As a consequence of this thickness dependence, the average value of the thickness independent quantity $-\Delta M_r/M_{ro}^{2/3}$ has been plotted against time for these samples in Fig. 9. These curves show a parabolic or logarithmic (the data does not enable one to distinguish) dependence typical of the formation of a protective oxidation product. It is interesting that despite the difference in early environment (*i.e.*, the plating solution), magnetic properties, and composition of the samples from the sulfate solution and the chloride solution, they exhibit almost identical corrosion behavior. The behavior for both series at 65.5°C and 80% relative humidity is shown in Fig. 10. In this case, the curve levels out at the same value of $-\Delta M_r/M_{ro}^{2/3}$ but rises to this value in about half of the time.

The residual compressive stress of the deposits increased in a manner similar to that of the decrease in remanent moment. The average stress (estimated by the bent strip method) as a function of exposure time at 43.5°C, 80% R. H. is shown in Fig. 11. This result indicates the formation of a corrosion layer of greater specific volume than the metal, again indicative of a protective product (6).

Reflection electron diffraction indicates that the corroded surface is mainly Co_3O_4. Furthermore, an estimate of the thickness of the corrosion film from electron diffraction data agrees fairly well with the 12% measured from the magnetic data for the 1000Å film.

Assuming the product is completely Co_3O_4, the parabolic rate constant in terms of oxygen pick-up can be estimated. This yields the following results for a 1000Å film

	43.5°C	65.5°C
K (g/cm²)²/sec	$3.6 \cdot 10^{-17}$	$4.7 \cdot 10^{-17}$

Conclusion

The magnetic properties of electroless cobalt deposits of variable thickness prepared in different solutions (a sulfate and a chloride solution) were found to be very similar. Furthermore, the variations of the magnetic properties with thickness are related to the crystallite size growth of the deposits. Magnetic moment measurements were used successfully as a very sensitive means of studying the corrosion of magnetic deposits. The amount of corrosion increased with increasing thickness, indicating that the deposits became rougher at increased thickness, *i.e.*, their surface area increased. The advantages of very thin metallic films for magnetic recording must be contrasted with the danger of significant atmospheric corrosion when their surface to volume ratio becomes large. In addition, magnetic and recording studies of such materials must be undertaken with precautions lest significant corrosion occurs during the sometimes extended period of investigation of specific samples.

Rotating Disk Study of the Dissolution of Zirconium in HF-HNO_3

R. E. Meyer

Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

ABSTRACT

The rotating disk electrode system was used to determine the rate constants of the reaction of zirconium with HF in solutions of HNO_3 and HF. The reaction was found to be first order with respect to HF, and the rate constants decreased slightly as the potential became more anodic. Possible mechanisms explaining the role of HF in the dissolution reaction are discussed.

When zirconium dissolves in aqueous solutions containing HF, the over-all rate of the reaction is controlled by the rate of mass transfer of undissociated HF molecules to the surface of the electrode (1, 2). An investigation in detail of the kinetics of this reaction requires that the concentration of HF be precisely controlled and determined at the reaction interface. A rotating disk electrode was therefore selected to study this system; for, as Levich (3) has emphasized, this system provides a uniformly accessible surface, *i.e.*, it provides a uniform, determinable concentration of the migrating species along the surface of the electrode. If this condition of uniform accessibility were not met, as would be the case if ordinary methods of stirring were employed, the overpotential would vary across the surface, and complicated current-voltage behavior would be observed.

The dissolution of zirconium in solutions containing HF appears to be complicated in that in some, and perhaps in all cases the reaction proceeds by the continuous formation and dissolution of a film (2). The study of the over-all reaction, therefore, involves the study of both the dissolution and film formation reactions. Some aspects of the kinetics of the film formation reaction were reported previously (2), but the dissolution reaction could not be studied until the mass-transfer conditions were better defined. In the work described here, the rotating disk was used to determine the rate constants of this surface reaction and the dependence of this rate constant on the potential and concentration. All measurements were carried out at potentials sufficiently anodic so that the rate of the hydrogen evolution reaction was negligible.

The derivations of the equations describing the rotating disk electrode system have been summarized by Levich (3). In this reference, it is shown that the flux of a neutral particle is given to within a few per cent by the expression

$$j = 0.62\, D^{2/3} \nu^{-1/6} \omega^{1/2} (C_B - C_i) \qquad [1]$$

where j is the flux, D is the diffusion coefficient, ν is the kinematic viscosity, ω is the angular velocity in

radians per second, C_B is the concentration in the bulk of the solution, and C_i is the concentration of the reactant at the interface. If the migrating species is neutral, or if the species is charged and there is a large excess of inert electrolyte (at least 100 to 1), then the current will be given by

$$I = 0.62\, nFSD^{2/3}\nu^{-1/6}\omega^{1/2}(C_B - C_i) \qquad [2]$$

where nF is the charge that is transferred per mole of the migrating species, and S is the area of the electrode.

In many cases of interest, the rate of the surface reaction is comparable to the rate of mass transfer. The reaction rate at the surface may be expressed by the equation

$$I = n'FkSC_i^m \qquad [3]$$

where k is the rate constant, C_i is the concentration of the reactant at the interface, and m is the order.[1] In the steady state

$$I = nFAS(C_B - C_i)\omega^{1/2} = n'FkSC_i^m \qquad [4]$$

where $A = 0.62\ D^{2/3}\nu^{-1/6}$. If $m = 1$, these equations may be solved with the elimination of C_i to give

$$\frac{1}{I} = \frac{1}{n'FkSC_B} + \frac{1}{nFASC_B\omega^{1/2}} \qquad [5]$$

A plot of I^{-1} *vs.* $\omega^{-1/2}$ should therefore be linear for a first order reaction, and the rate constant can be determined by extrapolation of the line to infinite frequency of rotation ($\omega^{-1/2} \rightarrow 0$). From the slope of the line, the expression nFA can be calculated, and n can be determined if the value of D is known (or D can be determined if n is known). If the order is not unity, the determinations of the order and the constants are less straightforward, but various techniques have been devised for treating the data (3, 4).

If the rate constant k is large so that the rate of the surface reaction is fast compared to the rate of mass transfer, then C_B will be much greater than C_i in Eq. [2] and the limiting current will be given by

$$I = nFASC_B\omega^{1/2} \qquad [6]$$

and a plot of I^{-1} *vs.* $\omega^{-1/2}$ will go through the origin.

In this work, a series of determinations were made of the current as a function of angular velocity, potential, and solution composition at several potentials anodic to the open-circuit potential. The rate constant k was determined, and n was calculated using estimates of the value of D.

Experimental

In the design of the experiment, the conditions assumed in the solution of the convective-diffusion equation must be maintained. The flow of the solution over the surface of the electrode must be laminar, and the dimensions of the electrode must be large compared to the diffusion and hydrodynamic boundary layers and small compared to the dimensions of the cell (3, 5, 6). In practice, the correct conditions are best determined empirically by varying the pertinent dimensions of the cell until reasonable results are obtained. The conditions depend on the degree of precision desired. If it is desired to determine diffusion coefficients, great care must be taken, for the slopes of plots of Eq. [5] are quite sensitive to the hydrodynamic conditions. If rate constants of surface reactions are desired, then the requirements are relaxed slightly as long as reasonable extrapolations can be carried out.

[1] In Eq. [3], the n is primed because it does not necessarily have the same value as the n in Eq. [2]. In the mass transfer expression, Eq. [2], n refers to the number of Faradays transported for every mole of HF that reacts with the zirconium at the surface. This number would therefore depend on the ratio of zirconium to HF in the complex that forms at the surface. The n' in Eq. [3] is the number of Faradays transported across the interface for every mole of zirconium that reacts and would therefore normally have a value of four.

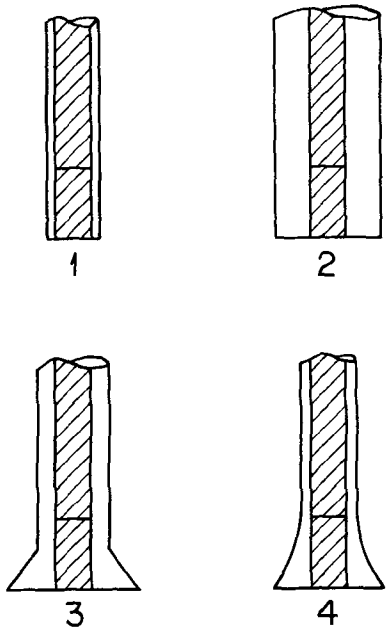

Fig. 1. Electrode shapes used in rotating disk experiments. The outer sections are Teflon.

The electrode shapes shown in Fig. 1 were tried. In each of these configurations, the working surface was the end of a cylindrical electrode ¼ in. in diameter, which was carefully machined perpendicular to the axis of rotation. The electrode was then threaded to a holder which was mounted so that the eccentricity of rotation was less than 0.0015 in. The cylindrical surfaces of the electrode were insulated with a lacquer, and Teflon sleeves of various shapes were fitted about the electrode. All of these configurations gave the same results, and most of the experiments were conducted with No. 1 and 4 of Fig. 1. The cell was made of Teflon with an outer steel liner for reinforcement, and it had an internal diameter of 2¾ in. and a depth of 4 in. Varying the depth of the solution and varying the position of the electrode did not affect the results. Gas inlets and exits were made by leading ⅛ in. diameter Teflon "spaghetti" tubing through holes in the Teflon cell just large enough to insure a tight fit. The saturated calomel reference electrode was also bridged into the solution with the Teflon spaghetti tubing. Varying the position of the tip of the tubing did not affect the results. The solutions contained the required amount of HF plus 1.2M HNO_3. The nitric acid served to minimize IR drop, to act as an inert electrolyte, and to suppress ionization of HF.

Speed control was effected by a General Radio 1701-AK Variac speed control driving a 1/15 hp d-c motor. This unit gave excellent regulation from about 100 rpm to 4000 rpm. The angular velocity was determined with a General Radio Strobotac.

During the experiments, the electrodes were held at constant potential with a potentiostat. Currents were recorded by measuring the potential drops across precision resistance with a Hewlett-Packard 425 AR DC Microvolt-Ammeter coupled to a Brown recorder. In some of the experiments, temperatures were maintained at 25°C with a water bath, but since the temperature coefficient of the reaction was quite small, many of the experiments were conducted at 25° ± 1°C with the room thermostat.

Results

The experimental apparatus was tested by investigating the reduction of oxygen on platinum in the limiting current region where Eq. [6] should be valid. For this purpose, a platinum disk electrode whose exposed surface area was identical to that of the zirco-

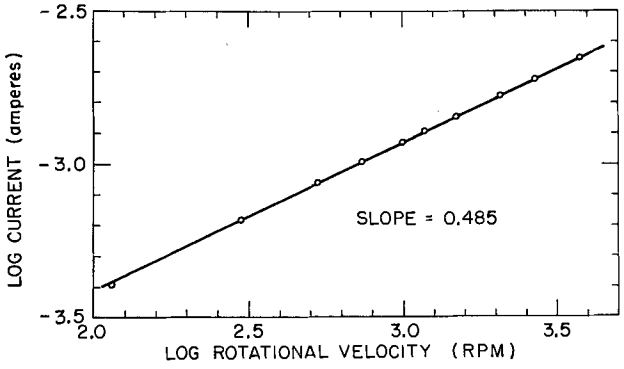

Fig. 2. Reduction of oxygen on rotating platinum disk electrode 0.1M Na_2SO_4, O_2-saturated, electrode area = 0.316 cm².

nium electrodes was used. Figure 2 shows a plot of log I *vs.* log ω for this system. The slope of the line is 0.485, which is very close to the theoretical 0.5. A few additional experiments were performed in which a large glass beaker was substituted for the Teflon container, and crystals of $KMnO_4$ were placed in the bottom. The flow pattern characteristic of rotating disks (3) was observed as the $KMnO_4$ dissolved.

Plots of I^{-1} *vs.* $\omega^{-1/2}$ are shown in Fig. 3 and 4 for two separate runs. According to Eq. [5], the extrapolations of these lines determine the fraction $1/n'FkSC_B$, *i.e.*, the reciprocal current at infinite frequency of rotation. The rate constant, k, was then calculated for each experiment, and values of the rate constant are recorded in Table I.

If the reaction were precisely first order with respect to the concentration of HF, the values of k would be independent of concentration. Instead they tend to decrease slightly as the concentration is reduced to 0.005N HF, and then they decrease more sharply as the concentration is reduced to 0.001N. Possible explanations for this effect are discussed below. The deviations from first order in an individual run did not appear to be large enough to affect the validity of the extrapolation to infinite frequency, for, as shown in Fig. 2 and 3, the deviations from linearity are not apparent.

The tendency for the apparent order to be slightly greater than unity can also be shown by calculating the concentration at the interface by using the following equation, obtained from Eq. [4]

$$C_i = C_B - \frac{I}{nFAS\omega^{1/2}} \qquad [7]$$

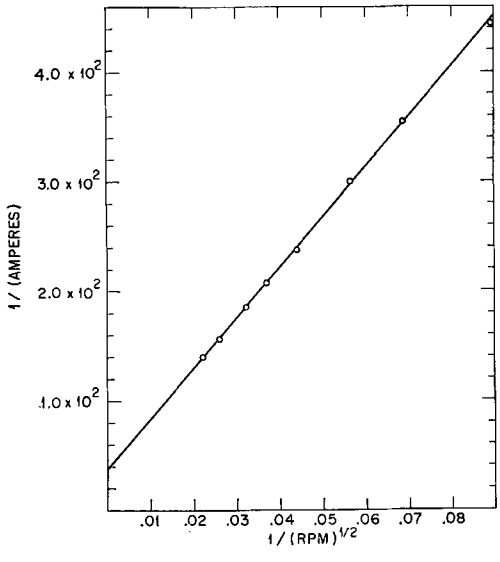

Fig. 3. Rotating disk plot of I^{-1} vs. $(\text{rpm})^{-1/2}$ for zirconium in 0.0213M HF and 1.2M HNO_3, 25°C, —500 mv *vs.* SCE, electrode area = 0.316 cm².

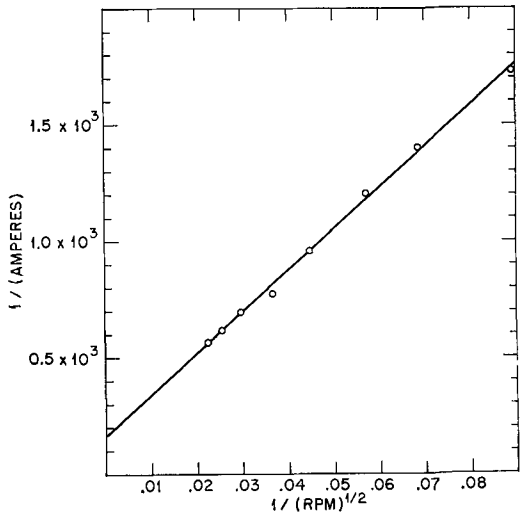

Fig. 4. Rotating disk plot of I^{-1} vs. $(\text{rpm})^{-1/2}$ for zirconium in 0.00535M HF and 1.2M HNO_3, 25°C, —500 mv vs. SCE, electrode area = 0.316 cm².

The numerical or effective order can be determined from a plot of log I *vs.* log C_i, since the slope of this plot is numerically equal to the order. The quantity nFA was obtained from the slope of the plots of $1/I$ *vs.* $1/\omega^{1/2}$ (Eq. [5]) for each run. The average value of nFA for all of the runs in 1.2M HNO_3 is 32.5. In this computation, the units of concentration were moles per cubic centimeter and the units of ω were rpm. An example of a plot of log I *vs.* log C_i is shown in Fig. 5 where an order of 1.17 was found. For most of the runs, the orders found were slightly above unity; values between 1.1 and 1.2 were most common.

The value of the quantity nFA was checked by another method of evaluation which took advantage of the fact that as the stirring rate tends to zero, the concentration at the interface also tends to zero. Therefore, if a plot of I *vs.* $\omega^{1/2}$ is extended to the origin, the slope of the tangent drawn to the line at the origin will be given by Eq. [8] [cf. ref. (4)].

$$\frac{dI}{d\omega^{1/2}} = nFASC_B \qquad [8]$$

This method is illustrated in Fig. 6 where it is estimated that nFA equals 33.7. This value agrees well with the values found above.

The value of n in the product nFA can be determined if the diffusion coefficient and the viscosity are known, as shown by Eq. [1]. The viscosity will be given to a

good approximation by the viscosity of the appropriate concentration of HNO_3. Since the viscosity enters as the 1/6 power, it need not be known precisely. To the author's knowledge, the diffusion coefficient of HF has not been determined experimentally. Further, it is difficult to make a reliable estimate of D because the degree of the interaction of HF with the water is unknown. However, because all known values of D in aqueous solutions are of the order of magnitude of 10^{-5} cm^2/sec, such a value would be expected. From the known values of nFA, the product $nD^{2/3}$ is calculated to be 7.6×10^{-4}. Therefore, if D is 2×10^{-5}, n is about 1, and if D is 10^{-5}, n is 1.65. If n would be 4, D would be 2.6×10^{-6}, a value that is probably too low. A value of D between 10^{-5} and 2×10^{-5} seems reasonable for HF and would be consistent with a complex containing from 2.5 to 4 fluoride ions per zirconium ion. The charge on the zirconium ion is assumed to be four.

Discussion

The essential results may be summarized as follows: (*A*) The reaction rate constant, k, is almost potential independent. (*B*) The reaction at the surface is first order with respect to HF. (*C*) The over-all reaction occurring at or very near the surface is $Zr + bHF \rightarrow ZrF_b^{4-b} + bH^+ + 4e^-$ where b probably has a value from 2.5 to 4. (*D*) There is an effect which tends to decrease the rate constants as the concentration of HF is reduced.

If the dissolution reaction were a simple electrochemical reaction with a normal potential dependence, then the rate constant, k, should increase as the potential becomes more anodic. Furthermore, if normal values of the Tafel slope are assumed, the current would increase by at least two orders of magnitude in the 300 mv potential region that was investigated. Instead, values tended to decrease slightly as the potential became more anodic. This effect is understandable if the potential at the film solution interface where the dissolution takes place remains essentially unchanged as the over-all potential between the metal and the solution is changed. The potential change would then occur primarily across the film or the film-metal interface. This would be in accord with a model, previously proposed (2), in which the dissolution reaction occurs by the continuous dissolution and formation of the film. In this model, the zirconium is oxidized to form a film of oxide on the surface, and the dissolution proceeds by the action of HF on the zirconium ions at the interface between the film and the solution. This is also similar to the case of passive iron (7) where it is observed that the rate of dissolution of the film is potential independent over a wide potential range. In the case of iron, it was assumed that the potential at the interface stays constant and is determined by the equilibrium $2H^+ + O^{=}_{lattice} \rightleftharpoons H_2O$. A similar equilibrium might also be proposed for the case of zirconium.

The following scheme seems reasonable for the reaction mechanism at the interface between the film and the solution

$$Zr^{+4}_{lattice} + HF \rightarrow ZrF^{+3} + H^+$$
$$ZrF^{+3} + HF \rightarrow ZrF_2^{+2} + H^+$$
$$\text{- - - - - - - - - - - - - -}$$
$$Zr_{b-1}^{4-(b-1)} + HF \rightarrow ZrF_b^{4-b} + H^+$$

The intermediate complexes may either be solution complexes at or near the surface, or they may be surface complexes in that they are bonded to the film. If the first reaction is rate-determining, then the rate of the reaction will be given by the expression

$$r = k_1(HF) \qquad [9]$$

where k_1 is the rate constant for the first reaction. If the succeeding complexing reactions occur rapidly in the solution at or very near the interface, a value of n in agreement with the results could be obtained. The complexing reactions must occur in a distance small compared to the width of the diffusion boundary layer so that the complexing affects the value of the concentration of HF at the interface. If the complexing reactions occurred in the bulk of the solution, then the value of n found experimentally would be four, because four units of charge (the Zr^{+4} ion) would be removed from the interface for every reacting HF molecule. The actual value of n is probably from 1 to 1.65 as shown above. Therefore, Eq. [9] could represent the correct mechanism if the complexing occurs at or near the interface.

A similar kinetic equation would result if some or all of the complexing reactions occurred with surface atoms as in the following scheme

$$Zr^{+4}_{lattice} + HF \rightarrow ZrF^{+3}_{lattice} + H^+$$
$$ZrF^{+3}_{lattice} + HF \rightarrow ZrF_2{}^{+2}_{lattice} + H^+$$
$$\text{- - - - - - - - - - - -}$$
$$ZrF_{b-1}{}^{4-(b-1)}{}_{lattice} + HF \rightarrow ZrF_b^{4-b} + H^+$$

In this scheme, all but the last complex is formed on the surface of the film. The expressions for the rates of these reactions are

$$r_1 = k_1(HF)\left(1 - \sum_{n=1}^{b-1} \theta_n\right) \qquad [10]$$

$$r_2 = k_2\,(\mathrm{HF})\,\theta_1 \qquad [11]$$

$$\cdots\cdots\cdots$$

$$r_b = k_b\,(\mathrm{HF})\,\theta_{b-1} \qquad [12]$$

In these equations, the θ's represent the coverages of the various complexes on the surface.

In the steady state, the r's are equal and

$$k_1(\mathrm{HF})\left(1 - \sum_{n=1}^{b-1}\theta_n\right) = k_2(\mathrm{HF})\,\theta_1 = \ldots = k_b(\mathrm{HF})\,\theta_{b-1} \qquad [13]$$

or

$$k_1\left(1 - \sum_{n=1}^{b-1}\theta_n\right) = k_2\,\theta_1 = \ldots k_b\,\theta_{b-1} \qquad [14]$$

Since there are $(b-1)$ equations in $(b-1)$ unknowns (the values of θ_n), this set of equations may be solved to give any of the values of θ_n in terms of the rate constants. Therefore, the resulting current expression will have the form

$$I = nFKS(\mathrm{HF}) \qquad [15]$$

where K is a combination of rate constants.[2] This has the same form as Eq. [9], and unfortunately, there seems to be no way of distinguishing between these two possibilities.

As noted above, the reaction is not exactly first order, but the effective order is slightly greater than unity. According to the above mechanisms, one would expect an exact first order. A possible clue to this behavior is provided by the experiments in 0.12M HNO_3. Although the concentration of HF is essentially unchanged, the rates are greater than the rates at the same concentration of HF and 1.2M HNO_3. It may be that the nitrate ion, which is present in large relative quantities, competes with the HF molecules at the interface. At high ratios of HNO_3 to HF, the reaction may be slightly inhibited. The ratio of HNO_3 to HF is decreased as the stirring rate is increased, and the rate would then increase faster than if a normal first order mechanism were operating.

Another possibility is that at the lower concentrations of HF, a thicker film may be formed on the surface [cf. ref. (2)]. Relatively thick films may be more resistant to the action of HF as compared to the very thin films formed in the more concentrated solutions. Therefore, as the HF concentration at the interface is changed by varying the rotational velocity, the film may vary in thickness, and, if the thicker films are more resistant, the effect would be to increase the order slightly above first order. This effect would also explain the slight decrease in rate at constant concentration as the potential is made more anodic, for at the more anodic potentials, thicker films are formed (2).

It is also possible that the above systems of equations do not describe this system correctly, and that a more complex mechanism leading to an order of 1.2 occurs. However, the mechanisms described above seem to be the simplest that will describe the data.

[2] If, for example, b equals three, then $K = (k_1k_2k_3)/(k_1k_2 + k_1k_3 + k_2k_3)$.

Manuscript received Nov. 19, 1964; revised manuscript received Feb. 23, 1964. This paper was presented at the Washington Meeting, Oct. 11-15, 1964. The research was sponsored by the United States Atomic Energy Commission under contract with Union Carbide Corporation.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

Electronic Paramagnetic Resonance Study of the Thermal Decomposition of Dibasic Calcium Orthophosphate

J. A. Parodi, R. L. Hickok, W. G. Segelken, and J. R. Cooper

Lighting Research Laboratory, Lamp Division, General Electric Company, Cleveland, Ohio

ABSTRACT

Electronic paramagnetic resonance (EPR) spectra of trace quantities of Mn^{+2} in solid solution in $CaHPO_4 \cdot 2H_2O$, $CaHPO_4$, γ-$Ca_2P_2O_7$, β-$Ca_2P_2O_7$, and α-$Ca_2P_2O_7$ are given. The utility of EPR in following phase changes is demonstrated. The transition from β-$Ca_2P_2O_7$ to α-$Ca_2P_2O_7$ is established as occurring within the temperature range, 1171°-1179°. The results of hydrothermal experiments indicate that γ-$Ca_2P_2O_7$ is a metastable phase. It is established by EPR that the amorphous gel formed as an intermediate in the dehydration-recrystallization of $CaHPO_4 \cdot 2H_2O$ is in dynamic equilibrium with the solution phase.

Although electronic paramagnetic resonance (EPR) has been used extensively in physics research and free radical chemistry (1, 2) since it was discovered by Zavoyskiy (3) in 1944, it has had rather limited use in the study of solid-state chemical reactions. It has been used to study the effect of pressure (4) and also of impurities (5) on the hexagonal to cubic phase transformation of ZnS, and to follow the course of the synthesis of calcium fluorophosphate (6). Phase changes were followed by observing the EPR spectrum of manganous ion introduced in solid solution in the concentration range of 0.005-0.05% by weight.

In the following paper the EPR of Mn^{+2} is used to follow the thermal decomposition of dibasic calcium orthophosphate dihydrate, beginning with the dehydration to $CaHPO_4$ and followed by pyrolysis to γ-$Ca_2P_2O_7$ with subsequent inversions to β-$Ca_2P_2O_7$ and α-$Ca_2P_2O_7$.

The mechanism of dehydration of $CaHPO_4 \cdot 2H_2O$, which has been studied by Vol'fkovich and Urusov (7), Boullé and Dupont (8-10), and Rabatin, Gale, and Newkirk (11), is dependent on the partial pressure of water vapor in contact with the salt and on the method of preparation. Dehydration is favored by high hu-

midity; indeed the recrystallization of $CaHPO_4 \cdot 2H_2O$ to $CaHPO_4$ goes to completion very readily above 75° in water (10). Chiola and Vanderpool (12) state that $CaHPO_4$ is formed by the dehydration of $CaHPO_4 \cdot 2H_2O$ in aqueous medium over the temperature range 65°-104°. The question of whether or not there is an exchange with the solution during recrystallization is taken up in this paper.

The thermal decomposition of dibasic calcium orthophosphate to γ-$Ca_2P_2O_7$ is apt to be rather complex depending on whether $CaHPO_4 \cdot 2H_2O$ or crystalline $CaHPO_4$ is the starting material and whether the ambient atmosphere is dry or humid (8-11). The highest reported temperature at which γ-$Ca_2P_2O_7$ is formed is about 475° (11). When γ-$Ca_2P_2O_7$ is fired at a somewhat higher temperature β-$Ca_2P_2O_7$ is produced. Temperatures reported for this phase transition are 555° (13), 700°-750° (14), and 850° (15). The transition temperature for the inversion of β-$Ca_2P_2O_7$ to α-$Ca_2P_2O_7$ is given as 1140° (16), 1270° (17), 1130° (18), and 1220° (15). The latter two inversions (γ to β and β to α) appear to be straightforward and will be used to illustrate the utility of the EPR method in following phase transformations.

Experimental

Preparation of materials.—The refractive indices and x-ray diffraction patterns of all preparations described below were in agreement with the literature.

1. $CaHPO_4 \cdot 2H_2O$, brushite

Dibasic calcium orthophosphate dihydrate was prepared by two methods. The first of these procedures, described by St. Pierre (19), produces high-purity crystals. It was not possible to introduce manganese into solid solution by this method, but incorporation of manganese was achieved by the second procedure described below.

A solution containing 0.4M $Ca(NO_3)_2$, 0.4M H_3PO_4, and 0.004M $Mn(NO_3)_2$ was slowly neutralized with dilute NH_4OH at 53°. The product was washed with 10^{-3}M H_3PO_4 to insure that no adsorbed Mn would remain. Although it is desirable to carry out this precipitation at low temperature in order to minimize hydrolysis, it was possible to incorporate manganese only at 53° and above.

2. $CaHPO_4$, monetite

Anhydrous dibasic calcium orthophosphate containing trace concentrations of divalent manganese was prepared in two ways: (*a*) by the dehydration-recrystallization of $CaHPO_4 \cdot 2H_2O$ (10, 12) and (*b*) by a homogeneous precipitation procedure (20, 21) in which a solution of the cation salts and phosphoric acid is very slowly neutralized by ammonia liberated during the hydrolysis of urea. The preparative details for the former method are given further on in this paper. Typical conditions for some of the preparations made by the latter method are given in Table I.

Chemical analysis of the recrystallized $CaHPO_4$ gave a Ca/PO_4 mole ratio of 1.023 and an ignition loss of 7.54%, indicating the presence of minor amounts of basic hydrolysis products. On the other hand chemical analysis of homogeneously precipitated $CaHPO_4$ (*e.g.*, Ca/PO_4 = 0.983 and ignition loss = 7.25%) suggests contamination with a small quantity of a more acidic phosphate, even though microscopic examination showed the crystals to be free of included impurity phases.

Table I. Homogeneous precipitation of $CaHPO_4$

Concentrations of chemicals used to make solution, and other conditions of preparation

Preparation No.	1 and 2	3	4
$Ca(NO_3)_2$	1.2M		
$CaCO_3$		0.1M	0.2M
$Mn(NO_3)_2$	2×10^{-3}M	10^{-4}M	2×10^{-4}M
H_3PO_4	1.5M	1.0M*	1.0M*
Urea	1.5M	0.4M	0.6M
Temperature	83°	85°-90°	85°-90°
Time	5 days	8 hr	1 hr
pH at end of precipitation	2.5	<3.0	2.3

* Actual hydrogen ion concentration is somewhat less than indicated, because acid was used to neutralize $CaCO_3$.

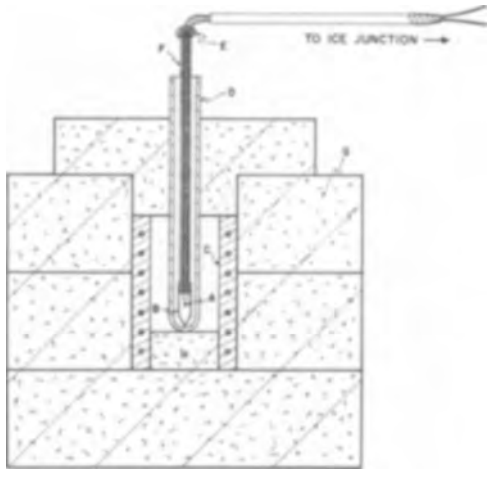

Fig. 1. Furnace for phase transition experiments. A, Pt, Pt-10% Rh thermocouple; B, Pt sample tube; C, heating element; D, mullite tube; E, epoxy cement; F, alumina thermocouple tube; G, alumina fire brick; H, alumina fire brick plug.

3. Calcium Pyrophosphate $Ca_2P_2O_7$

All of the calcium pyrophosphates were obtained from the pyrolysis of monetite or brushite. Gamma calcium pyrophosphate was obtained both by prolonged heating in a vacuum (*e.g.*, 8 days at 275°) and by firing for 4 hr at 500°. β-$Ca_2P_2O_7$ was prepared by firing at 1050° for 1 hr or by hydrothermal treatment: 4 hr at 450° and 30,000 psi. Alpha calcium pyrophosphate was prepared by ignition at 1250° for 1 hr. In addition to using dibasic orthophosphates containing manganese in solid solution, traces of manganese were incorporated in the beta and alpha polymorphs by slurrying the material to be ignited in acetone containing a manganous salt, drying, and firing.

Temperature of the phase transitions, γ-$Ca_2P_2O_7 \rightarrow \beta$-$Ca_2P_2O_7$ and β-$Ca_2P_2O_7 \rightarrow \alpha$-$Ca_2P_2O_7$.—The temperatures of the indicated phase transitions were determined by inserting a thermocouple directly into the center of the sample as shown in Fig. 1. The weight of the sample was about 0.2g. The thermocouple was calibrated both before and after the experiments against a standard thermocouple certified by the National Bureau of Standards. There was no change in calibration with use. The output of the thermocouple was read from a precision potentiometer.

Samples were fired from 16 to 20 hr, and the resulting structures were determined by x-ray diffraction and EPR (Mn^{+2} present in the approximate concentration, $Mn/Ca = 10^{-3}$).

Electronic paramagnetic resonance.—Electronic paramagnetic resonance of the polycrystalline calcium phosphate was measured on a Varian Associates V-4500 EPR spectrometer with a resonant frequency of 9480 Mc/s and a modulation frequency of 200 cps. Approximately ¾ in. of sample at one end of a fused quartz sample tube 4 mm OD x 3 mm ID x 4 in. or more in length was used. The EPR spectra reproduced in this paper are potentiometric recorder tracings of the first derivative of absorption of microwave energy versus the magnetic field, which increases from left to right in the figures.

Results and Discussion

EPR spectra of divalent manganese in $CaHPO_4 \cdot 2H_2O$, $CaHPO_4$, γ-$Ca_2P_2O_7$, β-$Ca_2P_2O_7$, and α-$Ca_2P_2O_7$ are presented in Fig. 2. All EPR spectra of a given compound, irrespective of method of preparation, are identical. This indicates that the local symmetry of the

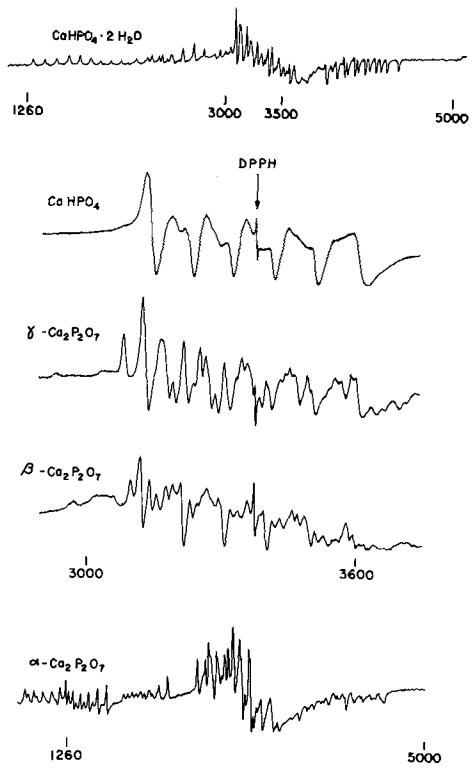

Fig. 2. EPR spectra of Mn^{++} in solid solution in the indicated dibasic orthophosphates and pyrophosphates of calcium. The field marker diphenyl picryl hydrazyl, g = 2.0036, is indicated by DPPH.

crystalline field about the manganous ion (assumed to substitute for Ca^{+2} in these structures) is not affected by minor deviations from stoichiometry which may exist (22, 23).

The high-temperature polymorph, α-$Ca_2P_2O_7$:Mn, has an EPR spectrum which, although unique, is similar to that of $CaHPO_4 \cdot 2H_2O$:Mn in broad outline. Further, both extend over a wide range of magnetic field, about 4100 gauss for the former and 3300 gauss for the latter. The crystalline field interaction with Mn^{+2} is, thus, quite intense for these two structures. On the other hand the effect of the crystalline field on Mn^{+2} in $CaHPO_4$, γ-$Ca_2P_2O_7$, and β-$Ca_2P_2O_7$ appears to be much less, because the range of all three spectra is only about 600 gauss. In the case of powdered samples, however, one cannot discount the possibility that the angular dependence of the spectral lines is such that lines which would appear at large separation in spectra of single crystals are washed out in spectra of powders, and therefore that the fine structure splitting constant is actually larger than it appears to be.

Recrystallization of $CaHPO_4 \cdot 2H_2O$

During the dehydration-recrystallization of $CaHPO_4 \cdot 2H_2O$ in an aqueous slurry the formation of an amorphous gel intermediate was observed. Nucleation and growth of the $CaHPO_4$ crystals occurs in and from this intermediate. One of the questions arising from this observation was whether equilibrium was established between this intermediate phase and the ions in solution. To answer this question experiments were conducted in which EPR measurements were used to follow the course of Mn^{+2} during the transformation.

$CaHPO_4 \cdot 2H_2O$, both with and without incorporated Mn^{+2}, was slurried at 82°C in water and in 0.01M H_3PO_4. For the latter starting material the solutions were also 1.44×10^{-4}M in $Mn(NO_3)_2$. In every case EPR showed that Mn^{+2} was incorporated in the recrystallized $CaHPO_4$.

To eliminate the possibility that incorporation of Mn^{+2} in $CaHPO_4$ had occurred after crystallization, $CaHPO_4$ was equilibrated in 0.01M $Mn(NO_3)_2$ at 90°-100°C for two weeks. EPR showed no trace of Mn^{+2} incorporation.

Table II. Determination of transition temperature, β-$Ca_2P_2O_7 \rightarrow$ α-$Ca_2P_2O_7$

Firing range, °C	Firing time, hr	EPR result	X-ray result
1170.1-1171.2	22	β	β
1172.8-1173.6	17½	α + small amt. β	α + small amt. of some other phase
1174.3-1175.4	17½	α + trace β	α
1177.3-1179.0	15½	α	α

The β-$Ca_2P_2O_7$:2×10^{-3} Mn used for this experiment was made by firing $CaHPO_4 \cdot 2H_2O$ plus manganous acetate at 1050° for 90 min. The $CaHPO_4 \cdot 2H_2O$ was made by the procedure described by St. Pierre (19).

The conclusion reached from these experiments is that the amorphous gel formed as an intermediate in the dehydration-recrystallization of $CaHPO_4 \cdot 2H_2O$ is in dynamic equilibrium with the solution phase. Exchange of ions appears to be rapid.

It is interesting that β-$Ca_2P_2O_7$ and not γ-$Ca_2P_2O_7$ is the result when dibasic calcium orthophosphate undergoes pyrolysis at 450° and 30,000 psi. This temperature is well below that reported for the transition of γ-$Ca_2P_2O_7$ to β-$Ca_2P_2O_7$. As a matter of fact the purpose of carrying out the original hydrothermal pyrolysis at 450° was to prepare well crystallized γ-$Ca_2P_2O_7$. Subsequent experiments in which $CaHPO_4$ was fired overnight or longer at 30,000 psi water pressure and at various temperatures over the range 300°-450° yielded only the starting material, $CaHPO_4$, or β-$Ca_2P_2O_7$. Products were identified by EPR and x-ray diffraction. Temperature and pressure were quenched simultaneously at the conclusion of each experiment. The transition from $CaHPO_4$ to β-$Ca_2P_2O_7$ occurred at 410° ± 15°. When β-$Ca_2P_2O_7$ was similarly treated at 398° and 376° the reverse reaction did not proceed. From these experiments it is concluded that γ-$Ca_2P_2O_7$ is a metastable phase. Mesmer and Irani (15) have shown that the transition from γ- to β-$Ca_2P_2O_7$ is exothermic and therefore also have concluded that the γ-phase must be metastable.

Temperature of the Phase Transition, β-$Ca_2P_2O_7$ *to* α-$Ca_2P_2O_7$

The transition from beta calcium pyrophosphate to alpha calcium pyrophosphate occurs over a narrow range of no greater than 8°. As is seen by reference to Table II the transition begins at a temperature of 1171° or greater. The upper limit of the transition is, according to x-ray results, 1175°; whereas according to EPR it is between 1175° and 1179°. The EPR interpretation is based on a small difference in relative intensity of three pairs of lines. Referring to Fig. 3, the line intensity ratios, A/B, C/D, and E/F, increase on going from the beta to the alpha pyrophosphate. In all samples ignited at 1179° and above the corresponding intensity ratios are the same, whereas for the sample fired at 1174°-1175° the ratios are all a little less than the respective ratios in the former samples. This indicates that perfection of the α-$Ca_2P_2O_7$ structure is not quite complete at 1175° and that at some temperature in the interval, 1175°-1179°, the transformation is complete. It should be emphasized that the temperatures given here are those of the thermocouple at a point within the sample and that there is bound to be some temperature variation along the ¾ in. length of the sample, which might account for the observed temperature range for the phase transition.

The data in Table II were obtained from a sample of β-$Ca_2P_2O_7$:2×10^{-3} Mn prepared by firing $CaHPO_4 \cdot 2H_2O$ to which manganous acetate was added prior to ignition. The same results were obtained with β-$Ca_2P_2O_7$:Mn prepared by the pyrolysis of $CaHPO_4$:Mn precipitated from homogeneous solution. This indicates that the transition is independent of the history of the

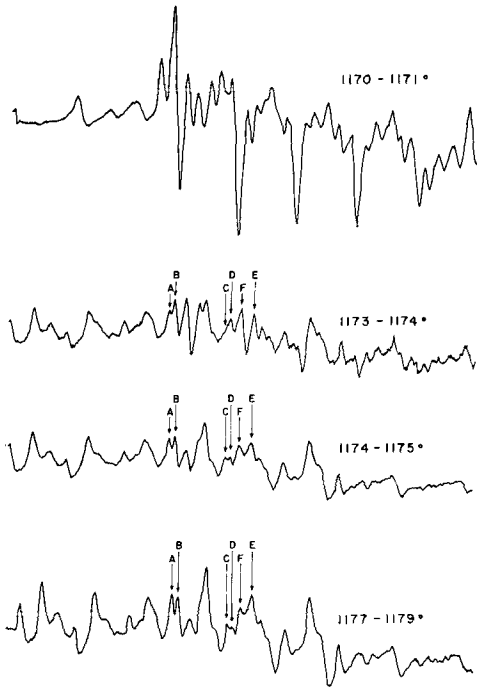

Fig. 3. EPR spectra of $Ca_2P_2O_7$:2 x 10^{-3} Mn fired overnight at indicated temperatures. A progressive change from the beta to the alpha polymorph is evident as the firing temperature increases.

starting material. Furthermore, inasmuch as the method of St. Pierre (19), which was used to prepare the brushite, is known to give very high-purity material, the results also indicate that the quantity and kind of impurities present in the homogeneously precipitated monetite have a negligible effect on the phase transition.

The transition temperature of 1175° ± 4° given here for the above materials is intermediate between the temperatures reported by Hill, Faust, and Reynolds (16) and Mesmer and Irani (15), 1140° and 1220°, respectively.

A point that perhaps should be brought up is the irreversibility of the above structure transformation under normal conditions of preparation for relatively pure material. If the structure change were reversible, quenching would have been necessary to preserve the high-temperature form. The phase transition is so irreversible, as a matter of fact, that α-$Ca_2P_2O_7$ has been prepared by firing at 1250° and annealing overnight in the range 1150° ± 20°, which it is seen is just below the transition range.

Temperature of the Phase Transition, γ-$Ca_2P_2O_7$ to β-$Ca_2P_2O_7$

The transition from γ-$Ca_2P_2O_7$ to β-$Ca_2P_2O_7$ is rather sluggish and poorly defined. Roughly, the temperature range in which the phase change occurs lies between 680° and 740°, in approximate agreement with McIntosh and Jablonski (14), but this appears to be partially dependent on the history of the sample. Results are summarized in Table III.

It is seen that for one starting material, A, there is practically a one to one correspondence between EPR and x-ray diffractometer results. The one exception is for the sample fired at 729°-730°: EPR indicates that conversion to β-$Ca_2P_2O_7$ is not quite complete whereas x-ray results indicate that the conversion is complete. The EPR interpretation is based on the disappearance of a line due only to γ-$Ca_2P_2O_7$:Mn and the appearance and subsequent growth of a line due only to β-$Ca_2P_2O_7$:Mn. As seen in Fig. 4, at 729°-730° there is still a trace of the γ-$Ca_2P_2O_7$:Mn line showing in the EPR spectrum.

Table III. Determination of transition range, γ-$Ca_2P_2O_7$ → β-$Ca_2P_2O_7$

Starting material	Run No.	Firing range, °C	Firing time, hr	EPR result	X-ray result*
A	1	689	16	γ	γ
	2	696	17½	γ + trace β	progressive change toward β
	3	701-702	16	γ + small amt. β	
	4	721	18	β + small amt. γ	
	5	729-730	19	β + trace γ	β
	6	737-739	17	β	β
B	7	685-687	7	γ + trace β	
	8	697-700	17	γ + β	
	9	704-705	21	β + small amt. γ	
	10	706	19	β + small amt. γ	
	11	711	19	β + trace γ	
C	12	686-687	17½		γ
	13	691-692	16½		γ + β
	14	700-704	15½		γ + β
	15	707-708	15½		β

Note: The EPR spectrum of Run No. 7 was identical to that of No. 2 and the EPR of No. 11 was the same as that of No. 5. Thus by comparison with starting material A, the estimated maximum transition range of B is 680°-720°. Starting materials: A, prepared by firing $CaHPO_4$:Mn 1 hr at 500°; B, prepared by firing $CaHPO_4$:Mn 18 hr at 500°; C, prepared by firing $CaHPO_4 \cdot 2H_2O$ 2-3 hr at 600°. $CaHPO_4 \cdot 2H_2O$ prepared by addition of calcium sucrate solution to a dilute solution of phosphoric acid (19).

* For group A the x-ray diffractometer was used; for group C the x-ray powder camera was used.

Summary

The thermal decomposition of dibasic calcium orthophosphate was studied by electron paramagnetic resonance (EPR) and x-ray diffraction. EPR spectra of trace amounts of manganous ion in solid solution in $CaHPO_4 \cdot 2H_2O$, $CaHPO_4$, γ-$Ca_2P_2O_7$, β-$Ca_2P_2O_7$, and α-$Ca_2P_2O_7$ are presented. The utility of EPR in following phase changes is demonstrated. The investigations of the phase transitions, γ-$Ca_2P_2O_7$ to β-$Ca_2P_2O_7$ and β-$Ca_2P_2O_7$ to α-$Ca_2P_2O_7$, delineate the fact that EPR is often more sensitive than x-ray diffraction in detecting phase changes.

Some results of the above study which are of possible interest to lamp phosphor technology are given below.

1. It is established by EPR that the amorphous gel formed as an intermediate in the dehydration-recrys-

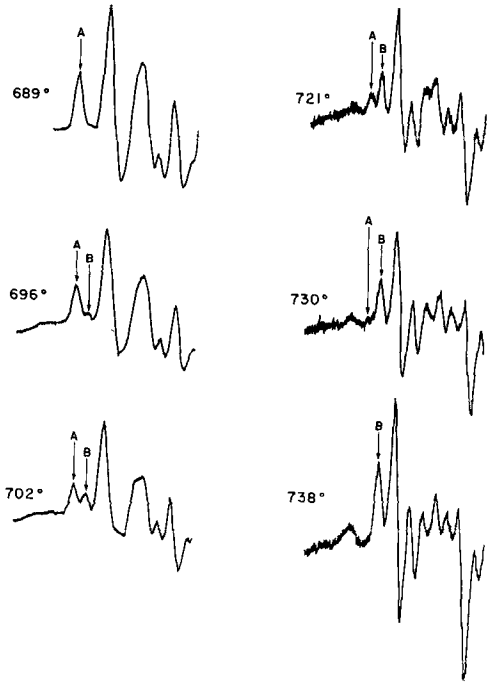

Fig. 4. Portion of EPR spectrum of $Ca_2P_2O_7$:Mn showing change from γ- to β-$Ca_2P_2O_7$:Mn as the firing temperature is increased. Peak A is due to γ-$Ca_2P_2O_7$:Mn and peak B is due to β-$Ca_2P_2O_7$:Mn.

tallization of $CaHPO_4 \cdot 2H_2O$ is in dynamic equilibrium with the solution phase.

2. The transition from β-$Ca_2P_2O_7$ occurs within the temperature range 1171°-1179°.

3. The phase change from γ-$Ca_2P_2O_7$ to β-$Ca_2P_2O_7$ is very sluggish and poorly defined, proceeding roughly between 680° and 740°.

4. When $CaHPO_4$ is heated over the temperature range, 300°-450°, under 30,000 psi water pressure only $CaHPO_4$ or β-$Ca_2P_2O_7$ is produced, the transition occurring at 410° ± 15°. This indicates that γ-$Ca_2P_2O_7$, which under normal atmospheric pressure is the product of the pyrolysis of $CaHPO_4$ in the approximate temperature range of 300°-700°, is a metastable phase.

Acknowledgment

The authors are greatly indebted to Dr. J. F. Sarver for his help in both the implementation and interpretation of the hydrothermal experiments.

Manuscript received Oct. 14, 1964; revised manuscript received March 9, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

APPENDIX

The following x-ray diffraction powder pattern was obtained for gamma calcium pyrophosphate made by the pyrolysis of both $CaHPO_4 \cdot 2H_2O$ and $CaHPO_4$ preparations described earlier. It is compared here with the earlier determination of McIntosh and Jablonski (14). It is seen that the two patterns are essentially in agreement, but that there are minor differences. The differences are probably accounted for, however, by the techniques used. The present data were taken on a modern goniometer with larger dispersion and better resolution than the film technique of McIntosh and Jablonski.

The Solidification of PbTe-SnTe Alloys under the Influence of Ultrasonic Agitation

H. E. Bates and Martin Weinstein

Tyco Laboratories, Incorporated, Waltham, Massachusetts

ABSTRACT

The previously described technique for the solidification of thermoelectric materials by ultrasonic agitation of a freezing melt has been applied to the solid solution 0.7 PbTe-0.3 SnTe. The material prepared by this technique is fine-grained, dense, and chemically homogeneous. The thermoelectric properties of lead telluride-tin telluride have been measured as a function of temperature. The room temperature figure of merit is approximately $0.6 \times 10^{-3}/°K$. Compressive-flow strength and ductility are improved by ultrasonic agitation; 0.7 PbTe-0.3 SnTe prepared in this study showed 35% reduction in length at an ultimate compressive stress of over 16,000 psi, compared to an ultimate compressive strength of 7,500 psi and 10% reduction in length for unagitated material. Precipitation in the PbTe-SnTe system is discussed. In particular the effects of ultrasonic irradiation on the precipitation phenomenon are described in detail.

Interest in the use of thermoelectric materials for power generation and refrigeration has led to important research into the fundamental nature of thermoelectric phenomena and the means of optimizing thermoelectric properties by alloying and doping (1). Of equal or greater importance to the designer of practical thermoelectric devices are what Klein (2) terms "the auxiliary properties": melting point, vapor pressure, coefficient of expansion, mechanical strength, etc. While the first three properties are quite insensitive to any manipulation of the material other than appreciable changes in composition, which may be incompatible with the desired thermoelectric properties, the possibility does exist of improving the mechanical properties without affecting the composition.

Because of the predominantly covalent nature of most thermoelectric materials, they tend to be highly susceptible to cleavage and brittle failure. The simplest way to decrease brittle fracture in any material is to decrease the grain size, that is, to interpose as many barriers (grain boundaries) as possible to the propagation of micro- and gross cracks. The irradiation of solidifying ingots with ultrasound as a means of producing a fine-grained, equiaxed structure has been studied extensively in the USSR and to a lesser extent in this country (3, 4). An entirely satisfactory mechanism for the refinement of grain structure by ultrasonic vibration has yet to be advanced, but there is general agreement that refinement is caused through decreasing the critical nucleus size by increasing the pressure at certain points in the liquid (3, 5) and/or disrupting the advancing solid-liquid interface by cavitation (4, 6).

The application of ultrasonic irradiation to PbTe-SnTe alloys can be expected to yield several benefits: a fine grained, equiaxed structure with good mechanical strength, free of inclusions and porosity; a chemically homogeneous material free of the gross and microsegregation which occurs under normal freezing conditions. Because of the tendency of doping elements to segregate during normal freezing, most commercial thermoelectric materials have been prepared by cold pressing and sintering or extrusion. The purpose of this investigation was to prepare crystalline, homogeneous alloys with satisfactory thermoelectric properties and mechanical properties superior to those of materials prepared by other techniques.

Experimental

The experimental equipment and procedures here outlined have been described in detail elsewhere (1). Figure 1 shows the assembly used to solidify a melt under ultrasonic agitation. A charge of 50-75g was sealed under vacuum in the quartz tube. A Pt-wound resistance furnace was lowered over the tube and heated until the charge melted, as indicated by a thermocouple attached at the base of the tube. At this point the piezoelectric transducer, epoxied to the base of the quartz pedestal, was energized. Shortly after agitation began, the furnace was raised by a motorized hoist so that solidification proceeded from the bottom of the ingot upward at a rate defined by the rate of removal of the furnace. As the freezing interface moved upward, the input frequency to the PZT crystal was varied to maintain a resonant condition. The input power was also increased gradually to compensate for attenuation of the ultrasonic waves in the solidified portion of the ingot.

Ingots of 0.7 PbTe-0.3 SnTe were solidified under agitation of 19-21 kc at approximately 50w nominal input power and 33-35 kc at 35w. Directional solidification was begun with the base of the melt at approximately 910°C. Growth rate in both cases was about 1.1 in./hr. Faster growth rates tended to diminish grain refinement.

A calorimetric technique was devised to measure the ultrasonic energy input to the melt. The heat capacity of a gallium melt of the same volume as an ordinary ingot was measured in the agitation assembly (Fig. 1), using a thermocouple and a small resistance heater immersed in the melt. The gallium melt was then agitated at various levels and frequencies. The energy absorbed by the melt during agitation was calculated from the known heat capacity and the temperature increase during the application of the ultrasound. The results of these measurements are shown in Fig. 2; the nominal power input refers to the electrical input to the transducer. It can be seen from Fig. 2 that the efficiency of the system is highest when operation takes place in the vicinity of the natural frequency of the transducer (36 kc). Efficiencies of over 35% were achieved at the 34.4 kc resonance. Inputs producing more than 10 w/cm^2 fractured the quartz tube at the tube-pedestal joint.

Results

Employing the process variables noted above, ingots of 0.7 PbTe-0.3 SnTe were produced 0.7 in. in diameter and over 1 in. long which were fine-grained, dense, and chemically homogeneous.

Microstructure.—The solidification of 0.7 PbTe-0.3 SnTe under the influence of ultrasonic agitation resulted in a microstructure (Fig. 3) free of inclusions, porosity, columnar grains, and the segregation asso-

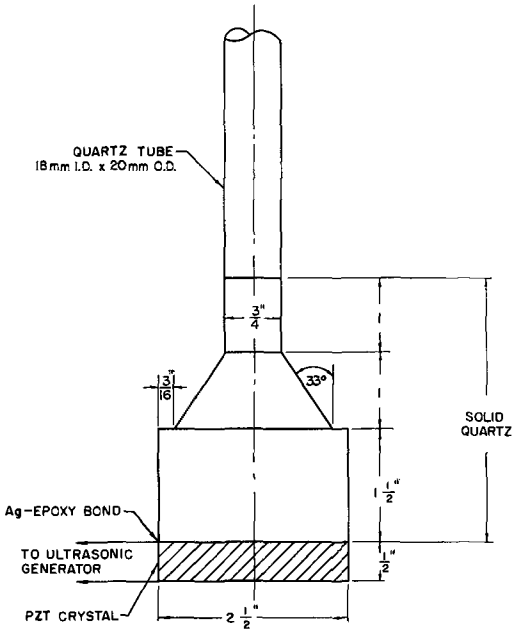

Fig. 1. Piezoelectric transducer, quartz concentrator, and crucible assembly.

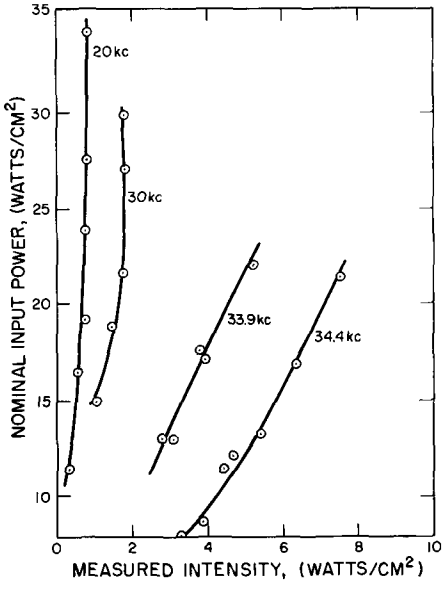

Fig. 2. Ultrasonic energy conversion efficiency for four resonant frequencies.

ciated with normal freezing. Directionally solidified ingots ordinarily consist of five or six columnar grains running the length of the ingot. The surfaces of unagitated ingots usually show considerable porosity and roughness, a feature which is eliminated by the ultrasonic agitation. The microstructure of a water-quenched 0.7 PbTe-0.3 SnTe ingot, with dendritic structure and extensive microsegregation characteristic of this treatment, is shown in Fig. 4. Annealing of this structure below the melting point for 2 hr produced spheroidization of the intergranular segregated phase with little accompanying recrystallization and grain growth. Evidence for the chemical homogeneity produced by ultrasonic agitation is shown in Fig. 5, where the room temperature resistance of p-type 0.7 PbTe-0.3 SnTe is plotted as a function of distance for an agitated and an unagitated ingot. Variations of this sort are even more pronounced in doped alloys where segregation of the dopant produces a quite abrupt variation in properties in the final portion of the ingot to freeze.

Thermoelectric properties.—The figure of merit $Z = \alpha^2/K\rho$ provides a means of comparing the efficiencies of different thermoelectric materials. In the above expression α is the Seebeck coefficient in volts per °C, K is the thermal conductivity in watts/cm/°C, and ρ the electrical resistivity in ohm-centimeters. The Seebeck coefficient and resistivity of cast, directionally solidified, and ultrasonically agitated 0.7 PbTe-0.3 SnTe ingots were measured as a function of temperature.

1. Seebeck Coefficient.—The variation of Seebeck coefficient with temperature is shown in Fig. 6. The ultrasonically agitated material contained a slight excess (0.3 at. %) of Te. The recent investigation by

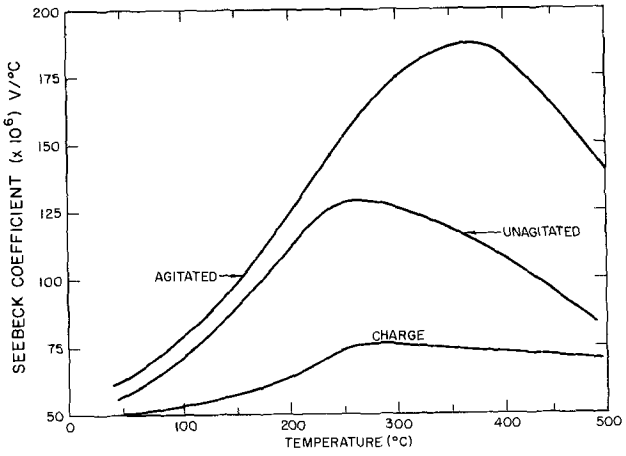

Fig. 6. Seebeck coefficient as a function of temperature of 0.7 PbTe-0.3 SnTe.

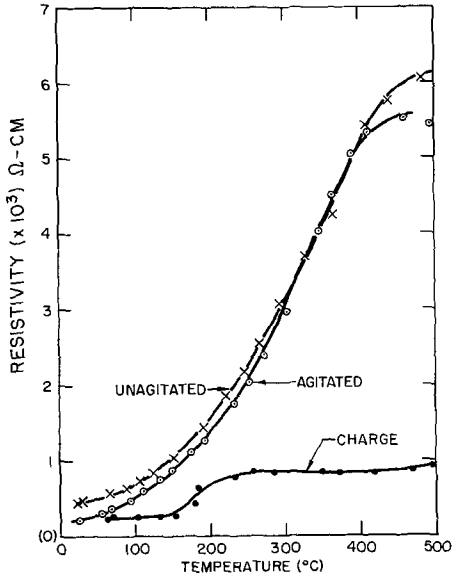

Fig. 7. Resistivity as a function of temperature of 0.7 PbTe-0.3 SnTe.

Machonis and Cadoff (7) which employed cation-rich single crystals of nominal composition 0.7 PbTe-0.3 SnTe showed a slightly different Seebeck behavior, giving a maximum Seebeck coefficient of 190 μv/°C at 180°C. Both the Te-rich and cation-rich specimens are p-type. The low value of the Seebeck coefficient for the directionally solidified material is probably due to segregation and inhomogeneities of the kind discussed by Cosgrove *et al.* (8). The directionally solidified, unagitated ingot also contained 0.3 a/o (atom %) excess Te. Metallographic examination of the cast material showed that the peculiar behavior of the Seebeck coefficient, and of the resistivity, was caused by melting of the interdendritic phase, probably Pb-Sn eutectic (eutectic temperature $\approx$ 185°C). Melting was evidenced by spheroidization of the phase in the pre-existant segregation pattern.

2. Resistivity.—The variation of resistivity with temperature is shown in Fig. 7. The difference between agitated and unagitated ingots is negligible. The resistivity as a function of temperature given by Machonis and Cadoff (7) for cation-rich 0.7 PbTe-0.3 SnTe varied from 0.9 x 10^{-3} ohm-cm at room temperature to 10 x 10^{-3} ohm-cm at 500°C.

3. Electrical Efficiency.—The electrical efficiency factor α^2/ρ is shown in Fig. 8 as a function of temperature. The low values of the directionally solidified material are due to lowering of the Seebeck coefficient by inhomogeneous distribution of excess constituents.

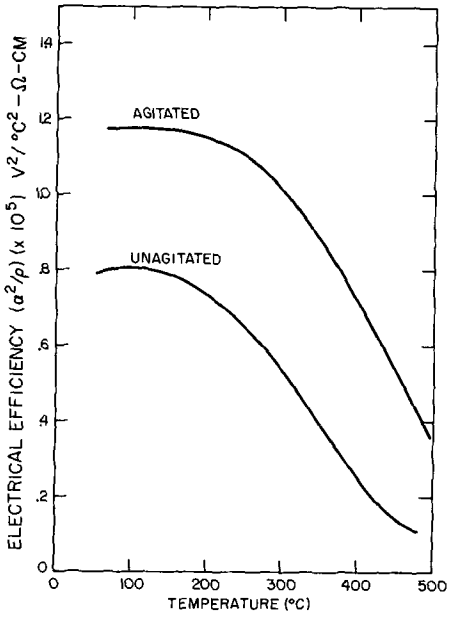

Fig. 8. Electrical efficiency factor as a function of temperature of 0.7 PbTe-0.3 SnTe.

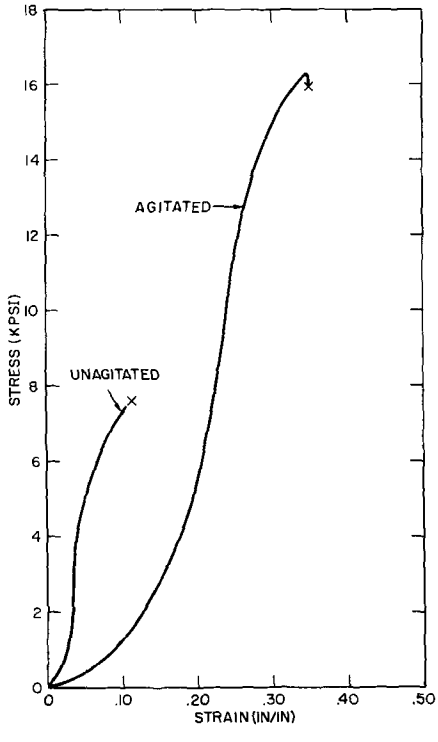

Fig. 9. Stress-strain behavior in compression of 0.7 PbTe- 0.3 SnTe prepared by directional solidification, and directional solidification with ultrasonic agitation.

The total thermal conductivity of 0.7 PbTe-0.3 SnTe has been estimated, in the absence of any measurements, as 0.02 w/cm °K at room temperature. It is probably actually lower, the data of Machonis and Cadoff indicate $k_T \approx$ 0.015 w/cm °K at 300°K; however, using 0.02 w/cm °K the room temperature figure of merit, Z, of ultrasonically prepared 0.7 PbTe-0.3 SnTe is approximately 0.6 x 10^{-3}/°K.

Mechanical properties.—The stress-strain characteristics in compression of 0.7 PbTe-0.3 SnTe prepared by directional solidification, with and without ultrasonic agitation, were measured. Rectangular specimens about 0.4 in. square by 0.3 in. long were compressed in a Hounsfield Tensometer, Type W. Strain rate was

approximately 5 %/min. Results of these measurements are presented in Fig. 9. Compression was parallel to the direction of solidification in both cases. The unagitated material showed 30-40% lower strength when compressed perpendicular to the growth axis, while the agitated ingots were isotropic. The considerable improvement in strength and ductility of the agitated

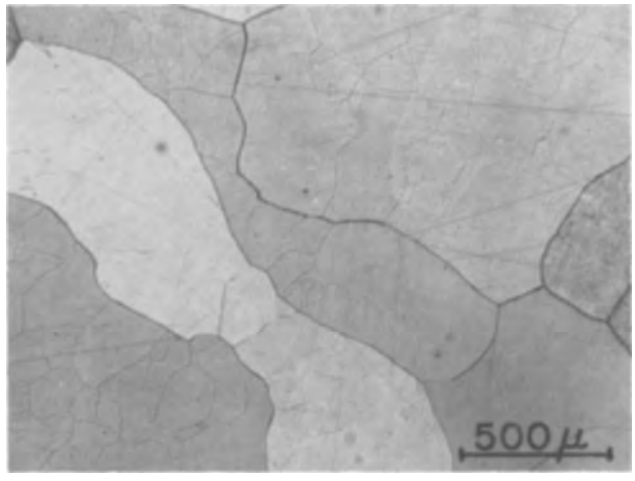

Fig. 14. Extensive subgrain array in bottom portion of ultrasonically agitated ingot of 0.7 PbTe-0.3 SnTe. Magnification approximately 42X.

material can be attributed, as in the case of PbTe in the previous study (1), to the production of a fine-grained, equiaxed structure free of inclusions and porosity. It is interesting to note that in both systems, PbTe and 0.7 PbTe-0.3 SnTe, the agitated material has twice the ultimate strength and three times the ductility of the unagitated.

Precipitation phenomena.—Some interesting observations of second phase precipitation were made during this investigation. Some ingots of 0.7 PbTe-0.3 SnTe when agitated with fairly high sound intensities (8-10 w/cm^2 at 35 kc) showed extensive intergranular porosity in the bottom third of the ingot. In the solid portion of the ingot there was an almost continuous network of eutectic phase (Fig. 10). These ingots were made with the stoichiometric amounts of Sn and Te. Due to the deviation from stoichiometry in SnTe (9, 10), a stoichiometric melt will contain an excess of Sn on solidification. It is felt that this eutectic is of Sn-Pb, which, because of its low ($\approx$185°C) melting point appeared in the grain boundaries as liquid and was then forced out by the ultrasonic irradiation and concentrated in the top of the ingot. To eliminate this problem, ingots were prepared with excess Te and the intensity of the ultrasound was slightly reduced. Addition of 0.3 a/o excess Te effectively eliminated precipitation of Sn. In the unagitated ingot a small amount of eutectic which is thought to be Te-PbTe was found in the last portion to freeze (Fig. 11). The interesting aspect of the precipitation of excess Sn in stoichiometric ingots was that moderate intensi-

ties of ultrasound resulted in a regular array of parallel stringers and tiny, random spheroids of Sn in the bulk of the grains, with very little precipitation in the grain boundaries. Figure 12 shows the intersection of the needle-like Sn with a grain boundary. Figure 13 shows the regularity of this structure and the virtual absence of Sn precipitated at the grain boundaries. It is felt that these precipitates occur on slip lines in the grains; the regularity of the array, the change in orientation from one grain to the next, the appearance of competing orientations intersecting the predominant one, (Fig. 13) and particularly the observation of subgrain formation in agitated ingots (Fig. 14) indicate deformation of the grains by the ultrasonic process. Lane, Cunningham, and Tiller (11) also observed decoration of slip lines by carbide precipitates in an Fe-Mn-Cr alloy with ultrasonic agitation of the solidifying ingot.

Silverstein *et al.* (12) found evidence of increased stress in the grain boundaries of ultrasonically agitated weldments in Ta, but in the present investigation the evidence from precipitation of excess Sn indicates that although the grain boundaries remain regions of high strain, the ultrasonic irradiation has effected a redistribution of the strain in the aggregate such that precipitation is now favored in the bulk.

Conclusions

1. Fine-grained, homogeneous p-type 0.7 PbTe-0.3 SnTe has been prepared by ultrasonic agitation of directionally solidified ingots.
2. The ultrasonic irradiation of solidifying 0.7 PbTe-0.3 SnTe produced material with twice the compressive strength and three times the ductility of directionally solidified 0.7 PbTe-0.3 SnTe.
3. The thermoelectric properties and efficiency of p-type 0.7 PbTe-0.3 SnTe (Te-rich) prepared by ultrasonic agitation are superior to those of directionally solidified unagitated material.
4. Ultrasonic agitation promotes the precipitation of excess Sn from 0.7 PbTe-0.3 SnTe in the bulk of the grains along slip planes, rather than at the grain boundaries.

Donor Diffusion into GaAs from Group VI Compounds

R. G. Frieser

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

A simple and reproducible technique is presented for diffusing donors into p-type GaAs using binary sulfides, selenides, or tellurides as donor sources. Using compound sources, the effective vapor pressure of the donor impurity is reduced, thereby limiting troublesome surface erosion of the wafers during diffusion. Either a sealed or a "closed box" system is suitable. With Al_2S_3 as a doping source, observed junction depth in zinc or in cadmium doped GaAs varied linearly with the square root of time. The diffusion coefficient of sulfur is given by $D = 2.6 \times 10^{-5} \exp(-1.86/kT)$ in Zn doped GaAs. Anomalous results were obtained in Cd doped substrates at higher temperatures where higher values of the effective diffusion coefficients were observed.

Donors such as S, Se, Te, or Sn have been diffused into GaAs by several investigators (1-4). In all reported cases the donor sources were the elements themselves. Reported difficulties with this technique were alloying and formation of sulfides during diffusion which produced severe surface erosion. At diffusion temperatures both donor elements and arsenic are not only quite reactive, but volatilize to an appreciable extent (5, 6). Furthermore, in the presence of sulfur the transport problem of arsenic and gallium from the surface of the GaAs wafers is enhanced, presumably by the formation of volatile compounds (5).

The present work was directed toward employing group VI compounds (sulfides, selenides, or tellurides) as donor sources, thus reducing the vapor pressure of donor elements during diffusion. This report describes a simple and reproducible technique, using compounds as donor sources for diffusion into GaAs. The effective diffusion coefficient of sulfur has been determined and will be discussed.

Experimental

Exploratory work indicated that a practical and useful donor diffusion system for GaAs should incorporate the following features: (*a*) a minimum temperature gradient across the diffusion system to prevent surface erosion caused by transport and redeposition of material elsewhere in the system; (*b*) an oxygen-free source of arsenic to satisfy the equilibrium arsenic pressure in the system; and (*c*) a source providing a constant and low concentration of donor atoms.

These conditions were approximated in the following manner. Sealed quartz tubes were used for the major portion of this work; however, equally good results

were obtained with a "closed box" system for the diffusions (7). The temperature gradient across the sealed diffusion tube was 3°C or less during the diffusion, thereby reducing surface erosion. Crushed undoped GaAs was placed in the system to limit arsenic as well as gallium loss from the slice to be diffused (5). Sulfides were chosen as donors since the concentration of donors over these compounds in a closed system is constant and only a function of the dissociation pressure, which is uniquely determined by the temperature. A wide range of surface concentrations and junction depth is therefore possible by merely choosing a sulfide with an appropriately low vapor pressure of sulfur and a suitable diffusion temperature and time. The same argument applies to selenides and tellurides as well. One limitation on the choice of source is that the second component of the source should not form a stable arsenide at diffusion conditions.

Materials.—Table I lists the properties of the GaAs used in this work as supplied by the manufacturer on the basis of Hall and resistivity measurements. All crystals were cut into slices perpendicular to their growth direction, <111> within 5°, and ~0.38 mm thick. The slices were lapped and then chemically polished (8) on the arsenic-rich side prior to diffusion. All donor compounds came from commercial sources and were used without further treatment.

To provide the partial vapor pressure of arsenic in the diffusion system, crushed undoped GaAs (B18) (Table I) was acid washed [70 ml H_2SO_4 (95%), 15 ml H_2O_2 (30%), 15 ml H_2O] (9), rinsed with deionized water, acetone, and dried. Table II is a list of all the compounds examined on an exploratory basis as donor sources. Diffusion temperature was 900°C except for those compounds in Table II marked with an asterisk for which it was 800°C. Diffusion time was 2 hr.

Primarily because of their melting points and because little surface erosion and good junctions were obtained, the following compounds were chosen for more detailed consideration as donor sources: As_2S_3, GeS, Ga_2S_3, and Al_2S_3. Aluminum sulfide provided the bulk of the data of this work.

Procedure.—Quartz tubes (9 mm ID, 1 mm wall) were thoroughly cleaned (HF, NH_4OH, DI water) and dried at 100°C in an oven. Precisely weighed amounts of crushed GaAs (1000-4000 μg), the donor source (100-1000 μg) and one or two wafers (of different zinc concentration) were placed into the bottom of a tube. The weight of the wafers ranged from 10,000 to 80,000 μg. This tube was evacuated to ~1 Torr, heated for about 5 min at 300°C to remove any moisture, oxygen, or free sulfur, if present, and sealed while still under vacuum and hot. For donor sources other than Al_2S_3 the temperature was 150°C. Diffusions were carried out in a high-temperature furnace operated in the range of 800° to 1100° for ½ to 16 hr. The sealed diffusion tubes were placed in a heavy stainless steel jacket. Temperature gradients of 3° ± 0.5°C or less in a 12 cm temperature zone were observed during diffusions. To prevent surface deterioration after diffusion and during cooling the following procedure was found to be best. The steel jacket with the tube inside was removed from the furnace and ~¼ in. of the tube was exposed to room air for ~1 min until the steel jacket reached ~750°C (cherry red). The ampoule was then completely withdrawn from the steel jacket and the end opposite the wafer was quenched.

Evaluation.—The diffused wafers were examined microscopically (37x — 235x) for etch pits and other signs of erosion. Also, each GaAs slice was checked for weight loss following each diffusion run. Most Zn doped and many of the Cd doped wafers exhibited blemish-free surfaces after diffusion. Pitting in spots was occasionally observed. Wafers which showed weight loss in excess of 0.3% were discarded.

Films that deposited occasionally on GaAs during the quenching operation were removed by boiling the wafers in CS_2 followed by boiling in dilute (1:1) HCl, (etch rate ~100 Å/min.).

The diffused wafers were angle lapped and stained. The staining solution[1] when applied to a junction under illumination darkens the p-region with respect to the n-region or decorates the n-region preferentially with copper, depending on the conductivity difference between the two sides of the junction. Junction depths were obtained by both the standard technique (10) and by interference microscopy (11) with a general accuracy of ±0.3μ.

No junctions were obtained with the following compounds	
HgS*	SnS_2
MoS_2	Tl_2S
$MoTe_2$	WS_2
P_4S_3	ZnS

Results

Table III indicates that higher concentrations of sulfur can be obtained with the lower melting sulfides employed in this study. Junctions were obtained in low resistivity GaAs using As_2S_3 as a donor source while Al_2S_3 produced a junction only at higher temperatures in the same material. The highest melting donor sources did not produce a junction at 900°C in the high conductivity GaAs.

Using Al_2S_3 as the donor source the presence of either elemental arsenic or crushed GaAs resulted in the same junction depth. This observation is in contrast with Vieland's results (2). He found that the junction depth of sulfur in GaAs depended on the arsenic pressure below 1 atm. The equilibrium pressure in the present system was presumably satisfied from the lapped side of the GaAs, since only one side of the wafer was polished. That this contention is justified is supported by the following observation. In some cases the wafers exhibited weight losses (2%) without any structural changes on the polished side of the GaAs wafer. Presumably the material was lost from the lapped rather than the polished side.

Zinc out-diffusion appeared not to have been very significant in this study, although it cannot be completely ruled out. A series of experiments was performed at 900°, 1000°, and 1100°C for 2- and 4-hr

[1] Staining solution: solution A: 10g $CuSO_4 \cdot 5H_2O$ + 50 ml H_2O; solution B (8, 9): 35 ml conc. H_2SO_4 + 5 ml H_2O + 5 ml H_2O_2 (30%); stain: 1 ml of solution B + 50 ml solution A.

diffusions into zinc-doped GaAs samples of two different acceptor concentrations within the same ampoule. The observed junction depths were found to be independent of the number of wafers in the diffusion capsule and the presence of wafers of other acceptor concentrations. Even though crushed undoped GaAs was present in all capsules, noticeable differences in the junction depth might have been expected if out-diffusion had been significant. Comparable experiments were not performed using the Cd doped series.

time for the various wafers using Al_2S_3 as the donor source. It is assumed, since no junction was observed for sample M10, that the maximum concentration of electrically active sulfur was $<4 \times 10^{18}$ cm^{-3} at 900°C. Because erosion problems were encountered in the Cd runs, the precision of these data is not as high as that of the Zn runs. For that reason the Cd data will be discussed separately. Figure 4 shows photomicrographs (90X) of representative junctions obtained in M15 (900°C, 16 hr) using Al_2S_3 as a donor source and in two samples of M15 (1100°C, 1 hr) using GeS and As_2S_3.

tribution profile of sulfur in these wafers was known, effective diffusion coefficients were estimated, using a modification of a method employed by Fuller (12). The following assumptions had to be made:

1. At a given temperature the same effective donor concentration exists above Al_2S_3 in all capsules.
2. All wafers have the same surface concentration of donors, under the same diffusion conditions.
3. The diffusion coefficient is independent of the donor and the acceptor concentration (a frequent, although not necessarily correct assumption).
4. The supply of donors is essentially unlimited in the diffusion system.
5. Sulfur diffusion in GaAs follows a complementary error function distribution.

On the basis of these assumptions, the surface concentrations are the same for a given temperature and the following equation is applicable

$$\frac{N_1}{N_2} = \frac{\text{Erfc } (X_1/2\sqrt{Dt})}{\text{Erfc } (X_2/2\sqrt{Dt})} \qquad [1]$$

X is the junction depth in cm, D the diffusion coefficient in cm^2/sec, t the diffusion time in seconds, and N_1 and N_2 are the Zn concentrations in the two crystals chosen (Table I). Using paired values of the observed junction depth in GaAs samples of different acceptor concentrations the diffusion coefficients of sulfur were calculated by a technique of successive approximations (curve fitting) (12). Table IV shows the values obtained by this technique for Zn doped wafers at 1100°C as well as the averages for 1000° and 900°C.

These values are plotted in Fig. 5 and, within experimental error, lie on a straight line. The activation energy for sulfur diffusing into GaAs computed from these data is 1.86 ± 0.01 ev. The diffusion coefficient can be thus described by the equation $D = 2.6 \times 10^{-5} \exp(-1.86/kT)$.

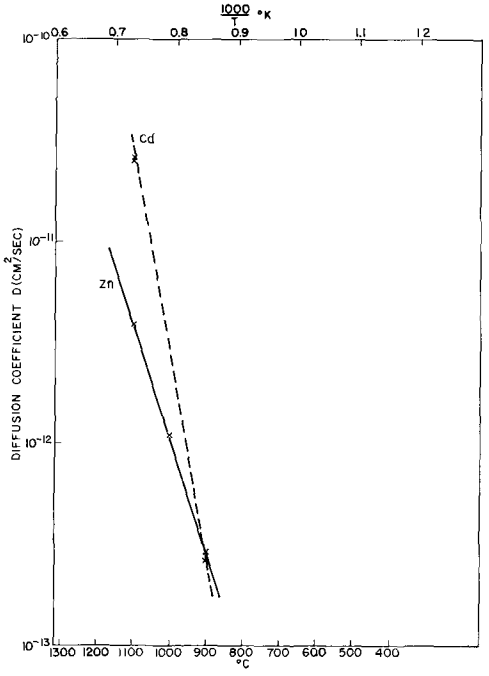

Fig. 5. Diffusion constants of sulfur in GaAs. The variation of the calculated D with $1/T$ for the Zn and Cd experiments is attributed partially to the effects of out diffusion. The Zn data (solid line) are considered more reliable (see text).

Zn doped
$D_{900} = 2.9 \pm 2.0 \times 10^{-13}$
$D_{1000} = 1.1 \pm 0.2 \times 10^{-12}$
$D_{1100} = 3.9 \pm 0.2 \times 10^{-12}$
$D = 2.6 \times 10^{-5} e^{-1.86/KT}$

Cd doped
$D_{900} = 3.6 \times 10^{-13}$
$D_{1100} = 2.6 \times 10^{-11}$
$D = 4.4\ e^{-3.06/KT}$

Discussion

The straight line relationship between the junction depth and $(\text{time})^{1/2}$ indicates that Fick's law is obeyed in these experiments. Out-diffusion of zinc was found to be small, if not negligible, on the basis of special experiments. The activation energy obtained in this study agrees closely with that reported by Vieland (2) who based his value on junction migration studies. The present value is about one half that reported by Goldstein (1) from his radiotracer studies. Table V summarizes the literature values and those of this study.

Fane and Goss, studying the diffusion of Sn and Se in GaAs (3), have observed that junction depths are consistently less than penetration depth when determined by radiotracer techniques. Tannenbaum had observed that the phosphorous concentration in silicon determined by radiotracer techniques was larger than that determined by electrical measurements (13) and concluded that not all impurity atoms in a semiconductor contribute to the conductivity.

It may be appropriate to consider the Cd data plotted as dashed lines on Fig. 1-3. Even though these data were not as reliable as the Zn data the points which could be determined lie on straight lines passing through the origin and, therefore, deserve consideration. The diffusion coefficients could only be calculated at 900° and 1100°C which yielded values of $D_{900} = 3.6 \pm 0.1 \times 10^{-13}$ and $D_{1100} = 2.6 \pm 0.1 \times 10^{-11}$. This is equivalent to an effective activation energy of 3.06 ev and a $D_o = 4.4$. As discussed previously, out-diffusion did not appear to play an important role in the zinc experiments. Unfortunately, even less is known about the out-diffusion of Cd. While it is possible that the effects observed here are due to some extent to Cd out-diffusion, this cannot be resolved on the basis of the present work. However, it is possible that the difference is due partially to another effect. Certain anomalies exist in the data as plotted in Fig. 1-3. Sulfur diffusion into Zn or Cd doped GaAs of the same acceptor concentration might be expected to yield data giving comparable slopes. This is observed for diffusions at 1100° and 1000°C, but not at 900°C (Fig. 1-3, M16 and M21). The relative position of the lines with respect to each other should be the same at each diffusion temperature. This is found to be the case for Zn doped GaAs. For Cd doped GaAs a reversal of this order takes place at 1000°C. While there is a large uncertainty in the precision of the Cd points, it appears that the general relationship of these lines to each other is real.

There appears to be a correlation between the relative position of these lines and the intrinsic temperature. GaAs is extrinsic at the indicated temperatures if the impurity concentration exceeds the values shown in Table VI. With the data of this table applied to the experimental findings, the following picture emerges.

Table V. Sulfur diffusions into GaAs

	E, ev	D_o, cm^2/sec*	$D_{1100°C}$, cm^2/sec
This work	1.86 ± 0.01	2.6×10^{-5}	3.9×10^{-12}
Vieland (2)	1.8 ± 0.8	—	—
Goldstein (1)	4.04	4×10^{3}	6.0×10^{-12}

*$D_T = D_o \exp - E/kT$.

Table VI. Intrinsic-extrinsic conditions of GaAs at diffusion temperatures

Intrinsic carrier concentration (14)
WAFERS

Desig-nation	Type	Acceptor conc, cm^{-3}	Condition at diff. temp. 1100°C 1.7×10^{18}	1000°C 7×10^{17}	900°C 3×10^{17}
M10	Zn	4.2×10^{18}	ex.	ex.	ex.
M15	Zn	8.1×10^{16}	int.	int.	int.
M16	Zn	5.6×10^{17}	int.	int.	ex.
M21	Cd	5.6×10^{17}	int.	int.	ex.
B10	Cd	9.2×10^{17}	int.	ex.	ex.

Table VI shows that M21, M16, and B10 are intrinsic at 1100° and extrinsic at 900°C. Figures 1 and 3 show that at these temperatures the slope of these respective lines increases regularly as the acceptor concentration of the wafer to be diffused decreases. Differences in the slope of M21 and M16 may reflect out-diffusion at these temperatures. At 1000°C (Fig. 2) the slope of B10 is steeper than that of M21 and M16. At this temperature, however, B10 is extrinsic whereas both M21 and M16 are intrinsic (Table VI). This may suggest an influence of the electric field on donor diffusions into GaAs and the possibility that the activation energy for the diffusion of sulfur into GaAs is dependent not only on the presence but on the type of acceptor (*i.e.*, Zn or Cd) as well. Further work to investigate these anomalies is required before definite conclusions can be drawn.

It should be pointed out, too, that defects in the crystal structure, which are known to affect the diffusion coefficient (4) were not taken into account in this study.

Summary

A simple and reproducible technique is described for the donor diffusion into GaAs using group VI compounds as sources. This technique limits surface erosion and permits control over the donor concentration. Junction migration studies have provided values for the effective activation energies for the diffusion of S in Zn-doped GaAs comparable to those in the literature. Discrepancies observed in Cd doped wafers could partially be attributed to out-diffusion. It is, however, suggested that the sulfur diffusion into GaAs may also be affected by the presence or absence of an electric gradient in the GaAs during the diffusion. This effect if present, appears to be impurity dependent.

Photovoltaic Effects at Rectifying Junctions to Deposited CdS Films

M.Bujatti[1] and R. S. Muller

College of Engineering, University of California, Berkeley, California

ABSTRACT

The photovoltaic response of blocking contacts to deposited CdS films has been measured in the wavelength range 0.3-1.3μ. Film properties as deduced from these measurements are compared with inferences drawn from photoconductivity behavior and with information on film treatment. Although evidence for photoemission of electrons from the rectifying contacts was sought, none was found. An interesting interference phenomenon was observed in thicker films. The phenomenon can be traced to standing-wave patterns in the films.

The photovoltaic effect at rectifying contacts made to vapor deposited CdS thin films has been studied. The CdS films were deposited using the technique described by Zuleeg and Senkovits (1). The quality of the CdS films deposited was found to depend critically on the temperature of the substrate with respect to the temperature of the source; films deposited on a cold substrate were dark orange or black and conductive, while those deposited on a properly heated substrate were lemon yellow and highly resistive. These characteristics are believed to be related to differing amounts of excess Cd present in the films.

The metals used to make contacts to the CdS films were Al, Cu, Te, and Au. Of these, only Al formed an ohmic contact; Cu, Te, and Au formed rectifying contacts. The photovoltaic effect at the junction was detected as a function of light intensity and wavelength. The dependence on light intensity was found to be linear. The dependence on wavelength varied slightly with the metal involved. Some common features were observed:

1. The photovoltage *vs.* wavelength plots achieved a maximum value beginning at a wavelength which varied with the metal involved and ending at approximately 0.5μ (which corresponds energetically to the CdS band gap).
2. The lower wavelength limits corresponded to photon energies varying linearly with the work function of the metal forming the junction.
3. In addition to the main response these photovoltage plots consistently exhibited a weak maximum (between 10^{-1} to 10^{-2} times weaker than the main peak) at a wavelength of 850 mμ. At this wavelength value a peak was observed both in the absorption and in the photoconductivity measurements on the CdS films. The peak at 850 mμ is therefore attributed to a transition internal to the CdS.
4. No evidence of photoemission from the metal was found. No simple relation holds between the response in the long wavelength region and the thickness of the metal layer or the metallic work function. The weak response which was detected at long wavelengths was probably due to the presence of impurity states in the CdS band gap.

Fabrication of the Samples

The structure of the diodes used in the experiments is shown in Fig. 1. The three differing geometries shown in Fig. 1 were adopted to determine if anisotropy in the properties of the films might affect photovoltage measurements. In fact, all diode structures behaved in substantially the same way. Two sources provided the CdS which was used to make the diodes: (*a*) CdS powder (mat 33-C-291) from RCA Laboratories;[2] (*b*) CdS powder of an ultra-high purity grade from Eagle Picher Company. The resistivity of the material was measured by compressing the powder in a ceramic cylinder between a copper plate and a screw tightened to the cylinder. The value of the resistivity as obtained from this measurement was of the order of 10^7 ohm-cm. The over-all electrical results obtained with either material (*a*) or material (*b*) were substantially the same.

The films were deposited on glass substrates which were heated to temperatures ranging from 150° to 350°C. A source similar to that described by Zuleeg and Senkovits (1) was used. The color of the films deposited ranged from a dark orange for substrate temperatures near 150°C to yellow for the higher temperatures. The resistivity varied correspondingly from 1 ohm-cm to approximately 10^4 ohm-cm in the dark. The films evaporated on warm substrates were all photosensitive to some degree, with the sensitivity depend-

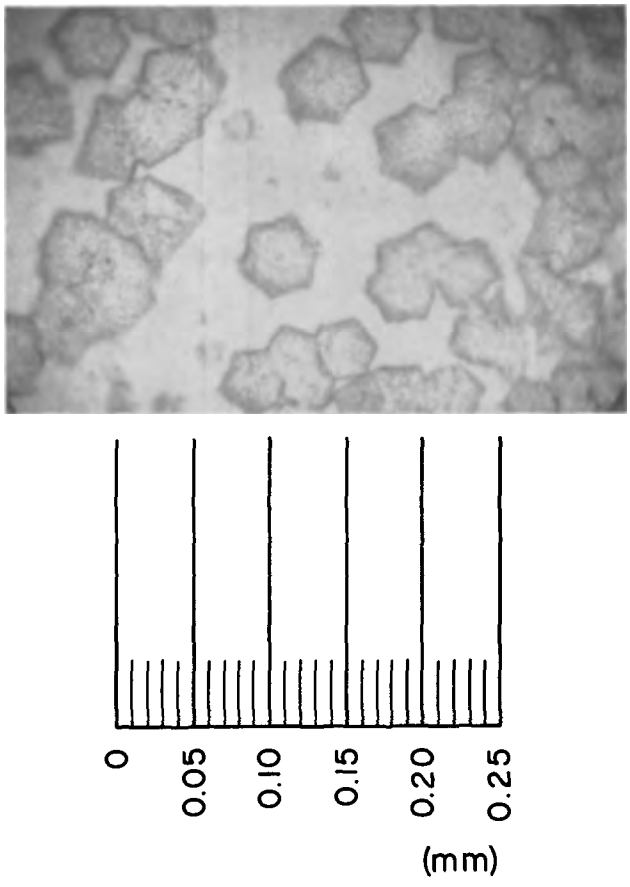

Fig. 2. Etch patterns on a CdS film deposited on a substrate warmed at 150°C.

ing on the temperature of the substrate. Ratios of dark to room-light resistivities of 2:1 or 3:1 were typical. When the temperature of the substrate reached or exceeded 300°-350°C, the deposition became slow and re-evaporation was observed. An optimum substrate temperature seems to be about 200°C when the source temperature is around 750°-800°C. The composition of the films also varied with the thickness of the deposit; thinner films showed higher conductivity than thicker ones for the same temperature of evaporation.

The crystallographic structure of the CdS films was studied via x-ray examination. Diffraction patterns from the films contained only one strong line corresponding to the (002) direction of the hexagonal structure. The line corresponding to the (101) direction (the strongest line for randomly oriented powders) was much weaker in the pattern from the films and was of the same order as the line corresponding to the (004) direction (*i.e.*, the second-order diffraction in the direction of the principal hexagonal axis). The intensity ratio between the (002) and (101) lines was approximately 10^4, while a randomly oriented sample would give a ratio 59/100 for these lines. Two weak lines corresponding to CdO were detected on the x-ray pattern from a sample deposited on a cold substrate and baked in air at 350°C.

Some of the samples were etched by exposure to warm vapors of concentrated HCl. Under microscopic examination at 200 magnification, no crystalline pattern was detectable on the samples evaporated on a cold substrate, postbaked or not. On films deposited on a warm substrate, hexagonal patterns ranging in size up to 40-50μ were observed (Fig. 2). These patterns may either be $CdCl_2$ precipitates or else actual etch pits. Recent work on this question will soon be published. The Al and CdS layers were deposited in a two-step evaporation, without opening the bell jar in order to avoid oxidation of the Al layer. The counter electrode (Cu, Au, or Te) was then deposited in a straight-forward manner. The metal-CdS diode cells fabricated in this laboratory and discussed in this paper belong to five sets of samples. Table I summarizes the fabrication data for these samples.

Table I. Sample fabrication properties

Slide No.	Structure	Evaporation pressure,* Torr	Temp. substr, °C	Temp. source, °C	Thickness of CdS, μ**	Dark resistivity, ohm-cm
51	Al-CdS-Au	1.9×10^{-7}	300	780	0.098	4.9×10^3
54	Al-CdS-Te	3×10^{-7}	250	780	0.243	5.8×10^2
55	Al-CdS-Cu	3×10^{-7}	275	770	0.164	6.6×10^3
56	Al-CdS-Cu	3.5×10^{-7}	250	760	0.115	2.3×10^3
59	Al-CdS-Au	1.2×10^{-7}	285	780	0.140	3.1×10^3

* The pressure was measured at the throat of the chamber just before the evaporation started; during evaporation, the pressure typically reached 2 or 3×10^{-6} Torr.

** The thickness was measured by using a Normarski-type interferometer.

Experimental Results

No appreciable bulk photovoltage was detected across CdS films deposited on warm substrates, the connections being made through In-soldered ohmic contacts. (In a few cases photovoltages which never exceeded a few microvolts were obtained at such junctions under very concentrated visible illumination.[3]) Somewhat larger bulk photovoltages were obtained on some CdS samples deposited on substrates at lower temperatures. The maximum value of the bulk photocurrent detected was 0.2 nA (1 Mohm meter resistance). This was measured on a 1μ thick sample having a resistivity of 2.75 ohm-cm. The bulk-generated photocurrent varied quite irregularly when a concentrated beam of light was moved along test samples which consisted of ohmic contacts made to the opposite edges of films 1.2 cm in length. This photocurrent probably stemmed from a nonuniform distribution of impurity states in the film, which gave rise to a nonuniform conductivity. Potential barriers at the microcrystal boundaries could also be responsible for the detected photoeffect. In all cases, however, and particularly in the case of the films deposited on warm substrates, the bulk photovoltage was negligible in magnitude when compared to the photovoltages measured at metal blocking contacts to the CdS films.

A Bausch and Lomb monochromator with a coil-filament tungsten bulb was used as a light source. Photovoltaic response was measured in a range of wavelengths extending from 0.325 to 1.6μ, obtained by using two different diffraction gratings (0.325-0.800μ and 0.700-1.600μ). The intensity of illumination at each

[3] G. O. Müller has reported measurements of ohmic-contact photovoltage responses. *Phys. Stat Solidi*, 3, 523 (1963).

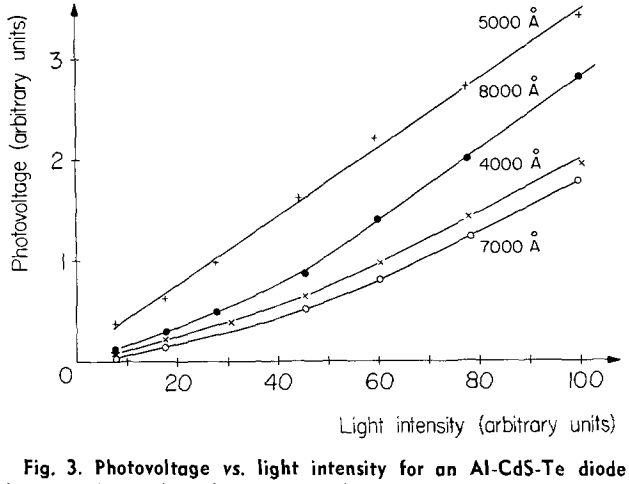

Fig. 3. Photovoltage vs. light intensity for an Al-CdS-Te diode (unit 54.3) at five different wavelengths. The polarity of the photovoltage was such as to make the blocking contact positive.

wavelength was varied by adjusting the monochromator supply voltage with a variac. The measured photovoltage depended linearly on the intensity, and was of a polarity to make the blocking contact positive. A typical curve of photovoltage *vs.* light intensity for an Al-CdS-Te sample is shown in Fig. 3.

Figure 4 shows typical curves of the measured photovoltage versus wavelength for three different metal-CdS rectifying contacts. Several features common to all three curves are easily understood.

1. The measured photovoltage drops in each case all three curves are easily understood.

ev, this energy is near to values reported for the CdS band gap at room temperatures (2).

2. In each case the photovoltage becomes appreciable at a short wavelength which varies with the metal used to make the blocking contact.

3. A much smaller peak is detectable for a wavelength of about 850 mμ.

In order to investigate further the nature of the peaks detected in the photovoltaic response, both the photoconductive response and the absorption spectrum of the CdS films were also measured. Curves obtained from these measurements are shown in Fig. 5 and 6. Finally, the photovoltage measurements obtained on the diodes fabricated in this laboratory were compared with the measurements made on samples supplied by R. Zuleeg of the Hughes Microelectronics Division, Newport Beach, California. Measurements on the Hughes units are plotted in Fig. 7 for a typical cell. The Hughes samples were Au-CdS diodes with different thicknesses of the Au-layer, deposited in the structure described by Zuleeg (1). The CdS powder used by Zuleeg was supplied by Harshaw Chemical Company.

Discussion of Results

It is found that evaporation in a vacuum of roughly 10^{-6} Torr leads to dark-colored low-resistivity films when the substrate temperature is roughly 150°C or less (with a temperature of about 850°C for the source). At temperatures below 150°C the vapor pressure of free Cd is less than 10^{-5} Torr, and hence free Cd condensation is likely. Free S has a vapor pressure more than four orders of magnitude higher than free Cd in this range of temperatures, so that excess S is not likely to be present in the evaporated films. The dark color and low resistivity can thus be plausibly connected with the presence of Cd excess, either by virtue of S vacancies in the lattice, or else because of interstitial Cd atoms. Recent work with radioactive tracers by Woodbury (3) has indicated that interstitial Cd is very unlikely in CdS crystals.

It was possible to alter the resistivity of the films, which were deposited on a cold substrate by baking them in an open tube under a H_2 atmosphere for roughly 30 min at 350°C. During this heat-treatment, the films changed color from dark orange to pale yel-

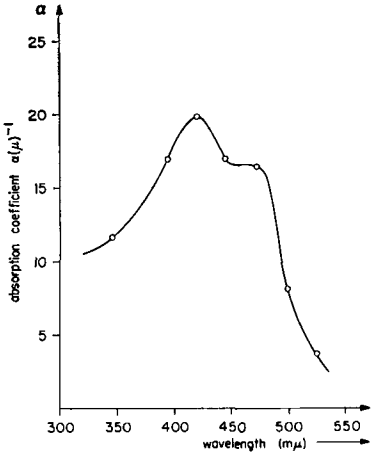

Fig. 6. Absorption spectrum for a deposited CdS film

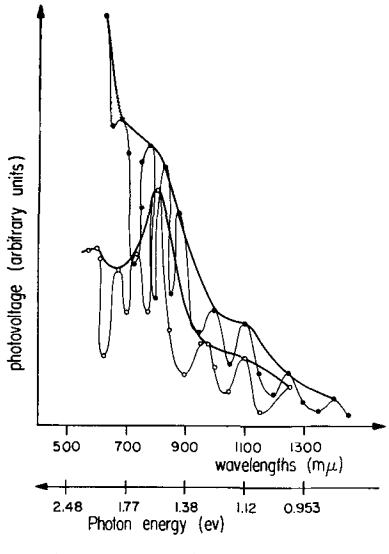

Fig. 7. Photovoltage *vs.* wavelength for two Al-CdS-Au diodes showing interference phenomena: ○, thinner Au layer (a); •, thicker Au layer (b).

low and simultaneously increased in resistivity by as many as six orders of magnitude from their as-deposited condition. By contrast, it was found that air-baking in an open tube of samples for times comparable to the hydrogen bake resulted in a much smaller resistivity change while preserving the striking color change. The increased resistivity is thought to stem from the elimination of the excess Cd at the crystallite surfaces. The comparative ineffectiveness of air baking may be a result of the oxidation of the Cd at the material surface; which may act to inhibit further Cd diffusion. (CdO was observed in the x-ray spectrum of air-baked samples.) Berger *et al.* (4) have explained measurements on CdS films which were heat treated in vacuum by postulating the presence of two competing processes. The first is the diffusion of excess Cd to the surface where it is vaporized, and the second is the creation of sulfur vacancies near to the crystal surface owing to CdS dissociation. The increase in resistivity and color changes which we have observed suggest that the elimination of excess Cd predominates at low temperatures outside of vacuum. Somorjai and Jepsen (5) argue that the relatively fast diffusion which adjusts the resistivity of annealed CdS films is due to sulfur-vacancy migration from the Cd-rich interior to the surface. The diffusion constant for substitutional Cd (3) is far too low to be effective for the annealing times and temperatures that we have used. The sulfur-vacancy diffusion constant, while not known in detail, appears to have a value of about 10^{-5} at 800°C and a very low, but as yet undetermined, activation constant. A diffusion constant of this order would fit the relatively rapid change in resistance which we have observed on annealing.

