = 400 cc/min. A maximum at about 1.5 mole % is observed. Similar maxima, but at different concentrations have been reported for the epitaxial vapor depositions Ge on Ge (5) and Si on Si (6). The dependence of the deposition rate on the total gas flow is seen in Fig. 3. The increase is linear up to our largest flow, 600 cc/min, corresponding to a linear flow of 1 cm/sec. The published data for Ge on Ge and Si on Si indicate a leveling-off at still higher flow rates, at or above 1.5 liters/min. The kinetic data of the Ge vapor deposition thus are similar to those reported for the epitaxial Ge/Ge and Si/Si depositions. The reaction mechanism at the hot Mo surface, therefore, should also be similar, consisting mainly of two simultaneous two-electron redox reactions

$$GeCl_4 + H_2 = GeCl_2 + 2HCl$$

$$GeCl_2 + H_2 = Ge_{(g)} + 2HCl$$

which lead to the steady state between the gaseous germanium-containing species

$$GeCl_4 + Ge_{(g)} = 2\,GeCl_2$$

An analysis of the analogous reaction mechanism for Si was made by Steinmaier (7) and was shown to be in good qualitative agreement with the experimental evidence.

Composition and structure of the Ge-Mo *interface region.*—Above 600°C the reactive diffusion of Ge into Mo became noticeable and a multiphase intermediate region consisting of several molybdenum germanides, Mo_xGe_y, was formed. Unless the deposition was done at high $GeCl_4$ concentrations (> 3 mole %) at which the deposition rate was lower and the deposit surface smoother, elemental Ge was present on the Mo substrate indicating that the vapor deposition rate ordinarily was higher than the Ge disappearance rate through the Mo_xGe_y formation. Near the melting point of Ge, the diffusion rate became comparable to the deposition rate (approximately 4 μ/min), and free Ge was sometimes absent. Figure 4 shows a fairly typical surface appearance of Mo slices deposited for 20 min at (a) 700°, (b) 800° and (c) 900°C, respectively, using 0.2 mole % $GeCl_4$. With increase in the deposition temperature, the Ge layer becomes more uniform and coherent. The slice (d) which has a thin, smooth coating has been deposited at 700°C and 3.4 mole % Ge for the same time. The Ge deposit usually was finely polycrystalline, and no preferential orientation was observed, either in the polycrystalline or single-crystal slices, from the Laue backreflection photographs. Above 900°C, however, the Ge sometimes contained large grains some of which were etched more rapidly than others by aqueous H_2O_2-HF and appeared to be of different orientation, Fig. 5. Also, another phase had segregated along the Ge grain boundaries. Figure 6 shows the needle like pattern of this phase at 1000X magnification. It is assumed that this phase is α-$MoGe_2$,

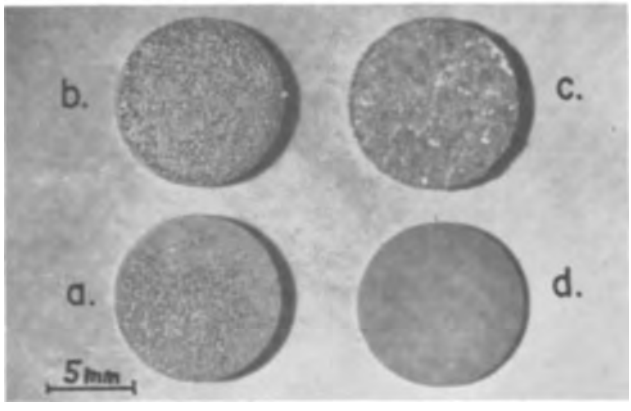

Fig. 4. Ge deposited on Mo substrate at: (a) 700°, (b) 800°, (c) 900°C using 0.2 mole % $GeCl_4$, and (d) 700°C and 3.4 mole % $GeCl_4$.

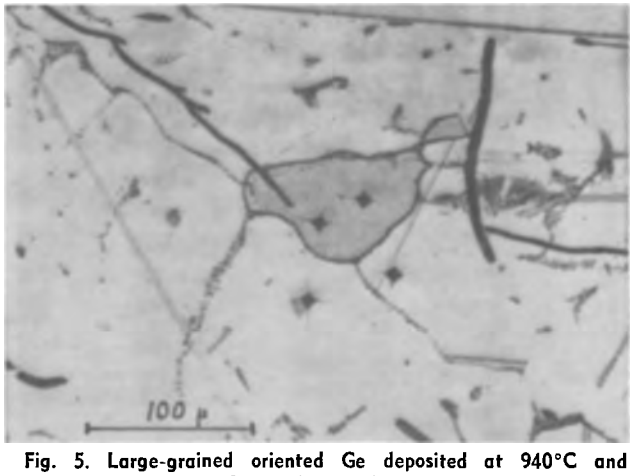

Fig. 5. Large-grained oriented Ge deposited at 940°C and etched with aqueous H_2O_2-HF (3:1:1). Note the segregated phase, the indentation cracks and the thermal stress cracks.

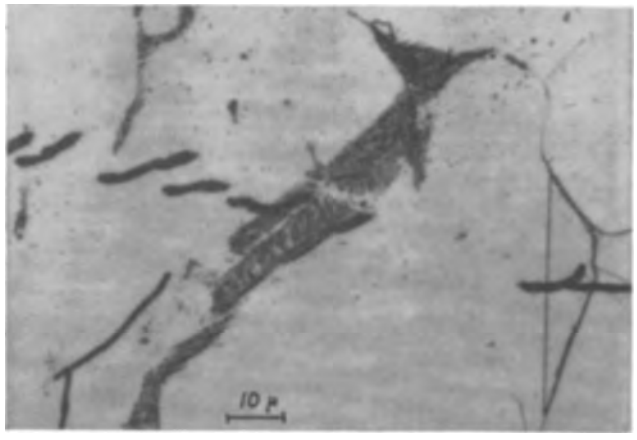

Fig. 6. Appearance of the segregated phase in the Ge, probably $MoGe_2$.

since x-ray diffraction data indicated its presence in the surface layer. The layer closest to the Ge formed by the reactive diffusion was always $MoGe_2$. The interface between the Ge and the $MoGe_2$ was very rough, although the initial Mo surface had been smooth. This indicates either solubility of the Mo in the Ge, or more likely, the reaction of the $GeCl_4$ with the Mo substrate, the thermodynamically most favorable reaction being

$$GeCl_4 + Mo = GeCl_2 + MoCl_2;$$
$$\Delta F\ 1000°K = +\ 9\ \text{kcal/mole}$$

Assuming typical values: F = 500 cc/min, $GeCl_4$ conc. = 1 mole % a deposition efficiency of 5%, and the above reaction in the steady state, the Mo removal rate was calculated as approximately 1 μ/min. Removal of Mo for the first few minutes of deposition would thus suffice to alter the original surface to the observed roughness of a few microns. The bulk of the $MoCl_2$ is probably reduced immediately to Mo which then reacts further to form Mo_xGe_y. Traces of Mo were identified in the waste products deposited on the chamber wall by means of potassium thiocyanate and stannous chloride spot tests (8). A mixture of several molybdenum germanides, usually Mo_3Ge, Mo_5Ge_3 and Mo_2Ge_3 up to 4μ thick, was found in the surface layer deposited at 600° at which the Ge diffusion is yet negligible. Since the thickness of this layer varied rather irregularly with the experimental conditions, the determination of growth rates of the various Mo_xGe_y phases was not possible. As the Ge diffusion proceeded during the deposition at higher temperatures, the mixed surface layer was converted completely into $MoGe_2$ and Mo_2Ge_3.