The energy levels associated with Cd or S vacancies or with interstitial Cd are not known exactly, although there is general agreement in the literature that S vacancies result in electronic energy levels located roughly 0.2 ev below the conduction band, if doubly charged, and 0.5 ev below the conduction band, if singly charged (6).

In order to interpret the photovoltaic response data, we first discuss the photoconductivity and transmission data of Fig. 5 and 6. The photoconductive response curve in Fig. 5 is a plot of $\Delta\sigma/n_o$ *vs.* photon energy where $\Delta\sigma$ is the increase in photoconductivity and n_o is the photon flux. The expected large photoconductive response for photon energies near and above the band gap is evident. Also present in the photoconductivity data is a smaller peak in the neighborhood of 1.5 ev (830 mμ). Evidence for energy absorption at 1.5 ev was also obtained from transmission measurements.

The general character of the observed photovoltage *vs.* wavelength curves (Fig. 4) is seen to be approximated fairly closely by the spectral absorption curves of Fig. 6. Minor variations in the curve shapes with varying metallic electrodes can be partly understood in terms of differing reflectivities by the contacts themselves. In the short-wavelength region, the photovoltage *vs.* wavelength curves drop more rapidly than does the absorption coefficient curve. The short wavelength decrease in photovoltage occurs at different wavelengths depending on the metal forming the junction. The photon energies which correspond to the point at which the curves drop are proportional to the work function of the metal, as is evident in Fig. 8. Although too many factors are unknown for an exact quantitative analysis, the proportionality between work function and photovoltage decrease may be caused by the dependence of space-charge layer thickness on surface-barrier height. The short free-hole diffusion length in CdS would confine all photovoltaic effects to the space-charge layer, and hence any photoresponse would be a sensitive function of the depletion layer width, which, in turn, is dependent on the electrode metal's work function.[4]

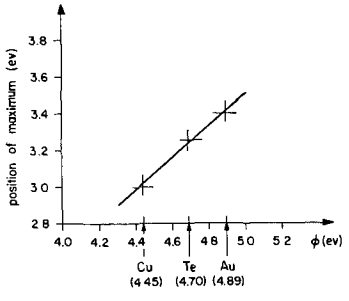

Fig. 8. Position of the first peak in the low wavelength region of the photovoltaic response as a function of the work function of the metal forming the junction.

No evidence is found in any of the samples of the presence of photoemission of electrons from the metal as found by Williams and Bube (7). There is in all the curves a background which could be interpreted according to Williams and Bube's theory, but no simple relation has been found between the responses obtained from samples with differing thicknesses of the metal layer and between the metal forming the junction and the shape of the curve. In the long wavelength region, where metallic photoemission should be observed under the Bube and Williams hypothesis, both the photoconductivity response and the transmission spectrum show evidence of transitions inside the CdS. The photoconductivity increases and the transmission shows many weak absorption and emission peaks. These points seem to suggest that the response in the region considered is probably due to the presence of distributed impurity and imperfection levels in the CdS. The peak at 850 mμ appears in all diodes studied and is therefore certainly due to a transition internal to the CdS.

Results quite similar to those obtained for the diodes fabricated in this laboratory were also measured on the diodes fabricated by the Hughes Semiconductor Division. Since the CdS layers in the Hughes diodes were almost ten times thicker than the CdS layers deposited in this laboratory, the response for energies higher than the band gap was nearly completely nulled by photon absorption in the CdS layer, when illuminating from the Al side of the Hughes diode. The response obtained with illumination from the Au side was quite similar to that obtained from the units fabricated in this laboratory. Also, for the Hughes diodes the response at higher wavelengths could be due both to photoemission and to distributed trapping levels in the CdS. Here we do not have any data on the CdS transmission and photoconductivity to be compared with the photovoltaic response. Again there is no evidence for photoemission from the metal, as no simple relation is found between the back and the front responses and between the responses of two units having differing thicknesses for the Au layer (Fig. 7). A rigorous comparison is not possible owing to the presence of superimposed oscillations in photovoltage *vs.* wavelength due to an interesting interference phenomenon in the CdS layer.

To prove the validity of an interference hypothesis in explaining these oscillations in measured photovoltage, we have compared the wavelength of the incident light corresponding to the maxima in the photovoltage oscil-

[4] This mechanism was suggested by Professor A. C. English.

Table II. Measured and calculated wavelengths at photovoltage maxima

m	$2nd/m$, μm, calc	Maxima, μm, meas.
6	1310	1250
7	1125	1100
8	990	1000
9	878	875
10	790	775
11	716	725
12	660	670
13	607	600

lations with the wavelength values obtained by assuming the effect to be caused by standing wave patterns formed from reflections at the Au and Al surfaces. If standing wave patterns are present one can predict the maxima to occur for $2nd = m\lambda$, where n is the refractive index of the CdS (2.5), $d = 1.58\mu$ is the thickness of the CdS layer, and m is an integer. In Table II the wavelengths of the maxima of sample a measured on Fig. 7 are compared with those calculated from the theory just proposed. A similar comparison holds for unit 6 of Fig. 7 which had a CdS layer 2.05μ thick.

It can be seen that the agreement between theory and measurements is quite reasonable. The presence of the interference phenomenon makes it difficult to detect clearly the position of any maxima in the long-wavelength region that may result from other physical mechanisms. The interference phenomenon is not present in the diodes fabricated in our laboratory because of the difference in structure and of the semitransparent metal layer.

Conclusion

CdS films obtained by evaporation with both the temperature of the substrate and the temperature of the source opportunely controlled show a microcrystalline structure, having a high degree of orientation. The pale-yellow color and the high resistivity of the films indicate that large amounts of excess Cd are not present. Metal junctions to these films show a photovoltaic effect when illuminated with light in the wavelength region between 350 and 500 mμ; the first limit depending on the metal involved. No evidence for photoemission in the long-wavelength region has been detected.

A Novel Crystal Growth Phenomenon: Single Crystal GaAs Overgrowth onto Silicon Dioxide

F. W. Tausch, Jr., and A. G. Lapierre, III

Engineering Department, Sylvania Semiconductor Division, General Telephone and Electronics, Incorporated, Woburn, Massachusetts

ABSTRACT

Epitaxial growth of GaAs in windows on SiO_2-masked GaAs substrates has been studied and found to yield smooth-surfaced single crystal epitaxial layers. Single crystal overgrowth onto the SiO_2 films, initiating from the windows and growing out laterally over the SiO_2, has also been observed to occur in many instances. Studies of growth habits and patterns, inspection of cleaved sections, x-ray studies, and crystallographic considerations have led to a proposed growth mechanism which is not only consistent with the experimental window growth and overgrowth observations, but also indicates that the processes are highly controllable; it has been shown that overgrowth can be virtually inhibited, and it is concluded that with proper mask geometry single crystal overgrowth can occur over large areas almost without restraint.

In the course of investigating the SiO_2-masked epitaxial growth of GaAs in windows, which has never been reported in the literature, it was observed that not only window growth of excellent quality was obtained, but that the epitaxial layer frequently grew out laterally from the windows in the SiO_2 mask, resulting in an area of sandwich structure with the single crystal epitaxial GaAs layer separated from the GaAs substrate by the amorphous SiO_2 film (*e.g.*, see Fig. 6 and 7). This behavior is quite different from that reported for growth of silicon in windows [*e.g.*, ref. (4)], where lateral overgrowth has not been reported. Since this phenomenon of overgrowth appears to be not only novel but also potentially useful for device fabrication, it has been further investigated. This paper includes some preliminary results and conclusions derived from study of growth in windows and overgrowth.

Experimental

Substrates used in the work reported here were heavily doped (tellurium) n-type GaAs, cut and polished within 3° of the $(\bar{1}\bar{1}\bar{1})$ As faces. Essentially similar results were obtained on the (111) Ga faces. SiO_2 films of 100-10,000Å thickness were deposited conventionally

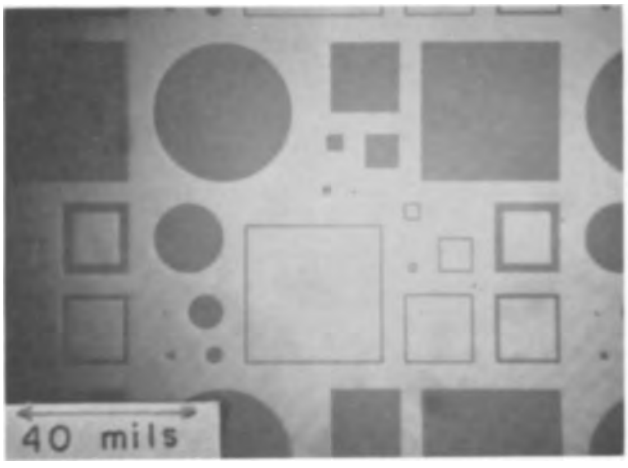

Fig. 2. Photomicrograph of specially designed mask for overgrowth study. Dark areas represent SiO_2 removal to GaAs substrate. Windows range from one-half to 32 mils over-all. Magnification approximately 25X.

by pyrolysis of tetraethyl orthosilane, and windows were opened in the SiO_2 by standard photolithographic techniques. Figure 1 shows the simple window pattern used in early work, consisting of an L-shape with legs 13 mils long and one-half mil wide, and with a 3 by 3 mil square in the center. Figure 2 shows a more elaborate pattern which was designed for study of overgrowth and which incorporates both round and square windows of various sizes (½-32 mils over-all) as well as frames of various sizes (2-32 mils over-all) and frame widths (½-2 mils). Masks were not intentionally aligned along specific crystallographic planes unless noted.

Epitaxial layers up to about 10μ thick were deposited on these slices in a conventional quartz vertical vapor transport reaction system, similar to that reported by Williams and Ruehrwein (1), utilizing an undoped GaAs source and either HCl or $AsCl_3$, in hydrogen, as the transport agent. Growth rates normal to the surface were generally 0.5-2.0 μ/min. The source temperature was 900°C, and the deposition temperature was from 710° to 730°C.

Results

Figures 3 and 4 show typical growths of about 10μ thickness obtained using the two masks previously described. It should be mentioned that most of the gross imperfections apparent in these growths are due to imperfect photolithographic work, incomplete removal of oxide, or imperfect cleaning of substrate surface. Laue back-reflection x-ray photographs confirm the single crystallinity of both growth in windows and

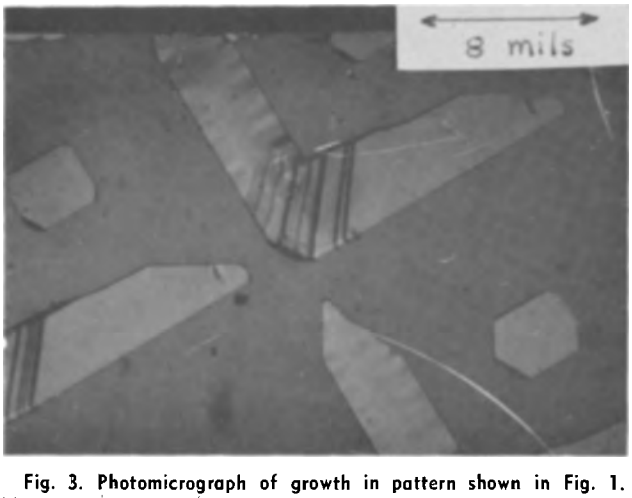

Fig. 3. Photomicrograph of growth in pattern shown in Fig. 1. Magnification approximately 125X.

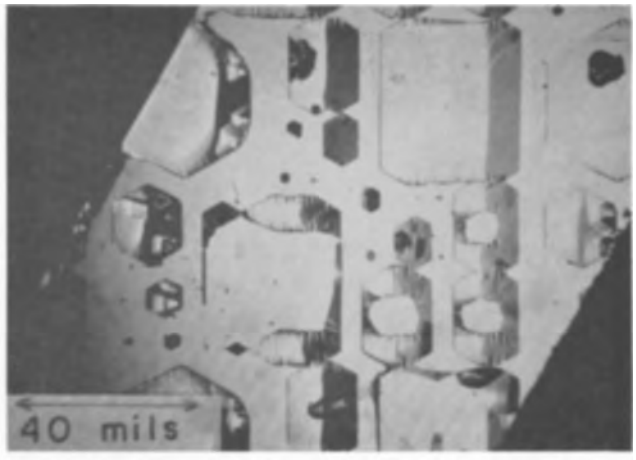

Fig. 4. Photomicrograph of growth in mask shown in Fig. 2. Magnification approximately 25X.

overgrowths, except where obvious polycrystallinity exists.

Comparison of Fig. 3 with Fig. 1 shows that lateral overgrowth of several mils has occurred from the one-half mil wide stripes, although growths of the central squares has tended to form hexagons and then virtually stop. Similarly, comparison of Fig. 4 with Fig. 2 shows that growth in all of the windows except the largest of the squares has formed hexagons, and that even the largest of the squares tend toward hexagons, and that the three smallest frames (2, 4, and 8 mils over-all) have been filled by overgrowth. Figures 5A, B, and C show an 8-mil frame before overgrowth, after almost complete overgrowth, and after complete overgrowth; these pictures not only demonstrate the development into the hexagonal shape, but also show that practically no growth occurred on two sides. It may be noted that the pattern is still faintly visible through the overgrowths of Fig. 5B and C. Finally, Fig. 5D and E show examples of better quality overgrowths of 2 and 4 mil frames, achieved by growing at a slower rate (*i.e.*, closer to 0.5 μ/min normal to the surface, rather than 1.0 or 2.0 μ/min).

A number of other features apparent in Fig. 3 and 4 may deserve comment here. For example, spurious nucleation occurred on a few places on the SiO_2 in some cases, especially at high growth rates, but was generally not a problem. Also, it can be seen that less perfect areas frequently occur wherever advancing growth fronts intersect; these may result in low-angle

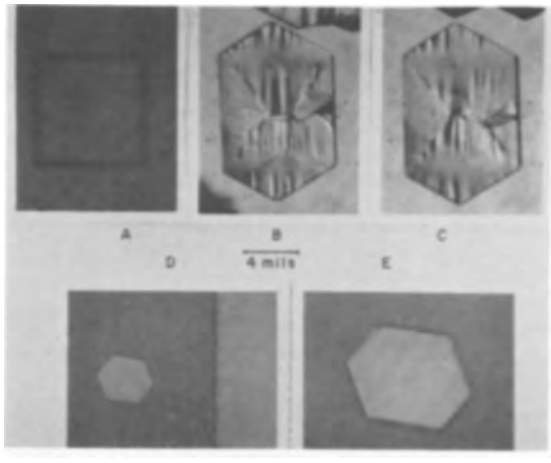

Fig. 5A. Photomicrograph (250X) of 8-mil frame before growth. Figure 5B and 5C. Same as Fig. 5-A except after almost complete overgrowth (5-B) and after complete overgrowth (5-C). Figure 5D. grain boundaries, which were observed in some x-ray photographs of these areas, although low-angle grain boundaries were also detected in some substrates. In any event, it will be shown later that the problem of intersecting growth fronts can be avoided by proper choice of mask geometry.

Identification of Faces

As previously mentioned, all growths reported here were carried out on the polished (111) surfaces of GaAs. The flat top surfaces of completed hexagons were in several instances measured to be oriented three degrees from the polished substrate surface by interferometry. Subsequent x-ray determination of the substrate orientation of these slices showed that the polished substrate surface was itself three degrees off the (111) plane in the corresponding direction. These observations not only indicate that the top surface tends to grow into a (111) facet, but also further support the single-crystallinity evidence of the growths. The tendency toward (111) facet formation may also explain some of the stepping which is apparent in Fig. 3 and 4, especially in large areas where not enough vertical growth has occurred to result in a single (111) facet across the entire top surface of the window.

In order to identify the slow-growing crystallographic planes bounding the growth figures, samples were cleaved along the {110} cleavage planes and inspected from the side; {110} cleavage was confirmed in several instances by x-ray orientation. It should be noted that there are three {110} cleavage planes, sixty degrees apart, perpendicular to any {111} face.

Referring again to Fig. 4, this is a top view of a sample twice cleaved along parallel {110} planes. It can be seen that these cleavage lines are perpendicular to one set of sides of any completed hexagon, and hence generally reveal the crystallography of the corresponding advancing growth front. A side view of such a cleavage through a completed hexagon invariable reveals a structure such as that sketched in Fig. 6A and 6B, and shown in photomicrograph 6C. The faces shown, at approximately 70° from the (111) plane, correspond to other {111} planes (see Table I). Consideration of the crystallography involved leads to the conclusion that the overhanging facet is chemically the same {111}

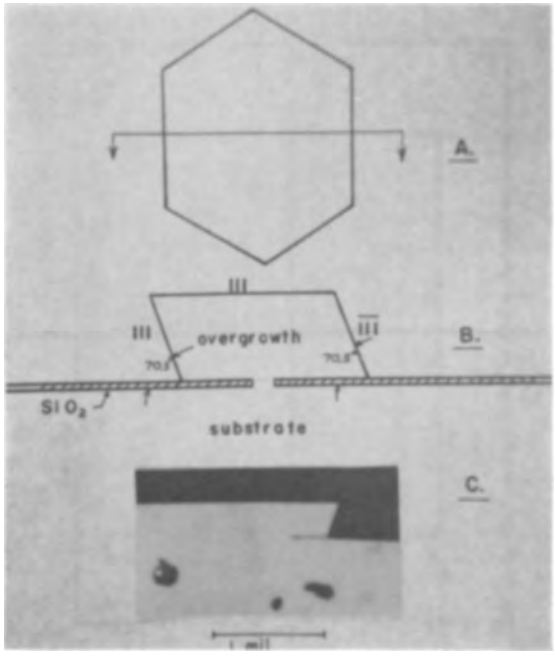

Fig. 6. Sketch of (110) cleavage of completed (grown) hexagon. Figure 6B. Side view of above cleavage through completed hexagon, showing opposing (111) facets. Figure 6C. Photomicrograph (1000X) of typical cleavage as above.

Table I. Angles between (111) and x planes along 110 zone

It may be mentioned that the difference between the two columns, as referred to in the text, is that one always refers to upward sloping faces while the other always refers to downward sloping faces; hence in a cleavage which reveals two upward sloping faces, both planes will appear in the same column, while if the cleavage reveals both on upward and a downward sloping face, one will appear in each column.

plane (*i.e.*, either gallium or arsenic) as the top (111) face, while the upward sloping facet is chemically the same {111} face as the bottom ($\bar{1}\bar{1}\bar{1}$) face of the substrate wafer. In any of the top-view photographs the upward sloping facets appear dark due to the illumination, while the downward sloping facets are not visible. From the photomicrograph in Fig. 6C of the cross section of a completed hexagon can be seen the flat top (111) plane of the growth in the window, the 70° overhanging {111} side facet, and the small amount of overgrowth which has resulted from the formation of that facet. The SiO_2 masking can be seen in this photograph as the dark line separating the overgrown layer from the substrate. Cleavages across overgrown L-shaped patterns such as in Fig. 2, as well as across frames and windows where the hexagonal shape has not yet developed, frequently reveal leading edges at angles as shown in Fig. 7B. Referring again to Table I, the facet at about 35° to the (111) appears to correspond to a {110}, and that at about 55° appears to correspond to a {100}; usually the two facets have been of approximately equal magnitudes, as indicated by

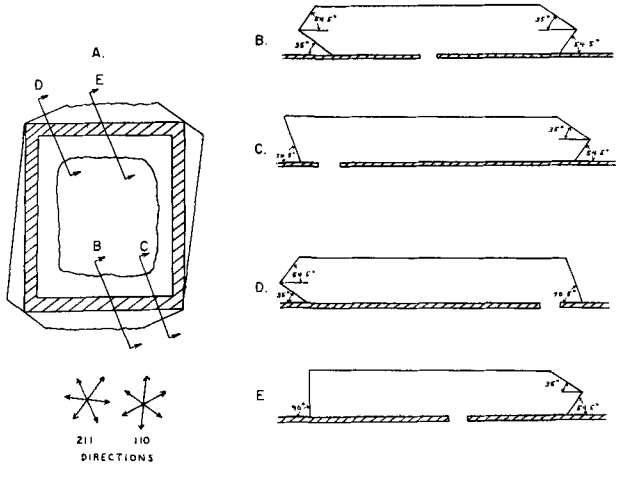

Fig. 7A. Partially overgrown frame with four cleavages indicated, for use with Fig. 7B through 7E. Figure 7B. Sketch of cleavage revealing both (100) over (110), and (110) over (100) double facets. Figure 7C. Cleavage revealing both a (111) facet and a (110) over (100) combination facet, also indicating relative lateral growth rates. Figure 7D. Cleavage revealing the other possible combination, with (111) and (100) over (110) facets. Figure 7E. Cleavage across a (110) perpendicular facet. (Note that vertical dimensions in side view sketches, Fig. 7B through 7E are exaggerated for clarity).

the sketches. Cross sections showing leading edges consisting of the {110} and {100} double facet on one edge and a {111} facet on the opposite edge have also been observed, as in Fig. 7C and 7D. The discovery of these combinations of facets is important in corroborating the identification of all the faces, since consideration of the crystallography involved (and reference to Table I) leads to the conclusion that the combinations pictured are the only ones consistent with the observed angles.

The above-mentioned existence of combination {110}-{100} faces deserves comment since it would be expected (2) that a (111) layer spreading over a substrate {111} surface in opposed [211] directions should result in a step along a {110} plane in one direction and a step along a {100} plane in the other direction. Similarly for the layer spreading over the chemically opposite (111) surface the {100} step should form in the first direction and the {110} step in the other. The distinctive feature of overgrowth, however, is that the (111) layer is effectively spreading over both (111) and $(\bar{1}\bar{1}\bar{1})$ faces simultaneously since the layer is growing over an SiO_2 substrate rather than a {111} oriented substrate; the combination growth front involving both {110} and {100} steps is thus not too surprising. It might be mentioned that epitaxial overgrowth is, in many respects, similar to dendritic growth.

Another facet frequently found on cleavage has been one at 90° to the (111) plane, as sketched in Fig. 7E. Although the {211} plane is in the {110} zone, and is 90° from the (111) plane (see Table I), it is not likely to form facets on GaAs (3). On checking the top view of these cleavages it was found that the cleavage {110} planes were not perpendicular to the growth front, as was true in Fig. 7A through 7D. Rather, the front was 60° from the cleavage plane, advancing in a direction 30° from any [211] direction. These directions are the [110] directions and, indeed, the 90° face is probably the {110} face. Note that in Fig. 4 the planes forming the interiors of the three 16-mil frames are 30° from the exterior {111} hexagonal facets and are probably these perpendicular {110} facets.

Facets at angles corresponding to other crystallographic planes have also been observed, but have not been identified with any degree of certainty.

Proposed Growth Mechanism

Considering now the factors which determine the growth pattern obtained, it is clear that the amount of overgrowth obtained with each possible facet as a leading edge will vary, and the {111} facets will advance most slowly (*i.e.*, at the same rate as the top (111) face).

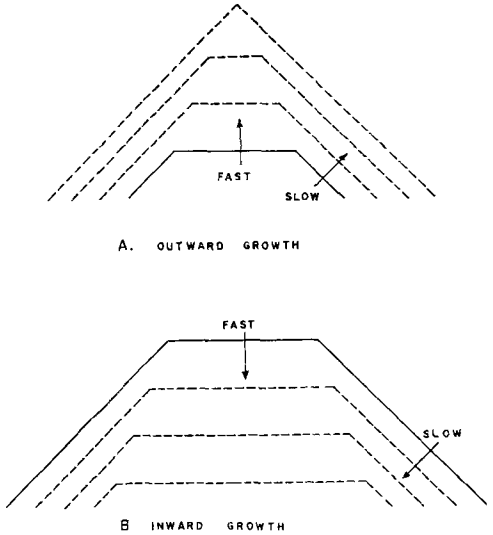

Fig. 8A. Sketch of effect of relative facial growth rates on habit of diverging growth front (outward growth). Figure 8B. Sketch of effect of relative facial growth rates on habit of converging growth front (*i.e.*, inward growth).

The factor determining which growth front forms is whether the growth front is diverging or converging. First consider the case where the growth front diverges, *i.e.* Fig. 8A. The length of the slow growing front increases at the expense of the fast growing front, and the final form is recognizable as the circumscribed {111} hexagonal facets to which all mask shapes tend to overgrow in the outward direction.

Considering next growth along a converging front, i.e., Fig. 8B, it is now the fast growing facets which tend to survive and predominate. For example, the interior overgrowths in the 16-mil frames of Fig. 4 appear to be forming facets which are aligned 30° from the {111} exterior facets, and hence are believed to be the relatively fast growing {110} perpendicular faces. The fact that fast growing faces are not self-annihilated in this case makes possible controlled rapid overgrowth of a converging growth front. The relatively extensive inward growth apparent in the L-shaped areas of Fig. 3 may be explained in terms of growth steps initiated at the inside corner.

It is interesting and informative to speculate briefly on some of the techniques by which overgrowths could be controlled, in the light of the previously developed mechanism. For example, by proper orientation of a hexagonal mask pattern, *i.e.*, with sides parallel to {111} faces, it should be possible to inhibit completely rapid overgrowth and thereby limit growth in all directions (including normal to the surface) to the slow {111} face growth rate; growth in circular windows approaches this condition. As another example, overgrowth over large areas should be possible by exploiting a geometry which avoids {111} facet formation, *i.e.*, straight lines or concave curvatures (see Fig. 8B). It may be noted that the problem of defects caused by intersecting growth fronts is avoided along straight or gently curving window openings.

Conclusions

It has been shown that single crystal epitaxial growth occurs in windows, and that the growth tends to rapidly overgrow the SiO_2 until a hexagonal figure bounded by {111} facets is formed. The overgrowth is itself single crystal, and rather extensive (several mils) overgrowths of good appearance have so far been achieved. A mechanism of overgrowth has been proposed which is not only consistent with the experimental observations, but also indicates that the overgrowth process is highly controllable; by proper geometrical relationship between the mask and the substrate crystallography overgrowth can be virtually inhibited, and it is concluded that overgrowth can also be made to occur over large areas almost without restraint. The integrity of the isolating SiO_2 film has been established since it is visible on sectioning and after the overgrown GaAs has been chipped away.

Kinetics of Epitaxial Silicon Deposition by a Low Pressure Iodide Process

John E. May

Semiconductor Products Department, General Electric Company, Auburn, New York

ABSTRACT

This report is primarily a study of the factors which control the vapor transport process of silicon in a modified closed tube low pressure cyclic iodide process. The kinetics of transport from the source to the substrate are examined and are found to agree with a diffusion controlled mechanism. The model is useful for estimating the deposition rate under a variety of conditions. The process is found capable of depositing silicon on silicon substrates at relatively high deposition rates. Impurity doping with this process is accomplished by incorporating the desired impurity into the source silicon.

Vapor phase transport-closed tube processes are of considerable interest for epitaxial deposition of semiconductor materials (1-4). Essentially, the process involves incorporating into a closed tube the substrate, the source of material to be deposited, and a carrier gas. By heating the source and substrate to different temperatures, the carrier gas reacts with the source material to form a volatile compound which then migrates to the substrate. Decomposition and deposition occurs at the substrate. The decomposition products may then travel back to the source to pick up more material. In the silicon-iodine system studied by Wajda and Glang (4), for instance, the substrate is maintained at about 950°C, the source at 1100°C, and iodine pressure at 20 atm. With a source to substrate distance of 10 to 15 cm they observe deposition rates of the order of 10 μ/hr. The dominant transport mechanism in this case is thermal convection.

Dash and Taft (5) on the other hand have used a low pressure silicon iodine cyclic process and have brought the source much closer to the substrate. The source and substrate can be heated inductively to different temperatures to achieve a steep temperature gradient. The close space geometry has been also used by Sirtl (6) and by Nicoll (7).

This paper shows that the combination of close spacing and low pressure lead to a substantially more rapid deposition rate, and that the process is diffusion controlled.

Preliminary Analysis

In this report we expand the initial work of Dash and Taft (5) on the cyclic iodide process, investigating further the effect of pertinent variables which control the transport and deposition processes. In addition, the kinetics and mechanism of transport are examined and estimates are made of the deposition rate as a function of the experimental variables.

An important feature of this process is the relatively small distance between the source and substrate. This distance is maintained by placing the substrate between two slabs of silicon which are separated by means of a quartz ring. Two arrangements are shown schematically in Fig. 1. One piece of silicon acts as the source of material and the other is the heater for the substrate. Transport from source to substrate is accomplished in an iodine atmosphere by heating the source to temperature T_1 and the substrate to temperature T_2 where $T_1 < T_2$. The iodine reacts with the source silicon to form a volatile iodide with an equilibrium partial pressure at the source greater than its equilibrium partial pressure at the substrate. This supersaturated iodide at the substrate drives the original reaction in the reverse direction leaving elemental silicon on the substrate. A concentration gradient of silicon iodide is therefore established between the source and substrate. At an average temperature of 1100°C and 1 mm of iodide pressure the mean free path is about 10^{-2} cm. We would expect then that a diffusion controlled process would operate down to spacer distances between source and substrate of the order of a millimeter.

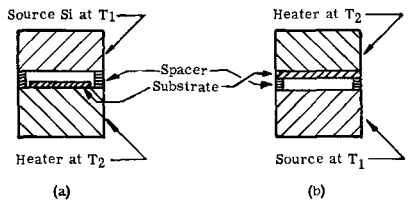

Fig. 1. Schematic of heater, substrate, and source assembly

For a diffusion controlled process the flux of material passing between the source and substrate is given by

$$J = -D\,\partial C/\partial X$$

where D is the gaseous interdiffusion coefficient of the iodide and $\partial C/\partial X$ is the equilibrium concentration gradient between the source and substrate. Since $C = n/v = p/RT$, the maximum growth rate (G) of the deposit is given by

$$G = D\,M\Delta p/\rho\,RT_a\,d \qquad [1]$$

where M is the atomic weight of Si, Δp is the difference in equilibrium iodide pressure between the source and substrate, ρ is the density of Si, R is a gas constant, T_a is the average temperature, and d is the distance between the source and substrate. Since Δp is a function of the iodine temperature and the temperature of the source and substrate, and D is a function of temperature and iodine pressure, we now have an expression containing the variables which influence the deposition rate. This approach is similar to that used by Schäfer *et al.* (8), in their study of metal-halide transport reactions.

This model assumes that there is no barrier to nucleation and growth of silicon on the substrate and that equilibrium iodide partial pressures are maintained at the source and substrate interfaces.

One important feature of silicon-iodine chemistry is that by varying the iodine pressure, silicon can be made to deposit in either the high or low temperature region (9). High pressures favor migration of silicon from the high temperature region to the low temperature region by means of the reaction

$$SiI_4 + Si \rightleftharpoons 2SiI_2 \qquad [2]$$

However (at low pressures) the additional reaction

$$SiI_4 \rightleftharpoons Si + 4I \qquad [3]$$

can occur, which in combination with reaction [2] will give the net reaction

$$SiI_2 \rightleftharpoons Si + 2I \qquad [4]$$

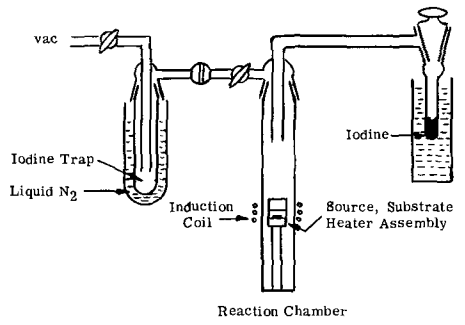

Fig. 2. Apparatus for epitaxial deposition by cyclic iodide process

Depending on whether reaction [3] or [4] is dominating, we would have

$$\Delta p \propto p^4_I \quad [5]$$

or

$$\Delta p \propto p^2_I \quad [6]$$

Another pressure sensitive term is the interdiffusion coefficient D. This varies as

$$D \propto T^n/P \quad [7]$$

where P is the pressure, T the temperature, and n a constant of about 1.5 to 2. Equations [5] or [6] in combination with Eq. [7] and [1] predict the rate of deposition to be proportional to the iodine pressure if SiI_2 is the dominant carrier species and proportional to p^3_I if SiI_4 is the dominant species. This dependence should be obeyed so long as the process is diffusion controlled, that is, when the source to substrate distance is about ten times the mean free path. At appreciably less than 1 mm iodine pressure, we would expect a departure from a diffusion controlled process with a source to substrate distance of 1 mm.

In the next sections we determine the effect of variables on the deposition rate and compare the results with those expected from the analysis.

Experimental

The apparatus used in this experiment is shown in Fig. 2. It is a demountable vacuum system consisting of a quartz reaction chamber with a tapered joint connected to an iodine source vessel and a liquid nitrogen trap to prevent the iodine from entering the vacuum pump. The source and substrate assembly which was used for most of this work is that shown in Fig. 1 (b) and consists of two Si rods (⅞ in. diameter x 1 in. long) of predetermined impurity content separated by a notched quartz ring. The source and substrate heater temperatures are established by positioning an induction coil at the appropriate elevation around the source and heater. The apparatus is enclosed by a box in which the interior can be heated above the iodine source temperature.

The operating procedure consists of pumping the system down to about 10^{-6} mm with the iodine source open to the liquid nitrogen trap. Once the desired temperatures of source and substrate are established the reaction chamber is closed off from the cold trap and vacuum pump, but the iodine source is kept open to the reaction chamber.

Temperatures were measured with an optical pyrometer by sighting on the periphery of the source and heater just above and below the quartz ring. The optical temperatures were corrected for emissivity (10) and true temperatures are reported here.

The iodine vapor pressure used here is that reported in the Handbook of Chemistry & Physics (11).

The substrates used here were 25 ohm-cm-N-type Si with (111) sufaces which were cleaned and then chemically polished with a solution of 100 cc HF, 180 cc acetic acid, 300 cc of HNO_3, and 0.35g of iodine. Immediately prior to loading in the reaction chamber they were immersed in HF and rinsed in deionized water.

The source silicon for this work was 0.01 ohm-cm P-type. Evaluation of deposit thickness was made by polishing a 6° bevel on the coated surface and staining the P region with HF-HNO_3 1000:1. The width of the P region was measured with a microscope and eye piece micrometer. This thickness was checked against the thickness determined from stacking fault measurements in order to determine whether a significant amount of diffusion of doping impurities into the substrate had occurred.

The deposition rates were obtained by dividing the deposit thickness by the total elapsed time starting after the desired temperatures were established and the cold trap was closed. Deposition rates determined in this manner could possibly be on the low side. Experiments have shown that it takes several minutes to achieve a linear growth rate. The total time of the run was therefore scheduled to be long compared with the time to achieve steady state conditions.

Results

Since Δp is a function of ΔT (the difference in temperature between the substrate and the silicon source), we shall present the deposition rate data *vs.* ΔT and then infer the proper iodide species from this and other data. The relationship between deposition rate and Δp will then be shown.

Dependence of epitaxial deposition rate on source and substrate temperatures.—In this experiment the substrate heater temperature was kept constant at 1290°C true temperature and the source temperature was varied. The iodine vapor pressure was maintained at 0.7 mm and the source to substrate distance was 1 mm. The data so obtained are shown in Fig. 3.

Dependence of deposition rate on iodine vapor pressure.—In this series of experiments the deposition rates were determined as a function of iodine pres-

sure over the range 0.3-2 mm. The source and heater were kept at 1150° and 1300°C, respectively, while the spacer distance was 1 mm. The results are shown in Fig. 4.

Effect of source to substrate distance on deposition rate.—The dependence of deposition rate on the distance between the source and substrate was studied with a source temperature of 1090°C, substrate heater temperature of 1300°C, and an iodine pressure of 0.7 mm. Quartz spacers of 1-9 mm were used. It was found that as the spacing increased, the uniformity of the deposit decreased. The data plotted in Fig. 5 indicates that the deposition rate is roughly proportional to the reciprocal of the distance.

Discussion and Results

The results of the study of the variation of deposition rate with iodine pressure indicates that the deposition rate is directly proportional to the iodine pressure at least within the limited range reported here. As discussed in the Preliminary Analysis, the result indicates that SiI_2 is the dominant species. This is in accordance with thermodynamic calculations. The slightly lower deposition rates at the lower iodine pressures are probably caused by the evaporation of silicon which becomes significant compared with the deposition rate.

With evidence that SiI_2 is the major transport species we can re-plot Fig. 4 ($G = f\Delta T$) as $G = f(\Delta p)_{SiI_2}$. For the net reaction

$$SiI_2 \rightleftharpoons Si + 2I \qquad [8]$$

we calculate from Schäfer and Morcher (9) the silicon diiodide pressure in equilibrium with iodine and silicon. This is given by

$$\log (P^2I/P\ SiI_2)_{mm} = 7.447 - 8256/T \qquad [9]$$

The experimental relationship G (exp) $= f(\Delta p)$ is shown in Fig. 6 and is interpreted to indicate that the deposition rate is directly proportional to Δp_{SiI_2}, in qualitative agreement with Eq. [1].

Comparison of calculated and observed deposition rates.—It is of interest now to compare quantitatively the observed results with those predicted from Eq. [1]. It is important first to consider the geometry of our system. We have relatively hot silicon connected to a distance source of iodine maintained at millimeter pressures. The wall temperature of the apparatus is about 75°C, which is lower than the silicon temperature but higher than the iodine source temperature. We assume that the pressure of iodine in the space between the silicon source and substrate is about the same as the equilibrium iodine pressure maintained at the iodine source. At these pressures and silicon temperatures the iodine is practically completely dissociated.

The coefficient of interdiffusion of SiI_2 in iodine may be estimated from kinetic theory (12, 13). (See Appendix.) Combining Eq. [1] and [A-1] and evaluating the constants, we obtain the following expression for the maximum rate of deposition

$$G = 23.5\ (T_a)^{1/2}\ \Delta p\ SiI_2\ (atm)/d\ (cm)\ \Sigma P_{mm} \qquad [10]$$

G is in mils per minute, ΣP is the total gas pressure in mm, and $\Delta p\ SiI_2$ is computed from Eq. [9].

The results calculated from Eq. [10] are compared in Fig. 6 with the experimental results. We see that the calculated transport rates are about three times the observed deposition rates. However, with an apparatus modified to permit hydrogen cleaning of the substrate and source surfaces, we have observed deposition rates quite close to the calculated maximum rates. For instance, with the source at 1150°C, substrate at 1300°C, and iodine pressure at 3.5 mm, we have observed on occasion deposition rates of 0.35 and 0.47 mil/min which compare with a calculated rate of 0.5 mil/min. No doubt the rate at which gases enter the system during the deposition period is a variable. It increases ΣP which has not been taken into consideration in the calculation, and one which we have not determined. The formation of more stable gas-silicon compounds will also decrease the deposition rate. Considering the assumptions and estimates which have been made in the calculation then, the agreement between observed and calculated maximum deposition rates is good.

APPENDIX

The interdiffusion coefficient was calculated from the theory of Maxwell, Chapman, and Enskog [see Dushman (12) p. 75, or Kennard (13) p. 194], and is given by

$$D_{12} = \frac{(v^2_1 + v^2_2)^{1/2}}{3\pi\, n_{12}\, \sigma_{12}^2} \qquad [A1]$$

where v_1 and v_2 are the average velocities $\left(\frac{8}{\pi}\frac{RT}{M}\right)^{1/2}$ of species 1 and 2, $n_{12} = n_1 + n_2$ = number of molecules/cm^3 of species 1 and 2 and $\sigma_{12} = \frac{\sigma_1 + \sigma_2}{2}$ where σ is the molecular diameter of species 1 and 2. Using values of $\sigma_I = 2.8 \times 10^{-8}$ cm and $\sigma_{SiI2} = 7.2 \times 10^{-8}$ cm we compute $D_{12} = 5.6 \times 10^2$ cm^2/sec at Ta = 1498°K and P = 0.7 mm.

The Anodic Synthesis of CdS Films

William McNeill, Leonard L. Gruss, and Dorsey G. Husted

Pitman-Dunn Institute for Research, Frankford Arsenal, Philadelphia, Pennsylvania

ABSTRACT

Cd is shown to behave as a typical "valve anode" in solutions of $Na_2S \cdot 9H_2O$ in ethanol and becomes covered with a film which acts as an electrical barrier, exhibits interference colors, increases in thickness as voltage is increased, and gives rise to sparking at voltages in excess of 150 V. Voltage-time curves, film thickness and electrical resistance, and x-ray diffraction analyses showing the films to be CdS are presented. The thickness-voltage ratio based on interference colors is 26 Å/v.

The synthesis and properties of anodic oxide barrier films on metals such as Al and Ta are well known and have been described in detail by Young (1). Among important properties of films of this type are: the approximate linear increase of thickness with formation voltage for nonporous films at constant current density (2); the appearance of interference colors during film growth (3); and the ability to sustain very large electric fields (4). The majority of papers on this subject deal with films which are composed mainly of oxides of the anode metal, although some work has been reported on non-oxide films such as AgCl (5, 6).

In this paper we describe the anodic behavior of Cd in electrolytes which contain sulfide ions.

Experimental

Electrolytes.—The anodic reaction of Cd was studied with a number of electrolytes, and "valve anode" properties were observed in solutions of Na_2S in dimethylformamide, liquid NH_3, CH_3OH, C_2H_5OH, and $Na_2S \cdot 9H_2O$ in C_2H_5OH. In all cases, anodic reaction products included CdS as shown by powder x-ray diffraction analyses. All further studies reported here were carried out in solutions of $Na_2S \cdot 9H_2O$ in C_2H_5OH. Reagent grade chemicals were used throughout.

The solutions of $Na_2S \cdot 9H_2O$ in C_2H_5OH were subject to slow air oxidation which resulted in formation of S_8^0 (rhombic), Na_2SO_3 and $Na_2SO_4 \cdot 10\,H_2O$ all of which were identified by powder x-ray diffraction. The stated concentrations of these solutions are therefore nominal and refer to conditions at the start of an experiment. Also, a yellow color, presumed due to polysulfide formation appeared in the solution during anodization.

Anodes.—Anodes were round Cd rods of 1.27 or 0.63 cm diameter. These were reagent grade Cd of 99.9% purity. Anodes used for study of voltage-time characteristics and determination of film structure and composition were machined to approximate hemispheric shape on one end, inserted in tight-fitting Teflon sleeves and chemically polished by alternate immersion in a 60:40 conc. HNO_3, glacial acetic acid solution, and water. This was followed by a 5 to 8 second immersion in a solution containing 32g CrO_3 and 6g Na_2SO_4 in 100 ml H_2O. The polishing solution was removed by washing in H_2O and the anode was given a final rinse in dry C_2H_5OH.

Anodes used for study of film thickness were embedded in polymethylmethacrylate blocks. These were subsequently cut and polished. In the polishing procedure a series of abrasive papers was employed through grit size No. 600. The specimens were then lapped on a gamal cloth wheel using first Al_2O_3 and finally a reagent grade MgO.

Anodic reaction.—Anodic reactions of Cd were studied at current densities of 0.0155, 0.0775, and 0.155 amp/cm^2 in 0.1*N* and in 0.05*N* $Na_2S \cdot 9H_2O$ in C_2H_5OH. Three replications were made for each set of conditions and the maximum cell voltages were reproducible within ±5%. Cell voltages are plotted as functions of time in Fig. 1. These curves exhibit the characteristic

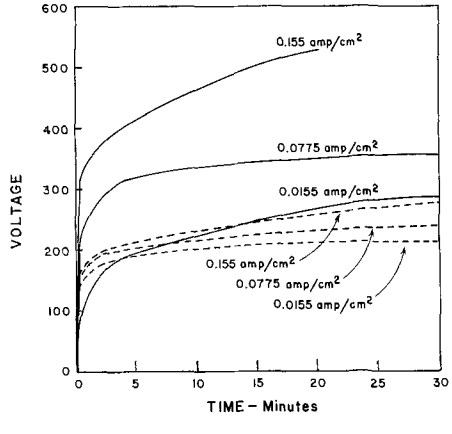

Fig. 1. Voltage-time curves for Cd anodized in solutions of $Na_2S \cdot 9H_2O$ in C_2H_5OH. Solid lines are for 0.05*N* solutions.

Table I. Electroluminescence and spark initiation voltages for anodic films on Cd in $Na_2S \cdot 9H_2O$ in C_2H_5OH

Conc. of $Na_2S \cdot 9H_2O$	Current density, amp/cm²	Electro-luminescence, v	Spark voltage, v
0.05*N*	0.155	40	230
0.05*N*	0.077	30	230
0.05*N*	0.015	35	200
0.10*N*	0.155	50	200
0.10N	0.075	30	170
0.10*N*	0.015	45	155

shape that is associated with the growth, breakdown, and sparking of anodic barrier films (7, 8). In the initial stage of the anode reaction, up to about 100v, the voltage rises very rapidly and is accompanied by the appearance of a film which exhibits a sequence of interference colors corresponding to increasing thickness. As the anodic film increases in thickness, its characteristic bright yellow color becomes more pronounced. In some cases, especially when films were grown at constant voltage, there was a tendency for films to be somewhat cloudy or opaque. The origin of this behavior is not clear as yet, but we assume it arises from contaminants in the electrolyte or in the anode, or from excessive current densities causing premature breakdown of the film. In the absence of such deleterious effects, it was usually possible to grow films to voltages in excess of 100v with no appreciable loss in transparency. In these cases gas evolution was observed starting at about 150v.

Electroluminescence and sparking were observed for the experimental conditions listed above, and the voltages at which these effects became visible are given in Table I. It is difficult to give precise voltages for the occurrence of these effects, but in replicate experiments the ranges for appearance of electroluminescence and sparking were approximately 5v and 10v respectively.

Films or coatings produced above the spark potential were all yellow or orange and opaque. The spark reaction products were normally adherent after completion of the anode reaction, but products of the same composition were ejected from the anode surface during the spark reaction.

Film and coating composition.—Qualitative chemical tests and powder x-ray diffraction analyses were used to determine film composition and structure.

Treatment of unsparked films with dilute HCl resulted in dissolution of the film, evolution of H_2S, and formation of a clear solution. No change in the appearance of smooth films, produced at 50v, was observed after immersion for two hours in CS_2. Some change such as pitting or erosion of the film would have been expected if elemental surfur had been present.

The results of powder x-ray diffraction analyses of anodic film samples obtained at different formation voltages is presented in Table II. The x-ray patterns were made on a Norelco x-ray unit using Ni filtered K_α radiation of Cu. Samples were exposed in a Debye-Scherrer camera for approximately 15 hr, with the beam at 18 ma and 40 kv.

The powder samples were prepared by scraping the film from the Cd anode after anodic formation and washing in C_2H_5OH. The Cd present in the 50 and 70v samples is introduced during the scraping and is not present in the samples of thicker coatings obtained at 90, 110, and 130v. Cd is present again in coatings formed at voltages in excess of 220v. All of the latter coatings were produced in the presence of sparking which may have been sufficiently energetic to dislodge metal from the anode. Attempts to obtain x-ray data from thin (50v) films *in situ* with the wide angle goniometer were unsuccessful and there was no evidence for either crystal structure or preferred orientation.

Electrical resistance.—The d-c electrical resistance was calculated from current and voltage values for films

Table II. X-ray diffraction analysis of films on Cd produced by anodic treatment in 0.05*N* $Na_2S \cdot 9H_2O$ in C_2H_5OH

Anodic formation voltage	Products determined by x-ray diffraction
50	Cd
70	Cd
90	CdS 3 diffuse lines
110	CdS 5 diffuse lines
130	CdS 10 diffuse lines
220 (sparking)	CdS 24 lines, Cd 20 lines
315 (sparking)	CdS 23 lines, Cd 11 lines
500 (sparking)	CdS 27 lines, Cd 8 lines
750 (sparking)	CdS 21 lines, Cd 15 lines

in contact with the electrolyte at various stages of formation. In this experiment the anodes were 1.27 cm diam Cd rods, 25 cm in length which were machined and chemically polished to produce smooth surfaces. These were masked with bands of a pressure-sensitive tape so that the anode surfaces prior to electrolytic treatment consisted of series of exposed areas 1.27 cm wide and separated by masked areas of equal width. The anodization procedure was to insert the anode to its full length in 0.05N $Na_2S \cdot 9H_2O$ in C_2H_5OH, anodize at predetermined constant voltage for periods of 10 and 45 min, and after each period of anodization to raise a section of the anode out of the electrolyte and increase the voltage to the next desired level. The data are plotted in Fig. 2. The resistance values are at least two orders of magnitude larger than the resistance of the solution in the anodic cell (which has a specific resistivity of approximately 1100 ohm cm), and thus the electrolyte contribution to the measured resistance is very small and may be neglected. The decrease in the resistance *vs.* formation voltage curves as shown in Fig. 2 at the higher voltages may be related to the development of crystal structure which the x-ray data in Table II show to occur to an increasing degree as formation voltage is increased.

A series of resistance measurements was also made with a film formed on Cd for 16 hr at 100v in 0.05*N* $Na_2S \cdot 9H_2O$ in C_2H_5OH. After forming under the above conditions, the circuit was opened and a 10 $K\Omega$ resistor was placed in series with the anode. The voltage drop across this resistor was measured with a vacuum tube voltmeter in order to calculate current flowing in the cell as voltage applied to the cell was raised in approximate 10v increments. At each voltage setting, current readings were taken over a period of time, sufficient for decay of transients, and the current density was plotted as a function of voltage on the film. These values are shown in Fig. 3. It is apparent from this plot that the current passing through the CdS film is nonlinearly dependent on the applied voltage.

Film thickness.—Film thicknesses were estimated from interference colors for samples prepared by anodizing in 0.05*N* $Na_2S \cdot 9H_2O$ in C_2H_5OH. The anodes were Cd rods mounted lengthwise in polymethylmethacrylate blocks and polished mechanically to expose a flat sur-

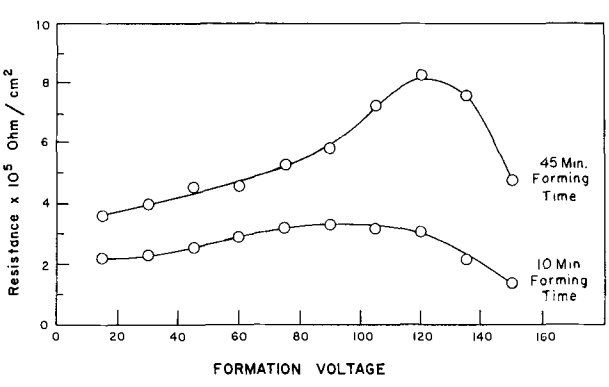

Fig. 2. Electrical resistance of anodic CdS films, formed and measured in 0.05*N* $Na_2S \cdot 9H_2O$ in C_2H_5OH at 25°C.

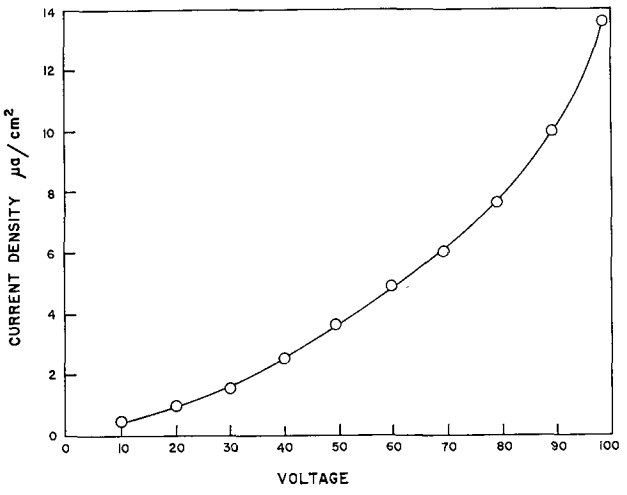

Fig. 3. Current density-voltage relation for CdS film: formed 16 hr; 100v; 0.05*N* $Na_2S \cdot 9H_2O$ in C_2H_5OH.

face measuring 0.7 x 2.4 cm. The film was prepared by anodizing at a current density which ranged between 0.3 to 2.5 ma/cm² as the applied voltage was increased from 0 to 200v at the rate of 2.4 v/min. The anode was simultaneously withdrawn from the electrolyte by means of a clock drive at a rate of 0.19 mm/min. Thus, a film increasing in thickness from 0 to that corresponding to 200v was displayed over a length of anode surface measuring 1.6 cm. There was some uncertainty as to the position of the first fringe but in the range 0 to 195v, fringes could be observed in sodium light (λ = 5893Å) and were found to be equally spaced, occurring at intervals of 45v. The last two fringes at about 150 and 195v were in a film that was slightly cloudy and it appears that in this voltage range, film growth and film breakdown occur simultaneously. Film thickness increase was calculated as a function of voltage with the aid of the expression cited by Booker and Benjamin (9)

$$d = r\frac{\lambda}{2n}$$

in which d is film thickness, r is the number of fringes, λ is the wavelength of incident light, and n is the refractive index. This latter value is assumed to be the same for the film as for bulk CdS in which n is 2.5 measured with light of the above wavelength (10). The film thickness difference between fringes is calculated at 1178Å and since this corresponds to a voltage interval of 45v, the thickness/voltage ratio is determined as 26Å/v.

Discussion

The experimental study, described in the preceding sections, of the anodic behavior of Cd in $Na_2S \cdot 9H_2O$ solutions in C_2H_5OH is of interest due to the barrier nature of the films which are produced, and the scientific and technical areas which appear as subjects for further investigation.

The barrier which forms on the Cd anodes consists of a thin film which sustains large electric fields as is shown by the appearance of interference colors, electroluminescence, and dielectric breakdown accompanied by sparking at elevated anodic voltages. Nearly all the voltage applied to the electrolysis cell is accounted for by the film since the solution resistance can account for only about 1% of the cell resistance. One can therefore estimate that fields in these films are of the order of 4 x 10^6 v/cm.

The question of composition of the films is not completely answered by the measurements made thus far, but it is clear that CdS is present in films obtained above 90v. The even spacing of interference fringes in films grown as wedges of uniformly increasing thickness, indicates that the refractive index of the film does not change appreciably over the voltage range 50 to 200v, and this would indicate that gross changes in film composition do not occur in this voltage range.

The ability to control anodic film composition and properties is of interest in connection with possible applications in electronic devices. We have prepared films similar to those described above on Cd anodes in which small quantities of Al, Cu and Mn were present as alloy constituents. Also, exploratory studies have shown that Cl can be incorporated in the CdS anodic films via anion deposition if NH_4Cl is added to the electrolyte.

The anodic formation of CdS films opens several areas of research which should yield useful results. Other Group II-IV and Group III-V compounds can probably be prepared in this form. It is also reasonable to expect that some of the compounds of Group V and VI elements with transition and inner transition metals will be accessible via anodic processes.

Conductivity Anomalies of Dimethyl Sulfone

Erik Kissa

Jackson Laboratory, Organic Chemicals Department,

E. I. du Pont de Nemours and Company, Wilmington, Delaware

ABSTRACT

The electrical conductivity of dimethyl sulfone has been measured while cooling it from 130° to 30°C at a rate of 0.5°C/min. Unlike diphenyl sulfone or chlorotriphenylmethane, dimethyl sulfone exhibited conduction anomalies attributable to proton conduction and interfacial polarization.

The chemical electret (1) was formed by solidifying a mixture of carnauba wax, resin, and beeswax in an electric field (2). Various substances have been shown to form electrets (3, 4). Unlike the classical electret, dimethyl sulfone exhibits long-lasting voltage reminiscence when a strong electric field is applied after freezing (5). Considering proton conduction and phase changes as possible causes, the conductivity-temperature relationship of dimethyl sulfone was studied.

Experimental

Purification.—Dimethyl sulfone was purified by neutralization of its acidic impurities and recrystallization from chloroform and from ethanol, dried *in vacuo* over metallic sodium, and sublimed twice. M.p. 108-109°C. Anal. Calc'd: C, 25.5; H, 6.4; S, 34.1. Found: C, 25.5; H, 6.4; S, 34.0.

Diphenyl sulfone was sublimed twice, M.p. 128°C. Anal. Calc'd: C, 66.0; H, 4.6; S, 14.7: Found: C, 66.1; H, 4.7; S, 14.7.

Chlorotriphenylmethane was recrystallized from a mixture of benzene and petroleum ether. M.p. 112-113°C. Anal. Calc'd: Cl, 12.7. Found: Cl, 12.6.

The purified compounds were stored and handled under anhydrous conditions.

Conductivity measurements.—The conductivity cells were 20 x 40 mm Pyrex vials equipped with a Teflon plug through which an inlet tube for dry argon, a thermocouple well, and two platinum wire electrodes, 10 mm apart, were introduced. The upper part of the electrodes was covered with a glass tubing, leaving a 10-mm long portion exposed.

The conductivity cells were charged with molten samples and cooled slowly to room temperature. After standing 16 hr they were heated to 130°C and cooled in an oil bath at a rate of 0.5°C/min. A General Radio impedance bridge was used at 1 kc frequency for measuring resistances up to 10^7 ohms. For higher resistances, a General Radio type 1862-B megohm-meter was used, by applying two 1-sec long d-c pulses of opposite polarity.

On heating from 28° to 130°C, dimethyl sulfone, diphenyl sulfone, and triphenylmethane did not exhibit conduction anomalies: the apparent conductivities increased gradually with the increasing temperature until melting occurred with a sharp conductivity increase.

Typical conductivity curves obtained by cooling the molten compounds from 130° to 30°C are shown in Fig. 1. The conductivity minimum slightly below the freezing point was present also with carbon electrodes or when switching from one pair of platinum electrodes to another pair arranged crosswise.

The conductivity of molten dimethyl sulfone changed only by 20% rel. when subjected to the (about 1-v a.c.) output of the impedance meter for 3 hr. However, an application of 50v d.c. increased the conductivity of molten dimethyl sulfone 2.7 times in 3 hr, and an acidic electrolysis product had formed.

Dielectric properties.—Dielectric measurements were carried out in the frequency range betwen 200 and 6000 cps with a General Radio Type 716-C capacitance bridge equipped with a Balsbaugh cell. The dielectric constant-temperature curve of cooling dimethyl sulfone exhibited a peak which was frequency-dependent and weakened with time. It was very strong at 200 cps and disappeared at 6000 cps (Fig. 2). The peak in the dissipation factor-temperature curve was also time- and frequency-dependent; at 200 cps (Fig. 2) it was too high to be measured.

Discussion

The conduction anomalies of dimethyl sulfone can be explained by accumulation of space charges associated with proton conduction and coexistence of two phases with different conductivities, already observed in long-chain alcohols (6). Frosch (7) explained the rise in dielectric constant of n-octadecanol by interfacial polarization, caused by the coexistence of liquid and solid phases. Hoffman and Smyth (8) believed this to be improbable and concluded that two solid phases formed on freezing. The highly conductive α phase, in which proton transfer was facilitated by molecular rotation, changed via a nonconductive β_1 form to the stable β_2 form.

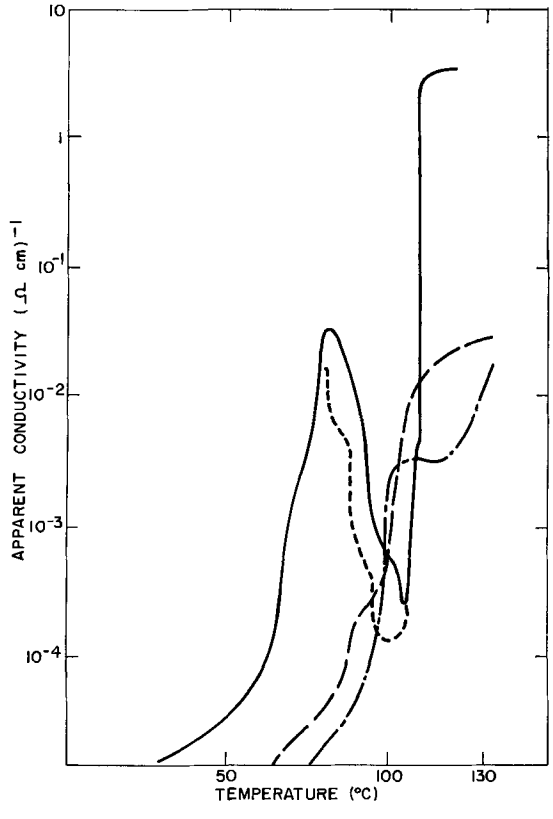

Fig. 1. Apparent conductivities of dimethyl sulfone, diphenyl sulfone, and chlorotriphenylmethane during cooling of their melts. ——, $CH_3SO_2CH_3$; — — —, $CH_3SO_2CH_3$ reversed direction; — - —, $C_6H_5SO_2C_6H_5$; —— ——, $(C_6H_5)_3$ CCl.

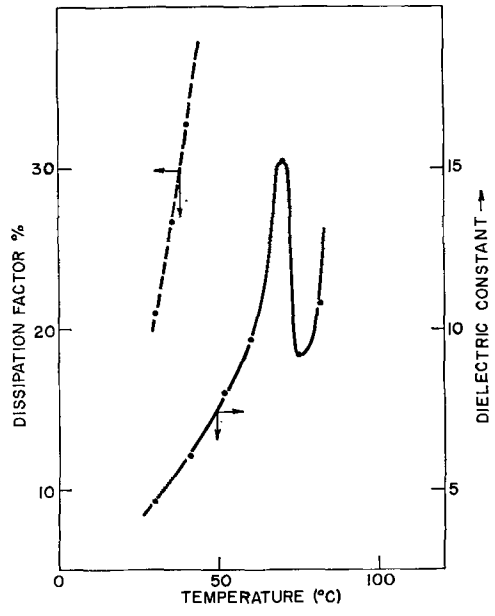

Fig. 2. Temperature dependence of the dielectric constant and the dissipation factor at 200 cps.

The conductivity minimum of freezing dimethyl sulfone appears with the formation of first crystals on the electrodes and is associated with interfacial polarization. With progressing solidification a conductive pseudo-solid is formed, in which molecular rotation may permit a proton transfer. On further cooling the metastable amorphous phase transforms into the stable crystalline form which does not permit molecular rotation, and the resistance increases again.

The release of protons in dimethyl sulfone under electric stress is indicated by its dielectric properties and by the formation of acidic electrolysis products. The somewhat acidic nature of hydrogen in dimethyl sulfone has been demonstrated by Hochberg and Bonhoeffer (9) who observed hydrogen-deuterium exchange in alkaline D_2O. Activation of hydrogen by the sulfonyl group is shown also by metalation with a Grignard reagent (10, 11).

Diphenyl sulfone and chlorotriphenylmethane cannot provide protons and do not show conductivity anomalies.

Measurements of electric conductivity change during phase transitions may provide a method for structure determination and identification of compounds which release a proton under electric stress.

Acknowledgment

Hydrogen Overvoltage on Rhenium and Niobium Electrodes

M. J. Joncich[1] and L. S. Stewart[2]

Department of Chemistry, University of Tennessee, Knoxville, Tennessee

and F. A. Posey

Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

ABSTRACT

Polarization curves of the hydrogen evolution reaction are presented for rhenium and niobium electrodes in dilute hydrochloric acid solutions as a function of temperature. The Tafel reaction is the rate-determining step in the hydrogen evolution reaction on rhenium. The behavior of niobium electrodes is much more complicated. The presence of the passive oxide layer on niobium produces an ohmic contribution to the total overvoltage. The corrected activation-overvoltage curves for niobium show a change of Tafel slope which is consistent with a Volmer-Tafel mechanism if certain assumptions are made about the distribution of potential at the interface. Activation energies of the hydrogen reaction are computed for both rhenium and niobium electrodes.

Comparatively few studies on the electrochemical behavior of rhenium and niobium electrodes have been reported. Pecherskaya and Stender (1) measured hydrogen overvoltage on rhenium. Hydrogen overvoltage on niobium was studied by Bockris (2), by Kononchuk and Barmashenko (3), and by Rotinyan and Kozhevnikova (4). The use of Nb as a pH-responsive electrode was investigated by Jensovsky (5) and by Galinker (6). An electrode potential-pH diagram for rhenium was constructed from available thermodynamic data by Pourbaix (7). Anodic oxidation of rhenium was studied by Lavrenko (8), while the anodic behavior of niobium has been the subject of a number of investigators (9-22).

Here we present data for hydrogen overvoltage on rhenium and niobium electrodes in dilute hydro-

[1] Present address: Department of Chemistry, Northern Illinois University, DeKalb, Illinois.

chloric acid solutions. Current densities from 10^{-6} to 10^{-2} amp/cm^2 were used and measurements were made over the temperature range, 5°-45°C. Conclusions are drawn about the mechanism of the hydrogen evolution reaction on rhenium and niobium under these conditions and the apparent activation energies of the reactions are calculated.

Experimental

The experimental cell was similar to that described by Ammar and Awad (23) except for certain modifications which facilitated cleaning and equalization of hydrogen pressure in the three cell compartments. Teflon stopcocks were used throughout the apparatus. A platinum electrode of large area was employed as a polarizing electrode, and the current density at this electrode was kept low enough so that no significant oxygen evolution occurred (24).

The hydrogen reference electrode was constructed of 30-gauge platinum wire and checked frequently against a standard calomel electrode. Cathodes for pre-electrolysis were made of the same metal as the electrodes used in the experiments. Rhenium electrodes were constructed from wires fabricated from 99.99% pure rhenium powder by Sylvania Electric Products Inc. Spectroscopic analysis of this material showed Ca, 0.01-0.1%; Fe, 0.01%; and Si, 0.1%. Niobium metal was obtained from a sheet cold-pressed at 40 tons/in.^{2} and purified by a zone-refining method. Spectroscopic analysis of the niobium showed O, 0.01%; N, 0.018%; C, 0.010%; Zr, 0.04%; and Ta, 0.14% by weight. Rhenium and niobium electrodes were mounted in Teflon holders, cleaned by immersion in hydrochloric acid, and rinsed repeatedly with distilled water and with conductance water.

Electrolytic tank hydrogen was purified by passage through a train consisting of an alkaline solution of potassium permanganate, cocoanut charcoal, silica gel, Anhydrone, Hopcalite, Ascarite, DeOxy Catalytic Purifier, and silica gel. A gas washer located between the purification train and the cell was used to saturate the hydrogen gas with the test solution. Temperature control was accomplished by use of an insulated air bath; temperature was constant to within ± 0.1°C.

Hydrochloric acid solutions were prepared by dilution of a constant-boiling distillate of reagent grade hydrochloric acid and conductance water. Pre-electrolysis was conducted for a minimum of 50 hr with a current of 4-5 ma. Several hours were allowed for the establishment of temperature equilibrium. A L&N pH Indicator was used to measure both potentials and currents. Current was supplied from a bank of batteries and regulated by use of variable resistors. Electrode potentials were measured by the direct method within a few minutes after application or change of polarizing current as recommended by Schuldiner (25). Potentials measured in this manner were stable and polarization curves were reproducible. Stirring by hydrogen gas was continued during the measurements.

Results

Tafel plots of data for hydrogen overvoltage on rhenium electrodes in 0.037*N* and 0.145*N* HCl are shown in Fig. 1 and 2. Resistance overvoltage due to IR drop in the solution phase between the electrode surface and the tip of the reference electrode capillary contributes significantly to the measured overvoltage at the higher current densities. The resistive contribution was subtracted from the measured overvoltage values by a series of successive graphical approximations. Use of this correction, together with a correction due to the rate of the anodic reaction near the equilibrium potential, leads to the dashed Tafel lines in Fig. 1 and 2. The exact value of the resistance correction varied with each series of measurements because of unavoidable differences in the placement of the reference electrode capillary. Values of the resistance corrections for the data of Fig. 1 are 13.9, 13.7, 8.7, and 12.3 ohm-cm^2 at

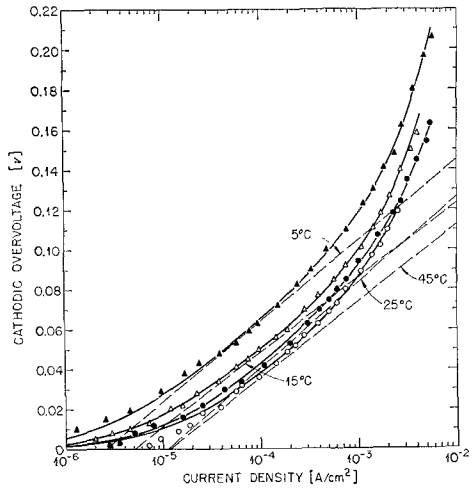

Fig. 1. Hydrogen overvoltage on rhenium in 0.037*N* HCl as a function of temperature; temperature in °C: ▲, 5; △, 15; •, 25; ○, 45. Solid lines are calculated polarization curves; dashed lines are cathodic Tafel lines corrected for resistance overvoltage and the rate of the anodic reaction.

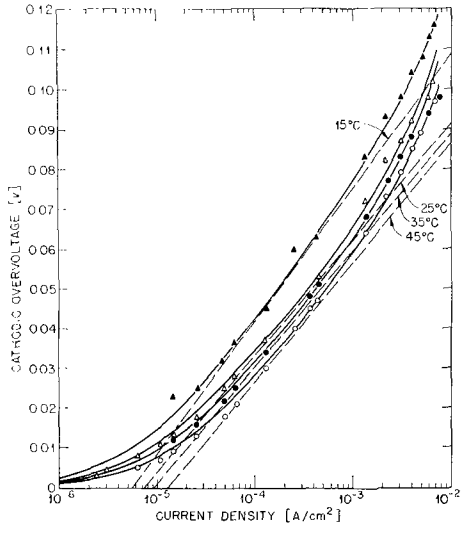

Fig. 2. Hydrogen overvoltage on rhenium in 0.145*N* HCl as a function of temperature; temperature in °C: ▲, 15; △, 25; •, 35; ○, 45. Solid lines are calculated polarization curves; dashed lines are cathodic Tafel lines corrected for resistance overvoltage and the rate of the anodic reaction.

5°, 15°, 25°, and 45°C, respectively. Corrections for resistance overvoltage for the data of Fig. 2 are similar, except that resistance values are only one-fourth as large as those necessary to correct the data of Fig. 1 because the solution concentration is approximately four times greater.

Tafel plots of the anodic reaction, calculated from the difference between the experimental data points and the dashed Tafel lines in Fig. 1 and 2 in the region near the equilibrium potential, show that the rate of this reaction is independent of the overvoltage. Use of this fact, taking into account the resistance overvoltage, leads to Eq. [1] for the total overvoltage. In Eq. [1], $|\eta|$ (V) is the absolute value of

$$|\eta| = |b| \log \left(1 + \frac{|j|}{j_o}\right) + |j|R_s \qquad [1]$$

the overvoltage, $|b|$ (V/decade of current) is the absolute value of the Tafel slope, $|j|$ (amp/cm^2) is the absolute value of the applied current density, j_o (amp/cm^2) is the exchange current density, and R_s (ohm-cm^2) is the resistance between the electrode surface

Table I. Parameters for hydrogen overvoltage on rhenium electrodes in dilute hydrochloric acid solutions

Solution	Temperature, °C	a, v	b($\times 10^3$), v	j_o, (amp/cm²)
0.037*N* HCl	5	−0.226	−40.5	2.65×10^{-6}
	15	−0.198	−37.5	5.1×10^{-6}
	25	−0.213	−43.0	1.14×10^{-5}
	45	−0.189	−38.4	1.18×10^{-5}
0.145*N* HCl	15	−0.176	−33.5	5.7×10^{-6}
	25	−0.150	−29.2	7.3×10^{-6}
	35	−0.147	−29.3	9.3×10^{-6}
	45	−0.147	−30.0	1.3×10^{-5}

and the reference electrode capillary tip.[3] Table I presents values of the Tafel a and b constants as well as values of the exchange current density calculated from the Tafel lines in Fig. 1 and 2. The a and b constants are defined conventionally by Eq. [2], which is Tafel's equation. Values of j_o, b, and R_s

$$\eta = a + b \log |j| \qquad [2]$$

were used with Eq. [1] to calculate the solid lines in Fig. 1 and 2; these theoretical lines fit the data very well.

Data for hydrogen overvoltage on niobium electrodes in 0.145*N* HCl are shown in Fig. 3. In this case, a large correction for resistance overvoltage is necessary; this correction was made in the same manner as that used for the data of Fig. 1 and 2. Resistive corrections in the case of the rhenium electrode in 0.145*N* HCl (cf. Fig. 2) average approximately 2.5 ohm-cm², which is consistent with the conductivity of the solution and the placement of the tubulus of the reference electrode, whereas those for the niobium electrode average approximately 216 ohm-cm². We suggest that, during the time necessary for the measurement of the overvoltage, no significant change occurs in the thickness of the oxide layer on the surface of the niobium electrodes. The poor electronic conductivity of the passive layer then accounts for the large resistive contribution to the measured overvoltage. Since the electronic conductivity of the passive oxide layer on niobium in solution is not known accurately, no reliable estimate can be given, in the absence of capacity measurements, of the film thickness on the electrodes used here. The resistive correction for the ohmic behavior of the film in this case may be defined by Eq. [3]

[3] Equation [1] is essentially Hammett's relation (26) for the Tafel mechanism of the hydrogen evolution reaction. In this case the exchange current density (j_o) is equal to j_r, the limiting current density of the Tafel reaction, which is independent of electrode potential.

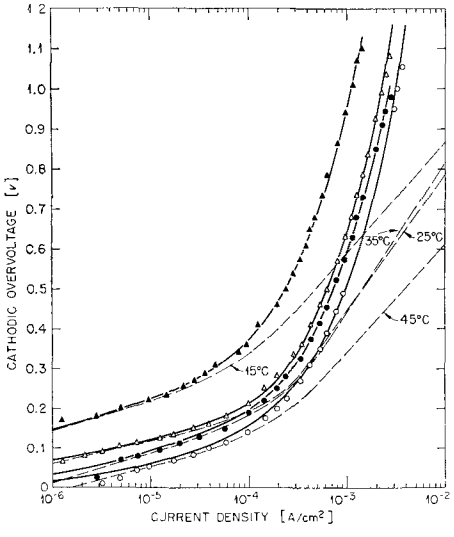

Fig. 3. Hydrogen overvoltage on niobium in 0.145*N* HCl as a function of temperature; temperature in °C: ▲, 15; △, 25; ●, 35; ○, 45. Solid lines are calculated polarization curves; dashed lines are cathodic Tafel lines corrected for resistance overvoltage and the rate of the anodic reaction.

$$R_{ox} \equiv \Delta\phi_{ox}/j = l/\sigma_{ox} \qquad [3]$$

where R_{ox}(ohm-cm²) is the resistivity correction, $\Delta\phi_{ox}$ is taken to be the potential difference across the oxide layer, j is current density, l is the thickness of the layer, and σ_{ox} is the specific conductance of the layer. For $R_{ox} = 200$ ohm-cm², σ_{ox} would have a value between 10^{-9} and 10^{-7} ohm^{-1} cm^{-1} if the film thickness were between 20 and 2000Å. This order of magnitude of specific conductance for the Nb_2O_5 layer at the temperatures of this study is not unexpected in view of the results obtained elsewhere on the specific conductance of sintered and single crystal Nb_2O_5 specimens as a function of departure from stoichiometry and of temperature (27-29).

Correction of the data of Fig. 3 for the ohmic contribution leads to the dashed Tafel lines shown in the graph. In this case, a change of Tafel slope occurs, corresponding to a change in the identity of the rate-determining step in the hydrogen evolution reaction. The corrected overvoltage data are described well by an expression of the form of Eq. [4]

$$j_c = \frac{j_{o,1}\, j_{o,2} \exp\left[-2.303\left(\frac{1}{b_1}+\frac{1}{b_2}\right)\eta\right]}{j_{o,1} \exp\left[-2.303\eta/b_1\right] + j_{o,2} \exp\left[-2.303\eta/b_2\right]} \qquad [4]$$

where j_c is the current density of the cathodic process, $j_{o,1}$ and $j_{o,2}$ are the exchange current densities obtained by extrapolation of the two Tafel regions to zero overvoltage, and b_1 and b_2 are the corresponding Tafel slopes (cf. Eq. [2]).[4] Values of parameters for the overvoltage in this case are given in Table II. The solid lines in Fig. 3 are theoretical polarization curves calculated by use of Eq. [4] and the data of Table II together with the correction for the ohmic behavior of the passive layer and for the rate of the anodic reaction near the equilibrium potential.

Estimated exchange current densities from the data of Fig. 1, 2, and 3 are plotted as a function of temperature in Fig. 4 and 5. In the case of the rhenium electrode, exchange current densities are essentially independent of the concentration of hydrogen ions, and the line shown in Fig. 4 is a least squares fit of all the data. The slope of the line is equivalent to an apparent enthalpy of activation of 5.96 kcal/mole. The apparent enthalpy of activation of the rate-determining process in the low current region on niobium is found from Fig. 5 to be 31.4 kcal/mole. The corresponding value for the process which determines the rate at larger overvoltages is 11.3 kcal/mole. Both values were determined by least squares fit of a simple Arrhenius-type equation to the available data.

Discussion

The data of Pecherskaya and Stender (1) for hydrogen overvoltage on rhenium were obtained in 2*N*

[4] Equation [4] is a generalized form for the cathodic polarization curve of the hydrogen evolution reaction in the case of a dual mechanism with small surface coverage of adsorbed hydrogen atoms. With $j_{o,1} = j_o^V/2$, $j_{o,2} = j_r$, $b_1 = 2.303\ RT/(1-\alpha_V)F$, and $b_2 = 2.303\ RT/2F$, Eq. [4] is a form of the Hammett equation (30) for the Volmer-Tafel mechanism of the hydrogen evolution reaction. In this case, j_o^V is the exchange current density of the Volmer reaction, j_r is the limiting current density of the Tafel or recombination reaction, and α_V is the transfer coefficient of the Volmer reaction. However, for $j_{o,1} = 2j_o^V$, $j_{o,2} = 2j_o^H$, $b_1 = 2.303\ RT/(1-\alpha_V)F$, and $b_2 = 2.303\ RT/(2-\alpha_H)F$, Eq. [4] is a form of Vetter's relation (31) for the Volmer-Horiuti reaction sequence. In this case, j_o^V and j_o^H are the exchange current densities of the Volmer and Horiuti reactions, respectively, and α_V and α_H are the corresponding transfer coefficients.

H_2SO_4 at 25°C. These authors reported an exchange current density of approximately 10^{-3} amp/cm² in the medium studied and a Tafel slope of $b = 0.14$v. Their data are not extensive, and only one data point is in very good agreement with this work. Pecherskaya and Stender report a cathodic overvoltage of 0.09v at a current density of 5 x 10^{-3} amp/cm²; this value compares favorably with the corrected Tafel lines of Fig. 1 and 2. Hydrogen overvoltage on rhenium is quite low; it is comparable to that found for iridium and rhodium (32).

We find that the Tafel slopes for the hydrogen evolution reaction on rhenium in dilute hydrochloric acid are close to 30 mv/decade (cf. Table I). The Tafel slopes obtained in 0.037*N* HCl are somewhat higher than this value, but double layer effects are probably important here, and the resistive correction is less certain in the more dilute solution. Calculations of the rate of the anodic reaction near the equilibrium potential show that the rate of this reaction is independent of potential, and the exchange current densities obtained by extrapolation of the Tafel lines are insensitive to the concentration of hydrogen ions in solution. These facts suggest that the Tafel reaction, $2H_{(ads.)} = H_{2(aq.)}$, determines the rate of the hydrogen evolution reaction on rhenium. This conclusion is supported by values of the stoichiometric numbers obtained from the polarization resistances and the estimated exchange current densities. All calculated stoichiometric numbers are near unity, ranging from 0.8 to 1.3.

Our value of the Tafel slope (30 mv/decade) may still be consistent with that of Pecherskaya and Stender (140 mv/decade) if a transition in the nature of the rate-determining step occurs near current densities of 10^{-2} amp/cm². In this case, an increase in cathodic polarization would increase the surface coverage of adsorbed atomic hydrogen to the point where the Tafel reaction would be essentially in equilibrium, and the rate of the over-all reaction would then be controlled by the Volmer reaction, $H^+_{(aq.)} + e^- = H_{(ads.)}$ (33). The apparent activation energy at the equilibrium potential of the hydrogen reaction on rhenium, obtained from Fig. 4 as 5.96 kcal/mole, refers in this case to the mean enthalpy of activation of the forward and reverse steps of the Tafel reaction.

The data on hydrogen overvoltage on niobium of Bockris (2) in 0.1*N* HCl and of Kononchuk and Barmashenko (3) in 1*N* H_2SO_4 are fragmentary, and the Tafel slopes do not agree with those observed here. The reason for this discrepancy is not known; it is possible that their measurements were influenced by the presence of impurities which could exert an important effect on the results in such a polarizable system. The measurements of Rotinyan and Kozhevnikova (4) are more extensive, and their observations resemble ours to a greater extent. These authors measured hydrogen overvoltage on niobium in 0.01-10.0*N* H_2SO_4 at temperatures from 25° to 55°C. They found nonlinear Tafel plots in the region 10^{-5}-10^{-4} amp/cm², whereas linear Tafel plots were obtained for current densities greater than 10^{-4} amp/cm². In addition, deviations from linearity were observed in dilute solutions for current densities greater than about 2 x 10^{-3} amp/cm² at 25°C.

The results of Rotinyan and Koshevnikova are understandable on the basis of the data in Fig. 3. The Tafel plot in the range, 10^{-5}-10^{-4} amp/cm², is nonlinear because of the effect of the anodic reaction and because the change in Tafel slope occurs in this range of current densities. Above approximately 10^{-4} amp/cm², linear Tafel plots could then be obtained in concentrated acidic solutions; under these conditions the thickness of the oxide layer on the surface of the niobium electrode and thus the ohmic contribution to the total overvoltage should be much less than in dilute acids. However, in dilute acids the ohmic properties of the passive oxide layer should contribute significantly to the total overvoltage, and in this case one should expect nonlinear Tafel plots, as found by Rotinyan and Kozhevnikova.

The Tafel slopes observed in the two linear regions of the polarization curves in Fig. 3 average $b_1 = 67$ mv and $b_2 = 318$ mv, respectively. Transitions in Tafel slope are expected for the hydrogen evolution reaction on electrodes with no superficial oxide layers for the Volmer-Tafel and the Volmer-Heyrovsky mechanisms (33). The Volmer-Tafel mechanism involves a transition in Tafel slope from 29 to 116 mv/decade at 25°C for normal values of the transfer coefficients, whereas Tafel slopes of the Volmer-Heyrovsky mechanism should show a transition from 39 to 116 mv/decade. Although the transition in Tafel slopes is observed on niobium, values of the slopes are roughly twice those expected at an interface with no passive oxide layer.

Unusual values of Tafel slopes for oxidation-reduction reactions on passive electrodes have been discussed by Posey, Cartledge, and Yaffe (34), Meyer (35), MacDonald and Conway (36), and Makrides (37). The dual-barrier model and its variations used by these authors account for high values of Tafel slopes which are frequently found on passive metals. In this model, the distribution of potential at the passive interface is recognized to be complex; only that part of the total potential difference between metal and solution which exists at the oxide-solution interface affects the rate of electrochemical charge-transfer steps

of oxidation-reduction reactions. For cases where transfer of charge must occur across two energy barriers, both of which are affected by changes in the total interfacial potential difference, the Tafel slope of the over-all reaction is given by Eq. [5], where

$$b_{(\text{dual barrier})} = 2.303 \frac{(\beta_1 + \beta_2)RT}{\beta_1 \beta_2 F} \quad [5]$$

β_1 and β_2 are the transfer coefficients of the separate energy barriers (34). If $\beta_1 = \beta_2 = 1/2$, then the Tafel slope will be 2.303 ($4RT/F$) instead of 2.303 ($2RT/F$) for a simple reaction in a system involving a single barrier. The Tafel slopes of Fig. 3 can be understood on this basis. The dashed lines are corrected for the ohmic behavior of the passive layer, so that only the potential differences at the metal-oxide interface and at the oxide-solution interface need be considered. If both of these potential differences can vary with cathodic current, then the dual-barrier model and the formula of Eq. [5] should be applicable. The ratio of Tafel slopes for regions of high and low current density in the case of the Volmer-Tafel reaction is 4; that for the Volmer-Heyrovsky reaction is 3. The ratio of the average Tafel slopes of Fig. 3 is 4.7, although that for the results at 15° and at 45°C is 3.9 and 4.2, respectively. We conclude tentatively that the Volmer-Tafel mechanism of the hydrogen evolution reaction operates on niobium in dilute hydrochloric acid solutions and that the high Tafel slopes observed are a consequence of the existence of a passive layer which is described to a first approximation by a dual-barrier model.

Activation energies calculated from the plot of exchange current densities as a function of temperature in Fig. 5 are 31.4 kcal/mole for the Tafel reaction on the niobium surface and 11.3 kcal/mole for the Volmer reaction. These values represent the mean enthalpies of activation of the forward and reverse steps of the respective reactions. The value of 11.3 kcal/mole for the Volmer reaction is comparable to the value of 10.5 kcal/mole calculated by Rotinyan and Kozhevnikova from their data in the range from 10^{-4} to 10^{-2} amp/cm^2. Extrapolation of the lines in Fig. 5 to their point of intersection shows that the exchange current densities of the Volmer and Tafel reactions should be equal in the vicinity of 90°C. Therefore at temperatures higher than about 90°C, the Volmer reaction alone should govern the over-all rate of the hydrogen evolution reaction and no change of Tafel slope should be observed in the cathodic polarization curve of niobium.

Conduction Properties of Valve Metal-Oxide Systems

I. A New Theory

M. J. Dignam

Department of Chemistry, University of Toronto, Toronto, Ontario, Canada

ABSTRACT

A theory of cooperative ion transport in anodic oxide films on valve metals has been developed on the basis of a dielectric mosaic model. The oxide, which is "amorphous," is considered to be composed of very small crystallites or polymeric units. Ion transfer from one such unit to another is strongly influenced by the distribution of ions within these units since the field assisting the transfer will be a function of the polarization of the dielectric oxide medium. Transient ionic conduction phenomena and anomalous charging currents arise as a result of the slow adjustment of the polarization of the medium to new conditions. Two mechanisms for the rate of change of the polarization are employed, one involving thermally activated ion migration, the other being associated with the large energies dissipated during an ion transfer event. The equations arising from this model have been solved for a number of particular experimental conditions.

Recent data (1-8) concerning the anodic oxidation of the valve metals have revealed serious limitations in all previous quantitative theories dealing with the growth mechanism for these oxides. The purpose of this paper is to present a new theory which is in accord with the facts now available. In the following paper this theory is compared with previous theories, the principal one being the high field Frenkel defect theory (9), in relation to most pertinent data.

It seems likely that the main fault of previous theories lies in their failure to allow for cooperative phenomena associated with ion migration through the film. Although the possibility of such phenomena has been mentioned by Young (9) no attempt has been made previously to allow quantitatively for them. According to the high field Frenkel defect theory, transient conduction phenomena arise as a result of a slow readjustment of the concentration of ionic current carriers following a change in the field strength or current density. In the present theory the transients are ascribed to cooperative transport phenomena, the concentration of current carriers being essentially independent of field strength and current density. The detailed model, which rests on time dependent dielectric polarization phenomena, can be regarded at the very least as an "incorrect model" which nevertheless leads to the correct form for the cooperative phenomena, and at most a satisfactory approximation to the "true model."

The paper is divided into five sections with this section followed by Outline of Theory and Summary and Discussion providing the descriptive development of the theory. The detailed mathematical development has been confined to the remaining two sections. The major support for the theory is presented in the following paper (10) in which excellent agreement between the present theory and data is demonstrated.

Outline of Theory

In the present theory the oxide is treated as a nonuniform dielectric, being composed of very small crystallites or polymeric "molecular" units. Since the bonding possesses a considerable covalent character (11), the intra-"molecular" bonding will be stronger than the inter-"molecular" bonding. This will lead to regions of low density, or quasi gaps, between adjacent molecular units. The low density found for these oxides compared with their bulk densities is consistent with the above model.

Two simultaneous rate-controlling processes for ion transport through such an oxide must be considered. The one is associated with the transfer of ions from one molecular unit to the next, and the other with ionic migration within the molecular units. We shall focus attention initially on the former.

Because of the discontinuous nature of the dielectric medium, the electric field, E_e, assisting this ion transfer process will depend on the polarization of the oxide, P, so that we may write

$$E_e = E + \delta P/\mathcal{E}_o \qquad [1]$$

where E is the applied field, $\mathcal{E}_o$ the permittivity of free space, and δ a geometric factor of the order of unity introduced since the detailed geometry of these quasi gaps is unknown.

In order to take account of ion migration within the molecular units, the polarization term is separated into two terms, $P = P_1 + P_2$, where P_1 is considered to arise from conventional inertial and electronic polarization processes and P_2 from ion transport within the individual molecular units. The ordinary polarization, P_1, will have a small relaxation time and may be considered to follow the applied field in the normal manner

$$P_1 = \mathcal{E}_o \chi_1 E \qquad [2]$$

where χ_1, the electric susceptibility of the oxide measured at sufficiently high frequencies, say 1 kc, is to a good approximation independent of field and time. The ion transport polarization, P_2, however, since it involves mass transport, will have a large relaxation time so that it will vary linearly with the applied field only under steady-state conditions of constant field and current density.

In attempting to predict the variation of the transport polarization, P_2, with the field strength, time, and current density, there are several factors which should be borne in mind. If the effective field strength, E_e, is sufficiently high to cause a significant number of ion transfer events per unit time per unit volume, then the energy imparted to the molecular units as a result of these events will be very important and must be taken into account. From the available kinetic data (12) one can estimate that the energy imparted to a molecular unit receiving a charged species will be, for example, about 5 ev or more for a tantala film, which in relation to the estimated diameter of a molecular unit, 9Å (10), represents a very considerable energy density. Indeed such a unit will possess about 10^3 degrees of freedom, giving an impact energy per degree of freedom of about 0.2 kt at room temperature, or about ½ the mean thermal energy. The impact energy will be highly localized initially, making its effect greater than the above estimate would suggest. Under conditions where the collision process will be important, that is for ion current densities which are

not too small, it is to be expected that the rate of change of the transport polarization, P_2, is controlled almost solely by the collision density per unit time, the rate associated with conventional thermally activated processes being negligible by comparison. For sufficiently low ion current densities, however, thermally activated polarization processes must predominate.

A possible mechanism for the collisionally activated polarization process follows: Immediately following an ion transfer event, the donor and acceptor molecular units will be depolarized or perhaps even acquire a dipole moment in the opposite direction. To re-establish their previous dipole moments or acquire their equilibrium dipole moments, ion migration in each is required. The high impact energy involved in the ion transfer event should be more than enough to produce both defects and sufficient vibrational excitation to establish in a short time the local equilibrium dipole moment for both the donor and acceptor molecular units.

To complete the outline of the theory, some statement as to how the ion current density varies with E_e and time is required. At any given moment it is apparent that certain of the molecular units will have a net electrostatic charge by virtue of their possessing an excess or deficit of the mobile species involved in the ion transfer process. Provided that the number density of these charged molecular units is independent of E_e at fixed temperature, the ion current density can be represented as a function of E_e and temperature only, the functional form being very similar to the exponential relationship conventionally used to interpret steady-state anodic oxidation data. Accepting this provision for the moment, we see that, for the present model, transient ionic conduction phenomena arise entirely from the time dependent polarization phenomena within the oxide film. The most critical tests of this model will therefore involve the measurement of transients, although certain unique predictions concerning steady-state anodic oxidation can also be subject to verification.

Mathematical Development of Model

In this section the model outlined will be used to obtain first a specific equation relating the ion current density to the effective field strength, then a differential equation for the variation with time of the dielectric polarization, and finally solutions of these equations for certain special cases.

Dependence of ion current on the effective field strength.—We shall assume, in accord with normal practice, that only one species bearing a charge rZe is involved in the ion transfer process and further that the majority of the molecular units are electrostatically neutral (where Z is the absolute value of the oxidation state of the species, e the charge on the proton, and $r = 1$ or -1 according to the sign of the charge on the species). The small contribution to kinetic processes made by units possessing a charge which differs from zero or $\pm Ze$ will be neglected.

From the above it is sufficient to consider the following four types of ion transfer processes:

1. Transfer from a neutral species to an adjacent neutral species, with a transfer probability, p_o
2. Transfer from a species with a charge rZe to an adjacent neutral species, with a transfer probability, $p_{+r} >> p_o$.
3. Transfer from a neutral species to an adjacent species with a charge $-rZe$, with a transfer probability, $p_{-r} >> p_o$.
4. Transfer from a species with a charge rZe to an adjacent species with a charge $-rZe$, with a transfer probability $>> p_{+r}$ or p_{-r}.

In a previous publication (12) it was shown that the net activation energy, $W'(E_e)$, for the transfer of a charged species across a potential energy barrier in the presence of a high electrostatic field, E_e, is given by

$$W'(E_e) = \phi' - E_e\mu^{*\prime}(1 - E_e\mu^{*\prime}/C'\phi')$$

where ϕ' is the zero field activation energy, $\mu^{*\prime}$ the zero field "activation dipole" (*i.e.*, effective charge times activation distance for the ion transfer process), and C' a dimensionless parameter the value for which depends on the shape of the potential energy barrier.[1] The transfer probability per unit time from a given molecular unit will therefore be given by

$$p_o = N'\nu \exp\{-[\phi' - E_e\mu^{*\prime}(1 - E_e\mu^{*\prime}/C'\phi')]/kT\} \quad [3]$$

Associating Eq. [3] with process 1 and assuming that a charge rZe on a molecular unit will change the transfer probability to or from this unit simply by contributing a constant additional field term, $\mathcal{E}_r$, to the effective field which would exist in the absence of such a charge, we may write

$$p_{+r} = N'\nu \exp\{-[\phi' - [E_e + \mathcal{E}_{+r}]\mu^{*\prime}(1-[E_e + \mathcal{E}_{+r}]\mu^{*\prime}/C'\phi')]/kT\} \quad [4]$$

or

$$p_{+r} = \kappa_{+r}p_o \quad [5]$$

where

$$\kappa_{+r} = \exp\{\mathcal{E}_{+r}\mu^{*\prime}[1-(2E_e + \mathcal{E}_r)\mu^{*\prime}/C'\phi']/kT\} \quad [6]$$

A corresponding set of equations is obtained for p_{-r} from the above by replacing $+r$ with $-r$. The terms $\mathcal{E}_{+r}$ and $\mathcal{E}_{-r}$ will be positive and represent the constant field contributed by the net charge on one of the molecular species. From geometric considerations, it follows that $\mathcal{E}_{+r} > \mathcal{E}_{-r}$ and hence that $\kappa_{+r} > \kappa_{-r}$. If the quadratic term in the field in the net activation energy did not exist (*i.e.*, $1/C' = 0$), then κ_{+r} and κ_{-r} would be strictly independent of E_e. The presence of the quadratic term introduces a variation in κ_{+r} and κ_{-r} with E_e which is negligible compared with the variation of p_o with E_e provided that $\mathcal{E}_{+r}\mu^{*\prime}/C'\phi' << 1$, a statement in accord with the values obtained experimentally for aluminum (10). Associating the ion current (*i.e.*, the current leading to film growth) i, with the ion transfer processes 1 to 4, we may write

$$i = Zed[n_op_o + n_{+r}\kappa_{+r}p_o + n_{-r}\kappa_{-r}p_o + (\kappa_{+r} + \kappa_{-r})p_od(f\sigma')n_{+r}n_{-r}] \quad [7]$$

where d is the mean dimension of a molecular unit along the field direction and n_o, n_{+r}, and n_{-r} the volume concentrations of molecular units which bear changes of zero, $+rZe$ and $-rZe$, respectively. The final term within the square brackets of Eq. [7] requires some explanation. It represents the rate of annihilation of charged molecular units by transfer process 4, which has been treated as a "collision" annihilation with a "capture" cross-sectional area ($f\sigma'$), which should be about equal to or somewhat greater than the mean cross-sectional area, σ' ($=1/Nd$, where N is the volume concentration of molecular units), of the molecular units in a plane normal to the applied field. In an analogous manner, the net rate of formation of charged molecular units is given by

$$\frac{dn_{+r}}{dt} = \frac{dn_{-r}}{dt} = n_op_o - (\kappa_{+r} + \kappa_{-r})p_od(f\sigma')n_{+r}n_{-r} \quad [8]$$

If at some time steady-state concentrations prevail (*i.e.*, $dn_{+r}/dt = 0 = dn_{-r}/dt$) it follows from Eq. [8] that any subsequent changes in the field, E_e, under isothermal conditions, will have a negligible effect on n_{+r}, n_{-r}, and n_o (since the variation of κ_{+r} and κ_{-r} with E_e is negligible). The equation

$$dn_{+r}/dt = dn_{-r}/dt \simeq 0$$

will therefore be satisfied even under conditions of rapidly changing field. Thus Eq. [8] reduces to

$$n_{+r}n_{-r} = n_o/(\kappa_{+r} + \kappa_{-r})d(f\sigma')$$

[1] It is probably more correct to regard ϕ' and $\mu^{*\prime}$ as extrapolated values, the extrapolation to $E_e = 0$ being based on the behavior at high fields only (12).

$$\simeq n_o^2/(\kappa_{+r} + \kappa_{-r})f$$

since for

$$n_o >> n_{+r} \text{ and } n_{-r},\ d\sigma' \simeq 1/n_o$$

In the bulk of the film, remote from the interfaces, the mean space charge will be essentially zero, so that we may set $n_{+r} = n_{-r}$. Under these conditions Eq. [7] and [9] yield

$$i = \frac{Ze}{\sigma'}\left[2 + \left(\frac{\kappa_{+r} + \kappa_{-r}}{f}\right)^{1/2}\right] p_o \qquad [10]$$

Equation [10] will only be valid remote from the interfaces. To allow for space charge phenomena, Eq. [7] and [9] must be solved in conjunction with Poisson's equation. For the present, however, we shall assume that the films involved are thick enough that Eq. [10] may be used without serious error.

It is now convenient to write Eq. [10] in the following form

$$i = (Ze/\sigma)\kappa^{1/2} p_o \qquad [11]$$

where

$$\sigma = \sigma'\left[2 + \left(\frac{\kappa_{+r} + \kappa_{-r}}{f}\right)^{1/2}\right] \Big/ \kappa^{1/2}$$

and κ is identically κ_{+r} or κ_{-r}, whichever is the greater. (From previous discussion, $\kappa_{+r} > \kappa_{-r}$.) κ is therefore given by

$$\kappa = \exp\{\mathcal{E}\mu^{*\prime}[1-(2E_e + \mathcal{E})\mu^{*\prime}/C'\phi']/kT\} \qquad [12]$$

where the subscript, r, has been omitted for brevity. It follows from our earlier assumption, $n_o >> n_{\pm r}$, that $\kappa^{1/2} >> 1$. Since f probably lies between about 1 and 2, we may set the following limits on σ, $\sqrt{2} \geqq \sigma/\sigma' \geqq 1/\sqrt{2}$. Furthermore, from the equations for κ_{+r} and κ_{-r} it is easily shown that σ/σ' will vary not more than 0.15% for a 1% change in absolute temperature. Its variation with the effective field, E_e, will be totally negligible. It follows, therefore, that $\sigma \simeq \sigma'$ and is for all practical purposes independent of both temperature and field strength (provided of course σ' is independent of these).

Combining Eq. [3], [11], and [12], the desired relationship is obtained

$$i = i_o \exp\{-[\phi - E_e\mu^* (1 - E_e\mu^*/C\phi)]/kT\} \qquad [13]$$

where

$$i_o = ZeN'\nu/\sigma \qquad [14]$$

$$\phi = \phi'\left[1 - \frac{\mathcal{E}\mu^{*\prime}}{2\phi'} + \frac{1}{2C'}\left(\frac{\mathcal{E}\mu^{*\prime}}{\phi'}\right)^2\right] \qquad [15]$$

$$\mu^* = \mu^{*\prime}\left[1 - \mathcal{E}\frac{\mu^{*\prime}}{C'\phi'}\right] \qquad [16]$$

$$C = C'\left[1 - \frac{\mathcal{E}\mu^{*\prime}}{C'\phi'}\right]^2 \Big/ \left[1 - \frac{\mathcal{E}\mu^{*\prime}}{2\phi'} + \frac{1}{2C'}\left(\frac{\mathcal{E}\mu^{*\prime}}{\phi'}\right)^2\right] \qquad [17]$$

From the space charge data for the anodic oxidation of aluminum, one can estimate that $\mathcal{E}\mu^{*\prime}/C'\phi' \simeq 0.07$ (10). Using this value and setting $C' \simeq 3.6$ (12) we have for this system

$$(\phi' - \phi)/\phi' \simeq 0.12$$
$$(\mu^{*\prime} - \mu^*)/\mu^{*\prime} \simeq 0.07$$
$$(C' - C)/C' \simeq 0.02$$

Experimentally determined values for ϕ', μ^*, and C will provide, therefore, reasonably good estimates of the more fundamental primed parameters.