The Mo_xGe_y compounds reported by Searcy and Peavler (4) were $MoGe_2$, Mo_2Ge_3, Mo_5Ge_3,[2] and Mo_3Ge. All of these phases have been identified in the intermediate layer at one time or another. Ordinarily, the phases were present in separate layers which could be delineated by selective etching. The single-phase character of the thicker layers, $MoGe_2$ and Mo_2Ge_3, could be established by x-ray diffraction analysis of successive thin layers removed from the deposited surface by means of a diamond-point tool. The thinner layers near the Mo could not be analyzed separately, and it was assumed that the other two delineated layers were the phases Mo_5Ge_3 and Mo_3Ge. These phases were delineated best by successive application of two etchants, one acidic, the other alkaline. The acid etchant was a mixture of conc. H_2O_2 (30%), conc. HF (50%), H_2O in vol. ratio 1:1:3. Since it etched Ge at a rate of approximately 5 μ/min at room temperature, it could be used to remove the Ge deposit if desired. The Mo_xGe_y etched much more slowly, 0.1-0.3 μ/min and the Mo least (< 0.05 μ/min). The alka-

[2] Originally called Mo_3Ge_2, but identified later as Mo_5Ge_3 (9).

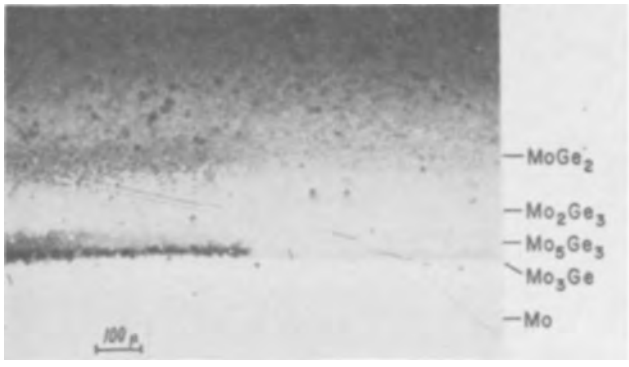

Fig. 7. Beveled section of the Ge-Mo interface at 800°C having four Mo_xGe_y phases present. Ge has been removed.

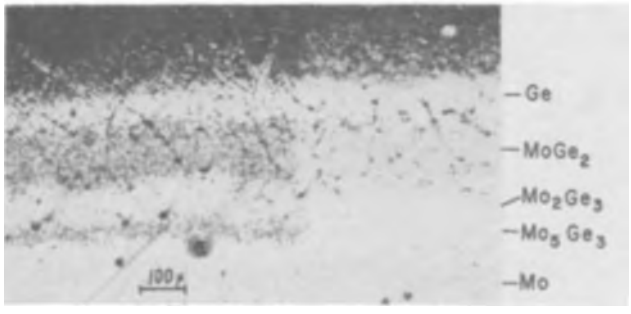

Fig. 8. Beveled section of the Ge-Mo interface at 900°C. Ge has not been removed.

line ferricyanide etchant was an aqueous solution of 10 w/o (weight per cent) KOH and 10 w/o $K_3Fe(CN)_6$. This reagent etched some of the molybdenum germanides selectively whereas Mo and Ge were essentially unetched. The application time was 10-30 sec for the alkaline and 1 min or longer for the acidic etchant. The acidic etchant outlined the boundaries: $Ge/MoGe_2$ and $MoGe_2$ Mo_2Ge_3/Mo_5Ge_3, Mo_3Ge and Mo_3Ge/Mo. Application of the alkaline etch outlined the boundaries $MoGe_2/Mo_2Ge_3$ and Mo_5Ge_3/Mo_3Ge of the sectioned specimen. Figure 7 shows a typical beveled section (5°) of the intermediate Mo_xGe_y layers present in a specimen deposited at 800°C for 60 min. The Ge on the top has been etched off with aqueous H_2O_2-HF. The area on the right has been etched with H_2O_2-HF only, whereas that on the left was further treated with the the ferricyanide etchant. The application of the latter provides a much better contrast between the phases, all four of which are seen. The contrast seems to be caused by selective etching and not by the formation of stained surface films. In Figure 8 the intermediate layer formed at 900° is seen. The light top layer is elemental Ge. The dark bottom layer (Mo_3Ge) near the Ge has disappeared. The Mo rich phases, in general, were present either at the surface at 700° or below or in the diffused layer at temperatures below 900°C. Above 900°C, the amount of $MoGe_2$ and Mo_2Ge_3 increased, while that of Mo_3Ge decreased. It has been observed that $MoGe_2$ decomposes into Mo_2Ge_3 + liquid above 1095°C (4).

The $MoGe_2$ and Mo_2Ge_3 layers displayed a network of broad grain boundaries which terminated at the Mo_5Ge_3 layer (Fig. 9). The disturbed appearance of these layers, which are nearly as hard and brittle as the Ge, may be ascribed to the thermal stresses created by the post-deposition cooling. The Mo rich phases, Mo_5Ge_3 and Mo_3Ge, were undisturbed and, therefore, would appear more suitable for thermal stress resistant contacts than the Ge rich ones.

Adherence.—Attempts to remove the surface layer from the substrate by means of adhesive tape sometimes resulted in the separation of Ge from the underlying $MoGe_2$. The strength of adhesion was qualitatively estimated to be much better than in the case of

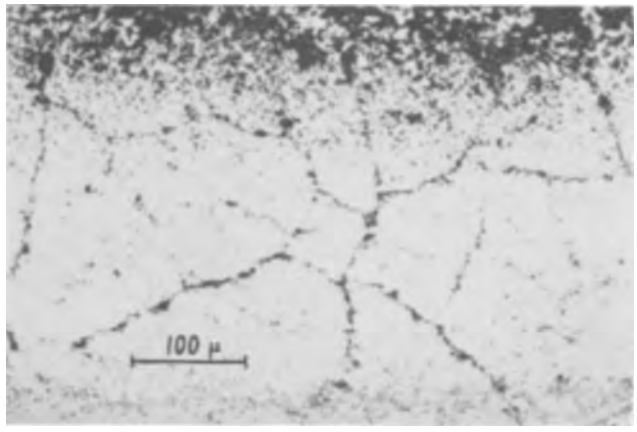

Fig. 9. Appearance of wide grain boundaries in the $MoGe_2$, Mo_2Ge_3 layer.

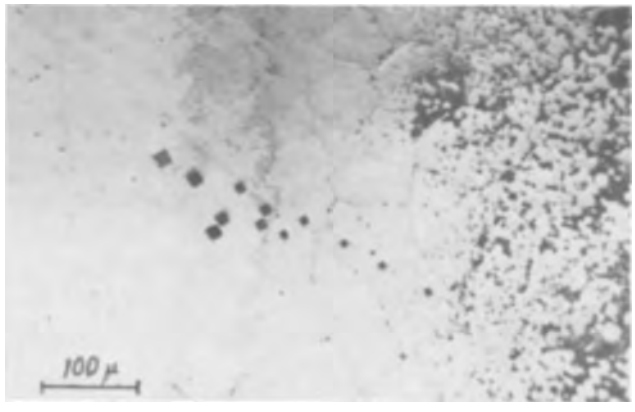

Fig. 10. A series of indentations showing the microhardness discontinuities across the interface.

diffusion-bonded elements. Since Ge was in contact with $MoGe_2$ in either case, the improvement was probably due to stronger mechanical bonding provided by the roughened, $GeCl_4$-etched Mo surface. Separation between the Mo_xGe_y phases or between the Mo_3Ge and the Mo substrate did not occur.

Hardness.—Microhardness measurements with Vickers diamond pyramid tester at 50g load indicated that the hardness of the Ge deposit depends on its grain size. The apparent hardness of small Ge crystallites imbedded in the polycrystalline matrix was 1340 ± 80; on large polycrystalline grains, it was 1140 ± 70; and on small polycrystalline aggregates it decreased to 930 ± 70 kg/mm². The $MoGe_2$-Mo_2Ge_3 phase hardness was 900 ± 30 kg/mm². There is a rapid decrease in microhardness and rather wide fluctuation from 600 to 350 kg/mm² in the Mo_5Ge_3-Mo_3Ge region. Another sharp hardness drop occurs at the Mo substrate, for which the hardness value agrees well with that of pure Mo, 210 ± 30 kg/mm². Figure 10 illustrates a series of microhardness measurements showing the two discontinuities across the beveled section of the Ge-Mo interface. The Ge has been etched off.

Electrical resistivity.—The resistance of the intermediate layer was measured by clamping the deposited specimen between two brass holders. The contact resistance was decreased to a negligible value by means of (*a*) brass foil which was inserted between the holder and the specimen and was wetted on both sides with In-Ga alloy and (*b*) four-point measuring technique using a Keithley 503 milliohmeter. The series resistance of Mo was sufficiently low to be disregarded. The resistance values obtained ranged from 0.5 to 0.05 milliohms, depending on the amount of Ge present. The lowest values were measured on specimens containing no free Ge. Attempts to remove the Ge by etching were not very successful because some

series resistance would arise, presumably from a thin oxide-containing surface film. Using specimens containing the least amounts of free Ge, the resistivities of the intermediate layer were between 6 and 20 milliohm cm, which in our opinion, should correspond to the upper resistivity limit.

Acknowledgments

The authors thank G. P. K. Chu for the encouragement of this work, and R. Oliva of the Analytical Section for conscientious identification of the various molybdenum germanides.

Anodic Oxidation of Methanol at Palladium Electrode in Alkaline Solution

Tsutomu Takamura and Ken'ichi Minamiyama

Central Research Laboratory, Tokyo Shibaura Electric Company, Ltd., Kawasaki, Japan

ABSTRACT

Carbonate formation from methanol at active palladium electrodes was confirmed in alkaline solution by measuring current-voltage curves for methanol and other related compounds and by determining the oxidation products formed at the test electrode. The current efficiency in the anodic oxidation was observed to be over 80% in the current density range from 20 to 400 mamp/cm^2. A probable mechanism was proposed for the oxidation reaction by determining the electrochemical reaction order (z). The z values obtained for methanol and hydroxide ion were 1/3 and 2/3, respectively. The activation process of the transfer reaction was considered to be the oxidation of methoxy radical by hydroxide ion.

Methanol is an attractive fuel for fuel cells because of its electrochemical reactivity, availability, and low cost. Several studies have been reported on the mechanism of the anodic oxidation of methanol at platinum electrode both in acidic and alkaline media (1-3). In acidic media, methanol could be oxidized at platinum electrode to carbon dioxide and water (1, 2), while in alkaline media, the main oxidation product was reported to be formate ion (3).

In view of the energy utilization, complete oxidation to carbonate ions is desirable, which was supposed by the present authors to be partially accomplished by the use of palladium electrode because palladium has a particular affinity for hydrogen (4). Preliminary experiments on the anodic oxidation of methanol at an active palladium electrode in alkaline solution showed that the fuel could be converted into carbonate ion.

In this paper quantitative studies on the anodic oxidation of methanol are described and a probable mechanism concerning the transfer reaction is proposed.

Experiment

Test electrode.—Pure palladium black (99.997%) was deposited electrolytically on the cleaned palladium plate from 0.2M solution of palladium chloride. The palladized palladium plate was washed thoroughly, then heated to expel occluded hydrogen at 200°C in nitrogen stream. The obtained disk had 1.2 cm diameter.

Electrolytic solution.—Commercial reagent of KOH was dissolved in distilled water, to which known amounts of K_2CO_3 and a test material (fuel) such as methanol, ethanol, etc., were added. Although pre-electrolysis of the solution is said to be necessary before adding test material in order to obtain a reversible potential, an identical stable potential was obtained for the test material in the present solutions regardless of pre-electrolysis. Accordingly, the measurements were carried out without pre-electrolysis.

The electrode, however, gave no stable potential in the solution whose concentrations of KOH and test material were less than 0.1 and 0.02M, respectively. Then all the measurements were done in the solution containing these reagents more than 0.2M.

Potential measurements.—Potentials were measured at 25°C by the direct method with a Luggin-capillary, a mercuric oxide half cell (2M NaOH) being used as a reference electrode. The change in the liquid junction potential due to the concentration variation in the test electrode compartment was corrected with the Lewis-Sargent equation.

Determination of current efficiency.—An H-type cell whose two parts were connected through a porous glass was used as an electrolysis cell, a smooth platinum plate being used as a counterelectrode. The concentration of the electrolytic solution was kept at 5.5M and 5.0M for KOH and methanol, respectively. Carbonate ion in the solution was previously removed by adding appropriate quantities of $Ba(OH)_2$. By polarizing the test electrode anodically, constant current electrolysis was carried out for several 10-min periods in the nitrogen stream. Carbonate ions formed at the test electrode were determined gravimetrically in the form of $BaCO_3$. On the other hand, the total numbers of electron used during the electrolysis were calculated from the current intensity and the electrolysis time.

Results

Current-voltage curves.—Examples of current-voltage curves of methanol at varied concentrations are

given in Fig. 1, which shows that methanol is very reactive at the test electrode. Each curve falls on a Tafel line with $\alpha = 0.50$ in the current density range below 30 mamp/cm^2. At larger current densities the current-voltage relation deviates from Tafel line, indicating that a diffusion process contributes in the region.

If the rate of methanol oxidation to carbonate at the test electrode (Eq. [1]) is sufficiently fast, only a small polarization is expected even at high anodic current density for solutions of formalin or formate, both of which are considered to be stable intermediates in the course of the methanol oxidation. If, for example, the final product were formate ions, very large polarization would be observed for formate even at very low anodic current densities.

$$CH_3OH + 8\,OH^- \rightarrow CO_3^{2-} + 6H_2O + 6e \qquad [1]$$

Current-voltage curves obtained for these two oxidizable substances are given in Fig. 2, which shows that even formate is very reactive at the test electrode. Unlike the case with platinum electrode, formate gives high current densities at small polarizations. These results suggest that methanol can be oxidized into carbonate at the test electrode.

Determination of current efficiency.—Existence of the oxidation reaction to form carbonate was expected in the measurement of current-voltage curve, but as the method is indirect, the formation of carbonate was determined in order to confirm that the carbonate formation is the main reaction. Carbonate ions formed at the test electrode were determined as $BaCO_3$.

The current efficiency was also determined coulometrically. In the oxidation reaction [1], one mole of carbonate ions should be formed from an equivalent mole of methanol, whereby six moles of electron are released at the test electrode. The efficiency is then defined as the mole ratio of the amount of carbonate determined analytically to that calculated from the observed electrical quantities. The efficiency was found to be always over 80% throughout the current densities studied. This shows that the activation process of the oxidation is independent of the current density. That the oxidation reaction to form carbonate was a main reaction was thus confirmed by the direct determination of oxidation product.

Reactivity of palladium for several substances.—Bearing in mind that palladium has a particular affinity to hydrogen and that the carbonium band occurs in the infrared spectrum for the gaseous adsorption of methanol on nickel (5), we can expect that methanol is likewise adsorbed on palladium with the hydrogen atom on the methyl group.

However, hydrogen atoms belonging to any alkyl group are not necessarily considered to combine with palladium. In order to check what kind of hydrogen atom is liable to undergo the oxidation, reactivity at the test electrode was measured for the following species: ethanol, isopropanol, glycerine, ethylether, acetone and acetic acid. Current-voltage curves for these compounds are shown in Fig. 3. Substances not shown in the figure are ether and acetic acid, which gave no stable potential even at very small current density. Contrary, alcohols, formalin, and formic acid were proved to be suitable as fuels. All these suitable substances have one or more hydrogen atoms attached to the carbon atom adjacent to the terminal oxygen atom, while unsuitable ones have not such hydrogen atoms. The hydrogen atom is considered to be liable to adsorb on palladium, bringing C-H bond scission.