Rate of change of the dielectric polarization.—In determining the rate of change of the dielectric polarization, and hence of E_e, as a function of the appropriate variables, it is convenient to work with the dipole moments of the individual molecular units. For conditions of uniform polarization of the oxide, the dipole moment per unit volume will be the same throughout the oxide, so that the dipole moment associated with a given molecular unit will be proportional to its volume. Since the volume of a molecular unit might vary from one unit to the next, the dipole moment per molecular unit appears at first to be a poor parameter with which to work. However, since the ultimate form of the equations involves a simple linear summation over all the molecular units, mean values for the dipole moments and polarizabilities may be used at the outset without it introducing an approximation in the final equations.

Accordingly, we shall define the following parameters:

- E_e field effective in assisting the ion transfer process
- E_p field effective in polarizing a given molecular unit
- N number of molecular units per unit volume
- μ dipole moment per molecular unit
- μ_1 dipole moment per molecular unit associated with the fast polarization process.
- μ_2 dipole moment per molecular unit associated with the slow, ion transport, polarization process
- α_s static polarizability associated with μ (*i.e.*, $\alpha_s = \mu/E_p$ for static conditions)
- α_1 differential polarizability associated with μ_1 (*i.e.*, $\alpha_1 = (\partial\mu_1/\partial E_p)_{\mu_2}$)
- α_2 static polarizability associated with μ_2 (*i.e.*, $\alpha_2 = \mu_2/E_p$ for static conditions)
- i ion current density associated with the growth of film (as opposed to charging current)
- Ze absolute magnitude of the charge transferred during an ion transfer process
- d mean dimension of a molecular unit along the applied field direction
- σ' mean cross-sectional area of a molecular unit in a plane normal to the applied field direction, $= 1/Nd$

Using these parameters, Eq. [1] becomes

$$E_e = E + \delta N\mu/\mathcal{E}_o \qquad [18]$$

where δ is a factor of the order of unity which allows for the uncertainty as to the precise contribution of the polarization of the medium to the effective field strength, E_e. Similarly, we have

$$E_p = E + \delta' N\mu/\mathcal{E}_o \qquad [19]$$

where δ' is a factor analogous to δ, introduced for the same reason. By definition, we also have

$$\mu = \mu_1 + \mu_2 \qquad [20]$$

For μ_2 constant, $(\partial\mu_1/\partial E_p)_{\mu_2} = \alpha_1$. However, the presence of μ_2 introduces a depolarization field proportional to μ_2 ($\gamma\mu_2/\alpha_2$ say), acting in the opposite direction to E_p. We may therefore write

$$\mu_1 = \alpha_1[E_p - \gamma\mu_2/\alpha_2] \qquad [21]$$

where $1 \geqq \gamma \geqq 0$, since for steady-state conditions, $\mu_2/\alpha_2 = E_p$.

From Eq. [20] and [21] it follows that

$$\alpha_s = \alpha_1(1 - \gamma) + \alpha_2 \qquad [22]$$

The principal equation now lacking is that for the rate of change of μ_2 with time, in accordance with the collisionally induced and thermally activated polarization processes discussed previously. We shall treat the collisionally induced process first.

The ion transfer frequency per unit volume of oxide is clearly given by i/Zed. In accordance with our previous assumption, ion transfer processes type 2 and 3 will predominate so that the effect of processes 1 and 4 on the rate of change of polarization will be neglected. This approximation amounts to neglecting $\kappa^{-1/2}$ compared with unity. Immediately before an ion transfer event, the uncharged molecular unit taking part in the event will have, on the average, a dipole moment nearly equal to the average of the di-

pole moments for all units. Following the ion transfer process, the dipole moment will be the equilibrium value, $\alpha_2 E_p$, so that the contribution to the change in $N\mu_2$ per collision made by the initially uncharged molecular unit is on the average $(\alpha_2 E_p - \mu_2)$.

The contribution made by the charged molecular unit must be calculated differently. Being few in number, a charged molecular unit will have been involved in a collision process much more recently on the average than the uncharged unit and hence will have, in general, a dipole moment differing appreciably from the average value. The contribution to the change in $N\mu_2$ made by the initially charged molecular unit can be represented approximately by $\alpha_2(dE_p/dt)\,\Delta t$ where $(dE_p/dt)\Delta t$ approximates the change in E_p between consecutive ion transfer processes involving the unit in question, Δt being an appropriately weighted average lifetime for a charged unit. For a molecular unit of charge rZe, the average lifetime is $1/p_{+r}$, while for a charge $-rZe$ it is $1/p_{-r}$. The combined average lifetime, weighted according to transfer frequency, is therefore given by

$$\begin{aligned}\Delta t &= [p_{+r}/(p_{+r}+p_{-r})]\,(1/p_{+r}) + \\ &\quad [p_{-r}/(p_{+r}+p_{-r})]\,(1/p_{-r}) \\ &= 2/(p_{+r}+p_{-r}) = 2/p_0(\kappa_{+r}+\kappa_{-r}) \\ &\simeq ZeNd/i\kappa^{1/2}\end{aligned}$$

where the last step involves Eq. [10].

Multiplying the ion transfer frequency per unit volume by the total change in $N\mu_2$ per transfer process, we now obtain the following equation

$$\left(\frac{d(N\mu_2)}{dt}\right)_c = \frac{i}{Zed}\,[\alpha_2 E_p - \mu_2] + \frac{N}{\kappa^{1/2}}\,\alpha_2\,\frac{dE_p}{dt}$$

or

$$\left(\frac{d\mu_2}{dt}\right)_c = \frac{i\sigma'}{Ze}\,[\alpha_2 E_p - \mu_2] + \frac{\alpha_2}{\kappa^{1/2}}\,\frac{dE_p}{dt} \qquad [23]$$

where the subscript, c, denotes that it is the collisionally induced component of $(d\mu_2/dt)$. Ultimately, it will be shown that the term in dE_p/dt can be neglected, so that the approximations involved in obtaining it are of little consequence. This is fortunate since this term is too large for sufficiently small i. (For $i = 0$ this term should be zero.)

The thermally activated component of $d\mu_2/dt$ will be equal to the ion current per molecular unit within the molecular units arising most probably as a result of surface ion transport. Assuming a single ionic species to predominate in this transport process, we may write

$$\frac{d\mu_2}{dt} = \frac{i\sigma'}{Ze}\,[\alpha_2 E_p - \mu_2] + \frac{\alpha_2}{\kappa^{1/2}}\,\frac{dE_p}{dt} + 2Z'ebv'n'\left[\exp\left(-\frac{Q}{kT}\right)\right]\sinh\left[\frac{w^{*\prime}\theta}{kT}\left(E_p - \frac{\mu}{\alpha_s}\right)\right] \qquad [24]$$

where the new symbols are defined as follows:

- $Z'e$ absolute magnitude of the charge associated with the ionic species
- b mean jump distance for the ionic species (*i.e.*, mean distance travelled per activation)
- ν' vibrational frequency along the reaction coordinate associated with the ionic species
- n' number of ionic species per molecular unit in preferred sites for migration
- Q zero field activation energy for migration of ionic species from preferred sites
- $w^{*\prime}$ activation dipole associated with Q (*i.e.*, activation distance times effective charge)

The first two terms of Eq. [24] come directly from Eq. [23], the final term being that for conventional ion transport allowing for the possibility of high field strengths (13). The internal field effective in assisting the ion transport will be proportional to $E_p - \mu/\alpha_s$. (This clearly has the correct form for $\mu = 0$ and also for $\mu = \alpha_s E_p$, *i.e.*, $d\mu_2/dt = 0$ for $\mu = \alpha_s E_p$.) The proportionality constant, θ, would appear to be somewhat greater than unity.[2] The quadratic term in the field strength, such as introduced in Eq. [3] (*i.e.*, the term containing C'), should be entirely negligible in the present case since $E_p - \mu/\alpha_s$ is at least a factor of 10 less than E_e for a given applied field, E. This statement can be verified readily from the equations presented in the remainder of this section and from empirical values for the constants presented in the following paper (10). However, the nature of the model would suggest a range of values for the parameters Q and $w^{*\prime}$, so that the hyperbolic sine function term in Eq. [25] can only be regarded as a rather rough approximation.

Elimination of E_p, μ_1, μ_2, and α_2 from Eq. [19], [20], [21], [22], and [24], and replacing $w^{*\prime}\theta$ with $w_e^{*\prime}$ yields

$$\begin{aligned}\frac{d\mu}{dt} + \left(\frac{1-\delta' N\alpha_s/\mathcal{E}_0}{1-\delta' N\alpha_1'/\mathcal{E}_0}\right)\frac{i\sigma'\mu}{Ze} &= \left(\frac{\alpha_1'}{1+\delta' N\alpha_1'/\mathcal{E}_0}\right)\frac{dE}{dt} \\ &+ \left(\frac{\alpha_s}{1-\delta' N\alpha_1'/\mathcal{E}_0}\right)\frac{i\sigma'}{Ze}E + \left[\frac{\alpha_s-\alpha_1}{\alpha_s-\alpha_1(1-\gamma)}\right] \\ &\left[\frac{2Z'ebv'n'}{1-\delta' N\alpha_1'/\mathcal{E}_0}\right]\left[\exp\left(-\frac{Q}{kT}\right)\right] \\ &\sinh\left[\frac{we^{*\prime}}{kT}\left(E - \frac{\mu}{\alpha_s}\left\{1 - \frac{\delta' N\alpha_s}{\mathcal{E}_0}\right\}\right)\right] \qquad [25]\end{aligned}$$

where $\alpha_1' = \alpha_1 + \dfrac{\alpha_s - \alpha_1}{\kappa^{1/2}}$. Assuming, as before, that $\kappa^{1/2} >> 1$, one may neglect $(\alpha_s - \alpha_1)/\kappa^{1/2}$ compared with α_1, thus eliminating this term as previously mentioned.

Equation [25] may be simplified considerably by introducing the dynamic and static electric susceptibilities, χ_1 and χ_s, respectively, defined as follows

$$\chi_1 = \frac{N}{\mathcal{E}_0}\,\underset{\dot{E}\to\infty}{\text{Limit}}\,\frac{d\mu}{dE} \qquad [26]$$

$$\chi_s = \frac{N}{\mathcal{E}_0}\,\underset{\dot{E}\to 0}{\text{Limit}}\,\frac{d\mu}{dE} \qquad [27]$$

From Eq. [25]

$$\chi_1 = N\alpha_1'/\mathcal{E}_0(1-\delta' N\alpha_1'/\mathcal{E}_0) \qquad [28]$$

$$\chi_s = N\alpha_s/\mathcal{E}_0(1-\delta' N\alpha_s/\mathcal{E}_0) \qquad [29]$$

Eliminating α_1' and α_s from Eq. [25], [28], and [29] and substituting $\mu = P/N$ where P is the polarization of the oxide, we obtain the desired equation

$$\frac{dP}{dt} = \mathcal{E}_0\chi_1\frac{dE}{dt} + Bi[\mathcal{E}_0\chi_s E - P] + i_{co}[\exp(-Q/kT)]\sinh[w_e^{*\prime}(E - P/\mathcal{E}_0\chi_s)/kT] \qquad [30]$$

where

$$B = \left(\frac{1+\delta'\chi_1}{1+\delta'\chi_s}\right)\frac{\sigma'}{Ze},$$

$$i_{co} = \frac{(\chi_s-\chi_1)(1+\delta'\chi_1)2Z'ebv'\eta'N}{\chi_s - \chi_1[1-\gamma(1+\delta'\chi_s)]}$$

Alternatively, eliminating $P = N\mu$ from Eq. [18] and [30], an equation for the effective field strength, E_e, is obtained

[2] For the simple electrostatic model in which the crystallites are treated as dielectric spheres in a uniform field, E_p, the internal field assumed to be the Lorentz field, and γ assumed to be unity, it can be shown that $\theta = (1 - \alpha_1/\alpha_s)^{-1}$. A more general treatment of the problem suggests a somewhat smaller value for θ.

$$\frac{dE_e}{dt} + BiE_e = (1 + \delta\chi_1)\frac{dE}{dt} + Bi(1 + \delta\chi_s)E + (\delta i_{co}/\mathcal{E}_o)[\exp(-Q/kT)] \sinh\left\{\frac{w_e^{*\prime}}{kT}\left[\frac{(1 + \delta\chi_s)E - E_e}{\delta\chi_s}\right]\right\} \quad [31]$$

To complete the development of the basic equations for the model, we note that the current flowing in the external circuit, I, will be given by

$$I = i + i_c + i_e \quad [32]$$

where i is the ion current leading to film growth, given by Eq. [13]; i_c is the total charging current, $d[P + \mathcal{E}_o E]/dt$, and i_e the current arising from electronic conduction through the film, which we shall assume to be zero. From Eq. [18] and [30], the charging current is given by

$$i_c = \mathcal{E}_o K_1 \frac{dE}{dt} + \frac{Bi\mathcal{E}_o}{\delta}[(1 + \delta\chi_s)E - E_e] + i_{co}[\exp(-Q/kT)] \sinh\left\{\frac{w_e^{*\prime}}{kT}\left[\frac{(1 + \delta\chi_s)E - E_e}{\delta\chi_s}\right]\right\} \quad [33]$$

where $K_1 = 1 + \chi_1$ is the dynamic dielectric constant for the oxide.

Elimination of E_e, i_c, and i from Eq. [13], [31], [32], and [33] leads to a differential equation which may in principal be solved to obtain I as a function of time, given E as a function of time and a suitable boundary condition. In the following sections we shall use these equations to obtain I as a function of E or t for a number of special cases, thus providing equations which are readily amenable to experimental verification. In general, however, digital computer methods are required.

Particular Solutions of Basic Equations

For simplicity, no case will be considered for which the rate of change of the polarization brought about by collision is of the same magnitude as that brought about by thermally activated ionic conduction. The discussion of transient phenomena will therefore be classified according to i large (*i.e.*, collision process dominant) and i small (*i.e.*, thermally activated process dominant). We shall begin, however, by obtaining the steady-state solution.

Steady-state solution.—For steady-state conditions ($dE/dt = di/dt = 0$) it follows from Eq. [13] and [31] that $E_e = (1 + \delta\chi_s E)$ and hence from Eq. [32] and [33] that $I = i$. Substituting these results into Eq. [13], we obtain the desired solution

$$I = i_o \exp\left\{-\left[\phi - E\mu_s^*\left(1 - \frac{E\mu_s^*}{C\phi}\right)\right] \Big/ kT\right\} \quad [34]$$

where $\mu_s^* = (1 + \delta\chi_s)\mu^*$. We note that, apart from space charge effects, four parameters, i_o, ϕ, μ_s^*, and C are sufficient to define the steady-state behavior according to this model.

It is convenient to define the steady-state reciprocal Tafel slope, β_s, as follows

$$\beta_s = \underset{\dot{E} \to 0}{\text{Limit}} \frac{d \ln I}{dE} \quad [35]$$

from which we have

$$\beta_s = \frac{\mu_s^*}{kT}\left[1 - \frac{2\mu_s^* E}{C\phi}\right] \quad [36]$$

General transient behavior for i large.—For i sufficiently large, the collisionally activated polarizing process will dominate so that the final term in Eq. [31] and [33] may be neglected. Equation [31] can then be written

$$\frac{d(\mu^* E_e)}{dt} + Bi(\mu^* E_e) = \mu_1^* \frac{dE}{dt} + Bi\mu_s^* E \quad [37]$$

where $\mu_1^* = (1 + \delta\chi_1)\mu^*$. From Eq. [32] and [33], and setting $[K_1 + (1 - \delta)/\delta] \simeq K_1$, we obtain

$$I - \mathcal{E}_o K_1 \frac{dE}{dt} = i\left[1 + B\mathcal{E}_o K_1\left(\frac{\mu_s^* E - \mu^* E_e}{\mu_1^*}\right)\right] \quad [38]$$

For both alumina and tantala the term in B does not exceed about 0.05 for any realizable experiment (10) so the above approximation should normally be a satisfactory one, particularly since one would expect δ to be close to unity and K_1 is large compared to unity.

Eliminating $\mu^* E_e$ and i from Eq. [13], [37], and [38], it is seen that apart from K_1, which is readily determined independently, only two parameters, μ_1^* and B, are required in addition to the steady-state parameters to define transient behavior for i large. Unfortunately, the solution of even this equation generally requires the use of a digital computer, although two important exceptions are for the cases $\dot{E}$ very large and $\dot{E} = 0$.

Transient behavior for i and $\dot{E}$ large.—In considering this case, it is convenient to define the transient reciprocal Tafel slope, β_1, as follows

$$\beta_1 = \underset{\dot{E} \to \infty}{\text{Limit}} \frac{d \ln I'}{dE} \quad [39]$$

where $I' = I - \mathcal{E}_o K_1 \, dE/dt$ can be obtained readily from the experimental measurements. Using the boundary condition that at $t = 0$, $E = E_o$, and $\mu^* E_e = \mu_s^* E_o$ (*i.e.*, steady-state conditions prevailed immediately before commencing the rapid change in field) Eq. [13], [37], [38], and [39] yield

$$\beta_1 = \frac{\mu_1^*}{kT}\left[1 - \frac{2\mu_s^* E_o}{C\phi} - \frac{2\mu_1^* \Delta E}{C\phi}\right] + B\mathcal{E}_o K_1\left[\frac{\mu_s^* - \mu_1^*}{\mu_1^*}\right] \quad [40]$$

where $\Delta E = E - E_o$ and the approximation

$$1 >> B\mathcal{E}_o K_1\left(\frac{\mu_s^* - \mu_1^*}{\mu_1^*}\right)\Delta E$$

has been made. The final term in Eq. [40] contributes less than 3% to β_1 for both alumina and tantala (10) so may usually be neglected. The integrated form of Eq. [39] and [40] can be written

$$\frac{1}{\Delta E}\ln\frac{I'}{I_o} = \frac{\mu_1^*}{kT}\left[1 - \frac{2\mu_s^* E_o}{C\phi} - \frac{\mu_1^* \Delta E}{C\phi}\right] + B\mathcal{E}_o K_1\left[\frac{\mu_s^* - \mu_1^*}{\mu_1^*}\right] \quad [41]$$

$$\simeq \beta_1 \text{ for } \Delta E \text{ small}$$

where I_o is the steady-state current density before effecting the rapid change in E. It is noteworthy that the variation of β_1 with E_o is closely related to the variation of β_s with E (Eq. [36]), a prediction which can readily be checked (10).

Constant field transients for i large.—From Eq. [37], on setting $\dot{E} = 0$, we obtain

$$\frac{d(\mu^* E_e)}{dt} = Bi(\mu_s^* E - \mu^* E_e) \quad [42]$$

Also, from Eq. [13] and [34], respectively, we have

$$kT \ln (i/A) = \mu^* E_e - (\mu^* E_e)^2/C\phi \quad [43]$$

$$kT \ln (I_s/A) = \mu_s^* E - (\mu_s^* E)^2/C\phi \quad [44]$$

where $A = i_o \exp(-\phi/kT)$ and I_s is the steady-state current density for the field, E, in question.

From Eq. [42], [43], and [44], the following equation may be readily verified

$$\frac{d \ln i}{dt} = Bi \ln (I_s/i) + \frac{(\mu_s^* E - \mu^* E_e)^2}{kT\, C\phi} \quad [45]$$

Solving for $\mu^* E_e$ and $\mu_s^* E$ from Eq. [43] and [44], respectively, we obtain

$$\mu_s^* E - \mu^* E_e = \frac{C\phi}{2} \left[\left(1 - \frac{4kT}{C\phi} \ln \frac{i}{A} \right)^{1/2} - \left(1 - \frac{4kT}{C\phi} \ln \frac{I_s}{A} \right)^{1/2} \right] \quad [46]$$

It is readily proven that for $a_1 < 1$ and $a_2 < 1$, $(1 - a_1)^{1/2} - (1 - a_2)^{1/2} = \frac{1}{2}(a_2 - a_1)/(1 - \xi)^{1/2}$ for some ξ in the interval (a_1, a_2), the first approximation value for ξ being $(a_1 + a_2)/2$.[3] Equation [46] can therefore be written

$$\mu_s^* E - \mu^* E_e = (kT/z^{1/2}) \ln (I_s/i) \quad [47]$$

where

$$z = 1 - (4kT/C\phi) \ln (i_*/A) \quad [48]$$

and i_* is some current in the interval (I_s, i), a first approximation for which is given by: $i_* \simeq (I_s i)^{1/2}$. An alternative expression for z can be obtained by replacing I_s in Eq. [44] by i_s (to avoid confusion of symbols), solving for $\mu_s^* E$ and evaluating $dE/d \ln i_s$

$$\frac{dE}{d \ln i_s} = \frac{1}{\beta_s(i_s)} = (kT/\mu_s^*)[1 - 4(kT/C\phi) \ln (i_s/A)]$$

where $\beta_s(i_s)$ is the steady-state reciprocal Tafel slope for a current density i_s. We may therefore write

$$z^{1/2} = kT\, \beta_s(i_*)/\mu_s^* \quad [49]$$

From Eq. [45] and [47] we now have

$$\frac{d \ln i}{dt} = Bi \ln (I_s/i) \left[1 + \frac{kT}{zC\phi} \ln (I_s/i) \right] \quad [50]$$

Eliminating $\mu_s^* E - \mu^* E_e$ from Eq. [38] and [47] we obtain

$$I = i \left[1 + B\mathcal{E}_0 K_1 \frac{kT}{\mu_1^* z^{1/2}} \ln (I_s/i) \right] \quad [51]$$

Recalling that the term in B is small compared with unity, we may write

$$\ln (I_s/i) = \ln (I_s/I) \left[1 + B\mathcal{E}_0 K_1 \frac{kT}{\mu_1^* z^{1/2}} \right] \quad [52]$$

Since $1 + B\mathcal{E}_0 K_1\, kT/\mu_1^* z^{1/2}$ varies only slowly with z, and z in turn varies only slowly with I, we may set

$$\frac{d}{dt} (1 + B\mathcal{E}_0 K_1\, kT/\mu_1^* z^{1/2} \simeq 0$$

and obtain from Eq. [52]

$$\frac{d \ln i}{dt} \simeq \frac{d \ln I}{dt} \left[1 + B\mathcal{E}_0 K_1 \frac{kT}{\mu_1^* z^{1/2}} \right] \quad [53]$$

Eliminating $d \ln i/dt$, i and $\ln (I_s/i)$ from Eq. [50] using Eq. [53], [51], and [52], respectively, we obtain

$$\frac{d \ln I}{dt} = BI \ln (I_s/I)[1 + a \ln (I_s/I)] \quad [54]$$

where

$$a = \frac{kT}{zC\phi} \left[1 - \frac{B\mathcal{E}_0 K_1 C\phi z^{1/2}}{\mu_1^*} \right] \left[1 + B\mathcal{E}_0 K_1 \frac{kT}{\mu_1^* z^{1/2}} \right]$$

Fortunately, for both aluminum and tantalum (10), $a \simeq 10^{-2}$ for typical conditions. It appears, therefore, that the term in a may usually be neglected. Accordingly, integration of Eq. [54] gives

$$\frac{1}{I} \simeq \frac{1}{I_o} - B \int_o^t \ln \frac{I_s}{I}\, dt \quad [55]$$

where I_o is the value of I at $t = 0$. An alternative integrated form of Eq. [54] may be written (neglecting the term in a)

$$\ln (I_s/I) = [\ln (I_s/I_o)] \exp (-Bq) \quad [56]$$

where

$$q = \int_o^t I\, dt$$

is the charge passed per unit area. We note that for a fixed value of I_s/I_o, $\ln (I_s/I)$ is a function of q only, being independent of both the steady-state current density and the temperature. The duration of these transients will of course depend on the current density.

The approximations made in deriving Eq. [55] and [56] should be valid within experimental error for $|\log I_s/I| \leq 2$. If approximate values for the various constants are known, a may be calculated as a function of I and the correction term included. In general, however, other sources of error will be more important.

It is perhaps worthwhile pointing out that the term in a in Eq. [54] arises as a result of two effects, the quadratic term in the field in the net activation energy (Eq. [3]), and the ionic contribution to the charging current. The two effects tend to cancel one another.

General transient behavior for i small.—For i sufficiently small so that the collisionally activated contribution to the polarization process may be neglected, Eq. [30] becomes

$$\frac{dP}{dt} = \mathcal{E}_0 \chi_1 \frac{dE}{dt} + i_{co} \left[\exp \left(-\frac{Q}{kT} \right) \right] \sinh \left[\frac{w_e^{*\prime}}{kT} \left(E - \frac{P}{\mathcal{E}_0 \chi_s} \right) \right] \quad [57]$$

For both alumina and tantala near 25°C Eq. [57] is a reasonable approximation only when i is vanishingly small, that is when $I = i_c$ (10). For other metal-oxide systems, however, or for alumina and tantala at sufficiently high temperatures, it is possible that $i_{co} \exp (-Q/kT)$ will be sufficiently large that Eq. [57] would apply even for reasonably large values of i. Before limiting the discussion to the case $i \approx 0$, therefore, the case where $i \gtrsim i_c$, yet is sufficiently small for the present approximation to be valid, will be considered.

Constant field transients for i small.—Making the substitutions

$$y = \frac{w_e^{*\prime}}{kT} \left(\frac{P}{\mathcal{E}_0 \chi_s} - E \right)$$

and

$$g = w_e^{*\prime} i_{co} [\exp (-Q/kT)]/\mathcal{E}_0 \chi_s\, kT$$

Eq. [57] becomes, for $\dot{E} = 0$,

$$dy/\sinh y = -g\, dt$$

which on integration gives

$$\ln [\tanh (y_o/2)] - \ln [\tanh (y/2)] = gt \quad [58]$$

or

$$-y = 2\tanh^{-1} [De^{-gt}]$$

where

$$D = \tanh (-y_o/2)$$

and

$$y = y_o \text{ at } t = 0$$

We may replace y by $(w_e^*/\mu_s^*)(\mu^* E_e - \mu_s^* E)/kT$ where $w_e^* = (1 + 1/\delta\chi_s) w_e^{*\prime} \simeq w_e^{*\prime}$ and obtain

$$\left(\frac{\mu_s^* E - \mu^* E_e}{kT} \right) = \frac{2\mu_s^*}{w_e^*} \tanh^{-1} [De^{-gt}] \quad [59]$$

and

$$g \simeq w_e^* i_{co} [\exp (-Q/kT)]\, \mu_1^*/\mu_s^*\, \mathcal{E}_0 K_1\, kT$$

[3] Defining $F(\xi) = (1 - \xi)^{1/2}[(1 - a_1)^{1/2} - (1 - a_2)^{1/2}] - \frac{1}{2}(a_2 - a_1)$, by substitution we have $F(\alpha_1) = -F(\alpha_2)$, so that $F(\xi)$, which is continuous in the interval (a_1, a_2), changes sign in the interval and hence is zero for some ξ in (a_1, a_2). Also, since $F(a_1) = -F(a_2)$, linear interpolation gives $\xi \cong (a_1 + a_2)/2$.

Eliminating $\mu^* E_e$ from Eq. [47] and [59] the following result is obtained

$$\ln (I_s/i) = 2z^{1/2} (\mu_s^*/w_e^*) \tanh^{-1} [De^{-gt}] \quad [60]$$

Since z varies only slowly with i, we may to a first approximation set it equal to the mean of the extreme values of z, given approximately by (see Eq. [48] and [49])

$$\bar{z} \simeq 1 - (4kT/C\phi) \ln \left(\frac{i_o I_s^3}{A^4} \right)^{1/4} = (kT \bar{\beta}_s/\mu_s^*)^2$$

where $i = i_o$ at $t = 0$ and $\bar{\beta}_s$ is the steady-state reciprocal Tafel slope for a current density equal to $(i_o I_s^3)^{1/4}$. Equation [60] therefore becomes

$$\ln (I_s/i) \simeq (2kT \bar{\beta}_s/w_e^*) \tanh^{-1} [De^{-gt}] \quad [61]$$

where $D \simeq \tanh [(w_e^*/2kT\bar{\beta}_s) \ln (I_s/i_o)$. Because of the complex form of the equation (derived in the next section) for the charging current, interpretation of data in terms of Eq. [61] will only be feasible for $I \simeq i$ (*i.e.*, $i >> i_c$).

We note that Eq. [61] predicts $\ln (I_s/i)$ to be a function only of time for i_o/I_s and temperature fixed. The duration of these transients is therefore independent of the steady-state current density, but is highly dependent on the temperature, since g contains a Boltzmann factor. This behavior is in marked contrast to that for constant field transients at high ion currents (cf. Eq. [56]). The two cases can therefore be readily distinguished experimentally.

Charging current for i small.—For i sufficiently small, we may combine Eq. [57] with the relation

$$i_c = d[P + \epsilon_o E]/dt$$

and obtain

$$i_c' = A_c \sinh \left[\frac{w_e^*}{kT} \left(\frac{\mu_s^* - \mu_1^*}{\mu_s^*} \right) \left(E - E_* - \frac{q_c'}{\mathcal{E}_o(\chi_s - \chi_1)} \right) \right]$$

or setting

$$1 + \chi_s \simeq (1 + \chi_1)(1 + \delta\chi_s)/(1 + \delta\chi_1) = K_1 \mu_s^*/\mu_1^*$$

$$i_c' \simeq A_c \sinh \left\{ \frac{w_e^*}{kT} \left[\left(\frac{\mu_s^* - \mu_1^*}{\mu_s^*} \right) (E - E_*) - \frac{\mu_1^*}{\mu_s^*} \frac{q_c'}{\mathcal{E}_o K_1} \right] \right\} \quad [62]$$

where $i_c' = i_c - \mathcal{E}_o K_1 \, dE/dt$ is the ionic contribution to the charging current; $A_c = i_{co} \exp(-Q/kT)$, $q_c' = \int_o^t i_c' dt$, $E_* = (P_o/\mathcal{E}_o - \chi_1 E_o)/(\chi_s - \chi_1)$ and P_o and E_o are the values of P and E at $t = 0$. For a fully annealed film, the ionic contribution to the polarization will be zero at $t = 0$ (*i.e.*, $P_o = \mathcal{E}_o \chi_1 E_o$) so that $E_* = 0$ for this case. If equilibrium polarization conditions prevail at $t = 0$ (*i.e.*, $P_o = \mathcal{E}_o \chi_s E_o$) then $E_* = E_o$.

The analysis of data in terms of Eq. [62] requires numerical integration to obtain q_c'. If we consider the special case of constant field, the charging current may be obtained as an explicit function of time. Accordingly, differentiation of Eq. [58] with respect to time yields

$$i_c = 2DA_c e^{-gt}/(1 - D^2 e^{-2gt}) \quad [63]$$

where

$$D = \tanh \left[\frac{w_e^*}{2kT} \left(\frac{\mu_s^* - \mu_1^*}{\mu_s^*} \right) (E_o - E_*) \right]$$

and E = a constant $= E_o$. An equation somewhat more convenient for fitting to empirical data is obtained by solving for e^{gt} and taking logarithms. The resulting equation is

$$\ln \left[\frac{|i_c/A_c|}{(1 + i_c^2/A_c^2)^{1/2} - 1} \right] = gt - \ln |D| \quad [64]$$

Summary and Discussion

A theory of cooperative ion migration in valve metal oxide films has been developed on the basis of a dielectric mosaic model of the film. The cooperative phenomena arise then as a result of time dependent polarization properties of the oxide film. Thus the ion current leading to film growth depends not only on the applied field strength and temperature but also on the polarization of the medium. The transient conduction properties of these systems are therefore determined by the kinetics of the polarization processes.

In addition to conventional "fast" polarization processes, for this model a "slow" polarization process, associated with ionic migration within a single mosaic component (crystallite or polymeric unit) must exist. Two independent mechanisms for the kinetics of the slow polarization process have been proposed; the "high ion current mechanism" in which the change in the slow component of the polarization is induced by the transfer of ions from one polymeric unit to the next and the "low ion current mechanism" in which the ionic migration within the polymeric units takes place by a conventional high field ionic conduction process. The terms "high" and "low" are of course only relative, implying correctly that at sufficiently high ion current densities, for a given temperature, one mechanism will predominate, while the other will predominate at sufficiently low ion current densities. For a given range of ion current densities, the low ion current mechanism should predominate at sufficiently high temperatures, and vice-versa.

In discussing the model it is convenient to consider steady-state and high ion current conditions separately from low ion current conditions.

For steady-state conditions, the following kinetic parameters are required to define the behavior of the system: a pre-exponential factor, i_o, an activation energy, ϕ, an effective charge-activation distance product, μ_s^*, and a parameter, C, to allow for the nonlinear dependence of the net activation energy on the field strength. A precisely analogous set of parameters is required for the high field Frenkel defect theory (14). For high ion current transient experiments, the present model required an additional two parameters; another effective charge-activation distance product, μ_1^*, and a constant, B, related to the cross-sectional area of a polymeric unit. For similar experiments, the high field Frenkel defect theory requires three additional parameters; parameters analogous to μ_1^* and B, plus an additional parameter similar to C of the present model (5).

As the high field Frenkel defect model does not predict anything analogous to the low ion current phenomena predicted by the present model, comparison in this area is not really possible. However, in order to predict conduction phenomena associated with annealing experiments (4, 5), the Frenkel defect theory requires a knowledge of an additional activation energy and another exponential factor. The present model is extended to cover these phenomena and also phenomena relating to low ion currents by the addition of three new parameters; a pre-exponential factor, i_{co}, an activation energy, Q, and an effective charge-activation distance product, w_e^*. The present model therefore involves, in total, the same number of disposable constants as does the Frenkel defect theory, so that agreement with data is not achieved simply by introducing more disposable constants. As most of the data presently available in fact are concerned with high ion current conditions (10), the present theory generally involves one less disposable constant.

Apart from the obvious tests which can be applied to most theories (*i.e.*, that they lead to functional forms in agreement with data and to reasonable values for the parameters) the present model offers two additional checks for internal consistency. The parameter, C, can be determined from both steady-state (Eq. [36]) and transient (Eq. [41] Tafel slope measurements. The parameters μ_s^* and μ_1^* can be evaluated from high ion current measurements (Eq. [36] and [41], respectively), with the ratio μ_s^*/μ_1^* also being obtainable from charging current measurements, since

$\mu_s^*/\mu_1^* \simeq K_s/K_1$, the ratio of the static to dynamic dielectric constant.

The parameters i_o, ϕ, μ_s^*, and C are most readily obtained from steady-state measurements (Eq. [34]); the parameter μ_1^* from high ion current measurements for conditions of rapidly changing field (Eq. [41]); and the parameter B from constant field transients for high ion current conditions (Eq. [55] or [56]). The remaining three parameters, i_{co}, Q, and w_e^* can be obtained from charging current measurements for fields sufficiently low so that the ion current is essentially zero (Eq. [62] and [64]).

In the following paper (10) the model is discussed in relation to existing theories and presently available data.

Acknowledgments

The author wishes to express his appreciation to Dr. J. P. Valleau for reading the manuscript and for many useful discussions.

Manuscript received Nov. 24, 1964. This paper was presented in part at the Pittsburgh Meeting, April 15-18, 1963.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

Conduction Properties of Valve Metal-Oxide Systems

II. Comparison of Data with New Theory

M. J. Dignam

Department of Chemistry, University of Toronto, Toronto, Ontario, Canada

ABSTRACT

Data from the literature for the anodic oxidation of a number of the valve metals have been analyzed in terms of the dielectric polarization theory of ionic transport, developed in Part I, and previous theories. The unique predictions of this theory were found to be in excellent accord with the data.

In the preceding paper (1) a theory of cooperative ion transport has been developed and equations appropriate to various experimental conditions derived. The purpose of the present paper is to test this theory against available data and compare its predictions with those of other theories. In respect to the latter, special attention will be paid to the high field Frenkel defect theory, proposed originally by Bean, Fisher, and Vermilyea (2) as this is the only other theory capable of describing, even qualitatively, most of the observed phenomena. Very briefly, in this theory the transient ionic conduction phenomena are attributed to a slow adjustment of the field dependent population of Frenkel defects to a change in the field. A detailed description of this model and others can be found elsewhere (3).

The theory and available data will be discussed under the headings: Steady-State Data, Tafel Slope Data, Constant Field Transients, and Space Charge Effects.

Examination of Available Data

Steady-state data.—The conventional empirical equation used to fit steady-state ionic conduction data can be written

$$I = \alpha \exp \beta E \qquad [1]$$

where α contains the Boltzmann factor for the zero field activation energy. In most previous theoretical treatments, β is predicted to have the form aq/kT where a is an activation distance or mean activation distance for the field assisted displacement of an ion of charge q.

In relation to Eq. [1], three kinds of anomalous behavior have been observed:

1. For zirconium, the parameters α and β have been found by Young (4) to depend on the thickness of the anodic film. The data for tantalum (5), aluminum (6), niobium (7), bismuth (8), and titanium (9) show no such anomaly for films thicker than about 100Å.

2. The Tafel slope, $(d \ln I/dE)_T$, has been found to vary more slowly with the absolute temperature than predicted by setting $\beta = aq/kT$, for both tantalum (5, 10) and niobium (7). For titanium, β appears to decrease more rapidly than $1/T$ with increasing temperature. Sufficiently accurate data are not available for other valve metals to check the temperature dependence of β.

3. For both tantalum (5) and aluminum (6) a variation of the Tafel slope with field strength at a given temperature has been observed. The data for other valve metals are not sufficiently precise to allow this observation to be made.

With regard to the first anomaly, zirconium appears to be unique among the valve metals in displaying film thickness dependent kinetic behavior for films thicker than about 100Å. This suggests either that additional complicating factors are present (for example film inhomogeneity) or that a different mechanism is involved. Young has suggested (4), and indeed it appears not unreasonable, that zirconium oxidizes anodically in accord with Dewald's two barrier model (11). The difficulty with this model, however, is that it requires no less than six disposable constants to define steady-state behavior, while Young's generalization of the model involves at least seven disposable constants (12). With such flexibility, agreement between data of limited scope, such as steady-state data, is almost guaranteed regardless of the validity of the model. Nevertheless, this model must be regarded as a possibility in connection with the anodic oxidation of zirconium.

Dewald's model has also been applied to the steady-state anodic oxidation of tantalum (10, 13) and niobium (14) with the purpose of explaining the Tafel

slope anomalies mentioned above. With the exception that the dependence on thickness predicted by this model has never been detected, the Tafel slope anomalies were accounted for quantitatively. Once again, however, it must be emphasized that this improvement over Eq. [1] is gained by introducing three new parameters, for a total of six. By contrast, Eq. [13] of the previous paper (1), reproduced below for convenience, is also able to account for the Tafel slope anomalies for the above metals and for aluminum (15) with the addition of only one positive parameter, C.

$$I = i_o \exp\left\{ - \left[\phi - E\mu_s^* \left(1 - \frac{E\mu_s^*}{C\phi} \right) \right] / kT \right\} \quad [2]$$

An equation of the form of [2] was first suggested by Young (5) on empirical grounds. He later justified the presence of a quadratic term in the field on the basis of a postulated variation of activation energy with the condenser pressure (16). In a recent paper by the author (15) it is pointed out that the condenser pressure effect is probably too small to explain the observed phenomena. Further, it is shown that the quadratic term arises quite naturally from a more detailed consideration of ion transfer processes at high electrostatic fields. Specifically, it was shown that not only the form of Eq. [2], but also the empirical values for C for Ta, Nb, and Al are predicted correctly by assuming that the interaction potential between the mobile ion and its immediate surroundings can be represented by a Morse function for small displacements. If one accepts the Morse function postulate, C is not an independent constant, so that the Tafel slope anomalies for Ta, Nb, and Al may be explained quantitatively without increasing the number of disposable constants above three. It would appear, therefore, that Eq. [2] represents a far more satisfactory explanation for the Tafel slope anomalies than does Dewald's model, at least in the cases of Ta, Nb, and Al, particularly since Dewald's model does not lend itself readily to explaining even qualitatively the transient conduction phenomena observed for the anodic oxidation of these metals.

It should be emphasized at this point that Eq. [2] cannot be regarded as specific to the theory developed in the preceding paper. An essentially identical equation can be expected for the Mott-Cabrera theory (17), the high field Frenkel defect theory, or Verwey's theory (18). The only way in which the present theory can be regarded as in any way unique in relation to Eq. [2] is that a Morse function interaction potential is more in accord with the new theory than it is with the other theories mentioned. Indeed, the ion transfer process from one molecular unit to the next would appear to be not unlike the dissociation of a diatomic molecule.

The Tafel slope anomaly for titanium cannot be interpreted in the same way as that for Ta, Nb, and Al, since the effect, being in the opposite direction, requires a negative value for C. A negative value for C can be explained in terms of a range or distribution of values for the activation energy and activation distance, as outlined by Young (5). However, an equally probable explanation of the titanium results would be that the current efficiency for formation of the film decreases with increasing temperature and decreasing current density. A further explanation is that the theory of the previous paper is applicable, but that μ_s^* decreases with increasing temperature as a result of a variation of χ_s, the static electric susceptibility, with temperature. A re-examination of titanium using the optical techniques developed by Young should resolve this uncertainty.

The situation is, therefore, that Ta, Nb, and Al give data in agreement with Eq. [2] where the values of C are in accord with that predicted on the basis of a Morse interaction potential; the data for Bi (8) are also consistent with this equation although of insufficient precision to verify the term in C; the data for Ti are uncertain since the current efficiency for film formation is unknown; and finally, the data for Zr are definitely not in accord with this equation. Accordingly, in this paper we shall be concerned primarily with the behavior of Ta and Al, for which the major amount of data are available, and to a lesser extent Nb and Bi. The data for other metals or semimetals which exhibit valve metal film forming properties are not sufficiently complete or precise to distinguish between alternative mechanisms.

A brief comment on the magnitude of the parameters found experimentally is relevant at this point. For Ta, Young (5) obtained a value for μ_s^* (qa in his notation) of 35 eÅ which on choosing the maximum possible effective charge on the mobile ion, + 5e gives an effective activation distance of 7Å, an extremely large value. If we assume a value for C for the anodic oxidation of Bi of the same order as that found for Ta, Nb, and Al (*i.e.*, about 3.3) then a value of 129 eÅ for μ_s^* may be calculated from Young's data (8). In this case, the value for the effective activation distance is no less than 43Å. Even without making any allowance for the covalent bonding in these oxides (which would be expected to lead to effective changes appreciably less than +5e and + 3e, respectively) it is seen that these values for μ_s^* are very much too large to be equated to the product of a charge and activation distance. The other valve metals also give high values for the steady-state effective activation dipole, μ_s^*. These high values are immediately explained in terms of the new theory, since $\mu_s^* = (1 + \delta\chi_s)\mu^*$ where μ^* is the "true" activation dipole, χ_s the static electric susceptibility of the oxide, and δ a geometric factor of the order of unity. A more quantitative consideration of this matter will be reserved for the following section. At this point, however, it is worth noting that the suggestion that the field effective in causing ion migration is greater than the applied field is by no means a new one. Indeed in 1941, Maurer (19) explained the temperature dependence of the ionic conduction of glasses on the assumption that the effective field was given by the static dielectric constant times the applied field. The point was first raised in connection with anodic oxide films by Young (20) in 1954. Until now, however, this concept has received very little attention.

Perhaps the most serious limitation of all previous theories lies in their failure to account for the recent data (21-25) regarding anionic and cationic transport in certain valve metal oxides. I wish to draw particular attention to the excellent work of Davies and colleagues (21-23) in which using β-spectroscopy in conjunction with Xe^{125} and Rn^{222} marker experiments, they were able to evaluate the transport numbers appropriate to the anodic oxidation of Al, W, Ta, and Zr. The anionic transport numbers were found to be (23) for Al_2O_3 0.45 ± 0.5; for WO_2 and Ta_2O_5 0.65 ± 0.04; and for ZrO_2 0.99 ± 0.01. In addition the transport numbers for Al_2O_3 were found to be independent of current density over the range 10^{-4} to 10^{-2} amp/cm^2, with a similar result found for WO_2 and ZrO_2. The effect of current density on transport numbers for Ta_2O_5 had not been investigated at the time this paper was prepared.

For previous theories to be compatible with these data, one must first assume that the activation dipole for anionic and cationic defects present in the film are nearly identical, since the transport numbers are independent of field strength. Next, since pre-exponential factors will be comparable for all defects, one must assume that the zero field activation energies for migration of the anionic and cationic defects are nearly the same. Such postulates if proposed to explain the results for only a single metal-oxide system should be regarded with great scepticism and must be considered entirely out of the question when required to explain the data for more than one metal oxide system. Indeed, if any of the previous theories are to be ac-

cepted even tentatively, one is forced to reject the validity of the transport number data.

Let us now examine the data of Davies and collaborators in terms of the newly proposed theory. The transport numbers will be determined largely by the fraction of the charge carried through the individual molecular units by anions and cations, respectively, since the gap between molecular units is presumably quite small compared with the dimensions of such units. Immediately following an ion transfer event, the donor and acceptor molecular units will be depolarized. To re-establish their equilibrium dipole moments, ion migration in each is required. In general one would expect both anionic and cationic defects to be produced in a somewhat random manner in the two molecular units by the highly exoenergetic ion transfer process. As the impact energy for ion transfer will be very nearly independent of current density, no significant dependence on current density would be expected. From this model we deduce, therefore, transport behavior, in accord with the above data. The theory is also in accord with the transport data presented in a recent paper by Amsel and Samuel (25) and an earlier paper by Verkerk, Winkel, and Groot (24).

Tafel slope data.—Two kinds of Tafel slope determinations have been made on a number of the valve metal-oxide systems: steady-state Tafel slopes, evaluated from the steady-state relation between current and field strength, and transient Tafel slopes, obtained from the relation between current and field strength when the field (or current) is changed very rapidly. The steady-state and transient reciprocal Tafel slopes, β_s and β_1, respectively, are given by Eq. [36] and [40] (or [41]) of the previous paper

$$\beta_s = \underset{\dot{E} \to 0}{\text{Limit}} \frac{d \ln I}{dE} = \frac{\mu_s^*}{kT}\left[1 - \frac{2\mu_s^* E}{C\phi}\right] \qquad [3]$$

$$\beta_1 = \underset{\dot{E} \to \infty}{\text{Limit}} \frac{d \ln I'}{dE} \simeq \left(\frac{\Delta \ln I'}{\Delta E}\right)_{\Delta t \to 0} \simeq \frac{\mu_1^*}{kT}\left[1 - \frac{2\mu_s^* E_o}{C\phi}\right] \qquad [4]$$

where the approximations amount to neglecting $\mu_1^* \Delta E / C\phi$ compared with unity and a further small term, cf (1) Eq. [40] and following.

From the excellent data of Young (5, 26), the field dependence of the Tafel slopes for the tantalum system are represented by the following equations

$$\beta_s\, kT = 34.98\ (1 - 9.58E)\ e\text{Å} \qquad [5]$$

$$\beta_1\, kT = 11.15\ (1 - 9.50\, E_o)\ e\text{Å} \qquad [6]$$

The manner in which β_1 was determined was such that $\Delta E << E$ so that the approximations contained in Eq. [4] are justified in this instance. We now note that the empirical coefficients of E and E_o in the above expressions are the same well within experimental error, as predicted by Eq. [3] and [4]. The same agreement within experimental error has been found for aluminum from recent data obtained in this laboratory (6, 27). Unfortunately, however, we have as yet been unable to obtain the coefficient of E_o in the expression for the transient Tafel slope any more accurately than ± 30%. Data of sufficient precision to test this prediction for other value metals are lacking at present.

On the basis of previous theories, and in particular the high field Frenkel defect theory, the agreement between the coefficients of E and E_o (Eq. [5] and [6]) must be regarded as entirely fortuitous, whereas it is a specific prediction of the present theory.

It is of interest at this point to show how χ_s may be estimated from Tafel slope data. If complete data are available, μ_s^* and μ_1^* can be determined from β_s and β_1 *vs.* E and E_o, respectively, from which one obtains $(\delta\chi_s + 1)/(\delta\chi_1 + 1) = \mu_s^*/\mu_1^*$ or assuming $\chi_s >> (1/\delta - 1)$ and $\chi_1 >> (1/\delta - 1)$,

$$\mu_s^*/\mu_1^* \simeq K_s/K_1 \qquad [7]$$

where K_s and K_1 are the static and dynamic dielectric constants. Using standard a-c capacitance data at sufficiently high frequencies (1000 cps would appear to be sufficiently high) the dynamic dielectric constant can be calculated and thence an estimate of the static electric susceptibility, χ_s, or static dielectric constant, K_s, obtained from μ_s^*/μ_1^*. If data for the variation of the Tafel slopes with field strength are not available, then for measurements such that $E \simeq E_o$ and ΔE small, it follows that

$$\beta_s/\beta_1 \simeq \mu_s^*/\mu_1^* \simeq K_s/K_1$$

To date, no independent determinations of K_s are available to test the validity of Eq. [7].

One of the more fundamental predictions of the present theory is that the transient Tafel slope and conventional dynamic dielectric constant are related, since

$$\mu^* = \mu_1^*/(1 + \delta\chi_1) \quad \text{or} \quad \delta\mu^* = \mu_1^*/(1/\delta + \chi_1) \simeq \mu_1^*/K_1$$
$$[\text{for } K_1 >> (1/\delta - 1)]$$

If oxygen ions are the ones involved in the ion transfer process for all the valve metal systems, then $\delta\mu^*$ should not differ greatly from one system to the next, so that μ_1^*/K_1 will be approximately a constant. The variation in ionic character, bond strength, and structure will of course introduce some variation in μ_1^*/K_1. The real justification for assuming oxygen ion transport between crystallites is, of course, that this postulate is in accord with the results. However, a reasonable case can be made for this postulate simply on the basis of the proposed model. Since the oxides are partially ionically bonded, the radius of the oxygen species will be appreciably larger than that of the metal species. The oxygen "ions" will therefore stand out from the surface of the crystallites, in relation to the metal "ions," so that the effective field at the oxygen ions should be somewhat higher. The higher polarizability of the anionic species should also favor oxygen ion transport between crystallites rather than cation transport.

Table I lists values of μ_1/K_1 for the systems tantalum, aluminum, niobium, and bismuth and their respective oxides. Young's values for μ_1^* (26) and K_1 (28) for Ta_2O_5 are reported, along with the corresponding values for Al_2O_3 obtained recently in the author's laboratory (27). In a previous publication (15) Young's data (7) for Nb_2O_5 were used to calculate μ_s^*. Combining this result with Young's value for K_1 (29) and Vermilyea's (30) determination of $\mu_s^*/\mu_1^* = 2.1$ ($q\lambda$ effective/$q\lambda$ initial, in his terminology) gives the required values of μ_1^* and K_1 for Nb_2O_5. Young's data for Bi_2O_3 (8) provides values for β_s, β_1, ψ, and K_1. Since the quadratic parameter, C, is nearly the same for Ta_2O_5, Nb_2O_5, and Al_2O_5 (15), μ_1^* for Bi_2O_3 was calculated from Eq. [4] and [5] assuming $C \simeq 3.3$.

As predicted, the values of μ_1^*/K_1 in Table I show much less variation than do the values of either μ_1^* or K_1 individually. Furthermore, the variation in $\mu_1^*/K_1 \simeq \delta\mu^*$ can be explained qualitatively on the assumption that it is due primarily to a variation in the effective charge on the oxygen "ion" from oxide to oxide. Thus the oxides in which the metal is in an

Table I. Relation between transient activation dipole and dynamic dielectric constant

Oxide	μ_1^* eÅ	K_1	$\mu_1^*/K_1 \simeq \delta\mu^*$ eÅ
Ta_2O_5	11.1$_5$	27.6	0.40
Nb_2O_5	16	41.4	0.39
Al_2O_3	7.8	8.8$_5$	0.88
Bi_2O_3	40	62	0.65

oxidation state of +3 should involve a higher proportion of ionic *vs.* covalent bonding than those involving a metal oxidation state of + 5, so that μ^* for Al_2O_3 and Bi_2O_3 should be appreciably greater than μ^* for Ta_2O_5 and Nb_2O_5. Between Ta_2O_5 and Nb_2O_5, according to the usual variation with ionic size, Ta_2O_5 should be slightly more ionic (31). The argument favoring more ionic bonding for Al_2O_3 than for Bi_2O_3 rests on the fact that the first ionization potential for Al is 1.3 ev lower than that for Bi (32).

Finally, as a check on the reasonableness of the magnitudes of the kinetic parameters μ_1^* and μ_s^*, we shall attempt to estimate the magnitude of the effective activation distance. From the crystal lattice parameters, Wells (33) estimates that the bonding in α Al_2O_3 is about 50% ionic. Assuming about the same proportion of ionic bonding is involved in the anodically formed oxide, we may estimate the effective charge on the oxygen species in Al_2O_3 to be about 1e. This leads to an effective activation distance at zero field strength of about $0.9/\delta$ Å, which for $\delta \simeq 1$ is an eminently reasonable value. It is tempting to suggest that this calculation justifies choosing a value for δ of about unity, however, the assumptions involved in this estimate are sufficiently bold to make such a proposition somewhat hazardous. Nevertheless, the calculation does indicate that the values of μ_1^* are of the correct magnitude.

In summary, the Tafel slope data for Ta, Nb, Al, and Bi are in complete accord with the theory presented in the previous paper. It would be very difficult to rationalize the data of Table I on the basis of any previous theory.

Constant field transients.—Measurements of transient conduction phenomena under conditions of very nearly constant field strength have been made by Young (26) on tantalum and in the author's laboratory on aluminum (27). Typical examples of these data are reproduced in Fig. 1 and 2. Young's data were obtained by heating a previously anodized sample to 100°C for a few minutes then returning it to the cell, applying suddenly an appropriate constant voltage and recording the current for the first few seconds. Our measurements were made following thermal treatment both for 1 hr at 60°C and for a few minutes at room temperature. The voltage was not applied suddenly but increased to its final value at a rapid linear rate, as shown in Fig. 2.

There are several points of interest in these curves which we shall discuss primarily with reference to Fig. 2. The initial upswing in the current during the

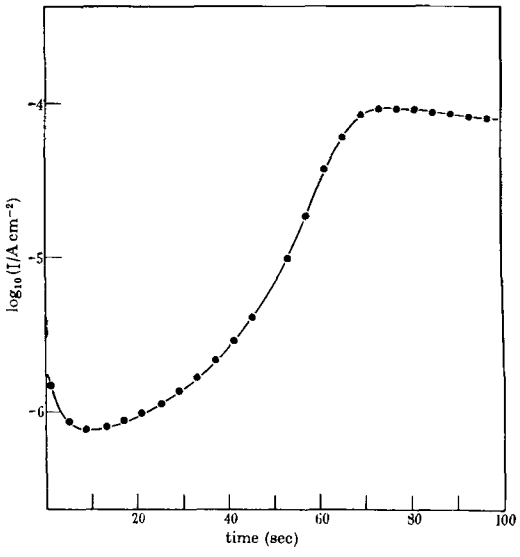

Fig. 1. Young's data for tantalum (26). Logarithm of the current density, *I*, as a function of time on reapplication of a fixed anodic potential.

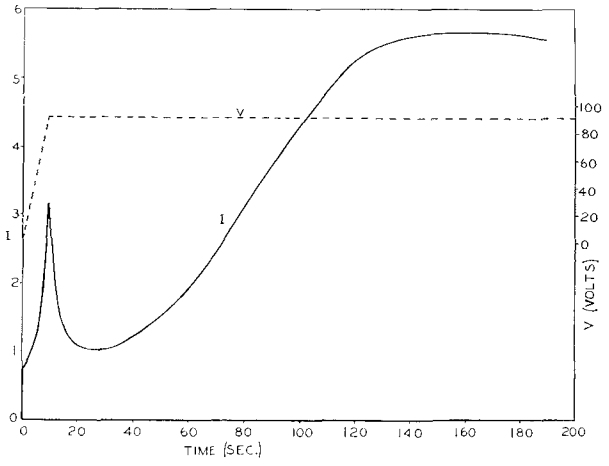

Fig. 2. Current density, *I* (μa cm^{-2}) as a function of time for aluminum on reapplication of anodic potential, *v*, as illustrated.

voltage build-up stage and the fall in current immediately after the voltage becomes constant cannot be explained by any previous theory, except by postulating fissures in the anodic film as Young has done (26). On the present theory, such charging currents are to be expected and represent strong evidence in support of an anomalous polarizing process which we have referred to as the transport polarization process.

A second point of interest is the fact that, apart from the present theory, there exists no quantitative theory even for the shape of the curves beyond the point where the anomalous charging currents will make a significant contribution. The high field Frenkel defect theory predicts a curve shape (log *I vs. t* or *I vs. t*) which is at all times concave downward, as pointed out by Young (26), whereas experimentally (Fig. 1 and 2) the curves are at first distinctly concave upward. It has previously been suggested to the author that effects such as these are likely brought about as a result of structural changes during thermal treatment, but all these same features have been observed in the author's laboratory for aluminum samples which have been merely held at room temperature and zero applied voltage for a minute before re-applying the voltage. Such an explanation, therefore, seems improbable.

Before attempting a quantitative fit of these transient measurements to the present theory, it is worthwhile to give a qualitative description, in terms of the present theory, of the processes occurring over the various regions of Fig. 2.

On applying the linearly increasing voltage, the conventional charging current rapidly achieves its constant value of $\mathfrak{S}_0K_1(dE/dt)$, giving rise to the initial current jump. This is then followed by the more sluggish build-up of the "anomalous" charging current, dP_2/dt, under conditions where the growth current, i, is negligible, so that the collision process is not contributing to dP_2/dt. This initial build-up of the charging current should be given by Eq. [62] of the previous paper, from which we see that the current should rise approximately according to a hyperbolic sine function of the voltage, in qualitative agreement with the observed shape. When the voltage rise is stopped, the polarization of the medium is still well below the equilibrium value for the applied field, so that E_e is still too small to produce a significant number of ion transfer events. The total current observed is therefore still only the charging current, which should drop abruptly by an amount $\mathfrak{S}_0K_1(dE/dt)$, equal to the initial abrupt rise, then decay approximately as a negative exponential of the time, according to Eq. [63] of the previous paper. Unfortunately, the slow response of the recorder used did not permit the resolution of the initial fast drop from the subsequent decay.

Up to about 200 sec, therefore, the polarization of the medium, and hence the effective field, E_e, has been increasing almost exclusively by the thermally activated polarization process, the effective field being too small to cause a significant number of ion transfer events to take place. Somewhat after 20 sec, however, the growth current starts to become of significance, so that by 30 sec the rate of increase of the growth current effected by the increasing polarization of the medium has more than overcome the rate of fall of the thermally activated component of the charging current. From about 30 sec onward, the thermally activated polarization process becomes negligible compared with the collision induced process and the charging current small compared with the growth current, i. As the growth current increases, it increases the rate of change of the polarization of the medium, and hence of E_e, thus increasing the rate of increase of i and producing the concave upward portion of the curve from 30 to 80 sec. Ultimately, this "autocatalytic" process is overcome as the polarization of the medium approaches its steady-state value, leading to the rounding off from 80 to 140 sec. The decrease in current beyond 160 sec is caused by the slow fall in the applied field resulting from the slow film growth.

The data relating to the charging current are not sufficiently accurate to warrant quantitative treatment. Measurements are now being undertaken in this laboratory to test this aspect of the theory. We shall at present analyze quantitatively only that part of the data for which the thermally activated component of the charging current can be neglected. The correct equation for these conditions, Eq. [55] of (1), is recorded below

$$1/I = 1/I_o - B\int_o^t \ln(I_s/I)\,dt \qquad [8]$$

where I_o is the current density at $t = 0$, and I_s is the steady-state current density.

In Figure 3, the data for aluminum are plotted according to Eq. [8] for the experimental points lying between about 30 and 150 sec. In order to illustrate more clearly the quality of the agreement between the data and Eq. [8], the data for tantalum have been plotted in Fig. 4 according to a rearranged form of Eq. [8], *viz.*

$$F = [1/I - B\int_o^t \ln(I/I_o)\,dt] = 1/I_o - [B\ln(I_s/I_o)]t \qquad [8']$$

Both these sets of data are in excellent accord with Eq. [8] and hence with the present theory. The values of B calculated from the slopes are 8.0 x 10^3 cm^2/coulomb for tantalum and 11.4 x 10^3 cm^2/coulomb for aluminum. A number of values for aluminum have been obtained which are in agreement to about ± 5%. From the theory we have

$$B = (\sigma'/Ze)\,(1 + \delta'\chi_1)/(1 + \delta'\chi_s) \simeq (\sigma'/Ze)\,(\mu_1^*/\mu_s^*)$$

since

$$(1 + \delta'\chi_1)/(1 + \delta'\chi_s) \simeq (1 + \delta\chi_1)/(1 + \delta\chi_s) = \mu_1^*/\mu_s^*$$

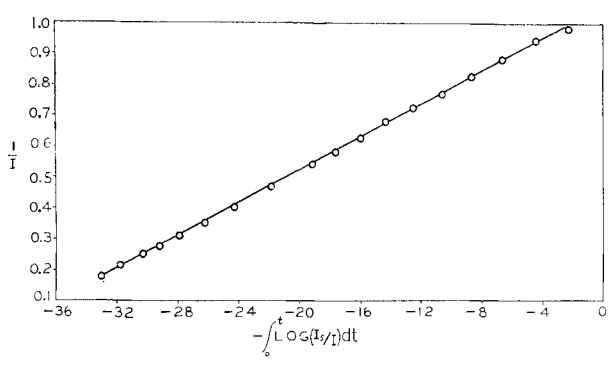

Fig. 3. Data of Fig. 2, plotted according to Eq. [8] (I in μa cm^{-2}, t in sec).

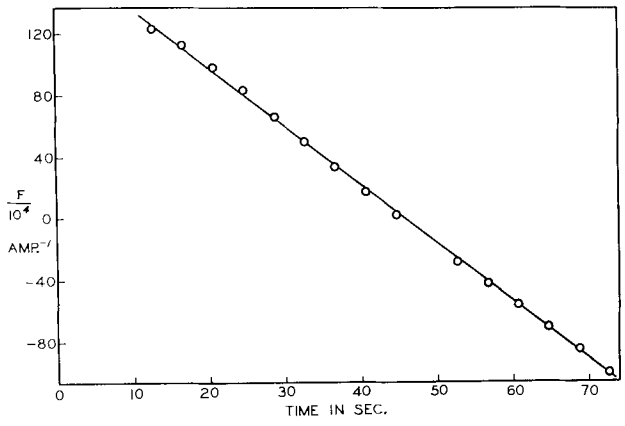

Fig. 4. Data of Fig. 1 plotted according to Eq. [8']

for $\chi_1 >> 1/\delta'$ and $1/\delta$, or $\delta' \simeq \delta$. Setting $Z = 2$ we then obtain $\sigma'^{1/2} = 8.9$Å for tantala and 11Å for alumina. On the reasonable assumption that the crystallites should contain at least one unit cell and be sufficiently small to give rise to the observed diffuse diffraction patterns, $\sigma'^{1/2}$ should lie between about 4 and 20Å, in excellent accord with the above values.

From the experimental value for the pre-exponential factor for the tantalum system, $i_o = 1.7_4$ x 10^8 amp/cm^2 (5), and the theoretical form for i_o, cf. Eq. [14] in (1), it follows that

$$1.7_4 \text{ x } 10^8 \text{ (amp/cm}^2) = ZeN'\nu/\sigma \simeq N'\nu\mu_1^*/\mu_s^* B$$

On substituting the empirical values for μ_1^*/μ_s^* and B we obtain $N'\nu \simeq 4$ x 10^{12} sec^{-1}, an eminently reasonable result since N', the number of charged species per molecular unit located at suitable sites for transfer to the next molecular unit, would be expected to be close to unity.

Since B contains a molecular unit dimension parameter, it is entirely possible that it will vary somewhat with film formation conditions. A thorough investigation to look for such an effect has not as yet been carried out but the present results (27) indicate that a variation in B of 20% or more can be effected by the choice of formation current density.

As stated previously, the data relating to the "anomalous" charging current are not sufficiently accurate to warrant quantitative treatment. A computer calculation to generate the entire experimental curve shown in Fig. 2, starting from Eq. [1], [13], [30], and [32] of the previous paper, has, however, been carried out. The result of this calculation was good qualitative, but not quantitative agreement with the experimental data. The failure to achieve a quantitative fit was traced to the form chosen for the "anomalous" charging current, dP_2/dt, *i.e.*, final term Eq. [30] of (1) or final term Eq. [24] of (1). It appears that the variation of dP_2/dt with E is in accord with Eq. [30] of (1) since the initial build-up of the charging current could be fitted well and for reasonable values of the parameters ($w_e^* \simeq 1.6$ eÅ and $Q \sim 0.8$ ev). The decrease of dP_2/dt from the peak under conditions of constant E, however, are not in accord with Eq. [30] of (1). The present equations appear to predict the wrong functional dependence of the anomalous charging current on P_2 or P. In view of the approximations made in deriving the equation for the thermally activated polarization process, this is not too surprising. It is felt, however, that this aspect of the theory can be substantially improved without altering the basic model. Efforts in this direction are now under way.

Influence of space charge on steady-state anodic oxidation.—As mentioned in the previous paper, Eq. [10] and hence Eq. [19] of the previous paper are only valid in a region of the film where the space charge is negligible. We shall now investigate the influence of

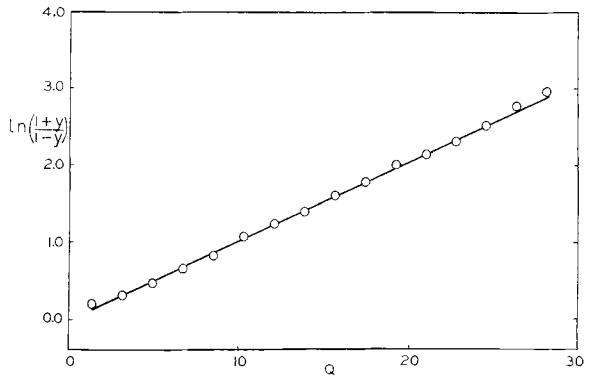

Fig. 5. Space charge data for aluminum (34) plotted according to Eq. [15]. (Q is charge passed in mcoul/cm^2).

space charge for steady-state anodic oxidation conditions.

From Eq. [7] and [9] of the previous paper and Poisson's equation, and assuming $\kappa_{+r} >> \kappa_{-r}$ we may write

$$i = ZedN + r\kappa p_o \quad [9]$$

$$n_{+r}n_{-r} = n_o^2/f\kappa = n_\infty^2 \quad [10]$$

$$dE/dx = (n_{+r} - n_{-r})Ze/\mathcal{E} \quad [11]$$

where $\kappa \simeq \kappa_{+r}$, $\mathcal{E}$ is the permittivity of the oxide ($K_s\epsilon_o$ for steady-state conditions), n_∞ the value of n_{+r} and n_{-r} beyond the space charge zone and x the distance into the oxide measured from the interface away from which the species of charge rZe move. The assumption $\kappa_{+r} >> \kappa_{-r}$ (or the converse) is required to obtain agreement with the data and would appear to be justified providing the molecular units are sufficiently small. Since $\sigma' \simeq 100$Å^2, we may assume a radius for a molecular unit of about 5Å and a nuclear separation between surface oxygen species on adjacent molecular units of about 2Å. The ratio of the two field terms (1), $\mathcal{E}_{+r}$ and $\mathcal{E}_{-r}$, should then be given approximately by $(\mathcal{E}_{+r}/\mathcal{E}_{-r}) \sim (5 + 2)^2/5^2 \simeq 2$. Therefore for $\kappa_{+r} \simeq 10^6$ (the value consistent with the experimental data reported below), $\kappa_{-r} \sim (10^6)^{1/2} = 10^3$ so that $\kappa_{+r}/\kappa_{-r} \sim 10^3$.

Returning to Eq. [9] to [11], we can write

$$dE/dx = (y - 1/y)Zen_\infty/\epsilon \quad [12]$$

where $y = p_{o\infty}/p_o$ and $p_{o\infty}$ is the value of p_o beyond the space charge zone. Since we shall consider only steady-state conditions y is given by

$$y = \frac{\exp\left[E_\infty\mu_s^*(1 - E_\infty\mu_s^*/C\phi)/kT\right]}{\exp\left[E\mu_s^*(1 - E\mu_s^*/C\phi)/kT\right]}$$

or

$$y = \exp\left[\bar{\beta}_s(E_\infty - E)\right] \quad [13]$$

where

$$\bar{\beta}_s = \frac{\mu_s^*}{kT}\left[1 - \frac{(E_\infty + E)\mu_s^*}{C\phi}\right]$$

and E_∞ is the field beyond the space charge zone, $\bar{\beta}_s$ is the steady-state reciprocal Tafel slope for thick films (*i.e.*, thicker than the space charge zone) measured at a field strength $(E_\infty + E)/2$ (see Eq. [3]). Since the small variation in the Tafel slope with field strength is only just detectable, taking $\bar{\beta}_s$ independent of field will be a satisfactory approximation for E close to E_∞.

Using the above expression for y and making the approximation that $\bar{\beta}_s$ is constant, Eq. [12] can be written

$$dy/dS \simeq (1 - y^2)/2 \quad [14]$$

where

$$S = (2\bar{\beta}_s Zen_x/\mathcal{E})x$$

Integrating this equation we obtain

$$\ln[(1 + y)/(1 - y)] = S + S_o \quad [15]$$

where S_o is the integration constant, so that a plot of $\ln[(1 + y)/(1 - y)]$ *vs.* distance from the appropriate interface should yield a straight line of slope $(2\bar{\beta}_s Zen_\infty/\mathcal{E})$. The space charge data previously published for aluminum (34) is plotted in Fig. 5 according to Eq. [15]. Differential field strengths as a function of charge passed were calculated from measurements of the time derivative of the anodic overpotentials as a function of charge passed. Details of the experimental procedure and assumptions involved in interpreting these data can be found in the original paper. However, it is worth pointing out that the assumptions are consistent with the present model.

As can be seen, the data fall on an excellent straight line. In the original paper it was shown that the slope of such plots was independent of current density, a result in conflict with the basic postulate of the high field Frenkel defect model and probably in conflict with any model which predicts a significant dependence of the bulk defect concentration on current density. Such a result, however, is in accord with the predictions based on the present model.

The slope of the graph was found to be $1.0_4 \times 10^2$ coulomb^{-1}, which for an oxide density of 3.2 g/cm^3 (35) corresponds to $1.8_6 \times 10^6$ cm^{-1}. Comparing this with the theoretical slope and setting $\bar{\beta}_s = 4.8 \times 10^{-6}$ cm/v (35), $\mathcal{E} = K_s\mathcal{E}_o \simeq (\beta_s/\beta_1)K_1\mathcal{E}_o \simeq 25.8\,\mathcal{E}_o$ (27), and $Z = 2$, we obtain $n_\infty = 1.4 \times 10^{18}$ cm^{-3}. Estimating n_o as follows: $n_o \simeq (\sigma')^{-3/2} \simeq 1.3 \times 10^{21}$ cm^{-3}, we have $n_\infty/n_o \simeq 10^{-3}$, a reasonable result.

We can obtain an estimate of $\mathcal{E}_r = \mathcal{E}$ in the following manner. From Eq. [10], $\kappa = (n_o/n_\infty)^2/f \simeq 10^6$. From Eq. [12], [15], [16], and [17] of the previous paper, it can be shown that

$$\ln\kappa \simeq \frac{\mathcal{E}\mu^*}{kT}\left[1 - \frac{2E_e\mu^*}{C\phi}\left(1 - \frac{4\mathcal{E}\mu^*}{C\phi}\right)\right] \quad [16]$$

where terms of the order of $(\mathcal{E}\mu^*/C\phi)^2$ have been neglected in comparison with unity. Assuming steady-state conditions and setting $(1 + \delta\chi_1) \simeq \delta K_1$ Eq. [16] can be written

$$\ln\kappa \simeq \frac{\mathcal{E}\beta_1}{\delta K_1} + \frac{8E\mu_s^*}{K_1^2kT}\left(\frac{\mathcal{E}\mu_1^*}{\delta C\phi}\right)^2 \quad [17]$$

where the term in $\mathcal{E}^2$ is fairly small compared to that in $\mathcal{E}$. Using previously reported values (*i.e.*, $\mu_s^* \simeq 23.5$ eÅ (15), $C\phi \simeq 7.8$ ev (15), $\mu_1^* \simeq 7.8$ eÅ, $K_1 \simeq 8.8_5$, and setting $E \simeq 8.5 \times 10^6$ v/cm. and $\kappa \simeq 10^6$, we calculate $\mathcal{E}/\delta \simeq 5 \times 10^7$ v/cm. (From this value, $\mathcal{E}\mu^*/C\phi \simeq \mathcal{E}\mu_1^*/\delta K_1 C\phi = 0.07$, a result consistent with the approximation made, *i.e.*, $(\mathcal{E}\mu^*/C\phi)^2 << 1$.) The value of $\mathcal{E}$ estimated in this way appears to be of the correct order, although a reliable independent estimate based on electrostatic considerations is difficult to make.

Summary

In the previous sections, selected data from the literature have been examined in the light of the newly proposed theory. The theory has by no means been applied, however, to the majority of the vast amount of data available in this field, an undertaking which lies outside the scope of the present paper. The principal features of the steady-state and transient behavior of electrodes formed by anodic oxidation of Ta, Al, Nb, and Bi have been examined and found to be in excellent accord with the theory. Specifically, the present theory is the only one to provide a reasonable explanation for: (*a*) the transport number data (Ta, Al); (*b*) the correlation between the field dependence of the transient and steady-state Tafel slopes (Ta, Al); (*c*) the correlation between the transient charge-activation distance product and the dielectric constant (Ta, Nb, Al, Bi); and (*d*) the form of constant field transients (Al, Ta). In addition, the theory provides a quantitative interpretation of space charge phenomena for thin films (Al). Again, all of the parameters deduced on the basis of this model are

of precisely the expected magnitude. Even the apparently discrepant behavior of Zr, mentioned earlier, can be reconciled with the present model. In this regard, the most obvious assumption to make is that the metal-oxide interface plays a major role in the conduction process.

Much additional data are required to properly test this theory. At present, however, it is the only quantitative theory which accounts for most of the observed conduction properties for these systems.

A Method for the Dynamic Measurement of Capacity at Electrode Interfaces

C. C. Krischer and R. A. Osteryoung

North American Aviation Science Center, Thousand Oaks, California

ABSTRACT

A potentiostatic method to permit determination of double layer capacity of electrodes under dynamic conditions has been developed. Small potential pulses are superimposed on a d-c sweep and the capacity is determined from the magnitude of current changes observed at the initiation and cessation of the pulse. Further, a method utilizing a transistor is described which permits rapid switching of a potentiostat from galvanostatic to potentiostatic operation.

Although several methods for the dynamic measurement of double-layer capacity have been reported, they appear to suffer from certain disadvantages. Breiter (1) utilized an a-c impedance technique to obtain qualitative curves at solid electrodes.

Boddy and Sundburg (2) developed a simple method of measuring the capacity continuously and rapidly. The authors used a current sweep which had superimposed short duration current pulses. The analysis of the resulting potential-time transients, properly displayed on a cathode ray tube, gave the value of the capacity over the whole length of the sweep. The disadvantage of this method is that the potential change, dE/dt, is not constant with time for a linear current sweep. dE/dt varies depending on the current-potential characteristic of the electrode. To keep dE/dt approximately constant these authors used a nonlinear sweep.

A potentiostatic method would be more convenient and is reported here. A linear d-c sweep voltage is applied directly to the electrode via a potentiostat. Superimposed on this potentiostatic sweep are low amplitude potential pulses. The pulse is short compared to the RC time constant of the electrode network.

In the first part of this paper it is shown how the electrode capacity can be calculated from the current transient that is caused by a potential pulse.

The advantage of using a linear potential sweep rather than a linear current sweep is quite evident if one recalls that the differential capacity curve that one is interested in lies in a potential region where dE/di of the indicator electrode has a maximum. Employing a galvanostatic method, the potential region of interest is passed rapidly if a linear current sweep is used.

In carrying out our work on germanium electrodes (3) we desired and devised a method to permit rapid switching of the cell from a potentiostatic mode to a galvanostatic mode of operation which is reported in the second part of this paper.

Dynamic Potentiostatic Measurement of Electrode Capacity

The electrical equivalent of the impedance of an indicator electrode in the potentiostatic circuit is shown in Fig. 1. It consists of a resistor, R, representing all series resistances in the circuit such as uncompensated resistance in the electrolyte, in the indicator electrode, etc., a resistor, R_p, representing the

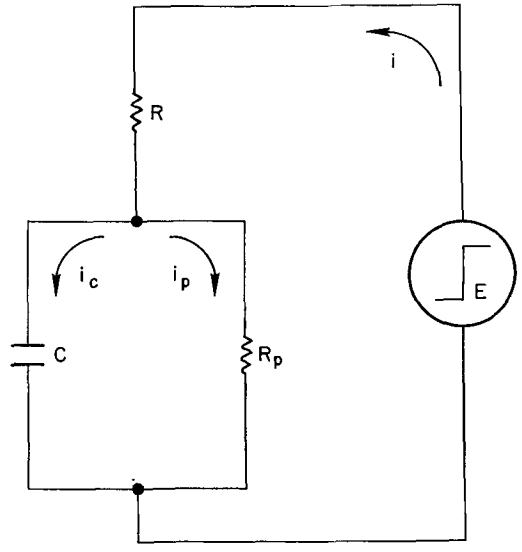

Fig. 1. Electrical equivalent circuit for the application of a potential step (potentiostatic operation) at a metal (or semiconductor) electrolyte interface.

impedance of the faradaic reaction and a capacitor, C, the capacitance of the double layer. [In the case of a germanium electrode, C represents the capacitance due to a space charge layer within the germanium (4).] The potentiostat is a potential source of effectively zero internal impedance. If it delivers a positive potential step of the magnitude, E, a current, i, will flow through the circuit. At $t=0$ the capacitor acts as a short circuit of R_p and an initial current

$$i_o = E/R \qquad [1]$$

will flow. The charging current i_c decays exponentially

$$i_c = \frac{E}{R}\exp\left(-\frac{t}{R'C}\right) \qquad [2]$$

where $R' = \dfrac{RR_p}{R+R_p}$. Simultaneously a current i_p starts to build up exponentially

$$i_p = \frac{E}{R+R_p}\left[1-\exp\left(-\frac{t}{R'C}\right)\right] \qquad [3]$$

The total current i is the sum of the two

$$i = i_c + i_p = \frac{E}{R}\exp\left(-\frac{t}{R'C}\right) + \frac{E}{R+R_p}\left[1-\exp\left(-\frac{t}{R'C}\right)\right] \qquad [4]$$

The initial slope of this curve is given by

$$\left(\frac{di}{dt}\right)_{t\to 0} = -\frac{E}{R^2C} \qquad [5]$$

At $t = \Delta t$ a negative step of the same amplitude, $-E$, is delivered (the sequence of the two steps is a rectangular pulse, Δt is the pulse width). At the beginning of the negative step the current changes by $-E/R$, followed by an exponential current-time behavior analogous to the one expressed in Eq. [4]. If the pulse width

$$\Delta t << R'C \qquad [6]$$

Eq. [5] can be approximated by

$$\Delta i = -\frac{\Delta t E}{CR^2} \qquad [7]$$

where Δi is the change in current during the time interval of the pulse. In this equation C and R are unknown; but according to Eq. [1], $R = E/i_o$ so the unknown capacity C becomes

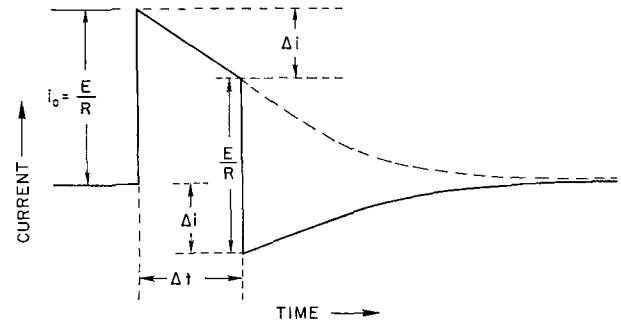

Fig. 2. Schematic of the current time behavior that results by application of a potential pulse in the circuit of Fig. 1 for $R_p >> R$. The line from which i_o rises represents the d-c level.

$$C = \frac{\Delta t}{E}\frac{i_o^2}{\Delta i} \qquad [8]$$

From this relationship it is seen that one can calculate C if at a known pulse width Δt and amplitude E the quantities i_o and Δi are measured. Figure 2 represents a schematic of the current transient that is caused by a potential pulse. The dashed line indicates the current decay that would occur if the negative step were missing. Note that the quantities i_o and Δi which are needed for the calculation of the capacity are the maximum positive and negative amplitudes of the transient.

In order to measure the capacity potential curve in a dynamic manner a single (or repetitive) linear potential sweep with superimposed short duration pulses is applied to the electrode. The duration of the pulses has to be sufficiently short so that the sweep d-c level may be considered constant over the interval of the pulse. The current transient which results as a consequence of this polarization is characteristic for the electrode impedance-potential curve. Figure 3 gives an example. The line with maximum intensity represents the d-c current through R_p of Fig. 1. This trace corresponds to the base line from which i_o rises, see Fig. 2. As the potential sweep is linear with time, this curve represents a conventional current potential plot. The envelope curves of low intensity above and below the most intense line are caused by the current excursions due to the superimposed pulses. Since there are 250 pulses of 3 μsec duration per horizontal division in Fig. 3, the current transients, one of which is

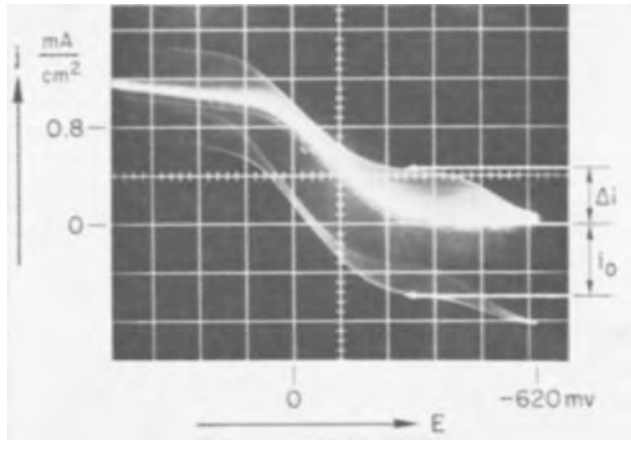

Fig. 3. Example of a current potential curve obtained potentiostatically with a single d-c sweep of 0.24 v/sec which had superimposed negative pulses of 100 mv amplitude and 3 μsec width. Repetition rate of the square wave pulse generator: 500 sec^{-1}. Electrode: 10 ohm cm n-Ge. Electrolyte 0.5M $NaClO_4$ 0.1M buffer pH 7, unstirred. The intense line (d-c voltage curve) within the trace became wider during the course of reproduction; it should be as narrow as in the left side of the figure. The arrows indicate typical current-transient amplitudes, see Fig. 2 and text.

shown in Fig. 2, merge together to yield an area of low intensity compared to the intensity of the main current-potential curve resulting from the voltage sweep. If the intensity of the oscilloscope beam is sufficient to permit observation of the current transients resulting from the voltage pulses, the main current potential trace from the voltage sweep is brighter and diffuse because of its longer duration relative to the transients. This problem, which affects the accuracy of the measurement, may be partially solved by intensifying the beam during appropriate portions of the trace. The deviations on either side of the d-c current trace directly represent the current amplitudes i_o and Δi, compare Fig. 2 and 3. With Eq. [8] one can then calculate C at any desired potential. From Fig. 3 it is seen that the condition $\Delta i << i_o$ is in most potential regions not fulfilled. Therefore, the exponential is at $t = \Delta t$ no longer near linear, condition [6] is not strictly fulfilled. Equation [8] then yields capacity values which are larger than in the case of validity of condition [6]. This error is however partly compensated by another effect. The rise time of the potentiostat tends to round off edges of the current transient: i_o will be measured smaller than it should be. These two errors tend to cancel each other. We found the accuracy to be within ±20%. The systematic error for one particular system will, however, be constant so that relative changes are easily detectable. In ref. (3) capacity potential curves are reported which are in good agreement with the calculated curves.

Intermittent Galvanostatic Switching of a Potentiostat

For the purpose of studying the surface of electrodes it may be desirable to polarize the electrode by a known amount of charge prior to the measurement of the characteristic. Most conveniently the charging is carried out under constant current conditions for a given time interval, *i.e.*, in a galvanostatic mode of operation. In order to minimize changes of the resulting state of the electrode before the capacity measurement is initiated, rapid switching to the potential where the capacity measuring sweep starts is required. A versatile, yet simple circuit is described which meets this requirement.

A transistor is placed in series with the cell. A voltage, E, is applied from the potentiostat to cause a potential drop, E_{trans}, across the transistor sufficient to drive it well into its limiting current region (reverse bias), (see Fig. 4). This results in the current through the cell being controlled by the limiting current characteristics of the transistor. The limiting current can be selected by appropriate transistor base current input (see Fig. 5). Changes in the voltage across the cell have little effect on the current through the system provided that such changes occur within the limiting current region of the transistor. When the voltage, E, is such as to result in a potential drop across the transistor which brings it into the forward biased region, there is little potential drop across the transistor. The current through the transistor can change appreciably with little change in potential drop across the transistor.[1]

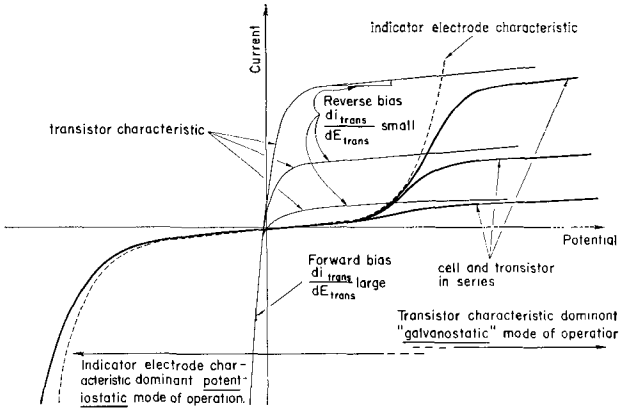

Fig. 4. Current potential behavior of a series combination of cell and transistor. The voltage drops as a function current are: dashed, of the indicator electrode; thin, of the transistor with three different base currents; and bold, of the cell and the transistor with three different base currents in series.

It was found (3) that in steep portions of the transistor characteristic (forward bias) the transistor capacity was much larger than the capacity of a germanium electrode in the flat part of its current potential curve. In this potential region, in which the potentiostatic mode prevails, the transistor capacity does not introduce a significant error in the measurement of the electrode capacity. Figure 4 represents a schematic construction of the current potential curves that result if a transistor with three different base currents is placed in series with an electrode which has an activation controlled current-potential characteristic. It is seen that the introduction of the transistor yields current clamping in one direction. It is in the potential region of small currents where the differential capacity curve is measured potentiostatically.

To summarize, placing the transistor in series with the indicator electrode serves the purpose of controlling the current through the cell. This is accomplished by applying a voltage that brings the transistor into reverse bias. The transistor characteristic then dominates. Under forward bias of the transistor, the indicator electrode characteristic prevails, and the transistor introduces only a slight perturbation on the indicator electrode characteristic. The base current, which has to be supplied by a current source other than the potentiostat, has two functions: (i) it determines the limiting current during the galvanostatic period, and (ii) it diminishes the interference of the transistor during the potentiostatic period. The perturbation of the indicator electrode characteristic during this period may be kept small by injecting a large base current, top curve in Fig. 4.

The design of the electrical circuit has to fulfill two requirements: short rise time of the potentiostat and versatility in the input system. The latter is needed in order to provide well-defined galvanostatic prepolarization followed by potentiostatic capacity measurement. We therefore employed the Wenking potentiostat in the adder configuration (6) rather than in the conventional differential mode. An oscilloscope with a delayed sweep capability is a convenient source of prepolarizing pulse and measuring sweep. The time base of such oscilloscopes may deliver two sawtooth and square wave voltages. One couple of sawtooth and square wave voltages corresponds to the normal or delaying sweep, the other to the delayed sweep. The voltages are of fixed amplitude and polarity. Attenuation and in some cases inversion is needed. The durations of the wave forms are calibrated and variable within a wide range. The beginning of the delayed sweep with respect to the normal sweep (and normal gate) is determined by the setting of the calibrated delay time potentiometer.

The details of the experimental arrangement are shown in Fig. 5. The response of the circuit is demonstrated in Fig. 6. It represents a photograph of a typical current transient that is caused by a rectangular potential pulse. The rise time is a little less than one μsec.

[1] Since the transistor is in series with the cell,

$$i_{trans} = i_{cell} = i(E_{trans})$$

and

$$E_{trans} = E - E_{cell}$$

$$\frac{di}{dE_{cell}} = \frac{di_{trans}}{dE_{trans}} \cdot \frac{dE_{trans}}{dE_{cell}} = -\frac{di_{trans}}{dE_{trans}}$$

$$di = -\frac{di_{trans}}{dE_{trans}} \cdot dE_{cell}$$

In the region of reverse bias, di_{trans}/dE_{trans} is very small (*ca.* 10^{-6} ohm^{-1}) so that a change in the cell voltage does not change i. In the forward bias region di_{trans}/dE_{trans} is very large, there is very little potential drop across the transistor, and dE_{cell} is unaffected by changes in i.

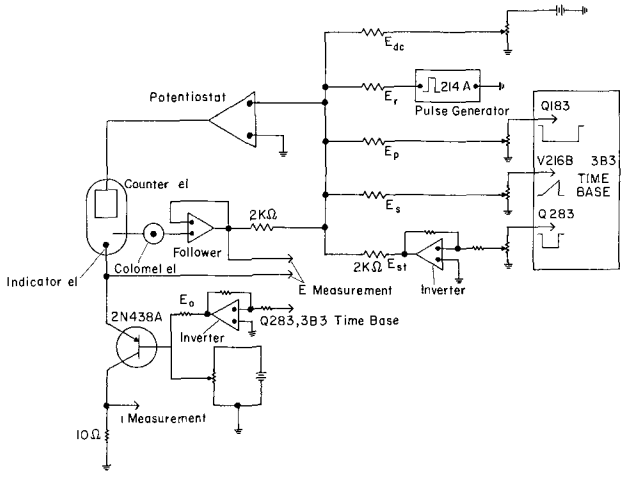

Fig. 5. Schematic representation of the electrical circuit for galvanostatic prepolarization followed by rapid potentiostatic measurement of the current and capacity-potential curve. The amplifiers are Philbrick, type P65A. The 3B3 time base is a Tektronix module, the numbers refer to the switching diagram of the time base manual. The pulse generator is a Hewlett-Packard product, type 214A. The potentiostat is a Wenking model.

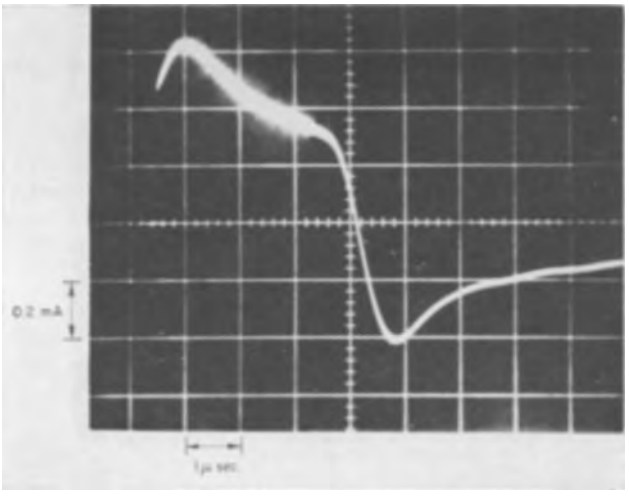

Fig. 6. Typical current time behavior that results upon application of a rectangular potential pulse to the following, not standard circuit elements: 150 ohm resistance in series with a 4 x 10^{-8}F capacitor which has a 10K ohm resistor in parallel. Pulse amplitude was 75 mv, duration 3 μsec. From the figure the series resistor is calculated to 125 ohm (instead of 150) and the capacitor to 3.6 10^{-8}F (instead of 4.10^{-8}F). The *R'C* network is similar to a 1 cm² Ge-electrolyte interface at the potential of the capacity minimum.

For studies of the germanium-electrolyte interface we were interested in pretreating the electrode with known amounts of cathodic charge prior to the impedance measurement. Therefore, in the circuit of Fig. 5 a n-p-n transistor was used to limit the cathodic current. For anodic pretreatment a p-n-p transistor would be chosen. Both current directions can also be limited if two transistors, n-p-n and p-n-p, with appropriate base currents, are placed in series.

Three waveforms of the timebase combined with two other voltage sources are used. The task of the individual potential sources is as follows:

1. Prior to the polarizing cycle the potential has to be set at a d-c level, $E_{d\text{-}c}$, which yields a reproducible steady state of the surface.

2. For the capacity measurements free running short duration rectangular pulses are needed. We used a Hewlett Packard 214A pulse generator.

3. To drive the transistor into its limiting current region in order to prepolarize, a high amplitude prepolarizing pulse, E_p, is applied. We chose the square wave of the normal or delaying sweep of the time base.

4. Furthermore, the measuring linear sweep, E_s, is needed. The sawtooth of the delayed sweep is used. The delay time of this delayed sweep with respect to the beginning of the normal sweep thereby determines the duration of the prepolarizing pulse.

5. In order to initiate the sweep at any desired potential, an additional pulse, E_{st} is required. Without this pulse the linear sweep would start in the limiting current region. The changeover from galvanostatic to potentiostatic mode would be gradual instead of abrupt. The gate of the delayed sweep which occurs simultaneously with the sawtooth can be used for E_{st} advantageously.

As indicated in Fig. 5, this latter pulse source, *i.e.*, the timebase, is also utilized to increase the transistor base current. Thereby a transistor characteristic is selected which causes the least interference of the indicator electrode characteristic at small current densities, compare Fig. 4. For further experimental details see Fig. 5 and its legend.

Figure 7 is a schematic representation of the waveform that appears at the output of the potentiostat by application of voltages 1-5 as listed above.

Listed below are some polarization cycles that can easily be obtained with the circuit of Fig. 5.

Prepolarization, anodic sweep (PA).—The cycle of Fig. 7 is described above in detail in which the voltage is increasing with time. This sweep will be called an anodic sweep. Decreasing voltage with time is called a cathodic sweep.

Prepolarization, cathodic sweep (PC).—If the same potential region as in Fig. 7 should be measured with a cathodic sweep, the amplitude of E_{st} is increased by the amount of E_s and E_s itself is inverted.

Anodic sweep (A).—If anodic sweep without galvanostatic prepolarization is desired one can (i) make the transistor limiting current very small by omitting the base current and making the delay time $\sim$ 0 or (ii) E_p is omitted and an inverted gate, $-E_{st}$, brings the sweep to a potential, $E_{d\text{-}c} - E_{st}$, which is desired as the sweep starting potential.

Cathodic sweep (C).—If cathodic sweep and no prepolarization is desired, the cathodic sweep is simply initiated at $E_{d\text{-}c}$. E_p and E_{st} are omitted.

Although our original interest in devising this procedure was focused on the studies of the germanium-electrolyte interface the technique is applicable to other electrodes such as metal electrodes and the dropping mercury electrode. For example, we have examined the differential capacity at a dropping mercury electrode in various electrolytes by this method and obtained agreement with literature results. Because a dropping mercury electrode has a longer time constant *R'C* than a germanium interface, the pulse dura-

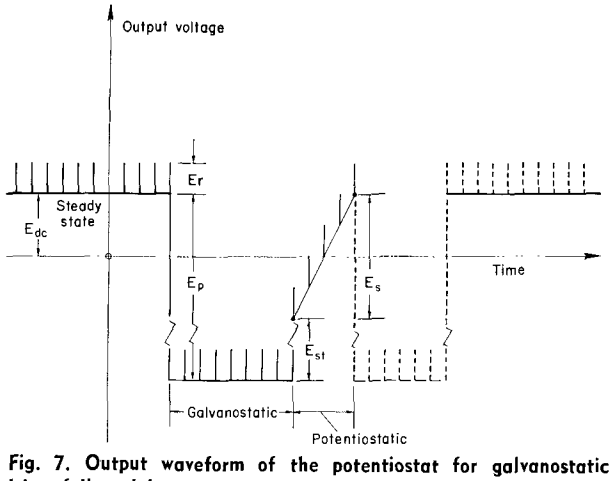

Fig. 7. Output waveform of the potentiostat for galvanostatic pulsing followed by a potentiostatic sweep. The voltages are with reference to Fig. 5. The dashed part following the sweep represents the termination of the galvanostatic pulse.

tion was chosen longer than in the case of germanium. Adjusting the pulse width to the particular RC network of the electrochemical system is necessary to obtain reasonable accuracy.

For low values of the time constant $R'C$ of the indicator electrode the method may be used up to high sweep rates $v = dE/dt$. At germanium electrodes sweep rates up to 300 v/sec were employed (3). For convenience we chose a combination of square wave and sawtooth voltages for the prepolarization and potential variation. The circuit described above allows, however, the use of other wave forms as well, such as a triangular or a sine wave. An application of this method to the study of germanium electrodes will be reported (3).

Summary

A dynamic capacity measuring method is devised. It is based on the analysis of current transients that are caused by short duration potential pulses. The dynamic variation of the potential is achieved with a linear potential sweep on which the pulses are superimposed. An oscilloscope serves as a sweep generator. The charge flow during the measurement of the capacity potential curve may be kept very small (in the order of a few μa sec/cm^2) if appropriate values of the sweep starting potential and the sweep rate $v = dE/dt$ are chosen.

This method may be employed advantageously in connection with a novel technique of switching the cell from the normal potentiostatic into a galvanostatic mode, as is also described in this paper. A transistor, placed in series with the indicator electrode, represents the fast switching element. The galvanostatic mode serves to charge the electrode surface to a known extent. The same oscilloscope (with delayed sweep capability) that delivers the sweep controls also the prepolarization time. With the method described above one is able to measure the electrochemical characteristic of a prepolarized electrode, since its state remains practically undisturbed in the course of the measurement. The galvanostatic prepolarization may be chosen in the cathodic, anodic or both current directions.

The Effect of Dislocations and Orientation on the Electrical Double Layer Capacity of Silver Surfaces

R. G. Rein, C. M. Sliepcevich, and R. D. Daniels

University of Oklahoma, Norman, Oklahoma

ABSTRACT

This study was undertaken in an attempt to obtain a better understanding of the effects of dislocations, crystal orientation, and surface imperfections on the catalytic activity of metals. Relative surface areas of pure silver crystals were determined from measurements of double layer capacities for {110}, {111}, and {211} planes with dislocation densities ranging from 10^6 to 10^8 cm^{-2}. Care was taken to insure that clean, oxide-free surfaces were used during measurements. Although it was found that the relative areas of {110} and {211} planes were proportional to the log of dislocation density, the relative area of {111} planes was found to be independent of dislocation density. The behavior of the double layer capacity as influenced by abrasion, cracks, notches, grain boundaries, and dislocations is discussed in terms of changes in physical area and changes in effective area resulting from additional dislocations. Models of metal surfaces and knowledge about the structure of the double layer are inadequate, at present, to allow positive conclusions to be drawn about the effect of dislocations on double layer capacity. The double layer capacity of mercury in 0.2N H_2SO_4 was experimentally determined to be 19.4 $\pm$ 2.2 μf/cm^2 which agrees favorably with values reported recently.

Crystal imperfections and surface orientation, particle geometry and surface irregularities are factors which can influence the activity of catalysts (1-3). The effectiveness of a metallic catalyst has been found to be dependent on the crystal face exposed to the reactants (4-8). In addition, Liedheiser and Gwathmey have found that {100} planes of copper become roughened while catalyzing the reaction of oxygen and hydrogen; whereas {111} planes remained smooth (6). Introducing imperfections into a crystal has also been reported to influence catalytic activity (9-12). Barnes and Mazey (13) show a change in surface area with irradiation, a common method for disturbing a metal lattice.

Although the BET area has been used frequently in correlating kinetic data for catalytic reactions, in most cases the superficial area, or some equivalent, is used without giving any consideration to surface conditions. Since it is possible that significant information can be masked if differences in surface area between crystal planes and differences in area due to crystal imperfections are not considered, this investigation was undertaken to determine changes in area as influenced by dislocation density and crystal orientation.

The many methods for determining surface areas have been summarized by Adamson (14), Brunauer (15), and Gregg (16). Of the methods mentioned, only the various adsorption methods, such as the well-known BET technique and the double layer capacity method are generally applicable. Gas adsorption techniques are not satisfactory in the case of metals because of their small area to volume ratio. The relative decrease in pressure or volume of the adsorbed gas is too small, for a reasonable size sample, to allow accurate analysis. For this reason the double layer capacity method first proposed by Bowden and Rideal (17) was used to determine the effective surface areas of the silver crystals employed in this study.

Throughout this paper three different area terms will be used: (*a*) superficial area, which is determined by the gross dimensions of the sample; (*b*) physical

area, which takes into account all mechanical surface irregularities such as roughness, notches, cracks, misorientation at grain boundaries, regardless of the scale of dimensions; and (c) effective area, which is determined by the double layer capacity measurement and which may be influenced both by the physical area as defined above and by energy factors associated with crystal surface orientation and crystal defects.

The double layer capacity method as originally conceived was based on the assumption that the double layer capacities of metal electrodes with equal physical areas are the same and independent of the metal being investigated. However, it is conceivable that the double layer capacity measurement considers not only the physical area but also area affects arising from crystal orientation and defects. Consequently, an attempt was made to isolate these latter factors by taking special precautions to maintain a constant physical area while varying only the dislocation density and crystal orientation.

The measured double layer capacity is given by

$$\left(\frac{\partial \Gamma}{\partial E}\right)_{T,\,P,\,\text{etc.}} = C \text{ (at time} = 0) \qquad [1]$$

where Γ is the charge in coulombs on the double layer per unit superficial area, E is the potential in volts across the double layer, and C is the differential capacity applicable for short durations of time (time < 0.10 sec) in farads per unit superficial area. The units of superficial area are hereafter denoted by an asterisk $(cm^2)^*$. Thus, $\partial\Gamma/\partial E$ represents the instantaneous measured value of the capacity at time equal zero.

If the superficial area of a metal and the effective area for capacity determination are identical, $\partial\Gamma/\partial E = C'$ will have the units of (farads/effective area in cm^2). The assumption is made for a mercury electrode that the effective area for capacity determinations is identical to its superficial area. Therefore the capacity of any metal electrode, C, divided by the capacity of a mercury electrode, C', gives the effective area of the metal electrode relative to its superficial area.

$$CAR = \frac{C}{C'}\,\frac{(cm^2)}{(cm^2)^*} \qquad [2]$$

The abbreviation, *CAR*, refers to the capacity area ratio and will be used throughout the paper. It is an indication of the effective area.

In these measurements care must be taken to eliminate concentration and ohmic polarization, which would distort the value of the potential applicable to the double layer. For reproducibility and accuracy of measurement, care must also be exercised to eliminate impurities on the electrode surface and in the electrolytic solution as impurities also tend to affect the capacity of the double layer (14, 17, 18).

Procedure

Apparatus and General Considerations

The effective areas of silver specimens were measured by the double layer capacity first proposed by Bowden and Rideal (17). The electrical circuit is shown in Fig. 1.

The oscilloscope (O) was used in conjunction with an oscilloscope camera to record the potential E (t) of the silver electrode. The integrated current through the cell Γ (t) was obtained from readings on the recorder (R) of the voltage across the capacitor. The output of the signal generator (SG) was a square wave of frequency 0.05 cps and supplied the polarizing current for the cell. The steady-state current density through the cell was 10^{-4}-10^{-3} amp/$(cm^2)^*$.

Since the signal generator output was from plus volts to minus volts and the desired output was from zero to plus volts, the circuit SGB was used to bias out the undesired negative output.

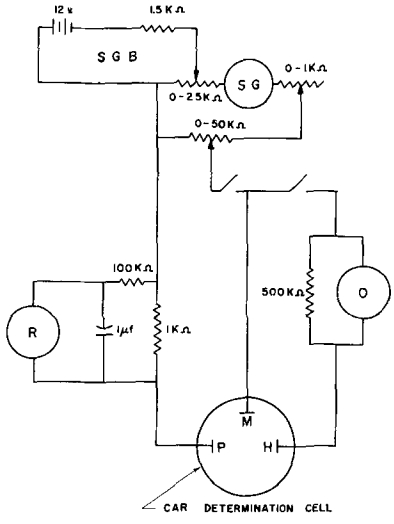

Fig. 1. Electrical circuit

(H) is a standard hydrogen electrode, (P) a platinum electrode, and (M) the metal electrode whose effective area is being determined.

The effects of ohmic polarization were minimized by putting the electrodes near each other (at the corners of an equilateral triangle of side 4 cm). Hydrogen bubbling from the hydrogen electrode agitated the solution to eliminate concentration polarization.

The electrolyte was $0.2N$ H_2SO_4 which had been freed from dissolved oxygen by heating under a slight vacuum for 1-2 hr and cooled to room temperature in a hydrogen atmosphere.

Although Bowden and Rideal (17) state that the determinations may be made either during polarization or depolarization of the double layer, the larger part of the data were obtained during polarization; however some data, which agreed with that obtained by polarization, were obtained during depolarization. All data were obtained at temperatures between 75° and 80°F.

Crystal Preparation

The silver single crystals used for effective area determinations were grown in the laboratory (19). The crystals were oriented by the Laue back-reflection x-ray technique and cut with a standard, water-cooled cut-off machine, so as to expose either {211}, {111}, or {110} planes. The desired surfaces were then mechanically polished with successively finer grit polishing disks, the final treatment being with a 600C disk. The crystals were then deformed to introduce a controlled number of dislocations. Two methods of deformation were used: (a) The crystals were bent to a U shape by either a 1.00 or a 4.00 cm radius plunger-die combination (see Fig. 2a); the deforming force was applied normal to the surface whose area was to be measured.

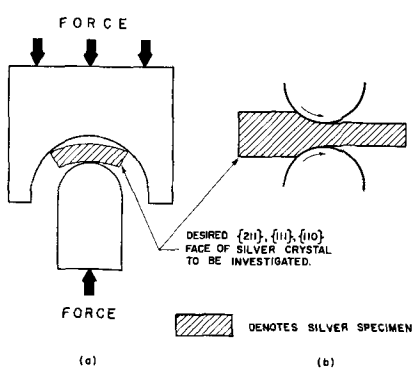

Fig. 2. Methods of crystal deformation

(b) The crystals were cold-rolled to a given reduction; the applied force again was normal to the surface whose area was to be measured (see Fig. 2b).

The crystals, after deformation were electropolished in a 5 w/o (weight per cent) KCN solution. This treatment lasted for 3-6 min at 1-2 amp/cm^2. The electropolished surfaces appeared bright, shiny, and free from microscratches as determined by microscopic examinations at 300X. The surfaces were also strain-free as evidenced by the distinct poles rather than smears obtained on a Laue back-reflection pattern of a sample prepared in this manner.

A thermal-etching technique applicable to silver (19, 20) was used to determine the dislocation density. The samples were annealed at 600°-615°C for 45-90 min in an argon atmosphere, etched 10-15 min in a 10% oxygen-90% argon mixture, and cooled to room temperature in an argon atmosphere. Etch pits were counted at magnifications of 1500-2500X on a metallograph. Figure 3 is representative of the etch pit observations. The macroscopic dimensions of the specimens were then measured with a micrometer and used to calculate the superficial area.

After thermal etching, an electrical lead was connected to the sample by an alligator clip and the sample was mounted in Koldmount. The face which was to be subjected to *CAR* determinations was protected by a strip of fiberglass tape during mounting. After mounting, the tape was removed, and the surface cleaned with methanol to remove traces of adhesive and fingerprints.

To insure the absence of any oxide layer either of two final surface preparations was used: (a) The samples were again electropolished for 15-20 sec, washed with distilled water, and then placed in the *CAR* determination apparatus, a technique found acceptable by Wisdon and Hackerman for iron (21). (b) The samples were subjected to 2-4 hr of electrolytic reduction to reduce any oxide layer (22, 23). For this treatment the sample served as the cathode, oxygen-free 0.2N H_2SO_4 as the electrolyte and platinum as the anode. A steady-state current density was passed through the cell; the range of densities used was between 5-15 μa/cm^2*. After this pretreatment the samples were immediately placed in the *CAR* apparatus. The double layer capacity, and hence the *CAR*, was found to be independent of the two techniques used for final surface preparation.

To isolate the dependence of *CAR* on undesirable effects, the following exceptions were made to the general procedure mentioned: (a) Sample *E*, an undeformed sample: the final polish was with a 240C polishing disk, instead of electropolishing, to determine the effect of scratches on the *CAR*. (b) Sample F, deformed 62% by rolling: it completely recrystallized during the annealing treatment. (c) Samples I and J: the *CAR* was measured after use of these samples as catalysts for the decomposition of formic acid. The surface of sample J was not cleaned prior to the *CAR* tests, while sample I was subjected to 4 hr of electrolytic reduction. (d) Sample K: the thermal etching treatment and determinations of dislocation density were made after the *CAR* tests to minimize possible recrystallization effects.

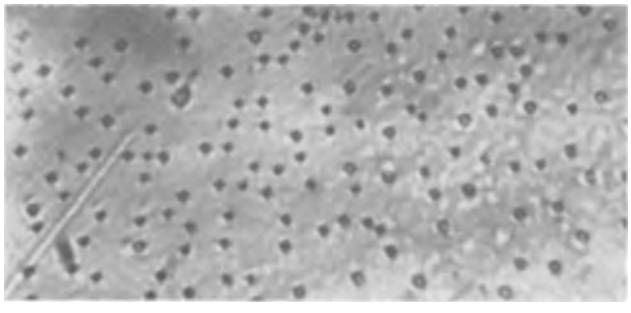

Fig. 3. Etch pits on a {211} plane of silver (2000X and 1.2 x 10^7 dislocations/cm^2).

Table I. Capacity area ratio (*CAR*) Data

Sample	Crystal face exposed	Dislocation density	Double layer capacity f/(cm^2)*	*CAR*	Number of determinations
A	211	3.2×10^6	52.6 ± 1.6	2.71	11
B	211	1.0×10^7	68.5 ± 2.6	3.53	16

[a] *CAR* determined after sample was used to catalyze the decomposition of formic acid. Surface cleaned prior to determination.
[b] *CAR* determined after sample was used to catalyze the decomposition of formic acid. Surface not cleaned prior to determination.
[c] Sample recrystallized.
[d] Final surface preparation was with 240C polishing disk.

It is possible that the cold work used to introduce dislocations into the specimens could cause recrystallization of the samples during the annealing and thermal etching treatment. The grain boundaries thus formed could also affect the area measurements. To determine the extent of recrystallization, if any, several specimens were etched in an ammonium persulfate-sodium cyanide solution. Sample F (noted above) was the only one which exhibited recrystallization.

To determine the double layer capacity of the mercury, a fresh pool of mercury was placed in a plastic tube; electric contact was made via a copper disk connected to a lead in the bottom of the tube. The tube was immediately placed in the cell and the necessary data were obtained. Sufficient holes and slots were cut in the tube to eliminate the possibility of concentration polarization.

Results

The results of this investigation are shown graphically in Fig. 4-7, and are given in tabular form in

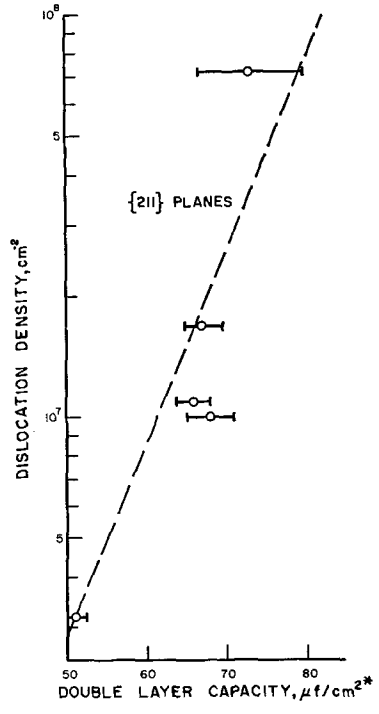

Fig. 4. Dislocation density vs. double layer capacity {211} planes

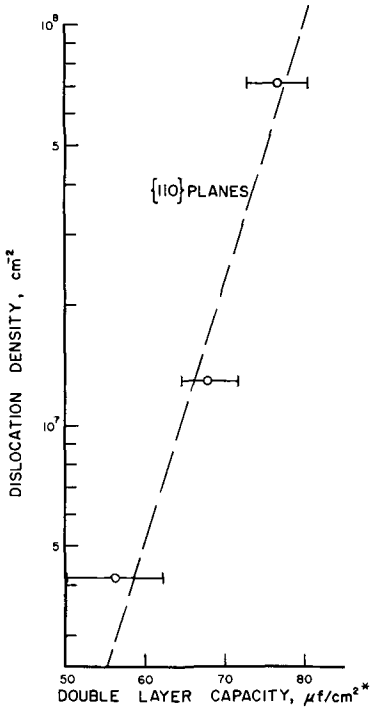

Fig. 5. Dislocation density *vs.* double layer capacity {110} planes

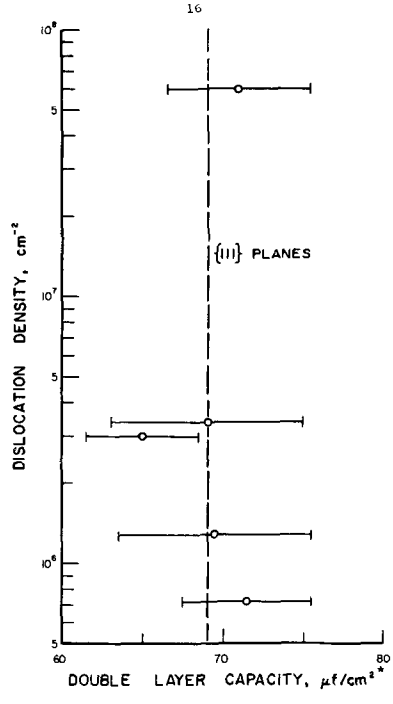

Fig. 6. Dislocation density *vs.* double layer capacity {111} planes

Table I. Since there is no theoretical correlation available, the data are represented by straight lines rather than resorting to curve fitting. Figures 4-6 are plots of log dislocation density in units of surface intersections per square centimeter for various crystal planes *vs.* double layer capacity (within 95% confidence limits). Double layer capacity, as noted earlier, has been assumed to be a measure of the effective area which takes into account both physical area and energy factors. However, since precautions were taken to keep the physical area constant, the changes in double layer capacity are attributed to energy effects arising from changes in crystal surface orientation and dislocation density. In Fig. 7 the previous results are condensed on a single graph to illustrate the influence

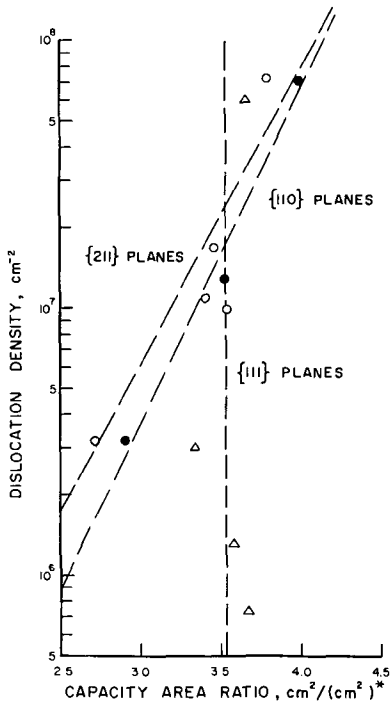

Fig. 7. Dislocation density *vs.* capacity area ratio for various planes: △, values for {111} planes; ○, values for {211} planes; ●, values for {110} planes.

of planar orientation on the effective area. In this figure double layer capacity is converted to *CAR*.

As indicated by Fig. 4-6, the *CAR* of {211} and {110} planes, which are the double layer capacities of these planes divided by that of mercury, appear to be sensitive to changes in dislocation density, while the *CAR* of {111} planes is insensitive to these changes. From Fig. 7, the effective area of {111} planes is about 3½ times the superficial area, while for {211} and {110} planes it changes from approximately 2½ times the superficial area at low dislocation densities to 4 times at higher densities.

In Table I notice that the effective area of sample E is 2½ times as great as that for undeformed, smooth {211} surfaces (samples A and I). This result is to be expected since the final surface preparation of sample E involved polishing with a 240C disk instead of electropolishing.

Comparison of data for samples A and I, with clean surfaces, and sample J, with a contaminated surface, indicates the necessity of clean surfaces.

As mentioned earlier, the *CAR* is merely the double layer capacity of the silver surface divided by that of a mercury surface. The capacity of mercury surfaces was found, within 95% confidence limits, to be 19.4 ± 2.2 μf/cm² (Table I).

Discussion

The value of 19.4 ± 2.2 μf/cm² for the double layer capacity of mercury in $0.2N$ H_2SO_4 obtained in this investigation agrees favorably with other recently determined values (24-27) and serves to confirm the reliability of the results obtained in this study.

Referring again to Table I, sample E was not electropolished after mechanical polishing with a 240C disk. In this case the double layer capacity of the single silver crystal was 128 ± 4.9 μf/(cm²)* or 6½ times that of mercury. It is assumed that this increase in effective area is indicative of an increase in physical area due to surface roughening. A comparable value was given by Bowden and Rideal (17) for a silver specimen which was polished with "flour" sandpaper. The value is 100 ± 10 μf/(cm²)*. The agreement is acceptable considering that the degree of mechanical polishing of the specimen used by Bowden and Rideal

is not accurately known. Furthermore, it is not known whether their specimen was polycrystalline or a single crystal.

In Table I, the double layer capacity for sample F which was electropolished, but was polycrystalline, was found to be 83.8 $\mu f/(cm^2)$*. This value is in the range of the double layer capacity for other polycrystalline metal surfaces in H_2SO_4; 70 $\mu f/(cm^2)$* having been observed for copper (28) and 85.5 $\mu f(cm^2)$* for a 10μ zinc coating on aluminum (29). These values are somewhat higher than those for the electropolished, single crystals and can possibly be attributed to increased area due to grain boundaries in the metals. In addition, surface irregularities in the substrate for the zinc coating could cause an increase in the area.

Figures 4-6 indicate that the precision involved in these measurements is not great, as evidenced by the spread of 95% confidence limits. Data of Bowden and Rideal (17) exhibit a similar lack of precision, which they attribute to the very small quantities being measured. Regardless of the precision involved, it appears that the *CAR* of {211} and {110} faces (Fig. 4 and 5) tends to increase with increasing dislocation density, while that of {111} faces (Fig. 6) does not. In addition, successive determinations of *CAR* on the same sample (constant dislocation density) gave a random spread of results, indicating that the silver surface did not become roughened during the measurements.

In considering the effect of dislocations on double layer capacity, and thus on the *CAR*, it is believed that the tendency of the double layer capacity to increase with increasing dislocation density (as in the cases of {110} and {211} planes) is not due to an increasing physical area since the intersection of dislocations with a surface which has been electropolished leads to no change in the physical area of that surface. In addition, since the specimens were not recrystallized the apparent change in double layer capacity or effective area is not produced by the introduction of grain boundaries. It appears that the *CAR* or effective area is influenced by something other than changes in physical area. This additional contribution to the effective area is assumed to be caused by the energy of dislocations intersecting the surface. However, present theoretical models of metal surfaces are inadequate quantitatively to analyze this effect; a more atomistic model is needed to characterize the surface in regions of defects and distortion.

In summary:

1. The double layer capacity for abraded metal electrode surfaces is significantly greater than that for electropolished surfaces; the difference is attributed to the increased physical area due to abrasion.

2. The double layer capacities of electropolished polycrystalline metal electrode surfaces are greater than those of electropolished single crystal surfaces, but far less so than those of abraded surfaces. Part of this difference in effective area is probably due to an increased physical area caused by grain boundaries. However, a portion of the change in effective area is thought to be caused by dislocations.

3. The double layer capacity of electropolished single crystal silver electrodes increases with increasing dislocation density on the {211} and {110} planes but not on the {111} planes.

Technical Notes

Molybdenum Oxidation Kinetics at High Temperatures

R. W. Bartlett[1]

Aeronutronic Applied Research Laboratories, Philco Corporation, Newport Beach, California

Oxidation of molybdenum results in condensed oxides at moderate temperatures and evaporation of gaseous oxide species at temperatures above approximately 700°C. Seven oxidation rate studies have been made at temperatures in excess of 1000°C (1-7). The recent investigation by Gulbransen *et al.* (6), was carried to the highest temperature, 1700°C. These studies have been conducted in air and oxygen but over narrow pressure ranges. The present study was conducted between 1380° and 2470°C (molybdenum mp 2625°C) and over a wider oxygen pressure range, 1 x 10^{-6} atm to 1 atm.

The experimental technique employed a 24-in. diameter cold wall furnace chamber. This permitted free convection around the sample without apparatus constraints on gas mixing or oxygen diffusion within the boundary layer formed by molybdenum oxide vapors diffusing outward from the sample. Polycrystalline molybdenum rods, 0.125-in. initial diameter, were used as samples and heated electrically. The furnace chamber was maintained at the appropriate oxygen pressure by controlling the flow of dry oxygen through the system. Oxidation rates were determined by measuring the sample diameter at suitable intervals using an optical technique. Temperatures were measured with either a color-ratio optical pyrometer or a disappearing filament pyrometer corrected for the emissivity of molybdenum. The apparatus and procedures are described more completely in a previous paper concerning oxidation of tungsten (8). Commercially pure molybdenum was used. The major impurities determined by spectrographic analysis were silicon 0.12%, iron 0.22%, and nickel 0.089%.

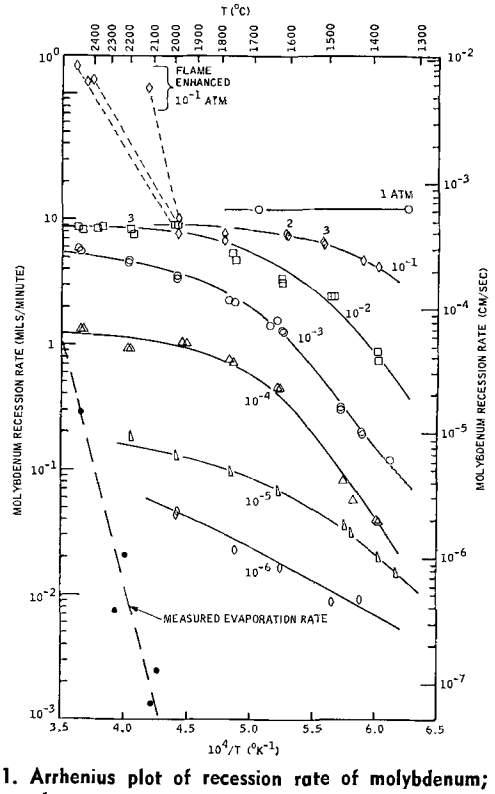

Fig. 1. Arrhenius plot of recession rate of molybdenum; isobars at indicated system oxygen pressure.

The surface recession data conformed with a linear rate law. This condition is consistent with either a surface reaction or transport within the gas boundary film acting as the rate controlling step. An Arrhenius plot of the rate data is shown in Fig. 1. Evaporation rates measured at a total pressure below 1 x 10^{-7} atm are plotted in the lower left-hand corner of Fig. 1. These data show that evaporation of molybdenum was not affecting the oxidation rates in Fig. 1.

Oxidation products were transported away from the sample and deposited on the chamber walls. X-ray diffraction analysis of several samples of this powder residue indicated MoO_3 to be the principal constituent. Variable amounts of Mo_9O_{26}, always below 30%, were also present in these samples.

The oxidation behavior of molybdenum at high temperatures is similar to the oxidation behavior of tungsten (8). The rate has an exponential temperature dependence at lower temperatures that is typical of chemical systems. Since the activation energy is too high for gaseous diffusion, an activation energy barrier at the surface is indicated. Above 1700°C the oxidation rates become less sensitive to temperature. Near the melting point the rate is independent of temperature provided the oxygen pressure is above 10^{-5} atm. The bends in the oxidation rate isobars plotted in Fig. 1 occur in the same temperature range as for tungsten. However, because of the lower melting point of molybdenum, an extended temperature region in which the rate was independent of temperature was not observed. The molybdenum oxidation rates are slightly lower at high pressures and considerably higher at low pressures than the corresponding tungsten oxidation rates. The change in temperature dependence of the rate suggests a transition in rate-controlling step from a chemically activated process to a gas kinetic process at high temperatures. For both processes, the boundary layer present at higher pressures probably affects the results by lowering the oxygen partial pressure at the surface compared with the oxygen pressure beyond the boundary layer. Although a boundary layer analysis was not attempted, the rate results are valid for any free convection application of molybdenum.

Comparisons with other investigators are difficult because of the variable effects caused by different experimental systems on the boundary layer. Gulbransen *et al.* (6) measured molybdenum oxidation rates in 0.1 atm of oxygen. Their samples were oxidized in a closed end tube which probably restricted oxygen input and oxide vapor purging. This system complicates the boundary layer analytical problem, but it makes the rate more sensitive to gas flow at moderate

[1] Present address: Stanford Research Institute, Menlo Park, California.

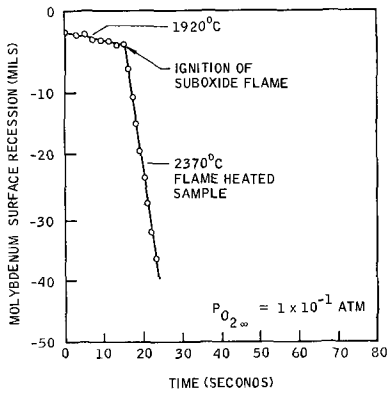

Fig. 2. Transition in the oxidation rate of molybdenum caused by ignition of the suboxide diffusion flame at 15 sec.

velocities than an open system. Their fastest rate data are consistent with the rate data at equivalent temperatures and pressures (10^{-1} atm) from this study. Rosner and Allendorf (7) measured the oxidation rate in an oxygen partial pressure of 3 x 10^{-2} Torr (4 x 10^{-5} atm) and reported molybdenum/oxygen molecule reaction probabilities. Their data were converted to equivalent slab recession rates, assuming a gas temperature of 300°K. An extrapolation of these rates to 1400°C joins the 1 x 10^{-4} atm Arrhenius isobar of Fig. 1, which is fair agreement. The molybdenum oxidation rates observed by Modisette and Schryer (4) in slow moving air above 1400°C vary between 1.3 and 2.8 mils/min. This rate is about 1/5 the oxidation rate in pure oxygen of the same partial pressure, 0.21 atm, observed in the present study. A lowered rate in air is expected because nitrogen impedes diffusion of oxygen in the boundary layer.

The most interesting aspect of oxidizing molybdenum at high temperatures and pressures is a large discontinuous increase in rate observed at oxygen pressures near 1 atm. This change in rate was accompanied by a sudden rise in temperature even when external heating was removed. Furthermore, the samples were surrounded by a typical gas flame, indicating the combustion of fuel in the gas phase rather than on the surface of the metal rod. Although oxidation of tungsten at 10^{-1} atm and 1 atm was self-supporting at high temperatures once initiated, the flame phenomena and discontinuous increases in rate were not observed with tungsten (8). The transition in behavior associated with flame ignition was easily distinguished. Rods burning normally without an accompanying flame appeared as bright incandescent objects. The surrounding cloud caused by condensation of molybdenum oxide particles could only be detected by reflected light. After flame ignition the reverse in light intensity occurred. The incandescent rod could not be visually distinguished from the flame surrounding it unless filters were used. Prior to ignition, temperature could not be detected by optical pyrometry within the vapor cloud. After ignition, the color temperature of the flame, measured by a color ratio optical pyrometer, varied from 2200° to 2500°C in 0.1 atm of oxygen and between 2700° and 2800°C in 1 atm of oxygen. These temperatures were recorded using fields of view which excluded the sample. The high flame temperature associated with an oxygen pressure of 1 atm caused the sample to melt within a few seconds after ignition of the flame.

Sample diameters were measured photographically using filters. A typical rate curve resulting from gas flame enhanced oxidation is shown in Fig. 2. Oxidation of the sample continued to obey a linear rate law after ignition but proceeded at a much faster rate. The flame enhanced oxidation rates at 0.1 atm were included in the Arrhenius plot, Fig. 1; average values are listed in Table I.

Table I. Effect of the diffusion flame on molybdenum recession rates at high temperatures (temperature independent region) and high oxygen pressures

	P_{O_2} = 0.1 atm	P_{O_2} = 1 atm
Avg. rate without flame	9 mils/min	12 mils/min
Avg. rate with flame	133 ± 25 mils/min	470 mils/min*

* Burn out prevented accurate rate data acquisition on four other samples.

In experiments conducted at both 0.1 atm and 1 atm oxygen pressures, ignition of the flame did not occur unless a temperature above approximately 1900°C was used. This temperature corresponds with the temperature at which the suboxide, $MoO_2(g)$, becomes appreciably more prevalent than $MoO_3(g)$ as the oxidation product determined by Berkowitz-Mattuck *et al.* (10), using mass spectrometric methods. This relation indicates that the flame results from the outward diffusion of the $MoO_2(g)$ and the subsequent reaction of $MoO_2(g)$ with oxygen to produce $MoO_3(g)$. Polymerization reactions are also strongly exothermic in this system. The heat released by these chemical reactions can account for the gaseous diffusion flames observed. The reactions are summarized as follows: neglecting the small amount of $MoO_3(g)$ produced at the metal surface, the primary surface oxidation reaction is formation of the molybdenum dioxide monomer

$$Mo + O_2 \rightarrow MoO_2(g)$$

The net secondary reaction in the gas phase, including oxidation and polymerization to the dominant equilibrium species $(MoO_3)_3(g)$, is

$$\frac{3}{2} O_2 + 3MoO_2(g) \rightarrow (MoO_3)_3(g)$$

$$\Delta H^\circ = -598 \text{ kcal/mole of product}$$

This reaction is 50% more exothermic than the equivalent reaction in the tungsten system (11, 12)

$$\frac{3}{2} O_2 + WO_2(g) \rightarrow (WO_3)_3(g)$$

$$\Delta H^\circ = -405 \text{ kcal/mole}$$

This difference in released heat provides a possible explanation for the presence of the diffusion flame with molybdenum under conditions where it was not observed with tungsten.

The casual relation between the adjacent diffusion flame and the increased metal surface oxidation rate is uncertain. The increased turbulence and temperature in the boundary layer caused by the flame may explain the rate increase. Analysis of mass transfer in turbulent boundary layers and flames is complex and was not attempted.

Effect of Concentration on the Fluorescence of Samarium in Cerium Dioxide

Michael Kestigian, Ronald H. Curry, and Fredric D. Leipziger
Sperry Rand Research Center, Sudbury, Massachusetts

This note is concerned with the effect of concentration on the fluorescence of samarium in cerium dioxide. A study of the spectral properties of rare earth phosphors was recently carried out by Ropp (1). This investigation was concerned with rare earth sesquioxide systems. The existence of a samarium-activated cerium-dioxide phosphor was first reported by Tomaschek (2).

Experimental Procedure

Cerium-dioxide samples in which the molar concentration was 0.01% or less were prepared by the addition of appropriate amounts of a solution of samarium ion to cerium dioxide. These preparations were completely dried, ground in an agate mortar, and calcined in platinum vessels at 1350°C in oxygen for 12 hr. On removal from the furnace, the specimens were cooled, reground, and the calcination procedure repeated. An oxygen atmosphere was used in the calcination process to ensure the formation of stoichiometric cerium dioxide. Cerium-dioxide samples in which the molar concentration of samarium was greater than 0.1% were prepared from the oxides. These preparations were ground under ethanol, dried, and calcined as outlined above. The cerium dioxide used was prepared from the oxalate by decomposition in an oxygen atmosphere (3). The chemicals were all reported to be 99.9+% pure.

The fluorescence was measured using a Jarrell-Ash 82-00 monochromator equipped with a 15,000 lpi grating, a fixed-slit width of 100μ, and a slit height of 5 mm. An EMI-9558A photomultiplier tube (S-20) was used as a detector. Standard amplification and recording techniques were applied. The excitation radiation used to record the samarium fluorescence was 3600Å. The intensity of the fluorescence observed with 2537Å excitation was insufficient for quantitative recording of the spectrum.

The samarium content of the cerium-dioxide samples was analyzed by a mass spectrograph using an AEI-MS7 spark-source instrument. The powdered specimens were mixed with equal weights of pure graphite powder and pressed into ⅛ x ¾ in. electrodes. The electrodes were sparked for a sufficient length of time to produce sensitivities of 1 in 10^{-8}. Analysis for samarium was performed by measuring the lines produced by the Sm^{147} and Sm^{149} isotopes. These lines were free of interference from other rare earth metals and rare earth oxides. Ilford Q-II plates were used to record the spectra and were developed and measured using standard techniques.

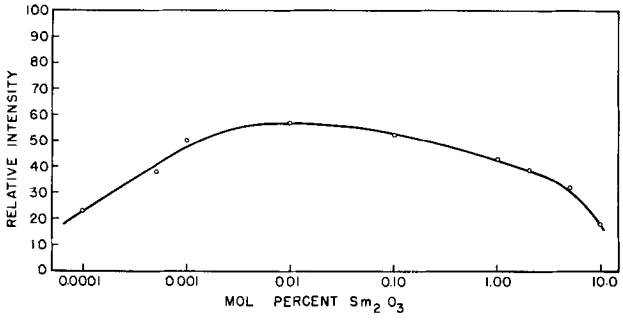

Fig. 1. Plot of fluorescence intensity vs. concentration

Experimental Results

Spectrographic studies indicated that four peaks were present in the fluorescence spectra of samarium-activated cerium dioxide. These were located at 573, 607, 615, and 621 mμ. Only the 573 and 615 mμ peaks were strong enough to be studied quantitatively. The decision to study the concentration dependence of samarium in cerium dioxide by investigation of the 573 mμ line was made because of the better signal-to-noise ratio of the photoelectric instrument described above. This fluorescence (573 mμ) was observed at concentrations as low as 10^{-4} mole % Sm_2O_3. A plot of fluorescence intensity versus concentration is shown in Fig. 1. Referring to the figure, it can be seen that the fluorescence intensity shows a slow increase with increased samarium-oxide concentration to a broad maximum at about 0.01 mole % followed by a decrease to a concentration of about 10 mole % Sm_2O_3. The fluorescence was not detectable at concentrations above 10 mole % Sm_2O_3. It was surprising that the maximum in the fluorescence-intensity curve occurred at so low a concentration. In most examples of concentration quenching, the effect does not become significant until concentrations of the order of 1% are reached. To what extent these anomalies are due to the use of finely divided powders or truly represent intrinsic material properties is not clear at this point.

In the course of this investigation, it was observed that numerous high-purity cerium compounds exhibited the same fluorescence described above. The fluorescence was observed in some cerium-dioxide samples in the "as-is" condition, while in other cerium-dioxide and cerium containing raw materials the fluorescence became visible only after calcination at high temperature. These samples were all found to be contaminated with other rare earths in concentrations ranging from 0.05 to 100 ppm. Samarium was present as an impurity in all cerium-dioxide samples which exhibited the fluorescence. The level of samarium ranged from 5 to 50 ppm ±50%.

Summary

The fluorescence of samarium as a function of concentration in a cerium-dioxide matrix has been investigated. Fluorescence is observed when only a few

ppm Sm are present in CeO_2. The fluorescence intensity increases with concentration until 0.01 mole % Sm_2O_3 has been added, after which concentration quenching sets in and the fluorescence intensity decreases with increased Sm concentration.

Epitaxial Growth of GaAs Through Cracks in SiO_2 Masks

M. Michelitsch

International Business Machines Corporation Laboratories, Boeblingen, Germany

SiO_2 layers several thousand Ångströms thick on GaAs wafers have shown excellent masking characteristics against epitaxial growth and diffusion (1, 2). Such films are commonly produced by pyrolytic decomposition of gaseous $Si(C_2H_5O)_4$ on GaAs wafers at several hundred degrees centigrade. About 5000Å can easily be obtained within 30 min.

Figure 1 shows the epitaxial growth apparatus. It consists of three quartz tubes, 20 mm in diameter. Two of these contain the separate source materials As and Ga (and if desired a dopant such as Se), the third one the GaAs wafer (seed). The source tubes are connected with the seed tube by capillaries 1 mm in diameter. To prevent deposition on the outer wall of the seed tube it is lined with a separate removable tube, which is surrounded by a H_2 counter flow. By changing the direction of the H_2 counter flow "growth" or "no growth" can be obtained. For no growth, the reaction gases pass through only the source tubes (HCl/H_2 in the Ga tube, H_2 in the As tube), and the reaction at the source materials can reach a steady state. The gases leave the system through valves A and B. Because of a hydrogen counter flow through the seed tube and the capillaries to the source tubes, no growth can occur. For growth, valves A and B are closed and valve C is opened. The reacted gases from the source tubes enter a mixing chamber through both capillaries near the quartz observation window. From there the gas mixture passes over the seed and leaves the system through the liner tube and valve C.

Each tube is heated by a separate furnace with three heating zones each. The observation window (mixing chamber) is heated by a separate small furnace to prevent GaAs deposition there. By means of a long focus microscope it is possible to observe the growth process while it occurs.

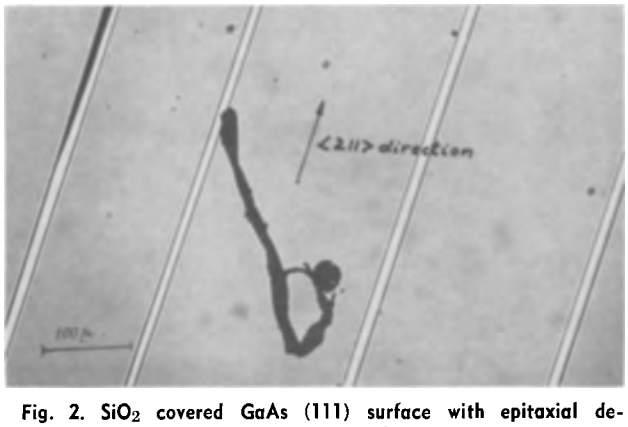

Fig. 2. SiO_2 covered GaAs (111) surface with epitaxial depositions through <211> oriented cracks.

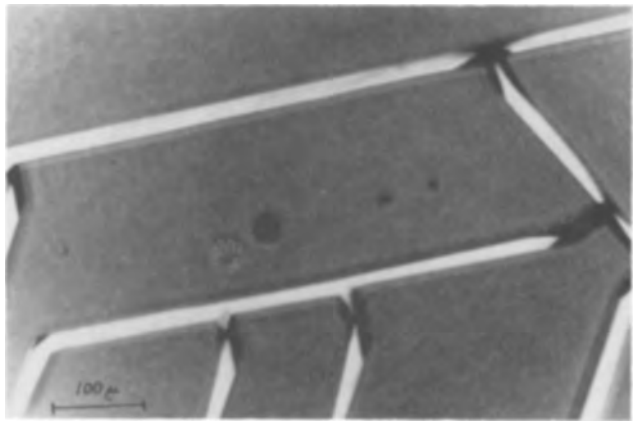

Fig. 3. Epitaxial deposition through <211> oriented cracks intersecting at 60°.

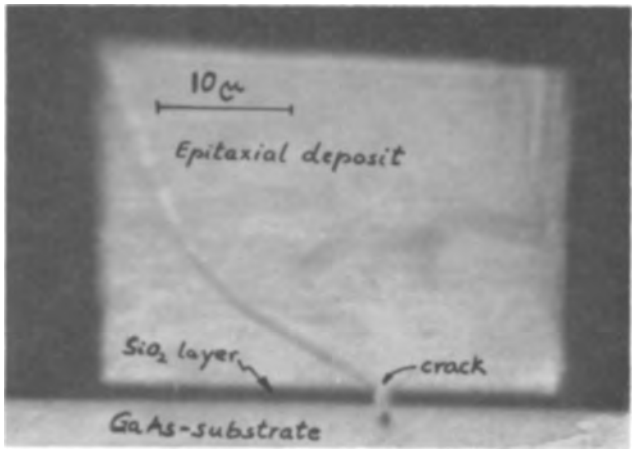

Fig. 4. Cross section (cleaved) of a crack with epitaxial overgrowth.

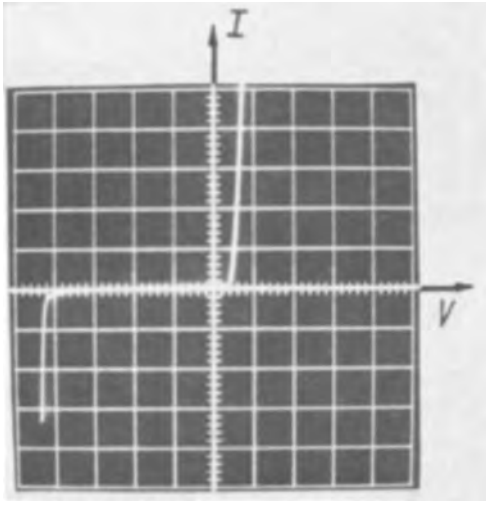

Fig. 5. I-V characteristic of a "crack diode" (substrate approx. 10^{18} cm^{-3} Zn-doped, epitaxy 5 x 10^{17} cm^{-3} Se-doped). Vertical, 0.1 ma/div; horizontal: 2v/div.

Typically the temperature at the Ga boat was 500°C, at the As boat 450°C, at the mixing chamber 900°C, and at the seed 780°C. The flow rates were 10 and 70 cm^3/min HCl and H_2, respectively, in the Ga tube, and 70 cm^3/min in the As tube.

During investigations of the epitaxial growth of GaAs on partially SiO_2 masked GaAs (111)-substrates, cracks in the SiO_2 layers were frequently observed during heat-up, which were due to differential thermal expansion of the SiO_2 and GaAs. Cracking occurs if the SiO_2 layer is thicker than about 5000Å. The cracks described in the following were about 0.5-1μ wide, several millimeters long, and parallel to <211> directions in the (111) oriented substrate. The bottoms of the cracks serve as nucleation sites for epitaxial growth. Once the cracks are filled up with epitaxial material, the growth spills over the SiO_2 layer (Fig. 2, 3, 4). Overgrowth 25μ high was produced in 2 min. Although the growth rate is rather high, it is consistent with rates obtained on uncoated substrates under similar conditions, and the material grown through the cracks which was examined by electron diffraction was shown to be monocrystalline having the same orientation as the substrate.

As the cleavage planes in GaAs are {110}, the line of intersection of the cleavage planes with a (111) surface lies in the <211> direction. It is therefore possible to produce long and narrow GaAs bars by cleaving. If the epitaxial layer has the opposite conductivity type to the substrate, GaAs diodes with long but extremely narrow junctions can be obtained. The electrical characteristics (Fig. 5) of such narrow vapor growth junctions are usually better than those of junctions grown on chemically cleaned GaAs substrates. This is due to the extreme cleanliness of GaAs surface in the cracks, which are not formed until the heat-up, just prior to deposition.

With proper doping this method should be useful for producing laser diodes. Other structures, such as, for example, narrow heterojunctions are possible.

Acknowledgments

The author wishes to thank Dr. G. Hellbardt for suggesting the design of the vapor growth furnace, Mr. K. Brack for performing the electron diffraction measurements, Miss H. Leistikow for performing the SiO_2 masking of the GaAs wafers, and Mr. C. E. Kelly for preparing Fig. 3.

Transpiration Studies of the Gallium-Hydrogen Iodide-Hydrogen System

V. J. Silvestri

International Business Machines Corporation, Watson Research Center, Yorktown Heights, New York

The transport of gallium by means of hydrogen iodide is of interest because of its importance in gallium arsenide synthesis and epitaxial growth systems (1). In addition, hydrogen iodide has been useful for transporting gallium as a dopant during the epitaxial growth of germanium (2).

In a recent thermodynamic evaluation of the Ga-HI-H_2 system, the conditions of temperature and pressure under which the efficient transport of gallium occurs were discussed (3). The application of these data to an experimental flow system requires that equilibrium be assured at the gallium bed. It was therefore the purpose of this investigation to determine gas flow conditions under which a hydrogen iodide-hydrogen mixture comes into equilibrium with a gallium source. The measurements also served to check the validity of the thermodynamic data employed in the evaluation of the system.

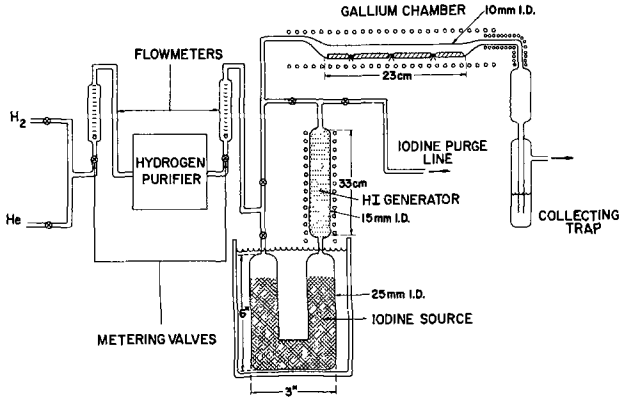

Fig. 1. Schematic representation of the flow system employed for transpiration studies.

Apparatus and Experimental Procedure

Figure 1 depicts schematically the flow system used. It consists of an iodine chamber followed by a hydrogen iodide generator, a gallium bed, and a collecting trap. The gases used were purified with molecular sieves,[1] to remove oxygen, primarily to avoid oxidation of the gallium. The latter presented a surface area of approximately 23 cm^2 to the flowing gas stream.

[1] J. Mickel Associates.

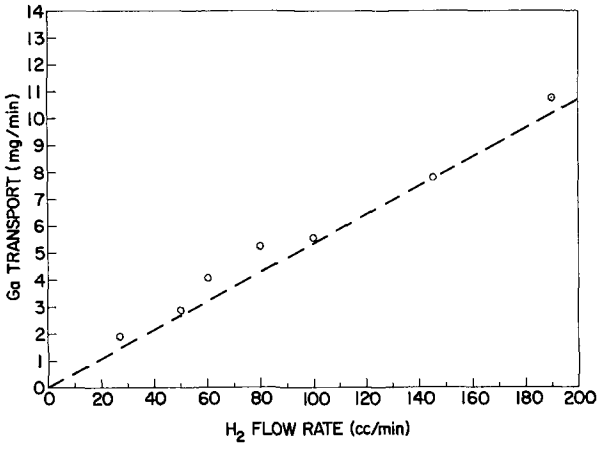

Fig. 2. Gallium transport as a function of hydrogen flow rate. Pressure of HI, 21.4 Torr; gallium temperature 433.4°C. Broken line represents the thermodynamically predicted gallium transport; ⊙, experimental values.

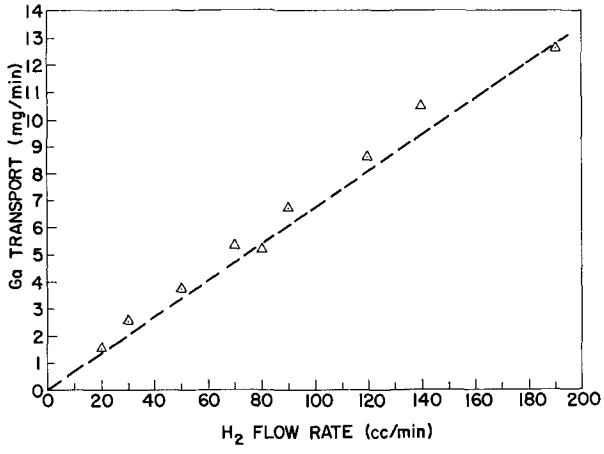

Fig. 3. Gallium transport as a function of hydrogen flow rate. Pressure of HI, 34.4 Torr; gallium temperature 408.8°C. Broken line represents the thermodynamically predicted gallium transport; △, experimental values.

For the experiments, monitored flows of hydrogen were passed through calibrated flow meters into the iodine source. The iodine bed was designed on the basis of previous iodine evaporation studies (4) such that vapor saturation would be achieved in this chamber. The temperature at the iodine source was controlled to ±0.5°C in a thermostated water bath. The catalysis of the reaction between hydrogen and iodine was effected by the platinum wool at 300°C, and the effluent from this column was then carried into the gallium bed. Here the following reactions to form gallium iodides occurred:

$$Ga(l) + 3HI(g) \rightleftarrows GaI_3(g) + 3/2H_2(g)$$
$$2Ga(l) + GaI_3(g) \rightleftarrows 3GaI(g) \quad (5)$$

The resulting iodides were collected in the two sectioned trap shown at the end of the system in Fig. 1. Condensation of the iodides occurred for the most part in the upper portion of the cold trap. The lower section contained a 6*N* KOH solution where any products escaping the freezeout zone were dissolved. The contents of both regions were then analyzed, using wet chemical techniques, for gallium and iodine.

Two different hydrogen iodide input pressures (21.4 and 34.4 Torr) were used at two different gallium bed temperatures (433.4° and 408.8°C), respectively, and for each set of conditions the amounts of gallium and iodine collected were determined for various flow rates. Experimental pressures and temperatures were chosen on the basis of thermodynamic calculations

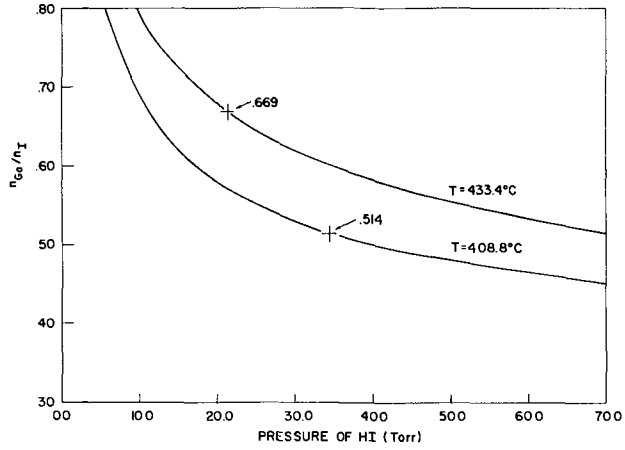

Fig. 4. Equilibrium data extracted from ref. (3) showing the predicted molar gallium to iodine ratio as a function of an initial pressure of HI entering a gallium bed at the indicated temperatures.

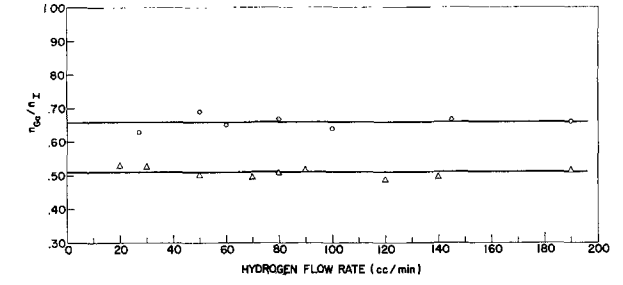

Fig. 5. Experimentally determined gallium to iodine molar ratios plotted as a function hydrogen flow rate: ⊙, pressure of HI, 21.4 Torr, gallium temperature 433.4°C; △, pressure of HI, 34.4 Torr, gallium temperature 408.8°C.

made specifically for a gallium arsenide flow system (1).

Results and Discussion

In order to determine whether equilibrium is achieved the data may be plotted in several ways. A comparison of either the gallium transport rate or the gallium to iodine ratio with those predicted thermodynamically may be made. Data as given below provide both comparisons.

In Fig. 2 and 3 the gallium transport rate has been plotted as a function of hydrogen flow rate for the two experimental conditions previously described. The agreement of the experimentally obtained values with the theoretical rates shows equilibrium was achieved for all flow rates.

In Fig. 4 the predicted (3) gallium to iodine molar ratios have been plotted for the two temperatures under consideration as a function of the initial pressure of hydrogen iodide entering a gallium source. For the experimental hydrogen iodide pressures employed, the indicated predicted ratios in Fig. 4 are obtained. Figure 5 presents the experimentally determined molar gallium to iodine ratios as a function of hydrogen flow rate. As would be expected from Fig. 2 and 3 the ratio is constant and the values are in close agreement with the predicted values in Fig. 4.

Theoretical Electromotive Forces for Cells Containing a Single Solid or Molten Fluoride, Bromide, or Iodide

Walter J. Hamer, Marjorie S. Malmberg,[1] and Bernard Rubin[2]

National Bureau of Standards, Washington, D. C.

In a previous paper (1) an electromotive force series for solid and molten chlorides was presented for temperatures ranging from 25° to 1500°C. This series was based on the Gibbs energy (free energy) of formation of the respective solid and molten chlorides and corresponded to the reversible emfs of cells of the type

metal | metallic chloride | chlorine gas [1]

It was also shown that it was unnecessary for practical purposes to divide the emfs into separate anodic and cathodic potentials, although one could assume that the potential of the chlorine electrode is zero (2) for each solid or molten chloride; the potential of each metal would then be, by convention, equal to the emf of the whole cell [1].

In this paper similar series are given for solid and molten fluorides, bromides, and iodides. These are given, respectively, in series arrangement, in Tables I, II, and III. A heavy vertical line in the tables indicates that the values to the left of the line are for solid halides while those to the right are for molten halides. When a sublimation, vaporization, or decomposition temperature is given in parenthesis, the emf directly above it is for that temperature rather than for the one heading the column. These potentials are given a positive sign here to be consistent with the procedure followed in the previous paper (1) on the chlorides. The emfs, therefore, correspond to the Gibbs energy of formation of the respective halides. If the Stockholm convention (3) were followed the opposite sign would be used and the emfs would correspond to the Gibbs energy of decomposition of the halides. As was done previously the Gibbs energies used were those published by Brewer (4) or the National Bureau of Standards (5) and the heat capacities used were those published by Kelley (6). In some cases the necessary heat capacity data were not available. In those cases the values were estimated using either the Kelley rule (7), namely, 7.0 thermochemical calories per degree C and mean gram-atom for solid compounds, 8.0 for liquid compounds, 7.3 for solid metals, and 7.5 for liquid metals, or the Shomate method (8) using the enthalpy and heat capacity data given by the National Bureau of Standards (5). Other compilations of thermochemical data are available, for example, the "Janaf Thermochemical Tables," Dow Chemical Company, Midland, Michigan, Loose Data Sheets, 1960—. Although these new compilations are undoubtedly in a better state of revision than NBS Circular 500 the latter source was adhered to here so that the fluoride, bromide, and iodide series, here presented, would be internally consistent with the chloride series previously published (1). The necessary equations and the sequence of the calculations for obtaining the emfs at different temperatures were given in the previous paper and need not be repeated here.

The uncertainties in emf listed in the tables for the solid cell at 25°C correspond to the uncertainties in the enthalpy of formation of the halides at 25°C quoted by Brewer; these uncertainties were assumed to apply also to the data in the National Bureau of Standards Circular (5) since these values agree closely with those of Brewer and the sources of the two sets of data are nearly the same. The uncertainties in entropy values are generally small compared to those in enthalpy values and accordingly the uncertainties in emf here listed are based on uncertainties in enthalpy rather than Gibbs energies of formation. In addition, the authors are more concerned with the order of the respective halides in any one series than with the actual values and these orders will probably remain the same whether the uncertainties are based on enthalpies or Gibbs energies.

It is emphasized here, as in the previous paper on the chlorides, that these emfs are for theoretical cells, *i.e.*, for ones in which there is no interaction between the metals or the halogen with the halides, no solubilities of the metals in the halides, or vice versa, or any other factors that would lead to deviations of the metals, the halides, or the halogens from their standard states. These emfs nevertheless have value in serving to indicate if deviations from the ideal state are present in actual cells.

In each table the values for the aqueous cell at 25°C are given for comparison (9). Since for these solid and molten systems at high temperatures, bromine and iodine exist as gases, the data for the aqueous system in these cases are for the gaseous state even though the stable state at this temperature is the liquid and solid, respectively. The emfs for liquid bromine and solid iodine for aqueous systems at 25°C would be 0.016v and 0.100v lower, respectively, than those given in the tables. In each case it may be noted that the order of the elements does not parallel that of the aqueous system. Furthermore, the orders for the solid and molten fluorides, chlorides (1), bromides, and iodides are not the same, *i.e.*, there is not a constant difference between any two halide series. Relative reducing power of an element, magnesium for example, must be confined to a single halide series. For example, if lithium were placed in fused barium fluoride it would displace the barium (1) with the formation of lithium fluoride, thus

$$2Li + BaF_2 \rightarrow 2LiF + Ba$$

However, in fused bromides or iodides the reverse would occur, namely

$$Ba + 2LiBr \text{ (or LiI)} \rightarrow BaBr_2 \text{ (or } BaI_2) + 2Li$$

S, sublimation; V, vaporization; D, decomposition.
* Values listed at the sublimation, vaporization, or decomposition temperatures obviously apply to cells with the solid or molten electrolyte, that is, slightly below the sublimation, vaporization, or decomposition temperature.

Table II. Standard electromotive forces for single, solid, or molten metallic bromide*

S, sublimation; V, vaporization; D, decomposition; dp, disproportionates.

* Values listed at the sublimation, vaporization, or decomposition temperatures obviously apply to cells with the solid or molten electrolyte, that is, slightly below the sublimation, vaporization, or decomposition temperature.

Hydrogen Peroxide Reactions on Gold Electrodes

A. K. M. S. Huq[1] and A. C. Makrides

Tyco Laboratories, Incorporated, Waltham, Massachusetts

Studies of the kinetics of oxygen reduction on metal electrodes are generally complicated by the formation of surface oxides which are stable in the potential range of interest (1). Frequently, both the two-electron and four-electron reductions occur, with the result that the kinetics are further complicated by reactions involving hydrogen peroxide (2). The difficulties introduced by surface oxide films are absent with gold electrodes; in this case, the oxide film is reduced at potentials above 1.0v (3,4) so that oxygen reduction and the peroxide reactions can be studied on an oxide-free metal electrode over a relatively wide potential range.

The hydrogen peroxide reactions on platinum and gold electrodes have been examined by a number of authors (5-8). The suggested mechanisms assume either a surface saturated with adsorbed hydroxyl radicals (6), or postulate reactions with either adsorbed hydrogen or oxygen atoms on the electrode (7). Some results, presented below, on the H_2O_2 reactions on Au show that the mechanisms suggested so far are not correct. A more detailed discussion of the reaction mechanisms is given elsewhere.

The standard experimental procedure and precautions for electrochemical measurements were followed. The electrolytic cell was a three-compartment, Pyrex vessel and was cleaned in chromic-sulfuric solution. The test electrodes, gold cylinders of spectroscopic purity,[2] were electropolished in a cyanide bath and were mounted so that only Teflon and the electrode were exposed to solution (9). The test electrodes were cleaned either in chromic-sulfuric or in hot, concentrated nitric acid and rinsed with distilled water and test solution before use. Both cleaning procedures gave the same results. The counterelectrode was platinized platinum or gold and the reference electrode was saturated calomel. The cell was thermostated at 30.0° ± 0.1°C.

Triply distilled water, one distillation being from $KMnO_4$, was used to make up solutions of H_2SO_4 (C. P. reagent). *p*H measurements were carried out both before and after a run with a Beckman *p*H meter. The solution was de-aerated either with a stream of nitrogen or of argon.

The steady-state, current-potential curves were established potentiostatically with a Wenking potentiostat. After a rest potential was established, the electrode was subjected to the following cycle: the potential was decreased stepwise (50 or 100 mv per step) to 0.0v *vs.* a reversible H^+/H_2 in the same solution; then it was increased stepwise through the rest potential to about 1.2v *vs.* a reversible H^+/H_2 in the same solution, and then back to the rest potential. Any number of cycles could be traced in this fashion with reproducible results.

Current densities are expressed in amp/cm² of geometric area. The electrode area (~1 cm²) was determined for each run. Reported current densities can be converted to current densities per true cm² by dividing by a roughness factor of about 1.1. All potentials are expressed *vs.* the standard hydrogen electrode (S.H.E.).

The rest potential.—The rest potential of Au in H_2O_2 solutions is essentially independent of the concentration of H_2O_2 (0.05- 2.1 M/l) at constant *p*H (0.4). The *p*H dependence of the rest potential is shown in Fig. 1; it follows the relation

Rest potential = 0.816 — 0.052 *p*H at 30°C

This is in fair agreement with the results of Bockris and Oldfield (6) who found

Rest potential = 0.842 — 0.059 *p*H at 25°C

Electrochemical reduction and oxidation.—The overall reactions for the electrochemical reduction and oxidation of H_2O_2 are

$$H_2O_2 + 2e^- + 2H^+ \rightarrow 2H_2O$$

and

$$H_2O_2 \rightarrow O_2 + 2H^+ + 2e^-$$

Typical Tafel curves for reduction and oxidation are given in Fig. 2. The main point which we wish to emphasize in this communication is that the reaction rate at a fixed potential increases directly with peroxide concentration both for oxidation and for reduction (Fig. 2). Thus, the electrochemical orders of both reactions are unity with respect to H_2O_2.

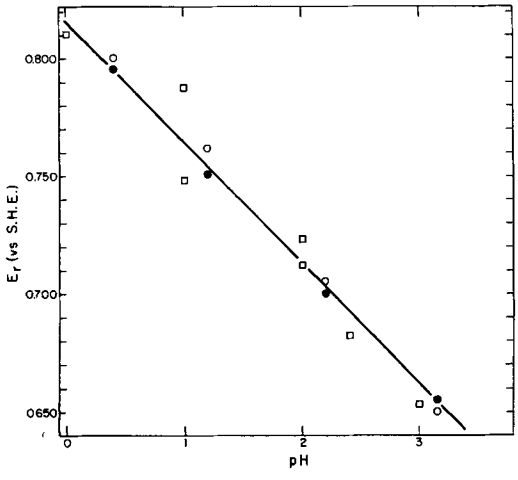

Fig. 1. Rest potential of gold in H_2O_2 solutions as a function of *p*H. Squares show values given by Bockris and Oldfield (6); open circles and solid circles are from this work.

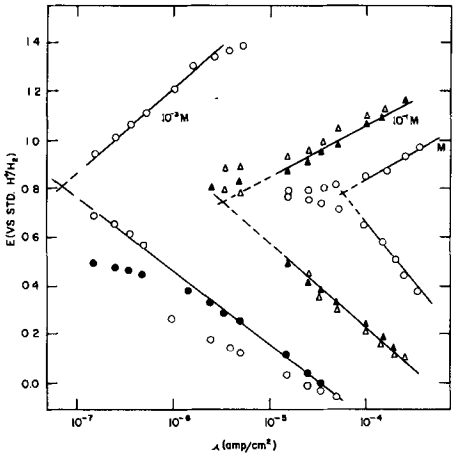

Fig. 2. Polarization curves for gold in H_2O_2 solutions. The solution was 0.1*N* H_2SO_4 in this instance. Open points are for increasing and full points for decreasing current densities.

[1] Present address: Atomic Energy Center, Dacca, Pakistan.
[2] Supplied by Johnson, Matthey & Company, Ltd., London.

These experimental results are not consistent with the mechanism advanced by Bockris and Oldfield (6) to account for the pH dependence of the rest potential. These authors suggested that the rest potential is determined by the activity of adsorbed OH radicals and that at even small H_2O_2 concentrations, the surface is saturated with OH radicals. This mechanism implies a zero order of reaction with respect to H_2O_2 which is contrary to observation.

Bianchi and collaborators (7) proposed that peroxide decomposes by a chemical, rather than electrochemical, process. According to these authors, peroxide decomposition takes place on cathodic polarization by reaction with atomic hydrogen adsorbed on the electrode surface, *i.e.*,

$$H_2O_2 + 2H_{ads} \rightarrow 2H_2O$$

A substantial cathodic current ($>10^{-5}$ amp/cm^2) was observed on gold at 0.5v *vs.* H^+/H_2. At this potential, no adsorbed hydrogen is detectable on gold. Therefore, this mechanism is not tenable. Furthermore, this mechanism does not account for the Tafel slope.

According to Bianchi *et al.* (7), H_2O_2 decomposes anodically by reacting with a surface metal oxide according to

$$M(0) + H_2O_2 \rightarrow M + H_2O + O_2$$

This mechanism does not account for the Tafel slope observed here on anodic polarization. It is of interest to note that in experiments with $C_{H_2O_2} = 10^{-1}$M, the anodic overpotential increased sharply at 1.4v *vs.* H^+/H_2, *i.e.*, at the potential where appreciable oxide formation takes place (4). Thus, contrary to the suggestion of Bianchi *et al.* (7), oxide formation may actually inhibit the electrochemical oxidation of H_2O_2 on gold electrodes.

It is apparent that the electrochemical reactions of H_2O_2 on gold are complicated. They are similar in some respects to those on platinum. For example, Gerischer and Gerischer (8) found Tafel behavior on Pt and a first order dependence on $C_{H_2O_2}$, but a highly complicated pH dependence: The coefficient $(\partial \log i/\partial \text{ pH})_E$ was a function of pH and changed from —0.3 at pH = 1 to —0.6 at pH = 5, while for anodic polarization this coefficient varied from 0.6 to 0.2 in the same pH range. No mechanism was advanced by these authors which explained these observations (8).

Finally, the suggestion that platinum or gold electrodes are reversible with respect to hydrogen ion in solutions containing H_2O_2 (2, 6), and that their operation does not depend on the activity of H_2O_2, provided some small amount is present (2, 6), are also not borne out by these studies. The relatively simple dependence of the rest potential on pH and its independence on the H_2O_2 activity are essentially accidental: they arise from summing up partial reactions which are not reversible and which have fairly complicated mechanisms.

Acknowledgment

The authors are grateful to Mrs. M. J. Turner for her skillful experimental assistance. This work was supported by the Harry Diamond Laboratories of the U. S. Army under Contract No. DA-49-186-AMC-136(D).

Manuscript received June 4, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

Brief Communication

Etching Characteristics and Light Figures of the {111} Surfaces of GaAs

Isamu Akasaki and Hiroyuki Kobayasi

Matsushita Research Institute Tokyo, Inc., Ikuta, Kawasaki, Japan

Because of various interesting properties and practical importance, the physical, chemical, and electrical properties of GaAs have been extensively investigated (1-3). GaAs has a zinc-blende structure and exhibits crystallographic polarity along the <111> directions (4), that is, the outermost atom layer in each {111} face consists of either Ga or As atoms which are triply bonded to the lattice. Conventionally (4) the former is designated as A(111) and the latter B($\bar{1}\bar{1}\bar{1}$). These two {111} faces are physically and chemically different.

In this paper, the differences in orientations of etch pits and light figures of both the {111} faces are described. An explanation for this will also be given in terms of the relative reactivities of some principal planes and the structural properties of GaAs. On the basis of these differences both types of {111} faces are easily distinguished.

Orientations of Etch Pits and Light Figures

To determine the crystallographic indices of facets developed on a crystal surface by grinding or chemical etching, the light figure method was used. The sample was cut from a GaAs single crystal in the form shown in Fig. 1. The base and both sides were ground within a few degrees parallel to the planes ($2\bar{1}\bar{1}$), Ga(111), and As($\bar{1}\bar{1}\bar{1}$), respectively. Figure 2 illus-

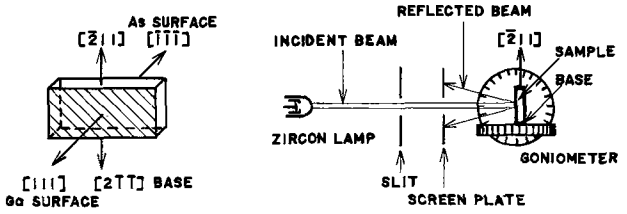

Fig. 1 (left). Form and orientations of sample. Fig. 2 (right). Light figure apparatus and arrangement of sample.

trates the light figure apparatus in which the sample was arranged with the [2̄11] direction up, and with a narrow beam of light (about 1 mm in diameter) normal to the {111} faces and the screen plate. The compositions of etchants and etching times used are similar to those summarized by Faust (2) (see Table I).

Ga *surface.*—Figure 3 shows a photomicrograph and a light figure of Ga(111) face ground with No. 500 emery powder. The light figure consists of threefold symmetrical arrows pointing in the [2̄11], [12̄1], and [112̄] directions. As seen in Fig. 4 and 5, upon the A-1 etching, the mechanically damaged layer was gradually removed, the <2̄11> arrows of the light figure becoming faint and giving way to three <211̄> arrows in opposite positions. This change of light figure is schematically depicted in Fig. 6. Similar light figures pointing in <211̄> directions were also obtained by the A-2 etching.

As *Surface.*—Optically the ground As(1̄1̄1̄) face resembled that of the Ga(111)) face, Fig. 3(a). The light figure from a ground As surface was also similar to that from a ground Ga surface, Fig. 3(b), and correspondingly pointed in [21̄1̄] directions. Since surface grinding introduces a center of symmetry, the resulting Laue symmetry m3m is that of the diamond structure. A light figure from the Ga(111) face of threefold symmetry with the arrows pointing in the [2̄11], [12̄1], and [112̄] directions, respectively, corresponds to a related light figure from the As(1̄1̄1) face with the arrows of the threefold symmetry pointing in the three opposite directions [21̄1̄], [1̄21̄], and [1̄1̄2], respectively.

Figure 7 shows a photomicrograph and a light figure of an etched As(1̄1̄1̄) face with the B-1 etchant. The vertices of the triangular etch patterns and the arrows of the light figure point in the [21̄1̄], [1̄21̄], and [1̄1̄2] directions. B-2 etchant produces the more complex light figure seen in Fig. 8. The form of the light figure has not yet been analyzed, but the arrows also point in <211̄> directions. Contrary to the case of Ga surface, these light figures from ground and etched As surfaces are always oriented in the same directions.

Etching Rate Measurement

Since the incident beam is normal to the {111} faces, the arrow parts of the light figures show reflectograms of many oblique facets developed on the surfaces. Accordingly the directions of arrows give the crystallographic indices of the facets; for example in the case of Ga surface, the <2̄11> arrows indicate that the oblique micro-facets may be {1̄11} or {110} planes assuming that only low index planes are developed. In surface grinding, {110} planes seem important, since these planes are predominantly developed in the microcleavage of GaAs (1, 2).

The directions of the light figure shown in Fig. 5 are the same as those of the Ga surface etched with Schell etchant, and the latter orientations were the [21̄1̄], [1̄21̄], and [1̄1̄2] directions as reported by Abrahams *et al.* (5). Therefore the side facets of the etch pits appearing on Ga surface with HNO_3-H_2O etchants may be {100} planes. An explanation for this is given by the relative reactivities of some principal planes with the etchant, because pits developed by etching are generally bounded by planes of minimum reactivity. Samples (about 5 x 10 x 1 mm in size) were cut from undoped n-type single crystal GaAs with carrier concentration of about 10^{17} cm^{-3} and were polished by Br_2-CH_3OH solution (6) previously to remove the mechanically damaged layers. One large surface of each sample within a few degrees parallel to Ga(111), (110), (100), or As(1̄1̄1̄) was prepared, and the remaining surfaces were completely coated with Apiezon

Table I. Compositions of etchants and etching times for production of light figures

Etchant				
Notation	Composition	Volume ratio	Etching time	Surface
A-1	$HNO_3 : H_2O$	1 : 1	7 min	Ga
A-2	$HNO_3 : H_2O$	2 : 1	10 sec	Ga
B-1	$HF : H_2O_2 : H_2O$	2 : 1 : 8	50 min	As
B-2	$HF : HNO_3 : H_2O$*	3 : 1 : 2	7 min	As

Concentration (wt %) : HNO_3, ~60; HF, 46; H_2O_2, 30.
H_2O : deionized water.
* Several drops of 1% $AgNO_3$ are added in mother solution of about 30 ml.

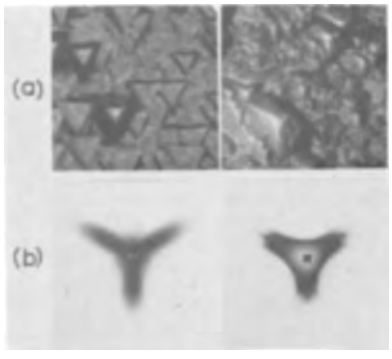

Fig. 7 (left) and 8 (right). As surface etched with B-1 etchant for about 50 min (Fig. 7) and with B-2 for about 7 min (Fig. 8).

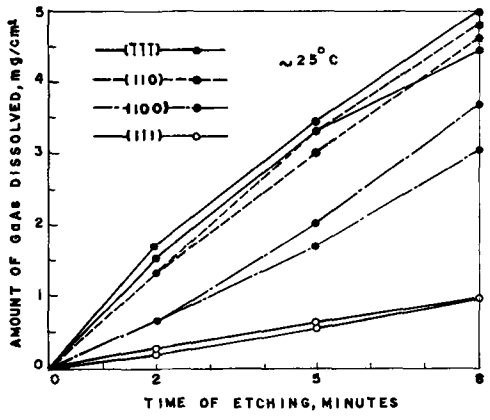

Fig. 9. Amount of GaAs dissolved with A-1 etchant as a function of orientation.

wax to protect them from the etchant. The etching rates of the respective planes were determined from weight losses of the samples which were simultaneously immersed in the A-1 etchant. The temperature of the etchant was kept at about 25°C. The results of Fig. 9 show that the etching rate decreases in the following order: As{$\bar{1}11$}>{110}>{100}>Ga{111}, which differs from the order in InSb for the etchants reported in (7). Since the {$\bar{1}11$} planes developed on Ga(111) face consist of As atoms only (4), it is not necessary to take account of the reactivity of Ga{$1\bar{1}\bar{1}$} planes. It appears that the pits obtained on the Ga(111) face by the A-1 etching are bounded by {100} planes which are more stable than the others.

On the other hand, the results of Fig. 6 suggest that the side facets of pits appearing on the As($\bar{1}\bar{1}\bar{1}$) face by chemical etching may be represented by either planes {$\bar{1}\bar{1}0$} or {$1\bar{1}\bar{1}$}. The etching rate of the four crystallographic planes with the B-1 etchant is in this order: As{$\bar{1}11$}$\simeq${110}$\simeq${100}>Ga{111}, which is in agreement with the results obtained by the A-1 etching. In this case, the reactivity of the Ga{$1\bar{1}\bar{1}$} planes must be compared with that of the {$\bar{1}\bar{1}0$} planes. Thus these side facets are thought to be the most stable Ga{$1\bar{1}\bar{1}$} family planes.

It is of interest that the side facets of etch pits appearing on the Ga surface may be {100} planes, whereas on the As surface {111} planes are predominantly revealed by these etchants. The former type of etch pit corresponds to the positive trigon pit and the latter to the negative trigon pit,[1] as observed in Ge (8). This relation differs from the case that etch pits on A surfaces of two kinds of III-V compounds. namely, GaP and InAs, are positive and negative trigon pits, respectively (2). As shown in Fig. 6, the light figures from the ground and etched Ga surfaces are oppositely oriented, while those of the As surface are in the same directions. These relations easily lead to the differentiation of both the {111} faces. From the orientations of light figures,[2] any crystallographic orientation of a sample can be readily determined with considerable accuracy.

Acknowledgment

The authors would like to express their thanks to Dr. Y. Koike and to Dr. K. Miyaji for their interests in this work. This experiment was greatly assisted by Messrs. T. Hara and M. Hashimoto.

Manuscript received Jan. 4, 1965; revised manuscript received April 12, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

A Transmission Electron Microscope Study of the Breakdown of Passivity on Fe-24% Cr

H. W. Pickering[1] and R. P. Frankenthal

Edgar C. Bain Laboratory for Fundamental Research,

United States Steel Corporation, Research Center, Monroeville, Pennsylvania

ABSTRACT

The application of transmission electron microscopy and of selected area electron diffraction together with potentiodynamic techniques is described in a study of the nature of the breakdown of passivity on Fe-24% Cr. When the potential is slowly swept from the passive region to the Flade region, local breakdown of the passive film occurs, followed by pitting of the substrate. Physical or chemical inhomogeneities in the passive film not associated with dislocation termini or grain boundaries in the alloy appear to be the most probable sites for the breakdown. However, the influence from multi-atomic steps in the alloy cannot be eliminated. On the other hand, if the rate of potential change from the passive region into the Flade region is rapid, general reduction of the film occurs followed by general etching of the alloy surface instead of pitting. In this case the effect of the inhomogeneities in the film is lost.

It has been shown that the size of the pits can be calculated assuming an equal and uniform current density on all the pit surfaces; this current density has been calculated to be slightly less than the critical current density for passivation. The observed pitting is discussed in relation to crystallographic etch pitting of dislocations on close-packed planes, the passive film acting to retard the lateral motion of steps. The results also show that an "aggressive anion" is not necessary for the initiation and initial propagation of pitting to occur if other conditions are fulfilled. Finally, the observed data appear to agree best with the theory of passivity that envisions a sequence of steps starting with the adsorption of an oxygen species and ending with the formation of an oxide.

The passivity of metals and alloys and its breakdown have been studied primarily by well-known electrochemical techniques, such as the amperostatic and the potentiostatic determination of polarization curves (1-3). Such studies usually measure an average current density. They give little information about the local current distribution, the nature and thickness of the passive film, or its distribution over the surface. To obtain such information nonelectrochemical techniques must be used. For example, some optical microscope examinations have been made of the pitting that occurs during the breakdown of passivity in certain media (4), ellipsometry has been applied to the measurement of the thickness of passive films (5, 6), and electron diffraction has been used to identify the passive films on iron (7). The work on iron (5, 7) has shown the passive film to be approximately 20Å thick so that it would be very difficult to see even in the electron microscope, Recently Kruger (5) has observed the sites of film breakdown on iron by optical and by transmission electron microscopy. His technique involved placing the passivated iron in a dilute copper sulfate solution until passivity decayed, as indicated by potential measurements. Copper deposited at the cathodic sites during the subsequent attack on the iron. Discrete, noncontinuous cathodic sites were observed, and it was determined indirectly that the breakdown depended on properties of the film, which in turn were affected by the metal substrate since surface orientation influenced the number of breakdown sites. However, no effect due to emergent dislocations in the alloy surface could be found.

In this work transmission electron microscopy and selected area electron diffraction have been applied to study the breakdown of passivity on an Fe-24% Cr alloy in H_2SO_4 by observing the sites of attack on the alloy at which the passive film had been reduced. It is assumed that those sites at which film breakdown occurs will be anodic to the areas still covered by the passive film and thus will preferentially dissolve. The advantage of this technique over Kruger's is that one observes the metal directly rather than observing copper decoration. On the other hand, by our technique it is necessary to allow the attack of the substrate to proceed to a point at which one can observe this attack by electron microscopy. In this work the passivation and breakdown thereof were controlled electrochemically by a potentiostat. An iron-chromium alloy was chosen primarily because this alloy system has been studied extensively (8-15) and because the alloy does not oxidize appreciably when exposed to air at room temperature; thus no complications arise during the transfer of the sample from the electrolytic cell to the electron microscope. It will be shown that when the potential of the specimen is changed slowly from the passive region to the Flade region, crystallographic pitting of the substrate alloy is observed, whereas when the change in potential is very rapid, a general etching of the alloy surface is observed. The observed data permit one to extend the theory of pitting corrosion and to discuss the nature of the film that causes passivity.

Experimental

The working electrode for the electrochemical measurements and the foils for the electron microscope specimens were prepared from a vacuum melt of high-purity Fe-24% Cr alloy which has the following analysis: Cr-23.8%; C-0.0075%; N-0.0068%; O-0.050%; P-<0.005%; S-0.004%; Si-<0.01%; Al-<0.005%; Cu-<0.01%; Mg-<0.001%; no other elements were detected. This is a bcc alloy. The bulk alloy was vacuum-annealed at 760°C for 64 hr and quenched in brine. Cylindrical electrodes (1 in. high and ¼ in. in diameter) were machined with a threaded hole for electrical connection at one end. The material for the foils was cold-rolled to 0.003 in. The electrodes and foils were then re-annealed in vacuum at 760°C for 40 hr and quenched in brine. Some foils were used in the annealed state and others were elongated up to 4% in a tensile machine. Immediately prior to use, the elec-

[1] On leave until September 1965 at the Max-Planck-Institut für Physikalische Chemie, Göttingen, Germany.

trodes and the foils were electropolished in a mixture of glacial acetic acid and perchloric acid (5:1) at 35v, rinsed in reagent-grade methanol, dried, and immediately inserted into the cell. Electrical contact was made to the electrode by means of a brass screw that was isolated from the environment by a Teflon sleeve. To obtain electrical contact with the foil, a thin platinum wire, covered by a glass sleeve, was spot-welded to one end of the foil. The opening in the sleeve at the weld area, as well as the weld, was sealed with polyethylene.

The studies were conducted in 1*N* H_2SO_4 made from reagent-grade acid and doubly distilled water with a conductivity of 3 x 10^{-7}mho-cm. The results obtained with pre-electrolysis of the solution for 24 hr at a current density of 15 ma/cm^2 between two platinum electrodes, each 10 cm^2 in area, did not differ from those obtained without pre-electrolysis. All solutions were purged with prepurified helium before and during use.

The cell was constructed completely of Pyrex. Both water-wetted stopcocks and Teflon stopcocks were used. A Luggin capillary connected the cell to the reference electrode via a salt bridge. The auxiliary electrode was a platinum cylinder (40 mm diameter), concentric with the working electrode to insure uniform current distribution. The working electrode was inserted through a ball joint, so that the electrode could be properly placed with respect to the Luggin capillary. A hydrogen reference electrode was used and all potentials are reported relative to the normal hydrogen electrode (NHE). Prepurified helium was swept through the cell at all times. The potential-current curves were obtained with a Wenking potentiostat and a motor-driven potentiometer. The rate of variation of potential was normally 100 or 200 mv/hr; this is referred to below as the slow sweep rate. The potential could also be switched rapidly from any one value to another. Current-time transients were observed on an oscilloscope and photographed with a Polaroid camera. When the bulk specimens and the foils were treated electrochemically in an identical manner, the potential-current curves were always similar. All work was done at 25° ± 1°C.

After a foil had been subjected to its specific polarization treatment, it was pulled from the cell with the potential still applied, rinsed with reagent-grade methanol, and dried. Some foils were examined immediately in the electron microscope; others were stored in a desiccator until they were examined. There was no effect due to storage. Each foil was examined by transmission electron microscopy in a Siemens Elmiskop. In addition, by selected area electron diffraction it was possible to obtain crystallographic data of specific interest. When thickness fringes were used for quantitative measurements, it was necessary to tilt the specimen until it was oriented in the exact Bragg condition (16).

Results

A potential-current curve for the alloy is shown in Fig. 1a. The potential region from —0.3 to +0.5v was measured by starting at +0.5v and sweeping the potential to —0.3v at 200 mv/hr. The transpassive region was measured by sweeping the potential from +0.5 to +1.8v at 200 mv/hr. A small cathodic loop is observed prior to the breakdown of passivity. This has been explained by Edeleanu (3) and is due to the beginning of hydrogen evolution prior to the breakdown. Figure 1b shows the anodic loop in greater detail.

Figures 2a and 2b show foils with electropolished surfaces. In Fig. 2a the smoothness of the surface is indicated by the uniform breadth of the thickness fringes at the edge of the foil and at the grain boundary. Figure 2b shows a typical dislocation distribution for this alloy after annealing followed by a 2% elongation.

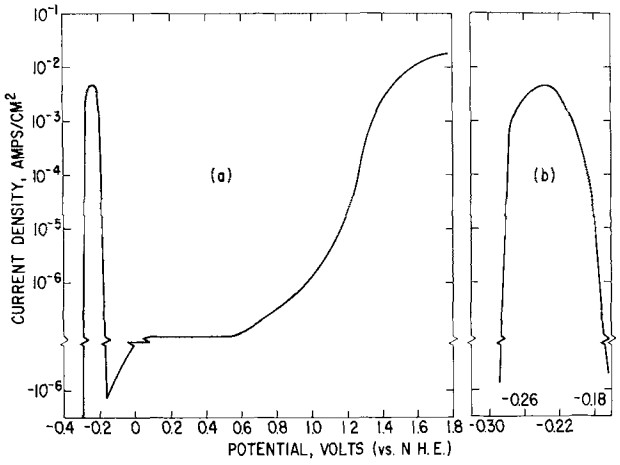

Fig. 1. Potential-current curve for Fe-24% Cr in 1*N* H_2SO_4; sweep rate, 200 mv/hr. (a) From hydrogen evolution to oxygen evolution; (b) anodic loop only.

If a specimen is passivated without going through the anodic loop, its appearance will be identical with those of Fig. 2a and 2b. This can be done by either immersing the sample directly at any potential in the passive potential range or by first immersing it at a potential more negative than —0.28v (hydrogen evolution range) and then switching the potential into the passive region. No differences are observed between the two methods.

When an electropolished and passivated foil is subjected to a slow potential sweep from +0.5v into the Flade region (—0.17v to —0.24v) and then examined by transmission electron microscopy, one typically observes crystallographic pits such as shown in Fig. 3-6. This type of pitting has been found on the following surfaces: {001}, {111}, {121}, {021}, {221}, {133}, {135}, and {231}. The morphology of the pits is a function of substrate orientation. However, the number of micrographs obtained were insufficient to evaluate

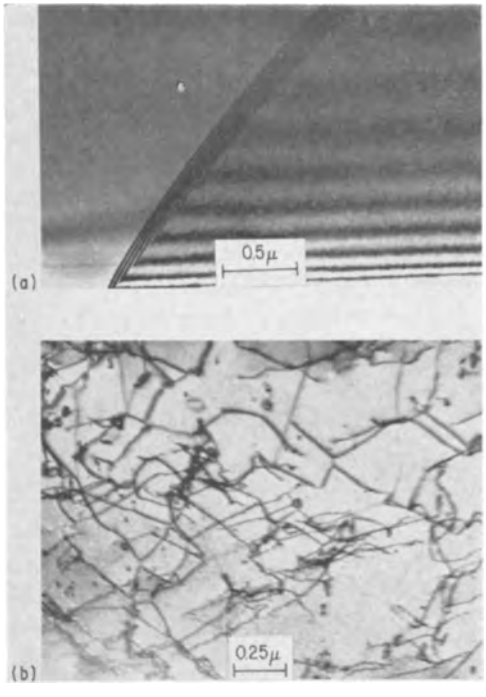

Fig. 2. Transmission electron micrographs of electropolished and/or passivated foils. (a) Smooth and uniform thickness fringes at edge of foil and at grain boundary indicate smoothness of foil surface; (b) smooth and undistorted image of dislocations in a foil annealed and elongated 2% indicates a polished foil surface.

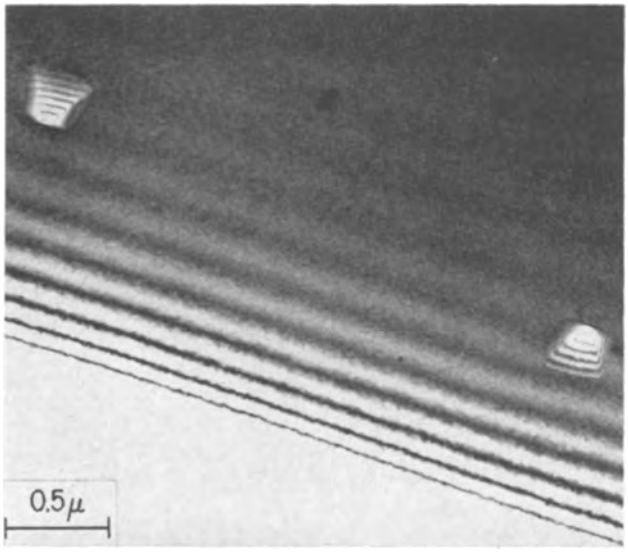

Fig. 3. Transmission electron micrograph of a foil with {121} surface on which passivity was slowly destroyed producing crystallographic pitting. Smooth thickness fringes at edge of foil indicate that no etching has occurred.

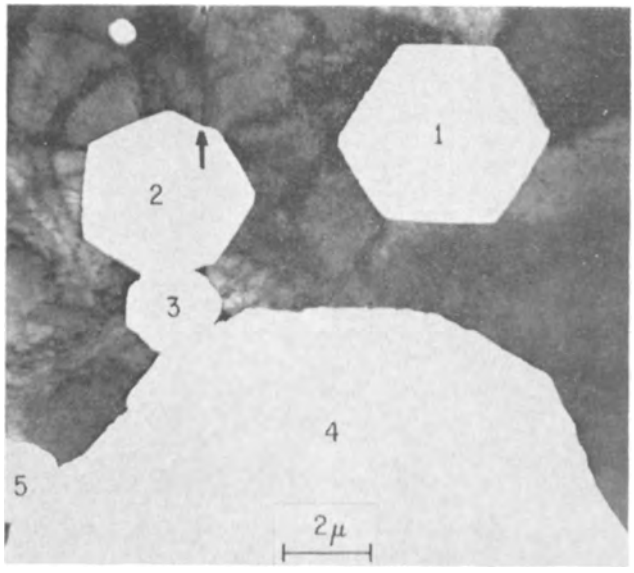

Fig. 4. Transmission electron micrograph of a foil with a {221} surface on which passivity was slowly destroyed producing crystallographic pitting. Arrow shows grain boundary.

whether or not the frequency of pitting, *i.e.*, film breakdown, is also a function of substrate orientation. It has also been established that pitting does not occur preferentially at dislocations, either present after the anneal or produced by plastic deformation, or at grain boundaries in the alloy. This was readily determined since the pits, dislocations, and grain boundaries could be observed simultaneously; this observation is consistent with previous electron microscopic observations (17) of pitting of metals and alloys covered by protective films. The effect of multi-atomic steps on the alloy cannot, however, be ruled out since examination of bulk specimens at low magnification (1900X, optical microscope) indicates possible mutual alignment of some of the pits.

The foil shown in Fig. 3 was swept from +0.5v to −0.19v. In this micrograph one sees pits with thickness fringes along their sides giving an indication of their angle with the surfaces. Selected area electron diffraction established that the pits are on a {121} surface and that the two sides of each pit which appear parallel to each other form <101> traces with the surface. The traces can be associated with the intersection of low-index planes with the surface; however, the traces of the other two sides do not correspond to low-index planes. The smoothness of the thickness fringes at the edge of the foil indicates that there has been little, if any, general etching of the foil surface. Crystallographic pitting and a lack of general etching were typical of all the experiments in which the breakdown of passivity occurred during slow potential sweeps.

The foil shown in Fig. 4 was swept from +0.5v to −0.24v. The pits are hexagonal in shape. A grain boundary runs through pits 2, 3, and 4 and the sides of the pits in the right-hand grain are rotated approximately 20° across the boundary from the sides in the left-hand grain. Equivalent sides of pits in the same grain are parallel. Although the sharp sides have been rounded off in pit 4, as is typical for later stages of pit growth, the basic shape of the hexagon can still be discerned, and the sides are parallel to the equivalent sides on the other pits. The left-hand grain has a {221} surface. The orientation of the right-hand grain was not established, but from the shape of the pits, it presumably also has a {221} surface. Surface traces for these pits could not be positively identified, but quite likely are in each case one of two possible traces, both of which lie within the error of the measurement

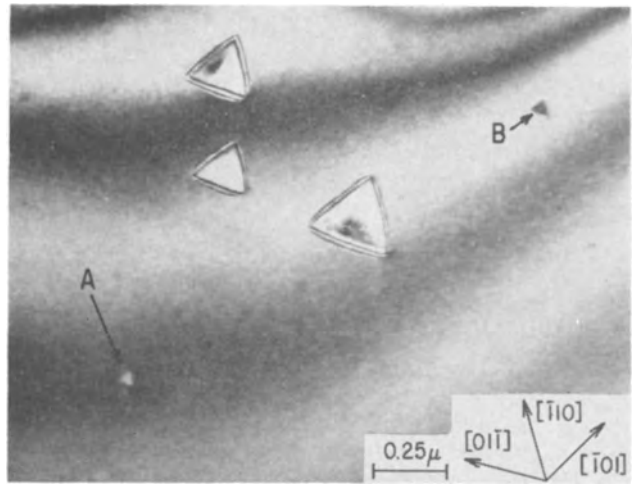

Fig. 5. Transmission electron micrograph of a foil with a (111) surface on which passivity was slowly destroyed producing crystallographic pitting. Vectors shown correspond to pit traces.

and both of which could be formed by low index planes.

In Fig. 5 one observes triangular pits on a {111} surface that was swept to −0.18v. The faces of the pits make <110> traces with the foil surface identifying them as probably belonging to one or more of the low-index planes. Taking a reasonable value for the extinction distance of 300Å in this alloy for the operating 110 reflection, it is possible to estimate the slope of the sides from the number and separation of the thickness fringes seen at the borders of each pit. A slope of greater than 60° but less than 90° is obtained indicating that of the low index planes only the {111} planes could be parallel to the pit sides. Furthermore, from contrast considerations, it may be deduced that the bottoms of the pits must be nearly flat and closely parallel to the surface and therefore must also be {111} planes. This is indicated by the observations that there are an equal number of thickness fringes at the borders of each pit and that for those pits lying fully within the bend contours (pit A, Fig. 5) or fully out of the bend contours (pit B), the contrast does not change within the pit.

Figure 6 shows an example of the rounding-off of a crystallographic pit as it gets large. It is obvious from

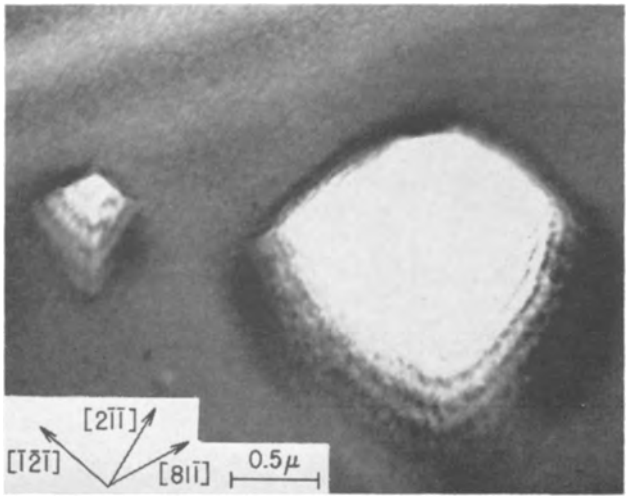

Fig. 6. Transmission electron micrograph of a foil with a (1$\bar{3}$5) surface demonstrating rounding of a pit at advanced stage of growth. Vectors shown correspond to pit traces.

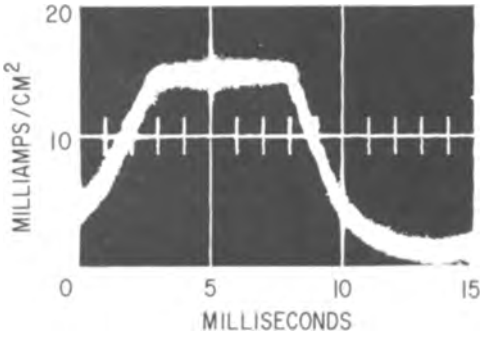

Fig. 7. Current-time transient. Potential switched from —0.18 to —0.19v.

this picture that the large pit had the same geometry as the smaller one before it started to become rounded. These pits have formed on a {135} surface and from electron diffraction data appear to have had sides parallel to {110} before rounding. Rounding was typical of all pits at later stages of growth. Also it appears that within each grain there might be groups of pits that have the same size. For example, in Fig. 4 pits 1 and 2 are about the same size, as are pits 3 and 5; in Fig. 3 the pits are of equal size; in Fig. 5 one observes three sizes for the five pits: one large, two slightly smaller, and the two very small. Similar results have been seen on other foils.

To determine whether the pitting attack was related to the aging, i.e., growth or thickening, of the initial passive film during lengthy periods at a passive potential, some foils were treated to the slow potential sweep after the foil was essentially, but not completely, passive. In this case, the current had decayed to approximately two to three times the value it has when complete passivity has been achieved. The same crystallographic pitting was observed as when the foil was passivated for extended times.

To help elucidate the mechanism of the observed pitting, current-time transients were observed when the potential was rapidly switched in the Flade region. For example, a specimen was held at —0.18v until the current density had reached a steady-state value of 4 ma/cm^2. The potential was then switched to —0.19v and the transient shown in Fig. 7 was observed. The new steady-state current density after some minutes was 6 ma/cm^2.

Figures 8 through 10 show the appearance of the foil when its potential is rapidly switched from the passive region into the Flade region. Similar results

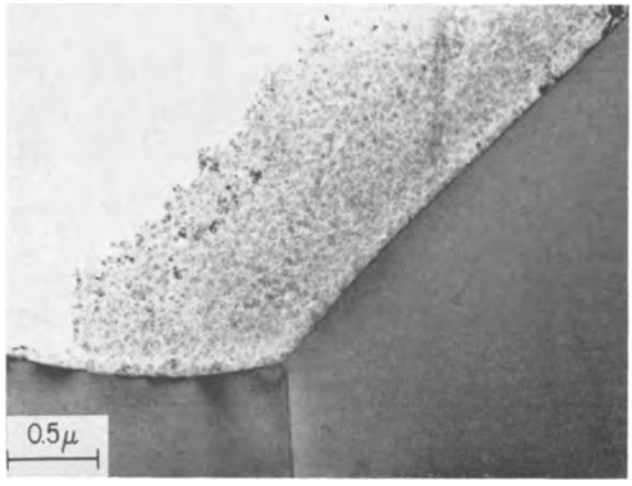

Fig. 8. Transmission electron micrograph of a foil on which passivity was rapidly destroyed resulting in anisotropic etching of the surface.

are also obtained when the potential of the foil is switched from the hydrogen evolution range ($E <$ —0.28v) into the Flade region. In all cases over-all etching of the surface is observed and pitting is never seen. Figure 8 shows a typical example at a fairly early state of etching. The potential was switched to a value at which the final current after 30 sec was approximately 0.3 ma/cm^2. It is seen that large variations in the initial rate of etching occur from grain to grain. The lighter grain is heavily etched, whereas the two darker grains have been etched to only a very slight degree. This anisotropy of etching was evident for all experiments in which the etching was stopped at a sufficiently early stage. At later stages the anisotropy of etching was no longer evident. Although Fig. 8 shows the severely etched grain at the edge of the foil, severe etching was also observed in grains which

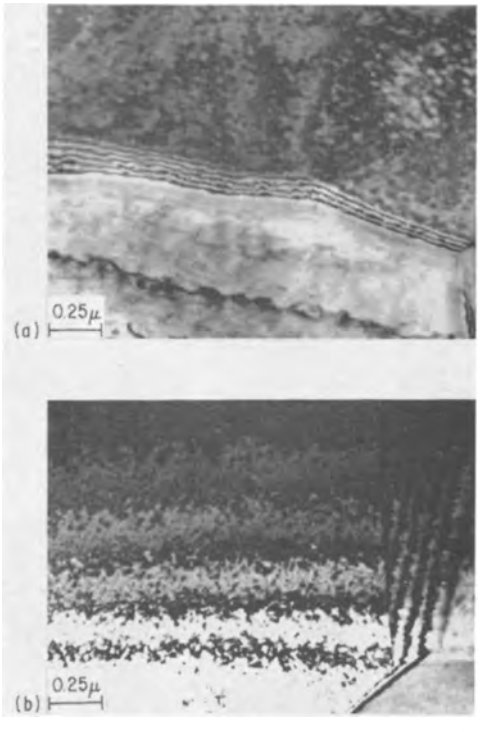

Fig 9. Transmission electron micrograph of a foil on which passivity was rapidly destroyed resulting in etching of the surface. (a) Roughening of surface is indicated by wavy thickness fringes at grain boundary and by the presence of thickness fringe patterns on grains; (b) severe roughening of surface is indicated by nonuniform ragged thickness fringes at edge of foil and at grain boundary.

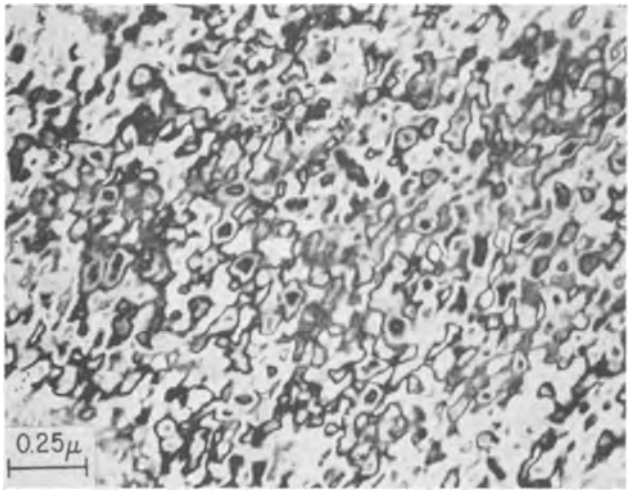

Fig. 10. Transmission electron micrograph of a foil on which etching is demonstrated by thickness fringes from which surface roughening can be measured as indicated in text.

were not at the foil's edge. In Fig. 9a and 9b the etched condition of the surface is shown by the raggedness of the thickness fringes at grain boundaries, within the grains, and at the edge of the foil. The uneven nature of the attack becomes more apparent when the condition of the fringes in these micrographs is compared to that of a foil with an electropolished surface (Fig. 2a). Figure 10 is a micrograph showing thickness fringes which effectively produce a relief map of an etched surface and can be used to give an indication of surface roughness. The thickness fringes show that the surface consists of many mounds and shallow depressions. Taking 300Å as a reasonable value of the extinction distance in this alloy for the operating 110 reflection, Fig 10 is then contoured in steps of this height. An average of 1 thickness fringe was observed at each depression, indicating a total depth of approximately 300Å. From measurements of the diameter of the thickness fringes, it is estimated that the average diameter of the depressions is of the order of ten times their depth.