Discussion

Vetter introduced the electrochemical reaction order, z_{rj} (or z_{oj}), into the analysis of electrode reaction (6). The probable mechanism of the oxidation of methanol will be considered here with the Vetter's method. Observed current i flowing across the test electrode at an appropriate anodic polarization is expressed by Eq. [2]

$$i = k_+ K_r C_{CH_3OH}^{zr'} \cdot C_{OH^-}^{zr2} \cdot \exp\left[\frac{n\alpha FE}{RT}\right] \qquad [2]$$

where notations are the same as those expressed in Vetter's text (6). With the condition that the poten-

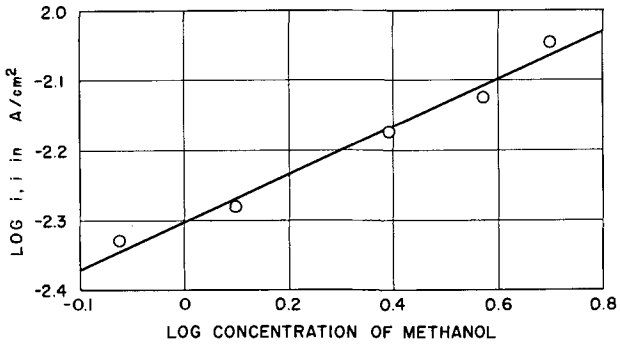

Fig. 4. Plots of log i vs. log c of methanol at $E = -0.625$v *vs.* HgO electrode. The potential variation due to the change in methanol concentration was corrected by assuming that the activity coefficient of methoxide is constant. [KOH] = 4M, [K_2CO_3] = 1M, 25°C.

tial difference between the Helmholtz double layer and the bulk of the solution is negligible, we obtain [3] at fixed C_{OH^-} and E.

$$\left(\frac{\partial \log i}{\partial \log C_{CH_3OH}}\right)_{C_{OH^-},E} = z_{r1} \qquad [3]$$

z_{r1} can thus be obtained from the plotting of log i measured at fixed E against log C_{CH_3OH}.

Current-voltage curves were measured at fixed concentrations of KOH(4M) and K_2CO_3(1M) by varying the methanol concentration. The curves were observed to be independent on the stirring rate of the solution. Since the presence of excess electrolyte is considered to maintain the condition supporting [3], z_{r1} can be obtained from the current-voltage curves measured at varied concentrations. The plottings of log i at 0.625v *vs.* HgO electrode against the logarithm of methanol concentration are shown in Fig. 4, which gives a straight line to give $z_{r1} = 1/3$.

Similarly z_{r2} was obtained by varying the hydroxide concentration at fixed concentrations of other species. The effect of the variation of the activity coefficient on E was evaluated from the mean activity coefficient of KOH (7) and the ion size parameter (8) in the ionic strength range between 2.5 and 7.5. Variation of the activity term in E in this range was estimated to be within a few millivolts, which is not an adequate quantity to allow a different conclusion. Plots of log i *vs.* log C_{OH^-} showed that z_{r2} was 2/3. This indicates that hydroxide ions participate in the activation process by a factor of 2/3.

A part of methanol in alkaline solution dissociates into methoxide ion, (9)

$$CH_3OH + OH^- \rightleftharpoons CH_3O^- + H_2O \qquad [4]$$

This could also be ascertained by the decrease of the infrared band at 1110 cm^{-1} with the increase of hydroxide concentration. Thus formed CH_3O^- would be adsorbed on palladium electrodes and easily release one electron to form methoxy radical, $CH_3O\cdot$ (10)

$$CH_3O^- \rightleftharpoons (CH_3O^-)_{ad} \qquad [5]$$

$$(CH_3O^-)_{ad} \rightarrow (CH_3O\cdot)_{ad} + e \qquad [6]$$

where $(\ )_{ad}$ denotes adsorbed species. $CH_3O\cdot$ has three identical hydrogen atoms which can be adsorbed on palladium.

The value of z introduced by Vetter is considered to correspond to b' given by Parsons (11), and b' is the mole number of species B', for example methanol, to form one mole of activated complex in the transfer reaction. z obtained for methanol at the test electrode was 1/3, showing that three moles of activated complexes are formed from one mole of methanol, while OH^- was shown to participate in the complex formation by a factor of 2/3. With reactions [4], [5], and [6] we can reasonably suppose that the activated complex ($A^{\ddagger}$) is formed through the activation reaction [7].

$$(CH_3O\cdot)_{ad} + 2\,OH^- \rightarrow (CO_2^-)_{ad} + 3A^{\ddagger} + H_2O + e$$

with

$$A^{\ddagger} \rightarrow (H)_{ad} \qquad [7]$$

In this reaction $(H^A)_{ad}$ would easily be combined with OH^- through

$$(H)_{ad} + OH^- \rightarrow H_2O + e \qquad [8]$$

and at the same time $(CO_2)_{ad}$ would be oxidized to carbonate ion through the rapid reaction [9].

$$(CO_2)_{ad} + 2\,OH^- \rightarrow CO_3^{2-} + H_2O \qquad [9]$$

This mechanism may be probable because $(CO_2^-)_{ad}$ is the adsorbed form of formate whose hydrogen atom attached to the carbon atom is released and because the reaction [8] was observed to be more rapid as compared to the methanol oxidation reaction.

Summarizing reactions [4] to [9], we obtain the over-all oxidation reaction [1]. The mechanism proposed here will be examined further by other methods.

Acknowledgments

The authors wish to express their deep thanks to Dr. Y. Miura, manager of this laboratory and to Dr. H. Shiratori a senior researcher of this laboratory for their helpful discussions and encouragement.

Manuscript received July 20, 1964; revised manuscript received Nov. 22, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1965 JOURNAL.

Electromotive Force Studies of Cadmium Chloride in Water, Water-Methanol, and Methanol Solutions

Jack D. Hefley[1] and Edward S. Amis

Chemistry Department, University of Arkansas, Fayetteville, Arkansas

ABSTRACT

The emf of cadmium chloride was determined in water, water-methanol, and methanol solvents over a concentration range of 0.0050 to about 0.1000*M*. Measurements were made using a L&N Type K-3 potentiometer and an amalgam cell without transference. In order to determine the standard potential of cadmium chloride in the various solvents it was necessary to extrapolate the molality to zero by a suitable linear function of the observed emf. Satisfactory values of the standard potential were determined over the entire solvent, temperature, and concentration ranges by assuming only one method of ionization and simultaneously varying the equilibrium constant as the solvent composition was varied. The justification for decreasing the dissociation constant as the dielectric constant was decreased was based on Bjerrum's theory of ionic association in media other than water. The laborious calculations involved in the determination of the standard potentials were accomplished by using an I.B.M. 7040 computer. The standard potentials which were determined were used to calculate the mean ionic activity coefficients of cadmium chloride in the various solvents. The calculations were made by using the form of the Nernst equation which is applicable to a 2-1 electrolyte. The activity coefficients of cadmium chloride in the various solvent systems are similar to those determined by other investigators for electrolytes in mixed and nonaqueous solvents. The general behavior is that deviations from the Debye-Hückel theory occur at lower concentrations as the dielectric constant of the solvent is decreased.

This is the second paper (1) on the emf studies of cadmium chloride in pure and mixed solvents.

Measurements of the emf of the cell

$$Cd\text{-}Cd_xHg(11\%) \mid CdCl_2(m) \mid AgCl\text{-}Ag$$

have been made at 25°, 30°, and 35°C throughout a cadmium chloride concentration range of 0.0005 to about 0.1000*M* and over the complete solvent range for the water-methanol system. From the results, the standard potentials of the cells, E_o, and the activity coefficients of cadmium chloride in the various solvent systems have been computed.