Discussion

Nature of breakdown of passive film.—The most definitive observation is that as passivity breaks down the mode of attack of the alloy substrate is a function of the rate of potential sweep. When it is sufficiently slow, *e.g.*, 200 mv/hr, crystallographic pitting of the alloy occurs, presumably at the sites at which the film has been destroyed, and no etching of the surface is visible. When the rate of potential change is sufficiently fast, *i.e.*, when the potential is switched from the passive range into the Flade region, the surface is etched into mounds and depressions and no pitting is observed.

It is thought that the nature of the sites for the initiation of breakdown of passivity during a slow potential sweep must be connected with local changes in some property of the passive film or of the alloy (it will be argued below that it probably is the passive film). However, when the potential is suddenly switched from the passive region into the Flade region, the driving force for film breakdown is so great that the local differences, which come into play during the slow potential sweep, are completely masked, an over-all reduction of the passive film occurs, and the entire alloy surface undergoes a general etching attack.

Local breakdown of passivity during slow potential sweep.—When the alloy is subjected to a potential in the passive region, it becomes covered by a protective film that essentially stops all corrosion but that which is equivalent to the small passive current density. As the potential is slowly swept into the Flade region, the film is destroyed locally; this is followed by pitting of the substrate at these local sites. From Fig. 4 to 6 it is seen that size variations exist among pits on the same grain, indicating that film breakdown prior to pitting was nucleated at different times, hence at different potentials. It is concluded that the nucleation of film breakdown is heterogeneous and must occur at physical or chemical defects in the film. These defects may be solely the property of the film or they may result from defects in the substrate.

With respect to the effect of the substrate, it has been found that dislocation termini and grain boundaries must be unimportant because pitting did not occur preferentially at these sites. Since monoatomic surface steps and kink sites have a close geometric similarity with a dislocation site, they too are probably unimportant as sources for the local film breakdown (17). Further, since pitting has been observed on many crystallographic planes of the alloy, the nucleation of film breakdown is independent of substrate orientation. Effects of the substrate arising from multiatomic steps cannot be ruled out since an indication of possible mutual alignment of some of the pits does exist. Also the effect of chemical inhomogeneities in the alloy on the film is not known, except that it would not be unreasonable to expect variations in the composition of the film to be associated with variations in the composition of the substrate.

Sources of local fluctuations in the passive film not related to the substrate would depend on the nature of this film. If it is a crystalline oxide, then any defect in the crystal structure, such as dislocations, grain boundaries, chemical fluctuations, etc., could provide sites for breakdown. If the film is either an amorphous oxide or an adsorbed layer, then pores, other physical defects, or chemical fluctuations could be the sites of attack. Chemical fluctuations could consist of nonstoichiometry such, as suggested by Caplan *et al.* (12) for films on Fe-26% Cr, by Sewell *et al.* (7) and by Pryor and Evans (18) for films on iron, or of impurity segregation which occurs during growth of the film (17).

As a particular potential peculiar to a specific defect is reached during the slow potential sweep, breakdown of the film followed by pitting of the alloy occurs. If it is assumed that for a particular surface orientation growth conditions are the same for all pits, then it follows that the larger the pit the more positive was the potential at which it was initiated.

It was reported that within each grain there appear to be groups of pits that have the same diameter. If this observation on further testing proves to be valid, it would appear to support the oxide film theory of passivity more than the adsorbed film theory, since it is easier to visualize numerous types of discrete local variations (chemical and physical) associated with an oxide film than with an adsorbed layer in the absence of preferential attack at dislocations and grain boundaries in the substrate.

Kinetics and morphology of pitting.—The kinetics of the pitting reaction must be consistent with the overall electrochemical behavior of the system and with the shape and size of the resulting pits. Since the crystallography of the pits shown in Fig. 5 is known, it is possible to calculate their size at any time, t, assuming that the current density is uniform and equal on all surfaces of the pit.

As previously stated, the sides and the bottom of the pits appear to be {111} surfaces. Since {111} surfaces intersect at 71° angles, the dimensions of the pit are related by

$$a = b + 3h(\tan 19°)\ (\sec 30°) \qquad [1]$$

where h is the pit depth normal to the foil surface, a is the length of a pit side on the foil surface, and b is the length of a pit side on the bottom surface. Assuming that all the sides dissolve continuously at the same rate, k

$$a = 2\sqrt{3}\,kt \sec 19° \quad [2]$$

and

$$h = kt \quad [3]$$

where t is measured from the time the pit is nucleated. Thus

$$h = \frac{a}{2\sqrt{3}} \cos 19° \quad [4]$$

and the dimensions of the pit may be calculated from the measured value of a and Eq. [1] and [4]. The largest pit in Fig. 5 is 3000Å on a side and the calculated depth is 820Å, in good agreement with the depth estimated from the thickness fringes at the edges of the pit to be between 750 and 900Å. Similarly the depth of the two smallest pits was calculated from the measured a and estimated from contrast considerations to be approximately 150Å. This good agreement supports the assumption of a uniform and equal current density on all surfaces of pits.

The dissolution rate, k, can be obtained from Eq. [2]. Assuming that the largest pit in Fig. 5 was nucleated at the potential at which passivity first started to break down, the growth time was 325 sec and $k = 2.5 \times 10^{-8}$ cm/sec. The equivalent current density, as calculated from the lattice parameter for the alloy and assuming an average valence of 2.25 (iron dissolves as ferrous ion and chromium as chromic ion), is 8×10^{-4} amp/cm^2.

To understand why the pitting reaction is stable, consider the transient behavior of the alloy when the bare metal surface is first exposed (Fig. 7). The limiting current density is most likely diffusion controlled by a precipitated corrosion product (8, 19, 20). The diffusion-controlled state is unstable and repassivation occurs within milliseconds, accounting for the fact that this phenomenon has not previously been reported for Fe-Cr alloys with Cr > 3%. The current-time relationship shown in Fig. 7 represents an average over the entire electrode surface. For the case of localized pitting, the build-up of the corrosion products within the confines of the pit is much greater than on an open surface (21, 22), resulting in a lower value for the limiting current density which persists. For the current density to remain constant during pitting, a steady state must be established between the rate of formation and rate of dissolution of the diffusion-hindering layer. The good agreement between the experimentally determined and the calculated pit depth, the reasonable value of the calculated current density for pitting, and the results of the current-transient experiments indicate that the dissolution reaction occurs at the same rate on all pit surfaces and that this rate, *i.e.*, current density, is constant over the period of time and potential investigated. That pitting does occur at a constant current density has been shown by Edeleanu (23).

When the pit has penetrated through the foil and the diameter-to-depth ratio becomes sufficiently large, the pit becomes rounded (Fig. 4 and 6). This must be due to a change in the kinetics and/or mechanism of the dissolution process. Additional work is required to elucidate the factors involved.

The results presented here also give a better understanding of the phenomenon of pitting corrosion. Since the foils that can be examined by transmission electron microscopy are normally 1000-2000Å thick, comments can only be made about the initiation and the initial growth of pits. It has been believed (22) that pitting corrosion can occur only in the presence of certain "aggressive anions," *e.g.*, chloride, the action of which has been explained in several ways (22, 24). Our work shows that the initiation and the initial propagation of pitting corrosion does not require an "aggressive anion," but only that under the experimental conditions the defects in the passive film are preferentially attacked and that anodic dissolution can proceed by the mechanism detailed above.

The observed crystallographic pitting resembles crystallographic etch pitting (c.e.p.) controlled by step nucleation normally used to etch dislocations on close-packed planes (25, 26), but differences exist. The pits in this work do not occur preferentially at emerging dislocation as in c.e.p. Furthermore, the pits here have been observed on many surface orientations and are not limited to close-packed planes. In c.e.p. the sides of the pits have been reported usually to consist of discrete steps of low-index planes. The pitting reported here appears to produce smooth planes on the sides.[2] Qualitatively, this may be seen from the thickness fringes in the pits in Fig. 3. If the sides were stepped, then statistically a thickness fringe must occasionally coincide either with the flat portion of the step or with the riser, resulting in fringes of variable width. Examination of fringes within many pits has never shown this. Also direct observation in the electron microscope has never shown any steps within the limit of resolution of the microscope (~20Å).

In c.e.p. the pit develops because the lateral motion of steps is retarded by a poison in the etchant permitting the nucleation of many steps before the first have moved appreciably from their source. In this work the principal agent that retards the lateral motion of steps is the passive film which is present on the surface of the foil but not on the walls of the pit. The sides will dissolve to expose the low-index planes and thus produce the observed crystallographic symmetry. The smoothness of the sides is consistent with the absence of any film that would retard step motion.

Etching of surface resulting from rapid breakdown of passivity.—The general etching shown in Fig. 8 through 10 always occurs when the potential of the specimen is rapidly switched from the passive range into the Flade region. This has been observed at potentials at which the breakdown of the passive film is just commencing, as well as at potentials in the high-current region. It has been established that the etching is not an advanced state of pitting. For example, in Fig. 8 the two darker grains have been etched slightly,[3] yet no pit is seen on either grain. Numerous other grains, with degrees of etching ranging down to almost none, have been examined and pitting was never observed. Thus it appears that under these conditions the passive film is reduced uniformly, at least over each grain, and etching can proceed through the thinned film. The anisotropy in the degree of etching (Fig. 8) must then be explained either on the basis of varying thickness of the film on different grains or on the basis of the anisotropy of corrosion rates on different crystal faces. Insufficient data exist at present to differentiate between these mechanisms.

From the experiments in which general etching was also observed when the potential was switched from the hydrogen-evolution region ($E < -0.28$v) into the Flade region, it appears that the low-index surfaces are consistently more etched than the higher-index surfaces.[4] This is in disagreement with the known anisotropy of corrosion rates in which low-index planes normally corrode more slowly than the higher index ones. The results, however, are understandable if the first step in passivation is the adsorption of some form of oxygen. Then less adsorption, and hence more etching, would be expected on the low-index planes since they make fewer nearest-neighbor bonds with the adsorbate and hence adsorb less strongly.

This suggestion coupled with the earlier one that the passive film after complete passivation may most likely be an oxide, would be in closest agreement with the theory of Hackerman (28).

[2] This is not meant to imply that a steady-state concentration of steps and kinks, analogous to the equilibrium concentration discussed by Burton, Cabrera, and Frank (27) does not exist.

[3] Although the etching is not obvious in this micrograph, it was evident in the microscope when the specimen was tilted at a different angle.

[4] This etching cannot be associated with the short time required to desorb and/or oxidize surface hydrogen and to form the initial surface film, because the same processes do not result in visible etching when the potential is jumped from the hydrogen-evolution range into the passive range (+0.5v).

Acknowledgments

The authors wish to thank Doctors S. Barnartt, S. S. Brenner, N. P. Louat, R. A. Oriani, and P. R. Swann for helpful discussions; Dr. J. K. Hurwitz and Mr. G. W. Momeyer for spectrographic and chemical analysis, respectively; and Mr. A. D. Damick for much help in setting up the experimental apparatus.

The Absorption of Electrolytically Generated Hydrogen

Fujio Matsuda and Thomas C. Franklin

Chemistry Department, Baylor University, Waco, Texas

ABSTRACT

A study has been made of the absorption of electrolytically generated hydrogen by iron wires and the migration of hydrogen through iron membranes. The data are in agreement with the assumption that the rate of absorption is proportional to the amount of adsorbed hydrogen. It was also indicated that the amount of hydrogen absorbed at equilibrium was governed by an equilibrium between the amount of adsorbed and absorbed hydrogen.

As a part of a series of correlation studies on the effect of hydrogen on different processes at solid metal electrodes and the effect of additives on these processes (1-3), a study was made of the effect of additives in solution on the rate of migration of hydrogen into iron and the resulting effect on the embrittlement of the iron. Much work has already been reported in this area as indicated by the early review of Buzzard and Cleaves (4) and by the recent symposium of the American Electroplaters Society (5).

A study of the migration of hydrogen through iron membranes has recently been completed by Devanathan (6).

Experimental

The iron electrodes were prepared by sealing varying lengths (1-8 cm) of Baker Analyzed Reagent Grade iron wire in glass. The electrodes were dipped in 6M nitric acid and rinsed with distilled water before using.

The coulometric techniques previously used (1-3) in studies of hydrogen at solid electrodes were used in this study. This is similar in principle to the coulometric technique described by Devanathan *et al.* (7, 8) for the determination of surface coverage by hydrogen. In this technique the iron reactions are subtracted graphically while Devanathan treated them mathematically. It has been experimentally checked as a method of measuring absorbed hydrogen in palladium (9) and iron (10) wires. Hydrogen was generated on the iron electrode for varying lengths of time at a constant current density and for varying current densities at constant times by connecting the cell to the batteries. The cell was then connected to the polarograph and the hydrogen was electrolytically oxidized. The nonpolarizable electrode was a large platinum gauze electrode. The solution was 2*N* sodium hydroxide.

The embrittlement of the iron was measured by a simple bend test. Each wire was usually long enough for three or four such tests, and the average results were reproducible within one-third of a bend.

The studies of penetration of hydrogen through iron membranes were made with a series of different cells. Figure 1 shows a typical cell. The electrical connections immersed in the water bath were coated with RTV-11 silicone rubber. In many of the runs the membrane was at the bottom of the generation cell to prevent bubbles from blocking the electrode. The iron membranes were prepared by etching shim steel sheet with 1M nitric acid. Both generation side and the diffusion side contained a 2*N* sodium hydroxide solution. Hydrogen was generated electrolytically on the iron electrode in the generation cell. Anodic current voltage curves were run on both the generation and diffusion sides by shifting the large platinum gauze electrode and using it as the nonpolarizable electrode.

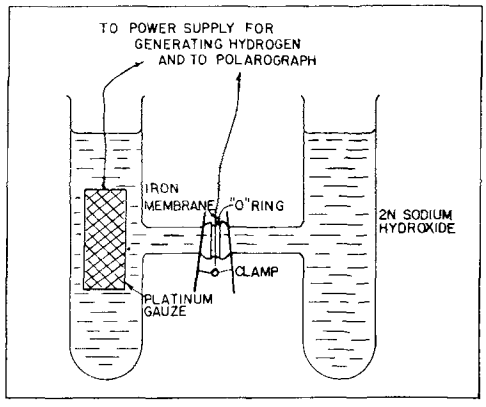

Fig. 1. Cell for iron membrane experiments

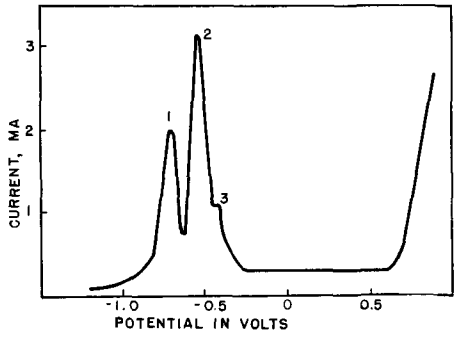

Fig. 2. Current-voltage curve for the oxidation of hydrogen on iron

In the quantitative penetration experiments hydrogen was generated on the electrode overnight before measuring the penetrated hydrogen. Therefore, the measurements were made with iron saturated with hydrogen. In order to study the effect of additives sodium sulfide was added to the generation side. The times recorded are the times of hydrogen generation after the surface hydrogen on the diffusion side of the membrane was removed by electrolytic oxidation.

In all cases the reagents were the purest available commercially. The temperature of the cells were maintained at 25° ± 0.5°C.

Data and Discussion of Results

Figure 2 is a typical current-voltage curve for the oxidation of an iron electrode on which hydrogen has been electrolytically generated. Above this potential region one obtains two pronounced maxima indicating oxide formation. As can be seen in the graph there are three maxima, indicating that there are three substances, presumably three different forms of hydrogen, being oxidized. The existence of various forms of hydrogen on platinum has been shown by a number of workers (2, 11-15). The existence of two different mechanisms of absorption of hydrogen by iron, indicative of two different forms of hydrogen, has been shown by the work of Le Boucher (16). The first two peaks were shown to be due to the oxidation of hydrogen by membrane experiments such as those run by Schuldiner and Hoare (17). After electrolytically generating hydrogen on one side of the iron membrane current voltage curves were obtained on both the generation and diffusion sides of the membrane. The two peaks were obtained at the same potentials on both sides of the membrane. If these are caused by hydrogen, then the area under each peak (since the voltage is increasing linearly with time) is a measure of the amount of hydrogen present in each form. The first form is oxidized very rapidly by air and potassium permanganate, while the second and third forms are oxidized more slowly by the chemical oxidizing agents, therefore it was concluded that the first peak was

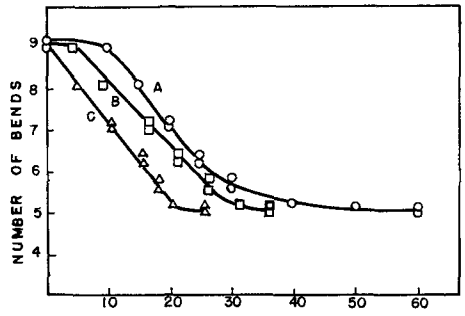

Fig. 3. Curve A, effect of generating time on number of bends needed to break iron wire; curve B, effect of total area under the curve on number of bends needed to break iron wire; curve C, effect of area of second and third maxima on the number of bends needed to break iron wire.

caused by the oxidation of adsorbed hydrogen at the surface of the electrode while the second and third peaks are caused by the oxidation of hydrogen in the interior of the iron. The two peaks in current potential curves obtained in the membrane experiments also behaved in a manner consistent with the interpretation that the first peak is caused by hydrogen on the surface of the iron and the second peak is caused by hydrogen absorbed in the iron. On the generation side the first peak builds in area with time, essentially reaches a constant value, and then, the second peak forms. On the diffusion side the second peak builds up first. The area of the second peak measured from either side was essentially the same. The third peak was not investigated to any extent since it forms only at high charging current densities or long charging times.

A further indication that the second peak was caused by absorbed hydrogen was obtained from embrittlement studies. It has been repeatedly observed that if one plots the number of bends necessary to break a specimen, or some similar measurement, against the charging time or charging current density one obtains a curve with a marked delay in it similar to A in Fig. 3. If one plots the total area under the curve in place of the charging time, one obtains a similar curve (curve B) with a delay in it. However, if one plots the area under the second peak against the number of bends needed to break the wire, one eliminates the delay entirely (curve C). There is still some curvature at the lower end of the graph because it has been impossible experimentally to separate the third form of hydrogen from the second absorbed form and the third form is produced in this lower region.

Figures 4 and 5 show the variation of the total area under the maximum with charging time and charging current density. Examination was made of these curves along with an examination of the original current-voltage curves and a visual examination of the electrode during the charging process. These indicated that

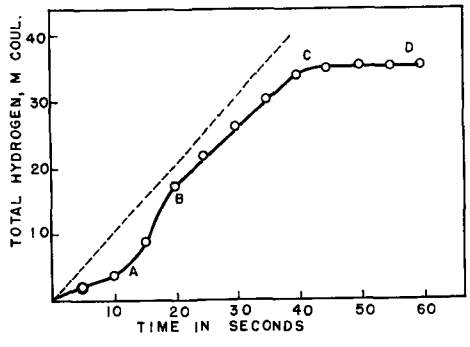

Fig. 4. Effect of time of generation on total area under the maxima (current density, 0.83 ma/cm^2). - - - -, Total hydrogen generated on the electrode; o——o——o, measured area under the curves.

up to the region of point A no hydrogen was visibly desorbed and only the first maximum was found. Therefore, it was concluded that the charging current was being used to reduce oxides and form adsorbed hydrogen. In the next region, AB, the second peak began to form, and in the straight line portion of the curve, BC, the surface was presumably saturated with hydrogen, since the first peak stopped growing, and the major process occurring was the migration of hydrogen into the interior of the metal. A small amount of desorption of hydrogen was observed in this region. Likewise, it is seen that the two curves drop off slightly from the theoretical slope. The fact that the curves approach the theoretical indicates once again that the area under the curve is a quantitative measure of the amount of hydrogen oxidized at the electrode, the drop off from theoretical being due to the small amount of hydrogen being visibly desorbed. At the upper end the rate of growth of the second peak slowed down and the third peak formed. In the final portion of the curve where the curve is parallel to the abscissa the electrode was saturated with hydrogen and all the hydrogen generated was desorbed.

From these observations it was concluded that the slope of BC was a measure of the rate of absorption of hydrogen by the iron from a surface saturated with adsorbed hydrogen under these conditions. It was also concluded that from the final height of the curve one can calculate the total amount of hydrogen present in the electrode at saturation.

Figures 6, 7, 8, and 9, show the effect of acetonitrile, 2, 7-disodium naphthalene disulfonate, sodium sulfide, and arsenious oxide on the rate of migration of the hydrogen into the iron (the slope of BC). The acetonitrile and disulfonate caused a decrease in the slope. The sulfide and arsenious oxide caused a decrease in slope at very low concentrations, but at higher concentrations the slope increased.

The generally accepted theory of migration of hydrogen into iron involves migration from an adsorbed

layer of hydrogen on the surface. Figure 10 shows plots of the slope of BC (the rate of adsorption of hydrogen) against the amount of adsorbed hydrogen on the electrode surface as measured by the area under the first peak. In agreement with prediction it is a straight line. The differences in slope of these four lines can be attributed to differences in surface area of the electrode in these four experiments. It can be seen that the curves do not go through the origin. This is because of a consistent error in taking the residual. Since hydrogen is generated, the amount of hydrogen in solution in the vicinity of the electrode changes, causing changes in the residual. It is seen that the effect of the additive in solution is to change the area under the first peak (the amount of adsorbed hydrogen). This in turn changed the rate of absorption of the hydrogen.

Similar results were obtained using iron membranes. Figure 12 shows a plot of the area under the first peak on the diffusion side as a function of time of hydrogen

generation at different current densities. It is seen that the area builds up linearly with time and then eventually levels off. Similar results are obtained if one varies the concentration of sulfide on the generation side (Fig. 13). In both cases, if one plots the area under the first peak on the generation side as a function of the rate of buildup of area on the diffusion side one obtains straight lines (Fig. 14). All of this is consistent with the viewpoint that the areas are proportional to the surface hydrogen on the respective sides and that the rate of diffusion of hydrogen through the saturated membrane is proportional to the amount of hydrogen on the surface on the generation side. This is further indicated since the rate of diffusion should be inversely proportional to the thickness of the iron membrane and the slope of the two straight

lines in Fig. 14, one obtained by variation in current density and the other by use of an additive, multiplied by the thickness of the membrane are 4.3 x 10^{-5} and 4.8 x 10^{-5} cm/in., respectively. These two figures are, within experimental error, identical.

Figure 15 shows that there is a linear relationship between the areas under the curves obtained on the two sides of the membrane in the final steady-state portion of the curves in Fig. 12 and 13. This is consistent with a steady state in which the rate of diffusion of hydrogen through the membrane equals the rate of desorption of hydrogen on the diffusion side.

Table I. Effect of electrode length on the third form of hydrogen

Electrode length, cm	Third peak area, m coulombs	Intercept, m coulombs
5	4 to 5	5.09
4	3 to 4	4.23
2	2 to 4	3.40

$$\left(\frac{dH_{II}}{dt}\right)_{diffusion} = -\left(\frac{dH_{II}}{dt}\right)_{desorption}$$

$$\left(\frac{dH_{II}}{dt}\right)_{diffusion} = kH_I \; ; -\left(\frac{dH_{II}}{dt}\right)_{desorption} = kH_{II}$$

$(H)_I$ is the hydrogen on the surface on the generation side, and $(H)_{II}$ is the hydrogen on the surface on the diffusion side. Therefore

$$k(H)_I = k'(H)_{II}$$

The two experimental slopes are not equal and should not be expected to be equal because the desorption mechanism is sensitive to the presence of impurities in the solution.

As previously observed (Fig. 6-9) the additives also affected the amount of hydrogen absorbed at equilibrium. Figure 11 shows the relationship between the amount of hydrogen absorbed at equilibrium and the amount of hydrogen adsorbed on the surface.

Although these curves have essentially the same slope they do not pass through the origin. This is because the final equilibrium area includes both the second and the third forms of absorbed hydrogen. It was not possible to accurately measure the amount of area under the third peak. It was possible to get the range of this area. In Table I this is tabulated along with the intercept, and it is seen that the intercept corresponds to the experimental value of the third area.

The average slopes of all four lines is 0.91 with the average deviation of the mean being 0.07. In all four cases then the amount of hydrogen absorbed at equilibrium is governed by an equilibrium constant of the following form

$$K_{eq} = \frac{H_{II\,eq}}{H_{I\,eq}}$$

It might well be assumed that the first and third peaks are caused by oxidation of two surface forms of hydrogen in line with previous reports on platinum. However, chemical oxidation does not attack the hydrogen rapidly in the third peak. Another interpretation would be that the third form of hydrogen is hydrogen in voids in the metal. However, so far the studies have not established the nature of the third form of hydrogen.

The Anomalous Codeposition of Iron-Nickel Alloys

H. Dahms and I. M. Croll

IBM Watson Research Center, Yorktown Heights, New York

ABSTRACT

The dependence of the anomalous codeposition of iron-nickel alloys on the pH at the cathode surface is investigated. An equation is derived to evaluate the surface pH as a function of bulk pH, rate of hydrogen evolution, buffer concentration, and diffusion conditions. The results obtained on rotating disk electrodes show that anomalous codeposition is due to a suppression of nickel discharge and that suppression occurs only when the surface pH is high enough to cause hydroxide formation. A type of mechanism is proposed by which the adsorption of ferrous hydroxide suppresses the deposition of nickel but permits a high rate of iron discharge. Experimental results which support this mechanism are discussed. This type of mechanism could be of general importance for other systems exhibiting anomalous codeposition.

In the electrodeposition of iron-nickel alloys from noncomplexing solutions the rate constant of iron deposition is higher than that of nickel, although the reverse order is observed when iron and nickel are deposited separately from their respective baths. This phenomenon of "anomalous codeposition" (1) has been reported under a wide variety of conditions in iron-nickel plating (2-6). Analogous anomalies, the preferential deposition of the less noble metal, have been encountered frequently in the electroplating of other alloys of the iron-group metals (7).

Several attempts to interpret this phenomenon have been made. Glasstone and Symes (2) suggested that "the presence of iron retards the change from metastable to stable nickel." No evidence for a metastable form of nickel has been given. Vagramyan and Fatueva

(4) discuss several possible causes in a rather general way. Sysoeva and Rotinyan (6) ascribe the shift in deposition rates to a shift in the zero charge potential. Their theory, which fits only their limited data, is, however, not in accord with our present knowledge of the dependence of reaction rates on zero charge potentials (8,9). Brenner (10) has developed an "addition agent theory" to account for the anomalous codeposition of zinc with the iron-group metals. He points out that the discharge of nickel is sensitive to the adsorption of addition agents and postulates that the addition agent is produced by the cathode reaction only when the current density is sufficiently high to raise significantly the pH of the cathode diffusion layer. In summary it can be said that the mechanism of anomalous codeposition is little understood. This fact has been stated clearly by Brenner (11) in his recent comprehensive survey on alloy deposition.

In the present investigation emphasis will be placed on the evaluation of the role of the pH at the cathode surface and its effect on codeposition. It has been shown recently at the dropping mercury electrode (12) that an increase in the pH at the interface and subsequent hydrolysis effects cause anomalies in the deposition of iron group metals which are analogous to those observed in the plating of iron-nickel alloys. In order to control the pH at the interface the diffusion to and from the electrode has to be well defined. For this purpose rotating disk electrodes (13) are used in this study.

Theory

The pH changes at the cathode surface are due to the over-all reactions

$$2H_3O^+ + 2e = H_2 + 2H_2O \qquad [1]$$

and

$$2H_2O + 2e = H_2 + 2\,OH' \qquad [2]$$

Both processes take place at iron (14) and nickel (15) electrodes. Diffusion processes will tend to compensate for these pH changes at the interface. The diffusion of the following species has to be considered: hydrogen ions, hydroxyl ions, and buffers. Any species reacting with H_3O^+ or OH' has buffering action. This buffering involves reactions of the type $nH^+ + A^- = H_nA$ as well as hydrolysis reactions $Me^{n+} + mOH' = Me\,OH_m^{(n-m)+}$. The diffusion of all buffering species can be treated in the same way taking into account the different direction of diffusion. In the treatment below, the species H_nA, therefore, represents hydrolysis products as well.

For the steady state in planar diffusion normal to the electrode we can write[1]

$$\frac{j_H}{F} = D_H\frac{\partial C_H}{\partial x} - D_{OH}\frac{\partial C_{OH}}{\partial x} + nD_{HA}\frac{\partial C_{HA}}{\partial x} \qquad [3]$$

where j_H is the current density of hydrogen evolution due to reactions [1] and [2]; F is Faraday's constant; $D_H'D_{OH}'$, D_{HA} are diffusion coefficients of hydrogen ions, hydroxyl ions, and buffer H_nA, respectively; C is the concentration of these species; and x is distance normal to the electrode. We can substitute C_{OH} and C_{HA} in Eq. [3] by using the relations

$$C_HC_{OH} = K_W \qquad [4]$$

$$C_H{}^nC_A = K_H \times C_{HA} \qquad [5]$$

and

$$C = C_{HA} + C_A \qquad [6]$$

where K_W is the ionization constant of water; K_H the dissociation constant of buffer; C, total concentration of buffer components; C_{HA}, concentration of undissociated buffer acid; C_A, concentration of buffer anion.

[1] The influence of migration is not taken into account. Migration is, however, negligible as long as the transport number of H^+, OH', and buffers is small; *e.g.*, in our case the transport number of HSO_4' (in 1M $MeSO_4$, 10^{-2}M H_2SO_4 solution) is about 0.02, *i.e.*, an error of 2% is introduced by neglecting migration. Similar arguments would hold for most plating baths.

We then obtain from Eq. [3]

$$\frac{j_H}{F} = D_H\frac{\partial C_H}{\partial x} + \frac{D_{OH}K_W}{C_H{}^2}\frac{\partial C_H}{\partial x} + n^2D_{HA}\frac{C\,C_H{}^{n-1}K_H}{(K_H + C_H{}^n)^2}\frac{\partial C_H}{\partial x} \qquad [7]$$

Equation [7] has to be integrated over the distance between electrode surface ($x = 0$, $C_H = C_H$) and the thickness of the "diffusion layer" ($x = \delta$, $C_H = C^o{}_H$). For the rotating disk electrode the thickness of the diffusion layer is given by (13)

$$\delta = 1.62\left(\frac{D}{\nu}\right)^{1/3}\left(\frac{\nu}{\omega}\right)^{1/2} \qquad [8]$$

where ν is the kinematic viscosity of the solution; $\omega = 2\pi f$ (f, number of rotations per second).

It follows from Eq. [8] that the thickness of the diffusion layer depends on the diffusion coefficient of the particular species. However, we have to assume an identical diffusion layer thickness for all species in order to integrate Eq. [7]. Using this approximation[2] we obtain by integrating Eq. [7]

$$\frac{j_H}{F}\delta = D_H(C^o{}_H - C_H) + D_{OH}K_W\frac{C^o{}_H - C_H}{C_HC^o{}_H} + nD_{HA}K_HC\frac{C^o{}_H{}^n - C_H{}^n}{(K_H + C_H{}^{o^n})(K_H + C_H{}^n)} \qquad [9]$$

It is interesting to note that in Eq. [9] the diffusion current consists only of additive terms although the equilibria among the species during diffusion have been taken into account. Ruetschi and Truempler (16) have derived an anologous additive expression for polarographic conditions on the basis of a simplified model allowing for equilibria only in the bulk and in the "reaction zone."

From Eq. [9] the hydrogen ion concentration at the surface, C_H, can be evaluated since all other quantities are experimentally amenable. An example is given in Fig. 1.

[2] Since in general the diffusion coefficients do not differ greatly the error involved is not too serious; *e.g.*, in our case with $D_{HSO_4'} = 1.1 \times 10^{-5}$, and $D_{Ni^{++}} = 0.69 \times 10^{-5}$ cm sec^{-1} (17) the thickness of the diffusion layer varies by ±6%.

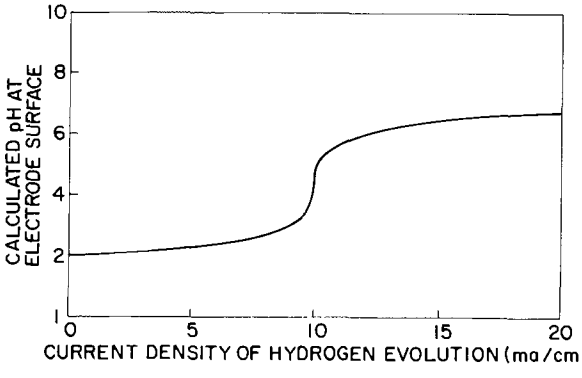

Fig. 1. Example of relation between current density and surface pH calculated from Eq. [9]. Solution: 0.5M $NiSO_4$, 0.5M $FeSO_4$, 10^{-2}M H_2SO_4. Quantities used for the calculation are: $\delta = 2.1 \times 10^{-3}$ cm [experimentally obtained for I_3' reduction in agreement with literature (18)], $D_{HSO4'} = 1.1 \times 10^{-5}$ cm^2 sec^{-1}; the second term of Eq. [9] can be neglected here since $C_H > 10^{-7}$ moles/l; the third term expressing the contribution of the hydrolysis reaction $Me^{++} + 2H_2O \rightleftarrows Me(OH)_2 + 2H^+$ yields a surface pH of 6.8 [calculated for a hydrolysis constant of $Ni(OH)_2$ $K = 1.6 \times 10^{-16}$ (20) and an activity coefficient of $NiSO_4$ $f = 0.042$ (24)]. Experimental determination of the pH in the presence of $Ni(OH)_2$ yielded pH = 6.7. The diffusion of species such as $NiOH^+$ and $FeOH^+$ have not been taken into account since their contribution is negligible due to their hydrolysis constants (21-23).

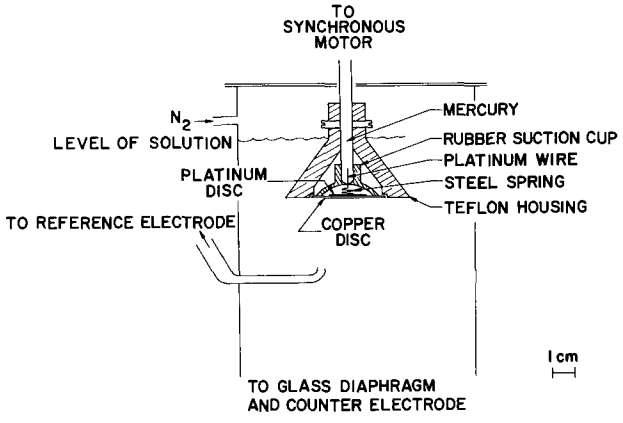

Fig. 2. Diagram of experimental arrangement

Experimental

Rotating copper disk electrodes with areas of 0.64 and 5.1 cm^2 were used. A schematic sketch of the larger electrode is given in Fig. 2. The disk is mounted simply by pressing it on the suction cup. Then the Teflon ring is adjusted so that disk and ring are in the same plane. This arrangement permits fast changing of the plated samples which are subsequently subjected to analysis. The electrical contact to the disk was satisfactory (resistance less than 0.1 ohm). The electrode was rotated by a synchronous motor at 10 rps. The performance of the whole arrangement was checked by measuring the diffusion limiting current of the reaction $I_3^- + 2e \rightarrow 3I^-$ which has been reported in the literature (18). Agreement within ± 5% was obtained.

The distance between electrode plane and probe of the reference electrode (a saturated calomel electrode) was kept constant. The potential drop due to ohmic resistance between cathode and reference electrode was determined by means of an oscilloscope from the decay of the electrode potential with time after switching off the current (19). All experiments were carried out under potentiostatic conditions at 22° ± 1°C. A Wenking potentiostat (rise time 10^{-5} sec) was used.

The electrolysis cell was U-shaped. The counter electrode was separated from the cathode compartment by two glass disks in order to avoid contamination by anode products.

The solutions were made up of analytical grade chemicals and conductivity water. Recrystallization and pre-electrolysis were used for further purification. Nitrogen was swept through the solution for at least 15 min prior to experiments. The mounted electrode disks were degreased in acetone, etched in warm nitric acid (diluted 1:1) for 30 sec, and then rinsed carefully in conductivity water. The samples were plated for 300 or 600 sec. The current was recorded on a fast-response recorder (0.1 sec full-scale deflection).

The electrodeposits were analyzed by x-ray fluorescence or by standard colorimetric techniques after dissolving the metal deposit. From these data and the knowledge of the total current passed the partial current due to hydrogen evolution was calculated. From the hydrogen evolution current the *p*H of the surface of the electrode was then evaluated on the basis of Eq. [9]. An example of the relation between hydrogen evolution current and surface *p*H is given in Fig. 1. Similar plots were constructed for other experimental conditions and the surface *p*H read off.

Results

The lower part of Fig. 3 shows Tafel plots of the separate deposition of iron and nickel compared to the deposition rates in alloy formation. It can be seen that the deposition of iron is hardly affected by the presence of nickel. The deposition of nickel is changed little at very low current densities, but is suppressed strongly

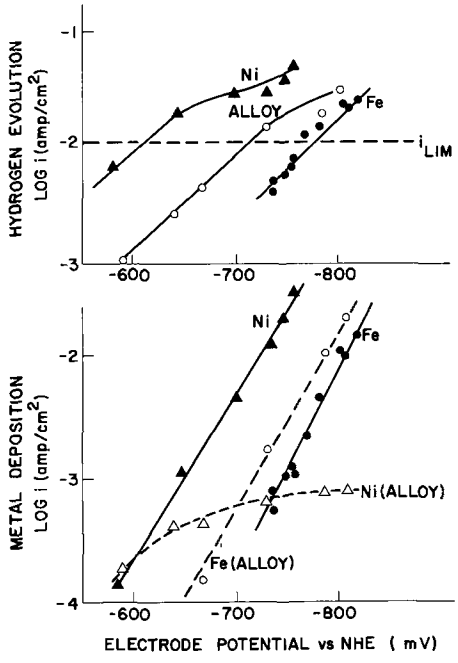

Fig. 3. Lower part: Tafel plots of iron-and-nickel deposition as separate metals and as alloys: ▲, nickel deposition from 0.5M $NiSO_4$, 0.01M H_2SO_4; ●, iron deposition from 0.5M $FeSO_4$, 0.01M H_2SO_4; △, nickel deposition from 0.5M $NiSO_4$, 0.5M $FeSO_4$, 0.01M H_2SO_4; ○, iron deposition from 0.5M $NiSO_4$, 0.5M $FeSO_4$, 0.01M H_2SO_4. at more negative potentials. The suppression of nickel discharge starts as soon as metal hydroxides are formed at the electrode, *i.e.*, at about the same potential at which the rate of hydrogen evolution exceeds the diffusion limited current of hydrogen ions i_{lim} (upper part of Fig. 3). Evaluation of the surface *p*H on the basis of Eq. [9] shows that this potential coincides with the rise of the surface *p*H from that of the bulk

to values sufficient for the formation of metal hydroxides. The dependence of plating rates on the surface pH is plotted in Fig. 4 and 5.

At higher bulk pH values (Fig. 6) the rate of hydrogen ion diffusion is so low that metal hydroxides are formed over the whole deposition range. It can be seen that under these conditions anomalous codeposition occurs throughout.

Figure 7 shows the influence of the iron ion concentration on the deposition rates. These measurements were done in a supporting electrolyte of 0.5M Na_2SO_4 in order to keep the activity coefficients and the ohmic voltage drop in the solution approximately constant. It can be seen that there is no noticeable increase in deposition rate with increasing iron concentration. Although there is some deviation from the averaged Tafel slope, no systematic trend to higher or lower deposition rates with increasing ferrous ion concentration is to be seen.

As hydrolysis appears to be responsible for the suppression of nickel discharge, and since ferric ions already hydrolyze at a pH of $\sim$ 3-4 (20), it was of interest to investigate the influence of traces of ferric ions present in the solution. Figure 8 shows the results of this study. No effect of ferric ions on the mechanism could be detected.

Discussion

The experimental results (Fig. 3-6) show a close relation between surface pH [3] and deposition rates: anomalous codeposition occurs when the surface pH is high enough to cause the formation of hydroxides. As long as the surface pH stays close to that of the bulk there are no anomalies in the deposition rates. In previous work (2-6) observations have been confined mainly to the region of anomalous codeposition (high surface pH) because no particular attention was paid to provide a sufficient rate of diffusion of hydrogen-ion-containing species to the electrode surface. Glasstone and Symes (2) used buffered solutions in order to maintain the bulk pH at the cathode surface. However, it can be calculated from their diffusion-limited deposition of iron (their Fig. 3, 4) that the maximal rate of diffusion of buffer acid was lower than the rate of hydrogen evolution observed (their Table I) in most of their experiments. It is interesting to note that at very low current densities, *i.e.*, at low hydrogen evolution currents, the authors do observe a sudden change to nickel-richer deposits. This is in qualitative agreement with the present work.

Since anomalous codeposition occurs only when metal hydroxides are formed in the cathode layer, the role of the hydroxides in deposition and codeposition has to be considered. It is clear that hydroxides of both iron and nickel ions are formed when the diffusion limited current of hydrogen ions is exceeded in all cases, in the deposition of single metals as well as in codeposition. However, since the anomalous suppression of the rate of nickel deposition occurs only during

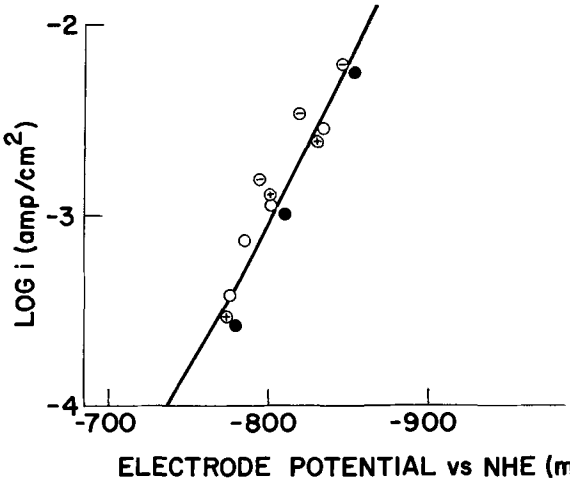

Fig. 7. Tafel plot of iron deposition as a function of ferrous ion concentration from solution of 0.5M Na_2SO_4, 0.01M H_2SO_4, 0.1M $NiSO_4$, xM $FeSO_4$. ○, x = 0.015M; ⊖, x = 0.03M; ⊕, x = 0.06M; ●, x = 0.1M.

[3] Recent direct measurements of the surface pH in nickel deposition [J. Matulis and R. Slizys, *Electrochim. Acta*, 9, 1177 (1964)] are in good agreement with our values calculated from Eq. [9].

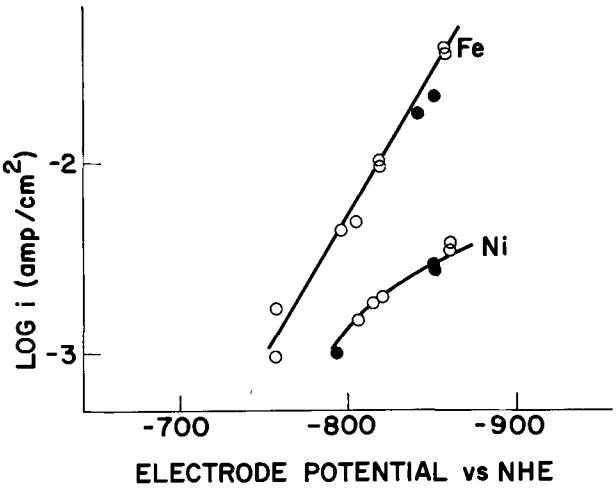

Fig. 8. Influence of Fe^{3+} content on deposition of iron-nickel alloys from a solution of 0.5M $FeSO_4$, 0.5M $NiSO_4$, 0.01M H_2SO_4. ○, Fe^{3+} less than 5 x 10^{-5}M; ●, Fe^{3+} — 5 x 10^{-3}M.

codeposition but not during deposition of nickel alone (Fig. 3) this effect must be attributed to the formation of ferrous hydroxide. The suppression of nickel discharge in the presence of ferrous hydroxide can be accounted for by assuming preferential absorption of ferrous hydroxide at the electrode which blocks the deposition of nickel.

This view is supported by the observation that preferential adsorption of ferrous hydroxide in the presence of nickel ions and subsequent suppression of nickel discharge occurs at the mercury electrode under analogous conditions (12).

Although the preferential adsorption of ferrous hydroxide in the presence of nickel cannot be interpreted on the basis of the hydrolysis constants [$Fe(OH)_2$: $K = 1.8 \times 10^{-15}$; $Ni(OH)_2$: $K = 1.6 \times 10^{-16}$], a higher rate of hydrolysis, rate of adsorption, or free energy of adsorption could account for the experimentally observed preferential adsorption. Another possibility is that ferric ions [hydrolysis constant $K = 6 \times 10^{-38}$ (20)] could form the first hydroxide layer. Figure 7 shows, however, that the addition of ferric ions has no effect on the anomalous codeposition. This result does not exclude the possibility that traces of ferric ions could form an initial monolayer of hydrolysis products.

The preferential adsorption of ferrous hydroxide would explain the fact that, although the rate of nickel discharge is suppressed, a high rate of iron discharge is maintained since the adsorbed ferrous hydroxide can provide the discharging species for iron deposition. The results shown in Fig. 7 support this point of view. It can be seen that the rate of iron discharge is independent of the concentration of ferrous ions in solution. This result means that the rate-determining step in iron deposition (in the presence of nickel) involves an adsorbed species, the surface concentration of which does not change with the ferrous ion concentration in solution.

On the basis of the discussion given above, the following type of mechanism can be proposed

$$2\,H_2O + 2e \rightarrow H_2 + 2\,OH' \qquad [1]$$

$$Fe^{++} + 2\,OH' \rightleftarrows Fe(OH)_{2,ads}\,(\theta_{Fe(OH)_2} \rightarrow 1) \qquad [2]$$

$$\text{At } \theta\text{: } Fe(OH)_{2,ads} + Fe(OH)_n^{(2-n)+} + 2e \rightarrow Fe + Fe(OH)_{2,ads} + n\,OH' \qquad [3]$$

$$\text{At } 1-\theta\text{: } (Ni(OH)_n^{(2-n)+} + 2e \rightarrow Ni + n\,OH' \qquad [4]$$

where θ is surface coverage with ferrous hydroxide.

Since anomalous codeposition is observed primarily in the electrodeposition of alloys containing one or more ions which are susceptible to hydrolysis (Fe, Co, Ni, Zn) (7), the type of mechanism given above could be of general importance in anomalous plating. It explains the two most characteristic features of anomalous codeposition: (i) the sudden change of systems from normal to anomalous codeposition with increasing current density which is caused by the equally sudden change of the *p*H at the electrode surface; (ii) the strong influence of temperature which effects the rate of evolution of hydrogen and the rate of diffusion to the electrode.

Acknowledgment

The authors wish to thank Mrs. J. D. Olsen for her skillful experimental assistance.

Manuscript received Nov. 20, 1964; revised manuscript received April 21, 1965. This paper was presented at the Washington Meeting, Oct. 11-15, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

Rare Earth Activated Phosphors Based on Yttrium Orthovanadate and Related Compounds

Frank C. Palilla, Albert K. Levine, and Maija Rinkevics

General Telephone & Electronics Laboratories, Inc., Bayside, New York

ABSTRACT

The adoption of YVO_4:Eu as a new red-emitting primary in color television has stimulated investigation of a new class of phosphors obtained by appropriate substitutions in YVO_4:Eu. Substitution of Y^{3+} by Gd^{3+} and Lu^{3+} provides equally efficient hosts for Eu^{3+} with no significant spectral differences. Substitution of Y^{3+} by La^{3+} leads to a less efficient host with important differences in the emission characteristics of Eu^{3+}. Use of rare earth activators other than Eu^{3+} provides a series of phosphors which emit over most of the visible range. Spectral data and preferred concentration ranges are presented as well as the effect of temperature on the fluorescent emission intensities.

The cathodoluminescent response of YVO_4:Eu has recently been described (1, 2) and, in particular, attention has been drawn to it because of its wide adoption as the new red-emitting primary in color television. The ultraviolet excited emission from this phosphor has been reported by Van Uitert *et al.* (3, 4), and more recently by Levine and Palilla (5) who have shown it to be extremely efficient under this mode of excitation. The notable properties of YVO_4:Eu has stimulated investigation of a new class of phosphors obtained by appropriate cation substitution in YVO_4, and by use of rare earths other than europium as activators.

Lanthanum, Gd, and Lu were investigated as host cations replacing Y. All four elements have the same valence electron configuration (d^1s^2) and are optically inert. Their ionic radii in the trivalent state are 1.14, 0.97, 0.85, and 0.92Å, respectively (6); the ionic radii of all the other trivalent rare earths lie within this range. In their trivalent state Y, La, Gd, and Lu possess spherically symmetrical electronic structures and are characterized by considerable stability: Y^{3+} and La^{3+} have a noble gas electronic structure (f^0), Lu^{3+} possesses a complete 4f shell (f^{14}), and Gd^{3+} has a half-filled shell (f^7). Such configurations provide the basis for effective host crystal structures because of the absence of lower lying energy levels by way of which excitation energy might be dissipated. Moreover, when combined with proper anions these cations form matrices which exhibit no absorption in the visible region and hence are white in body color. Reference to the similar properties of Y^{3+} and Gd^{3+} as host cations for luminescence has already been made by several investigators (3, 7, 8).

The elements Tm, Er, Ho, Dy, Tb, and Sm in the trivalent state were selected as the activators. All fluoresce when excited and their emissions cover most of the visible range. Their similarity in ionic size and valence state to the selected host cations permits incorporation into the selected hosts without the complications of charge compensation. Furthermore, in common with Y^{3+}, Gd^{3+} and Lu^{3+}, they all crystallize in the tetragonal system with the xenotime structure (9-12). It is particularly desirable that the host and activator cations form isostructural compounds when the activator concentrations may be high, as is the case in this class of compounds. Lanthanum, because of its larger ionic radius, provides an exception and crystallizes in a different system from the rest of the lanthanides.

Experimental Procedure

The rare earth orthovanadates were prepared by blending the mixed oxides or the coprecipitated oxalates of the rare earths with an appropriate compound of vanadium and then firing the mixture in a silica or platinum crucible at 900°C or higher.

The arrangement for recording the excitation and emission spectra of the powders is indicated in Fig. 1. The phosphor sample is packed in a flat plaque with a quartz window and centered in the bottom of a dewar having observation ports at 90° to one another. Excitation radiation enters by one port and the sample fluorescence is observed through the other. Room temperature data are obtained before the liquid nitrogen is added to the dewar for the low-temperature observations. This procedure makes both sets of traces quantitatively comparable. Excitation is provided by a 200-w d-c xenon lamp, whose output is passed through a Leiss quartz prism monochromator, to select the desired wavelength, and then focused on the sample.

Fluorescence from the sample is focused on the entrance slit of a Jarrell-Ash 0.5-meter Ebert grating monochromator, and that portion reaching the exit slit is detected by a 6255B-EMI photomultiplier (S-13 surface). Either monochromator may be scanned automatically: the prism monochromator provides excitation spectra; the grating monochromator emission spectra. The integrated luminous output of the samples under 253.7-nm excitation was measured with a Photovolt photometer Model 520-M using a 1P21 photomultiplier as a detector in conjunction with a Wratten 106 filter.

Results and Discussion

The orthovanadates of Y^{3+}, Lu^{3+}, and Gd^{3+}, prepared as above, consist of well-formed crystallites. The powders give sharp x-ray patterns which confirm that these compounds crystallized in the tetragonal system with the xenotime structure, and that secondary phases are absent. In this structure the vanadium atoms are tetrahedrally coordinated with oxygen atoms, while

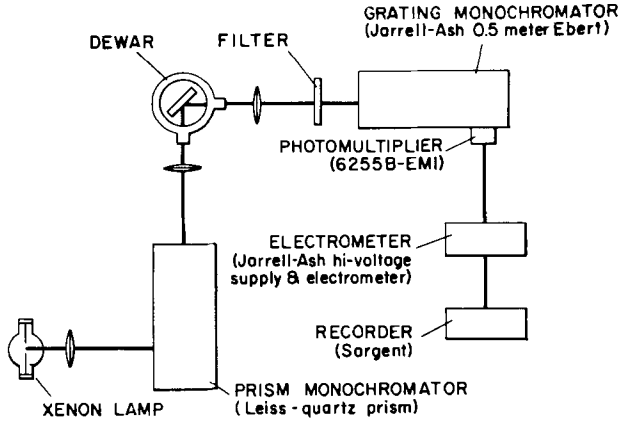

Fig. 1. Experimental arrangement for determining excitation and emission spectra.

each rare earth ion is surrounded by eight oxygen neighbors arranged in the form of two distorted tetrahedra. Lanthanum orthovanadate crystallizes in the monoclinic system with the monazite structure.

Under u.v. excitation the unactivated vanadates of Y^{3+}, Lu^{3+}, and Gd^{3+} exhibit broad-band blue-white luminescence which gives a peak in the photomultiplier response near 450 nm (Fig. 2). Since the response of the S-13 surface is reasonably flat between 400 and 500 nm, the corrected peak for this host fluorescence also lies near 450 nm. The difference in fluorescence intensity between liquid nitrogen temperature and room temperature indicates that lattice vibrations lead to dissipative transitions as the temperature is raised. The multiplets which are superimposed on the YVO_4 host emission are due to Dy^{3+} (481 and 576 nm) and Tm^{3+} (477 nm) impurities in the Y_2O_3 source material. The emission spectrum of $GdVO_4$ is very similar to that of YVO_4 except that it shows multiplets at 619 and 595 nm due to Eu^{3+} impurity in the Gd_2O_3. The same broad fluorescence at 450 nm is observed with $LuVO_4$. In the case of $LaVO_4$ no host emission was detected. Brixner and Abramson (13) recently reported weak broad-band host emission centered at 475 nm from YVO_4, $GdVO_4$ and $LaVO_4$ at room temperature. Careful examination of their spectra indicates that the peak near 475 nm is probably due to Tm^{3+} and/or Dy^{3+} impurities, which probably account also for the multiplets at 480 nm. The multiplets reported at 525 and 555 nm should be attributed to Er^{3+}, that at 575 nm to Dy^{3+}, and those at 595 and 618 nm to Eu^{3+}. This argument is supported by the data presented immediately below.

When selected lanthanides are incorporated into these vanadates they function as activators and introduce characteristic emission and absorption lines. Furthermore they are effective in quenching the host luminescence. From Fig. 2 it is seen that when activators are added to YVO_4, the host luminescence is almost completely quenched at room temperature, but remains pronounced at reduced temperature. The apparent exception in the case of Eu^{3+} is due to its high concentration (5 mole %) as compared with the others (0.5 mole %). When the Eu^{3+} concentration is reduced below 1 mole % the host emission at −196°C begins to become prominent. The emission lines due to the activators are sharp and occur in groups characteristic of each particular rare earth. In the cases of Er^{3+} and, particularly, Ho^{3+} sharp absorption lines are superimposed on the host emission at −196°C. These lines are due to transitions from the ground states of the ions followed, at least in part, by nonradiative processes. The nonradiative processes of excited Er^{3+} and Ho^{3+} in YVO_4 probably limit the emission intensity at room temperature also. The lines at 576 nm which appear in most of the spectra are due to Dy^{3+}, an impurity generally found with Y^{3+}. In those cases where the relative photomultiplier response as shown in Fig. 2 is small, the spectral details shown were verified by measurements made at higher gain. Table I presents a summary of the principal groups of emission lines, relative luminosity under 253.7-nm excitation, and preferred concentration ranges of activators in YVO_4. It should be noted here that activation by Dy^{3+} gives the most luminous phosphor. However, activation by Eu^{3+} gives a phosphor of almost equal luminance despite the fact that its emission is in a region where the luminosity function is smaller. In terms of radiant energy output Eu^{3+} is the most efficient of the rare earth activators for YVO_4. The weak emission with Tb^{3+} as activator is not consistent with the correspondence suggested by Dieke and Hall (14) between fluorescence efficiency and the magnitude of the energy gap between excited and low-lying levels of the rare earth ions. The poor fluorescence of Tb^{3+} in YVO_4 may be attributable to inefficient energy transfer from the crystal lattice. The fluorescence from terbium in $GdVO_4$ and $LaVO_4$ is also weak.

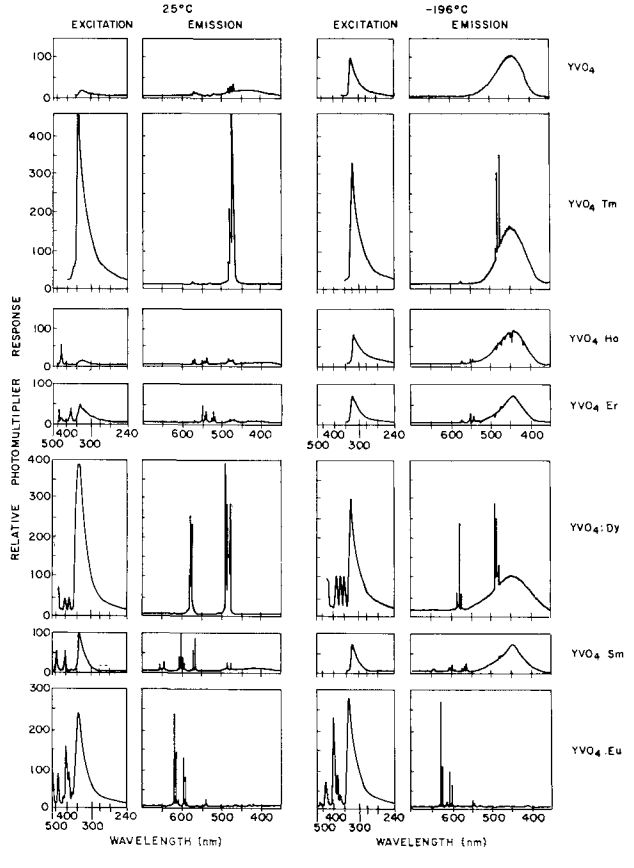

Fig. 2. Emission and excitation spectra of YVO_4 and YVO_4:Ln at 25° and −196°C. Ln = Tm^{3+}, Ho^{3+}, Er^{3+}, Dy^{3+}, Sm^{3+}, and Eu^{3+}. The excitation spectra are for the emission peak in each case and terminate when the excitation wavelength coincides with the emission being monitored. Similar spectra are obtained when Gd^{3+} and Lu^{3+} are substituted for Y^{3+}. Relative response refers to 6255B-EMI photomultiplier.

Table I. Summary of principal groups of emission lines, relative luminosity, and preferred concentration ranges of activators

Phosphor	Preferred conc. range of activator, mole %	Principal emission line groups, nm	Visual emission color	Relative luminosity, 253.7 nm excitation
YVO_4:Tm	0.5-1.0	477	Blue	12.2
YVO_4:Tb	—	—	Green	<1.0
YVO_4:Ho	0.1-1.0	545	Green	8.8
YVO_4:Er	0.4-0.8	553, 525	Green	20.5
YVO_4:Dy	0.3-0.7	576, 481	Yellow-white	130.0
YVO_4:Sm	0.1-1.0	650, 606, 569	Orange-red	63.0
YVO_4:Eu	3.0-10.0	619, 595, 698	Red	100.0

Figure 2 also shows that the excitation spectra of rare earth activated yttrium vanadates are similar for all the rare earths, except that beyond 330 nm each of the activator ions exhibits the narrow excitation bands characteristic of its own direct absorptions. These direct absorption bands are in most cases considerably weaker than the broad u.v. excitation band which has the same general character as in the unactivated vanadates. The rare earth activated orthovanadates of gadolinium and lutetium also give essentially identical excitation spectra. When corrected for the variation of output intensity with wavelength of the excitation source (discussed in the following paragraph) the excitation spectrum is intense over a wide range (Fig. 3). Because this excitation band is independent of the host cation or activator species, it must be considered as associated with the vanadate ion in this structure.

The vanadate-associated excitation band was determined by the method of Eby (15) which gives corrected spectra. This method employs a deuterium arc lamp in conjunction with a 0.5-meter Seya-Namioka

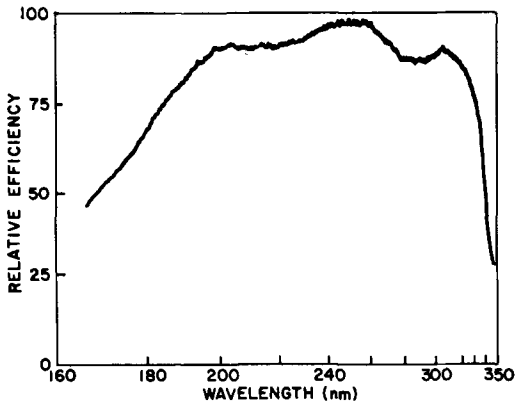

Fig. 3. Excitation spectrum typical of RVO_4 and RVO_4:Ln. R = Y, Lu, Gd, and La.

type of vacuum grating monochromator. Most of the radiation from the monochromator is used to excite the phosphor, but a portion of the beam is intercepted and measured by a monitoring system which leads to corrections for the variation of light output with wavelength. The resulting spectra are thus corrected for the various instrumental effects. Figure 3 shows the spectrum obtained with YVO_4:Eu. Several of the systems described above were studied in this way; all were found to give similar excitation spectra. The host-associated excitation spectrum is seen to be unusually broad. Furthermore the excitation efficiency is uniformly high from 180 to 330 nm, a property which indicates the potential of this phosphor system in mercury discharge lamps.

Comparison between the orthovanadates of the isostructural Y, Lu, and Gd compounds and $LaVO_4$ as hosts was made using europium ion as activator. Under 253.7 nm excitation YVO_4:Eu, $GdVO_4$:Eu, and $LuVO_4$:Eu exhibit almost equal emission intensity, and are about four times more intense than $LaVO_4$:Eu. Figure 4 gives the excitation and emission spectra of these compounds. With Gd, Lu, and Y hosts, the Eu^{3+} emission at 619 nm was monitored; with La, the Eu^{3+} emission at 615 nm was monitored. It is apparent that only minor differences exist between the isostructural orthovanadates, but important differences appear in the case of $LaVO_4$:Eu. In addition to the weaker fluorescence intensity of Eu^{3+} in $LaVO_4$, there is a pronounced alteration of the relative intensities of the principal emission lines, which appear at the same wavelengths. For example, within the structurally sensitive electric dipole $^5D_0 \rightarrow {}^7F_2$ transition, the 615 and 612.5 nm emissions in $LaVO_4$:Eu are considerably more

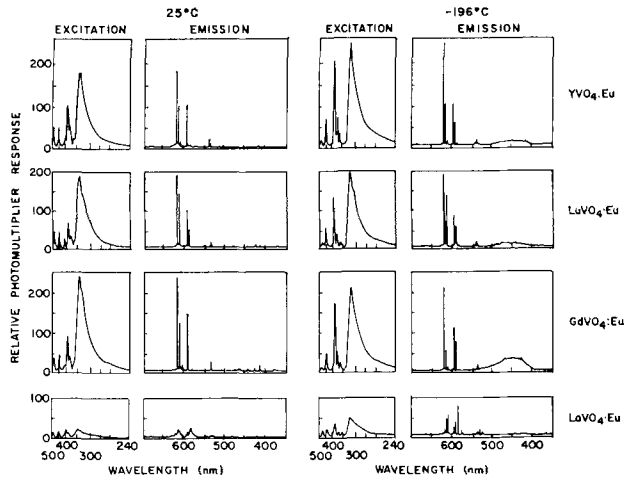

Fig. 4. Emission and excitation spectra of RVO_4:Eu at 25° and —196°C. Relative response refers to 6255B-EMI photomultiplier.

intense with respect to the 619 nm emission than is the case with the other orthovanadates. These results are consistent with previous observations (1, 5) pertaining to crystal field effects on Eu^{3+} emission from Y_2O_3 and YVO_4, two hosts which present substantially different environments. Also, in the Y, Lu, and Gd orthovanadates activated with Eu^{3+}, the preferred transitions by far are those involving $^5D_0 \rightarrow {}^7F_2$ levels, while in $LaVO_4$, the transitions originating from the $^5D_0$ excited level and terminating at the $^7F_1$ multiplets occur to a greater extent, when allowance is made for the photomultiplier response. The former transitions correspond to the emissions centered between 612 and 619 nm, while the latter correspond to those near 595. The prominence of these emissions in $LaVO_4$:Eu represents an example of an increase in the probability of an allowed magnetic dipole transition ($^5D_0 \rightarrow {}^7F_1$) with decrease in environmental symmetry. The lines evident in the $LaVO_4$:Eu emission at about 587 (the most pronounced emission at —196°C) and 579 nm were not detected in the spectra from $GdVO_4$:Eu, $LuVO_4$:Eu, and YVO_4:Eu. These emissions appear to correspond to an additional $^5D_0 \rightarrow {}^7F_1$ component and to the $^5D_0 \rightarrow {}^7F_0$ transition, respectively. It should be noted also that although the Eu^{3+} emission intensity is little affected by a reduction of temperature in YVO_4, $GdVO_4$, and $LuVO_4$, the effect in $LaVO_4$ is pronounced. In contrast to the differences observed in the fluorescence of Eu^{3+} in these hosts little difference, except for intensity, is detectable in the excitation spectra. This constitutes further confirmation that the principal absorption of energy occurs by way of the vanadate

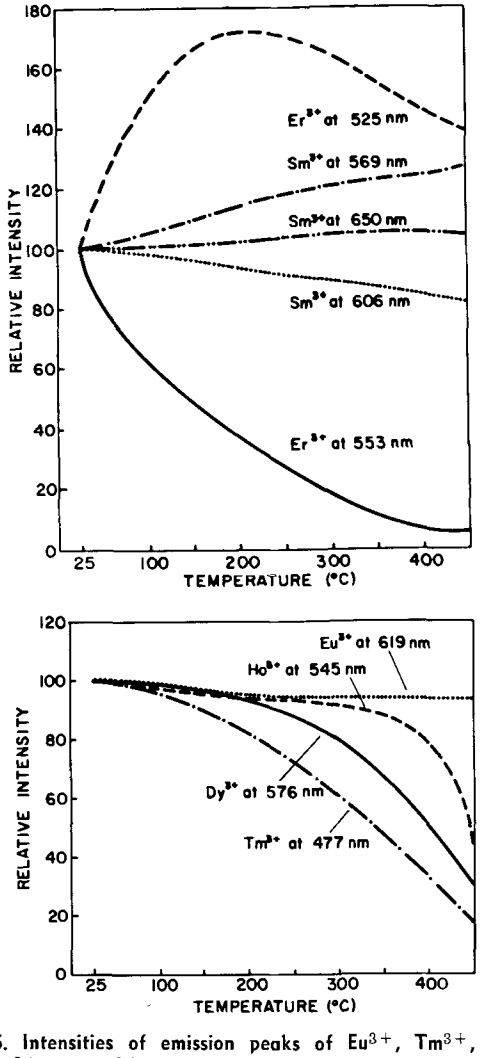

Fig. 5. Intensities of emission peaks of Eu^{3+}, Tm^{3+}, Ho^{3+}, Dy^{3+}, Sm^{3+}, and Er^{3+} in YVO_4 with temperature relative to their intensities at 25°C.

ligand. In all cases, there is a small shift in peak excitation intensity toward shorter wavelength with decrease in temperature to —196°C.

Figure 4 also shows that in all the systems activated with Eu^{3+}, little line sharpening occurs as the temperature is reduced from 25° to —196°C. This indicates that there is negligible dissipative interaction between the Eu^{3+} and the crystal lattice of these hosts. This temperature relationship continues, so that even at elevated temperatures YVO_4:Eu emits quite strongly. Figure 5 indicates that there is no appreciable temperature quenching up to at least 400°C. This, together with its excellent response, evident from Fig. 3, to the principal lines from both low- and high-pressure mercury discharges indicates the potential of YVO_4:Eu as a red color-correcting component in mercury lamps.

Not all activators in YVO_4 behave similarly, as is shown in Fig. 5. Unless otherwise stated, only the relative intensities of the major emission groups are plotted. It is seen that Dy^{3+} and Ho^{3+} fluoresce strongly from room temperature up to about 200°C, beyond which strong temperature quenching occurs. With Tm^{3+} a continuous decrease with increasing temperature above room temperature is found. On the other hand, Sm^{3+} shows a continuous, but small increase in intensity of its emission at 650 nm, a steady decrease in its shorter wavelength emission at 606 nm, and a continuous increase in its minor emission at 569 nm. Finally Er^{3+} exhibits a sharp and steady decrease in its emission at 553 nm, while its emission at 525 nm reaches a peak intensity at 200°C. Quantitative and detailed measurement of the different behavior with temperature of the various activators in YVO_4 should provide valuable data for fundamental studies of the mechanism of energy transfer and emission processes in this system of phosphors.

Acknowledgments

Grateful acknowledgment is made to B. O'Reilly for his assistance in the preparation of many of the phosphors, to V. Brophy for much of the spectral data, and to J. Eby for the investigation of the excitation characteristics in the short wavelength u.v. region. The authors also wish to express their thanks to F. Avella, L. Bodi, C. Brecher, and C. Wiggins for helpful discussions and suggestions.

Laser Characteristics of Niobium Compensated $CaMoO_4$ and $SrMoO_4$

P. A. Flournoy and L. H. Brixner

Engineering Physics Laboratory and Pigments Department, respectively,

E. I. du Pont de Nemours and Company, Inc., Wilmington, Delaware

ABSTRACT

The niobium-compensated $CaMoO_4$ and $SrMoO_4$ systems have been found to be excellent host materials for rare earth ions. A discussion is given of pertinent crystal properties, fluorescence spectra, laser output wavelengths, thresholds for stimulated emission, and other parameters of importance in practical utilization of these materials for pulsed and CW lasers. A comparison with the sodium compensated $CaWO_4$:Nd^{3+} system is given where data are available.

Laser action has been observed in several single crystal materials containing trivalent neodymium ions (1). Of particular interest is the calcium tungstate host lattice (2), which was the first to provide a continuously operating solid-state laser at room temperature. Neodymium-doped calcium and strontium molybdates were first demonstrated to lase by Johnson (3), but he observed high thresholds due to poor crystal properties. Brixner (4) developed a procedure for purifying and stabilizing these materials to improve their growing characteristics and produce large single crystals of excellent optical quality. In the present study, the fluorescence and stimulated emission characteristics of neodymium-doped calcium and strontium molybdate are presented, and where possible compared to calcium tungstate as a host.

Crystal Properties

Although rare earth ions can be introduced into the scheelite lattice without a secondary compensating ion (creating a defect lattice), valence compensation by a second ion is generally preferred since it simplifies the fluorescent emission spectrum and lowers the threshold for laser action. The most common scheme, as outlined by Nassau (2), is to compensate with Na^+ for each Ca^{2+} ion replaced by a rare earth ion. Although the structural match for these ions is nearly perfect, sodium presents problems because of its vola-

Table I. Crystal properties

[a] K. Nassau, Proc. Symposium Optical Masers, p. 451, Brooklyn Polytechnic Press, New York (1963).

tility at high melt temperatures and its relatively low segregation coefficient. Therefore, in the work reported here, we balanced in the Mo^{6+} site by introducing the same amount of Nb^{5+} for each Ca^{2+} or Sr^{2+} ion being replaced by Nd^{3+}. Compared with sodium containing compositions, niobates are considerably more stable, and no losses are experienced at melt temperature. Moreover, the segregation coefficient is much more favorable, being close to unity.

Brixner (4) recently published a detailed study of the niobium compensated calcium molybdate, its Czochralski crystal-growth characteristics, crystal structure, and fluorescent properties. Additions of rare earth niobate as small as ½ mole % stabilize $CaMoO_4$ and keep it from losing oxygen and turning deep blue. Other workers (1) had difficulty eliminating this blue coloration on direct growing and have had to anneal under oxygen. Since the molybdates can be grown at 1480°-1490°C (100°C lower than calcium tungstate), fewer impurities are introduced from the melt container. Using a Jarrell Ash 3.4m grating plane spectrograph, semiquantitative analysis of singly pulled $CaMoO_4$ of our own preparation and $CaWO_4$ grown from Sylvania "crystal grade" feed gave the following results:

	Na	Mg	Zn	Pb	Mn	Ni	Co	Al	B	Si
$CaMoO_4$	<100	~20	<100	<100	<10	<100	<100	<10	<10	~80
$CaWO_4$	<100	~100	<100	~100	~10	<100	<100	~10	<10	~100

Although most of the elements analyzed were below the limit of detection, the results reflect the higher quality of the $CaMoO_4$ feed.

A comparison of some important crystal properties of $CaMoO_4$, $SrMoO_4$, and $CaWO_4$ is given in Table I. The average segregation coefficient for $NdNbO_4$ in $CaMoO_4$ based on the analytical evaluation of over 50 crystals is 1.31. The $CaO:MoO_3$ ratio never deviates more than 1% from unity. If equal starting quantities of Nd_2O_3 and Nb_2O_5 are used, excellent charge compensation over the length of the crystals is obtained without the need for stoichiometric correction. The neodymium concentration varies linearly along the length of the crystal on the order of 3%/in. The segregation coefficient for $NdNbO_4$ in $SrMoO_4$ was found to be unity within the accuracy of the measurement, and variations of the neodymium concentration along the length of 6-in. crystals were too small to measure. On the other hand, variations in neodymium concentration as large as 20-30% per inch are typical for sodium compensated $CaWO_4$ unless large excesses of sodium are used.

Fluorescent Properties

Fluorescence spectra of Nb^{5+}-compensated $CaMoO_4$ and $SrMoO_4$ containing 1.3 mole % Nd^{3+} were recorded with a Bausch & Lomb two-meter-grating spectrograph using Kodak 1-Z infrared sensitive spectroscopic plates. The samples were placed in a quartz dewar containing liquid N_2. Fluorescence emission was excited by a Gates HBO 100 W/2 high-pressure mercury arc through a Corning 4600 filter.

The $4F_{3/2} \rightarrow 4I_{11/2}$ emission from niobium compensated $CaMoO_4:Nd^{3+}$ is shown in Fig. 1, as obtained from a microdensitometer scan of the original spectroscopic plate. The emission line widths are approximately 12Å at 295°K and 5Å at 77°K. Stimulated emission is observed for the lines indicated by arrows under the conditions discussed below. The spontaneous emission lifetime for neodymium in the $CaMoO_4$ host at 295°K was observed to vary nearly linearly with concentration over the range from 0.5 to 2.0 mole % $NdNbO_4$ as shown in Fig. 2. Fluorescence yield measurements as a function of rare earth concentration indicate an optimum Nd^{3+} concentration of 1.3 mole %. The fluorescence yield determined in this way is, of course, a function of the absorption coefficient, and no attempt was made to correct the data for this effect. Therefore the "optimum" values of concentration are usually slightly lower than that required for optimum laser performance.

Fluorescent emission from the strontium host is shown in Fig. 3. The data are similar to that of Fig. 1, but shifted by 20-30Å to the short wavelength side with a significant change in the intensity distribution among the stronger bands. Line widths vary from 35

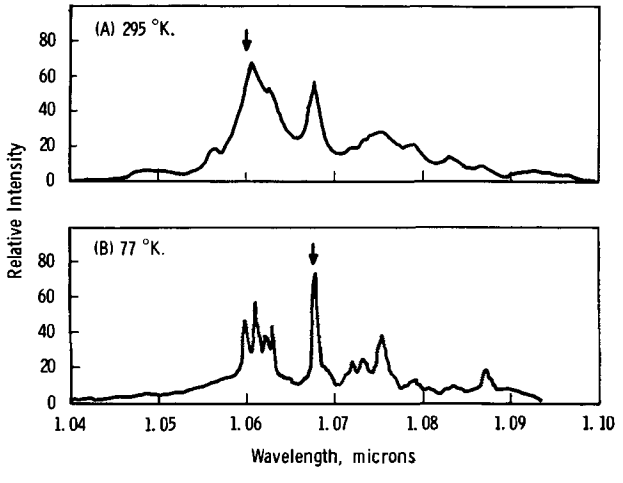

Fig. 1. $4F_{3/2}$ $4I_{11/2}$ emission in $CaMoO_4:Nd^{3+}$ with Nb^{5+} compensation: (a) 295°K, (b) 77°K. Observed laser lines are indicated.

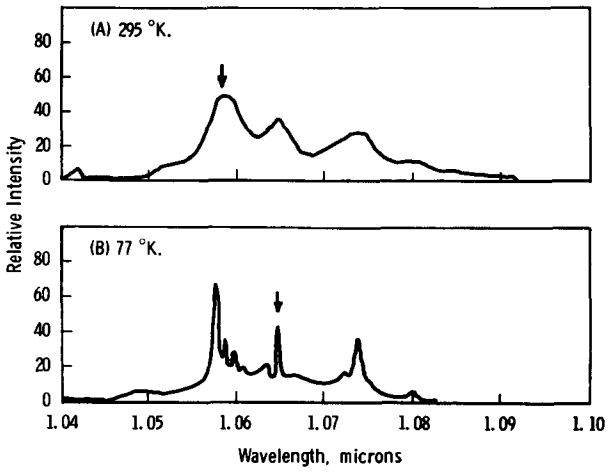

Fig. 3. $4F_{3/2}$ $4I_{11/2}$ emission in $SrMoO_4:Nd^{3+}$ with Nb^{5+} compensation: (a) 295°K, (b) 77°K. Observed laser lines are indicated.

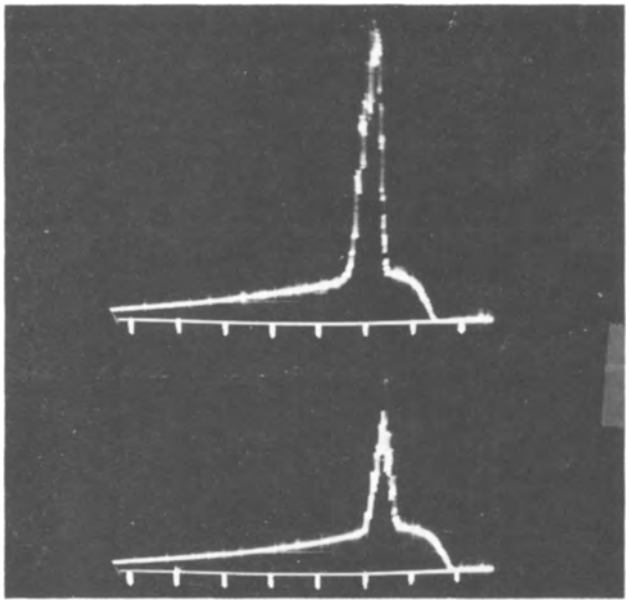

Fig. 4. Light output of a $CaMoO_4:Nd^{3+}$ crystal at 1.060μ with $T = 134$°K. Upper trace: 12% above threshold; lower trace: 8% above threshold; time scale is 100 μsec/div.

to 40Å at 295°K to 6 to8Å at 77°K. Room temperature lifetimes for this host are longer by approximately 20 μsec for 1% neodymium. Fluorescence yield measurements show an optimum Nd^{3+} concentration of 1.2 mole %.

Laser Experiments

Single crystal boules were cut and ground into cylindrical rods ¼ in. diameter and 3 in. long. The cylindrical surfaces were left rough and the ends polished to form a Fabry-Perot resonator. Silver was evaporated onto the end surfaces; one end was 5% transmissive and the other completely opaque.

Laser characteristics were measured under pulsed illumination in a Lear-Siegler LS-3 laser head with a Kemlite FT100B helical xenon flash lamp. Temperature from 135° to 295°K was controlled by placing the laser crystals in precooled flowing nitrogen gas. The lamp was flashed by discharging a 5-μf condenser charged to 2000v. Light from the laser rods was detected with a Dumont K1485 photomultiplier through a 3-mm silicon filter. Figure 4 shows a typical laser emission just above threshold for $CaMoO_4$. For 2 or 3 in. long rods, thresholds invariably less than 10 joules have been observed at 135° and 295°K under these conditions. In a more efficient setup, Duncan (5) reported thresholds as low as 0.6 joules at 77°K and 1.0 joules at 300°K on our $CaMoO_4$:Nd crystals.

The spectral distribution in the output was recorded on Kodak 1-Z spectroscopic plates by focusing the emitted radiation into a Bausch & Lomb 2-meter grating spectrograph. At room temperature, stimulated emission is observed at 1.0595μ in $CaMoO_4$ and 1.0573μ in $SrMoO_4$. The line width decreases to ~0.8Å in both cases. At 134°K, the same transitions are observed with the output wavelength decreasing by 4Å in $CaMoO_4$ and 7Å in $SrMoO_4$. However, at 77°K the lowest thresholds are observed for the 1.067μ line in $CaMoO_4$ and 1.064μ line in $SrMoO_4$.

Continuous operation of the $NdNbO_4$:$CaMoO_4$ system at both 77°K and room temperature has been achieved and is reported elsewhere (5). The niobium compensated $CaMoO_4$ can also be readily "Q-spoiled" (6).

Summary

The niobium-compensated $CaMoO_4$ and $SrMoO_4$ systems show promise as excellent, active materials for lasers. The thermal stability of the rare earth niobates combined with the favorable segregation coefficients allows the growth of uniform crystals of excellent optical quality. In addition low melting points minimize contamination from the melt container. The fact that Duncan (5) observed continuous laser operation at room temperature with $CaMoO_4$:Nd crystals clearly indicates the high optical perfection necessary for continuous oscillations and makes this particular composition only the second scheelite-type host after $CaWO_4$:Nd (7) to do so. The principal practical advantage we see in the $CaMoO_4$ over the $CaWO_4$ host is the appreciably higher thermal conductivity which will greatly alleviate cooling problems during operation, since heat will be dissipated much faster. While the difference in refractive indices is not very great, it certainly constitutes a further small advantage for $CaMoO_4$. The fluorescence of Nd^{3+} in $CaMoO_4$ has a narrower line width and simpler emission spectrum than Nd^{3+}-doped $CaWO_4$, which also is rather desirable since it results in lower thresholds.

In conclusion, we can state that $CaMoO_4$ as a solid-state laser host has come a long way since the original experiments by Johnson (1) and can now be considered at least equivalent to the corresponding tungstate and further, more detailed studies seem indicated.

Solubility and Electrical Behavior of Zinc, Sulfur, Selenium, and Tellurium in Gallium Phosphide

F. A. Trumbore, H. G. White, M. Kowalchik, R. A. Logan, and C. L. Luke

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

A thermal gradient technique was used to grow GaP crystals at ~1040°C from gallium solutions doped with zinc, sulfur, selenium, or tellurium. The solid solubilities of the donor impurities appear to vary linearly with the melt concentrations at the lower doping levels and with the square root of the melt concentration at higher doping levels, all in the extrinsic range. This behavior contrasts with that of zinc, for which the solid solubility varies only as the square root of the melt concentration as expected for a singly ionized acceptor dissolving in an extrinsic semiconductor. The excess donor or acceptor concentrations were significantly lower than the impurity concentrations at the higher doping levels.

In an earlier paper (1) we discussed the solid solubility and electrical behavior of tin, an amphoteric group IV impurity, in GaP. In this paper we present the results of similar studies on GaP crystals grown from gallium solutions containing the group VI donors sulfur, selenium, or tellurium or the group II acceptor zinc. Of particular interest here is the variation of doping level and electrical activity as a function of impurity concentration in the liquid at constant temperature. We shall see that, while the behavior of zinc is relatively simple, the donor behavior does not appear to be completely consistent with models previously suggested for the incorporation of group VI impurities in III-V compounds.

Experimental

The crystals were grown from gallium solutions contained in sealed, evacuated vitreous silica tubes by using a thermal gradient method described previously (1, 2). Seventeen crystals were grown at 1040° ± 20°C in a single run lasting five weeks. The thermal gradient in the furnace was ~15 to 20 deg/cm. Large grained polycrystalline ingots weighing about 2g were obtained.

Values of $|N_D - N_A|$, the excess donor or acceptor concentration, were obtained from surface barrier capacitance measurements as described previously (1, 3). As will be evident from the results, the agreement between duplicate capacitance measurements on different parts of the crystals varied considerably from crystal to crystal, presumably due to variations in the quality of the crystal (freedom from micro-occlusions, grain boundaries, etc.). In seeking evidence of precipitation of the dissolved impurities some samples were heated to ~1000°C for periods of 1-8 min and then quenched either in a jet of nitrogen or in a silicone oil. After etching to avoid any surface effects the samples were remeasured.

The impurity concentrations were determined by using spectrophotometric techniques. Prior to analysis the samples were crushed and digested for a day or more in hot concentrated hydrochloric acid to insure removal of any occluded gallium or other phases containing the impurity in question. The tellurium- and selenium-doped samples were also digested briefly (~5 to 15 min) in aqua regia. Rods were cut from ten samples (doped with zinc, selenium, or tellurium) for mass spectroscopic analysis. The principal contaminant was found to be silicon, generally at levels of about 1×10^{17} atoms/cc or lower.

Results and Discussion

The results of the chemical analyses and of the capacitance measurements on the quenched and as-grown crystals are summarized in Table I.

* One crystal, as indicated in the table, was grown at 1050°C; the temperatures are uncertain to ~±20°C, largely because of the high thermal gradient which was measured outside the sample tubes. The individual results of the chemical analyses, performed on different portions of the crushed sample, and capacitance measurements are tabulated in order to give a measure of the reliability of the data especially with regard to the elimination of occluded impurity. Values of $|N_D-N_A|$ in brackets are not to be trusted as much as the other values and may be in error by a factor of two or more; this is due to the fact that certain junctions were very lossy at high doping levels and the necessary size of the evaporated gold dots, on which the capacitance is measured, was prohibitively small.

Zinc.—The solid solubility data for zinc at 1040°C are plotted in Fig. 1 along with some data at 800°C obtained by Chang and Pearson (4) from radiotracer diffusion measurements. Also included is the solid solubility at 1040°C corresponding to the pseudobinary solidus point interpolated from Chang and Pearson's data. It is seen that, at the lower melt concentrations (≲ 10 atom % zinc), both sets of data are fit very well by a straight line with a slope of ½.

The usual model for describing the incorporation of a singly ionized acceptor, A, in a III-V compound, *e.g.*, GaP, involves the following equations and equilibrium constants:

$$A(l) + V_{Ga} = A_{Ga}^- + e^+;\ K_1 = (A_{Ga}^-)p/(A_L)(V_{Ga}) \quad [1]$$

$$Ga(l) + V_{Ga} = Ga_{Ga};\ K_2 = (Ga_L)(V_{Ga}) \quad [2]$$

$$0 = e^+ + e^-;\ K_i = n_i^2 = np \quad [3]$$

$$(A_{Ga}^-) + n = p \quad [4]$$

where the quantities in parentheses represent concentrations of the respective entities, n and p are the

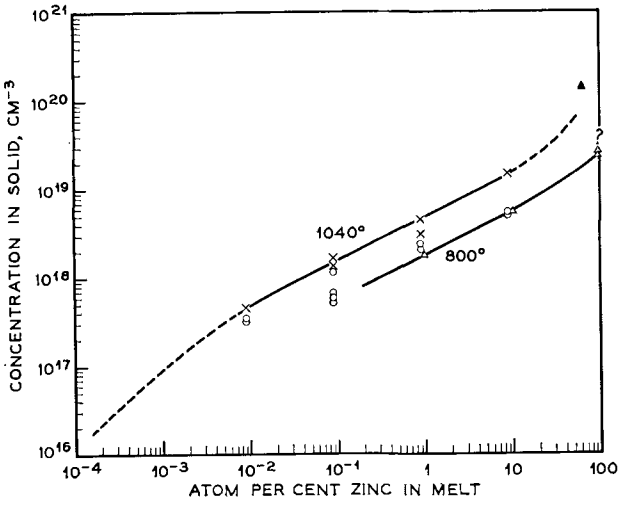

Fig. 1. Zinc and excess acceptor concentrations in GaP crystals as a function of the concentration of zinc in gallium solution at 1040°C. Also included are some data of Chang and Pearson (4) from diffusion experiments at 800°C and a point on the solidus curve at 1040°C from their work. The dashed curves are extrapolations of the data as discussed in the text. The question mark indicates that the liquidus curve for the pseudobinary Zn-GaP system is unknown at 800°C. X, Zinc concentration at 1040°C, ○, N_A-N_D at 1040°C; △, zinc concentration at 800°C (Chang and Pearson); ▲, zinc concentration at 1040°C (Chang and Pearson).

free electron and hole concentrations, and n_i is the intrinsic carrier concentration. Ideal dilute solution behavior is assumed. In an intrinsic semiconductor, where $(A_{Ga}^-) << n_i$, it follows from Eq. [1] that

$$(A_{Ga}^-) = \left\{ \frac{K_1(V_{Ga})}{n_i} \right\} (A_L) \equiv K_5(A_L) \text{ (intrinsic)} \quad [5]$$

In the extrinsic case where $(A_{Ga}^-) = p >> n_i$ one obtains

$$(A_{Ga}^-) = [K_1(V_{Ga})]^{1/2} (A_L)^{1/2} \equiv K_6(A_L)^{1/2} \text{ (extrinsic)} \quad [6]$$

where it has been assumed that (V_{Ga}) is constant, *i.e.*, the solutions are dilute enough so that (Ga_L) is constant (see Eq. [2]). If it is assumed further that the acceptor is completely ionized, then $(A_{Ga}^-) = (A_S)$, the total concentration of acceptor in the solid. The fact that, at 1040°C, (Zn_S) is proportional to $(Zn_L)^{1/2}$ down to a level of $\sim 5\times10^{17}$ cm^{-3} indicates that $n_i < 5\times10^{17}$ cm^{-3} which is consistent with the expected value of $\sim 2\times10^{17}$ cm^{-3}.[1] Extrapolation of the zinc solubility to lower doping levels assuming $n_i = 2\times10^{17}$ cm^{-3} is shown in Fig. 1 by the lower dashed curve.

An estimate of the solubility of zinc at higher concentrations, where (Ga_L) and (V_{Ga}) are changing significantly, may be obtained from the more exact form of the equilibrium constant in Eq. [1]

$$(A_S) = K_7 \left\{ \frac{\gamma_A{}^L(A_L)}{\gamma_{Ga}{}^L(Ga_L)} \right\}^{1/2} \quad [7]$$

where $\gamma_A{}^L$ and $\gamma_{Ga}{}^L$ are the activity coefficients in the liquid phase. By using available thermodynamic data for $\gamma_{Zn}{}^L$ and $\gamma_{Ga}{}^L$ for the binary Ga-Zn system (5) extrapolated to 1040°C a first approximation can be made as shown by the upper dashed curve in Fig. 1. In this approximation it is assumed that the values of $\gamma_{Ga}{}^L$ and $\gamma_{Zn}{}^L$ are the same in the ternary system as in the binary system, *i.e.*, they are unaffected by the presence of phosphorus. Preliminary work by Panish (6) indicates approximately 60 a/o (atom per cent) zinc for the pseudobinary liquidus point at 1040°C. This value leads to a predicted solid solubility of $7\text{-}8\times10^{19}$ atoms/cc compared with the solidus point of $1\text{-}1.5\times10^{20}$ atoms/cc obtained by Chang and Pearson (4) and by Allison (7).

It should be noted that no account has been taken of the presence of neutral zinc atoms, especially at the higher doping levels, as discussed by a number of authors (8-10). This might increase the predicted solubility by a factor of two or more; however uncertainties in the effective masses, degeneracy factors, and other parameters make this calculation sufficiently uncertain so that it is not deemed worthwhile in this paper.

Turning to the capacitance measurements, the data in Table I show that for the most lightly doped sample, containing 4.5×10^{17} atoms/cc of zinc, the value of $(N_A—N_D)$ was precisely the same before and after quenching (3.3×10^{17} cm^{-3}). Aside from experimental error, the difference between (Zn_s) and $(N_A—N_D)$ is consistent with the probable presence of $\sim1\times10^{17}$ atoms/cc of silicon, acting as a donor impurity.

At higher zinc concentrations there is a significant difference between $(N_A—N_D)$ and (Zn_S); for example, at a doping level of 1.5×10^{19} atoms/cc of zinc, $(N_A—N_D)$ is a factor of three lower in the as-grown crystal. The surface barrier junction on the quenched sample was too lossy to measure, indicating a higher $(N_A—N_D)$ value and suggesting the presence of precipitation. Precipitation of zinc in GaP has been observed previously by Gershenzon and Mikulyak (11). Thus, it appears that the zinc in solid solution is electrically active. This is consistent with the behavior of zinc in GaAs as reported by Black (12), who found that for zinc diffused into GaAs the free carrier concentration is equal to (Zn_S) within ±20%.

The variation of (Zn_S) as a function of either the zinc pressure, p_{Zn}, or of the zinc concentration in a liquid phase has been studied previously in a number of III-V compounds, *e.g.*, in GaAs (4,13) GaSb (14), InSb (15), and GaP (4). In three cases (13-15) where a wide doping range was studied, (Zn_S) varied linearly with p_{Zn} or (Zn_L) at low values of (Zn_S) and at higher concentrations was proportional to a lower power of p_{Zn} or (Zn_L). A change from a linear to a square root dependence of (Zn_S) on P_{Zn} or (Zn_L) is the normal behavior expected for a singly ionized acceptor as shown in Eq. [5] and [6]. However, in each of these three cases the change from linear behavior was found to occur at doping levels much greater than the values of n_i extrapolated from low temperature n_i data. McCaldin (13) discusses these results in detail. For example, Hall and Racette (16) quote an extrapolated value at the melting point of GaAs for n_i of 5×10^{18} cm^{-3} which is inconsistent with the value of 4×10^{18} cm^{-3} at 1000°C deduced by McCaldin from the zinc solubility data. There is obviously a need for reliable data on n_i at high temperatures. In the case of GaP the data in Fig. 1 are consistent with the predicted value of n_i, as mentioned earlier.

Selenium, sulfur, and tellurium.—The results of the chemical analyses and the capacitance measurements are plotted in Fig. 2, 3, and 4. The most extensive and precise data were obtained in the case of selenium. The results of the chemical analyses indicate the existence of a linear dependence of (Se_S) on (Se_L) at concentrations below $\sim5\times10^{18}$ atoms/cc and a square root dependence at concentrations above 10^{19} atoms/cc. The square root dependence of the doping level in the crystal on the melt concentration at higher doping levels is also consistent with the chemical data for sulfur and tellurium. Unfortunately, the analytical technique for tellurium was not sufficiently sensitive for the most lightly doped samples and for sulfur the scatter in the data at the lowest doping level was quite large so that the evidence for a linear dependence at lower concentrations is not as clear cut as for selenium. If we accept the square root dependence as the true behavior at high doping levels it is seen that the inflec-

[1] This figure was calculated assuming density of states effective masses of $m_p^* = 1.1\ m_o$ and $m_n^* = 0.9\ m_o$, where m_o is the free electron mass, and an energy gap given by $E_{Gap} = 2.39 - 5.5 \times 10^{-4}T$ ev (M. Gershenzon, private communication).

tion point, presumably to linear behavior, occurs at different doping levels for the three donor impurities with a spread of an order of magnitude between sulfur and tellurium. Also, the inflection points occur at doping levels appreciably above the expected value of 2×10^{17} cm^{-3} for n_i.

The situation is complicated further by the results of the capacitance measurements which, as in the case of zinc, indicate agreement of the donor concentration with (N_D-N_A) values at low concentrations within the precision of the data. However, as seen in Table I, there is little or no evidence from the quenching experiments for precipitation, at least for the selenium, although (N_D-N_A) is as much as a factor of four or five lower than (Se_S) at the high doping levels. In the case of tellurium there is a relatively small difference between (N_D-N_A) and (Te_S) and the quenching experiments indicate that precipitation may be responsible for at least part of the difference. Whether or not the apparent increases in (N_D-N_A) as a result of quenching are real, especially for the most lightly doped sample, could be determined only by more extensive work on better quality crystals. Only two quenching experiments were performed on sulfur-doped samples, including one sample which was not analyzed chemically. The results on the latter sample indicated, as in the case of selenium, that no change occurred in (N_D-N_A) on quenching.

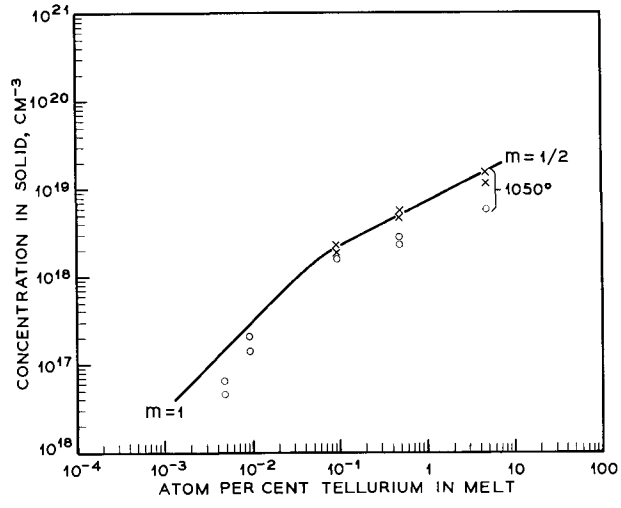

Fig. 4. Tellurium and excess donor concentrations in GaP crystals as a function of the concentration of tellurium in gallium solution at 1040°C. X, Tellurium concentration; ○, N_D-N_A.

Summarizing the situation for the donor impurities, a successful model for the incorporation of a group VI donor, D, in GaP grown from solution apparently must explain the following: (*i*) a linear dependence of (D_S) on (D_L) at low concentrations and a square root dependence at higher concentrations, all at doping levels above the expected value of n_i, (*ii*) inflection points in the (D_S) *vs.* (D_L) plots at different doping levels for the three impurities, (*iii*) relatively high concentrations of electrically inactive or compensated donor impurities at the higher doping levels, and (*iv*) the fact that the (N_D-N_A) values for all three donors appear to depart from the (D_S) values at doping levels of $\sim2\text{-}5\times10^{18}$ cm^{-3}, suggesting the presence of some "intrinsic" interaction common to all three donors.

There has been considerable work on the properties of other III-V compounds doped with group VI donor impurities. For detailed references and discussions of this previous work, see the recent papers of Black and Lublin (17) and Wooley and Blazey (18). Of particular interest here is the work of Vieland and Kudman (19) on the behavior of selenium in GaAs grown near the melting point of GaAs. They observed a linear dependence of (Se_S) on (Se_L) over a doping range well above and below the "accepted" value of n_i of $\sim5\times10^{18}$ cm^{-3}, in contrast to our square root dependence of (Se_S) on (Se_L) at the higher doping levels in GaP.

A number of workers have observed electrically inactive or compensated group VI donors in III-V compounds such as GaAs (17-21). Both Vieland and Kudman and Black and Lublin report a cube root dependence of free carrier concentration on (Se_S) [and in the latter case, (Te_S)] in GaAs at high doping levels. This finding is not inconsistent with our results for GaP as illustrated in Fig. 5. Black and Lublin pointed out that, in view of the work of Fuller and Wolfstirn (22) on reversible control of free carrier concentration in Se- and Te-doped GaAs by suitable heat treatment and quenching, the cube root behavior might be fortuitous and simply a result of similarity in growth conditions. In contrast to the GaAs studies, our crystals were grown over 400° below the melting point of GaP and still appear to show the same cube root behavior. Also, our quenching experiments yield little evidence of precipitation.

In order to account for their results and to explain some anomalous optical absorption data, Vieland and Kudman (19) invoked the formation of a neutral complex involving a gallium vacancy and three selenium atoms. This appears to be a reasonable assumption since the II-VI compounds Ga_2S_3, Ga_2Se_3, and Ga_2Te_3 all have defect zincblende structures with 1/3 of the gallium sites vacant. A number of III-V and II-VI

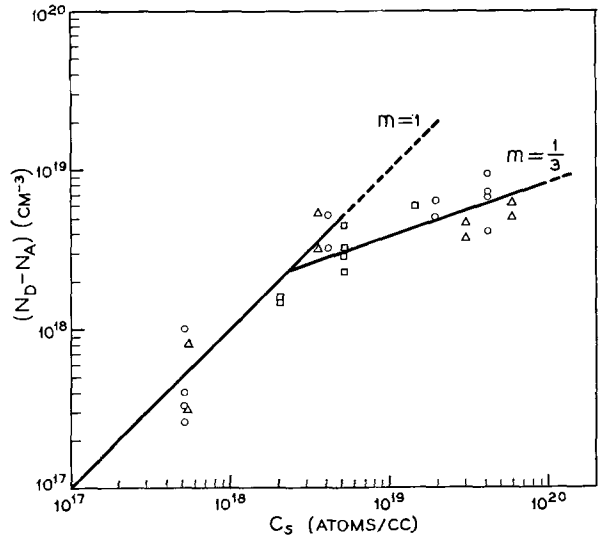

Fig. 5. Plot of excess donor concentration as a function of doping level in the solid for sulfur, selenium, and tellurium in GaP. Here the individual capacitance measurements are plotted while the photometric analyses were averaged to give a single point. As seen in Table I, only in the case of the most lightly sulfur-doped sample do the duplicate photometric analyses differ appreciably. The capacitance data for as-grown and quenched samples are included in this plot. ○, Selenium; □, tellurium; △, sulfur.

compounds form a continuous series of solid solutions (23) and the incorporation of one vacancy for every three selenium atoms, for example, into the III-V compounds is certainly to be expected as the concentration of selenium increases.