Experimental Procedure

The silver-silver chloride electrodes of the kind designated by Harned (2) as type 2 were used. The cadmium amalgam was prepared from distilled mercury and high-purity cadmium metal supplied at special request from the E. H. Sargent Company. The amalgam electrodes containing 11% of the total cadmium were made individually in each cell vessel according to the method of Harned and Fitzgerald (3).

A standard concentrated stock solution was made from Baker Analytical Reagent cadmium chloride and conductivity water. Its strength was found by gravimetric determination of its chloride content. More dilute solutions were prepared by adding weighed amounts of the standard solution to known weights of water. This same procedure was used in mixed solvents.

In order to prepare solutions in pure nonaqueous solvents, a known weight of the standard concentrated aqueous stock solution mentioned above was evaporated and dried at 150°C for 24 hr and the solute dissolved in the methanol which had been purified according to the procedure of Foster and Amis (4). More dilute solutions in the nonaqueous solvent were then prepared in a manner similar to that for aqueous and mixed solvents.

Oxygen was removed from each cell by purging it with argon saturated with vapor whose composition and temperature were the same as the solvent in the individual cell. The cells came to equilibrium in 1-2 hr after preparation. The temperature control was within ± 0.01°.

The emf of each cell was measured seven times with a L&N Type K-3 Universal Potentiometer, and each observed emf value which is recorded in this work is the average of these seven measurements.

plotted against the molality. It can be seen from Fig. 1 that the data of this work, which is indicated by squares, is in very good agreement with the data of Harned and Fitzgerald (3), which is represented by circles.

The emf measurements of cell containing cadmium chloride in water-methanol and methanol solutions are shown in Table II and Fig. 2. Because of the small temperature coefficients, only those data for 25°C are shown graphically. It can be seen from Fig. 2 that the emf data in the various methanol solutions are a smooth function of the molality.

The experimental precision in aqueous solutions was in general of the order of 0.02 mv. In the alcoholic solutions the precision was somewhat less, about 0.03 mv. Due to the nature of the calculations, the accuracy of the values of the standard potentials discussed below is believed to be at least ± 2.0 mv.

Evaluation of the Standard Potentials

The determination of the standard potentials of cadmium chloride in the different solvent systems was based on the method used by Harned and Fitzgerald (3) to determine the standard potential of cadmium in an aqueous solution. In their work they assumed that cadmium chloride is an incompletely dissociated electrolyte and then corrected for the degree of dissociation, α, from the equilibrium constant, K, and the activity coefficient of barium chloride by using the Law of Mass Action and the Debye and Hückel theory.

In this work it was necessary to modify the method of Harned and Fitzgerald (3) in two ways. These two modifications will be discussed below.

Representing the electromotive force of the cell by the equation

$$E = E_o - k \log 4m^3\gamma_\pm^3 \qquad [1]$$

and replacing $\log \gamma_\pm$ by $(-S_{(f)}\sqrt{m} + B'm)$ one obtains the equation

$$E + k \log 4m^3 - 3kS_{(f)}\sqrt{m} = E_o - 3k'Bm = E_H \qquad [2]$$

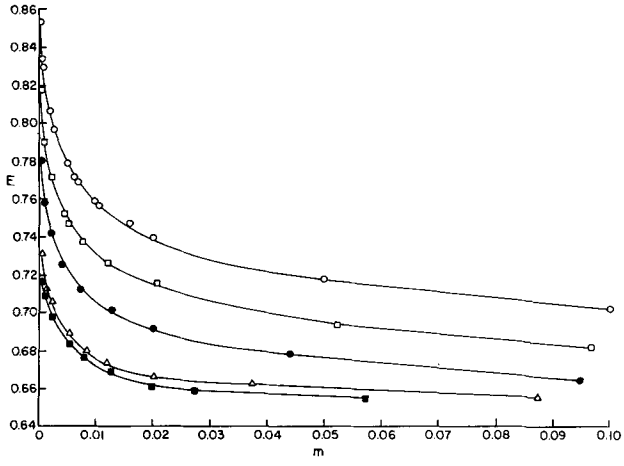

Fig. 2. EMF of the Cd-Cd$_x$Hg (11%) $|CdCl_2(m)|$ AgCl-Ag cell in water, water-methanol, and methanol at 25°C. ○, H_2O; □, 30% MeOH; ●, 60% MeOH; △, 90% MeOH; ■, 100% MeOH.

In the above equations E_o is the standard cell potential, m is the molality, $\gamma_\pm$ is the mean ionic activity coefficient, k is $2.303RT/2F$, and $S_{(f)}$ is the limiting slope of the Debye-Hückel theory. E_H is a function that should be linear with m in dilute solutions when the Debye-Hückel theory holds and provided the electrolyte were completely dissociated. $S_{(f)}$ is later used as the limiting slope of a 1-1 electrolyte.

If cadmium chloride were a completely dissociated electrolyte, according to Eq. [2] a plot of E_H and therefore of $E + k \log 4m^3 - 3kS_{(f)}\sqrt{m}$ should, in dilute solutions, be linear with m. However, cadmium chloride is not completely dissociated as indicated by conductance data, and hence the plot is not linear.

Equations [3] and [4] below give the dissociation data most in harmony with the data in this report.

$$CdCl_2 \rightarrow CdCl^+ + Cl^- \qquad [3]$$

$$CdCl^+ \rightleftarrows Cd^{++} + Cl^- \qquad [4]$$

The first step in the dissociation is represented as complete, while the $CdCl^+$ ion is only partially dissociated. Cadmium chloride itself is probably only partially ionized; however, the incompleteness of this dissociation is neglected in the assumed mechanism of dissociation for dilute solutions represented by Eq. [3] and [4].

If one assumes that $\gamma' = \gamma'_{Cl^-} = \gamma'_{CdCl^+}$; where γ' is the activity coefficient; if $\gamma'_{Cd^{++}} = \gamma'' = (\gamma')^4$; and if the concentrations of the $CdCl^+$, Cd^{++}, and Cl^- ions are, respectively, $m(1-\alpha)$, $m\alpha$, and $m(1+\alpha)$, then the equilibrium constant for step two from Eq. [4] becomes

$$K = \frac{(\alpha m\gamma'')(1+\alpha)\gamma' m}{m(1-\alpha)\gamma'} = \frac{m\gamma''\alpha(1+\alpha)}{1-\alpha} \qquad [5]$$

where α is the degree of dissociation of the $CdCl^+$ ion. Solving for α yields

$$\alpha = \frac{1}{2}\left[-\left(1 + \frac{K}{m\gamma''}\right) + \sqrt{\left(1 + \frac{K}{m\gamma''}\right)^2 + \frac{4K}{m\gamma''}}\right] \qquad [6]$$

Noyes and Falk (5) estimated K to be between 0.007 and 0.002 from the conductance data of Wershoven (6) taken at 20°C in aqueous solutions. Reghellato and Davies (7) found K to be 0.010 at 25°C by applying Onsager's theory to the same data and assuming a reasonable value for the mobility of the $CdCl^+$ ion.

Harned and Fitzgerald (3) treated the cadmium chloride data by first calculating α employing Eq. [6] and assuming the values of K to be between 0.005 and 0.015. They then computed γ''-values from the Debye-Hückel equation

$$\log \gamma'' = -\frac{4S_{(f)}\sqrt{\mu'}}{1 + A\sqrt{\mu'}} \quad [7]$$

In this equation γ'' and $S_{(f)}$ have their usual significance, and A is the Debye-Hückel constant and is given by the equation

$$A = \frac{\sqrt{2}\,(35.57)\,\overset{\circ}{a} \times 10^8}{(DT)^{1/2}} \quad [8]$$

where $\overset{\circ}{a}$ is the mean diameter of the ions, that is the distance between their centers in the position of closest approach of the ions. In the above equations, a quantity is sometimes primed and sometimes unprimed. The primed quantities are real the unprimed ones are stoichiometric. Thus

$$\mu' = \frac{1}{2}\sum m_i' z_i^2 \quad [9]$$

where m_i' represents the actual ionic concentrations.

The calculations were made by assuming a value of α, say 0.80, for the values of K and of m being used. The value of μ' for the assumed value of α and the selected value of m was calculated using the equation

$$\mu' = (2\alpha + 1)m \quad [10]$$

and γ'' was obtained from Eq. [7]. This value of γ'' was used in Eq. [6] to recalculate α, from which, using Eq. [10], a better value of μ' was calculated. This better value of μ' substituted in Eq. [7] yielded a better value of γ''. This process was repeated until the same value of α, to within a few thousandths of a unit, was obtained twice. These calculations were carried out for each concentration in each solvent, at each temperature to obtain values of α and of K under these conditions.

Equation [1] in terms of the stoichiometric activity coefficient may be written in terms of the real activity coefficient $\gamma'_{\pm}$ and the actual ionic concentration as follows

$$E = E^o - k \log \alpha(1 + \alpha)^2 m^3 \gamma^3_{\pm} \quad [11]$$

and by subtracting E^o from both sides of Eq. [2] one can write

$$E_H - E^o = E - E^o + k \log 4m^3 - 3kS_{(f)}\sqrt{2\mu} \quad [12]$$

Substituting the value of $E - E^o$ from Eq. [11] into Eq. [12] there results

$$E_H - E_o = k \log 4 - k \log \alpha(1 + \alpha)^2 - 3k \log \gamma'_{\pm} - 3kS_{(f)}\sqrt{2\mu} \quad [13]$$

Harned and Fitzgerald (2) computed the right-hand side of Eq. [13] for various values of K using the activity coefficients of barium chloride obtained by Tippetts and Newman (8) for the real activity coefficients of cadmium chloride. These computed values were plotted *vs.* $\sqrt{m}$ and compared with E_H calculated from Eq. [2] and plotted against $\sqrt{m}$. The values of K which caused the curve of Eq. [13] to be most nearly symmetrical with the curve of Eq. [2] was taken as the dissociation constant. Values of the right hand member of Eq. [13] were read from the proper curve and subtracted from the original unsmoothed E_H function. According to Eq. [12] and [13] this gives

$$E^o = E + k \log \alpha(1 + \alpha)^2 m^3 \gamma^3_{\pm} \quad [14]$$

Harned and Fitzgerald averaged the values of E^o obtained in the above described manner by drawing a straight line of zero slope through the points resulting by plotting the values of E^o against $\sqrt{m}$. They obtained a value of 0.57300v for E^o.

In this work, data on cadmium chloride in aqueous solutions were taken initially to check the experimental procedure for reproducibility. Since this data compared favorably with the data of Harned and Fitzgerald (3), the two sets of data were listed together and treated according to the above theory with the aid of an IBM 7074 computer. The value of E^o obtained from the mixed data was 0.57340v.

The next step in the treatment of the data was to replace the activity coefficients of barium chloride by the value of γ'' for cadmium chloride from which the best value of α was computed in the reiterations by the use of Eq. [6], [7], and [10]. The complete procedure described above was then applied. The value of E^o determined in this case was 0.57162v. Since this treatment of the data gave a value within 1.5 mv of the value determined by Harned and Fitzgerald (3), it was decided to write a program for the IBM 7074 computer which was similar to the above treatment except for the two changes listed below.

The first change naturally was that γ'' cadmium chloride was used instead of γ barium chloride.

The second change was that the curves corresponding to Eq. [2] and [13] were not considered separately, but rather their difference was computed since this difference is E^o. The obtaining of the final form of the equation is shown below.

At 25°C Eq. [2] becomes

$$E_H = E + 0.08875 \log m - 0.1557\sqrt{m} + 0.01781 \quad [15]$$

Equation [13], at 25°C, reduces to

$$E_H - E^o = 0.01781 - 0.02958 \log \alpha(1 + \alpha)^2 - 0.08875 \log \gamma_\alpha - 0.08987\sqrt{\mu} \quad [16]$$

where γ_α is the value of γ'' calculated from the proper modification of Eq. [7] using the best value of α determined in the reiterations described above. $\gamma_\alpha = [\gamma'']^{1/2}$.

When one substitutes the value of E_H from Eq. [15] into Eq. [16], the following equation is obtained

$$E^o = E + 0.08875 \log m\gamma_\alpha - 0.1557\sqrt{m} + 0.08987\sqrt{\mu} + 0.02958 \log \alpha(1 + \alpha)^2 \quad [17]$$

This is the final form which was used to evaluate E^o for each observed value of E at a given molality. The values of E^o computed from this equation for each value of E and m were averaged. The IBM 7074 computer program was stated so that different values of K and a selected value of $\overset{\circ}{a}$ were tried until the correct combination gave an average E^o value with an average deviation of 1.5 mv. This amounts to the difference between the curves from Eq. [2] and [13] being a straight line with a slope of zero within 1.5 mv. In the higher alcohol solutions the average minimum deviation of E^o was somewhat higher. The points on the Harned and Fitzgerald plot showed comparable deviations to those in Table III.

In Table III the E^o values which were determined are listed. In addition the values of the equilibrium constants and the mean distance of approach of the ions which were necessary for E^o to reach a suitable minimum deviation are listed. Other derived quantities and the dielectric constants of the media are presented in this table.

In order for E^o to reach this minimum deviation it was not necessary to change the value of $\overset{\circ}{a}$ as the solvent was varied from water to 100% methanol. Oiwa (9) found a trend for $\overset{\circ}{a}$ when HCl was studied in the water-methanol solutions, although the range of variation for $\overset{\circ}{a}$ for HCl was not great in this study. He indicated that this was due to a preferential solvation effect of the ions. It has been found that the value for $\overset{\circ}{a}$ for cadmium chloride in water-ethanol solvents did not change (1).

* Smoothed values.

In Fig. 3 the E° values listed in Table III are plotted against the reciprocal of the dielectric constant of the medium in which each E° value was determined. The resulting lines are almost straight in agreement with the data taken by Hefley and Amis in the ethanol-water system (1). Corsaro (10) studied zinc chloride in water-methanol solutions. He found that the E° of that solution varied linearly with the reciprocal of the dielectric constant of the medium in which the E° was determined, when methanol and methanol-water solutions were used. These data have been discussed theoretically by Harned and Owen (11) and by Amis (12).

Variations in the values of the dissociation constant K were discussed in the case of ethanol water solvents, and the same discussion would apply here. In brief the dissociation and hence the dissociation constant decreased as the dielectric constant of the media decreased due to the addition of increasing quantities of methanol. This is in agreement with Bjerrum's (13) theory of ionic association in liquid media. The decrease in the dielectric constant of the ethanol-water solvents by a factor of about 2.5 caused K to decrease by a factor of about 10^{-2} as was found in the methanol-water media. Fuoss and Kraus (14) found a decrease of 10^{-3} fold in the K values for tetraisoamylammonia nitrate when the dielectric constant of the dioxane-water media decreased by threefold.

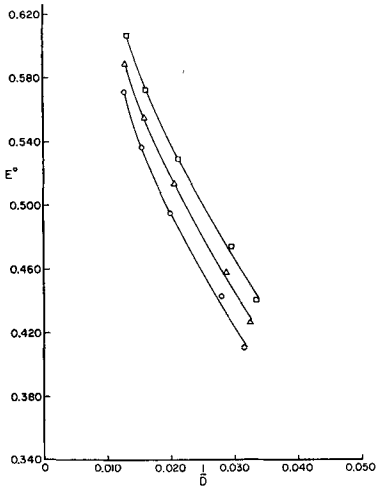

Fig. 3. Standard potentials of the Cd-Cl_xHg (11%) $|CdCl_2(m)|$ AgCl-Ag cell plotted against $1/D$ using methanol solutions. ○, MeOH solutions at 25°C; △, MeOH solutions at 30°C + 0.02000v; □, MeOH solutions at 35°C + 0.04000v.