A second model is the one proposed by Gasson *et al.* (24), to explain their results on $(InAs)_{3(1-x)} - (In_2Te_3)_x$ solid solutions and related systems. They considered the gallium vacancy to be a compensating triply charged acceptor and only for very heavily doped material did they consider the formation of complexes involving a gallium vacancy and one, two, or three tellurium atoms. Vieland and Kudman, however, point out that for their selenium doped GaAs crystals the electron mobilities are higher than for silicon-doped (compensated) crystals with comparable carrier concentrations. This argues against compensation of the group VI impurity by a triply charged vacancy. Other variations of these models are discussed by Kröger (25).

A third suggestion concerning the presence of inactive donors in certain III-V compounds is that of Woolley and co-workers. For example, in the case of InSb it was postulated (26) that as more and more tellurium or selenium is added the electrons start filling up broader conduction band minima and are not detected by Hall effect measurements, even though the tellurium and selenium still behave as donors. In the case of GaP, however, the data are based on capacitance measurements which presumably would not be affected by such band structure considerations.

The various equilibria can be written for the models involving charged vacancies, complexes, etc. (19, 24, 25). However, none of the models is completely consistent with our GaP data. For example, the triply charged vacancy model does predict a cube root dependence of n on the doping level of the group VI impurity at high doping levels. However, it is also predicted that in this range, $(D_S) \propto (D_L)^{3/4}$ which is not in agreement with either our square root or Vieland and Kudman's linear dependence of (D_S) on (D_L). The latter authors' vacancy complex model predicts that $n \propto (D_L)^{1/6}$ [not as $(D_L)^{1/3}$ as stated in their paper] which may not be inconsistent with the GaAs or GaP results considering the scatter in the data. However, the dependence of (D_S) on (D_L) in this treatment is not clear since Vieland and Kudman invoke the presence of Se and Ga_2Se_3 species in the liquid phase and one must know the appropriate equilibrium constants in order to carry out the calculation. At any rate, the behavior of selenium in GaP and GaAs differ markedly insofar as the dependence of (D_S) on (D_L) is concerned and it seems unlikely that a simple model could explain both cases.

In conclusion, there is one point that should be stressed. This is that most of the various proposed models involve the assumption of equilibrium conditions; if the crystal growth conditions depart significantly from equilibrium, agreement with theory would not be expected. The diffusion coefficient of zinc in GaP is large enough so that equilibrium conditions should be closely approached. Although very slow growth rates prevailed in these experiments, the situation with regard to the slower diffusing donor impurities is not so definite, and facet effects could play a role.

Electrochemical Behavior of Grown Oxide Films on Silicon

Frank C. Collins

Department of Chemistry, Polytechnic Institute of Brooklyn, Brooklyn, New York

ABSTRACT

The large shifts in surface potential which are observed after biasing oxidized silicon surfaces at elevated temperatures may be explained in terms of a simple ionic polarization effect. The electrostatic potential and the ionic concentration profiles and the ionic surface density are calculated in terms of the known bias potential and the measured surface potential of the semiconductor. Exact solutions are found for the limiting case of zero ionic flux, using the Poisson-Boltzmann relation. First order approximate solutions are found for the case of small ionic flux in a final polarized steady state. The several mechanisms which have been proposed to account for the film polarization are examined.

Thermally grown silicon dioxide films have often been used to passivate exposed p-n junctions in diode and transistor structures and as active elements in insulated gate field effect transistors. Polarization of these films and the appearance of built-in fields at the silicon-silicon dioxide interface are accordingly of technical importance.

Some previously reported studies of the electrical properties of these films have employed a metal-oxide-semiconductor (MOS) structure formed by evaporating small contacts of aluminum or other metal on the surface of the oxide. Capacitance measurements of these structures after various treatments have been particularly useful. The MOS capacitance as a function of applied voltage is well understood (1-3). The reciprocal of the total measured capacitance is the sum of the reciprocals of the constant capacitance of the oxide dielectric film and the potential-dependent semiconductor surface capacitance. The capacitance C_s per unit area of an n-type semiconductor is given by (2) $C_s = q\ (\epsilon n/kT)^{1/2}$ when the surface and bulk electrostatic potentials of the semiconductor are equal, corresponding to the flat band condition. (The symbols in the equation have conventional significance. The equation may be appropriately modified for a p-type semiconductor.) In the MOS structure, the flat band condition is established in the semiconductor if the work function difference between the metal and the semiconductor is equal and opposite to the applied potential difference, providing that no surface states exist and no built-in potential difference exists in the oxide film. If either exist, the applied potential must be correspondingly altered in order to establish the flat band condition. If surface states are absent, the required change in the applied potential will be equal and opposite to the built-in potential of the oxide film, plus the work function difference.

It has long been known that silicon dioxide films are electrically unstable under bias at elevated temperatures. In order to study this instability, there have been several investigations which have involved the application of a bias under elevated temperatures, in the neighborhood of 200°C, for times up to 1 hr followed by the measurement at room temperature of the voltage dependence of the MOS capacitance (4-6).

The initial built-in potential before the temperature-bias treatment may be of the order of −5 to −40v in terms of the sign and magnitude of the potential which must be applied to the metal contact in order to restore the flat band condition in the semiconductor surface (4). A bias of the order of ±20v is applied to the metal contact in the temperature-bias treatment. Only a small change of the built-in potential of the film is observed if a negative bias is applied in the temperature-bias treatment. Under the positive bias-temperature treatment, the built-in potential of the film becomes more strongly negative. Built-in potential shifts of −80v and more have been observed after temperature bias treatments in the cases where the film has been thermally grown in wet oxygen (4). Much smaller initial built-in potential shifts occur in the case of film grown in dry oxygen (5).

Studies of the conduction of the film under temperature-bias treatment show that the integral of current flowing with the metal contact positive is of the right order of magnitude to account for the observed degree of film polarization (4, 6. 7). It is considerably larger than the integral of the current flowing with the metal contact negative, particularly in the case of wet-grown films (8). The current decays in the time of about an hour to a final saturation value corresponding to a small residual steady current. Only a very small part of the decaying portion of the current time curve is accounted for by the displacement current, the time dependence of which is determined by the RC constant for the circuit. The remainder of the time-dependent current brings about the observed polarization of the film. This part of the current may be recovered as a reverse current on removing the applied bias (8). The charge reversibly transferred in the temperature-bias treatment appears to result from the field migration of ionic constituents of the film under the applied bias.

Thomas and Young (9) have related the experimental shift in the surface potential of the semiconductor to an arbitrarily chosen distribution of positive charge in the oxide film. In this paper, the calculations are extended to an ionic distribution which obeys the Poisson-Boltzmann relation. An exact solution is obtained for a limiting case of zero ionic flux after polarization of the film and a first order solution for the case that the residual ionic fluxes are nonzero but small. The solutions enable the ionic concentration and the ionic surface density in the film to be calculated directly in limiting cases.

There are two possible extreme situations which cannot be distinguished on the basis of presently available experimental information: (i) the charge consists of cation only, and (ii) the charge consists of equal numbers of anions and cations summing to a net charge of zero within the film. The potential and ionic concentration distributions and the ionic surface density are obtained in closed form for the first case, which is also that treated by Thomas and Young (9). An approximate solution is developed for the second case on the basis of symmetry arguments.

Where a final residual ionic flux exists in the film, the Poisson-Boltzmann equation cannot be used. A perturbation treatment of the problem is presented using the Poisson equation and Fick's law. The first order term is integrable, and expressions in closed form are obtained for the potential profile and the surface ionic density. The magnitude of the perturbation term in the surface ionic density is such that it probably may be neglected over the range of observed final currents. Neither the identity of the diffusing ions

nor the mechanism of the transport of the final residual current across the film are yet established.

The plausibility of the various proposals which have been advanced for the electrochemical mechanisms of these processes are reviewed and related to the quantitative calculations presented in the first section of this paper.

Calculation of the Polarization of the Film

The number fluxes of the several species which may be present are given by

$$J_i = -D_i \frac{dc_i}{dx} \mp \frac{D_i \alpha_i q}{kt} c_i \frac{dV}{dx} \qquad i = 1,2,... \quad [1]$$

where J_i is the flux rate for the ith species, D_i, c_i, and $\alpha_i q$, respectively, its diffusion constant, concentration and electric charge, and V is the electrostatic potential. Where the species is nonionic, $\alpha_i = 0$, and only the free diffusion term remains. The remaining symbols have conventional significance. The negative sign applies to cations and the positive to anions. In the final steady state of current flow, the fluxes J_i must all be constant. They will be zero only in the case that the mechanism of the final residual charge transport through the film is purely electronic. We shall treat both cases, beginning with the simpler case of zero flux.

Where all $J_i = 0$, Eq. [1] may be immediately integrated and, with the boundary conditions $V(O) = 0$, and $c_i(0) = c_{io}$, (the origin being taken at the silicon-silicon dioxide interface) assume the form

$$c_i(x) = c_{io} \exp [\mp \alpha_i q V/kT] \qquad i = 1,2,... \quad [2]$$

where the ambiguity in sign has the same meaning as before.

If the concentrations of electrons and holes are small compared to those of the major ionic species, Poisson's law takes the form

$$\frac{d^2V}{dx^2} = -\frac{\rho}{\epsilon} = -\sum_i \frac{\alpha_i q}{\epsilon} c_{io} [\exp \mp \alpha_i q V(x)/kT] \quad [3]$$

where the sum is over all ionic species present in the film. Multiplying the last equation by $2(dv/dx)$ transforms it into a readily integrable form. By use of the previous boundary conditions and the additional one, $(dV/dx)_{x=o} = \mathcal{E}_o$, we obtain

$$\left(\frac{dV}{dx}\right)^2 = \mathcal{E}_o^2 \mp \sum_i \frac{2c_{io}kT}{\epsilon} (1 - e^{\mp \alpha_i qV/kT}) \quad [4]$$

For further integration, Eq. [4] is rearranged as follows

$$dx = \left[\mathcal{E}_o^2 \mp \sum_i \frac{2kT}{\epsilon} c_{io} (1 - e^{\mp \alpha_i qV/kT}) \right]^{-1/2} dV \quad [5]$$

Equation [5] is well-known and arises in a number of situations involving electrolytes. MacDonald (10) has made a critical review of the literature of solutions of it under various conditions. The case of a single ionic species is of particular interest here and does not appear to have been previously handled. Where only one species of ion is present, the integration may be carried out in closed form. Following Thomas and Young (9), we shall suppose that the species is cationic. Equation [5] may then be put into the form

$$dx = (a + b\, e^{-mV})^{-1/2}\, dV \quad [6]$$

where

$$a = \mathcal{E}_o^2 - \frac{2kT}{\epsilon} c_o$$

$$b = \frac{2kT}{\epsilon} c_o$$

$$m = \frac{\alpha q}{kT}$$

The integral of Eq. [6] with the boundary conditions $V = 0$ at $x = 0$ is (11)

$$x = \frac{V}{a^{1/2}} + \frac{2}{ma^{1/2}} \ln \frac{a^{1/2} + (a + b\, e^{-mV})^{1/2}}{a^{1/2} + \mathcal{E}_o} \quad [7]$$

The integral may assume a different form if $2kTc_o/\epsilon > \mathcal{E}_o^2$, but this condition does not arise in this problem. The known quantities are the potential difference $V(X)$ across the film under which the film was polarized and the field $\mathcal{E}_o$ in the oxide at the semiconductor boundary. Here X is the outer surface of the oxide film. The potential difference $V(X)$ differs from the bias between metal and semiconductor by the amount of the band bending in the semiconductor which is small at the temperatures under which the temperature-bias treatments are conducted. The field $\mathcal{E}_o$ is determined from the bias dependence of the metal-oxide-semiconductor capacitance at room temperature (see Appendix A). This involves the assumption that the ionic distribution is frozen when it is quenched from the temperature at which the polarization was effected.

Except in the immediate vicinity of the silicon interface, $x = 0$, $mV >> 1$, Eq. [7] takes the limiting form

$$\lim_{mV >> 1} x = \frac{V}{a^{1/2}} + \frac{2}{ma^{1/2}} \ln \frac{2a^{1/2}}{a^{1/2} + \mathcal{E}_o} \quad [7a]$$

Thus in most of the thickness of the film

$$dV/dx = a^{1/2}$$

so that the electrostatic field is constant in this region and is, in fact, very little less than ideal dielectric field $V(X)/X$ where X is the value of x at the outer surface of the film. This enables a simple evaluation of the constant $a^{1/2}$ from Eq. [7a], after substitution of the boundary condition $V(X) = V_X$, by the method of successive approximations. The first approximation is

$$a^{1/2} = \frac{V_X}{X} + \frac{2}{mX} \ln \frac{2V_X/X}{X_X/X + \mathcal{E}_o} \quad [7b]$$

The error involved in taking the first approximation only is smaller than the usual errors of the measurements.

Having an approximate value of $a^{1/2}$, the boundary value of the concentration c_o may be evaluated in terms of the known quantities by making use of the definition of a. Table I gives values of the limiting field $a^{1/2}$ and the boundary concentration c_o for se-

lected values of the experimental variables over a range of these parameters.

Equations [7] and [2] enable the calculation of the electrostatic potential and concentration profiles in the film. Figure 1 illustrates the results for a typical set of experimental parameters. The forms of the curves do not differ appreciably for other choices of the values of the experimental parameters. Some observations are noteworthy: The ionic concentration is negligible except within a very short distance of the silicon interface. This is in agreement with the finding of Kuper and Nicollian (5) that film polarization persisted when etched away to a few hundred Angstroms of the silicon interface. As the electrostatic field $a^{1/2}$ differs but little from the ideal dielectric field V_X/X in most of the thickness of the oxide film, the polarization of the film does not affect the field migration of the ions. This in contrast to the model of Thomas and Young (9).

The foregoing analysis permits the total ionic surface density to be readily calculated. This is given by

$$\sigma = \int_o^X c(x)\,dx$$

$$= \int_o^X c(V)\,\frac{dx}{dV}\,dV \qquad [8]$$

Insertion of Eq. [2] and [6] into [8] followed by integration yields

$$\sigma = \frac{\epsilon}{q}\left[\mathcal{E}_o - (a + b\,e^{-mV_X})^{1/2}\right] \qquad [9]$$

which simplifies to

$$\sigma = \frac{\epsilon}{p}\,(\mathcal{E}_o - a^{1/2}) \qquad [9a]$$

for the case that $mV_X >> 1$.

Values of the surface densities σ corresponding to various values of the experimental variables are also given in Table I. The calculated surface densities correspond roughly to an ion fraction of 0.001 in the interfacial layer of atoms.

Several significant conclusions may be drawn from the calculated quantities tabulated in Table I. The potential shifts V_R and the boundary field $\mathcal{E}_o$ are very roughly proportional to the ionic densities c_o and σ. The temperature dependence of the relation between the ionic concentrations c_o and σ and the boundary field $\mathcal{E}_o$ is quite small, c_o decreasing only a few per cent for a given $\mathcal{E}_o$ in the interval 200°-225°C. A given ionic content σ produces a larger potential shift V_R in the thicker films.

Another case of interest is that where no net charge excess exists in the film so that the charge distribution is that of a pure dipole. An exact solution for this problem has been obtained by Jaffé (12) in terms of elliptic functions and by an approximate solution by MacDonald (13). Another excellent approximation may be obtained for the special case of a symmetrical electrolyte if $qV(X) >> 2kT$. Equation [5] takes the form

$$dx = \left[\mathcal{E}_o^2 + \frac{2kT}{\epsilon}\,c_{+o}\,(1 - e^{-\alpha qV/kT}) - \frac{2kT}{\epsilon}\,c_{-o}\,(1 - e^{\alpha qV/kT})\right]^{-1/2} dV$$

As the problem is completely symmetrical relative to the axis at $X/2$, the following relations hold

$$V(X/2) = V(X)/2$$

$$c_+(X/2) = c_-(X/2)$$

and

$$c_{-o} = c_{+o}\,e^{-\alpha qV(X)/kT}$$

Further, if $\alpha qV(X/2) >> kT$, $c_+(x)$ is completely negligible for all values of $x > X/2$ and $c_-(x)$ is similarly negligible for $x < X/2$. The problem is then reduced to the calculation of the distribution of a single ionic component in the region 0 to $X/2$. This problem has already been solved for the interval 0 to X. It will be seen that solution for the pure dipole case amounts only to the introduction of the scale factor 1/2 into the variables V and x. It is to be particularly noted that it leaves the field $\mathcal{E}_o$ at the boundary unchanged. Thus the existence of a given value of the field $\mathcal{E}_o$ under the applied bias $V(X)$ across the film at the semiconductor boundary is consistent with either the excess charge or pure dipole case. The presence or absence of anions in the outer region of the oxide film can only be determined by outer surface potential measurements.

It is probable that the residual current flowing in the film in the final steady state is due to ionic transport, rather than purely electronic processes, and thus involves redox reactions occurring at the semiconductor interface and at the metal electrode at the outer surface of the film. The foregoing treatment is invalid in this case.

No exact method exists for the calculation of the potential and ionic concentration profiles for the single ion case under the condition of nonzero flux rate. Fromhold (14) has developed numerical solutions to the problem, but it is not easy to extract from his data values for the potential and ionic concentration profiles corresponding to arbitrary values of the bias potential $V(X)$ and the boundary field $\mathcal{E}_o$ appropriate to the present situation. In the following a method of successive approximations will be developed for the case that the flux J is small compared to the other terms in Eq. [1]. While this is not generally valid for all values of $x < X$, it will be true in the important regions near the boundaries of the film which are the only ones contributing significantly to the various integrals arising in the treatment. We shall here confine attention to the simpler case in which only cations are present in the film.

Equation [1] for the steady-state case takes the form

$$J = -D\,\frac{dc}{dx} - \frac{D\alpha q}{kT}\,c\,\frac{dV}{dx} \qquad [10]$$

which may be rearranged as follows

$$d \ln c = -mdV - \frac{J}{Dc}\frac{dx}{dV}dV \qquad [11]$$

where m has the previous significance of $m = \alpha q/kT$.

While Eq. [11] is not readily integrable, a first order approximation in a method of successive approximations may be integrated in closed form. We assume that in the limit of small J, the last term of the right hand side of Eq. [11] is small compared to the first and make use of the $J = 0$ solutions for c and dx/dV as zeroth order approximations in this term. The integral of Eq. [11] is

$$c = c_o e^{-mV - JK/Dc_o} \qquad [12]$$

where

$$K = \int_o^V \frac{e^{mV}dV}{(a + b\,e^{-mV})^{1/2}} = \int_o^V \frac{dK}{dV}dV$$

$$= \frac{1}{ma}[e^{mV/2}(a\,e^{mV} + b)^{1/2} - (a+b)^{1/2}]$$

$$-\frac{b}{ma^{3/2}}\ln\frac{a^{1/2}e^{mV/2} + (a\,e^{mV}+b)^{1/2}}{a^{1/2} + (a+b)^{1/2}} \qquad [13]$$

and where a and b have the same meaning as before and the derivative of K has been formally introduced for future reference. The procedure used in the integration is given in the Appendix (B). For the purposes of later manipulation, it is desirable to rearrange Eq. [13] as follows

$$K = \frac{1}{ma}[e^{mV}(a + b\,e^{-mV})^{1/2} - (a+b)^{1/2}] - \frac{b}{2a}X^o(V) \qquad [14]$$

It will be observed that substitution of reasonable experimental values into Eq. [14] will lead to the condition $JK/D\ c_o > mV$ in Eq. [12] for larger values of mV. However, this situation is not serious if the range of admissibility of the treatment is explicitly taken to apply only in the region of small values of x. It is only in this region that $c(x)$ is appreciably larger than zero.

In order to make further progress it is necessary to make use again of the assumption that the last term on the right-hand side of Eq. [11] is small compared to the first. We expand Eq. [12] as follows with neglect of terms beyond first order

$$c = c_o e^{-mV}(1 - JK/Dc_o) \qquad [15]$$

The last equation may now be inserted into Poisson's equation, Eq. [3]

$$\frac{d^2V}{dx^2} = -\frac{\alpha q c_o}{\epsilon}e^{-mV}(1 - JK/Dc_o) \qquad [16]$$

The last equation may be integrated by the same methods earlier used in the $J = 0$ case and we obtain

$$\frac{dx}{dV} = (a + b\,e^{-mV} + Q)^{-1/2} \qquad [17]$$

where

$$Q = \frac{aqJ}{D\epsilon}\int_o^V e^{-mV}K(V)\,dV \qquad [18]$$

In the limiting case of small J, $a + b\exp(-mV)$ is much larger than Q in the region of V where the values of the integrand of Eq. [17] contributes significantly in the integration of x. Thus Eq. [17] may be expanded by use of the binomial theorem and we obtain

$$x = \int_o^V (a+b\,e^{-mV})^{-1/2}\left[1 - \frac{1/2\,Q(V)}{a+b\,e^{-mV}}\right]dV$$

$$= x^o - \frac{1}{2}\int_o^V \frac{Q(V)\,dV}{(a+b\,e^{-mV})^{3/2}} \qquad [19]$$

where $x^o = x^o(V)$ denotes the solution of x for the $J = 0$ case.

The integrations indicated in Eq. [18] and [19] are not difficult. Integrating Eq. [18] by parts and making use of the definition of $K(V)$ in Eq. [13] yields

$$Q = \frac{\alpha q}{\epsilon}\frac{J}{D}\left\{-\frac{1}{m}e^{-mV}K\,\Big|_o^V + \frac{1}{m}\int_o^V e^{-mV}\frac{dK}{dV}dV\right\}$$

$$= \frac{\alpha q}{\epsilon}\frac{J}{D}\left\{-\frac{1}{m}e^{-mV}K(V) + \frac{1}{m}\int_o^V \frac{dV}{(a+b\,e^{-mV})^{1/2}}\right\}$$

$$Q = \frac{\alpha q J}{Dm\epsilon}[x^o(V) - e^{-mV}K(V)] \qquad [20]$$

The final integration is then

$$x = x^o(V) + \frac{\alpha q J}{Dm\epsilon}\left\{\int_o^V \frac{x^o(V)\,dv}{(a+b\,e^{-mV})^{3/2}} - \int_o^V \frac{e^{-mV}K(V)\,dV}{(a+b\,e^{-mV})^{3/2}}\right\} \qquad [21]$$

The details of the integration of Eq. [21] are somewhat lengthy and are given in the Appendix (C). The final results are

$$x = x^o(V) + \frac{\alpha q J}{\epsilon D m}\left\{\frac{x^{o2}(V)}{2a} - \frac{x^o(V)}{2m\,a^2}\left[\frac{3}{(a+b\,e^{-mV})^{1/2}} - \frac{1}{(a+b)^{1/2}}\right] - \frac{V}{2\,ma^2} + \frac{1}{2\,m^2a^2}\ln\frac{a+b\,e^{-mV}}{a+b} + \frac{2}{m^2\,a\,b}\left[\frac{(a+b)^{1/2}}{(a+b\,e^{-mV})^{1/2}} - 1\right]\right\} \qquad [22]$$

Equation [22] is approximately valid only for small values of x and V. Accordingly, it may not be used in conjunction with the boundary condition $V(X) = V_X$ in order to determine the value of a as was done with Eq. [7a]. However, in the former case, it was found that $a^{1/2}$ differed but very little from the ideal dielectric field V_X/X. The value of a calculated from Eq. [7a] could be used in Eq. [22] to obtain an approximate potential profile. This has not been pursued because it appears from the following calculation of the ionic surface density that the perturbation term may be small over the range of experimental variables actually encountered.

The calculation of the ionic surface density is initiated by combining Eq. [8], [15], and [17] which yields

$$\sigma = \int_o^V \frac{c_o e^{-mV}(1 - JK/Dc_o)}{(a+b\,e^{-mV} + Q)^{1/2}}dV \qquad [23]$$

On expanding the denominator by use of the binomial theorem, the following is obtained after neglect of higher order terms in QJK

$$\sigma = \int_o^V c_o e^{-mV}(a+b\,e^{-mV})^{-1/2}\left[1 - \frac{Q}{2(a+b\,e^{-mV})} - \frac{JK}{Dc_o}\right]dV \qquad [24]$$

The upper limit of the integral will be set after examination of convergence.

The first term in Eq. [24] is the same as that appearing in Eq. [8] and is immediately integrable. The remaining two terms are integrated after some analysis. However, the integrals and techniques involved

are quite analogous to those employed in the integration of Eq. [21] and will not be reproduced here. The final results are

$$\sigma = \sigma^0 - \frac{4\,c_0 \alpha q J}{bm\epsilon d}\left\{ \frac{2(a+b)^{1/2}}{m^2 ab}\left[(a+b\,e^{-mV})^{1/2} - (a+b)^{1/2}\right] + \frac{x^0}{ma}\left[(a+b\,e^{-mV})^{1/2} - (a+b)^{1/2}\right] \right\}$$

$$- \frac{2\,c_0 \alpha q J}{bm\epsilon D(a+b\,e^{-mV})^{1/2}} \frac{2}{m^2 a}\left\{ \left[(a+b)^{1/2} - (a+b\,e^{-mV})^{1/2}\right] + \frac{b\,e^{-mV}}{2\,ma} x^0 + \frac{1}{m} x^0 \right\}$$

$$- \frac{J}{D}\left\{ \frac{2(a+b)^{1/2}}{m^2 ab}\left[(a+b\,e^{-mV})^{1/2} - (a+b)^{1/2}\right] + \frac{x^0}{ma}\left[(a+b\,e^{-mV})^{1/2} - (a+b)^{1/2}\right] \right\} \qquad [25]$$

where σ^0 is the solution for the zero flux case, Eq. [9], and x^0 has analogous significance. It will be seen that Eq. [25] is convergent for large values of mV and in fact reduces to the comparatively simple form for $x = X$

$$\sigma = \sigma^0 - \frac{2c_0 \alpha q J}{bm\epsilon D}\left[\left(\frac{2}{m^2 a^{3/2}} - \frac{4\mathcal{E}_0}{m^2 ab} - \frac{2x^0}{ma}(\mathcal{E}_0 - a^{1/2}) + \frac{x^0}{ma^{1/2}}\right] + \frac{J}{D}\left[\left(\frac{2\mathcal{E}_0}{m^2 ab} + \frac{x^0}{ma}\right)(\mathcal{E}_0 - a^{1/2})\right] \qquad [25a]$$

where note has been taken that $a + b = \mathcal{E}_0^2$.

The approximate magnitudes of all quantities appearing in Eq. [25a] are known, thus enabling the order of magnitude of the difference $\sigma - \sigma_0$ to be calculated. The final residual current density αqJ for oxide film of 7000Å thickness grown in a wet oxygen process is of the order of 3×10^{-11} amp/cm^2 at 200°C under a potential bias of 20v (8, 15). The diffusion constant D and its temperature coefficient for the migrating ionic species in the film have been calculated from measurements of polarization rate and high-frequency conductivity at 300°C (16). The value of D extrapolated to 200°C is 1.8×10^{-10} cm^2/sec. The remaining quantities required for the numerical calculation may be obtained from Table I. The relative magnitude of the first order term compared to that of zeroth order thus calculated is $(\sigma - \sigma_0)/\sigma_0 = 0.01$. This indicates that the deviation from the Poisson-Boltzmann distribution is quite small and may be neglected entirely over the range of experimental variables examined in this work.

Qualitative Considerations

There appears to be little question that the polarization under bias occurs because of diffusion of ions in the film. Among the questions remaining to be resolved are those of the species of ions involved in the diffusion and the nature of the charge transport process in the final steady-state flow of current after the polarization has been effected. These questions may be related if the final irreversible current arises from ionic motion rather than by purely electronic processes.

The impurities involved in the film polarization are probably cationic. This is supported by the observed fact that very little current flows and very little film polarization occurs when a negative bias is applied to the film in the given temperature range (8). With negative bias, the impurity cations are swept away from the semiconductor interface, but some minor polarization must however remain. The silicon is now anodic with respect to the oxide layer and any oxidation would be attended by the formation of oxide ion vacancies at the interface which would migrate away more slowly than they are formed. The field at the semiconductor boundary would then remain positive as actually observed instead of becoming negative.

The identity of the cationic species remains in question. It has been suggested by Thomas and Young (9), and by Seraphim, Brenneman, d'Heurle, and Friedman (17) that the cation responsible for the polarization may be an oxide ion vacancy in the oxide film. This explanation no longer seems plausible in view of the recent measurements of the diffusion constant and diffusion activation energy for the ionic species responsible for polarization of the film (16). These are $D = 1.8 \times 10^{-10}$ cm^2/sec and $E = 0.62$ ev at 200°C, which indicate a more easily diffusing species than an oxide ion vacancy.

In conductivity studies on bulk quartz (18), current transport has been ascribed to ionic carriers, including sodium, the magnitude of the conductivity agreeing roughly with the measured impurity content. In the present system, however, current transport by protons may be significant in view of the strong dependence of the magnitude of the degree of polarization of the film on the presence or absence of water vapor during growth (5).

In the ionic migration bringing about the polarization of the film, it is necessary that the cathodic reaction involving these ions be at least partially blocked. Otherwise, the cations diffusing up to the silicon interface would be discharged and polarization at this surface would not occur. Electrode processes involving the ions in question are probably fairly reversible under the conditions of the experiment. However, high concentrations of the reduced species could be built up at the silicon interface as a result of the electrolytic reduction. The resulting unchanged species would diffuse away only by field-free diffusion instead of by field drift, which brought the cations up to the surface. The resulting unfavorable ratio of the activities of reduced species to the cations at the interface would thermodynamically lower the electrode potential sufficiently so that the interface would become a partially blocking electrode with resulting polarization of the film.

The explanation of film polarization on the basis of a blocked electrode effect predicts decreased polarization of the film when it is biased at temperatures which are significantly higher than 200°C. This is because outward diffusion of the reduced species from the semiconductor interface will occur more rapidly as the temperature is raised. The consequent lowering of the thermodynamic potential of the reduced species at the cathode then will unblock this electrode, permitting electron transfer and the depolarization of the oxide film.

Acknowledgment

The author is indebted to Dr. Donald P. Seraphim, Dr. Harold L Friedman, and Dr. Donald R. Young for helpful discussions of the problem and to Messrs. Morton Schrager and Robert Poignant who checked the integrations and numerical calculations.

The research was supported in part under the Office of Naval Research Contract Nonr-839(38).

APPENDIX

A. *Relation of the "flat-band" potential to the boundary field $\mathcal{E}_0$ under temperature bias.*—The boundary field $\mathcal{E}_0(V_X)$ corresponding to the saturation condition under the applied bias $V(X) = V_X$ is readily calculated from the value of the reverse bias V_R necessary to produce the capacitance corresponding to zero field at the surface of the semiconductor. Assuming that the ionic distribution is frozen in on quenching to room temperature and the absence of surface states, the boundary field prevailing when the bias is removed is given by

$$\mathcal{E}_0(0) = \mathcal{E}_0(V_X) - V_X/X$$

To obtain zero field at the boundary $x = 0$, we must apply the reverse potential V_R so that

$$\mathcal{E}_0(0) + V_R/X = 0$$

Then

$$\mathcal{E}_0(V_X) = (V_X - V_R)/X$$

where V_R will be in general negative.

B. *Integration of Eq. [13].*—In order to effect this integration, the equation is first rearranged as

$$K = \int_0^V \frac{e^{3mV/2}\,dV}{a^{1/2}[e^{mV} + (b/a)]^{1/2}} \qquad [A\text{-}1]$$

and the substitution $y = \exp(mV/2)$ is introduced. Equation [A-1] then becomes the standard form (20)

$$K = \int_1^{e^{mV/2}} \frac{2y^2\,dy}{ma^{1/2}[y^2 + (b/a)]^{1/2}}$$

which, after substitution of the limits, becomes the second part of Eq. [13].

C. *Integration of Eq. [21].*—The first of the integrals appearing in Eq. [21] may be integrated by parts after noting that

$$\int \frac{dV}{(a + b\,e^{-mV})^{3/2}} = \int \frac{e^{3/2\,mV}\,dV}{a^{3/2}[e^{mV} + (b/a)]^{3/2}} \qquad [A\text{-}2]$$

which may be converted to a readily integrable form (19) by making the substitution $y = \exp(mV/2)$ and becomes

$$\frac{2}{ma^{3/2}}\left\{-\frac{a^{1/2}}{(a + b\,e^{-mV})^{1/2}} + \frac{mV}{2} + \ln\left[\frac{a^{1/2} + (a + b\,e^{-mV})^{1/2}}{a^{1/2}}\right]\right.$$

The second operation required in the integration by parts is simply

$$\frac{dx^o}{dV}\,dV = \frac{dV}{(a + b\,e^{-mV})^{1/2}}$$

The integral in question after integrating by parts as above indicated becomes

$$\int_0^V \frac{x^o(V)\,dV}{(a + b\,e^{-mV})^{3/2}} = \frac{x^{o^2}(V)}{a} - \frac{2x^o(V)}{ma(a + b\,e^{-mV})^{1/2}} + \frac{2}{ma}\int_0^V \frac{dV}{(a + b\,e^{-mV})} - \frac{1}{a}\int_0^V x^o(V)\,\frac{dx^o}{dV}\,dV \qquad [A\text{-}3]$$

The last two integrals are easily reduced and we obtain

$$\int_0^V \frac{x^o(V)\,dv}{(a + b\,e^{-mV})^{3/2}} = \frac{x^{o^2}(V)}{2a} - \frac{2x^o(V)}{ma(a + b\,e^{-mV})^{1/2}} + \frac{2V}{ma^2} + \frac{2}{m^2a^2}\ln\frac{a + b\,e^{-mV}}{a + b} \qquad [A\text{-}4]$$

After the introduction of Eq. [16], the last integral of Eq. [21] becomes

$$\int_0^V \frac{e^{-mV}K(V)\,dV}{(a + b\,e^{-mV})^{3/2}} = \frac{1}{ma}\int_0^V \frac{dV}{(a + b\,e^{-mV})} - \frac{(a + b)^{1/2}}{ma}\int_0^V \frac{e^{-mV}\,dV}{(a + b\,e^{-mV})^{3/2}} - \frac{b}{4a}\int_0^V \frac{x^o(V)\,e^{-mV}\,dV}{(a + b\,e^{-mV})^{3/2}} \qquad [A\text{-}5]$$

The first two integrals on the right hand side of Eq. [A-5] are well-known forms. The last is integrated by parts making use of the relations

$$\int \frac{e^{-mV}\,dV}{(a + b\,e^{-mV})^{3/2}} = \frac{2}{bm}\,(a + b\,e^{-mV})^{-1/2}$$

$$\frac{dx^o}{dV}\,dV = \frac{dV}{(a + b\,e^{-mV})^{1/2}}$$

On carrying out these operations, Eq. [A-5] takes the form

$$\int_0^V \frac{e^{-mV}K(V)dV}{(a + b\,e^{-mV})^{3/2}} = \frac{1}{ma}\left[\frac{V}{a} + \frac{1}{ma}\ln\frac{a + b\,e^{-mV}}{a + b}\right] - \frac{1}{m^2ab}\left[\frac{(a + b)^{1/2}}{(a + b\,e^{-mV})^{1/2}} - 1\right] - \frac{x^o(V)}{2ma}\left[\frac{1}{(a + b\,e^{-mV})^{1/2}} - \frac{1}{(a + b)^{1/2}}\right] \qquad [A\text{-}6]$$

Equation [22] results from the introduction of Eq. [A-4] and [A-6] into Eq. [21].

Growth and Morphology of Silicon Ribbons

S. N. Dermatis,[1] J. W. Faust, Jr., and H. F. John

Research and Development Center, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

Ribbons of silicon were grown from a supercooled melt and examined by various techniques. From the morphology of the ribbons, dislocation patterns, twin structures, and microsegregation traces, it was shown that the basic growth sequence is similar to that given for germanium. Some differences are found, however, and these are described. Microsegregation traces were used to elucidate the growth sequence of degenerate ribbons.

Germanium and indium antimonide can be pulled under controlled conditions from a supercooled melt in the form of long ribbons (1, 2). The ribbons are very uniform and have flat faces that approximate {111} planes (3). It has been shown that at least two twin planes parallel to and approximately midway between the flat faces are necessary for continuous ribbon growth (4, 5), and that the growth of the ribbons involves two propagation mechanisms, one for lengthwise growth and one for lateral growth (6). The obvious usefulness of material in ribbon form and the greater interest in silicon devices focused attention immediately on ribbon growth of silicon. It is the purpose of this paper to discuss the growth and morphology of silicon ribbons, and to compare the observations with the extensive data available on germanium ribbons.

Examination Techniques

In this investigation the morphology, internal structure, and perfection of the seeds, buttons, and ribbons were studied. Table I gives a summary of the techniques used and the sample preparation for each technique. In some cases other etchants can be used, but those listed here were found to give the best results. The morphology of the buttons and ribbons was examined with a binocular and a standard metallurgical microscope. In the pulling experiments, the seeds were oriented by means of the etch pits produced by the NaOH etch (see Table I). The furnace used is described elsewhere (7). The twin spacing of the seeds and ribbons was measured by fracturing (8) while those in the button were measured by potting the button, cutting a cross section, polishing, and etching. The etchants used are given in Table I. To reveal the growth history by microsegregation striations (6, 9), special ribbons were pulled from highly doped melts. The dopants used were boron and aluminum. To obtain the best results several different concentrations of dopant were investigated over the range from approximately 10^{17} to 10^{20} carriers per cc. Microsegregation striations were revealed by examination of etched main faces, potted and etched cross sections, and also some fractured cross sections. The etchants used for this purpose are also given in Table I.

Dislocations on the main faces could be revealed by several etchants, two of which are given in Table I. Dislocations intersecting the cross sections were revealed on fractured cross sections by the two etchants listed or on polished cross sections by the Dash etch.

Results and Discussion

When it was attempted to use a furnace similar in design to that used for germanium, it was found that in order to get enough supercooling in the center of the melt, the silicon at the sides of the crucible was also supercooled. This supercooling plus reaction of the silicon with the crucible walls resulted in nucleation and growth from the sides of the crucible quickly stopping the controlled growth of the ribbon. Although this problem could be reduced by a crucible material that would not be wet by the silicon, no materials were found that met these requirements. The problem was overcome by the use of a heat shield (10). It was found that in the modified furnace any of the materials ordinarily used for pulling silicon could be used as a crucible, such as quartz, boron nitride, or silicon carbide. Supercoolings between 5° and 20° were used; the pulling speed ranged to 12 ipm (inches per minute); however, ribbons have been pulled as fast as 20 ipm.

Seeds.—As in the case of germanium ribbons, seeds are of the utmost importance for controlled dendritic growth. The initial seeds were primitive dendrites obtained in the normal fashion (1, 4). That is, a single crystal or a crystal containing one twin plane oriented in the directions given for germanium (1, 4), was plunged into a supercooled melt. After growth commenced, the resulting mass was withdrawn at a rapid rate, the order of 12 ipm.

General features of buttons and dendrites.—Several growth masses from which primitive dendrites were obtained were examined and then potted, polished,

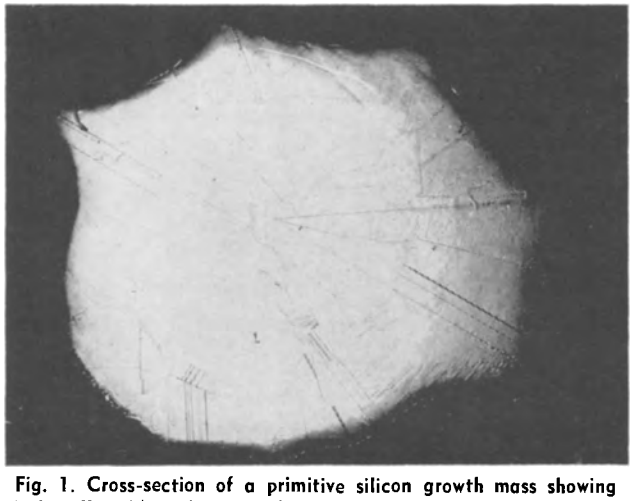

Fig. 1. Cross-section of a primitive silicon growth mass showing twin lamellae. Magnification 6X.

and etched. It was found that the number of primitive dendrites found on each growth mass varied. Figure 1 shows the cross section of a growth mass of silicon. The width of the twin lamellae varied from less than 1μ to several hundred microns. This is to be compared with germanium where the maximum width of the twin lamellae reported in the growth mass was about 70μ and the widest twin spacing found for primitive dendritic growth was 35μ (4).[2]

The protuberance in Fig. 1 shows where primitive dendrites grew from the growth mass. Figure 2 shows one of these protuberances at a higher magnification. Since the melt was highly doped, the core structures of two primitive dendrites that propagated downward can be seen (these are marked by arrows in Fig. 2). Comparing silicon and germanium primitive growth masses, many more twin lamellae are found in the silicon. This observation is consistent with the fact that with single twin seeds of silicon it was relatively easy to generate additional twin planes.

When seed, properly oriented (4) were used for controlled dendritic growth, faceted buttons resulted (see Fig. 3). The buttons, although similar to those found in germanium, were not as well formed. In the button of Fig. 3 a ribbon grew from each wing. Only one ribbon could be made to continue growing by suitable adjustment of pulling speed and/or temperature. The ribbons grew in the $<2\bar{1}\bar{1}>$ directions as long thin ribbons and were faceted along the sides by {111} planes. The side facets can be seen on Fig. 4 for a narrow ribbon.

The two main faces were essentially atomically flat {111} planes. Microscopic examination of the unetched main faces showed that they contained growth steps as shown in Fig. 4. Booker (12) has measured these steps and found them to be ramps of varying height; on good ribbons the step heights were usually not greater than 500 to 1000Å, although growth steps as high as 10,000Å were measured on some ribbons. This height is greater than those reported for germanium by about a factor of two. He also reported some reverse steps on these ribbons which were not found on ribbons of germanium. Under the best growth conditions these steps were spaced far enough apart so that the thickening of the ribbon over a foot length was not greater than 1 mil. The formation of growth steps which takes place at the meniscus (3) is one thickening process for ribbons. It is more difficult to keep under control for silicon than for germanium. Another thickening process, that of degenerate growth below the surface of the melt, will be mentioned later.

[2]Hamilton and Seidensticker have reported wider twin spacings, but the rate of propagation of their ribbons was greatly reduced (11).

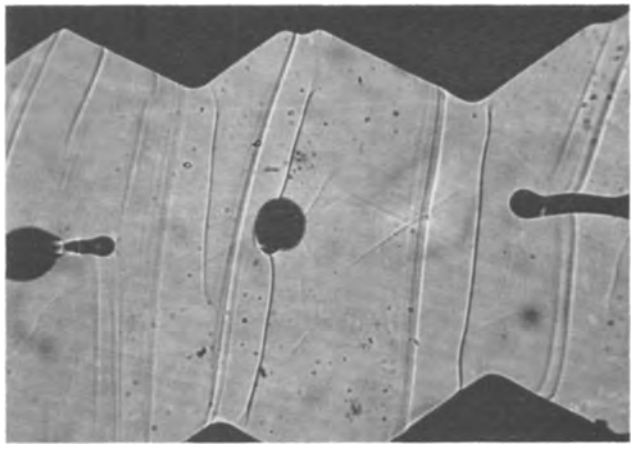

Fig. 4. Growth steps and slip patterns on a natural face of silicon ribbon. Magnification approximately 80X.

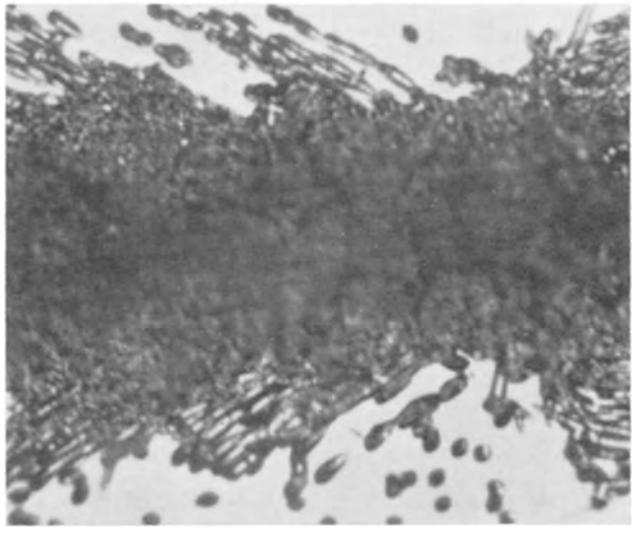

Fig. 5. Dislocations in central strip of natural face. Magnification 200X.

Dislocation studies.—The crystal perfection of the ribbons varied greatly. The dislocations were limited to the three general areas given previously for germanium ribbons (13). In most cases slip patterns (see Fig. 4) were found along the central part of the main faces. This central stripe of slip patterns was shown to consist of patches with a very high density of dislocations, Fig. 5 [area I dislocations (13)]. The fast etching rate of the Dash etch along a dislocation gave an elongated slot instead of the two pits at the end of dislocation half loops as obtained for germanium (13). The slip and dislocations have been shown to arise from small pockets of liquid which became trapped, subsequently froze, and expanded to deform the surrounding material (13). An entrapped droplet can be seen in Fig. 8. Dislocation loops radiate in all possible slip directions from the entrapped droplets. They can be revealed on polished and etched cross sections as seen in Fig. 6. The entrapped droplet shows a high density of dislocations on one side of this two twinned

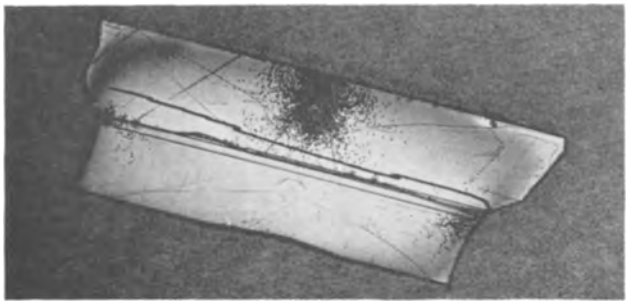

Fig. 6. Cross section of silicon ribbon showing dislocations and microsegregation traces. Magnification approximately 75X.

ribbon, while the other side is relatively free of dislocations.

Random dislocations were found along one or both edges of the main faces [area II dislocations (13)]. Pockets of dislocations were found, but only rarely, on the cross sections running parallel to the twin lamellae near one or both edges [area III dislocations (13)]. In the case of germanium ribbons (13), it was suggested that the area III dislocations arise from stresses set up by a mechanism similar to that for the slip and dislocations in area I. In area III, the liquid became trapped by freezing taking place across the extremities of the H-arm. The term H-arm will be more evident later; they can be seen quite clearly in Fig. 8 and 11. The rare occurrence of dislocations in this area in silicon suggests that this is not taking place, and that the growth between the H-arms takes place more uniformly from the core and the inner part of the H-arm.

Pulling experiments.—Ribbons with an even number of twin planes grew in any one of six <211> directions; however, once a ribbon started to grow in the vertical direction, it usually continued to grow in that direction without branching. Ribbons with three twin planes were grown in both the "right" and "wrong" directions [this terminology is explained elsewhere (1, 4)] as determined by the etch pits from the NaOH etch (see Table I). When the seed was used in the right direction (*i.e.*, the $<2\bar{1}\bar{1}>$ direction), a single ribbon resulted growing vertical to the melt.

These findings are the same as those reported for germanium (1, 4). When the three-twin seed was used in the wrong direction (*i.e.*, the $<\bar{2}11>$ direction), ribbons preferred to grow normal to the melt rather than at 60° to the vertical as was reported for germanium (1, 4). Some 60° growth was found, however. On examination of the flat faces and cross sections of highly doped ribbons that grew normal to the melt, the slip pattern on the main faces and the core of the ribbon on the cross sections was found to be in the center. Ribbons that grew 60° to the vertical, *i.e.*, those with an odd number of twin planes growing in the wrong direction or 60° branches of ribbons with an even number of twin planes, have the central slip pattern and the core of the ribbon displaced to the warmer edge of the ribbons. This asymmetric growth was also obtained when ribbons were purposely pulled from a position close to the crucible walls rather than in the center which is, of course, the center of thermal symmetry.

Segregation studies.—The addition of dopants to the melt from which ribbons were grown proved invaluable in elucidating the growth mechanism of the germanium ribbons (4, 6). Boron or aluminum was added to the silicon melts for similar studies; however, the boron proved more effective with the etchants listed in Table I. Etching was carried out on the main flat face, the potted polished and etched cross sections, and on fractured cross sections to bring out the microsegregation traces. Figure 7 shows the main flat face; both the A and the B traces [this terminology is explained elsewhere (9)] are visible as is the "backbone," or core, of the ribbon. Figure 8 shows a polished and etched cross section of a three-twinned silicon ribbon; two of the three twins do not extend all the way across the cross section. Here the central core is clearly visible as are the B traces going out to form the H-arm structure. The outside of the H-arms are concave and have been filled in by parallel {111} overgrowth while the area between the H-arm shows little structure. It is this area where any macrosegregation is found (6). Some of the melts were so highly doped that excessive macrosegregation was observed as shown by the stained cross section in Fig. 9. The microsegregation studies show that the growth mechanism for silicon ribbons is the same as that given for germanium (4, 6, 14).

The traces around the core of the dendrite are particularly interesting. For the most part the general features of this cross section are similar to those found in germanium ribbons (6); however, the core area is different. Figure 10 is an enlargement of the core area of this cross section; the accompanying sketch

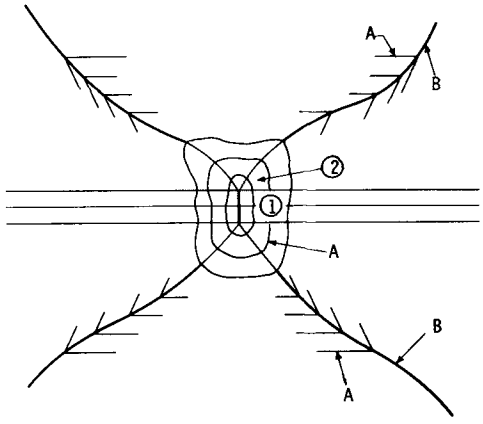

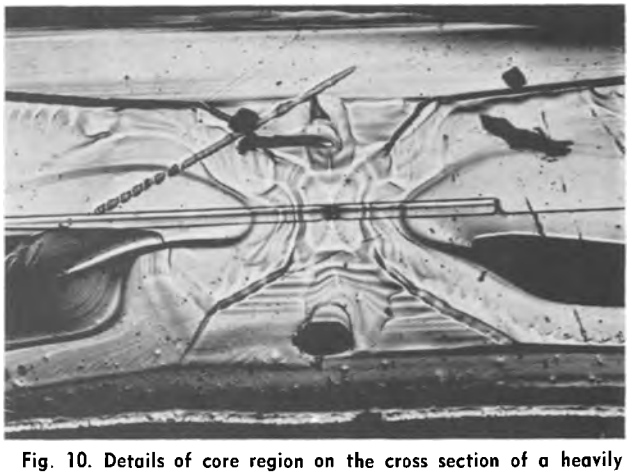

Fig. 10. Details of core region on the cross section of a heavily doped silicon ribbon. Magnification approximately 150X.

is included to aid in interpretation of the cross section. In the case of germanium well-defined A and B traces were found from the core outward. Here, however, it is noted that the B traces are poorly defined in the immediate vicinity of the core (area 1). The A traces, instead of being straight along {111} planes, are curved entirely around the core. This suggests that the core itself is highly faceted, as in the case of germanium, but that just behind the core the ribbon is not highly faceted. Farther out one can see A traces outlining the {111} planes and the B traces that are the intersection of the growth fronts indicating that good faceting exists once again. Figure 11, although not exhibiting all of the A and B traces of Fig. 6, shows the displacement of the core to the side for a ribbon grown at 60° to the melt; the H-arm growth is clearly visible as is the core. In general it was not as easy to reveal the microsegregation traces in silicon ribbons as it was in germanium ribbons (6).

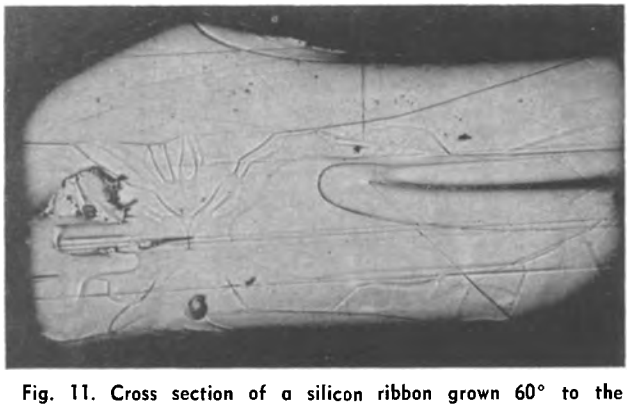

Fig. 11. Cross section of a silicon ribbon grown 60° to the vertical. Magnification approximately 75X.

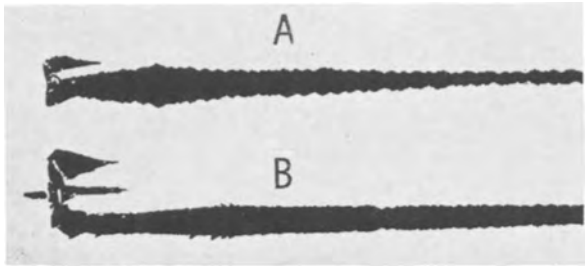

Fig. 12. Silicon ribbons: (a) degenerate; (b) nondegenerate.

Degenerate growth.—Although, as is evidenced from the above, the silicon ribbons are similar in appearance and growth to germanium ribbons, there is one growth problem that is almost exclusively peculiar to silicon ribbons. When a ribbon is pulled, it invariably at the beginning is wide with excellent surfaces, but in many cases degenerates within the first inch or two into a thick narrow ribbon with highly faceted edges and with very irregular main faces, *i.e.*, large growth steps and deep pits instead of slip patterns. An example of such a ribbon is shown in Fig. 12a. How this degeneration takes place can be found by studying the cross sections of various regions of the ribbons. Figure 8 shows the good ribbon with the well developed H-arm growth. Figure 13 shows an intermediate region where one can note the concave and the convex nature of the B traces going out to the corners of the ribbon and the A traces ending at a concave line. This suggests a considerable degeneration of the previously good H-arm growth. Figure 14, on the other hand, shows the cross section of a completely degenerate ribbon. Here one can see that the B traces go out to the corners, and the A traces go from it to convex B traces. Such a phenomenon suggests that degeneration occurs in the earliest stages of the core development at a time well before any growth at the meniscus (*i.e.*, growth steps) could influence the morphology of the ribbons. This degeneration could be caused by changing thermal conditions at the tip or by impurity influenced modification of nucleation and layer completion. Actually, by the time the growing ribbon has reached the meniscus it has assumed its maximum width (6); thus, the observed narrowing could not

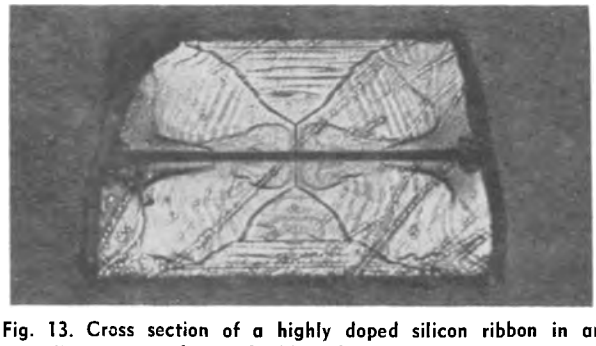

Fig. 13. Cross section of a highly doped silicon ribbon in an intermediate stage of growth. Magnification 200X.

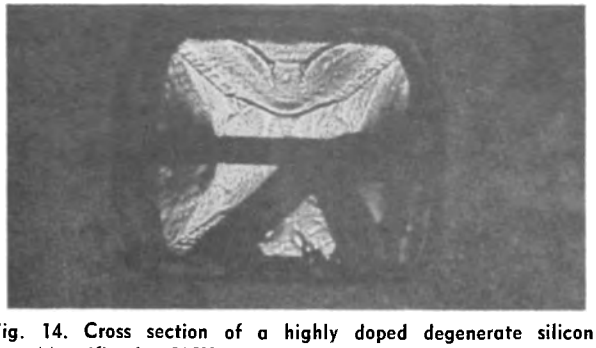

Fig. 14. Cross section of a highly doped degenerate silicon ribbon. Magnification 200X.

take place at the meniscus. Although the relative importance of thermal conditions at the growing tip and impurity effects on core development have not been determined, the development of improved thermal shielding systems, which give a more nearly isothermal melt but which may also cut down on impurity transfer from the outside, have made it possible to grow long lengths of ribbons without degeneration or excessive thickening, see Fig. 12b.

Spikes (*i.e.*, incipient branching) occasionally show up at low pulling speeds. From the length of the spikes one can say that this growth initiates between the growing tip and the meniscus, possibly in the area where the faceting is not pronounced. Although the effects of various twin spacings on the growth morphology have not been extensively studied, it does seem that the spikes show up more frequently at the larger twin spacings.

Further improvement in the technique for growing silicon ribbons has been made much less important by the development of the web technique (10) which yields a more versatile material. It is of relatively little importance whether the side dendrites in the web material are degenerate or not.

Summary

The general morphology of the buttons and ribbons, the location of the dislocations, and particularly the growth history as shown by microsegregation traces suggest that the basic growth mechanism of silicon ribbons is the same as that for germanium. There are, however, differences between the growth of silicon and germanium ribbons. These differences are:

1. Difficulty in obtaining 60° silicon ribbons when a seed containing an odd number of twins is used in the "wrong" direction.
2. Less highly faceted area of the silicon ribbons just behind the growing tip.
3. Tendency of the silicon ribbons to become degenerate.
4. Tendency of the silicon ribbons to spike, especially at low pull rates or wide twin spacings.
5. Easier to generate additional twin planes in silicon.
6. Less difference in the core faceting between silicon ribbons grown in the "right" and the "wrong" direction with three twinned seeds.
7. Higher growth steps on silicon ribbons.

Items 2, 3, and 6 suggest perturbations to the basic growth mechanism of germanium. The other differences are in control of the growing technique. The tendency of the ribbons to degenerate has been reduced by the addition of heat shields.

Acknowledgments

The authors wish to express their gratitude to Mrs. H. Larson and Mrs. S. Hillbeck for preparing the ribbons for examination.

Appreciation also is expressed to the Air Force Logistics Command, Aeronautical Systems Center, Wright Patterson Air Force Base, for their partial support of this work.

Electrical Properties of Copper Segregates in Silicon P-N Junctions

J. E. Lawrence

Fairchild Semiconductor, Division of Fairchild Camera & Instrument Corporation, Palo Alto, California

ABSTRACT

The electrical properties of segregated copper are greatly influenced by the structure of the lattice disorder to which the impurity precipitates. Two crystal defects, the sessile fault and the lattice void, act as precipitation sites for the copper impurities discussed in this work. Copper which precipitates at a small sessile fault will acquire a platelet distribution within the limits of the newly formed disorder. The copper platelet will cause a P-N junction to exhibit a soft reverse characteristic if the platelet is in the depletion region of the junction. Copper which precipitates at a lattice void will redistribute to form loosely packed {110} arrays. These {110} copper segregates contribute a constant multiplier to a copper-free P-N junction's electrical I-V trace.

Segregated copper impurities near a planar diffused P-N junction will contribute irregular reverse bias characteristics to the electrical junction in semiconductor crystals. The physical and electrical behavior of nonsegregated copper in silicon and germanium has been the topic of many publications in the last decade. Copper is reported to diffuse interstitially as a single charged positive ion (1). Interstitial copper ions combine with vacancies in the silicon lattice to create a substitutional impurity. Substitutional copper has been

identified as a triple acceptor in both silicon and germanium crystals by Hall and Racette (2), who also report the diffusivity, solubility, and electrical charge values for copper impurities in silicon, germanium, and gallium arsenide.

Copper has a strong temperature-dependent solid solubility in silicon which causes supersaturation and the formation of precipitates during a crystal's cooling from an annealing treatment. The Cottrell interaction energy relating interstitial copper impurities to regions of lattice distortion is favorable to the formation of precipitates during a thermal treatment. Dash (3), Schwuttke (4), and Thomas (5) have provided experimental evidence of the interaction of copper impurities with crystal disorders in the silicon lattice. Schwuttke discusses the influence of oxygen on the precipitation of copper. Early work by Goetzberger and Shockley (6) identified precipitated metallic impurities as contributing to excessive reverse currents below avalanche breakdown. However, they did not associate a specific distribution of metallic impurities with particular electrical characteristics.

Structure of the Copper Precipitation Site

In this work, the behavior of copper at a crystal defect was investigated at a sessile fault and a lattice void. Both of these crystal disorders form near the surface of silicon wafers during a thermal treatment.

The silicon wafers used in this investigation initially contained either antimony, boron, or phosphorus bulk dopant impurities at dopant concentrations from 4 x 10^{14} to 4 x 10^{18} atoms/cm^3. The wafers contained a known dislocation density varying from less than 10 to greater than 10^5/cm^2. Thermal treatments were conducted at temperatures between 1000° and 1260°C in atmospheres of dry oxygen, steam, or nitrogen. The thermal treatments varied from 5 min to 10 hr while the quenching times varied from 30 sec to 10 min.

The sessile faults are formed during the recovery of a plastically deformed surface. The deformation was introduced by mechanically polishing silicon wafers. These mechanically worked wafers were annealed to permit the recovery of the distorted surface. The sessile faults which form at the crystal's surface grow in size in a direct relationship to the annealing time and temperature. The sessile faults described here develop along the inclined {111} planes and thus distort the exposed (111) surface along the $<\bar{1}10>$ directions. This crystal disorder has a half-hexagonal configuration in its inclined $(\bar{1}11)$ plane as shown in Fig. 1. The peripheral distribution of lattice strain of this crystal defect has been delineated on a cleaved $(\bar{1}11)$ plane by copper decoration and Sirtl etching. Copper precipitates will resist brief periods (less than 60 sec) of etching with the Sirtl solution (7).

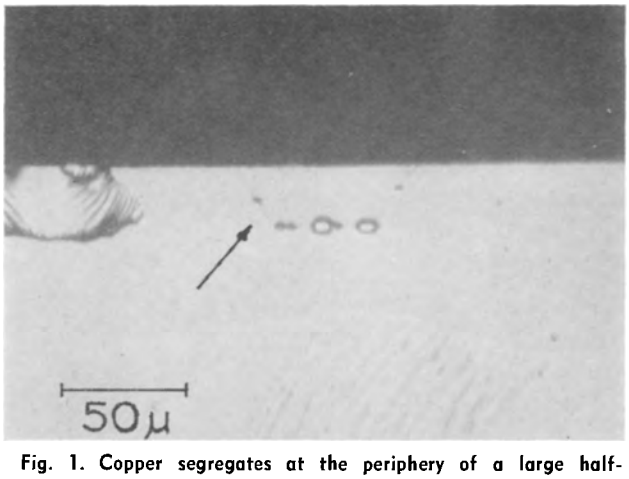

Fig. 1. Copper segregates at the periphery of a large half-hexagonal sessile fault delineated on a cleaved $(\bar{1}11)$ face by Sirtl etching.

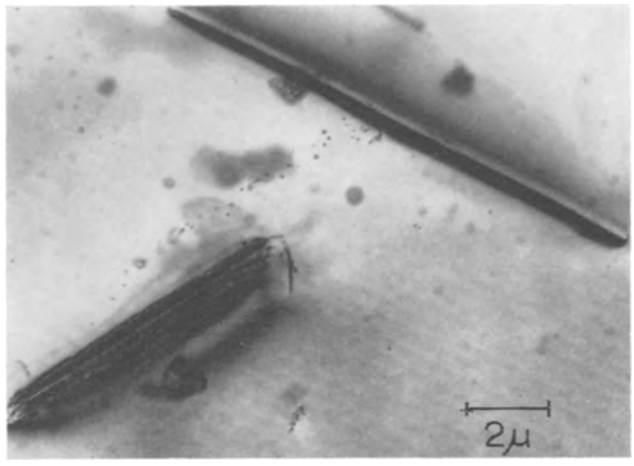

Fig. 2. Two sessile faults. Electron transmission micrograph

This plastic deformation induced crystal defect was identified as a sessile fault from an analysis of the defect's electron transmission properties. Such analysis was aided by the development of a quick and reliable technique for preparing uniform films 1000Å thick and greater than 2 mm in diameter (8). The extinction contrast fringes in the crystal disorders shown in Fig. 2 identified the imperfections as being two dimensional sessile faults such as twin faults or stacking faults. These are very likely stacking faults for they do not contribute to a twin diffraction pattern when analyzed by selective area electron diffraction. Also, a single planar slip at the surface, producing a stacking fault, will form more readily during the recovery of a plastically deformed lattice than will a double slip which produces a twin lamalla. Thomas (5) investigated a similarly formed crystal defect by the selective area electron diffraction technique and drew the same conclusion.

A large amount of crystal disorder develops near the surface of "strain free" wafers during high temperature annealing treatments. This structural disorder does not form in crystals containing a high degree of initial lattice strain from bulk dislocations or surface faults. The silicon wafers prepared for analysis of this thermally induced disorder contained less than one hundred dislocations per square centimeter and had 150μ of material removed from each lapped wafer face by chemical polishing. The electron transmission micrographs in Fig. 3a and 3b show the structural order of the silicon surface before and after a thermal treatment at 1200°C for 1 hr in a dry nitrogen ambient. The interference fringes in Fig. 3a and 3b

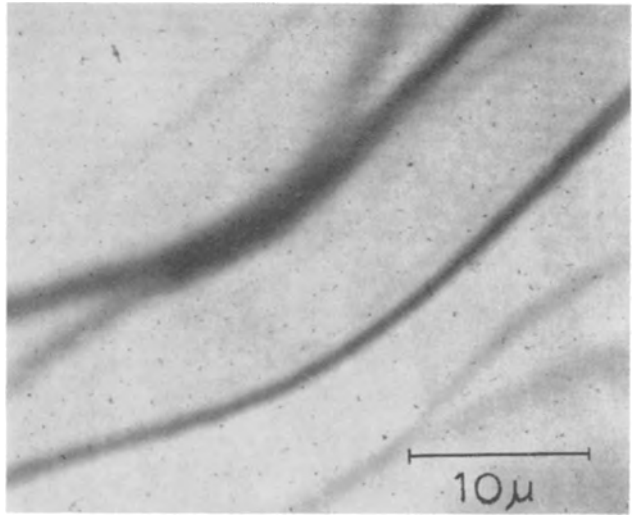

Fig. 3a. Electron transmission micrograph: defect free lattice before thermal treatment.

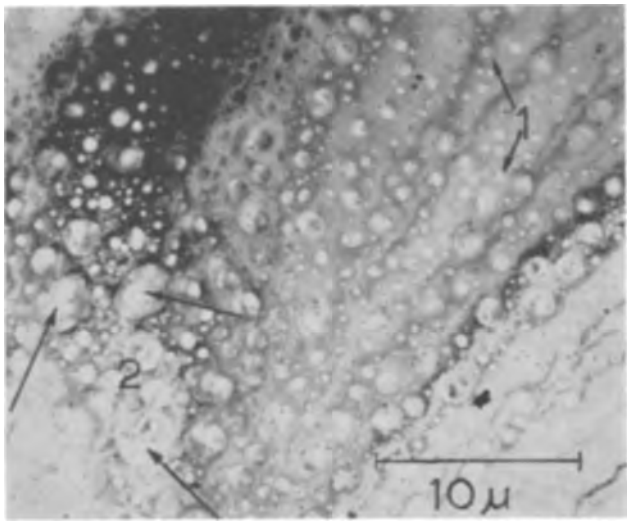

Fig. 3b. Electron transmission micrograph: surface lattice voids formed during thermal treatment.

provide a sensitive means of identifying lattice disorders and slight variations in film thickness. The micrograph in Fig. 3a illustrates a surface free of lattice distortion which is characteristic of the nonheat-treated material used in this investigation. The transmission micrograph in Fig. 3b identifies the structure of the thermally induced crystal disorders.

Several stages in the development of this crystal imperfection may be interpreted from the disorders in Fig. 3b. The disorders initially appear as flat disk-like structures in the (111) plane (No. 1 in Fig. 3b). These disk structures, as a unit, are immobile; however, they can grow by acquiring some unidentified unit such as a vacancy and by expanding into a neighboring disorder of similar formation. Large thermally induced disorders can combine with adjacent disorders that do not lie in the same (111) layer. The large disorders (No. 2 in Fig. 3b) possess irregular configurations which suggest they have developed by a recent combination.

These thermally induced disorders do not appear to be dislocations or sessile faults for they do not have a Burgers vector that can be resolved by the extinction contrast technique of the electron microscope. These disorders are volume discontinuities in the silicon lattice, such as voids. This identification seems probable since their formation is only a function of the structural order of the initial material and the treatment temperature and not a function of the annealing ambient. The subject imperfection is not an impurity inclusion for the disorders do not have unique electron transmission or diffraction properties. Recent work by Booker and Stickler (9) discusses a similar disorder that is reported to be of amorphous material, probably an oxide.

Incomplete work by the author has lead to the belief that the fundamental unit of a thermal lattice void, the vacancy, is created at a crystal surface by a wafer's dopant impurity forming a Schottky vacancy. (Thermal voids form more readily in highly doped material than lightly doped materials.) The slow quenching of a low dislocation density material would produce a supersaturation of vacancies. In the absence of a readily accessible vacancy sink such as a surface or dislocation, many vacancies could combine to initiate a void in this treatment environment.

The formation of a Schottky defect and the diffusivity of a vacancy in germanium reported by Goldberg (10) supports the author's preliminary model for vacancy formation. The interaction of vacancies to form clusters, a primary unit of a void, has been recognized as possible by Melngailis and O'Hara (11) and Elbaum (12). The existence of surface lattice voids in thermally treated low dislocation density germanium crystals has been reported by Tweet (13).

The Distribution of Precipitated Copper

Copper was introduced to the test wafers in a manner that allowed reference wafers to be exposed to the thermal treatment at the same time without being exposed to the metallic impurity. This was accomplished by placing two test wafers 8 in. apart on a furnace carriage with a copper-plated silicon wafer between them. The carriage was then passed into a furnace which was continually flushed with fresh oxygen. Different temperature zones in the furnace allowed tests to be conducted at temperatures between 1000°C and 1260°C.

The distribution of segregated copper at a sessile fault is dependent on the size of the lattice disorder and the amount of copper available to precipitate. Diagrams representing the distribution of copper at sessile faults, when a limited amount of the impurity is available for precipitation, is presented in Fig. 4a and 4b. The lines identified by the letters in the schematics represent ($\bar{1}$11) planes of atoms at their intersection with the (111) wafer surface. The discontinuous "C'" rows represent simplified sessile faults. The cross-hatched lines represent the manner in which copper impurities prefer to segregate in a small sessile fault (Fig. 4a) and a similarly formed fault which has grown in size during a prolonged thermal treatment (Fig. 4b).

Copper impurities appear to seek a platelet distribution in small newly formed sessile faults. This is graphically represented by the uninterrupted cross-hatch lines in Fig. 4a. Experimental evidence of the platelet distribution of segregated copper was achieved

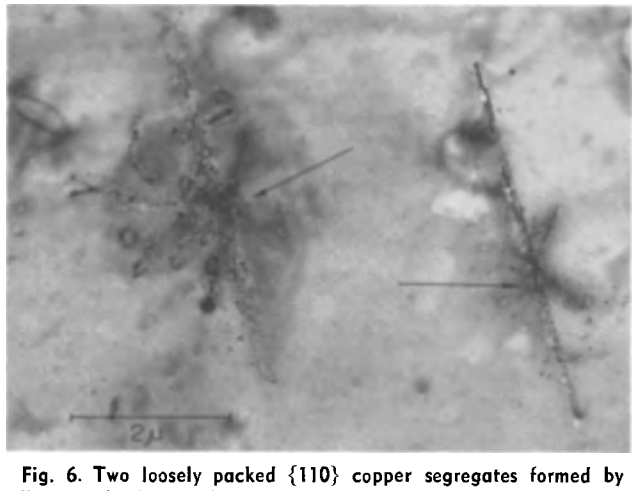

Fig. 6. Two loosely packed {110} copper segregates formed by collapsing lattice void precipitation sites.

by cleaving a wafer containing many copper decorated sessile faults and observing the distribution of segregated copper at several exposed lattice faults. Copper platelets possessing half-hexagonal configurations and occupying the entire region within the limits of newly formed sessile faults have been delineated.

The region of greatest lattice distortion of a large sessile fault is along its subsurface perimeter. Copper impurities are, thus, more likely to segregate to the periphery of large sessile faults as represented graphically in Fig. 4b and illustrated in the micrograph shown in Fig. 1. This micrograph also indicates that the copper does not achieve a uniform distribution along the total perimeter of the large sessile fault, but rather segregates into localized regions.

A model for the development of a copper segregate at a thermally induced lattice void is graphically illustrated in Fig. 5. Diagram 1 in this figure represents the structure of a simplified lattice void. Copper is initially attracted to the crystal void because of its lattice distortion and free electrical bonds. The cross-hatched lines in diagram 2 represent copper impurities that have precipitated at the lattice void. It is reasonable to assume that copper impurities prefer to precipitate at existing segregates rather than to nucleate a new site. Therefore, copper impurities will continue to be attracted to a lattice void long after it has become saturated with copper atoms. Diagram 3 represents the precipitated impurities as extending beyond the limits of the crystal void. The lattice surrounding the crystal void cannot accept the acquired supersaturated concentration of copper. Therefore, the copper precipitates are forced to redistribute along low energy crystal planes. Diagram 4 illustrates the (111) intersection of three of these planes of segregated copper.

Copper is redistributed to form a loosely packed array of secondary precipitates along specific {110} planes following the collapse of a lattice void precipitation site. The redistribution planes were identified as {110} by determining the direction at which individual copper segregate planes intersected the (111) wafer surface and a $(\bar{1}11)$ cleaved face. The planes of segregated copper which intersected one {111} plane at a $<\bar{2}11>$ direction, also intersected the other {111} plane at a $<\bar{1}10>$ direction. The distribution of copper following the collapse of a lattice void was determined by analyzing electron transmission micrographs, such as that shown in Fig. 6. This micrograph illustrates two loosely distributed arrays of secondary precipitates, which resulted from a forced redistribution of copper impurities at two collapsed lattice void precipitation sites. The widely separated secondary precipitates appear as well defined dark dots in Fig. 6. These two collapsed void segregates appeared in a silicon wafer into which a low concentration of copper impurities had been introduced.

Copper impurities in the silicon lattice precipitate during thermal treatments above 1000°C and not solely during the cooling from the annealing temperature. This was determined by studying the configuration of oxide irregularities which develop over copper decorated surface lattice disorders. The oxide irregularities are aligned to the same $<\bar{2}11>$ or $<\bar{1}10>$ directions as the copper segregates on which they develop. They alter the uniform topography of the oxide film by nearly one tenth the thickness of the silicon dioxide layer. The copper impurities could not have segregated during a 30 sec quenching period and still contributed to the oriented oxide irregularities.

Electrical Behavior of Segregated Copper

As mentioned earlier, the electrical behavior of segregated copper is governed by the structure of the precipitated impurities in the silicon lattice. Copper which segregates to form a tightly packed platelet, *e.g.*, at a small newly formed sessile fault, will exhibit a different electrical behavior from copper which segregates to form a loose distribution of secondary precipitates, *e.g.*, following the collapse of a lattice void precipitation site.

A copper platelet in the space charge region of a reverse biased P-N junction will emit visible light from a pair of oriented microplasmas and alter the I-V characteristics of the electrical junction. It has been reported (14) that small points of emitted light (microplasmas) carry essentially all of a reverse biased P-N junction's premature breakdown current. The intensity of an individual point of emission is proportional to the carrier recombination multiplication factor, which, is, in turn, proportional to the field strength at the small localized point of emission (15). The detection of a $<\bar{1}10>$ aligned pair of microplasmas with a separation of approximately 10μ identified an electrically active copper platelet and the principal location of premature junction breakdown for the diodes prepared in this investigation. The localized points of emission coincide with the crystal surface intersection of a copper platelet's edges at low voltage (10-50v). Additional emission occurs at the subsurface corners of the platelet at higher voltages (50-100v). The diameter of the microplasmas increases from 0.5 to 1μ with an increase in the reverse bias.

The depletion layer that encounters a copper platelet appears to envelope the impurity aggregate, thus creating a band of very high field strength along the periphery of the platelet. The field reaches its greatest strength at the four corners (see Fig. 1) of the half hexagonal platelet. Assuming a platelet width of 10Å, the field intensity could be substantially above 10^6 v/cm. On the other hand, copper impurities in the depletion region which have formed a loosely distributed {110} array of secondary segregates following the collapse of a lattice void precipitation site do not emit visible light.

The structure of the segregated metal impurity located in the depletion region of a P-N junction greatly effects the electrical behavior of the junction. The log I *vs.* log V traces of several planar deep-diffused diodes are shown in Fig. 7 to illustrate the electrical effects of two structures of segregated copper. Curve "A" illustrates the reverse characteristics of a P-N junction containing a single active sessile fault copper platelet near the surface. The copper platelet, 8μ long and a small fraction of a micron wide, contributes to a soft I-V characteristic at low voltages and an ohmic slope at high voltages. Only the low voltage portion of the characteristic trace is shown in

Fig. 7. The voltage dependent field strength at the periphery of the platelet dominates the spreading resistance factor at low voltages, thus contributing the soft slope. However, at high voltages, the spreading resistance factor is dominant, thus the ohmic slope. Essentially all of the electrically active copper in the 12μ of silicon nearest the surface was confined to the first 3μ, the depth of the copper platelet. The diode's I-V trace gradually changed from the initial slope shown at "A" to that shown at "B" as the surface lattice was removed in graduated steps by chemical polishing. Curve "B" illustrates the electrical characteristic of a copper free P-N junction.

Curve "C" identifies the reverse characteristics of a P-N junction containing over one hundred separate loosely packed {110} arrays of secondary copper precipitates. (The distribution of the secondary precipitates following the collapse of a lattice void was shown in Fig. 6.) The parallel displacement between curves "B" and "C" indicates that reverse current in the loosely packed metal precipitates case is larger than the reverse current of a copper-free P-N junction by a constant factor of nearly 70.

The slope of curve "D" is characteristic of the deep diffused P-N junctions created in very low dislocation density material when foreign metallic impurities were absent. The difference in slope between curves "B" and "D" could be caused by thermally induced surface lattice voids acting as recombination centers. This assumption seems reasonable since dislocations have been shown to act as recombination centers for electrons and holes (16).

Conclusions

The foregoing discussion has established certain qualitative conclusions about the behavior of copper segregates at sessile faults and surface lattice voids produced in silicon by heat treatments at 1200°C.

1. Copper impurities acquire a half-hexagonal platelet configuration within the limits of small newly formed sessile faults.
2. Copper impurities which precipitate at surface lattice voids are redistributed to form loosely packed {110} arrays of secondary precipitates.
3. The platelet distribution of copper contributes to a soft electrical characteristic at low voltage, and an ohmic I-V slope at high voltages.
4. The loosely packed {110} distribution of copper contributes a constant multiplier to a P-N junction's leakage current on a log I *vs.* log V plot.

Acknowledgment

The author wishes to acknowledge Dr. R. N. Tucker for his stimulating suggestions during the development of the work summarized in this paper. The assistance of H. Koehler, R. Dyck, and G. Daughters on this work is greatly appreciated.

Manuscript received Feb. 9, 1965. This paper was presented at the Washington Meeting, Oct. 11-15, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

Doped Anodic Oxide Films for Device Fabrication in Silicon

II. Diffusion Sources of Controlled Composition, and Diffusion Results

P. F. Schmidt,[1] T. W. O'Keeffe, J. Oroshnik, and A. E. Owen[2]

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania

ABSTRACT

Control of sheet resistance and surface concentration subsequent to diffusion was achieved by controlling the doping level in the oxide. The ternary system diethylphosphate (DEP)-nitrite-tetrahydrofurfuryl alcohol was found suitable for producing doped oxide films that can be used for base or collector diffusions. The correlation between concentration of DEP in the solution and amount of phosphorus incorporated into the oxide was determined by tracer experiments with P-32 tagged DEP. The more dilute solutions were found to be sensitive to temperature and current density during anodization. Incorporation of alkali ions into the anodic oxide film can be avoided if the number of anodizations in the same batch of solution is limited. The out-diffusion of phosphorus from the doped oxide source can be suppressed by placing a non-doped anodic oxide over it. Reproducibility data for the diffusion results are given. The fabrication of simple device structures and the electrical performance of such devices are described.

Part I of this communication (1) dealt with the doping of anodic oxide films on silicon by incorporation of phosphorus. The emphasis in Part I was on achieving very heavy doping levels and on studying the properties of the oxide film itself. Part II deals with the utilization of these novel diffusion sources. The emphasis is therefore on (*a*) the reproducibility of the doping level in the oxide at those doping levels suitable for emitter, base, and collector diffusions, (*b*) on the reproducibility of the diffusion results,

and (c) on the actual fabrication of simple device structures.

Choice of Anodizing Solution

The use of a 15 v/o solution of pyrophosphoric acid in tetrahydrofurfuryl alcohol was described in the previous communication (1). This solution yields a very heavily doped oxide and is being used for emitter diffusions. When stored under complete exclusion of moisture, it appears to be stable over periods of months. On the other hand, its viscosity and hygroscopicity pose handling problems, and it is not so well suited for the preparation of anodizing solutions for base or collector diffusions where a greater degree of control is required.

An anodizing solution useful for these purposes was found in the ternary system diethylphosphate-alkali nitrite-tetrahydrofurfuryl alcohol. The concentration of nitrite is kept fixed at 1.50g NO_2^-/100 ml tetrahydrofurfuryl alcohol (THF), while varying the ratio of diethylphosphate (DEP) to nitrite in decade steps. The ratio of DEP to nitrite determines the amount of phosphate incorporated into the oxide, while the nitrite at the same time serves to maintain the conductivity of the solution at a more or less constant value and contributes only oxygen to the electrode reaction. The THF does not seem to participate in the anodic electrode reaction to an appreciable extent in the presence of the DEP and nitrite.

Initially, sodium nitrite was used until it was found that under certain conditions sodium ions are incorporated into the oxide film, and are diffused subsequently into the silicon, resulting in uncontrolled N-type doping. Substitution of potassium nitrite eliminated this trouble. Potassium can also be incorporated into the oxide film (compare below under tracer run with K-42), but apparently to a much lesser extent than sodium. The use of ammonium nitrite is not feasible because ammonium nitrite is not stable chemically. Apart from this consideration, it is doubtful that it would be useful for the anodization process; the electronic leakage current during the formation of anodic oxide films on silicon in solutions of ammonium nitrate is intolerably large and results in inferior oxide quality. Perhaps hydrogen is getting into the oxide during formation, as has been claimed in the case of beryllium (2).

Nitrite is used rather than nitrate because of its good solubility in organic solvents, and because it also gives lower leakage currents than nitrate. No chemical instability of the nitrite-DEP-THF solutions has been noticed. The electrical conductivity (approximately 1 k-ohm-cm) of these solutions hermetically sealed into a conductivity cell remained unchanged for months.

Pure DEP and distilled THF was obtained from Distillation Products Industries, Rochester, New York. Analytical grade sodium or potassium nitrite by Fisher was used without further purification. Anodizations were in general carried out at 6 ma/cm^2 to 150v and the leakage current was then permitted to decay at constant voltage for ½ hr, after which time further changes in leakage current become very small. At constant voltage a 10-min decay proved sufficient to reach constancy of the count from wafers anodized in radiotracer solution; increase in oxide thickness[3] after 10 min at constant voltage is apparently negligible.

In order to investigate the correlation between concentration of DEP in the solution and concentration of phosphorus in the oxide, a tracer run was carried out in which the DEP was tagged with P-32.

Relationship between Ratio DEP/NO_2^- in anodizing Solution, and Concentration of Phosphorus in Oxide

P-32 tagged DEP with a specific activity of 10.4 mc/ml DEP was obtained from Nuclear Chicago Co. The DEP was diluted with a solution of 1.80g $NaNO_2$ in 100 ml THF in a 1:1 ratio by volume. This master solution was then used to prepare more dilute solutions in which the DEP/NO_2^- ratio was varied in decade steps. The volume of each batch of radioactive solution was about 7 cm^3, so that stirring of the solutions would have been very difficult to accomplish. Anodizations were therefore carried out in unstirred solutions but under rigorous exclusion of moisture.

The solutions most concentrated with respect to DEP showed instability with time; the amount of phosphorus incorporated kept decreasing with a time constant of days. The more dilute solutions did not show this behavior. No analogous behavior is observed with nonradioactive, concentrated DEP solutions, as shown by the fact that diffusion results obtained on Si wafers anodized in these solutions did not depend on the age of the solution. The most plausible explanation is that the radioactivity of the sample caused radiolysis of the solution, perhaps accompanied by the formation of water, and that the chemical change caused by the radiolysis is responsible for the decrease in the amount of phosphorus that is incorporated into the oxide by anodization.

Anodizations in the radioactive solutions of different strength were carried out in rapid succession on the same day; thus the results obtained are not falsified by the above mentioned instability of the more concentrated solutions. Chemically polished P-type silicon bars of resistivity 2 ohm-cm were used. The bars were approximately 6 x 0.5 x 0.1 cm in size, and their large surfaces were <110>, <100>, or <121> oriented.

After anodization the samples were thoroughly rinsed with methanol and with water to remove adherent liquid and after drying were inserted in tight fitting plexiglas holders and placed in a lead shield underneath the window of a Geiger-Muller counter. The holders exposed a 1 cm length of the top surface of the samples. The region located near the meniscus of the solution during anodization was shielded by a lid in order to ensure uniformity of the sample surface to be counted. The procedure for measuring the P-32 concentration in the oxide or in the silicon has been described in Part I of this paper (1).

Counts from radioactive oxide films are sensitive to the surface roughness factor of the sample. For this reason the same wafers were used again[4] for subsequent anodizations, with the same side up during counting. Since anodization is known to result in smoothing of the surface, some decrease in surface area during a series of runs was unavoidable. However, the surface roughness factor of chemically polished silicon wafers is generally accepted to be 1.3, and can therefore not vary much, in view of the fact that a chemically polished surface shows no asperities but only long-range undulation.

[4] After stripping of the oxide film in HF.

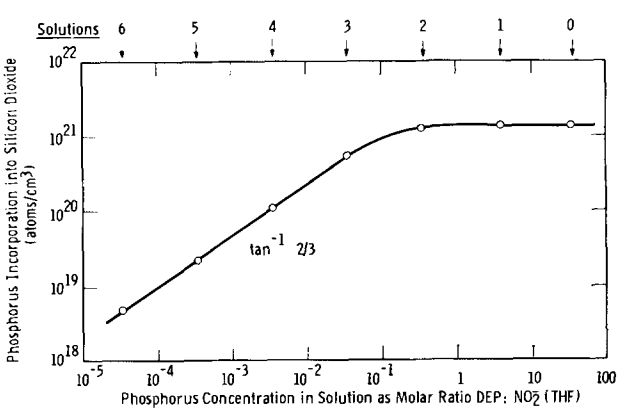

Fig. 1. Relation between phosphorus incorporation and molar ratio DEP:NO_2^- in the solution. Solution temperature, 25°C; current density, 6 ma/cm^2.

[3] The oxide thickness after anodization to 250v (at constant voltage for 30 min) in the KNO_2-THF solution was determined both by ellipsometry and from the reflectance minimum as a function of wavelength in the ultraviolet. The thickness/voltage increment was found to be 5.6 Å/v. The refractive index was found to be 1.48 at the mercury green line.

Figure 1 shows the relationship between the DEP/NO_2^- ratio in the anodizing solution, and the resulting concentration of phosphorus in the oxide. The NO_2^- concentration in all solutions was 1.5g/100 in THF. The amount of phosphorus incorporated saturates quite sharply at a molar ratio of 0.3. This is, however, not the upper limit to which phosphorus can be incorporated. Concentrations of 4.1 x 10^{21} atoms P/cm^3 SiO_2 have been obtained by anodization in solutions of pyrophosphoric acid in THF, and even higher concentrations can be achieved by anodization in the pure acid. The reason why the amount of phosphorus incorporable from DEP solution saturates at a molar DEP:NO_2-ratio of 0.3 may be that either the dissociation of the DEP molecule or its adsorption to the electrode surface reaches a limiting value at this concentration. Formation of water at the anode due to oxidation of the ethyl radical is another possibility.

At lower DEP/NO_2^- ratios there is a simple 2/3 power relationship; this linear portion (on a log-log plot) probably extends to even lower DEP/NO_2^- ratios, but these have not been investigated. The simplest explanation for this 2/3 slope would be to assume that the concentration of DEP at the oxide surface is related to the bulk concentration of DEP in the solution by a 2/3 power law. Nitrite and phosphate ions contribute to oxide growth in a proportion determined by their concentration at the oxide surface and by the given electrode potential.

No indication of incorporation of the ethyl radical into the oxide has been observed; it is known from other experiments with glycerine as the solvent that incorporation of organic matter into the oxide can occur and will result in severe degradation of the oxide during the heat treatment necessary for diffusion. No degradation of oxides grown in the DEP-NO_2^--THF solution has been observed subsequent to diffusion. Conclusive proof, one way or the other, could be obtained by using C-14 tagged DEP, but this was not available. If incorporation of the ethyl radical does not occur, then it must be postulated that the DEP molecule dissociates at the oxide surface during the electrode reaction. However, the composition of the phosphorus-oxygen complex incorporated into the oxide by the electrode reaction (P_xO_y) is not known.

Figure 2 shows the average sheet conductivity after diffusion. The actual points of measurement are shown. The spread of the data would be determined by the inaccuracies of measuring sheet resistances and junction depths (compare below). Figure 3 shows the surface concentration calculated from the data in Fig. 2 and from the junction depths shown in Fig. 4. It can be seen that the electrical data, obtained independently from the tracer experiments, parallel the tracer information quite closely. It should be noted that the surface concentrations shown in Fig. 3 refer only to

electrically active phosphorus and do not allow for the fact that the diffusion of phosphorus at very high concentrations does not follow a complementary error function (erfc) distribution (3). The nontracer data of Fig. 2-4 were obtained on <111> oriented Si disks, 2 ohm-cm resistivity, so that any effects due to formation of SiP precipitates were minimized (4).

Temperature and Current Density Effects on Amount of Phosphorus Incorporated into Oxide

Table I, top half, shows the effect of the temperature of anodization on the amount of phosphorus incorporated into the oxide at a constant current density of 5.6 ma/cm^2.

It can be seen that the temperature sensitivity of the solution increases with its dilution. The existence of this effect indicates that the amount of DEP adsorbed to the oxide surface decreases with increasing temperature and is approximately in equilibrium with the concentration of the DEP in the bulk of the solution at the current densities here employed.

Table I, bottom half, shows the effect of current density on amount of phosphorus incorporated at two different temperatures, and in solutions of three different concentrations of DEP. It can be seen that the amount incorporated increases consistently with in-

Table I. Effect of current density and temperature on amount of phosphorus incorporated

Solution No.	25°C	0°C	
Temperature effect at constant current density of 5.6 ma/cm²			
1	4.2×10^{21} cm^{-3}	4.6×10^{21} cm^{-3}	10% increase
4	3.0×10^{20} cm^{-3}	4.6×10^{20} cm^{-3}	53% increase

Current density effect at different temperatures

Solution No.	Temp, °C	4.7 ma/cm²	5.6 ma/cm²	7.1 ma/cm²	12.0 ma/cm²
1	0	4.2×10^{21} cm^{-3}	4.6×10^{21} cm^{-3}		
4	0		4.6×10^{20} cm^{-3}	5.0×10^{20} cm^{-3}	
5	25		5.7×10^{19} cm^{-3}		8.4×10^{19} cm^{-3}

creasing current density. In view of the fact that the solutions were of relatively high resistivity (in the 1 k-ohm-cm range) and that it was not possible to stir them mechanically, it is clear that the silicon anode was at a higher temperature than the external water bath, especially at the higher current densities. Since the effects of current density and temperature are in opposite directions, the current density effect is probably more pronounced than indicated by Table I.

Table II provides essentially the same information on the temperature effect, but by way of the electrical data after diffusion from oxides anodized at the different temperatures in nontracer solutions. Also shown in Table II are data for the pyrophosphoric acid/THF system. As expected for a solution very concentrated with respect to phosphate ions, the temperature effect is small. As reported previously (1), no current density effect could be observed in the $H_4P_2O_7$-solution in the range 3-5 ma/cm². The $\overline{C_s}$ values in Table II were taken intermediate between the values calculated from either a Gaussian or an erfc distribution.

The above discussion shows that anodization cells must be thermostated and that the current density must be carefully controlled if good reproducibility is to be obtained; the more dilute the solution with respect to DEP, the more stringent this requirement. It is also advisable to stir the solutions in order to improve heat exchange between the interior of the anodization vessel and the thermostating solution; Teflon-coated magnetic stirrers have been found very satisfactory for this purpose.

Surface Roughness Factor and Reproducibility of Doping Level in Oxide

The oxide diffusion source follows the surface of the sample in every detail. There is less of a smoothing-out effect than occurs by penetrating a small distance into the silicon when predepositing phosphorus from the gas phase. It is therefore necessary to control the surface roughness of the silicon samples rather carefully. Confirmation of this hypothesis was obtained when counting opposite sides of the same Si bar after anodization in the tracer solution. While the reproducibility of the amount of phosphorus incorporated into the oxide was in general better than 1%, the two surfaces of the sample usually had distinctly different counts, each fully reproducible.

Table III. Tracer data on reproducibility of phosphorus incorporation

Anodization carried out in solution of $H_4P_2O_7$ in THF

Sample No.	Phosphorus concentration in oxide (150v film)
1	3.1×10^{21} cm^{-3}
2	3.2×10^{21} cm^{-3}
3	3.1×10^{21} cm^{-3}
4	3.1×10^{21} cm^{-3}

Note: Tracer data are sensitive to surface roughness of individual wafers.

Table III shows the kind of reproducibility obtained by successive anodizations in the same batch of pyrophosphoric acid/THF solution. The same kind of data also were obtained with the most concentrated DEP/NO_2^--THF solutions. No attempt was, however, made to establish reproducibility data by tracer experiments with the more dilute solutions because of the temperature effect and the practical impossibility of stirring these solutions. Reproducibility data with the more dilute solutions were obtained therefore from the diffusion results with doped oxides grown in nontracer solutions (thermostated and stirred). Figure 5 shows these results for the 10^{-3}:1 DEP/NO_2^-/THF solution. These data represent, so to say, the "worst possible cases," since 16 consecutive anodizations were carried out in the same batch of solution, the series spanning a period of 36 days. Normally, solutions would be discarded after a much smaller number of anodizations. In addition, the statistical error inherent in the diffusion procedure enters into the results. In view of these additional factors the reproducibility of the average sheet conductivity, calculated on the assumption of an error of $\pm$ 0.2μ in junction depth, and $\pm$ 10% in sheet resistance measurement is considered satisfactory at this level (about 26 ohms/square) of sheet resistance.

Loss of Phosphorus from Doped Oxide During Diffusion

Unprotected films.—During the earlier phases of this work nondoped anodic oxide films of sufficiently good quality to prevent out-diffusion of phosphorus from the doped oxide underneath were not available. For this reason the doped oxide was not covered by a nondoped film, and the tracer runs were carried out in sealed quartz tubes. Considerable loss of phos-

4	20	30	34	36
5	45	13	40	47
6	60	18	37	45

phorus to the surroundings during the first few minutes at high temperature was observed, as well as some back-indiffusion of phosphorus into the oxide during longer diffusion times. Due to the density of quartz the diffusion of phosphorus into the quartz walls is slow, so that the surface concentration of phosphorus at the surface of the wall remains high. When the anodic oxide source becomes depleted due to diffusion into the silicon, phosphorus from the quartz walls diffuses back into the anodic oxide and from there into the silicon. Table IV gives some semiquantitative data. It has been established that the losses of phosphorus to the surroundings are even greater in an open flow system.

It was also observed that heavily phosphorus-doped anodic films disintegrated when heated to high temperatures in high vacuum. A background pressure of 0.025 ± 0.005 Torr of oxygen was required to stabilize an anodic oxide film with about 10 w/o (weight per cent) P_2O_5 for 2 hr at 1170°C under continuous pumping. Anodic oxide films grown in a nitrite/THF solution (no phosphorus) showed no deterioration at oxygen pressures as low as 0.01 Torr under the same conditions. The background pressure of oxygen required for stabilization is presumably a function of the phosphorus concentration of the film.

Protected films.—All of the diffusion results presented here (with the exception of Table IV) were obtained from silicon samples on which the doped oxide had been anodized to 150v, and a nondoped oxide grown to a total of 250v in a solution of 1.5g nitrite in 100 ml THF. The nondoped oxide grows on top of the doped oxide because anodic oxide growth on silicon, in all electrolytes tested so far, occurs by cation migration (1). It was found that the quality and thickness of the oxide grown in the nitrite-THF solution was sufficient to practically eliminate out-diffusion of phosphorus from the sample for about ½ hr at 1200°C in the case of very heavily doped oxide films and for correspondingly longer times in the case of more weakly doped oxide films. The diffusivity of phosphorus in SiO_2 is strongly concentration dependent (5). Since heavily doped oxide films are used for shallow emitter diffusions and do not require more than 20-30 min at 1200°C, these anodic oxide covers can be used for emitter, base, and collector diffusions. It is therefore possible to cover anodic oxide diffusion sources on silicon with a nondoped anodic oxide film, and to diffuse the sample in an open tube without contaminating the furnace tube or unprotected regions of the surface. This is an important aspect to be considered when fabrication of complementary device structures (6) by simultaneous diffusion of boron and phosphorus is undertaken. It also should enable considerable simplification of the diffusion apparatus. Table V shows the losses of phosphorus from the doped oxide during anodization to a higher voltage in the nitrite/THF solution, as well as the subsequent losses from the Si-SiO_2 system during subsequent diffusion at 1200°C. It can be seen that the losses in either case are quite small. It is not certain that there is any loss of that phosphorus which is incorporated into the doped oxide, when the sample is anodized to a higher voltage in the nitrite/THF solution. It is known that phosphate is tenaciously adsorbed to the oxide surface subsequent to anodization in phosphate solution

Table V. Tracer data on loss of phosphorus from doped oxide films during subsequent anodization to deposit protecting oxide, and during diffusion for 2 hr at 1200°C in flowing nitrogen

Counts/sec from silicon bars anodized in DEP^{32}-$NaNO_2$-THF solution, normalized to standard date: (a) after anodization to 150v in tracer solution; (b) after coating with additional SiO_2 (anodic or pyrolytic); (c) after diffusion for 2 hr at 1200°C in flowing N_2, flow rate 1500 cc/min, 1 in. Φ tube.

* Sample C was diffused for 3 hr at 1200°C.

** These anodizations were carried out at a time when solution No. 2 had already deteriorated by radiolysis and the amount of phosphorus incorporated had dropped drastically.

*** Sample Y has an emitter type doped oxide, which normally would be diffused only for 20-30 min. The prediffusion phosphorus concentration in the oxides of samples C through K was of the order 1.5×10^{20} atoms P/cm³ SiO_2. The prediffusion concentration of phosphorus in the oxide of sample Y was 3.2×10^{21} atoms P/cm³ SiO_2.

Legend for the different coating methods:
1. Additional nondoped anodic oxide film equivalent to 150v (900Å).
2. Additional nondoped anodic oxide film equivalent to 200v (1200Å).
3. 5000Å pyrolytic SiO_2 on top of nondoped oxide (type 1 coating).
4. 5000Å pyrolytic SiO_2 directly on top of doped anodic oxide.

(1), and cannot be removed completely by rinsing with various solvents. It may be this chemisorbed phosphorus which shows up as a "loss" during anodization to a higher voltage in the nitrite/THF solution. Also shown in Table V is sample Y, anodized in $H_4P_2{}^{32}O_7$ in THF solution (*i.e.*, an "emitter anodization"). It can be seen that this sample suffered an 11% loss during the 2 hr diffusion.

An unexpected effect, recorded in Table VI, was noticed when the effectiveness of oxide films of different thicknesses and of different methods of deposition, in suppressing the out-diffusion of phosphorus during heat treatment, was investigated. The ratios shown in Table VI were obtained by counting the oxide covered Si wafers in situ, the stripping the oxide in HF, and recounting the wafers in situ. The HF solutions also were evaporated to dryness and measured as an additional check. It can be seen that thicker oxide films cause a greater percentage of the original total phosphorus present in the oxide source to diffuse into the silicon. The density of the oxide film may also be involved. Since in every case not more than about 5% of the phosphorus was lost to the surroundings during heat treatment, there is no obvious explanation for this effect.