The value of 5Å found for the distance of closest approach of the ions of cadmium chloride is not unreasonable since the divalent cadmium ion has a radius of about 0.95Å and the monovalent chloride ion a radius of about 1.90Å. The solvent would no doubt play a part in the determination of the value of $\overset{\circ}{a}$, making this value greater than the sum (0.95Å + 1.95Å) or 2.85Å. Therefore $\overset{\circ}{a} = 5$Å is reasonable.

Values of ΔF°, ΔH°, and ΔS° recorded in Table III were calculated using standard equations for these quantities. The chemical reaction to which these calculations apply is the cell reaction. Thus

$$Cd(s) \rightarrow Cd^{++}(m) + 2\epsilon \text{ (anode reaction)} \quad [18]$$

$$2Ag^+(s) + 2\epsilon \rightarrow 2Ag(s) \text{ (cathode reaction)} \quad [19]$$

$$Cd(s) + 2Ag^+(s) \rightarrow Cd^{++}(m) + 2Ag(s) \text{ (cell reaction)} \quad [20]$$

In the methanol-water as in the ethanol-water system, the change in standard free energy increases (becomes less negative continually) as the per cent of nonaqueous component in the solvent increases. This means that the process becomes less spontaneous with increasing amounts of methanol in the solvent. As discussed in the ethanol paper, this decrease in spontaneity might result from one or several causes. Difference in nature and extent of solvation, change in the structure of the solvent, and increased association of the ions at the lower dielectric constants might be among the pertinent factors. However, here again the latter factor is perhaps the predominant one. That this is true is supported by the observation that the standard free energy change toward a more positive value is less in going from water to 100% methanol than in going from water to 100% ethanol, and the change in dielectric constant is also less in the water-methanol case.

As in the case of ethanol water. the ΔH°-values have been rounded off to three significant figures because the quantities depend on differences in ΔF°-values and hence are no doubt not so reliable as the ΔF°-values themselves. Nevertheless, the quantities are presented here so as to be available for comparison with future data. The reaction is exothermic throughout and shows

a negative entropy increment in all instances. In ethanol-water the process was exothermic throughout and showed a negative entropy increment in all instances. The ΔS^o-values were rounded off to two significant figures since the differences in ΔF^o and ΔH^o contained only two, or at most, three significant figures. The precision of these values were calculated from the precisions of the ΔF^o- and ΔH^o-values.

The negative entropy increments for the process probably indicate an ordering process as discussed in the ethanol-water paper. In this paper the ordering process is apparently greater at the higher temperature interval and is probably related to the lower viscosity and reduced dielectric constant at the higher temperature permitting a more ready orientation of the molecules.

Activity Coefficients

After the E^o values were determined for each solvent composition, the activity coefficients were calculated from Eq. [1].

The logarithm of the activity coefficients which were determined in this manner are listed in Tables IV and V. A graphical representation of this data in which

The variation of the activity coefficients of cadmium chloride with the dielectric constant (or solvent composition), as shown in the figures, follows the same general trends which Harned and Morrison (15, 16) observed for hydrochloric acid in water-dioxane solvents. This trend is a deviation from the straight line limiting slope of the Debye and Hückel theory at a lower value of the molality as the dielectric constant is decreased.

Significance of Nonsteady-State A-C and D-C Measurements in Electrochemical Adsorption Kinetics

Applications to Galvanostatic and Voltage Sweep Methods

B. E. Conway, E. Gileadi,[1] and H. Angerstein-Kozlowska[2]

Department of Chemistry, University of Ottawa, Ottawa, Canada

ABSTRACT

Information obtainable from nonsteady-state electrochemical studies is examined with particular reference to the determination and significance of capacitance associated with adsorbed intermediates in consecutive reactions. The frequency dependence of the capacity in a-c measurements is related to the rise-time dependence in d-c charging transients and the concept of an equivalent frequency in d-c measurements is proposed. The nonsteady-state kinetics for a galvanostatic charging process is examined for a reaction sequence involving adsorbed intermediates, and it is shown how the capacitance behavior depends on the charging current density. Applications to the triangular voltage sweep method are made, and it is shown that for this case where neither steady-current nor steady-state kinetics apply, care must be exercised in interpretation of results derived from this method. The nonsteady-state kinetics for this case are derived and the dependence of the capacity on sweep-rate is deduced. The differential galvanostatic method leads to results which can be much more explicitly analyzed in a rigorous kinetic manner, for irreversible charging processes. Applications to experimental results which support the treatment given are discussed.

The adsorption pseudocapacitance (1) arising in certain electrochemical reactions, where an initial discharge step is at quasi-equilibrium when followed by a rate-determining step, may be defined as

$$C = k\,(d\theta/dV) \qquad [1]$$

where θ is the fractional surface coverage by intermediates formed by the discharge of an ionic species, V is the metal-solution potential difference, and k is a proportionality constant, representing the Faradaic charge which has to cross the metal-solution interface for a complete monolayer of discharged species (*e.g.*, adsorbed radicals, metal adions) to be formed on unit real surface area of the electrode.

Experimental methods for determining the adsorption pseudocapacitance have been reviewed recently (2-4) and the form of the $C - V$ relationship has been derived, assuming that the electrode system obeys an ideal Langmuir isotherm (5, 6) and for the more general and experimentally applicable case when the variation of the heat of adsorption with coverage (Temkin type of isotherm) is also taken into account (1, 7). Cases for which the assumption of quasi-equilibrium in the initial ion discharge step cannot be made have also been considered (7, 8).

The capacitance at the metal-solution interface can be obtained from a-c impedance determinations by a compensating bridge method or from phase angle measurements. The electrode is first polarized to a steady-state by applying a constant current or potential, and its impedance with respect to a small a-c signal is measured and resolved into its capacitative and resistive components. The amplitude of the a-c signal is maintained very low so that the steady current condition at the electrode is not significantly disturbed. The capacitance measured by the method is usually found to depend on the frequency and at any frequency it is the sum of the ionic double-layer capacitance $C_{d.l.}$ and the adsorption pseudocapacitance C. Dolin and Ershler (9) have shown that the total capacitance C_p measured in a parallel circuit arrangement depends on frequency according to the equation

$$C_p = \frac{C}{1 + \omega^2 r^2 C^2} + C_{d.l.} \qquad [2]$$

where C is the value of the adsorption pseudocapacitance at zero frequency (referred to by the above authors as the "equilibrium value"), and r is the reaction resistance in the initial ion discharge step, obtainable by extrapolation of the observed resistance R_p in the same parallel arrangement to infinite frequency. From Eq. [2], it is clear that $C_{d.l.}$ and r can be obtained by measuring C_p and R_p at high frequencies and extrapolating the results to infinite frequency. With these quantities known, the adsorption pseudocapacitance can be obtained from a single measurement of the total capacity C_p at an accurately known frequency. Equation [2] was derived assuming a completely homogeneous electrode or would correspond to a heterogeneous one with completely unhindered lateral motion of the adsorbed species on the surface. That this model is not quite realistic, was already realized by Dolin and Ershler (9) who found that the value of C calculated from Eq. [2] at various frequencies was still strongly frequency dependent. The capacity C could in principle, be obtained by extrapolating the measured value C_p to $\omega = 0$ and subtracting from it $C_{d.l.}$, but the measurement becomes experimentally difficult at very low frequencies ($\nu <$ 10 cycles sec^{-1}), and the experimental error is much larger. Thus, while the a-c bridge method can usually yield the most accurate experimental results, the interpretation of the values obtained is by no means straightforward.