Contamination of Anodic Oxide with Sodium or Potassium Ions. Tracer Run with K-42

The early work with the DEP-nitrite-THF system was done with sodium nitrite. It had been established

Table VI. Effect of additional nondoped oxide on percentage of phosphorus driven from the oxide into the silicon by diffusion for 2 hr at 1200°C

Kind and thickness of oxide coating	Ratio $\frac{\text{Phosphorus in Si}}{\text{Phosphorus in Si} + SiO_2}$, %
1. 150v doped oxide + additional 100v of undoped anodic oxide	42
2. 150v doped oxide + additional 200v of undoped anodic oxide	65
3. 150v doped oxide + additional 150v undoped anodic oxide, followed by 5000Å of pyrolytic oxide (deposition temperature 750°C)	68
4. 150v doped oxide + additional 5000Å of pyrolytic oxide (deposition temperature 750°C)	75

that 5 ohm-cm p-type silicon, anodized in a sodium nitrite/THF solution and then diffused at 1200°C gave no indication of the presence of an n-type dopant (sodium ions) in the anodic oxide film. During the course of the work unexplained n-type doping to a depth of a couple of microns was observed on silicon surfaces protected with this type of anodic oxide, especially if the oxide had been grown at 0°C instead of at room temperature. Substitution of potassium nitrite for sodium nitrite solved the difficulty from the point of view of device fabrication. It was felt desirable to investigate whether potassium is at all incorporated into the anodic oxide film, and what precautions have to be observed to prevent incorporation. A tracer run with K-42 was therefore carried out.

Since $K^{42}NO_2$ is not available commercially, and its synthesis would have posed considerable difficulties, a small quantity of $K^{42}NO_3$ was obtained from Oak Ridge National Laboratories, and was diluted 10:1 with nonradioactive KNO_2. The specific activity after dilution was 200 mc/g potassium. While in general, it is not desirable to have nitrate ions present during anodization, because of the increase in electronic leakage current, it was expected that nitrate ions could be tolerated at the 10:1 dilution. Anodizations in the tracer solution (0.22g "KNO_2"/10 ml THF) showed no anomalous behavior. The half-life of K-42 is only 12.5 hr. The experiments therefore had to be carried out essentially without control runs, and the results should be considered only as qualitative.

It was found that the anodic SiO_2 film formed in the tracer solution showed an appreciable activity but that 2/3 of this activity could be removed by anodization to a slightly higher voltage in nontracer KNO_2/THF solution. It is not known whether the amount of K-42 that could be removed was only chemisorbed to the surface of the oxide or some of the potassium ions were sufficiently mobile to be extracted by the anodic bias. The incorporation of protons into anodic oxide films grown in aqueous solutions is by now well documented (7). A model has been proposed (8) according to which protons diffuse into the oxide film when the anodic field strength opposing such diffusion, is lowered below a certain critical value. Due to the relatively large size of the potassium ion this explanation for the removal of 2/3 of the radioactive potassium appears unlikely but cannot be disregarded altogether. In any case, only 1/3 of the potassium initially present was incorporated into the anodic oxide in immobile form. This amount corresponded to 1.06×10^{-3} w/o K_2O.

A sample treated in this way was diffused at 1200°C for 2 hr in a sealed quartz tube with argon backfill. The amount of K-42 on the sample was then found to have decreased appreciably. It is not known whether this decrease is due to out-diffusion only, or whether isotopic exchange with nonradioactive potassium on the walls of the quartz tube may also be involved. 80% of the K-42 which had remained on the sample had remained in the oxide film, since it could be removed from the sample by a dip in concentrated HF. The remaining 20% had diffused into the silicon, confirming the suspected n-type contamination by alkali ions. The activity on the Si sample was too low to attempt establishment of a diffusion profile.

Next experiments were carried out to measure the effects of current density and temperature of the anodizing solution on the amount of potassium incorporated into the oxide. While such effects may exist, they were completely overshadowed by another effect; the amount of potassium incorporated into the oxide increased with each additional anodization in the same batch of solution, and eventually reached a value about 100 times larger than that observed during the first anodization. It thus appears that the passage of current through the solution causes a chemical change in composition which favors the incorporation of alkali ions. Since the volume of the tracer solution was very small, the effect would be very pronounced.

Enough DEP was then added to the K-42 tracer solution to arrive at the over-all composition of solution No. 1 (see Fig. 1). Anodization in this solution seemed to indicate that the amount of potassium incorporated into the oxide had decreased due to the presence of DEP in the solution; the data on this particular point are questionable, due to the statistical error involved in counting the activity. The more surprising result, however, was that after diffusion at 1200°C all of the potassium present on the sample had been transferred into the silicon. No activity could be detected when the anodic oxide, after diffusion, was dissolved in HF, the solution evaporated to dryness and the residue counted.

The above observations explain why n-type doping by alkali ions had been observed only in sporadic fashion when the sodium nitrite/THF solution was used; the number of anodizations in one and the same batch of solution (for a given volume of solution) is of great importance.

Device Fabrication

Phosphorus-diffused diodes.—Many diodes were fabricated in a preliminary attempt to show the feasibility of producing good junction characteristics. Sharp reverse breakdowns in the range of 60-80v on 2 ohm-cm p-type substrate were typical. The breakdown voltage is less than expected from the resistivity of the substrate. This is probably an impurity effect since the diodes had not been gettered (9).

Phosphorus and boron.—The availability of localized, phosphorus-doped diffusion sources opens the way to the simultaneous, side by side, diffusion of n-type and p-type dopants. Since boron and phosphorus have very nearly equal diffusivities in silicon and because the diffusion of boron into silicon is masked by SiO_2, it is possible to obtain nearly identical diffusion profiles for n-type and p-type dopants in this manner, and to fabricate complementary integrated devices on the same chip of silicon. Figure 6 shows a complementary pnp-npn pair [Fig. 3 of reference (6)] in which the n-type diffusions were carried out from phosphorus-doped anodic oxide films. The diffusion data, obtained on simultaneously diffused control chips, are shown in Table VII.

Figure 7 shows the collector characteristics of an npn double diffused planar transistor. The n-type silicon substrate of 1 ohm-cm resistivity served as collector, the base was produced by conventional diffusion of boron from the gas phase, and the emitter was diffused from a phosphorus-doped anodic oxide. Figure 8 shows the performance of a pnp transistor in which the collector was produced by conventional diffusion of boron into 1 ohm-cm n-type silicon. The base region was produced by diffusion of phosphorus from a doped oxide, and the emitter by conventional boron diffusion. It must be stressed that these devices have not yet been optimized as to their base widths, since the goal was merely to show feasibility; nor has any gettering procedure been applied. The general

Fig. 6. Complementary npn-pnp transistor pair produced by phosphorus diffusion from doped anodic oxide films.

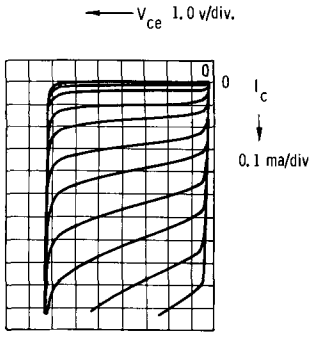

Fig. 8. PNP common emitter transistor characteristics: i_b = 0.01 ma/step; h_{fe} = 12.

method of fabricating complementary npn-pnp transistor structures on the same silicon substrate is described elsewhere (6).

Phosphorus and gallium or aluminum.—If a p-type dopant is used which penetrates SiO_2 masks easily, and which diffuses faster in silicon than does phosphorus, then the fabrication of npn mesa type transistors, or of 4-layer npnp power switches, by a single heat treatment is possible. Gallium and aluminum satisfy this requirement.

Phosphorus-gallium simultaneous double diffusions have been carried out using sealed quartz tubes with argon backfill. The silicon samples (30 ohm-cm n-type) were anodized to either 100 or 150v in the pyrophosphoric acid-THF solution, but were not given a protective oxide coating. During diffusion the silicon was kept at 1175°C, the metallic Ga source at 900°C by means of a two-zone furnace. All junctions produced were perfectly planar. Table VIII lists the values obtained in separate experiments for surface concentrations and diffusion constants after gallium diffusions from the gas phase and phosphorus diffusion from the anodic oxide source under the specified conditions. The diffusion constant for Ga was found experimentally to lie between the values given by Fuller and Ditzenberger (11) and by Kurtz and Gravel (12). The values found for phosphorus under the given special conditions will be discussed in more detail in Part III of this paper (10). Table VIII also shows the junction depths predicted by using the values obtained from the single diffusion experiments, while the last column gives the experimentally measured junction depths of the npn structures produced. There is apparently no large interaction between the two diffusants for these experimental conditions.

Table IX is analogous to Table VIII for an aluminum-phosphorus double diffusion. The whole system (Si + anodic oxide source + metallic aluminum sources) was held at 1175°C in this case. The silicon samples had been anodized only to 60v in the pyrophosphoric acid-THF solution. The measured value of D for aluminum from the single diffusions agreed with that of Fuller and Ditzenberg. Again the agreement between the experimental and predicted junction depths is good, somewhat better than 10% in this case.

A TRINISTOR was also fabricated from one of the phosphorus-aluminum double diffused structures, with a breakover voltage of 800v at room temperature.

Conclusions

It has been shown that electrochemical techniques can be employed for the fabrication of phosphorus-doped diffusion sources on silicon. Sufficient control can be exercised over the amount of phosphorus incorporated into the diffusion source, and its out-diffusion into the surroundings practically eliminated by means of a protective nondoped oxide film, to make the technique useful for all phases of device fabrication (emitter, base, and collector diffusions). Diodes, transistors, and some trinistors fabricated in this way had acceptable characteristics.

Acknowledgments

This work was jointly supported by the Electronics Development Laboratory, Aeronautical Systems Division, Wright-Patterson Air Force Base, Dayton, Ohio, and by Westinghouse Electric Corporation. Thanks are due to Professor J. O'M. Bockris, of the University of Pennsylvania, for a helpful discussion, and to Mr. A. Knopp, of the Westinghouse Semiconductor Division, Youngwood, for the aluminum diffusions. The untiring help of N. Roney and J. Moyles with the experiments is gratefully acknowledged.

Note added to revise manuscript: The authors are indebted to the reviewer for drawing their attention to ref. (13), which deals with the diffusion of impurities from doped SiO_2 films prepared by co-sputtering into GaAs.

Manuscript received Jan. 25, 1965; revised manuscript received April 20, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

Interstitial-Substitutional Diffusion in a Finite Medium, Gold into Silicon

G. J. Sprokel

Systems Development Division, International Business Machines Corporation, Endicott, New York

ABSTRACT

A differential equation describing interstitial-substitutional diffusion is derived. Boundary conditions are selected pertinent to diffusion into a finite medium. Laplace's tranformation is used to solve the differential equation. The result is plotted as a relation between dimensionless quantities. The quantities D_1 and C_{01} can be calculated from the intercept and the initial slope, respectively. The theory is applied to the diffusion of gold into silicon wafers of varying thickness.

Interstitial-substitutional diffusion was proposed by Frank and Turnbull (1) to explain the diffusion of copper in germanium. The idea was used by Dash (2) and by Wilcox and LaChapelle (3, 4) for the diffusion of gold in silicon. More recently, this same idea was used by Weisberg and Blanc (5) to describe the diffusion of zinc in GaAs and by Pumper and Prostoserdova (6) for zinc in InSb.

Briefly, it is assumed that the diffusing species occupies interstitial positions in the host lattice; however, as it approaches sufficiently close to a lattice vacancy it may convert to a substitutional position by occupying that vacancy. Substitutional diffusion is not ruled out, but it is assumed that interstitials diffuse several orders of magnitude faster than either substitutionals or vacancies.

The continuity equation for this model is

$$\frac{\partial c_i}{\partial t} = D_i \frac{\partial^2 c_i}{\partial x^2} - k' c_i c_v \qquad [1]$$

The first term on the right describes the diffusion of interstitials into the volume element. The second term is the decrease in the local interstitial concentration caused by the conversion of interstitials to substitutionals. Since each conversion requires one vacancy, the rate is proportional to the local concentrations of

interstitials (c_i) and vacancies (c_v). The rate constant is k'.

The general solution of Eq. [1] is derived below. In order to illustrate its use in calculating D_i, the solution is applied to the diffusion of gold in silicon. Sufficient data for this system were available. Some consequences of the model are also discussed. The solution is an application of Laplace transformation theory; this approach has not been taken in earlier publications.

General Solution of the Diffusion Equation

The boundary requirements to be imposed on Eq. [1] must reflect the experimental conditions. The boundary conditions are

$$c_i(0,t) = c_0 \quad t > 0 \qquad [2]$$

$$c_i(x,0) = 0 \quad 0 \leq x \leq w \qquad [3]$$

$$\left(\frac{\partial c_i}{\partial x}\right)_{x=w} = 0 \quad t > 0 \qquad [4]$$

Equation [2] is the supply equation; it requires that the concentration of interstitials at the surface $x = 0$ be constant throughout the experiment. The quantity c_0 is interpreted as the solubility of interstitials, and w is the wafer thickness. Equation [3] is self evident. Equation [4] states that the gradient be zero at the opposite surface of the wafer, $x = w$. Experience indicates that fast diffusing impurities penetrate through the entire wafer during a normal diffusion run. The boundary condition merely states that the diffusant shall not leave the wafer at the opposite side. It excludes any interaction between the surface and the diffusing impurity.

The solution of Eq. [1], subject to the boundary conditions, determines $c_i(x,t)$ everywhere. However, the experimentally observed concentration at a point x is the sum of the local interstitial and substitutional concentrations. The two terms cannot be determined independently. During the experiment, the rate at which substitutionals are formed is given by the second term on the right in Eq. [1]. Thus

$$\frac{\partial c_s}{\partial t} = k' c_i c_v \qquad [5]$$

Equation [5] is assumed to be valid until the lattice becomes saturated with substitutionals. Once $c_i(x,t)$ is found, $c_s(x,t)$ can be obtained by integration. The sum $c_m = c_i + c_s$ is the experimentally observed concentration.

In solving Eq. [1], as well as in carrying out the integration [5], it is assumed that c_v is independent of t. To solve Eq. [1], let

$$\bar{c}(x,p) = \int_0^\infty c_i(x,t)\, e^{-pt}\, dt \qquad [6]$$

Equation [1] transforms to

$$\frac{\partial^2 \bar{c}}{\partial x^2} - \frac{p+k}{D_i}\bar{c} = 0 \qquad [7]$$

in which $k = k'c_v$.

The general solution of Eq. [7] is

$$\bar{c} = A\, e^{+\sqrt{\frac{p+k}{D_i}}\,x} + B\, e^{-\sqrt{\frac{p+k}{D_i}}\,x} \qquad [8]$$

Equations [2] and [4] transform to

$$\bar{c}(0,p) = \frac{1}{p} c_0 \qquad [9]$$

$$\left(\frac{\partial \bar{c}}{\partial x}\right)_{x=w} = 0 \qquad [10]$$

Inserting Eq. [9] and [10] into Eq. [8], one obtains expressions for A and B. Inserting these back into Eq. [8] one arrives at

$$\bar{c} = c_0 \frac{\cosh \sqrt{\frac{p+k}{D_i}} \cdot (x-w)}{p \cosh \sqrt{\frac{p+k}{D_i}} \cdot w} \qquad [11]$$

The inverse transform is [8], [9]

$$\frac{c_i}{c_0} = \frac{\cosh \sqrt{\frac{k}{D_i}}\,(w-x)}{\cosh \sqrt{\frac{k}{D_i}}\,w} - 2\sum_0^\infty (-1)^n \frac{(2n+1)\frac{\pi}{2} \cos (2n+1)\frac{\pi}{2}\left(1-\frac{x}{w}\right)}{\left\{(2n+1)\frac{\pi}{2}\right\}^2 + \frac{kw^2}{D_i}} e^{-\left[\left\{(2n+1)\frac{\pi}{2}\right\}^2 + \frac{kw^2}{D_i}\right]\frac{D_i t}{w^2}} \qquad [12]$$

In view of Eq. [5], c_s is obtained from

$$\frac{c_s}{c_0} = k \int_0^t \frac{c_i(x,\tau)}{c_0} \cdot d\tau \qquad [13]$$

$$\frac{c_s}{c_0} = \frac{kt \cosh \sqrt{\frac{k}{D_i}}\,(w-x)}{\cosh \sqrt{\frac{k}{D_i}}\,w} - 2\sum_0^\infty (-1)^n \frac{(2n+1)\frac{\pi}{2}\cdot\frac{kw^2}{D_i} \cos (2n+1)\frac{\pi}{2}\left(1-\frac{x}{w}\right)}{\left[\left\{(2n+1)\frac{\pi}{2}\right\}^2 + \frac{kw^2}{D_i}\right]^2} \cdot \left\{1 - e^{-\left[\left\{(2n+1)\frac{\pi}{2}\right\}^2 + \frac{kw^2}{D_i}\right]\frac{D_i t}{w^2}}\right\} \qquad [14]$$

Finally, the sum of Eq. [12] and [14] can be written as follows

$$\frac{c_m}{c_0} = 2\frac{kw^2}{D_i}\cdot\frac{D_i t}{w^2} \sum_0^\infty (-1)^n \frac{(2n+1)\frac{\pi}{2} \cos (2n+1)\frac{\pi}{2}\left(1-\frac{x}{w}\right)}{\left\{(2n+1)\frac{\pi}{2}\right\}^2 + \frac{kw^2}{D_i}} + 2\sum_0^\infty (-1)^n \frac{\left\{(2n+1)\frac{\pi}{2}\right\}^3 \cos (2n+1)\frac{\pi}{2}\left(1-\frac{x}{w}\right)}{\left[\left\{(2n+1)\frac{\pi}{2}\right\}^2 + \frac{kw^2}{D_i}\right]^2} \left\{1 - e^{-\left[\left\{(2n+1)\frac{\pi}{2}\right\}^2 + \frac{kw^2}{D}\right]\frac{D_i t}{w^2}}\right\} \qquad [15]$$

Equation [3] was used to express the cosh in terms of a cos series. This simplifies the numerical calcu-

lations slightly. As noted previously, Eq. [15] is valid up to the saturation concentration of substitutionals.

Equation [15] is the desired solution. It is expressed as a relation between the dimensionless quantities c_m/c_0 and $(x/w, D_it/w^2, kw^2/D_i)$. Numerical values of c_m/c_0 can be calculated in terms of these three parameters, although the absolute values of D_i, c_0, and k are as yet unknown. Values of x/w were selected in increments of 0.1 from 0.01 to 1. For each value of x/w, the quantity c_m/c_0 was calculated as a function of D_it/w^2 and kw^2/D_i. A Fortran program[1] was written to perform these calculations. In certain cases, *viz.*, $D_it/w^2 >> 1$ and $x/w = 1$, the series converges rapidly, and manual calculation becomes feasible. For the sake of brevity, numerical values of c_m/c_0 for $x/w = 1$ only, are listed in Table I. However, these are sufficient for calculation of D_i.

Figure 1 illustrates the function c_m/c_0 (Dt/w^2) for kw^2/D_i from 0 to 10. The function has a maximum for $kw^2/D_i \approx 3.5$ and the curves beyond this maximum are indicated as broken lines for purposes of clarity. First, consider the family of curves for which kw^2/D_i is far below 3.5. For this group, $c_m/c_0 \approx 0$ for $D_it/w^2 < 0.2$. As a first approximation this can be regarded as an intercept and an estimate of D_i can be made independent of c_0 or kw^2/D_i. As D_it/w^2 increases from approximately 0.2 to 1, c_m/c_0 increases rapidly and almost independently of kw^2/D_i. A first estimate of c_0, independent of kw^2/D_i, can be made from this section of the curve. Finally, beyond $D_it/w^2 \approx 1$, the slope of the curve is determined mainly by kw^2/D_i, and an estimate of k is obtained from this part of the curve. Once approximate values of D_i, c_0, and k are known, further refinement is achieved by iteration. The amount of labor involved is not excessive.

The physical interpretation of the shape of these curves is quite evident. It takes a finite interval of time before the diffusing impurity reaches the opposite end of the wafer. This time lag is mainly determined by the diffusion constant. At the surface $x = w$, most of the impurity is initially in the interstitial mode, and the rate of increase is nearly proportional to c_0. Later on, the interstitial concentration is close to its maximum value, c_0, and is practically constant. The substitutional concentration now increases at a constant rate which is proportional to k.

Consider the curves for which kw^2/D_i is larger than 3.5. These graphs are straight lines and the sharp rise after the initial time lag has disappeared. A large ratio of k/D_i means that the rate at which interstitials change to substitutionals is large compared to the diffusion of interstitials and the interstitial concentration is small everywhere. Thus, the increase in c_m becomes smaller as k/D_i increases.

Inspection of experimental data reveals which case is applicable. For example, if gold is diffused in silicon, the concentration at the surface $x = w$ increases rapidly for short diffusion times and much slower thereafter [ref. (7), Fig. 3 and 4]. Thus, for this system it is probable that $kw^2/D_i < 1$.

[1] This program has not been released and is not available.

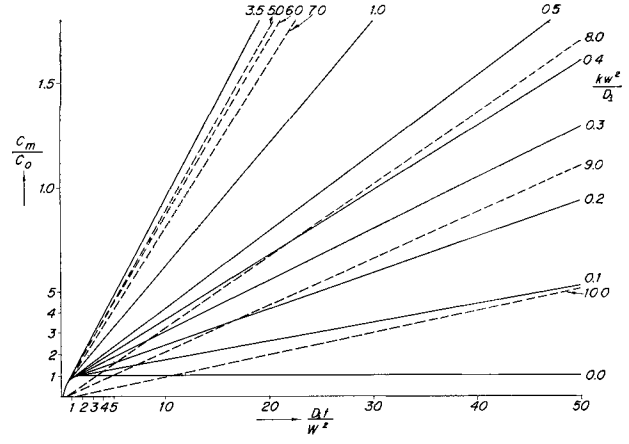

Fig. 1. Graphical presentation of Eq. [15]. c_m/c_0 vs. D_it/w^2 with kw^2/D_i as a parameter. The function has a maximum for $kw^2/D_i \approx 3.5$.

Experimental Data on the Diffusion of Gold in Silicon

Tables II and III summarize data on the diffusion of gold in silicon at 1000° and 1100°C, respectively. The data at 1000°C were taken from the earlier paper (7). The experimental quantities listed in the tables are: the diffusion time; the thickness, w, of the wafer; and the observed gold concentration, c_m, at the surface $x = w$.

The experimental procedures involved have been described before. Briefly, one side of the wafer $(x = 0)$ is plated with gold doped with Au 199. The plated

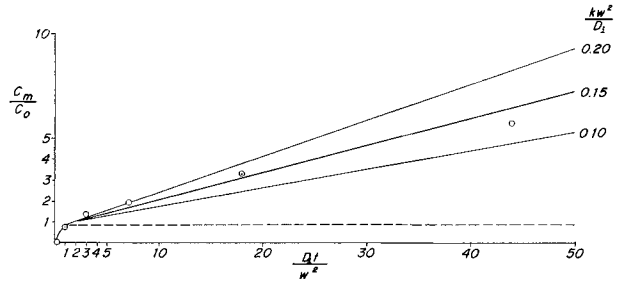

Fig. 2. Graph of Eq. [15] for $kw^2/D_i = 0.15$. Data points are for Au diffused into Si at 1000°C calculated with $D_i = 2 \times 10^{-6}$ cm² sec and $c_o = 7 \times 10^{14}$ cm^{-3}. The broken line represents c_i/c_o for $kw^2/D_i = 0.15$. For $D_i t/w^2 < 1$ $c_i \approx c_m$.

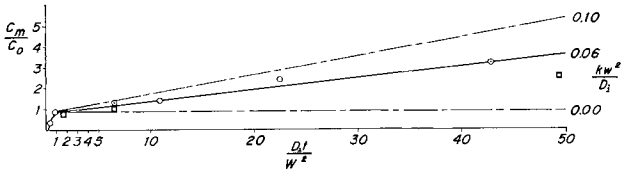

Fig. 3. Graph of Eq. [15] for $kw^2/D_i = 0.06$. Data points are for Au diffused into Si at 1100°C calculated with $D_i = 5 \times 10^{-6}$ cm² sec and $c_o = 9 \times 10^{15}$ cm^{-3}. Data marked (□) from ref. (7). The graph of c_i/c_o for $kw^2/D_i = 0.06$ coincides for all practical purposes with the graph of c_m/c_o for $kw^2/D_i = 0$ and was therefore omitted.

wafer is heated either in an argon atmosphere or in an evacuated capsule. After diffusion, thin slices are etched off sequentially starting at the surface $x = w$. The amounts of gold and silicon in the etchant are determined and concentration profiles are constructed from these data. It was found that the gold concentration was nearly constant throughout most of the wafer. Close to the surface, at $x = w$, c_m is slightly higher. This is a surface effect which was discussed in the earlier paper (7), but is ignored here.

In the last two columns of the tables the values of c_m/c_o and $D_i t/w^2$ are listed for each experiment. D_i and c_o are calculated from the intercept and initial slope of a graph of c_m *vs.* t/w^2 and refined by iteration as discussed above. Figures 2 and 3 represent graphically Eq. [15] for $x/w = 1$ and kw^2/D_i as indicated. The experimental data fall on these curves to within the experimental uncertainty (estimated at 10%). Thus, it is concluded that the model, differential Eq. [1], adequately accounts for the experimental observations. Table IV lists the numerical values of D_i, c_o, and kw^2/D_i.

Wilcox and LaChapelle published (4) values for the diffusivity and the activation energy of gold diffusing in silicon. From these data, one calculates:

$$D_i = 3.2 \text{ to } 15.5 \times 10^{-6} \text{ (at 1000°C)}$$

$$D_i = 4.3 \text{ to } 9.0 \times 10^{-6} \text{ (at 1100°C)}$$

which is in good agreement with the results presented here.

Discussion

The gold diffusion mechanism.—In Fig. 4, c_m/c_o is plotted against x/w for values of $D_i t/w^2$ and kw^2/D_i which are within the range of interest for the gold diffusion problem. For $D_i t/w^2 \geq 1$, the concentration is nearly constant throughout the wafer; for $D_i t/w^2 < 1$, c_m/c_o decreases from approximately 1 to 0. Experimental data on diffusion are usually presented as c_m *vs.* x, but in this case such graphs are not suitable for calculations. Experimental gold concentration profiles were found to conform with Fig. 4 throughout most of the wafer. Data for $x/w < 0.1$ are uncertain because of alloying at the plated surface; whereas for $x/w > 0.9$ the effects of the opposite surface are noticeable. In this region an increase in c_m is observed. This was attributed to an increase in the vacancy concentration near that surface (7).

Table IV. Numerical values

	1000°C	1100C°
D_i in cm² sec^{-1}	2×10^{-6}	5×10^{-6}
c_o in at. cm^{-3}	7×10^{14}	9×10^{15}
kw^2/D_i	0.15	0.06

In Fig. 5, c_i/c_o is plotted against x/w for values of $D_i t/w^2$ and kw^2/D_i as in Fig. 4. If Fig. 4 and 5 are compared, it is seen that for $D_i t/w^2 \leq 1$, $c_i \approx c_m$ everywhere and for $D_i t/w^2 > 1$, $c_i \approx c_o$. Initially and up to diffusion times such that $D_i t/w^2 \approx 1$, gold is present almost exclusively as interstitials. For longer diffusion periods, the interstitial concentration has reached its maximum value, c_o. Further diffusion into a volume element is limited by the rate at which substitutionals are formed. The substitutional gold concentration increases throughout the wafer as $c_o kt$ until saturation is reached.

There is a practical consequence to this. The data in Table IV indicate that c_o increases strongly with diffusion temperature, but k remains constant. Therefore, to obtain a large ratio of c_s/c_i, it is better to diffuse at lower temperature and for a longer time interval. In Fig. 2 and 3, c_i/c_o is also plotted and the ratio c_s/c_i can be obtained from these curves. Note that for an average diffusion run c_s/c_i is still less than 10.

Effect of vacancy concentration.—For the average gold diffusion experiment, $D_i t/w^2 > 1$ (for a 0.010 in. wafer $t = 5$ min at 1000° and 2 min at 1100°C) and, therefore, the parameter k is important. The experiments at 1100°C were performed with wafers obtained from two suppliers. The two kinds of samples do not show a significant systematic difference. It may be assumed that the data in Table IV hold for any carefully grown silicon crystal, in particular, for the average crystal $kw^2/D \approx 0.1$. The parameter k was defined as

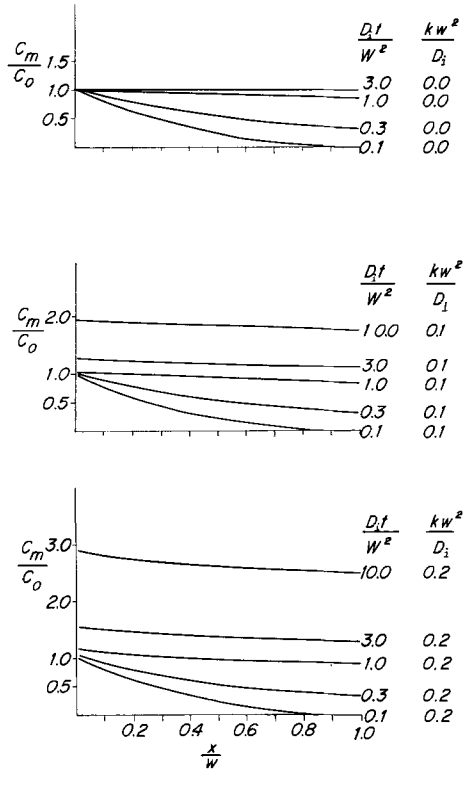

Fig. 4. c_m/c_o *vs.* x/w for $D_i t/w^2$ and kw^2/D_i in the range of interest for gold diffusion (Eq. [15]).

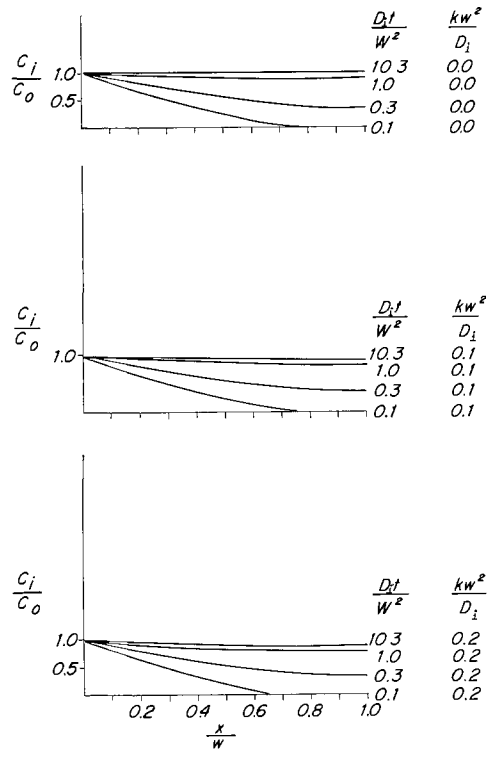

Fig. 5. c_i/c_0 vs. x/w for $D_i t/w^2$ and kw^2/D_i as in ref. (4) (Eq. [12]).

$k = k'c_v$. A local increase in c_v, as expected near a dislocation, results in a proportional increase in kw^2/D_i and therefore in c_m/c_0 (see Fig. 1). The effect is quite large. Take for example a local c_v, 10 times larger than the average. The local gold concentration must then increase about 8 times faster than the average. The diffusion process imposes no limit on c_m, but in practice saturation is soon reached. From the solubility of gold in silicon, as determined by Collins (10) and from the data in Table IV, it follows that at saturation c_m/c_0 is about 18 at 1000° and about 4 at 1100°C. A relatively small local increase in c_v is sufficient to cause an increase in c_m until saturation is reached. Since interstitial gold is still diffusing into the wafer, gold must precipitate out. Dash (2) observed that gold precipitates out at dislocations and discussed this in terms of the interstitial-substitutional mechanism. This is confirmed here in a more quantitative manner.

Comments on the Model

The model, Eq. [1], requires only that the conversion of interstitials is first order in c_i. In particular, no assumptions are made as to the magnitude of c_0 or the value of the ratio c_s/c_i at saturation. If the supply of gold is sufficient, the interstitial and substitutional concentrations will eventually attain their saturation values and these are determined from the experiments. At any point in the wafer the interstitial concentration reaches its maximum (c_0) long before the substitutional. It would be of interest to keep the gold supply below the amount needed to saturate the sample. According to the model, all gold atoms would eventually be incorporated as substitutionals and one could search for any differences in the electrical behavior of the gold. It is questionable whether such experiments can ever be performed (7).

In a sense then, the existence of interstitials is caused by the experimental conditions, and this is a flaw in the model. A different model can be formulated in which one accounts for the generation of interstitials from substitutionals as Frenkel defects. Interstitial gold is properly a cation (11) and as such will tend to react with charged vacancies

$$Au_i^+ + V^- \leftrightarrows [Au_s] + V^o$$

$$V^o \leftrightarrows V^- + \oplus$$

$$[Au_s] + \ominus \rightleftarrows Au_s^- \qquad \text{acceptor center}$$

$$[Au_s] \leftrightarrows Au_s^+ + \ominus \qquad \text{donor center}$$

The continuity equation is

$$\frac{\partial c_i}{\partial t} = D_i \frac{\partial^2 c_i}{\partial t^2} - \alpha c_i + \beta c_s \qquad [1a]$$

which is Eq. [1] with the additional βc_s term describing the generation of interstitials from substitutionals. Equation [1a] cannot be integrated at once; further assumptions are necessary, some of which are briefly discussed below.

If the reverse reaction is allowed, it is tantamount to assuming that equilibrium exists or is eventually reached. Application of chemical reaction kinetics (1, 5) leads to a relation between c_s and c_i. If this relation is linear, as it would be in this case, substitution of it into Eq. [1a] leads to an equation which is of the same form as Eq. [1] except for the factor multiplying c_i. Only the numerical value of this factor is found from the diffusion experiments, but more information is not available. For the reactions outlined above this factor would contain the hole concentration. Wilcox *et al.* (4) found that the diffusion of Au in Si did not depend on the hole concentration which suggests that the correction is not important in this case. However, in other cases (5) such considerations can be quite important.

Formal application of reaction kinetics is questionable, since a substitutional atom does not "react with" a vacancy. The procedure must be regarded as an attempt to arrive at some relation between c_i and c_s which makes Eq. [1a] integrable. Justification lies in the agreement with experimental results.

Diffusion of substitutionals is not ruled out, but the net transport is assumed to be negligible compared to that of interstitials. In a recent article by Kucher (13), no attempt was made to establish a relation between c_i and c_s. Two continuity equations, one for interstitials and the other for substitutionals (each with their own boundary conditions), are solved simultaneously. The rate constants are assumed to be proportional to their respective equilibrium concentrations (solubilities). An expression is obtained for $D_s << D_i$, $c_s^o >> c_i^o$, and $\alpha >> \beta$ (in the terminology of Eq. [1a]). Direct comparison with Eq. [15] is not possible because Kucher assumes the specimen to be infinitely thick even for the fast diffusing species. If the ratio D_s/D_i is indeed of the order 10^{-3} or 10^{-4} (Kucher), the concentration profiles would be given by the sum of a nearly straight line (c_i) and a function which is approximately erfc $x/2\sqrt{D_s t}$ for a diffusion experiment such that $D_i t/w^2 > 1$ but $D_s t/w^2 << 1$. The effect of the erfc term should be largest for small x/w. The experimental data are uncertain near $x/w = 0$ and definite conclusions are not possible. Near $x/w = 1$, still for a short diffusion time, only the interstitial component is important and Kucher's model is arbitrarily close to the one discussed in this paper. Experimental results are available over a range in t/w^2 of nearly 10^3. For long periods the effect of the D_s term should be noticeable throughout a substantial portion of the wafer. However, it was not observed because the concentration profiles remain essentially straight lines (7).

A final comment on Eq. [15] should be made. The series converges slowly and therefore calculations are cumbersome if a computer is not available. The inverse transform of Eq. [11] can be determined by another method. If the cosh term is expanded, a series is obtained which can be transformed term-by-term [ref. (12) lists the appropriate transform]. The series obtained in this way often converge faster; however, the final answer (after solving integral [13]) turned

out to be more involved than Eq. [15]. Therefore, it was decided to program Eq. [15] instead. A complete set of tables for c_m/c_0 and c_i/c_0, for x/w between 0.01 and 1, in increments of 0.1 is available on request.

Conclusion

The diffusion of gold in silicon can be described quite well by an interstitial-substitutional mechanism. Initially and up to the diffusion period, $D_i t/w^2 \approx 1$, gold is present almost exclusively as interstitials. Toward the end of this period the interstitial concentration has become constant throughout the wafer. Further diffusion is limited by the rate at which substitutionals are formed. The gold concentration remains constant throughout the wafer and increases linearly with time until the maximum solubility is reached. Dissociation of substitutionals is not excluded, but information on the equilibrium between interstitials and substitutionals is not available from the diffusion data. A local increase in the vacancy concentration results in an accumulation of substitutional gold in that area.

The Etching and Polishing Behavior of Ge and Si with HI

A. Reisman and M. Berkenblit

IBM Watson Research Center, Yorktown Heights, New York

ABSTRACT

Studies of the etching and vapor polishing behavior of Ge with HI as a function of temperature, linear gas stream velocity, etch rate, and etchant concentration, indicate that temperature is the most significant parameter affecting the smoothness of the etched surfaces. A less pronounced effect is the occurrence of microscopic pitting above a critical etchant concentration. The other parameters did not appear to affect surface characteristics. Less detailed studies of the HI etching of Si have been used to define practical conditions for the vapor polishing of Si. A qualitative analysis of the requirements for a usable vapor polish and the experimental conditions necessary to quantitatively define the kinetics of solid-gas etching reactions are presented.

During the past few years, several reports have been issued on the etching kinetics and polishing behavior of Ge and Si in anhydrous HCl at elevated temperatures (1-5). Analogous studies using HBr and HI have not been reported during this period, perhaps due to the unavailability of these reagents in pure enough form.

Recently, a method for instantaneously and continuously generating HI of high purity in a noncorrosive system was described in conjunction with its use in a Ge disproportionation transport system (16). Since the possible effects of contamination are minimized with this HI source, and because the use of HI as an in situ polishing agent is compatible with open tube vapor growth schemes, investigation of its etching and polishing behavior with Ge, Si, and GaAs was begun. The present report describes the results of studies with Ge and presents some less extensive Si data. From the observed etching characteristics as a function of the several experimental parameters examined, specific requirements for deriving kinetic data from open tube experiments are indicated.

Experimental Procedure

Semiconductor preparation.—As starting materials, two different 0.01 ohm cm p-type Ge crystals pulled in the <111> direction were cut into circular wafers 1.39 cm^2 with their surfaces perpendicular to the <211> direction. When suitable vapor polishing conditions were established, other common orientations and a range of resistivities of both n- and p-type wafers were also studied with comparable polishing results to those on <211> surfaces being obtained. The quantitative etching and polishing data to be described, however, were all obtained on <211> surfaces.

The sawed wafers were chemically polished with NaOCl solutions (7) in order to remove surface damage introduced during sawing and lapping procedures. Final wafer thicknesses were from 18-20 mils.

Chemical reagents.—The HI generator described in ref. (6) was charged with Gallard-Schlesinger Ultrapure I_2, and during the course of the studies two separate charges were used without any resultant differences in etching behavior. Matheson Ultra High Purity H_2 (10 ppm maximum impurity) and Matheson Commercial He (100 ppm maximum impurity) were employed as carrier and flushing gases, respectively, without further purification. A number of bottles of each gas were used without any differences observed among them insofar as etching results were concerned. The Pt wool catalyst tower at the output side of the iodine bed was maintained at between 400° and 450°C, and gas flow rates were monitored with wet test meter calibrated ball flow meters.

Apparatus and etching procedure.—Figure 1 is a schematic representation of the apparatus employed.

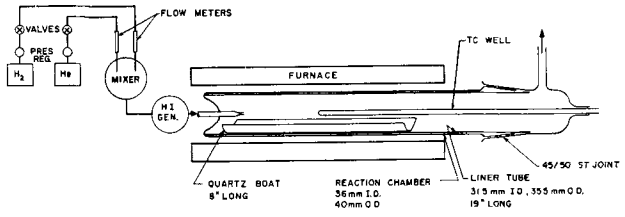

Fig. 1. Schematic representation of III etching apparatus

It consists of the HI generator and a resistance wound furnace surrounding an etching chamber. Close fitting liner tubes of known bore were used to facilitate cleaning after each etching experiment, and nests of these liners could be used to vary linear gas stream velocities without altering the quantity of etchant passing over the wafer in a defined time.

A wafer, after being x-ray analyzed to verify the exactness of orientation subsequent to chemical polishing, was placed horizontally into a quartz open ended boat and loaded into the liner of the etching chamber. In this position, the wafer made contact with the boat at only two points, being essentially suspended in the gas stream. The system was flushed for 15 min in H_2 flowing at 177 cm/min at room temperature (1380 cm³/min input flow rate). The furnace, monitored by a moveable Pt-10% Rh thermocouple encased in a quartz well along the furnace axis, was then brought to temperature. The etchant mixtures were fed into the system at different velocities, at different concentrations and for different time periods, depending on the conditions being evaluated. When the flow of etchant was terminated, the system was flushed with H_2 for 30 min at the flow rate employed, then for 5 min at 1380 cm³/min after which time the furnace was turned off. The gas flow was continued while the furnace cooled.

Results

Figure 2 presents graphs of Ge etch rate in mg loss/defined time/defined area as a function of linear gas stream velocity at each of four etching temperatures. The data when multiplied by the factor 0.144 are converted to mg/cm²/min. The design of the HI generator is such that the H_2 carrier gas passing through it becomes saturated with iodine at the flow rates required to generate the linear velocities specified; therefore, for a given iodine source temperature, the mole fraction of HI in the gas input to the etching chamber was constant for the temperatures and linear gas stream velocities shown. For the data used to define the curves of Fig. 2, the iodine source was maintained at 95°C providing an HI mole fraction of 0.0927. Weight losses for these and subsequent etching experiments were reproducible to ±1 mg, at least three determinations being made for each piece of data.

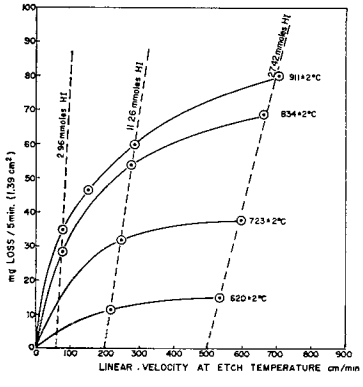

Fig. 2. Variation of etch rate with linear velocity at different etch temperatures; <211> 0.01 ohm-cm P pulled Ge; NaOCl prepolished; I_2 source 95°C.

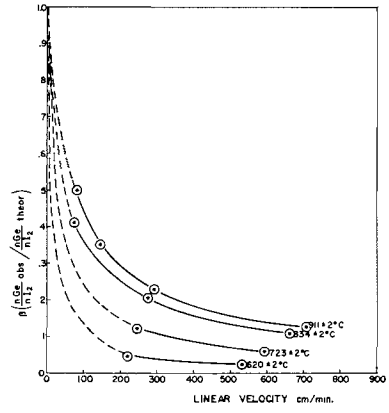

Fig. 3. Plot of efficiency *vs.* linear velocity; <211> 0.01 ohm-cm P pulled Ge, NaOCl prepolished; I_2 source 95°C.

It is seen from Fig. 2 that each of the curves exhibits a sharp initial slope and then tends to level off. The dashed lines connecting the different isotherms represent lines of constant etchant flux. Since at a given input flow rate of hydrogen, the linear velocity in the etching chamber will increase with increasing temperature due to gas expansion, these constant flux lines exhibit a finite positive slope. Consequently, under conditions of constant HI input mole fraction, constant system geometry, and constant HI flux, the average residency time of an etchant particle in the vicinity of the wafer decreases with increasing temperature. The temperature interval covered by the curves of Fig. 2 was specifically chosen because the theoretical amount of Ge brought into the vapor phase per mole of I_2 introduced as HI at each of the temperatures is essentially the same (8). Thus at 620° the thermodynamic vapor phase Ge/I_2 mole ratio is 0.64, and at 723°-911° it is 0.65. It is seen, therefore, from Fig. 2 that at constant HI flux the efficiency increases with increasing temperature. Fig. 3 presents efficiency *vs.* linear velocity graphs for the data of Fig. 2. The efficiency, β, is the fraction of the theoretical (thermodynamic) quantity of Ge removed from the sample.

Under the etching conditions leading to the data of Fig. 2, the appearance of wafers after treatment was found to be independent of linear gas stream velocity at any particular etching temperature. There were, however, marked differences in the appearance of wafers from temperature to temperature, these surface effects being shown in Fig. 4 and 5. Starting at 834° the wafers began to give evidence of nonselectivity of

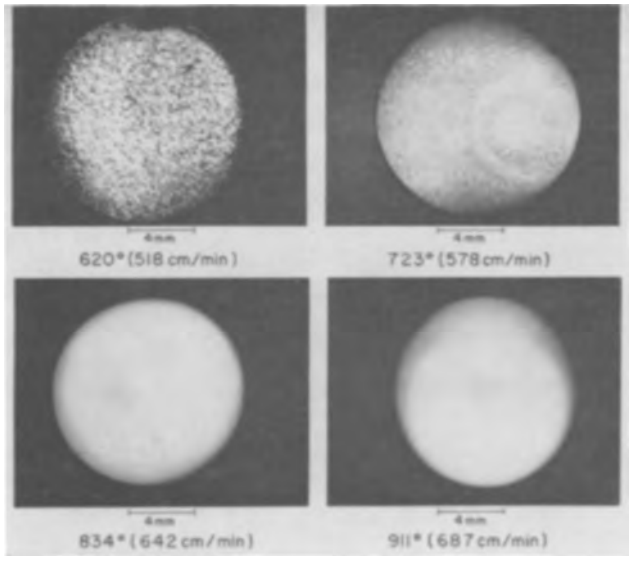

Fig. 4. Variation of surface characteristics with etch temperature

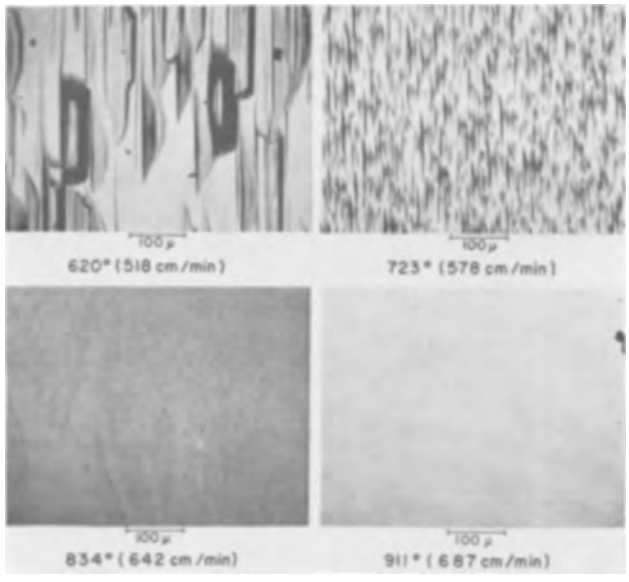

Fig. 5. Variation of surface characteristics with etch temperature

surface etching, and at 911° etching appeared to be completely surface nonselective. Although some edge rounding was observed on polished wafers, there was little tendency for the lead edge of the wafer to etch faster than the tail end. The significance of this observation will be discussed subsequently.

Figure 6 shows plots of the variation of etching rate with source iodine pressure at three different temperatures. The data for each of the curves was taken at constant input flow rate of H_2 (1380 cm³/min). Consequently, the linear velocity at each etching temperature is different as noted in Fig. 6. In addition, a small variation in linear velocity occurs along each curve due to the variation of HI mole fraction. The linear velocities given were calculated by considering only the H_2 input flow rate and the etching temperature.

With increased iodine pressure it is seen that the curves tend to level off, this leveling off being more pronounced at the lowest etching temperature. In addition, it is seen that at low I_2 source pressures, the effect of source temperature on the etch rate becomes small as the temperature of etching is increased. Figure 7 demonstrates this behavior more effectively. The data for Fig. 7 were acquired by determining the variation of etch rate with variation of etching temperature at three different iodine source temperatures. Again each of the curves was evaluated at a constant H_2 input flow rate of 1380 cm³/min. Consequently, the linear velocity in each of the curves varies along the curve, this time because of temperature variation. Relative to the lowest etching temperature on each curve, T_1, the fraction variation with increasing temperature, T_2, is given by $(T_2 - T_1)/T_1$. In addition, at

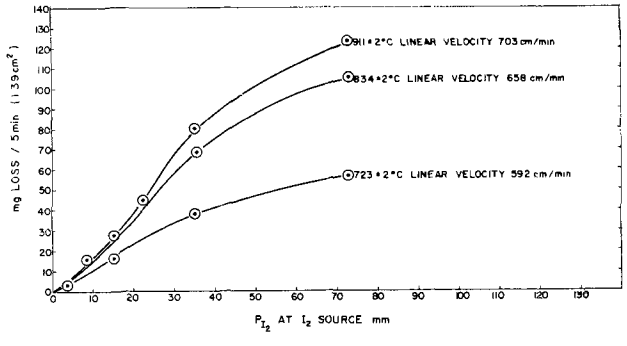

Fig. 6. Variation of etching rate with iodine source pressure at different etching temperatures. <211> 0.01 ohm-cm P pulled Ge, NaOCl prepolished; input flow rate of 1380 cm³/min.

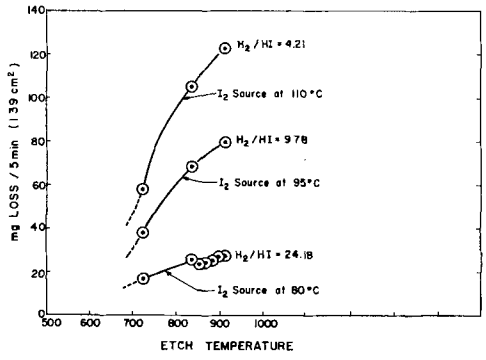

Fig. 7. Variation of etching rate with etching temperature at different I_2 source temperatures. <211> 0.01 ohm-cm P pulled Ge, NaOCl prepolished; input flow rate 1380 cm³/min.

any given temperature, the linear velocity for each curve is slightly different due to the effect of different HI mole fractions being present.

The macroscopic polish quality as a function of iodine source pressure was essentially independent of etchant concentration, evidence for good polishing becoming noticeable at 834°, and superior polishing being detected at 911° at all etchant concentrations. However, a less pronounced effect at 911° due, it appears, to etchant concentration was observed. Thus, the surfaces showed few microscopic pits at an iodine source pressure of *ca.* 15 mm (I_2 source at 80°), a higher density of pits at *ca.* 35 mm (I_2 source at 95°), and a still larger pit density at 73 mm (I_2 source at 110°). These effects are shown in Fig. 8. The polish quality as a function of T at an 80° iodine source temperature became excellent at 890° and above, which is coincident with the plateau for the 80° iodine curve of Fig. 7.

Finally, Fig. 9 presents etch rate *vs.* linear velocity data for an iodine source at 15 mm (I_2 source at 70°). These conditions are the ones currently employed by us in vapor polishing Ge.

Discussion

Effect of experimental parameters on polishing.—The results of the experiments depicted in Fig. 2-9 indicate that absolute etch rate is unimportant in achieving good polishing. Furthermore, variation of etch rate at a

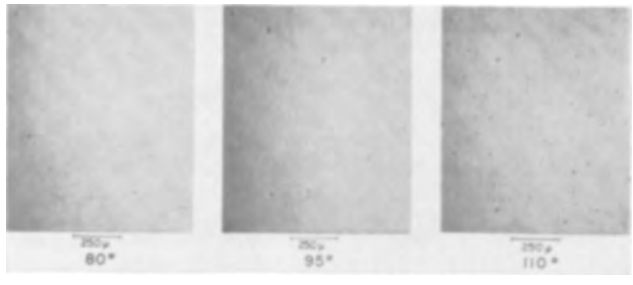

Fig. 8. Variation of polish quality with iodine source temperature

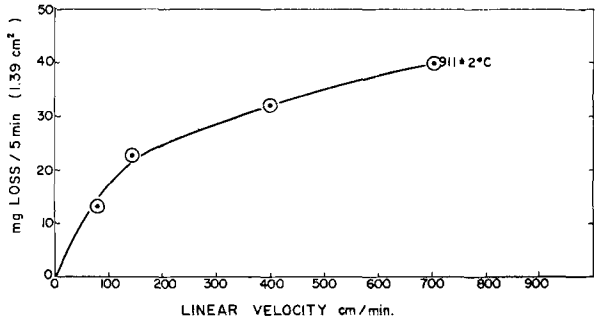

Fig. 9. Plot of etch rate *vs.* linear velocity for iodine source at 15 mm. <211> 0.01 ohm-cm P pulled Ge, NaOCl prepolished; I_2 source at 70°C.

given temperature, by varying etchant flux via a variation in linear gas stream velocity, did not result in variation in surface characteristics for the temperature in question. In addition, for the constant etchant concentration conditions of Fig. 2 identical etch rates again achieved by varying the gas stream linear velocity and, therefore, etchant flux resulted in different surface characteristics at different etch temperatures. As noted above, variation in etchant concentration which represents another way of changing etchant flux and etch rate does appear to cause a second order effect, namely pitting, when the mole fraction of HI exceeds approximately 0.09. Thus, we may conclude that of all the parameters considered the only one which markedly affects surface characteristics during etching is the temperature.

There are, however, certain practical reasons for operating within defined linear velocity and etchant concentration ranges as can be seen from the data. Thus, from Fig. 2 it is evident that if polishing is effected at high linear gas stream velocities, the variation of etch rate with linear gas stream velocity is small, making possible precise control of etch rate without precise control of linear gas stream velocity. Similarly, from Fig. 6 and 7 it is observed that at lower etchant concentrations, the variation of etch rate with temperature is small, again making possible precise control of etch rates without very precise control of temperature. Specifically, the lowest HI partial pressure employed in which etch rate variation with temperature in the polishing range is small, also represents the concentration at which the formation of microscopic etch pits was no longer observed.

Kinetic model to explain polish behavior.—If we visualize the surface as comprised of protrusions and depressions, successful polishing of a rough surface is possible only if the protrusions tend to etch at a faster rate than do the depressions. Conversely, if we begin with a polished surface and desire to retain this polish as the surface is stripped, the process must proceed either by a uniform removal or in a step wise fashion where, after a step forms it tends to be preferentially etched. Starting with polished surfaces, therefore, the expected crystallographic variation in etch rate would tend to result in development of depressions and protrusions. The generated protrusion heights must remain small via preferential etching of them after a certain height is attained in order that the polish remain usable. Thus, beginning with a very smooth surface in which damage is minimal, it is to be expected that vapor polishing will tend to result in some degradation depending on the ability to minimize surface controlled processes.

If the prepolished surface is relatively uniformly damaged, as is probably the case for a mechanically polished surface, crystallographic specificity should be minimized, due to the effects of the damage. In this instance the etching is expected to proceed via a more or less uniform stripping procedure. The use of mechanically damaged surfaces has been utilized frequently in the HCl-Si polishing technique, and the reason for the latter's success may in part be due to the above explanation.

The following rather simplified and idealized models may be invoked to discern the roles of temperature, etchant concentration, and linear gas stream velocity in achieving surface smoothness.

We have assumed that because of position, because of greater turbulence around the apex of a protrusion, and because of a mean free path considerations at 1 atm pressure, protrusions present themselves more frequently to fresh etchant than do depressions. Under the most favorable conditions, where every etchant molecule strikes a protrusion apex on encountering the surface, the maximum reduction in protrusion height, h_p, occurs if the etchant molecule reacts immediately. Actually, one expects an etchant molecule to travel along the surface a distance, d, before reaction occurs. The greatest reduction in protrusion height that would result on the average under the most favorable conditions, therefore, is given by h_p-d. This difference, h_p-d, would increase if the value d decreases, and the resultant surface would acquire enhanced smoothness. The effects of temperature in decreasing the value of d are evident. In general, therefore, we seek an etchant with a very high specific reaction rate constant, and we want the effects of crystallographic orientation to be minimized.

As one increases the etchant concentration in the system, the etchant collision frequency at any given site on the surface begins to increase. If the time interval between successive collisions with a site begins to approach either the residency time of etchant at the site, or of a reaction product species at the site, enhanced replenishment in depressions will increase because the reaction distance d will in effect increase. This undesirable occurrence implies an advantage is to be accrued from operation at lower etchant pressures.

If we now consider the following proposed model of the kinetics of a usable gas-solid polishing reaction, the effects of linear velocity on etch rate, but not on polish quality become evident. This picture also serves to point out the nature of the problems attendent with conducting definitive kinetic experiments of solid-gas reactions under steady state conditions.

From our studies of the HI-Ge polishing behavior it has been found within experimental limits, that for the wafer size employed, the entire surface was found to etch at a uniform rate. This evidence is further supported by the fact that edge rounding, which may indicate that the edges are more damaged than the surface, is uniform around the perimeter. Since the wafer surface extends in the direction of the gas stream drift velocity, one may conclude that the average etchant pressure over the entire wafer surface, and reasonably therefore at least one diameter distance radially, is constant. The indication of uniform etchant partial pressure axially over the wafer in our experiment does not, however, simultaneously imply that this pressure is equal to the input pressure P_i of reactant or that no gradient existed radially, one diameter removed from the sample, for the following reason: Assuming that the etch rate for the forward reaction of the defined system is given by an equation of the form $R = kP^n$ where R is the rate, k the specific rate constant, and P the pressure of HI over the wafer, the rate will be maximum only when P is the input HI pressure in our system.[1] Examination of Fig. 2, however, reveals that such was not the case over the velocity range examined. For if indeed the apparent uniform pressure over our wafer was the input pressure, the etch rate would have reached a maximum immediately after the equilibrium velocity range was exceeded. We know, however, from calculations of the observed efficiencies, and the fraction these are of the thermodynamically predicted values, that under the conditions described by Fig. 2 no regions of equilibrium were actually observed. This is demonstrated in Figure 3 for the data of Fig. 2.

The value β represents

$$\frac{\left(\dfrac{\text{Ge etch rate in moles/defined time defined area}}{\text{I}_2\text{ input rate moles/defined time defined area}}\right)}{(\text{Ge}/\text{I}_2)_{\text{theoretical}}}$$

Since in the range of temperatures used $(\text{Ge}/\text{I}_2)_{\text{theoretical}}$ is constant, *i.e.*, 0.64 at 620° to 0.65 at 723°-911°, the curves of Fig. 3 are all on the same efficiency scale. That the etchant pressure was axially uniform, but not equal to the input pressure and that a radial gradient was present was experimentally demonstrated as follows. For the experiment used to define the curves of Fig. 2 further studies were conducted at 911° and 723° in which a nest of liner tubes was used in place of the

[1] This is true of course only if $n > 0$. If the value of n were zero, it is evident that in our plots of etch rate vs. linear velocities, following an initial transpiration region as velocities approach zero, the curves would level off.

single linear tube used in deriving the data of Fig. 2. Since the input flow rate used was the same as for the highest velocities shown in this figure for the two temperatures in question, the effect of using a nest of liner tubes was to increase the linear gas stream velocities over the wafers, but not to change the number of etchant molecules/unit time passing the wafer. In other words the number of etchant molecules remained constant but their residency time decreased. For the case cited, the linear gas stream velocities were 1164 cm/sec at 911° rather than 703 cm/sec and 979 cm/sec rather than 592 cm/sec at 723°. In both instances the etch rate increased, *i.e.*, 92 mg *vs.* 80 mg/defined time/defined wafer area at 911° and 42 mg *vs.* 38 mg/defined time/defined wafer area at 723° and the etch proceeded uniformly over the wafer. A reasonable explanation for an enhanced etch rate accompanying a decreased residency time at constant flux is that in addition to uniform axial pressure distribution being maintained when the radial distance between the wafer and the chamber walls was decreased, the radial pressure gradient also decreased. In other words more complete mixing occurred radially. Since the partial pressure of etchant at the chamber wall is expected to be greater than the partial pressure at the wafer surface, the increase in etch rate accompanying the radial distance decrease implies that the effective etchant pressure more nearly approximated the input pressure when the etching chamber diameter was decreased, due to more complete mixing of the gas in a radial direction.

Relating our Fig. 2 curves with our model then, we see that as our flows tend toward zero, the system tends toward equilibrium, and the etch rate *vs.* linear velocity curves tends toward linearity. In this region the rate of the forward and reverse reactions approach one another. As the transpiration region is exceeded, the rate of the forward reaction becomes greater than the reverse reaction. This is caused by an increase in the actual HI partial pressure over our wafer which results in an over-all etch rate increase. With further increase in gas stream velocity, the average pressure immediately in the vicinity of the wafer continues to increase until it is effectively equal to the input pressure. At this point the etch rate becomes constant since the input pressure determines the maximum rate that can be observed.

Thus, in order to define the kinetics of the process, it is seen that the pressure dependency of etch rate must be evaluated in the plateau linear velocity region. At lower linear velocities two uncertainties are present; (*a*) the value of the pressure that exists at the surface; (*b*) the effect on the forward rate caused by the back reaction.

In a closed system, the same problems obtain and may presumably be overcome by measuring the instantaneous weight-time or pressure-time change at the start of the reaction or by creating turbulence throughout the chamber by rapid stirring.

The effect, however, of uniform, but less than input etchant pressure in the surface vicinity, while a barrier to quantitatively describing the kinetics does assist in achieving good polishing. For example, if we consider the protrusions and depressions separately in terms of turbulence in each area, we see that the average etchant pressure around the apex of a protrusion will tend to be greater than the average etchant pressure in the depression. This will result in faster removal of protrusion regions. Again, with increasing linear velocity, this microscopic removal rate difference will serve to enhance removal rate, but will not particularly affect polish quality. This because, at both slow and fast velocities, the turbulence effect will diminish as the protrusions disappear and both regions will begin to see the same effective pressure. At this point the quality of polish becomes solely a function of the specific reaction rate constant and the latter's tendency toward variation in different crystallographic directions.

Conditions for Polishing Si

Based on the results obtained with Ge and the suggested model, studies have been initiated to determine the feasibility of using HI as a vapor polish for Si, and ultimately to compare the HCl-Si and HI-Si reactions. Al_2O_3 lapped <111> oriented 10 ohm cm "p" type Si was tried using the etching temperature as the sole parameter. The I_2 source pressure was arbitrarily chosen as 35 mm and the linear velocity of the H_2 input was chosen equally arbitrarily at 1380 cm^3/mm. At 1175° the polish quality showed first indications of improvement. In the range 1220°-1250°C superior polishes to those obtained by conventional chemical solution means were observed.

Tetragonal Germanium Dioxide and Equilibria in the Ge-O-H System

M. M. Faktor and J. I. Carasso

Post Office Reserach Station, Dollis Hill, London, England

ABSTRACT

The thermodynamic stability of tetragonal germanium dioxide has been characterized by measurements of the equilibrium H_2/H_2O ratios in the temperature range 830°-1020°K. Results are extrapolated to 298°K using estimated heat capacities, to give the standard thermal parameters, and to the tetragonal-hexagonal transition point to give the free energy of formation of both modifications at that temperature. Hence, using published entropy and specific heat data for hexagonal germanium dioxide, the standard thermal parameters of this modification are computed. Sizeable crystals of tetragonal GeO_2 have been grown by vapor transport under near-equilibrium conditions.

The aims of this paper are to establish the energy relationships of the solid modifications of germanium dioxide. There are two crystalline allotropes, hexagonal and tetragonal, and there is also a glassy form, all of which persist at room temperature and atmospheric pressure. Some of the physical properties of the three forms are summarized in Table I.

Inspection of Table I reveals a major difference in density and in chemical reactivity between the allotropes, brought about by the change from 4:2 to 6:3 coordination. The solubilities given in Table I unambiguously characterize the stability sequence of the three forms and suggest a value of at least 4 kcal $mole^{-1}$ for the standard free energy of the transformation reaction

$$GeO_2(hex,s) \rightarrow GeO_2(tetr,s) \qquad [1]$$

but they do not afford a reliable estimate of the free energy difference for reasons which we have discussed previously (6). The enthalpy of formation of hexagonal germania has been measured by a number of workers; the results (given in Table II), show serious disagreement.

No thermodynamic parameters for tetragonal germania have appeared in the literature explicitly. In this paper we report measured equilibrium constants for the reaction

$$Ge(s) + 2H_2O(g) \rightarrow GeO_2(tetr,s) + 2H_2(g) \qquad [2]$$

and other derivable thermochemical parameters of interest. The results, when manipulated by standard thermochemical procedures, allow us to reject as spurious some of the values for the enthalpy of formation of the hexagonal modification listed in Table II [including a recent, authoritative measurement (14), and to confirm some of the other values (11, 13)].

Observations on the interconversion and crystal growth of these materials under quasi-equilibrium conditions in the presence of water vapor are also reported.

The unusually large difference in free energy between the allotropes suggested the feasibility of growing the stable modification under conditions of absolute instability of hexagonal germanium dioxide. Since tetragonal germania films can be expected to show desirable stabilizing and diffusion masking properties (unlike the other forms), the controlled production of these films could have interesting repercussions in device technology. Reactions producing germania under conditions thermodynamically compatible with all the forms have hitherto invariably yielded either the hexagonal or the glassy form, and the extreme sluggishness of the transformation to the stable tetragonal allotrope under "clean" conditions, *i.e.*, in the absence of mineralizing catalysts or high-pressure hydrothermal conditions, has been stressed frequently (1, 15, 16).

Experimental

Materials.—Elementary germanium: monocrystalline, zone-levelled, 2 ohm-cm n-type germanium was ground in an agate mortar to a fine powder.

Hexagonal germania: semiconductor grade (Johnson Matthey) germania was dried in a muffle at 700°C for 30 min. This oxide, although exceptionally low in

metallic impurities, is known to contain chlorine (0.075% by weight was found after drying). The oxide was soluble in 40% aqueous hydrofluoric acid with a negligible residue, confirming that it was the pure hexagonal modification.

Tetragonal germania: previously suggested fluxes (1) for the conversion to the tetragonal form were thought unsuitable. The catalyst used was lithium germanate, prepared from equimolar quantities of hexagonal germania and lithium carbonate by heating the mixture slowly to 1250°C in a platinum dish. The melt was cooled and ground to a fine powder in an agate mortar. Hexagonal germanium dioxide was mixed with 0.1% of the lithium germanate and heated in a muffle in a covered platinum dish at 900°C for 24 hr. The progress of the reaction was followed by taking samples for x-ray powder analysis, which can detect hexagonal germania down to ~0.1%. After 12 hr the allotropic transformation reaction was complete. Attempts to decrease the amount of catalyst by a factor of 10, with a corresponding increase in heating time, led to only ~5% conversion and were not pursued. However, spectrographic analysis of the final product revealed the presence of only 20 ppm of lithium as well as 4 ppm of chromium. No other metallic impurities were detected above the 1 ppm level. The material showed a faint pink coloration.

Measurement of allotropic transformation temperature.—The temperature of the tetragonal-hexagonal GeO_2 transformation was redetermined in a commercial (Netsch) thermal analysis apparatus, using the differential dynamic calorimetry assembly with a cylindrical liner of sheet platinum to minimize thermal gradients. The reference crucible contained a small gold ingot (mp 1063°C). An endothermic peak (corresponding to the allotropic transformation) was observed at a temperature 28° ± 5° below the fusion point of the gold in the reference crucible. Thus the transformation temperature is 1035° ± 5°C.

Measurement of specific heat.—The room temperature specific heat of tetragonal GeO_2 was measured by the cooling time-constant method in an apparatus designed to give a precision of better than 1% with powdered samples of low thermal conductivity. A thin-walled copper calorimeter (1 cm diameter x 5 cm long), filled with the dried powder, was heated to 35°-40°C, and allowed to cool in a double-walled glass tube (2 mm air gap) immersed in a water thermostat set at 25°C. The cooling curve was plotted using very fine copper-constantan thermocouples (5 junctions) to measure the temperature of the copper calorimeter. The cold junctions were kept at the thermostat temperature, and the temperature difference (ΔT) was measured on a d-c potentiometer with an electronic balance detector sensitive to 1 μv, giving a discrimination of 0.005° in the measurement of ΔT. The cooling was rigorously Newtonian ($\Delta T = \Delta T_o e^{-t/\tau}$) for values of ΔT between 5° and 0.5°. The cooling time-constant τ was calculated from the slope of plots of log ΔT against time; the thermal resistance was obtained by calibration with water. The reproducibility of heat capacity measurements was of the order of 0.05% at the 95% confidence level. No significant systematic errors were observed when the calibration was repeated with standards having widely different thermal conductivity and heat capacity.

High-temperature equilibrium measurements (static method).—Most of the measurements of the H_2/H_2O ratio in equilibrium with Ge and GeO_2 at 800°-1025°K were made in a "constant water-vapor pressure" apparatus in which the H_2O pressure was clamped at 13.3 mm Hg by a pool of liquid water kept at 15.7° ± 0.05°C, thus enabling the H_2/H_2O ratio to be measured simply by monitoring the total pressure. As a check, some measurements were also made in a "constant total pressure" apparatus not including a liquid water phase, in which gas-phase compositions had to be determined by gas analysis. The results of the latter experiment had to be corrected for thermal diffusion by the empirical formula for H_2/H_2O mixtures derived by Shibata and Kitagawa (28)

$$\log\left(\frac{P_{H_2O}}{P_{H_2}}\right)_{T_2} = \left(1 + 0.065 \log\frac{T_2}{T_1}\right) \log\left(\frac{P_{H_2O}}{P_{H_2}}\right) - 0.205 \times 10^{-3} (T_2 - T_1)$$

This correction was unnecessary in the former experiment, because the gas phase was recirculated past the solid phase in a closed loop by means of a diaphragm pump. The agreement between the two experimental approaches was satisfactory. However, only the constant water-vapor pressure results were used in the calculations because their precision was significantly higher.

Constant water-vapor pressure apparatus.—The apparatus (Fig. 1) was built round a fused silica tube inserted in a horizontal, Kanthal-wound, furnace, fitted with water-cooled brass end-plates. The sample (crushed Ge + tetragonal GeO_2, ~50g) is contained in a fused quartz cell 1 of 250 cc capacity provided with a small effusion orifice. (The desirability of thus restricting the flow of vapor to and from the sample is discussed under "Procedure.") The apparatus can be evacuated to 10^{-2} mm Hg by a two-stage rotary pump. By suitable manipulation of the taps, the distilled water in bulb 2 can be thoroughly degassed and partly transferred to the horizontal Liebig condenser 3 which is maintained at 15.7° ± 0.05°C by circulating water from a thermostat. (Room temperature was not allowed to fall below this temperature at any time during the work.) The total pressure in the system is measured by a differential oil manometer via a glass spoon gauge 4 fitted with a galvanometer mirror 5 of one-meter focal length. The sensitivity of the

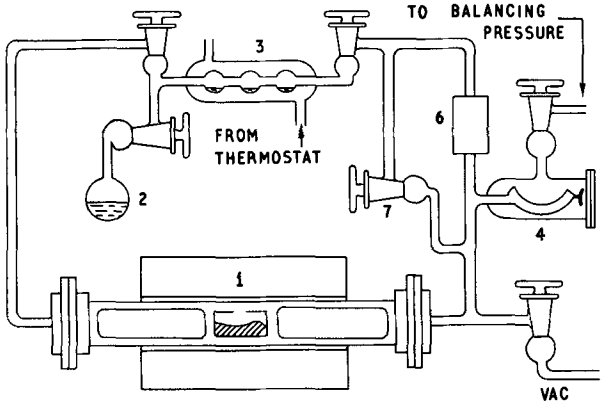

Fig. 1. Apparatus for measuring H_2/H_2O ratios in equilibrium with Ge + GeO_2 tetragonal (constant water vapor pressure).

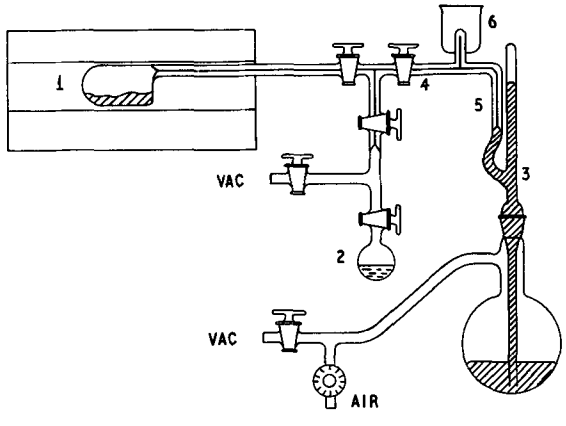

Fig. 2. Apparatus for measuring H_2/H_2O ratios in equilibrium with Ge + GeO_2 tetragonal (constant total pressure).

spoon gauge was matched to that of the oil manometer, giving an over-all discrimination of the order of 0.05 mm Hg in the reading of total pressure. The gas mixture is recirculated past the hot solids by diaphragm pump 6, provided with a shunting tap 7 for controlling the flow. The dead volume of the apparatus was reduced from 3 to 1 liters by inserting two well fitting quartz "sausages" into the furnace tube. The time constant of the approach to equilibrium under these conditions was about 1 hr at 650°C.

Constant total pressure apparatus (Fig. 2).—The solid sample of crushed Ge + GeO_2 (~10g) was held in a 25-ml fused quartz bulb 1 with a long capillary tubulation of 2 mm bore extending beyond the mouth of the furnace. The small flask 2 contains a few milliliters of distilled water. The required pressure of water vapor is introduced into the system and measured in the constant volume mercury manometer 3 by means of a cathetometer. The composition of the gas phase is measured by isolating a fixed volume of the gas between tap 4 and reference mark 5, and measuring its pressure before and after freezing out the water at liquid-nitrogen temperature in cold finger 6. Dead volumes are kept small by using capillary connections and taps. Uniformity of gas composition can be checked by discarding the stagnant gas in the connecting tubes.

Procedure

The design of these experiments was strongly influenced by the significant vapor pressure of the lower oxide, GeO (18) at the temperatures in question. The reactions are

$$Ge + H_2O = GeO + H_2; \frac{P_{H_2} P_{GeO}}{P_{H_2O}} = K_1 \quad [3]$$

$$GeO_2 + H_2 = GeO + H_2O; \frac{P_{H_2O} P_{GeO}}{P_{H_2}} = K_2 \quad [4]$$

Germanous oxide can also be formed by the proportionation reaction

$$Ge + GeO_2 = 2\,GeO \quad [5]$$

but this solid-solid reaction is not expected to proceed at a rate comparable with the rates of the reactions involving gaseous species. Unless the tendency of GeO to sublime to the cooler parts of the furnace is checked, the steady-state pressure of this compound in the reaction zone will be significantly lower than its equilibrium value. This, in turn, will force the H_2/H_2O partial pressure ratio to take on spuriously high or spuriously low values, according to whether reaction [3] or reaction [4] is the faster.

Experimentally, we found that the H_2/H_2O ratio in the constant water-vapor pressure apparatus decreased as the orifice size was decreased, pointing to the pressure being determined by reaction [3]. Adequate Knudsen conditions were obtained with orifice areas of 4 mm^2 or less. Measurements were made with an orifice of ~0.4 mm^2. In the constant total pressure apparatus, Knudsen conditions were provided by the long capillary connection.

In some of the runs, equilibrium was approached from the reduction (instead of from the oxidation) side by starting with a hydrogen-rich mixture produced in a previous run at a lower temperature. The agreement between oxidation and reduction runs was entirely satisfactory (see Table III). It should be stressed, however, that this is not a sufficient test of true equilibrium conditions as had been previously implied (13), and that very serious errors may arise if the partial pressure of a volatile intermediate species is allowed to depart significantly from its equilibrium value. The steady-state hydrogen-water ratio observed with the sample in an open boat at 650°C could be reproduced exactly, whether it was approached from the oxidation or from the reduction side, but this was shown to be a false equilibrium by working under Knudsen conditions, which gave quite a different value for the equilibrium H_2/H_2O ratio.

Table III. Data for reaction [2]

Temperature, °K	P_{H_2}/P_{H_2O}	log K	$\Delta G°$, cal $mole^{-1}$	Direction of approach to equilibrium
831	2.780	0.8880	−3375	Reduction
848	2.658	0.8490	−3226	Oxidation
873	2.459	0.7816	−3121	Oxidation
873	2.345	0.7402	−2956	Reduction
886	2.288	0.7188	−2913	Reduction
921	1.525	0.3664	−1544	Reduction
923	1.508	0.3568	−1506	Oxidation
923	1.485	0.3436	−1451	Oxidation

1021	0.959	−0.0364	+170	Oxidation

Transformation of a metastable solid phase into the stable modification is another possible source of error. We attempted to check Yokokawa's results (13) for the hexagonal form of GeO_2 in our apparatus, and we observed a drift of the "equilibrium" gas-phase composition toward the value for tetragonal GeO_2. The drift was barely significant at temperatures below 600°C, but should in principle be guarded against by extrapolating to zero time when dealing with a metastable phase. At 650°, approximately 15% conversion of hexagonal to tetragonal GeO_2 took place in times of the order of a day, and the gas composition plateau drifted from $\frac{P_{H_2}}{P_{H_2O}} = 1.00$ to $\frac{P_{H_2}}{P_{H_2O}} = 1.16$ (cf. ref. (13) and Table III).

Results and Discussion

Experimental results are shown in Table III together with the computed equilibrium constants and free-energy changes for reaction [2]. The last column of Table III indicates the direction of approach to equilibrium.

The results in column four of Table III were linearized by least squares, yielding the equation

$$\Delta G_T^o = -20800 + 20.7\,T \text{ cal } mole^{-1} \quad [6]$$

for the free-energy change of reaction [2] in the temperature range 830°-1020°K. By combining the experimental values obtained above (Table III) with the corresponding free energies of formation of water (19) we find the free energies of formation attending reaction [7].

$$Ge(s) + O_2(g) \rightarrow GeO_2 \text{ (tetr,s)} \quad [7]$$

Least-squares linearization then allows us to express the free energy of formation of tetragonal germania as

$$\Delta G_T^o = -139970 + 47.6\,T \text{ cal } mole^{-1} \quad [8]$$

in the same temperature range. Both the above linearization procedures are admissible over our narrow temperature range because the curvature caused by specific heat differences between reactants and products is small compared with other experimental inaccuracies.

Allowance for ΔCp terms is important, however, when the results are projected downwards to 298°K or upward to the transition point. The specific heat of tetragonal germania, not previously reported, was measured at room temperature by the cooling method and found to be 11.2 ± 0.1 cal deg^{-1} $mole^{-1}$. The temperature dependence of the specific heat was estimated assuming a linear behavior up to the metastable melting point of tetragonal GeO_2 where its value should be indistinguishable from that of hexagonal germania (20). A purely empirical procedure (21) led to the same result

$$Cp\ (GeO_2, \text{tetr}) = 9.1 + 7 \times 10^{-3} T \text{ cal } deg^{-1} \text{ } mole^{-1}$$

This was combined with the corresponding equations for gaseous oxygen and crystalline germanium (22, 29) to yield the specific heat change involved in reaction [7] as a function of temperature, with adequate precision by the linear equation

$$\Delta Cp = -3.7 + 4.6 \times 10^{-3}T \text{ cal deg}^{-1} \text{ mole}^{-1} \quad [9]$$

If we assume that Eq. [8] is strictly applicable at the mid-point of the temperature range studied, then for reaction [7]

$$\Delta H^\circ_{298} = -139970 - \int_{298}^{925} (-3.7 + 4.6 \times 10^{-3}T)\, dT$$
$$= -139400 \text{ cal mole}^{-1} \quad [10]$$

$$\Delta S^\circ_{298} = -47.6 - \int_{298}^{925} \left(-\frac{3.7}{T} + 4.6 \times 10^{-3} \right) dT$$
$$= -46.3 \text{ cal deg}^{-1} \text{ mole}^{-1} \quad [11]$$

The standard entropy change computed above, coupled with the standard entropies for oxygen gas (22) (49.0 cal deg^{-1} mole^{-1}) and for crystalline germanium (22) (7.4 cal deg^{-1} mole^{-1}), yields $S^\circ_{298} = 10.1$ cal deg^{-1} mole^{-1} for tetragonal germania, for which we estimate an uncertainty of not more than ±2 entropy units. Standard entropies derived from "second law" measurements by extrapolation to room temperature are notoriously inaccurate: in the absence of "third law" values, their reasonableness should be scrutinized. At first sight, the difference of 3 cal deg^{-1} mole^{-1} in standard entropy between hexagonal germania (23) and the value calculated above for tetragonal germania seems startlingly large for a solid-solid transformation. Yet, some of the best semi-empirical methods for estimating the entropy of solids (24) suggest an even lower value for S°_{298} (GeO_2, tetr). Thus, Venner's (25) plot of the logarithm of formula weight *vs.* the entropy, and Karapetyants' (26) linear plot of room-temperature specific heat *vs.* the entropy, for a related family of isomorphous crystals, both lead to 8 cal deg^{-1} mole^{-1} for the standard entropy of tetragonal germanium dioxide on the basis of the value for tetragonal tin dioxide and lead dioxide. These semiempirical methods have been well tested and found to be reliable to ±2 cal deg^{-1} mole^{-1}. Our second-law value of 10.1 ± 2 cal deg^{-1} mole for S°_{298} (GeO_2, tetr) therefore is not unreasonable.

The transition temperature of tetragonal to hexagonal germania was redetermined and found to be 1308°K ± 5° in excellent agreement with Laubengayer and Morton's (1) but not with a more recent value (16, 27).

Extrapolation of the values in Eq. [8] to the transition temperature, which must take into consideration the enthalpy and entropy of fusion at the melting point of germanium (14), enables us to obtain the free energy of formation of both modifications at the transition point

$$\Delta H_{1308} = -139970 - 7600 + \int_{925}^{1308} (-3.7 + 4.6 \times 10^{-3}T)dT$$
$$-147000 \text{ cal mole}^{-1} \quad [12]$$

and

$$\Delta S_{1308} = -47.6 - 6.3 + \int_{925}^{1308} \left(-\frac{3.7}{T} + 4.6 \times 10^{-3} \right) dT$$
$$= -53.4 \text{ cal deg}^{-1} \text{ mole}^{-1} \quad [13]$$

which, when combined by the Gibbs-Helmholtz relation, yield the free energy of formation of germania at the transition temperature

$$\Delta G_{1308} = -147000 + 53.4 \times 1308$$
$$= -77100 \text{ cal mole}^{-1} \quad [14]$$

The entropy of hexagonal germania has been measured as a function of temperature (20, 23), and the entropy change on formation of hexagonal germania from the elements has been computed as a function of temperature (29, 30). Using these literature data we derive the standard enthalpy of formation of hexagonal germania as

$$\Delta H^\circ_{298} = -133000 \pm 500 \text{ cal mole}^{-1}$$

the free energy of formation of hexagonal germania as

$$\Delta G^\circ_{298} = -120100 \pm 500 \text{ cal mole}^{-1}$$

and the enthalpy of formation of hexagonal germania at the transition temperature as

$$\Delta H^\circ_{1308} = -138500 \pm 500 \text{ cal mole}^{-1}$$

From the above and Eq. [12] the enthalpy of transformation at the transformation temperature is

$$\Delta(\Delta H)_{1308} = -8500 \pm 1000 \text{ cal mole}^{-1}$$

and thus the entropy of transformation is

$$\Delta(\Delta S)_{1308} = 6.5 \text{ cal deg}^{-1} \text{ mole}^{-1}$$

The free energy of formation of tetragonal GeO_2 between 298°K and 1308°K is described by the three-term equation

$$\Delta G^\circ(GeO_2, \text{tetr}) = -138.5 + 6.3 \times 10^{-3}\, T \log T$$
$$+ 27.3 \times 10^{-3} T \text{ kcal mole}^{-1}$$

In view of the experimental and computational uncertainties of the present work, no useful purpose would be served by introducing further terms into the free energy equation.

The computational procedure is summarized in Fig. 3.

Growth of Tetragonal Germania

This communication is not concerned explicitly with the rates of the reactions considered. However, in view of the technological interest in the preparation of tetragonal germanium dioxide as a protective film on germanium, or in single crystal form, a few general comments on the reaction rates may not be out of place.

The significant conversion of hexagonal to tetragonal germania observed in the course of this work, and the time scale involved, have already been mentioned in the experimental section. This suggests that the growth of tetragonal germania is promoted by participation of the gaseous transporting agents appearing in Eq. [3] and [4].

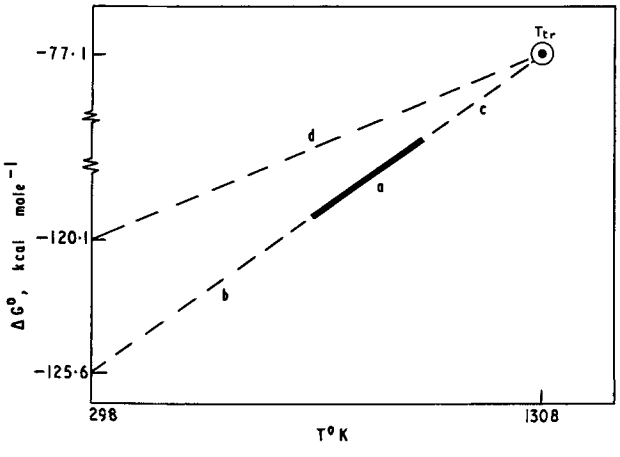

Fig. 3. Free energy of formation of germanium dioxide (not to scale): (a) measured for tetragonal GeO_2 (830°-1020°K); (b) projection to 298°K, using the slope of (a) and measured room temperature specific heat; (c) projection of (a) to the transition point T_{tr} by the same procedure; (d) projection from T_{tr} to 298°K for hexagonal GeO_2, using published entropy and specific heat values.

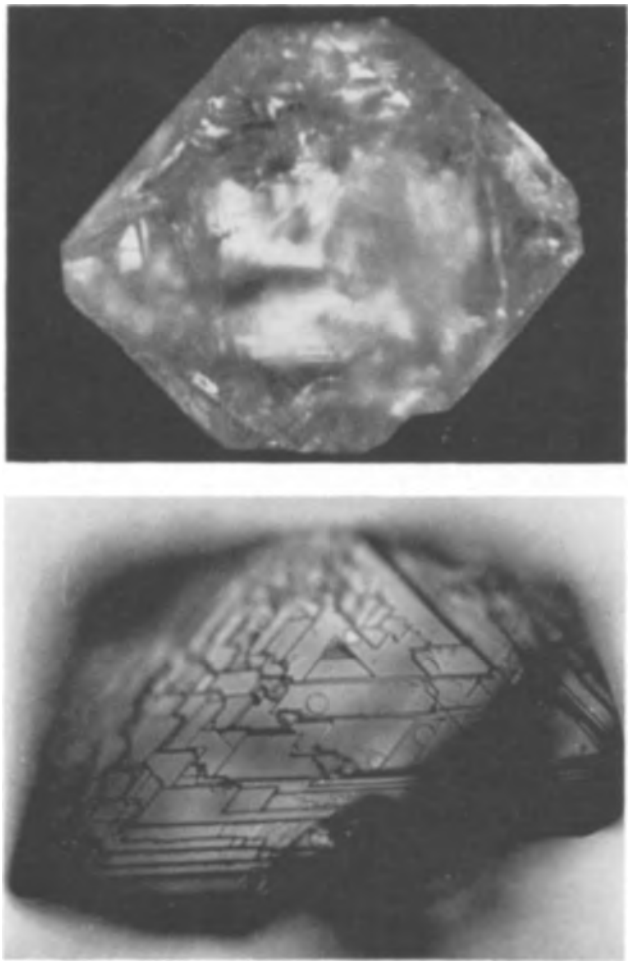

Fig. 4. Tetragonal GeO_2, grown by the transport reactions [3] and [4]: (a) (top) crystal habit, 200X; (b) (bottom) surface topography, 1000X.

This possibility was further tested as follows. A 25 cc silica tube was charged with 5g of hexagonal germania and 25 mg of elementary germanium. It was then evacuated to 5μ pressure, filled with saturated water vapor from liquid water at 22°C, and sealed off. After 30-hr heating at 700°C, the charge was examined by x-ray powder analysis, which revealed complete conversion to the tetragonal modification.

In an attempt to grow some sizeable crystals, a small silica boat containing 5g of germania glass and 10 mg of Ge was placed in a 25 cc silica capsule which was pumped out (to 5μ) and back-filled with water vapor saturated at room temperature. Then the capsule was sealed off and placed in a furnace with a temperature gradient so that the end containing the charge was at 700°C while the other end was at 660°C. After 40 hr the capsule was removed from the furnace. Some 10% of the charge had been transferred to the cold end, where it had grown as small well-developed crystals (Fig. 4). X-ray analysis of these, and of the remainder of the charge, revealed the presence of tetragonal germania only.

Summary

The numerical values measured and derived in this investigation, and their estimated uncertainty limits, are summarized below.

The parameters derived for the formation of tetragonal germania are

$$\Delta H^\circ_{298} \text{ kcal mole}^{-1} — 139.4 \pm 1.0$$

$$\Delta G^\circ_{298} \text{ kcal mole}^{-1} — 125.6 \pm 1.6$$

$$S^\circ_{298} \ (GeO_2, \text{tetr}) \ 10.1 \pm 2.0 \text{ cal deg}^{-1} \text{ mole}^{-1}$$

and

$$\Delta G_T = -138.5 + 6.3 \times 10^{-3} T \log T + 27.3 \times 10^{-3} T \text{ kcal mole}^{-1}$$

(in the temperature range 300°-1350°K)

The parameters derived for the formation of hexagonal germania are

$$\Delta H^\circ_{298} \text{ kcal mole}^{-1} — 133.0 \pm 0.5$$

$$\Delta G^\circ_{298} \text{ kcal mole}^{-1} — 120.1 \pm 0.5$$

The free energy of formation of both allotropes at the transition point is

$$\Delta G^\circ_{1308} \text{ kcal mole}^{-1} — 77.1 \pm 0.5$$

The parameters for the transformation reaction at the transition point are

$$\Delta H^\circ_{1308} \text{ kcal mole}^{-1} — 8.5 \pm 1.0$$

$$\Delta S^\circ_{1308} \text{ cal deg}^{-1} \text{ mole}^{-1} \ 6.5 \pm 1.0$$

The experimentally determined free energy of the reaction

$$Ge(s) + 2H_2O(g) = GeO_2(s, \text{tetr}) + 2H_2(g)$$

is

$$\Delta G^\circ_T = -20800 + 20.7T \pm 250 \text{ cal mole}^{-1}$$

in the temperature range 830°-1020°K.

Acknowledgment

The authors are grateful to G. R. Newns for much helpful discussion and for redetermining the allotropic transition point, and to A. K. Chatterjee for experimental assistance. Acknowledgment is due to the Engineer-in-Chief of the British Post Office for permission to publish this paper.

Manuscript received Jan. 6, 1965; revised manuscript received April 5, 1965. This paper was prepared for delivery before the Washington Meeting, Oct. 11-15, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

Electrical Conductance of Alkali Germanate Melts at 1300°C

E. F. Riebling and S. D. Gabelnick[1]

Research and Development Laboratories, Corning Glass Works, Corning, New York

ABSTRACT

Electrical conductance data are presented for a series of binary alkali germanate melts containing from zero to 30 mole % M_2O (where M = Li, Na, K). The equivalent conductance at 1300°C and the activation energies for conductance change rather sharply (increase and decrease respectively) with the addition of less than 2 mole % of alkali oxide. Equivalent conductance is related to cation-oxygen attraction forces while activation energy is related to cation volume. Some of the specific deviations can be explained in terms of the presence of GeO_6 octahedra. Results are compared with similar data for alkali silicate melts, molten salts, and alkali germanate glasses.

Previous viscosity and density studies have shown that the addition of alkali oxides to molten GeO_2 causes germanium(IV) to change from tetrahedral to octahedral coordination (1, 2). The maximum stability of octahedrally coordinated germanium(IV) at 1300°C appears to occur for melts containing from 15 to 30 mole % M_2O. A rapid return to tetrahedral coordination takes place for most germanate melts as the alkali oxide content is increased above 30 mole %. This sequence of events is radically different from that observed by Bockris and co-workers for similar alkali silicate melts (3).

Bockris *et al.* (3) have shown that electrical conductance (or cation mobility) can also be of value in interpreting the structure of molten oxides. They found that the equivalent conductance tended to increase as the molten silica network was altered. This suggested the possibility that cation mobility would be altered in a slightly different fashion by the unusual structure changes that occur during breakup of the molten germania network.

This paper presents electrical conductance results for alkali germanate melts at 1300°C (200°C above the melting point of the network forming species) that contain from 0 to 30 mole % M_2O. Similar information is not available for alkali silicate melts containing less than 20 mole % M_2O. The data will be compared with similar results for alkali germanate glasses (4).

Experimental

The preparative techniques and chemical analysis procedures for most of these samples have been previously described (1). Individual melts were prepared in several cases. Eagle Picher Electronic Grade GeO_2 and Baker reagent-grade analyzed Li_2CO_3, Na_2CO_3, and K_2CO_3 were used to prepare the melts.

A dipping electrode arrangement was used to measure the melt resistances. It consisted of a pair of parallel Pt·40 % Rh wires imbedded in a partially split mullite rod. Each melt was contained in a 37 mm diameter by 50 mm high platinum crucible under an air atmosphere. A General Radio Company Impedance Bridge (Type 1650-A) was used in conjunction with a Cenco Audio Oscillator to measure resistance as a function of frequency. All leads were shielded. Temperatures were measured with calibrated Pt·6 % Rh *vs.* Pt·30 % Rh thermocouples and a Rubicon Potentiometer (Model No. 2745). A 24 in. Pt·30 % Rh alloy wound alumina muffle furnace was used as the heat source. Details of the instrument and its unusual calibration procedures are described in greater detail elsewhere (5).

Resistances were measured at 10 kc for an electrode immersion depth of 8 mm. Any contributions to the total impedance by capacitive reactances in the melt were negligible at that frequency. Indeed, capacitive effects were rather small between 1 and 10 kc.

Results

The individual specific conductance values (κ) were calculated from the experimental resistances with the aid of log κ *vs.* log Ω calibration equations that were developed for each electrode arrangement. All of the specific conductance data observes the relationship:

$$\kappa = C \exp(-\Delta H^{\neq}_{\kappa}/RT) \quad [1]$$

or

$$\log \kappa = a - b\,[10^4/T(°K)] \quad [2]$$

This allowed the use of a least squares treatment of the individual specific conductance values that were obtained in the temperature range 1075°-1350°C. Table I gives the least squares constants of the log κ equations for all of the alkali germanate compositions as well as for a sample of pure GeO_2.[2]

The equivalent conductances (Λ) were calculated for the purpose of determining to what extent network alteration contributes to cation mobility. The following equation was used

$$\Lambda = 100\,\kappa M/\rho n Z X \quad [3]$$

[1] Present address: Department of Chemistry, University of California, Berkeley, California.

[2] Emission spectroscopy showed that this sample contained from 0.001 to 0.01 w/o (weight per cent) Na_2O as the chief alkali impurity both before and after the run. This impurity level is slightly higher than the level encountered during a previous viscosity study of pure GeO_2 (1).

where M is the molecular weight of M_xO_y, ρ is the melt density (g/cc), n the w/o M_xO_y, Z the charge on M, and X the number of M atoms per molecule of M_xO_y. The equivalent conductance so calculated is that due to one gram equivalent per cc and is free of concentration effects. Equation [3] is valid only when the network forming species does not contribute significantly to conductance (6). As will be seen, this is a justifiable assumption in this case. A composition dependent increase in the observed Λ values can therefore be associated with an increased cation mobility.

Figure 1 shows the equivalent conductance isotherms for 1300°C as a function of composition for the zero to 30 mole % alkali oxide region. The rather sharp increases are significant in that even small amounts of alkali oxide cause large cation mobility changes. Figure 2, drawn on a large scale, depicts the Λ isotherms for the 0 to 5 mole % alkali oxide region.[3] Equivalent conductance at infinite dilution values (Λ_0) can be obtained from this plot. This was not possible with the available molten alkali silicate conductance data.

The composition dependence of the activation energy for electrical conductance ($\Delta H^{\neq}_{\kappa}$) is depicted for each series of melts in Fig. 3. Small amounts of either Na_2O or Li_2O appear to have a more pronounced influence than do similar amounts of K_2O. It is possible to use $\Delta H^{\neq}_{\kappa}$ for comparative purposes because $\Delta H^{\neq}_{\kappa} \approx \Delta H^{\neq}_{\Lambda}$ for melts with small expansion coefficients. The two energies differ by only a few tenths of a kilocalorie for the melt with the largest expansion coefficient (~30 mole % K_2O).

Discussion

Analysis of equivalent conductance results.—The most likely phenomenon that could be responsible for enhanced cation mobilities (Fig. 1) would involve network alteration. Previous viscosity and density results (1, 2) for these systems are indicative of extensive network alteration that accompanies small additions of alkali oxide to molten germania. The trends of these equivalent conductance isotherms thus generally agree with the previously developed model for the structure of these alkali germanate melts.

The general order of Λ ($Li^+ > Na^+ > K^+$) for all compositions at 1300°C is similar to that observed for simple molten salts and is therefore what one would expect if ionic field strength strongly influenced cation mobility. Isocomposition plots of Λ_{1300} *vs.* cation volume are not linear. However, similar plots of Λ_{1300} *vs.* I {where $I = 2z/(r_+ + r_-)^2$ = cation-oxygen attraction force} exhibit a closer adherence toward linearity (Fig. 4). These plots are completely linear for the zero, 1, 20, and 30 mole % M_2O lines at 1300°C. This linear dependence appears to be related to composition in that it becomes more pronounced (by ~3x) as the alkali oxide content is increased from infinite dilution to 30 mole %.

One can assume that the $\Delta\Lambda_0/\Delta I$ slope (for the case of infinite dilution in Fig. 4) represents a norm because the current carriers are essentially isolated from each other while migrating through a somewhat unperturbed O-Ge-O network. If this assumption is correct, then Λ_{K^+} is less than expected for the 5 to 15 mole % K_2O region. This conclusion is supported by the fact that the $\Delta\Lambda/\Delta I$ slope for the Na^+ to Li^+ region increases in a fairly regular fashion as the alkali content is increased. It would thus appear that the field

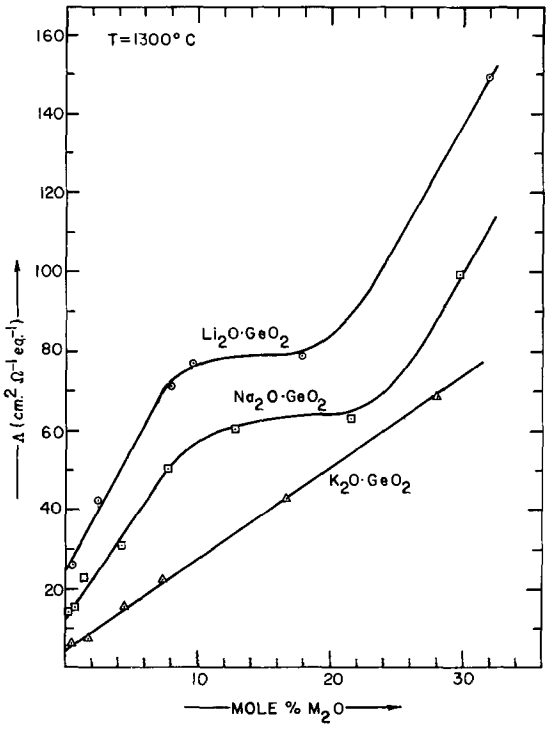

Fig. 1. Equivalent conductance isotherms for alkali germanate melts as a function of composition at 1300°C.

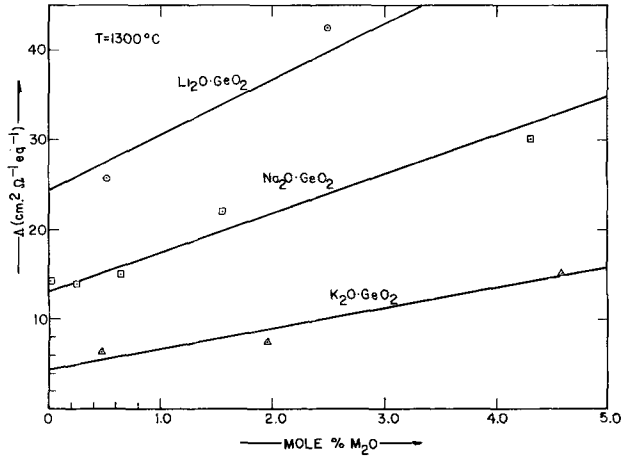

Fig. 2. Large-scale plot of equivalent conductance isotherms (1300°C) for GeO_2 rich alkali germanate melts.