An alternative group of methods, widely used to determine the total capacity at the metal solution interphase, depends on the relation

$$i = C\,(dV/dt) \qquad [3]$$

in which i is the direct current used to charge the capacitance C. Constant current charging curves (taken over an interval of potential where the part of the current used for the relevant over-all Faradaic process is negligible) have been used by Frumkin *et al.* (10)

[1] Present address: John Harrison Laboratory of Chemistry, University of Pennsylvania, Philadelphia, Pennsylvania.

[2] On leave of absence from the Technical University, Warsaw, Poland.

and by Butler (11), and the method has since become a generally used technique. Initial rates of decay of overpotential on open-circuit have also been used (12, 13) to determine C. This method is based on the assumption that the electrode reaction continues on open-circuit by a self-discharge process which momentarily, at the commencement of the open-circuit transient, has the same rate as that corresponding to the steady-state polarizing current density. The latter method has been extended (12, 14-16) to enable the calculation to be made of the adsorption pseudocapacity effective at any potential along the whole open-circuit decay curve, provided that the steady current-potential relation is known in an independent experiment. The assumption made in this case is that the rate-determining Faradaic reaction continues on open-circuit and acts as a potential dependent resistance shorting the terminals of the "pseudocapacitor." The value of the current to be used in Eq. [3] to evaluate C at any potential is equal to the current observed during steady-state polarization at the same potential. For current-potential relations which show hysteresis between the ascending and descending direction of change of potential, the results obtained potentiostatically for descending currents and potentials are to be used for the calculation of C.

When d-c techniques are applied, it is implicitly assumed that the pseudocapacity measured is the "equilibrium" value, namely, that which would be obtained by extrapolating the measured a-c values to infinitely low frequencies. This assumption is usually made irrespective of the magnitude of the constant current used for charging or discharging the electrode and, in fact, in the study of adsorption of atomic hydrogen, use of high current densities is required (1, 3, 17-19) to minimize readsorption of hydrogen.

The question whether the capacity measured during a constant current charging process is, in principle, the "equilibrium capacity" in the sense defined above (*i.e.*, the value corresponding to extrapolation to zero a-c frequency), or if a change in charging current and/or a change in dV/dt during charging at a given total constant current, can be looked on as a change in "equivalent frequency" (see below) is of great importance in the study and quantitative interpretation of the shape of transients for electrochemical reactions. Thus, if the effective capacity does depend on i and/or dV/dt during a galvanostatic transient (as indeed it does in certain cases to be discussed below), it is evident that this dependence should be considered when an attempt is made to evaluate kinetic and coverage parameters from transient behavior (5, 7, 8, 20).

It is the purpose of the following discussion to provide a physical picture and mathematical treatment for the variation of adsorption pseudocapacity with frequency and rise-time or charging current, and to predict the effect of variation of applied current on the shape of galvanostatic transients and on the values of the pseudocapacitance calculated from them. Experimental tests of these predictions will also be presented, which qualitatively support the theory given.

Physical Origin of Frequency Variation of Pseudocapacitance

Amplitude.—It is convenient to consider a general anodic reaction

$$M + A^- \underset{k_{-1}}{\overset{k_1}{\leftrightarrows}} MA + e \qquad \text{(I)}$$

$$2MA \xrightarrow{k_2} 2M + A_2 \qquad \text{(II)}$$

and it will be assumed that the rate constants k_1, k_{-1} for reaction (I) are relatively large compared with that for step (II), so that (I) is at quasi-equilibrium with step (II) rate-determining throughout the potential range studied. The concentration of intermediates will hence be determined solely by the equilibrium in step (I)[3] and will not be significantly affected by the kinetics of step II. If an a-c signal of small amplitude and very small frequency were now superimposed on the d-c current or potential used to polarize the system to a steady-state, the value of the coverage at any time would be that corresponding to the electrochemical steady-state at the momentarily prevailing net potential. Under these conditions, the true "equilibrium" pseudocapacity would be measured. If, on the other hand, the frequency of the a-c signal were sufficiently high, it is clear that the equilibrium in step (I) would not be disturbed at all, and the impedance at the metal-solution interface would be only that associated with the ionic double layer. Between these two extreme conditions, there can exist a frequency interval in which the rate of change of coverage can be comparable with the rate of change of potential and a dispersion of the measured capacity is observed.[4] In this range of frequencies, the coverage cannot change fast enough with the change in potential, and the smaller change in coverage then corresponds to a smaller observed pseudocapacity. It can therefore be concluded that as long as $dV/dt >> d\theta/dt$ the tendency would be for little or no pseudocapacity to be observed. When $dV/dt << d\theta/dt$, the equilibrium pseudocapacity is observed and when $dV/dt \doteq d\theta/dt$, a variable pseudocapacity can be observed which depends on dV/dt and hence on frequency. If the applied a-c signal has a sinusoidal form, the time-dependent value of the potential may be written as

$$V = V_o + A \sin(\omega t) \qquad [4]$$

where A is the amplitude of the a-c signal and V_o is the steady-state (d-c) value of the potential. Differentiating Eq. [4] with respect to time gives

$$dV/dt = A\,\omega \cos(\omega t) \qquad [5]$$

hence

$$|dV/dt|_{\text{max.}} = A\,\omega = 2\pi A\nu \qquad [6]$$

$$|dV/dt|_{\text{ave.}} = \frac{2A\omega}{\pi} = 4A\nu \qquad [7]$$

The *max*imum and *ave*rage absolute values of the rate of change of potential with time are hence proportional to the product of frequency multiplied by the signal amplitude.

The results in Eq. [6], [7] would seem somewhat unexpected since it is known experimentally, and has been shown theoretically (22), that the observed pseudocapacity is independent of the amplitude of the a-c signal (so long as it is kept small enough so that the steady-state polarization is not significantly disturbed). This apparent disagreement can be explained as follows: since it has been assumed that step I remains at quasi-equilibrium during steady-state polarization, we may regard the a-c signal as a small overpotential of variable magnitude applied to a step which is otherwise at equilibrium. The net rate of a reaction close to equilibrium is proportional to the so-called "affinity" in terms of Prigogine's terminology (23, 24), and in the case of an electrochemical reaction is proportional to the overpotential (25). Also since only step I is considered, the net reaction rate is proportional to $d\theta/dt$ and we may write

$$\frac{|dV/dt|_{\text{max.}}}{|d\theta/dt|_{\text{max.}}} = \frac{2\pi\nu A}{i_o FA/kRT} = \frac{(2\pi kRT)}{i_o F}\nu \qquad [8]$$

[3] See, however, ref. (7), (8) for a discussion of the limitations of this statement when a large dependence of apparent standard free energy of adsorption of the intermediate upon surface coverage is involved (Temkin-type conditions).

[4] It is important to realize that the above explanation (which also applies to the model leading to Eq. [2]) only predicts a variation of capacity over a relatively narrow range of frequency, *i.e.*, *ca.* two orders of magnitude in ν. The fact that, experimentally, C is found to be a function of ν over a much wider frequency range (5, 21), coupled with the apparent frequency dependence of C calculated from Eq. [2] [cf. ref. (9)], can be regarded as evidence for the existence of surface heterogeneities at which step (I) proceeds with a distribution of rate constants.

where k is the charge associated with formation of a monolayer of adsorbed intermediates (cf. Eq. [1]) and i_o is the exchange current density for the initial ion discharge step I. Equation [8] may be rewritten as

$$\frac{|dV/dt|_{max.}}{|d\theta/dt|_{max.}} = (2\pi kr)\nu \qquad [8a]$$

in which r is the reaction resistance for step I (cf. Eq. [2]), given by $r = RT/i_oF$ at low overpotentials. Thus, both quantities on the l.h.s. of Eq. [8a] are proportional to the amplitude A of the a-c signal, and their ratio is independent of it.