[3] The conductance point for the lowest Na_2O content in Fig. 2 (pure GeO_2 containing 0.001-0.01 w/o Na_2O impurity) was calculated with Eq. [3], 0.01 w/o Na_2O assumed. This point falls close to the Na_2O isotherm and is within the deviation experienced by the other data points. This offers a possible explanation of the fact that the present value of κ_{1300} for GeO_2 is 1.59×10^{-4} ohm^{-1} cm^{-1}. Essentially the same value was obtained for a second sample run in a dry O_2 atmosphere. It is slightly higher than Mackenzie's value of 6.8×10^{-5} ohm^{-1} cm^{-1} (7) for a sample that contained 0.1 w/o CaO and less than 0.001 w/o Na_2O, MgO, and SiO_2.

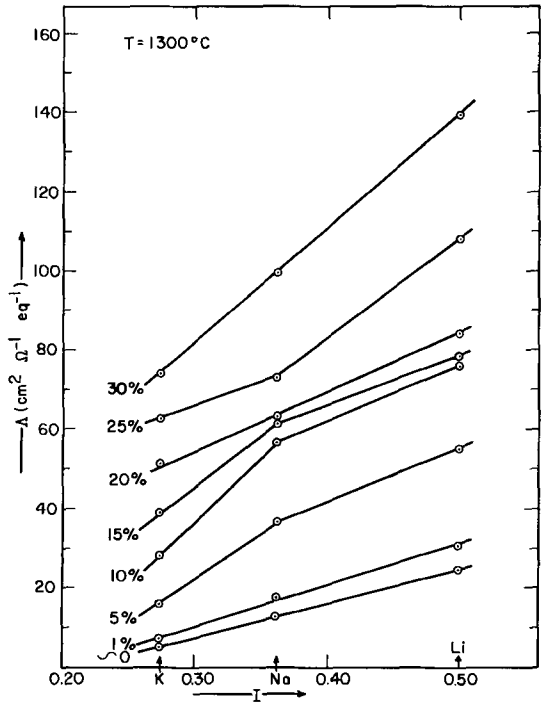

Fig. 4. Isocomposition plots of equivalent conductance at 1300°C as a function of *I*, the cation-oxygen attraction force.

strength of K^+ is not large enough to dominate mobility completely in the 5 to 15 mole % K_2O region.

It is now suggested that (*a*) the aforementioned change of Λ_{1300} dependence on *I* and (*b*) the apparent Λ_{1300} deviations experienced by K^+ are both indirectly associated with the gradual formation of clusters of GeO_6 octahedra. The appearance of clusters of edge shared GeO_6 octahedra can lead to small, local regions of order that are randomly dispersed throughout the O-Ge-O liquid. Instead of a silica like situation, there would be a different distribution of hole sizes that could conceivably lead to a greater dependence of cation mobility (under conditions of an applied electric field) on field strength.

The coordination change for germanium(IV) is accompanied by a slightly more voluminous packing of oxygens around the Na^+ and K^+ ions (2). This could superimpose a volume restriction on the field strength factor for the mobility of the relatively large potassium containing polyhedra at 1300°C.

The general trend for each cation at 1150°C is similar to those observed at 1300°C. However, small differences do occur. The Λ_{1300} plateaus for Li^+ and Na^+ (Fig. 1) tend toward slight Λ_{1150} maxima at about 10 mole % M_2O and Λ_{1150} minima at about 20 mole % M_2O, while Λ_{1150} for K^+ curves slightly as it approaches infinite dilution at pure GeO_2. A collective comparison of the three Λ_{1150} isotherms reveals one reversal. Thus, $\Lambda_{K^+} > \Lambda_{Na^+}$ for the 19 to 25 mole % M_2O region. Clearly, cation mobility at 1150°C (just 35°C above the melting point of pure GeO_2) is not the reasonably simple or linear function of *I* that it appears to be at higher temperatures. The fact that these additional irregularities are found in a composition region where extensive GeO_6 octahedra formation occurs suggests a possible relationship.

Activation energies.—The large activation energy decreases that are discontinuous functions of composition (Fig. 3) indicate a possible change of conductance mechanism, especially for small concentrations (less than 1 mole % M_2O) of Li^+ and Na^+ ions. The general trend of $\Delta H^{\neq}_K$ for the zero to 15 mole % M_2O region ($K^+ > Na^+ > Li^+$) is similar to that observed for simple alkali halide molten salts (which possess much smaller $\Delta H^{\neq}_K$ values).

The activation energies for these alkali germanate melts are not linearly dependent on *I*. However, they are linearly dependent on cation volume (Fig. 5) for compositions in the 0 to 15 mole % M_2O region. The fact that this dependence gradually decreases and finally becomes nonexistent at 17 mole % M_2O suggests that network alteration proceeds in such a fashion as

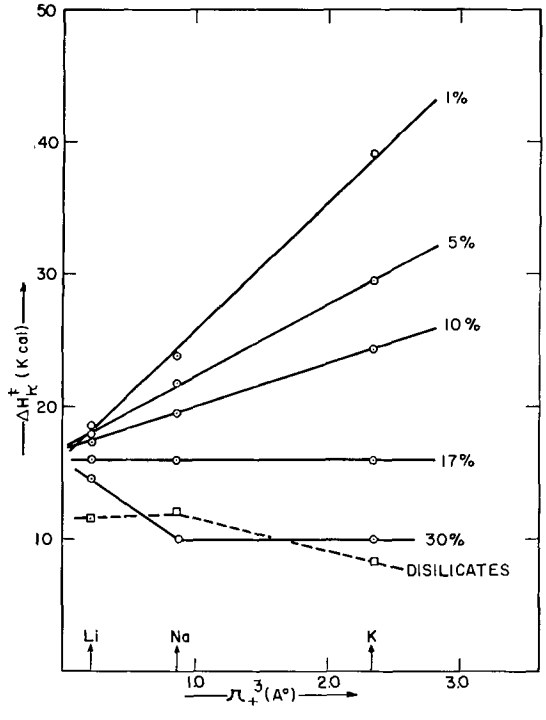

Fig. 5. Isocomposition plots of activation energy for electrical conductance ($\Delta H^{\neq}_K$) as a function of cation volume.

to produce a similar energy barrier for electrical conduction when an alkali germanate melt contains a mixture of GeO_6 and GeO_4 polyhedra.

It is suggested that since $\Delta H^{\neq}_{\kappa}$ is initially related to cation volume, hole size plays a role in the conductance mechanism. Apparently, the critical hole size for the 0 to 10 mole % M_2O region lies between the sizes of the Na^+ and K^+ ions, K^+ being a trifle too large. This could explain the absence of an immediate rather sharp decrease of $\Delta H^{\neq}_{\kappa}$ with increase of K_2O content (Fig. 3).

Comparison with alkali silicate melts.—No conductance data are available for molten binary alkali silicate systems containing less than 20 mole % alkali oxide. Extrapolation of the silicate data from the 20 mole % M_2O region to pure SiO_2 would be risky because of the sharp property changes to be expected. However, comparisons are possible for melts close to the 33 mole % M_2O composition.

Figure 6 reveals a marked difference in the field strength dependence of Λ for the 30 mole % M_2O germanate melts at 1150°C and the 33 mole % M_2O silicate melts at 1750°C. Although the temperatures are different, each isocomposition line represents a temperature region just above the melting point of the respective network forming species. Cation mobility in the silicate melts is clearly not a simple function of ion-oxygen attraction. This is an additional indication that (*a*) the molten germania network is altered in a fashion that is different from that suggested by Bockris *et al.* (3, 6) and (*b*) the structure of these germanate melts differ from that postulated for the corresponding silicates.

The interpretation of the cation volume dependencies observed for $\Delta H^{\neq}_{\kappa}$ in the 30 mole % M_2O region (Fig. 5) is not as simple as for the lower alkali concentration melts. Although the trends are not exactly similar for the two network formers, the relative values for $\Delta H^{\neq}_{\kappa}$ in each cation system suggest that they possess similar conductance mechanisms at about 33 mole % M_2O.

Bockris *et al.* developed the following equation for the calculation of the entropy of activation ($\Delta S^{\neq}_{\Lambda}$) for molten alkali silicate melts (6). They used Eyring's theory of absolute reaction rates

$$\Lambda = 3.26 \times 10^{19}\, zd^2 \exp(\Delta S^{\neq}_{\Lambda}/R) \exp(-\Delta H^{\neq}_{\Lambda}/RT) \quad [4]$$

where z is the ion charge and d the 1.5Å (jump distance).[4] The free energy of activation ($\Delta F^{\neq}_{\Lambda}$) can then be calculated from

$$\Delta F^{\neq}_{\Lambda} = \Delta H^{\neq}_{\Lambda} - T\,\Delta S^{\neq}_{\Lambda} \quad [5]$$

The conduction model for Eq. [4] involves cation movement from one interstitial hole in the oxide network to the next. The calculation of $\Delta S^{\neq}_{\Lambda}$ and $\Delta F^{\neq}_{\Lambda}$ in such a fashion is at best approximate. These quantities have been calculated for the present alkali germanate melts solely for the purpose of comparing them with the alkali silicate values.

Figure 7 depicts $\Delta S^{\neq}_{\Lambda}$ and $\Delta F^{\neq}_{\Lambda}$ as functions of melt composition for the alkali germanate systems. Comparison of the $\Delta S^{\neq}_{\Lambda}$ values with the $\Delta H^{\neq}_{\Lambda}$ curves of Fig. 3 shows that $\Delta H^{\neq}_{\Lambda} >> T\Delta S^{\neq}_{\Lambda}$ for all of these germanate melts (usually by a factor of 3 to 7 x greater). It would appear that the enthalpy (or energy barrier) predominates over any steric factor in the activated complex during cation displacement.[5] This predominance of $\Delta H^{\neq}_{\Lambda}$ is manifest in the slight $\Delta F^{\neq}_{\Lambda}$ trends (Fig. 7) where $K^+ > Na^+ > Li^+$ for all germanate compositions studied.

Bockris *et al.* (6) reported more negative entropies of activation and slightly smaller enthalpies of activation (by about 4 kcal at 20 mole % M_2O) for the alkali silicates at 1750°C. This reveals the larger relative role of a steric factor in the activated complex for silicates when compared to germanates. The trend toward more negative entropies of activation for the alkali rich germanate melts (Fig. 7) is one that suggests a slight similarity with the higher temperature silicate analogues.

Although it would appear that similar cation jumping mechanisms occur in the 20-30 mole % M_2O region for both network formers, there are differences of detail that can be related to melt structural differences.

Comparison with molten salts.—Figure 6 compares the Λ *vs.* I plots of 30 mole % M_2O germanate melts at 1150°C with similar data for a comparable series of alkali disilicate melts at 1750°C and with a series of alkali chloride melts at $T = 1.05$ (T_{MP}) {temperature range 650°-890°C}. Two facts stand out: (*a*) the Λ *vs.* I trend for the alkali germanates is similar to the trend for alkali chlorides, and (*b*) cation mobility is higher in the alkali chloride melts than in either of

[4] A dielectric constant of 5 was assumed for the silicate melts. The same value has been assumed for the corresponding germanate melts.

[5] This observation reinforces the significance of the dependence of $\Delta H^{\neq}_{\Lambda}$ on cation volume for the 0 to 20 mole % M_2O region.

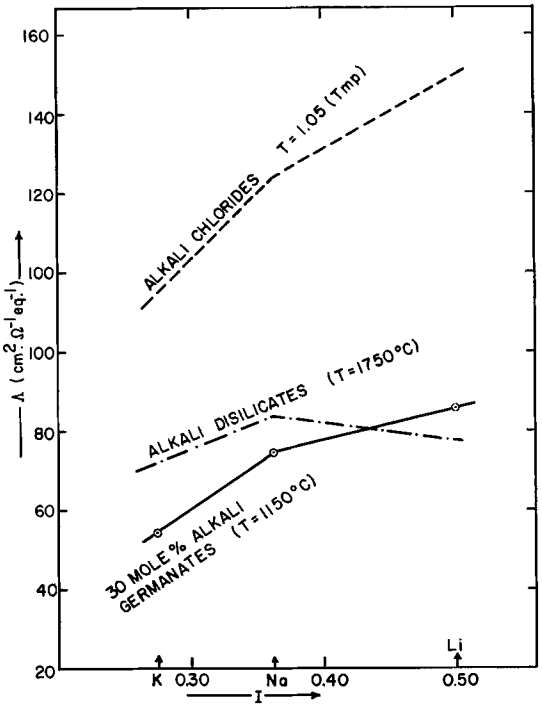

Fig. 6. Equivalent conductance *vs.* I for a series of selected molten salts, molten silicates, and molten germanates.

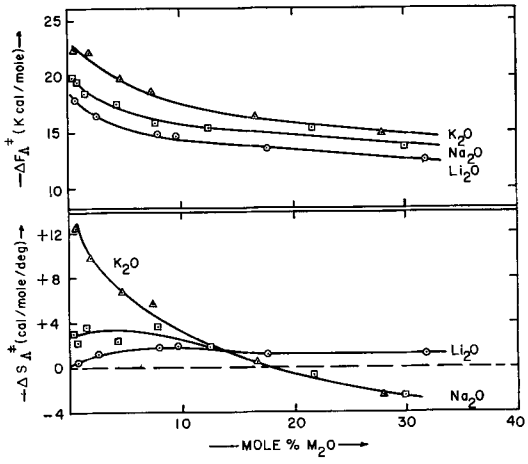

Fig. 7. Free energy of activation ($\Delta F^{\neq}_{\Lambda}$) at 1300°C and entropy of activation ($\Delta S^{\neq}_{\Lambda}$) as a function of composition for a series of alkali germanate melts.

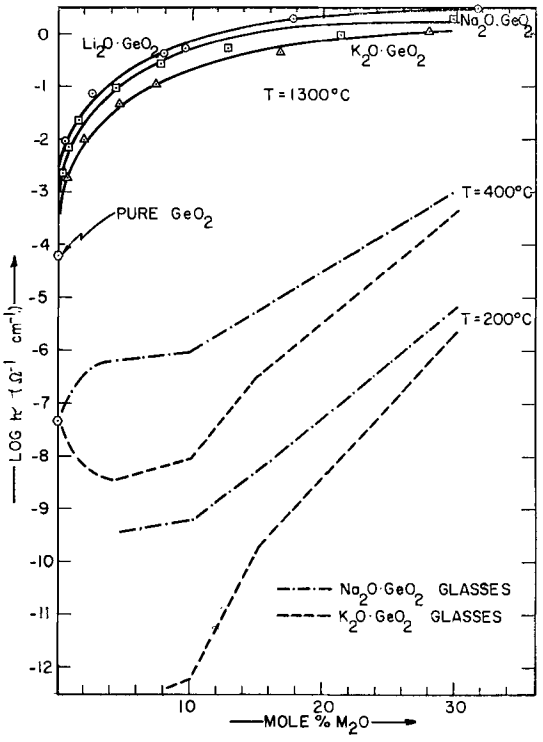

Fig. 8. Specific conductance *vs.* composition for alkali germanate melts and alkali germanate glasses: — • — • —, $Na_2O \cdot GeO_2$ glasses; — — —, $K_2O \cdot GeO_2$ glasses.

the oxide liquids at much higher temperatures {for $T \sim 1.05$ (T_{MP}) of the network former}.[6]

Thus, although the cation mobilities are reasonably large in a 30 mole % alkali germanate melt, they are still only one-half the value experienced in a simple chloride melt. The mixture of holes produced by the presence of GeO_6 and GeO_4 polyhedra in the anionic portion of the liquid obviously does not enhance cation mobility to the same extent as the holes in a simple chloride ion matrix.[7]

Comparison with alkali germanate glasses.—The specific conductances of the sodium germanate melts at 1300°C are from 10^3 to 10^5 times higher than the values reported by Ivanov (4) for the analogous glasses at 400°C (Fig. 8). These differences are even larger for the potash compositions. This is indicative of a greatly reduced charge carrier mobility for the glassy state and is to be expected. These conductance differences reach a maximum at an alkali oxide content of about 10 mole % M_2O (Fig. 8) and are followed by a continuous decrease as far as measured (to about 30 mole % M_2O).

It appears that cation mobility in the glass is altered in a slightly different fashion with change of composition than that encountered for melts at 1300°C.[8] The specific conductance in the 0 to 15 mole % M_2O region appears to be more steeply dependent on ion field strength for a given glass than for its corresponding liquid.

The $\Delta H^{\neq}_{\kappa}$ differences between melt and glass (Fig. 3) are not nearly as pronounced as those just discussed for specific conductance. The glass state values reported by Ivanov (4) are always larger than the melt values reported herein, but only by about 1-5 kcal. Also, $\Delta H^{\neq}_{\kappa}$ for K^+ is generally larger than $\Delta H^{\neq}$ for Na^+ for both glass and melt. However, $\Delta H^{\neq}_{\kappa}$ in the glasses is independent of ion type (for K^+ and Na^+) at about 30 mole % M_2O compared to 17 mole % M_2O for the melts.

In conclusion, the similarity of energy barriers for alkali germanate glasses and melts suggests that the same activated process or mechanism of electrical conduction holds for both condensed states.

[6] The temperature coefficients (or activation energies) are largest for the alkali germanate melts.

[7] Disruption of a simple anion lattice also appears to account for the conductance decreases that occur during the melting of α-AgI and the addition of Ga^+ to either molten Ga_2Cl_4 (8) or molten Ga_2I_4 (9).

[8] Examination of Eq. [3] might suggest that significantly different density changes with composition between glass and melt might be responsible. This is not the case. Other studies have shown (10-14) that the density *vs.* composition plots for most of the alkali germanate glass systems exhibit maxima similar to those reported for the high-temperature melts (2). This justifies the use of κ in the above comparison.

Vacuum Deposited Molybdenum Films

R. A. Holmwood and R. Glang

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York

ABSTRACT

Vacuum evaporation of molybdenum with an electron bombardment source on oxidized silicon wafers produces films whose properties depend on the condensation temperature. At 600°C or above, the films have resistivities comparable to molybdenum wire, satisfactory adhesion, and tolerable stress. They are potentially useful as interconnections for silicon devices and monolithic circuits. All films are polycrystalline with (110) fiber texture. Other crystallite orientations appear above 500°C, while simultaneously the intrinsic film stress becomes decreasingly tensile and, at 625°C, compressive. Film stress and preferred orientation are considered to result from the interaction of lattice defects during the entire growth process and not merely from lattice distortions at the film substrate interface.

Vacuum deposited metal films are finding increasing application in silicon devices and monolithic circuits. At present aluminum films are widely used for contacts and interconnections. However, these films are easily scratched and tend to corrode when exposed to moisture. Among alternative metals, molybdenum is attractive because its coefficient of thermal expansion is closer to that of silicon than any other metal except tungsten. Furthermore, it is harder than aluminum, while its resistivity is only about twice as high. However, the vapor pressure of molybdenum is less than 10^{-2} Torr at 2530°C, which has long been an obstacle in attempts to produce evaporated coatings (1). Recently, the development of electron bombardment sources has made possible the evaporation of refractory metals (2, 3). In this investigation, electron bombardment has been used to evaporate molybdenum, and the properties of the resulting films have been studied to evaluate their applicability in microelectronic circuits on silicon substrates.

Experimental Techniques

The molybdenum films were prepared in a commercial vacuum system equipped with a 4 in. oil diffusion pump and a liquid nitrogen trap located directly over a water-cooled baffle. A schematic diagram of the vacuum chamber is shown in Fig. 1. It consists of an 18 in. open end stainless steel bell jar with aluminum top plate and dutchman collar. The insertion of a liquid nitrogen shroud greatly improved the ultimate pressures obtainable. Molybdenum was evaporated from a work-accelerated electron beam source shown in Fig. 2.

The source material was vacuum zone purified molybdenum rod with a specified purity of 99.999% (4). The weight of a charge varied from 4 to 9g. The charge was placed on a water-cooled copper pedestal at ground potential. A heated tungsten filament surrounding the charge and enclosed by a tantalum deflection shield served as an electron source. Filament and shield were at —5 kv relative to the charge. The power supplied to the source was adjusted by varying the temperature of the tungsten filament. About 500w were required to initially melt the charge, and 1.5 kw to produce a deposition rate of 10 Å/sec. During evaporation, some molybdenum was deposited on the tungsten filament thus lowering its resistance. Similarly, the increasing thermal contact between the melting charge and the cooled pedestal as well as the gradually decreasing size of the melt necessitated continuous power adjustments to maintain a constant deposition rate.

The deposition rate was monitored by a quartz crystal oscillator operating at 4.1 mc. A programmed cam opened a shutter exposing the crystal to the evaporant for 10 sec, and then closed the shutter for another 10 sec. Just prior to opening again, the frequency was measured and printed on tape. The frequency difference between intervals was converted to an average rate for the exposed time. The conversion factor was obtained by an initial calibration, after which the crystal remained fixed in relation to source and substrates. The resonant frequency becomes temperature sensitive when the crystal exceeds approximately 100°C. To avoid unnecessary radiant heating from the substrate holder and to facilitate faster temperature stabilization after exposure to the source, the crystal was placed in a water-cooled copper holder. This mode of operation provided thickness and rate control with an accuracy of ± 10%.

The substrate heater assembly consisted of a stainless steel cylinder with a closed bottom suspended from the top plate. Three cartridge heaters embedded

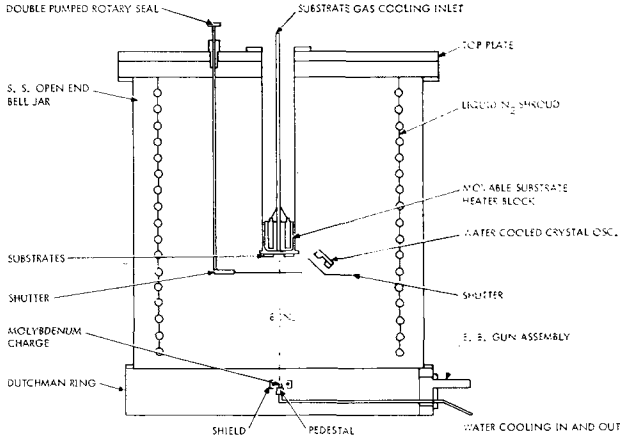

Fig. 1. Schematic diagram of vacuum chamber

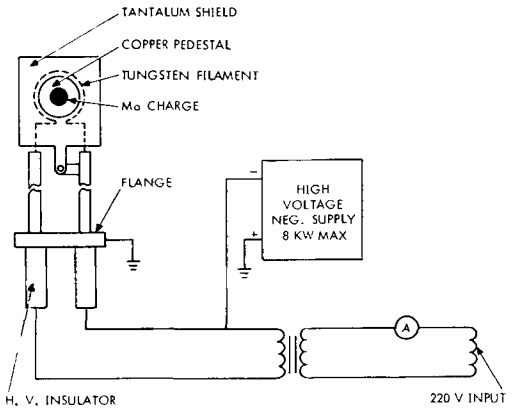

Fig. 2. Schematic diagram of Mo evaporation source

in a nickel block with a gas cooling tube attached were inserted into the steel cylinder as shown in Fig. 1. Thus, heat supply to the substrates was regulated external to the vacuum chamber. Inside of the vacuum chamber, a molybdenum plate was fastened to the bottom of the steel cylinder. This plate had three circular recesses to accommodate 1 in. diameter silicon substrates, which were held in place by ring shaped clamps. Good thermal contact between the substrates and the molybdenum holder was achieved by applying gallium metal to the interface. The temperature was monitored by a thermocouple attached to the molybdenum holder. Comparison measurements with thermocouples silver soldered to the front surfaces of silicon wafers showed the substrate temperatures to be within 5°C of the holder temperature. However, at substrate temperatures above 600°C, gradual loss of thermal contact occurred because the gallium alloyed with the molybdenum. Consequently, substrate temperatures higher than 600°C may be in error as much as 20°C. By adjusting heater current and gas flow manually, the substrate temperatures were maintained within ± 5°C.

The chamber was evacuated while the substrates were heated to 400°C and with liquid nitrogen circulating through the shroud. The ultimate pressure prior to energizing the source and with the substrates at deposition temperature was always below 1.10^{-7} Torr. When the molybdenum was melting, some outgassing occurred bringing the pressure temporarily up to about 2.10^{-6} Torr. During the evaporation, the pressure remained below 2.10^{-7} Torr.

Film Properties

Early evaporation experiments demonstrated that molybdenum film properties are most sensitive to the deposition temperature. Other experimental conditions were held constant. All films were approximately 1μ thick and deposited at 10 ± 1 Å/sec. The substrates were 0.006-0.008 in. thick silicon wafers, cut from (111) oriented single crystalline rods. They had been lapped, chemically etched, and thermally oxidized. The oxide was approximately 6000Å thick. Prior to deposition, the wafers were cleaned ultrasonically in detergent solution, demineralized water, and acetone and stored in a vapor degreaser containing isopropanol.

All measurements on films were made after the samples had been removed from the vacuum system. The thickness was determined with a stylus instrument (5) after a step had been etched into the film. Reproducibility was about ± 4%. Control measurements were made on parallel monitor slides using interferometric techniques. Thickness data of both methods agreed within the error limits of the stylus method.

Resistivities.—The sheet resistances of the molybdenum films ranged from 0.05 to 0.55 ohm/sq at room temperature. Measurements were made with a commercial instrument containing four probes in a linear array. For comparison, voltage drop measurements were performed on subtractively etched film patterns of known geometry. The four point probe data were always about 4% lower than the voltage drop values. The room temperature resistivity of molybdenum films as a function of the deposition temperature is shown in Fig. 3.

The resistivity of etched film patterns was measured from 25° to 100°C in 5° intervals. These data were evaluated by the method of least squares to determine the temperature coefficient α and the resistivity at 0°C, ρ_0, as defined by the equation

$$\rho(T) = \rho_0 + \rho_0 \cdot \alpha \cdot T \qquad [1]$$

Results are shown in Table I along with the ratio of resistivities at liquid nitrogen temperature and 0°C. Resistivity data are a good indication of the combined effects of chemical impurities and physical defects on

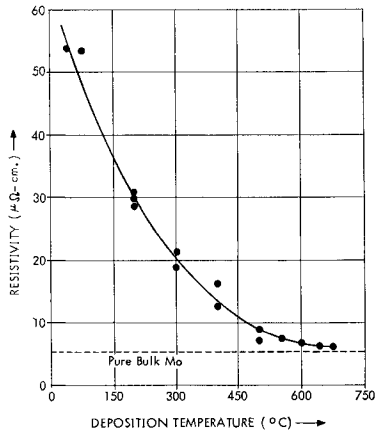

Fig. 3. Room temperature resistivity of molybdenum film vs. deposition temperature.

the mean free path of electrons (6). For a transition metal such as molybdenum, size effects on the mean free path need not be considered for films 1μ thick (7, 8), particularly since the structure of these films must be expected to be highly defective. In evaporated chromium films, for example, the mean free path of electrons has been estimated to be about 30Å (9), and in films of tantalum and tungsten the resistivity becomes independent of thickness from 300 to 400Å on (3).

The resistivity curve shown in Fig. 3 indicates increasing film purity and decreasing structural defects with increasing deposition temperature. At 600°C the film resistivity and its temperature coefficient approach the values of the bulk metal and are similar to those of drawn pure molybdenum wire (10). Mattiessen's rule holds with fair approximation as shown in column V of Table I. Thus, the magnitude of the residual resistivity of high-temperature films can be explained with the assumption of stress and a moderate concentration of point defects. Examples of electrical properties of heavily deformed wire in Table I show that stress contributes relatively little to the residual resistivity. Therefore, low-temperature films must have a large number of scattering centers. The highest film resistivities observed cannot be attributed merely to lattice defects, but indicate chemical impurities. The large deviations from Mattiessen's rule suggest the presence of a second phase. Molybdenum is known as an effective getter material for many gases including oxygen (11). The lower molybdenum oxides are thermodynamically stable in the pressure-temperature range in question. Although data for this temperature interval are not available, it is known that 1545°C are required to produce a total sublimation pressure of 0.25 Torr over MoO_2+Mo (12). Furthermore, oxide formation has been observed to occur at the grain boundaries if molybdenum was annealed in vacuum containing minute quantities of oxygen (13).

Therefore, the presence of grain boundary oxide in molybdenum films deposited at low temperatures is quite possible. The assumption can be reconciled with a positive temperature coefficient of resistivity such as observed if the grain boundary phase merely constricts the conductive paths between grains, but does not form a coherent barrier layer.

The process of oxide formation during film deposition must be preceded by chemisorption of oxygen atoms. With increasing substrate temperature, the probability of desorption of adatoms increases, and fewer oxide nuclei will form. Some adatoms are trapped before desorption or incorporation into an oxide nucleus occurs, thus forming impurity scattering centers. The latter must also decrease with increasing substrate temperature as desorption becomes more complete.

In conclusion, the mechanisms suggested to interpret the resistivity *vs.* temperature curve of molybdenum films attribute the greatest contributions toward residual resistivities to grain boundary oxide and impurity scattering. Both effects decrease with deposition temperature due to increasing desorption of adatoms. At the highest temperatures, the residual resistivity is small enough to be explained largely on account of lattice defects and stress.

Adhesion.—The adhesion of the molybdenum films to the substrates varied with the deposition temperature. Films prepared below 100°C did not adhere well and sometimes peeled off on exposure to air. The best adhesion was achieved between 200° and 500°C; these films could not be torn off the substrates by repeated attempts with adhesive tape (14). Films prepared at 100°-200°C or above 500°C adhered firmly enough to withstand the application of photosensitive lacquer, chemical etching, and similar process steps, but could be partially removed with adhesive tape.

Crystalline structure.—The films were investigated by x-ray diffraction techniques using CuK_α radiation and a pulse height analyzer. All films were polycrystalline and showed diffraction peaks associated with bcc molybdenum lattice. The relative peak intensities indicated a fiber texture typical for bcc metals with the lattice plane of greatest packing density, (110), parallel to the substrate surface (15). This texture has been reported before for evaporated molybdenum films (16). The only other orientation consistently present was (211). Crystallites with planes of higher indices parallel to the surface appeared regularly at or above 500°C deposition temperature. In this range, the intensities of (211) peaks increased slightly, but (110) still remained the strongest peak.

It has been attempted to determine the average grain size from the width of the diffraction peaks. Due to the absence or weakness of most peaks, it was not possible to apportion line broadening accurately to grain size and random lattice distortion effects. Estimated grain sizes of films deposited between room temperature and 400°C are in the range of 250-500Å. At deposition temperatures of 600°C or higher, the diffraction peaks are very sharp, and the average grain size must be greater than 1000Å. For several films, the lattice constant in the direction perpendicular to the film surface has been calculated. Although these data are not very accurate, they indicate tensile strain of 0.10 to 0.25% parallel to the surface for all films. This is the same order of magnitude which was obtained by separate stress measurements discussed below.

Film stress.—Stresses of considerable magnitude have been observed in evaporated films (17-19), and various measuring techniques have been reported (20, 21). If the films are attached to a thin substrate, the latter experiences an elastic deformation which can be used to determine the stress. A modification of this technique was applied to evaluate the stress in molybdenum films. It can be shown that a circular substrate wafer assumes a parabolic curvature resulting from the presence of a stressed film (22). The curvature can be measured and expressed by the parameter (ϵ) of the parabola $\delta = \epsilon \cdot r^2$, δ being the upward deflection of the substrate at a distance r from the center. The film stress parallel to the surface (σ) is given by

$$\sigma = \frac{E}{3(1-\nu)} \cdot \frac{t_{Si}^2}{t_{Mo}} \cdot \epsilon \text{ [dynes/cm}^2\text{]} \qquad [2]$$

where t_{Si} and t_{Mo} are the thicknesses of substrate and film. The proportionality factor includes Young's modulus and Poisson's ratio for (111)-oriented silicon wafers; its numerical value is $10^{12}/1.30$. Stress data obtained by this method are accurate within about $\pm$ 10%.

All films were found to be under tensile stress, and depending on the deposition temperature, their values ranged from $2.5 \cdot 10^9$ to $7.5 \cdot 10^9$ dynes/cm^2. This is the same order of magnitude published by Hoffman *et al.* for thin films of Ni, Fe, and Co (18). The tensile strength of sintered or cast molybdenum ingots is typically 3 to $5 \cdot 10^9$ dynes/cm^2, but may increase to $1.7 \cdot 10^{10}$ dynes/cm^2 after cold deformation (23). Because of the highly defective structure, the strength of evaporated films is probably similar to cold deformed bulk material. Besides, the tensile strength of films even several microns thick often exceeds the strength of bulk material due to pinning of dislocations at the surface, particularly if the metal forms oxide films which further impede the motion of dislocations (24). It is therefore safe to conclude that the stress values observed are below the fracture strength of the films. Indeed, microscopical investigation of slightly etched molybdenum films over oxidized silicon surface has never revealed the presence of cracks. This is not true for films on bare silicon surfaces, where solid-state diffusion at 600°C produces molybdenum silicide phases which are brittle and subject to cracking.

The stress data quoted for molybdenum films have been measured after cooling the substrates to room temperature. Therefore, part of this total stress is due to the difference between coefficients of expansion of molybdenum and the silicon substrate. This portion of the stress can be subtracted to arrive at the intrinsic stress, which is a more meaningful quantity in regard to the film condition at the deposition temperature (25). For purposes of this discussion, the total stress (σ) has been converted into total strain (Δl) parallel to the substrate surface

$$\Delta l = \frac{1-\nu}{E} \cdot \sigma \qquad [3]$$

where $\nu = 0.324$ and $E = 3{,}17 \cdot 10^{12}$ dynes/cm^2 are Poisson's ratio and Young's modulus of elasticity for molybdenum (26). The strain contribution of differential thermal expansion ($\Delta l_{d.e.}$) has been calculated from expansion data of both materials. Dilatometer measurements on 1 x 0.1 x 0.1 in. bars of zone purified molybdenum and of silicon, the latter cut from a (111)-oriented single crystal wafer, have been performed in the same apparatus to ensure that the data are comparable. The measured values were in excellent agreement with published data for silicon (27) and molybdenum (23, 28-32). Finally, the intrinsic strain (Δl_i) was calculated according to

$$\Delta l = \Delta l_{d.e.} + \Delta l_i \qquad [4]$$

The three types of strain are shown as a function of temperature in Fig. 4. Between room temperature and 500°C, the intrinsic strain is tensile and nearly constant. Above 500°C, there is a gradual decrease and finally a reversal to compressive strain at about 625°C.

Discussion

It could be argued that the amorphous SiO_2 films may become plastic at the higher temperatures and thus allow the molybdenum films to relieve part of

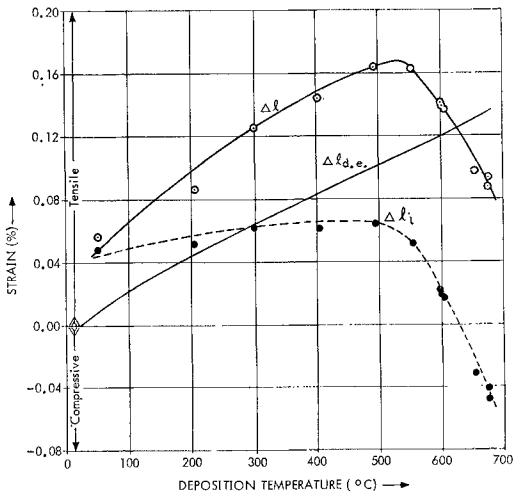

Fig. 4. Strain in evaporated molybdenum films vs. deposition temperature.

the intrinsic stress. If this were the case, the total strain curve would approach the differential expansion curve but not cross it as observed. Similarly, stress relief by contraction of the molybdenum film alone is not possible since this requires movement relative to the SiO_2 film and thus total loss of adhesion. Finally, the possibility of a permanent plastic deformation of the silicon wafer itself must be excluded since the shape of several substrates has been examined closely before film deposition and after its removal without finding any changes. Therefore, the effect of decreasing intrinsic tensile stress and reversal to compression above 500°C must be real.

It is interesting to note that the change in stress behavior occurs in the same temperature range where the films begin to show a trend toward random crystallite orientation. While there is not sufficient information to postulate a detailed mechanism for the origin of intrinsic stress in thin films, experimental results may be interpreted within the concepts of Hoffman and coworkers (18, 19, 25). These authors assume that imperfections formed during deposition undergo change shortly after being trapped by succeeding layers of deposited metal. This rearrangement of atoms, for instance, the conversion of dislocations into vacancies, or vice versa, produces a change in lattice volume and thus causes intrinsic stress. If the mobility of atoms is high enough, the lattice defects may consolidate by forming grain boundaries. The results of this investigation suggest that from 500°C on, lattice defects have sufficient mobility to interact by forming crystallites of orientations other than (110), and that this process is coupled with some relief of tensile stress. At the lower temperatures, the lower atomic mobility or the presence of grain boundary oxide or both of these factors confine the interaction of defects to individual crystallites which maintain their orientation and remain highly stressed.

This does not explain the occurrence of compressive intrinsic stress above 600°C. There may be another defect interaction mechanism at the higher temperatures with the effect of increasing rather than reducing the lattice volume. Another possible cause for compressive stress is the presence of residual gas atoms in solid solution (21). However, additional assumptions have to be made to explain why the compressive effect of dissolved gases should be observed only at higher temperatures.

The question of stress as determined by the SiO_2-Mo film interface has also been investigated. Cabrera (33) has discussed stress in epitaxial films under the aspect of lattice mismatch between substrate and film. Although thermal SiO_2 is not crystalline, it consists of a distorted network of cross-linked tetrahedrons with

Table II. Effect of low-temperature nucleation on film strain

Run No.	Total strain, % Film prenucleated at 400°C	"Pure" 650°C film
115	0.117	0.081
120	0.118	0.100
122	0.128	0.116

an average Si-Si distance of 3.2Å (34). The atomic distances in various molybdenum lattice planes are 3.15Å for (001), 2.76 and 3.15Å for (110), 2.76 and 4.46Å for (211), and 4.46Å for (111). Consequently, the mismatch of spacing between substrate molecules and molybdenum atoms should produce tensile film stress for (110) and compressive stress for (111) crystallites. The experimental data do not contradict this concept, but are certainly not conclusive. However, it has been investigated whether the structure and stress of the films are determined by the conditions prevalent during nucleation, *i.e.*, by the mismatch at the interface.

Two silicon wafers were loaded into the vacuum system, and one of them was exposed to receive 500-1200Å of molybdenum at 400°C while the other was shielded by a shutter. After raising the temperature to 650°C, a molybdenum film of 10,000Å was deposited over both wafers. If the lattice mismatch at the interface determines the character of the film, the samples prenucleated at 400°C should continue to grow at the higher temperature without changing their (110) orientation and thus maintain the high stress typical for low-temperature films. Considering the difficulties of close temperature control at high temperatures, the "pure" 650°C film should show a total strain of 0.08-0.12%, while a 400°C film would vary between 0.14-0.15%. The results of three pairs of samples are shown in Table II.

The data indicate that the prenucleated films are consistently more strained than the "pure" 650°C films, but not as high as a "pure" 400°C film. Furthermore, all samples show x-ray diffraction peaks of (200), (310), (222), and (321) crystallites typical for high-temperature films in addition to (110) and (211). Consequently, the structure and stress situation of the prenucleating layer does not propagate throughout the entire 650°C film. While the slightly higher stress values may be indicative of a gradual transition, the high-temperature mechanism of defect interaction dominates, causing reorientation of small crystallite regions and partial stress relief. In conclusion, these results, too, support a stress generation and relief mechanism effective during the entire film growth as suggested by Hoffman and, at least for these polycrystalline films, contradict the concept of stress being determined exclusively by lattice distortions at the substrate interface.

Summary and Conclusions

A vacuum evaporation process for molybdenum with a 2 kw work accelerated electron gun has been developed. Thickness control for films of about 1μ may be accomplished within ± 10% by a shielded and water-cooled quartz crystal oscillator. The properties of molybdenum films condensed on oxidized silicon wafers are determined by the substrate temperature. To achieve resistivities of 10 μ ohm-cm or less, condensation temperatures above 450°C are required. Resistivities comparable to molybdenum wire are obtained at or above 600°C. At these temperatures, the adhesion to thermal SiO_2 is weaker than in the interval 200°-500°C but still sufficient for subsequent device fabrication processes. All films have tensile stresses close to the fracture strength of bulk molybdenum. However, this is not considered to be critical since the tensile strength of thin films is usually higher than for the same material in bulk form; accordingly, film cracking has not been observed. Consequently, molyb-

denum films are compatible with passivated silicon substrates and may be used for integrated circuit interconnections. In contact with bare silicon, the applicability is temperature limited on account of the formation of brittle molybdenum silicides through solid-state reaction. The films exhibit an interesting stress behavior insofar as the intrinsic component is nearly constant up to a deposition temperature of 500°C, then decreases and changes from tensile to compressive stress at 625°C. This is accompanied by a transition from almost pure (110) to more random crystallite orientation in the same temperature interval. A casual relationship between the two phenomena is suggested in accordance with concepts about the origin of stress proposed by Hoffman *et al.* The increased atomic mobility at the higher temperatures allows consolidation of lattice defects by reorienting small regions of material and simultaneously reducing tensile stresses. It is also shown that crystallite orientation and generation of stress are not determined by the first layer of deposit attached to the substrate, but are subject to change during the entire film growth if temperature conditions are altered.

Acknowledgment

The authors would like to thank Mrs. C. Walter for stress measurements, Messrs. B. L. Graves for sample preparation, B. Narken for expansion measurements, E. J. Taschler for valuable help in the assembly of the vacuum system and evaporation source, Ch. H. Ma, J. S. Makris, and N. R. Stempel for x-ray diffraction work.

Manuscript received Feb. 17, 1965; revised manuscript received April 2, 1965. This paper was presented at the San Francisco Meeting, May 9-14, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

Contact Potential Difference between Silver Nitrate and Silver

James L. Copeland[1] and Ralph L. Seifert

Department of Chemistry, Indiana University, Bloomington, Indiana

ABSTRACT

The silver nitrate-silver contact potential was determined from 190° to 280°C by the Zisman dynamic condenser method. At the melting point of the salt the contact potential of liquid silver nitrate relative to silver is —530 mv, with a temperature coefficient of 0.14 mv/deg, and that of the solid salt is —608 mv. The discontinuity of 78 mv at the melting point is attributed primarily to a greater excess surface concentration of silver ions in the liquid than in the solid salt.

Of the various methods that have been used to measure contact potential between two dissimilar substances, only the electron beam deflection method (1), the Kelvin variable condenser method (2, 3), and the Zisman dynamic condenser method (4) do not involve ions and/or electrons impinging on the test surfaces during part of the procedure. Therefore these methods are most acceptable for study of the contact potential of a metal and its salt, either molten or in solution. The Zisman dynamic condenser method was

[1] Present address: Department of Chemistry, Kansas State University, Manhattan, Kansas 66504.

used in this study because it permits greatest precision of measurement.

One plate of the dynamic condenser is vibrated relative to the other. If there is a difference in the Volta (or outer) potentials of the facing surfaces, the periodic change in capacitance of the condenser produces an alternating current in a high resistance in the circuit joining the plates. The a-c potential across the resistor is amplified. A variable emf source between one plate and the resistor permits equalization of the Volta potentials as indicated by zero a-c signal. This balancing emf at zero signal equals the contact potential between the substances of which the plates are made if there is no net thermal emf in the external circuit and the error due to fringing field (5) is avoided. To the extent that any net error from these two sources can be held constant in two successive series of measurements, the error can be cancelled out by using one condenser plate as a reference surface, determining the apparent contact potential of each of the two desired substances relative to the reference plate (6), and calculating the contact potential of the two substances.

To determine the contact potential between silver and silver nitrate in contact with the silver, a silver vibrating plate was used as a reference. Its contact potential was determined relative to the surface of a stationary silver plate and then relative to silver nitrate covering the stationary silver plate.

Experimental

Materials.—Reagent grade silver nitrate (Baker Analyzed) was used without purification other than drying. Helium used as an inert atmosphere had a stated impurity content of 0.01%.

The two plates comprising the dynamic parallel-plate condenser were fabricated from silver with a purity of 999+ fine as quoted by the Baker Platinum Division of Engelhard Industries, Inc. Before all runs the plates were abraded with No. 1 steel wool and boiled successively in the following concentrated aqueous solutions for about 30 min each, with intervening rinsings in distilled water: (*a*) ammonium hydroxide, (*b*) hydrochloric acid, and (*c*) potassium cyanide. After thorough washing in distilled water, the plates were treated as above but in reverse order for the solutions, rinsed in distilled water, heated in air at 500°-600°C for approximately 4 hr, and then transferred to a desiccator while still hot. During and following this treatment the plates were handled only with clean tongs or surgical latex gloves, care being taken not to touch the active surfaces.

Apparatus.—The vibrating condenser was mounted inside a cubic brass vacuum chamber, designed to permit all operations during a run to be performed without opening the chamber. Viewing ports were provided in the front of the chamber, and three adjustable supports permitted leveling the chamber to insure that the lower surface of the upper condenser plate would be parallel to the surface of the molten silver nitrate. Details of construction are given in ref. (7).

The silver plates of the dynamic condenser are shown in Fig. 1, with the mounting assembly and heater for the vibrating plate. Upper plate (G) was vibrated at a frequency of 40 cps, with an amplitude of 2 mm, by means of a drive shaft which linked connector (A), through a Sylphon bellows, to an external ⅛ hp synchronous motor, geared to deliver 2400 rpm. Heater (C) was supported by its heavy copper leads and did not touch any part of the vibrating plate assembly.

Silver cylinder (H), serving as stationary plate, was mounted above a leveling platform by three silica tubes and a transite ring. The leveling platform could be raised and lowered through a distance of 3.2 cm from outside the vacuum chamber. When (H) was in its lower position a rectangular stainless steel salt pan could be moved between the condenser plates. A

Fig. 1. stud on the sliding bottom of the pan caught on rim (P), dumping silver nitrate into the plate cavity as the pan was pushed over it. The lower portion of cylinder (H) was surrounded by a small cylindrical furnace positioned inside the three silica supports but not touching the cylinder. Thermocouple (D) extended to within 4 mm from the lower surface of plate (G), and thermocouple (I) was about 0.8 mm below the center of the top surface of cylinder (H).

Storage batteries were used for heater current during measurements. Alternating current was used during prolonged periods when measurements were not being made. One side of each electrode heater circuit and of each thermocouple circuit was grounded. A grounded wire shield between each plate and its heater eliminated an observed change in measured contact potential which was proportional to the d-c heater current. The shields also reduced the slight dependence of measured contact potential on mean plate separation to less than the random error in the measurements. This dependence of apparent contact potential on plate separation (5) had already been greatly diminished by making the vibrating plate smaller than the stationary one.

For balancing the contact potential between the plates a K-2 potentiometer was connected by a reversing switch to the vibrating plate and to ground. The off-balance 40-cycle signal was passed through a 50 megohms input resistor of a high-gain amplifier with a band-pass filter tuned to 40 cps. The amplified signal was displayed on an oscilloscope. Although shielded wires were used throughout the circuit for signal-carrying leads and batteries were used for the heaters and amplifier, a small amount of 60-cycle pickup was present in the amplified signal.

Procedure.—To detect a very small amplitude 40 cps signal in the presence of the 60 cps pickup, use was made of the fact that the combined signal was repeti-

tive every 1/20 sec. With oscilloscope triggered by a 60 cps signal and set at a sweep rate of 0.1 msec/cm, a 40 cps component in the input signal produced three almost linear and parallel traces, with vertical displacement proportional to the amplitude of the 40 cps component. The null point, at which a single trace was observed, could be detected within ± 0.2 mv. However, over periods of 2-5 min, the applied potential necessary to obtain a null signal was observed to exhibit random fluctuations, sometimes as large as 3.5 mv but for the majority of experimental points less than 0.8 mv.

With the system evacuated to less than 0.1 mm Hg, the plates were heated for 1 hr at about 300°C. The decomposition pressure of silver oxide at 300°C is 19.8 atm (8). Helium was then admitted to about 50 mm Hg above atmospheric pressure. Contact potential measurements were made at regular intervals until the values became constant. To establish a blank curve for the contact potential of the silver surface of the stationary plate relative to the vibrating reference plate, measurements were then made at plate temperatures comparable to those at which measurements were later to be made with silver nitrate on the stationary plate.

Helium was chosen as ambient gas because studies by Mignolet (9) showed that helium, with the lowest polarizability of any gas, should have undetectable effect on the measured contact potentials of metals. Since its dielectric constant of 1.0000684 at S.T.P. is the smallest of any gas, it would best approximate the dielectric properties of a vacuum while decreasing the rate of loss of salt by vaporization. At no time during the course of a complete run was the condenser chamber opened or the ambient gas altered (except for hydrogen treatment in the last run).

After completion of measurements for the blank curve, the stationary plate was lowered, and silver nitrate was placed in the plate cavity and melted before the plate assembly was raised to measuring position. The dynamic condenser was now composed of the reference plate and the surface of the liquid silver nitrate in contact with the silver surface for which the blank curve had been established. Contact potential measurements were made at a temperature near 250°C until a constant value was attained, and then at different temperatures. For all the silver nitrate measurements, except those in run 3 near the melting point [209.7°C (10)], the temperature of the vibrating reference plate was held 10° ± 1°C above that of the stationary plate to preclude possible condensation of vapor from the molten salt. From 199° to 214°C in the third silver nitrate run some measurements were made with a temperature difference of only 2°, but the average difference was about 3.5°C. Many runs were terminated before constant values were attained at 250°C, owing to such factors as loss of salt by creepage and possibly evaporation, failure of electrical connections within the housing, and electrical shorting by the creeping salt. Generalizations concerning behavior during the blank measurements are therefore based on many more runs than those associated with the three completed salt runs.

In the final run the bare plates were heated in hydrogen as well as helium before constant values were obtained. Prior to this run the stationary plate had been contaminated by silver chloride, which permeated the surface. Since the thermocouple channel was exposed when the contaminated surface was cut away, the plate cavity was refurbished with molten silver and subsequently faced-off and polished prior to routine plate preparation. Since molten silver dissolves more than 20 times its own volume of oxygen (S.T.P.) and solid silver just below its melting point dissolves its own volume (11), the oxygen content of the surface stratum of the refurbished plate must have been considerably greater than that in earlier runs. This was borne out by the initial silver-silver contact potential of about —75 mv at 300°C,[2] which did not change for several days. The helium was then replaced by dry electrolytic hydrogen, whereupon the contact potential abruptly changed polarity and then remained fairly constant at about 100-130 mv. This positive potential of the stationary plate surface, relative to the smaller vibrating plate, could result from reaction of hydrogen with the greater concentration of oxygen diffusing to the surface of the more massive silver cylinder, forming transiently adsorbed water molecules with the positive end of their dipoles outward. On replacement of the hydrogen by helium, the contact potential became even more negative than before, possibly owing to accelerated depletion of oxygen from the small reference plate by the hydrogen treatment. A second hydrogen treatment gave the same behavior, but to less extent. When stability in the vicinity of zero contact potential was finally attained, the system was evacuated at less than 0.1 mm Hg for 24 hr, flushed with electrolytic hydrogen, again evacuated for 24 hr, and then flushed and filled with helium. The plates were aged therein for 48 hr at about 500°C. Subsequent agreement of measurements in this run with the two earlier completed runs indicates that any effect that oxygen may have had on the earlier completed runs was very small.

The silver-silver contact potential measurements in each blank run indicated the time when both plates had aged adequately to nearly identical states, and provided a correction curve for application to the silver nitrate data to compensate for possible temperature-dependent voltages appearing elsewhere in the circuit.

Results

Condenser stabilization.—Figure 2 is a plot of observed contact potential *vs.* time for a typical blank during its stabilization period and illustrates the long time required to attain constant values as well as the tendency to proceed from negative values to zero or slightly positive ones. Since the concentration of oxygen absorbed during the preliminary plate treatment would decrease relatively rapidly in the small reference plate, the slowly diminishing negative contact potential must have resulted from continuing diffusion of oxygen to the surface of the massive silver cylinder forming the stationary plate. The final constant contact potentials obtained in practically all the blank runs were close to zero, indicating that the two silver surfaces were finally almost identical.

Each dynamic condenser composed of silver nitrate surface and vibrating reference plate required two to three weeks to attain constant contact potential at constant temperature. The variation of observed values with time did not display a qualitatively reproducible trend. The general tendency was to begin at negative values, to rise with time to less negative values, and to fall back eventually to a constant value near the ini-

[2] The sign of the contact potential is taken as the sign of the potential applied to the vibrating reference plate to achieve a null point, *i.e.*, the contact potential is the Volta potential of the stationary plate (silver or silver nitrate) relative to that of the vibrating reference plate.

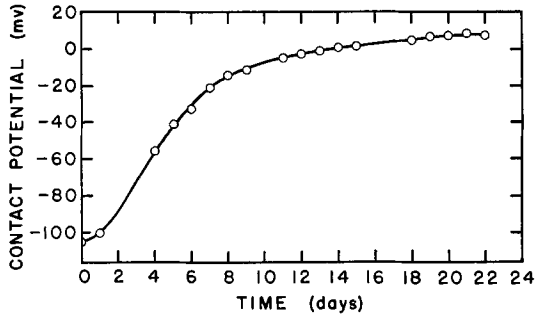

Fig. 2. Typical variation of contact potential between silver plates during stabilization at 280°C for blank run.

tial values. However, plots of the data were erratic, with numerous maxima and minima.

Contact potentials.—Results obtained in the three completed runs are shown in Fig. 3, 4, and 5. Each plotted point represents the average of at least three readings taken over a period of several minutes at the given temperature, which is that for the stationary plate. Time intervals between points at different temperatures varied from 30 min to several hours. After the initial stabilization period, each of the blank runs required two days for completion, and the three silver nitrate runs required three, six, and two days, respectively. Reproducibility of both blank and salt runs was verified by taking data both with descending and ascending temperatures—circles and dots, respectively, in Fig. 3, 4, and 5.

The lower curves in Fig. 3, 4, and 5 give the contact potential, or difference in Volta potential, between the silver nitrate surface and the surface of the reference plate. Subtraction of the potential of the stationary silver plate relative to the reference plate at each temperature (upper curves) gives the desired contact potential, which is the Volta potential of the surface of the silver nitrate, ψ_{AgNO_3}, minus the Volta potential of the silver plate in contact with the salt, ψ_{Ag}. This difference in Volta potentials is given as a function of temperature in Fig. 6, as determined from the smoothed curves in Fig. 3, 4, and 5.

The curvature observed above 214°C in run 1 (Fig. 3) for both the blank and silver nitrate data was unusual, being observed in neither the other two completed runs nor in the numerous sets of blank measurements made in incompletable runs. This curvature must have resulted from some temperature-dependent voltage bias not connected with the silver and silver nitrate surfaces of the stationary plate, since it cancelled out in the calculation of the silver-silver nitrate contact potential, giving a resultant curve similar to those of runs 2 and 3, as shown in Fig. 6. This illustrates the advantage of using a reference plate.

Above about 217°C the blank and silver-nitrate

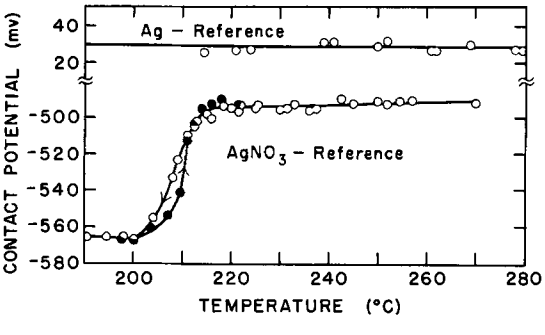

Fig. 4. Contact potentials obtained in run 2. Ten degrees temperature difference between plates for all points.

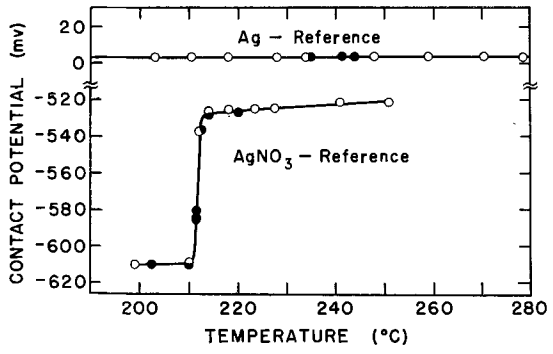

Fig. 5. Contact potentials obtained in run 3. Temperature difference between plates only 2°-5°C for salt data between 199° and 214°C.

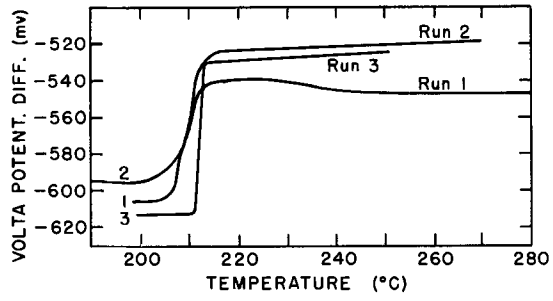

Fig. 6. Volta potential of silver nitrate surface minus that of silver in contact with silver nitrate.

curves for runs 2 and 3 are linear within experimental error. The best linear equation was determined by the method of least squares for each of the four sets of data and the equations for the blank and salt measurements in each run were combined to give the following:

Run 2: $\psi_{AgNO_3\ (l)} - \psi_{Ag} =$

$$-(541.9 \pm 11.5) + (0.085 \pm 0.046)t \qquad [1]$$

Run 3: $\psi_{AgNO_3\ (l)} - \psi_{Ag} =$

$$-(563.2 \pm 5.8) + (0.155 \pm 0.025)t \qquad [2]$$

where t is temperature in °C at the position of the thermocouple in the stationary plate. Equation [1] is based on salt data for t = 218°-270°C and Eq. [2], 218°-251°C. The error terms are standard deviations calculated for the least squares evaluations of the constants. Standard deviations of experimental points from the calculated equations for the blank and salt measurements were, respectively, for run 2, 2.3 and 1.9 mv, and for run 3, 0.12 and 0.74 mv.

Corresponding calculations for linear portions of the curves below the melting point of silver nitrate gave:

Run 2: $\psi_{AgNO_3\ (s)} - \psi_{Ag} =$

$$-(570.5 \pm 19.8) - (0.127 \mp 0.096)t \qquad [3]$$

Run 3: $\psi_{AgNO_3\ (s)} - \psi_{Ag} =$

$$-(622.0 \pm 11.9) + (0.043 \pm 0.058)t \qquad [4]$$

Standard deviations of experimental points for the solid salt measurements were 0.73 mv for run 2 and 0.56 mv for run 3.

If values given by Eq. [1] to [4] are weighted by the reciprocal of their variance, the following average values are obtained. At the melting point of pure silver nitrate, 209.7°C (10), the Volta potential of the liquid salt relative to silver is about —530 mv, with a temperature coefficient of about 0.14 mv/deg, and that of the solid salt relative to silver is about —608 mv, with a temperature coefficient of —0.003 mv/deg. In each phase the silver nitrate is saturated with silver,

helium at about 800 mm Hg, and nitrogen dioxide and oxygen at their decomposition pressures for the silver-saturated solution.

Discussion

Temperature gradients in silver nitrate.—Vertical and radial temperature gradients in the melt resulted from the higher temperature of the reference plate and the cooling of the edge of the stationary plate by convection currents in the helium. Resulting convection currents in the melt may have produced transient local variations in the liquid salt surface during the stabilization period. Mixing by convection may have accelerated the approach to near steady states for processes occurring in the melt, although temperature dependent states would continue to be affected slightly by the temperature gradients.

Silver-silver nitrate interface.—The surface of the stationary plate after a run had the same appearance as following its initial preparation, except that small adherent crystals of silver formed on the inner surface of the cavity rim (P in Fig. 1) at approximately the position of the initial molten salt surface. They were formed in this region of lowest temperature by crystallization of dissolved silver and/or by electrochemical deposition resulting from the radial temperature gradient in the silver. Some localized solution and recrystallization of silver may have occurred at all parts of the interface due to the different work functions of different crystallographic faces. It proved to be impossible to remove the last trace of silver nitrate from the stationary plate by creepage and evaporation before the creeping salt caused electrical leakage inside the condenser chamber. Therefore no measurements were made of the contact potential of the final silver surface relative to the reference plate. If it were different than the value obtained initially, all the calculated contact potentials would be in error by approximately the same small value. The magnitude of the observed discontinuity near 210°C would not be influenced significantly.

Solutes in silver nitrate.—After the long stabilization period the melt must have been saturated, at the stabilization temperature, with helium, silver dissolved from the stationary plate and formed from decomposition of the melt, and the nitrogen dioxide and oxygen from decomposition of the melt. No determinations of solubilities of these substances in silver nitrate have been made.

Since the final stabilized contact potential for the salt runs was always close to the values obtained at the beginning of the stabilization period, the less negative values for the intervening period were caused either by transient effects such as unknown trace impurities in the silver nitrate diffusing to the surface and eventually vaporizing, or by differing rates of increase of the effects due to decomposition of melt, solubility of silver and helium, and electrochemical solution and deposition of silver at the salt-metal interface. If the latter, the influences of the different effects on the final equilibrium state approximately cancelled each other. After a steady state was finally achieved at the stabilizing temperature, any further changes with temperature of effects influencing contact potential must have been reversible and have occurred rapidly enough to be completed by the time the plate temperatures were stabilized, since only small random changes were observed during the 2-5 min periods that measurements were made at each experimental temperature. Any changes occurring more slowly and any irreversible temperature dependent changes must have had no effect on contact potential in view of the observed reproducibility of measurements with ascending and descending temperatures. Thus the presence of any nitrogen dioxide and oxygen from decomposition of the melt must not have influenced the measurements significantly. Reported decomposition pressures (12) increase from 7 mm Hg at 248°C, which is near the stabilization temperatures for the three runs, to 80 mm Hg at 280°C, the highest temperature at which contact potential measurements were made. If the pressure of decomposition products in the condenser chamber increased during high-temperature measurements and these products did affect the measured contact potential, values determined initially at the stabilization temperatures would not have been reproduced later.

Discontinuity of contact potential at the melting point of silver nitrate.—Because of the radial temperature gradient in the silver nitrate, its temperature below the center of the vibrating plate was higher than that near the edge. Therefore, contact potentials obtained near the melting point were influenced by the fraction of the salt surface that had solidified with descending temperatures and the fraction that had melted with ascending temperatures. During run 2 (Fig. 4) thirty minutes elapsed between the measurements at 203.5°, 207°, and 209.5°C, made with ascending temperatures. This was twice the time allowed for stabilization between descending temperatures. Therefore the lower curve must represent a closer approach to equilibrium. When a still closer approach to uniform temperature was achieved near the melting point in run 3 by reducing the temperature difference between plates and waiting about an hour for stabilization at each temperature, the resulting data (Fig. 5) indicated that there must be a discontinuity in the contact potential at the melting point. As measured by the stationary plate thermocouple, the temperature at the sharp rise in Fig. 5 is about 2°C above the melting point of pure silver nitrate (10). This is the combined error resulting from temperature gradients and use of an uncalibrated small-wire thermocouple.

The observed discontinuity in value of the contact potential indicates that the surface potentials of solid and liquid salt at the helium interface differ by about 78 mv. The observed difference may result from the influence of surface concentrations of the solutes discussed above, which would be different for the two phases, and/or from preferential concentration of silver ions in the surface of the melt to a greater degree than in the solid and/or a similar concentration of nitrate ions in the surface of the solid. The concentrations of gases in the melt must have been small and were probably exceeded by the concentration of silver. Since solidification of the silver nitrate progressed toward the warmer reference plate, any silver forced out of solution would tend to collect on the surface of the salt under the reference plate. This would cause a discontinuity in the opposite direction from that observed. Therefore it is concluded that the major cause of the observed discontinuity in the contact potential is a larger concentration of Ag^+ ions than NO_3^- ions in the free surface of the melt.

The Anodic Reaction Mechanism in Fused Silver Nitrate

Nirmal Gupta[1] and Benson R. Sundheim

Department of Chemistry, New York University, New York, New York

ABSTRACT

The oxidation of the nitrate ion at a Pt anode in molten $AgNO_3$ has been studied by steady-state and fast-sweep voltammetry. Two mechanisms are found, both leading to $NO_2 + \frac{1}{2} O_2$. The first is susceptible to transport control and has an $n\alpha$ value of 1.17 at 238°C. It is postulated that this mechanism involves the preliminary dissociation of the nitrate ion to form $NO_2^+ + O_2^=$, the latter (possibly bound as orthonitrate) being the electroactive species. The second mechanism is not subject to transport control and has an $n\alpha$ value of 0.90. This is thought to involve the formation of NO_3 radical followed by its decomposition to form the products. If the E_o values of 0.357v and 1.25v (*vs.* Ag/Ag^+) are adopted, the two mechanisms are characterized by exchange current densities of 2.4×10^{-3} and 0.14 amp/cm², respectively. The corresponding values calculated for k_o, the heterogeneous rate constant, are 1.3×10^{-7} and 1.1×10^{-7} cm/sec.

The objective of this study is to devise and test a mechanism for the electrochemical oxidation of a nitrate ion on a platinum electrode in molten silver nitrate. The information obtained from the preliminary investigation of potential *vs.* current curves in the steady-state condition led to the exploration of the possibility of there being more than one reaction mechanism in different potential regions.

Experimental Procedures

Reference electrode.—A 1 cm² piece of silver metal dipping in the molten silver nitrate was used as a reference electrode. In a preliminary test a current voltage curve wherein the potential of a silver cathode was measured with respect to a resting silver reference electrode was carried out over a considerable range of current densities. A graph of current *vs.* observed potential showed a straight line corresponding to an apparent resistance of 0.53 ohm. On this basis, it was concluded that the reference electrode showed no noticeable polarization and therefore could be used safely. The stability of the potential of two such silver electrodes with respect to one another over a period of time was excellent.

Instrumentation.—The temperature of the cell was maintained at an arbitrarily selected temperature of 238.6° in a large pot melting furnace fitted with temperature regulating and stirring equipment. An equimolar mixture of sodium nitrite and sodium nitrate was used as the melt. The assembly was capable of maintaining the temperature to within 0.02 of a degree of the desired temperature. Since the temperature measured in these experiments was actually that of the bath and not of the silver nitrate, the cells were allowed to remain in the melt for at least 2 hr in order to attain the correct temperature before any measurements were made.

Preparation of silver nitrate.—Silver nitrate of analytical quality (Baker Analyzed) was melted in a cell and subjected to continuous evacuation by a mechanical vacuum pump for several hours. During this time, gases, mostly water vapor, were evolved. Two electrodes of platinum and silver, respectively, and of 3.5 cm² geometrical surface area were then inserted in the melt and an electrolysis carried out for 48 hr under vacuum at a current density of 4.5 ma/cm². This pre-electrolysis procedure was found to be necessary in order that the current *vs.* potential measurements be reproducible. Presumably, heavy metal ions were removed by this procedure. The silver nitrate thus obtained was transparent and colorless and could be subjected to a number of melting and solidification cycles in the presence of light under vacuum without any perceptible change in color. Figure 1 shows a Pyrex cell for potential *vs.* current measurements fitted with a multiple pulley which was used to rotate at various speeds, the large platinum electrode having a geometrical surface area of 3.45 cm². The two silver electrodes were placed symmetrically with respect to the rotating platinum electrode. All three of the electrodes were completely immersed in the molten silver nitrate during the experiment. It was found that reproducible results could be obtained only if the cell was continuously evacuated. A satisfactory rotating seal was made by choosing the glass tube and bottom glass joint for a snug fit. Both of the joints had the same inner diameter. Such a contact could be used with mercury at speeds up to 2000 rpm. At higher rotation speeds, the glass tube was coated with a thin layer of platinum in place of the tungsten spiral around the glass tube. Number 8 cup grease was used as a lubricant between the cup and the glass tubing. For rotating the platinum microelectrode at speeds greater than 1200 rpm, a Bodine synchronous motor was used at 1800 rpm. The armature of this motor was connected to a gear arrangement with a 1:1 ratio. One of these gears had a hollow center shaft which was used to hold the platinum microelectrode. The rotating contact was established by inserting copper wire in the mercury pool.

Analysis of reaction products.—The cell shown in Fig. 2 was used to collect the reaction products. The cell had one platinum electrode and one silver electrode. Break seals in the side arm were used to col-

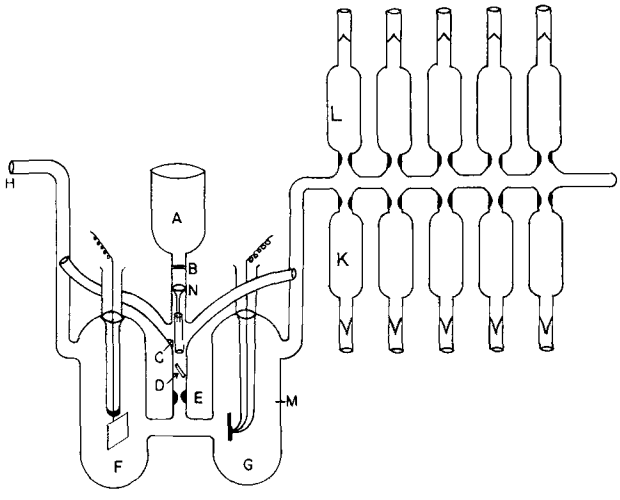

Fig. 2. Arrangement for analysis of products of electrolysis. Liquid pre-electrolyzed $AgNO_3$ is transferred to A. Suction at H causes it to flow through the sintered disk B up to the level M. The magnet D is manipulated so as to adjust N and C to prevent $AgNO_3$ from touching the walls near the seal-off. The remaining $AgNO_3$ in A is allowed to solidify and the tube C allowed to drop to E. The outer tube is cut just below the ring seal N and sealed off. After electrolysis between the silver electrode F and the platinum electrode G, the accumulated products are sealed off in, say, L. The open end of the break seal in K is joined to the vacuum system and the cell evacuated. The apparatus is sealed and the procedure continued.

lect successive samples for mass spectrographic analysis.

Electrodes.—The platinum microelectrode was made from a number 40 B and S gauge platinum wire by sealing it in lead glass tubing to make a vacuum tight seal. The end was ground and polished to a fine finish exposing only the crosssection of the wire. This was subjected to boiling hydrochloric acid for 5 min, washed with distilled water, and dried at 160°C. The large platinum electrode consisted of a circular platinum disk, 2 cm in diameter and 2 mm thick with a center shaft (2 in. in length) made out of 0.5 mm diameter platinum wire. This wire was spot welded to tungsten wire, and a junction was placed in a long Pyrex tube, the sleeve encasing the tungsten, giving a vacuum tight joint. The cleaning treatment was the same as in the case of the platinum microelectrode. Silver electrodes were made in two ways. A silver wire of B and S gauge 14 was spot welded to tungsten wire and both were enclosed in Pyrex tubing as in the case of the large platinum electrode. A piece of 1 cm^2 silver was then welded to the bare silver wire. A second method was to clean B and S gauge 24 silver wire by dipping it in concentrated ammonium hydroxide solution for 30 min and then carefully melting a fine Pyrex capillary over it with a small flame. A thick Pyrex tube was sealed on to the thin capillary. This was then subjected to an annealing process. Liquid tight Pyrex-silver seals could be made in this fashion. Current voltage curves were measured with a Sargent model XV Polarograph or with a combination of a Fluke differential voltmeter model 801 BR and a Greiback model 700 expanded scale milliammeter as appropriate. The programmed potentiostat was synthesized from the type O Plug-in Preamplifier unit and the type 545A oscilloscope (Tektronix Corporation). This preamplifier contains two stabilized differential amplifiers as well as a d-c preamplifier. It is capable of dealing with time constants down to 10 μsec and currents up to 1 ma. The circuit was arranged as shown in Fig. 3. The first operational amplifier served as a potentiostat and the second as a current-to-voltage converter. The program for the potentiostat was obtained from the oscilloscope (saw-toothed for single sweeps) or from a Hewlett Packard signal generator (triangular waves for cyclic voltammetry). A suitable bias was added when necessary from a battery and resistance network. The output voltage of the second operational amplifier, being proportional to the current, was connected to the vertical plate preamplifier of the oscilloscope and the program to the horizontal amplifier. In this way, the display on the oscilloscope was current *vs.* electrode potential. The traces were photographed using a Beattie-Coleman oscilloscope camera fitted with a Polaroid back. Voltage and time calibrations of the scales and circuits were made periodically.

Experimental Results

The effect of the speed of rotation of the platinum electrode on the steady-state potential *vs.* current density curves is shown in Fig. 4. All of these measurements were taken at one temperature only, *i.e.*, 238.6°C. No change in the potential *vs.* current density curves was noted at speeds greater than 1200 rpm. This was therefore considered to be a rotation speed sufficient to reduce the diffusion overpotential at these current densities and hence effectively to separate the activation overpotential from the diffusion overpotential. Figure 5 shows the potential *vs.* current density curves in the range 0-420 $\mu a/cm^2$, both when the platinum electrode was kept stationary and also when it was

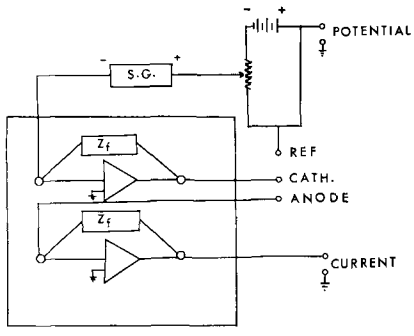

Fig. 3. Arrangement for oscillographic voltammetry. For this purpose the upper amplifier serves as a potentiostat with $Z = \infty$ and the lower one as a current to voltage converter with $Z =$ 0.1M.

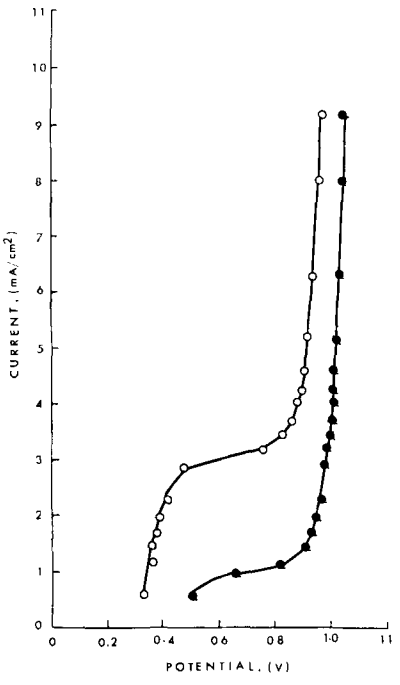

Fig. 4. Current density as a function of potential (with respect to Ag/Ag^+) for a Pt anode in $AgNO_3$ at 238.6°C; ○, 1100 rpm; ●, 0 rpm.

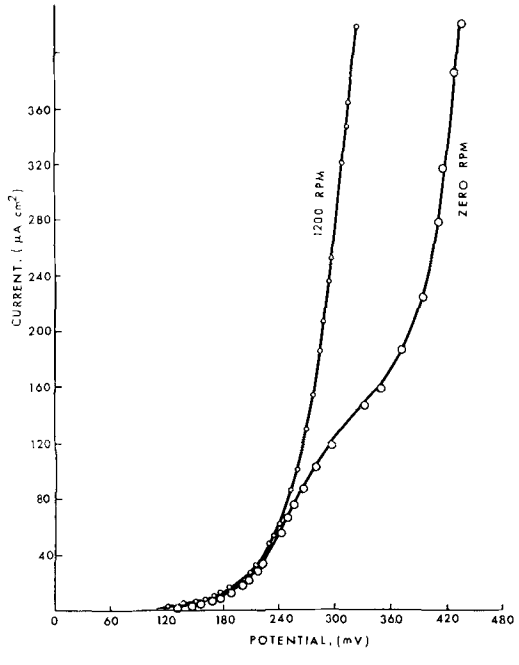

Fig. 5. Current density as a function of potential (with respect to Ag/Ag^+) for a Pt anode in $AgNO_3$ at 238.6°C.

rotated at speeds of 1200 rpm or more. Thus these curves represent the continuation of Fig. 4 into the lower current density region. The over-all curve shows two distinct reactions. The first occurs below +0.5v and the second near 0.95v. The process taking place below +0.5v seems to be transport controlled while the one near 0.95v is essentially independent of transport.

Table I shows the results of the mass spectrographic analysis of the reaction products collected by electrolyzing pre-electrolyzed molten silver nitrate at 238.6°C using platinum as the anode and silver as the cathode. Variations with current density (or equivalently with electrode potential) are not significantly different for various regions of the current potential curve.

Table I. Anodic reaction products

Current density, ma/cm²	% NO	% O_2	% NO_2
1.3	43.8	56.2	0.00
0.06	45.0	55.0	0.00
0.013	44.0	56.0	0.00

Table II. n and α as functions of temperature

Temp, °C	$n\alpha$	if n is	then α is
238.6	1.17	2	0.59
246.5	1.25	2	0.62
255.0	1.26	2	0.63

In Table II the values of n and α calculated from the Tafel lines as plotted in Fig. 6 are given. The exchange current density cannot be obtained from this graph since the value of E_o for this reaction has not yet been evaluated.

Cyclic voltammetry.—These experiments were carried out at 256°C using a platinum microelectrode of area 1.167×10^{-3} cm². It is observed that a slow sweep gives rise to a potential *vs.* current curve which resembles the steady state. As the sweep rate is increased to values greater than 10 cps, a separation of anodic and cathodic curves is noted which increases with increasing sweep rate. At frequencies equal to or greater than 50 cps a sharp peak near +0.5 appears. Above 500 cps another peak is observed near +0.9v but only in the cathodic curve. In addition, a small loop due to the reversible dissolution of silver from the platinum electrode is seen near 0 potential. As the potential becomes greater than 1v, very large currents are obtained, the curves being strongly distorted by gas bubbles.

In order to identify the source of these peaks, current-potential curves were determined on systems to which additions of potassium nitrite and of water were made. It was observed that the presence or absence of either of these substances had no effect on the details of the curve. Controlled potential pre-electrolysis at 0.5v produced no change in the peaks.

Discussion

The standard electrode potential for the over-all reaction $AgNO_3 = Ag^o + NO_2 + \frac{1}{2} O_2$ is calculated (1, 2) to be 0.357v at 238°C. These products are favored by 87 mv over NO + O_2 at this temperature. The dissociation of NO_2 is a relatively slow reaction, at least in the gas phase (3). A recent study (4) has shown that a reversible electrode with the expected potential is established in molten $AgNO_3$ by bubbling NO_2 + O_2 over a Pt bristle. It was noted that the electrode polarized readily but depolarized rapidly. The

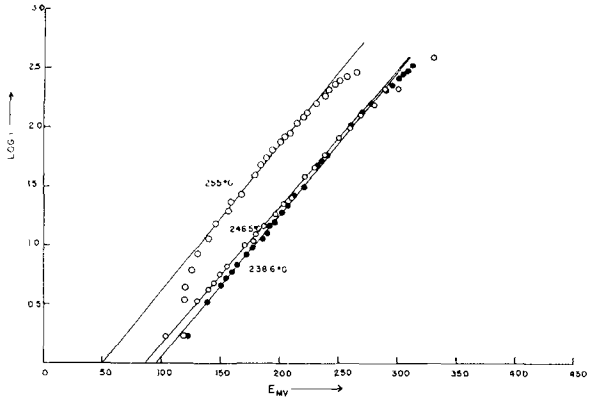

Fig. 6. Tafel diagram for the lower potential reaction. Logarithm of current density (μa/cm²) *vs.* potential. Platinum electrode rotated at 1200 rpm.

stability of the $NO_2 + O_2$ mixture in the melt was verified by analysis of the effluent gases.

The experimental results clearly indicate that there are two reactions. The Tafel graphs (Fig. 6) for the first (lower potential) reaction lead to $n\alpha$ values of 1.17 at 238°C so that $n \neq 1$. Furthermore, this reaction is susceptible to transport control and is limited long before the products break into free bubbling (as occurs for the second reaction). In order to account for these facts, we postulate that the electrode reaction involves the preliminary dissociation of the nitrate ion

$$NO_3^- = NO_2^+ + O^=$$
$$O^= = O + 2e$$
$$O + O = O_2$$
$$NO_2^+ + NO_3^- = [N_2O_5] = 2NO_2 + \tfrac{1}{2}O_2 \qquad \text{(i)}$$

If the last reaction is not too rapid, depletion of the electroactive species, $O^=$, from the vicinity of the electrode produces the concentration polarization. The species NO_2^+ by now is well known. Duke and Yamamato (5) concluded that chemical redox equations suggest that the equilibrium dissociation of the nitrate ion into the nitronium and oxide ions takes place to a significant extent in fused alkali nitrates. Raman studies have suggested (6) that there may be more than one species of nitrate ion in molten silver nitrate. (It might well be that the oxide ion is actually solvated as NO_4^{3-}, the orthonitrate ion.) The oxide ion has also been postulated as an intermediate in the oxidation of the $CO_3^=$ in molten carbonates.

This hypothesis may be tested by making use of the acidic nature of the pyrosulfate ion in nitrate melts.

$$S_2O_3^= + NO_3^- = NO_2^+ + 2SO_4$$
$$NO_2^+ + O^= = NO_3^- \qquad \text{(ii)}$$

That is, the addition of $Na_2S_2O_3$ to the $AgNO_3$ melt may be expected to suppress the oxide ion. Current-voltage curves were taken on successive additions of $Na_2S_2O_3$ and show (Fig. 7) that the expected effect is indeed produced, namely, that the overpotential is substantially increased.

These data may be used to obtain an approximate value for the dissociation constant of NO_3^- as follows:

For curves 1 and 2 in Fig. 7 the increase in potential is about 0.013v at 253.5°C when 1g of potassium pyrosulfate is added to 100g of silver nitrate. Assuming that all of the pyrosulfate reacts at once with NO_3^- ions to produce NO_2^+ in equivalent proportions and that the whole of this NO_2^+ stays in the $AgNO_3$, we can proceed with the calculation. The pertinent reactions are

$$NO_3^- \underset{k}{\rightleftharpoons} NO_2^+ + O^= \qquad [1]$$

$$S_2O_7^= + NO_3^- \rightarrow 2SO_4^= + NO_2^+ \qquad [2]$$

where k is the equilibrium constant for reaction [1].

We set X equal to the unknown concentration of $O^=$ or NO_2^+ ions before addition of the $S_2O_7^=$ and set Y equal to the concentration of NO_2^+ according to Eq. [1] but after the addition of S_2O_7. The latter is also equal to the concentration of $O^=$ after the $S_2O_7^=$ addition.

$$[NO_2^+]_o = X = [O^=]_o \qquad [3]$$
$$k = [O^=][NO_2^+] \qquad [4]$$
$$[NO_2^+] = Y\,[S_2O_7^=] \qquad [5]$$
$$[O^=] = Y \qquad [6]$$

Rearrangement of these equations leads to the relation

$$k = Y(Y + [S_2O_7^=]) = X^2 \qquad [7]$$

According to the Nernst equation, the overpotential before, E_o', and after E_f', the addition of $K_2S_2O_7$ one respectively

$$E_o' = E_o^o + [2.303\,RT/2F]\,\log \text{products}/X \qquad [8]$$
$$E_f' = E_o^o + [2.303\,RT/2F]\,\log \text{products}/Y \qquad [9]$$

Therefore, $2.303\,RT/2F \log (X/Y) = 0.013$v or $\log (X/Y) = 0.2474$; $Y = X/1.768$; $X = 1.94 \times 10^{-2}$; $k = 3.76 \times 10^{-4}$.

Similar calculations for the 0.024v rise in overpotential on the addition of a total of 2g of $K_2S_2O_7$ to 100g of $AgNO_3$ yield the value of the equilibrium constant k as 1.4×10^{-4} (m^2/l^2). The smaller value of k on the addition of larger amounts of pyrosulfate suggests that the assumption that the concentration of NO_2^+ after the addition of $S_2O_7^=$ is increased by equivalent amounts is not quite correct because of the gradual spontaneous evolution of NO_2 gas.

$$NO_2^+ + NO_3^- \rightleftharpoons [N_2O_5] \rightarrow 2NO_2 + \tfrac{1}{2}\,O_2 \qquad [10]$$

The faster this reaction takes place the greater is the error introduced in the evaluation of k, the error being in a direction to make the calculated value too large.

If we accept the value of E^o for the reaction at 238° to be 0.357v (2, 3), then a value of i_o can be found from the Tafel curve. This value for i_o is found to be 1.4×10^{-4} amp/cm².

We turn now to the second reaction and recall that it shows no evidence of transport control until free bubbling occurs at the surface. In fact, if the electrode is strongly polarized and then open circuited, it is found that a potential of approximately 1.25v is established within a few milliseconds of the current interruption. This potential is independent of the applied current density over wide limits. (The details of the later decay depend on the applied current density.) The current-potential curves must first be corrected for the limiting current (1.1 ma) from the first reaction. After this correction is made a graph of the logarithm of the current *vs.* the applied potential is found to give a reasonably straight line (Fig. 8). If

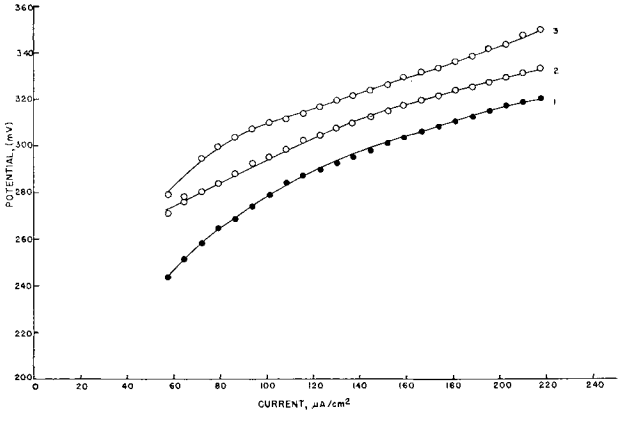

Fig. 7. Effect of successive additions of $Na_2S_2O_7$, 253.5°C

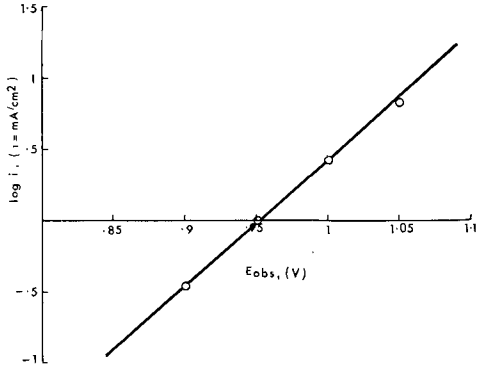

Fig. 8. Tafel diagram for the higher potential reaction. (The limiting current density from the lower potential reaction has been subtracted from the observed current density.)

we assume that the usual exponential relationship between current and voltage applies to reactions very far from the equilibrium, then the Tafel slope of this is found to be 0.90 corresponding to possible values of $n = 2$, $\alpha = 0.45$ or of $\alpha = 0.90$, $n = 1$. If we assume that the value of E° (for the continuous reaction) at this potential is 1.25v, then a value for i_o is computed as 2.4×10^{-3} amp/cm^2.

The definitions of i_o and E_o in systems of this sort need special attention. The general question is discussed elsewhere (7). Here it is sufficient to say that the equilibrium potential between reactants and products in their solid states is chosen for E_o when this is known. In the case where it is not known but the reaction is found to proceed reversibly, then the experimental value of E in the steady-state condition with reactants and products in their standard state (here sufficiently well achieved at the point of free bubbling of gaseous products) can be used. It is possible that this reversibility refers to some relatively short lived state which is an intermediate, but whose concentration never becomes large at reasonable current densities. The element of arbitrariness in the definition of E_o for a system which is irreversible under the conditions of the experiment and for which no thermodynamic potential is known means that there is no real significance to be attached to the comparison of this i_o with that of other reactions in the absence of auxiliary assumptions. In the present case, it is not clear whether the higher potential reaction is reversible at all. The appearance of a reverse potential at 1.25v may be due to reasons other than a back reaction, such as the concentration overpotential from the first reaction which no longer can be stirred away when the products bubble freely over the electrode. The higher potential reaction might well consist of the oxidation of nitrate ion to a short lived nitrate radical, which then rapidly and irreversibly decomposes.

Finally, we note that heterogeneous rate constants for the low potential and high potential reactions can be formally calculated by use of the calculated concentration of oxide ion in the one case and that of nitrate ion in the other case (assuming unit activity of the products). The values obtained in this way are 1.3×10^{-7} and 1.1×10^{-7} cm/sec, respectively.

Acknowledgment

It is a pleasure to acknowledge the assistance to this work of the Office of Naval Research (Contract 285-37 with New York University).

Manuscript received March 11, 1965. This paper was abstracted from a thesis submitted to the Graduate Faculty of Arts and Science, New York University in partial fulfillment of the requirements for the Ph.D. degree. This paper was presented at the San Francisco Meeting, May 9-13, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

The Electrodeposition of Coherent Deposits of Refractory Metals

II. The Electrode Reactions in the Deposition of Tantalum

S. Senderoff, G. W. Mellors, and W. J. Reinhart

Development Department, Parma Research Laboratory, Union Carbide Corporation, Parma, Ohio

ABSTRACT

The reduction of pentavalent tantalum to tantalum metal in molten LiF-NaF-KF eutectic mixture has been studied by chronopotentiometry between 650° and 850°C. It is a two-step reduction apparently involving a three-electron step followed by a two-electron step. The first step is diffusion controlled, and the diffusion coefficient of the reacting species is 1.5×10^{-5} cm^2/sec at 750°C and its activation energy 8.5 kcal/mole.

In a previous paper (1) the electrodeposition of coherent deposits of refractory metals, alloys, and compounds from molten fluoride electrolytes was described. In order to improve our understanding of the mechanism of metal deposition in these systems, a study of the electrode processes by means of chronopotentiometry was undertaken. In this paper the mechanism for the deposition of tantalum from the solution of K_2TaF_7 in the KF-LiF-NaF eutectic mixture is discussed.

Experimental

Solvent preparation.—The solvent was the eutectic mixture LiF-NaF-KF (46.5-11.5-42 mole % mp 454°C), and was prepared from analytical reagent grade salts. These were fused in a graphite crucible with 15 w/o (weight per cent) NH_4HF_2 to prevent hydrolysis, allowed to cool to a temperature just above the freezing point and poured into a nickel crucible, transferred to a nickel purification apparatus and sparged with H_2 for 48 hr at 750°C to remove the NH_3 and HF remaining from the decomposition of NH_4HF_2 and to reduce to metallic nickel the NiF_2 formed by attack on the crucible. During the last 4 hr of sparging the melt was electrolyzed between two graphite electrodes at 5 ma/cm^2 with a total current of 100 ma. This purification procedure resulted in $i\tau^{1/2}$ values for the solvent of less than 1×10^{-3} amp cm^{-2} sec$^{1/2}$ at a current density of 0.04 amp/cm^2 and −1.2v *vs.* a Ni/Ni^{+2} reference electrode.

Solutes.—Recrystallized potassium fluotantalate (K_2TaF_7) was obtained from the Kawecki Chemical Company and dried under vacuum at 150°C. The NiF_2 used for the reference electrodes was prepared using the method of Priest (2) except that ClF_3 was used instead of F_2.

Furnace.—The furnace for the chronopotentiometric cell was constructed around two well insulated Hevi-Duty semicylindrical heating elements type 5712-KSP. The temperature was controlled with a chromel-alumel thermocouple and a Model 402 Wheelco controller.

Chronopotentiometric circuit.—A conventional chronopotentiometric circuit was used with a pulsing mechanism and voltage cut-off switch similar to that de-

scribed by Senderoff, *et al.* (3), except that an automatic current reversing switch was added. The constant current source was a 200-375v power supply, and its current output was measured by feeding the voltage from a precision resistor to a Sargent Recorder No. S-72150. The potential between the indicating electrode and reference electrode was fed into a Tektronix 535A oscilloscope with type D plug-in. The resulting chronopotentiograms were photographed with an attached Polaroid camera.

Chronopotentiometric cell.—The cell bottom (K) (Fig. 1) was an 18 in. high, 4⅞ in. OD can constructed from 1/16 in. Hastelloy alloy X sheet and a ½ in. steel flange. The cell top (H) was a 12 in. high, 4⅞ in. OD cylinder constructed from 1/32 stainless steel sheet and two steel flanges. The flange of the can (J), and the upper flange of the cell top (G), were fitted with "O" ring grooves, and the cell top and flanges of the cell bottom were water cooled with ⅛ in. copper tubing to protect the "O" rings and Plexiglas cover (F). Fittings on the side of the cell top provided for a vacuum line (C), vacuum gauge (B), and a gas exit tube (A), through a paraffin bubbler (D).

Cell components.—Containers for the test melt were molybdenum cups (I), 6 cm wide by 4 cm deep, No. Q14792-A from the Fansteel Metallurgical Corporation (see Fig. 2). The reference electrode cups (C), the addition cup (E), and sampling cup (D) were machined from nickel rod. The addition cup had a small hole drilled through the bottom to permit molten salts (but not solids) to pass through. The molybdenum cup was suspended by means of a nickel hanger (J), the reference electrode cups by means of nickel rods joined by welding.

Insulation problems.—At 700°-800°C recrystallized alumina insulators acquired appreciable conductivity in the presence of the vapors of the fluorides and led to electrical leaks from the anode through the test melt container to the grounded metal electrolysis can giving rise to abnormally long transition times. The only effective means of electrical isolation has been to support all of the cell components from separate nickel rods leading from the cold zone of the cell where they are held by Swagelok fittings on the Plexiglas cover. There are no contacts among any of the components of the cell or with the walls of the can below the Plexiglas cover.

Electrodes.—Disk indicating electrodes were stamped from tantalum or platinum sheet (5 mil) and spot welded to either tantalum or platinum wire (15 mil). Counter electrodes were strips cut from ⅛ in. tantalum sheet. All of the electrodes were cleaned with concentrated HNO_3 and distilled H_2O. Both platinum and tantalum indicating electrodes with areas ranging from 0.49-1.67 cm^2 were successfully used, yielding identical results, although the majority of the experiments were carried out with platinum electrodes having an area of about 0.9 cm^2.

Reference electrode.—Approaches to reference electrodes in molten fluorides have been reported by Grjotheim (4), Manning (5), Coriou (6), and Crouthamel (7), but our most successful approach was a half-cell similar to Grjotheim's in which a solution of 1 mole % NiF_2 in KF-LiF-NaF was contained in a nickel crucible which acted as the electrode. The NiF_2 solutions were obtained as dip samples from a 1000g, 1 mole % NiF_2/KF-LiF-NaF bath. Contact between the reference and experimental electrolyte was made with the porous alumina bridge described below.

Salt bridge.—The salt bridges (Fig. 2B), were cut from Norton Company alumina filter disks (RA-98 coarse particle size). They were leached in concentrated HNO_3 for 24 hr, continuously washed with distilled H_2O for ½ hr, immersed in boiling H_2O for 1 hr, and vacuum dried at 400°C. They were saturated with purified molten KF-NaF-LiF bath under argon, cooled, and stored in closed bottles in a dry box. Bridges so prepared had a resistance of less than 10 ohms at 750°C, but on long contact with the molten fluorides they introduced impurities into the melt which were reduced at —1.5v and at —0.5v. Introduction of the impurity at —0.5v could be avoided by immersing the bridge in the melt only during the recording of the chronopotentiogram. The impurity reduced at —0.5v is probably iron and the less noble one reduced at —1.5v is aluminum.

Procedure.—The apparatus was assembled and evacuated to less than 5μ overnight, while held at 600°C. The cell was then cooled, vented to argon, and the reference electrode slug, solvent slug and salt bridge inserted followed by evacuation at 400°C overnight. The salts were fused under vacuum at 600°C for 2 to 3 hr, the system vented to argon, and the furnace temperature elevated to 750°C. After equilibrium had been attained the transition time of the solvent was recorded. The tantalum-bearing salts contained in a nickel addition cup in the cold zone of the cell were then plunged into the melt. The usual procedure for recording chronopotentiograms was followed. At a given concentration and temperature, runs at a number of current densities were recorded. The temperature was then changed, allowed to become constant, and recordings at another group of current densities were made. When the appropriate temperature and current density range had been completed a sample for analysis was taken and the run terminated. Another experiment was then performed in the same way with a new solution at another concentration.

Results

Chronopotentiograms were run at concentrations of K_2TaF_7 ranging from 0.02 to 0.1 millimoles cm^{-3}, at current densities which varied from 0.05 to 0.25 amp/cm^2 and at temperatures of 640°-860°C. In Fig. 3 is illustrated a typical chronopotentiogram showing the two reduction steps with $E_{1/4}$ values at about 1.0 and 1.2v. In Fig 4 is shown the relationship among transition time, τ, current density, i, and concentration, C, at 750°C for the first plateau. Each of the points represents the average of about 10 chronopotentiograms and includes the maximum practical current density range for that concentration. The average value for $[E_1]_{1/4}$ for this set is 1.03 ± 0.05v for the first plateau. The average value of the $[E_2]_{1/4}$ for the second plateau is 1.26 ± 0.06v. The transition time of the second plateau is on the average about 80% longer than that of the first plateau. Tables I and II summarize the data obtained at 750°C.

In Fig. 5 is shown the chronopotentiogram for the solvent only, indicating the absence of anything significant below the alkali metal reduction potential near 2v.

In Fig. 6 is shown the result for successive cathodic and anodic chronopotentiometry on the system. The ratio $\tau_{anodic}/\tau_{cathodic} = 0.83$.

Discussion

Precision of Data

An over-all precision of about 5% in the value of $[E_1]_{1/4}$ for the first plateau is indicated by the data in Table I. This corresponds to a standard deviation of about 50 mv in the potential, and at least 20 mv of this can be ascribed to the instability of the reference electrode. Additional work on a reference electrode for molten fluoride systems is required. $E_{1/4}$ is independent of concentration and of current density.

The transition time constant $i\tau_1^{1/2}/C$ for the first plateau also has a standard deviation of about 5%. Since the graphical determination of τ_1 is rendered imprecise by the slope of the plot between the two plateaus (Fig. 3) the major portion of this deviation in the transition time constant is ascribable to the irreversibility of the second step. Within this degree of accuracy $i\tau_1^{1/2}/C$ is independent of both current density and concentration.

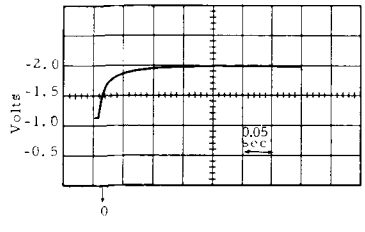

Fig. 5. Cathodic chronopotentiogram of Flinak solvent only; current density, 0.0336 amp/cm^2; temp, 750°C; cathode, tantalum.

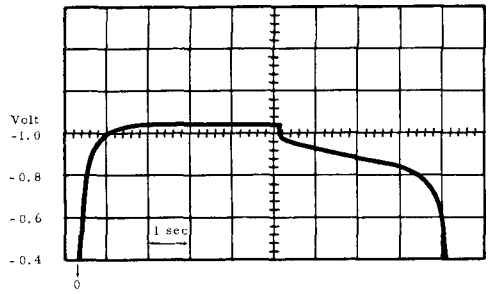

Fig. 6. Cathodic-anodic chronopotentiogram of K_2TaF_7 dissolved in Flinak. Cathodic portion on left, anodic on right: current density, 0.00964 amp/cm^2; temp, 750°C; cathode, platinum.

In Table II it is seen that while the $[E_2]_{1/4}$ values are only slightly less precise than the $[E_1]_{1/4}$ values the quantities associated with the transition times are very much less precise. Also, except for the highest concentration, the transition time constant for the second step, $i\tau_2^{1/2}/C$, is not constant, but decreases with increasing concentration. This lack of precision and constancy in transition time data arises from the fact that the second step is not diffusion controlled, but has rather complex kinetics which will be discussed below.

It will be noted in Tables I and II that the standard deviation of the $E_{1/4}$ values for each concentration is generally less than that of the over-all average. This suggests that the stability of the reference electrode during one experiment on one electrolyte is better than its reproducibility from experiment to experiment. In the case of the transition time constants, however, the per cent standard deviations for the individual experiments are about the same as the over-all value, but the deviations for the individual experiments decrease with increasing $i\tau_1^{1/2}$ values. The absolute values, however, show no consistent variation with concentration or $i\tau_1^{1/2}$ and suggest, therefore, that there is an absolute error in the measurement which is independent of the concentration, current, or any of the variables. This absolute error is most likely the graphical measurement of the transition time which becomes smaller percentagewise as the transition time increases.

Kinetics of the Electrode Reaction

Figure 3, when compared with Fig. 5, shows three steps at 1, 1.2, and 1.5v not associated with the solvent. The last of these arises from aluminum introduced from the salt bridge and is eliminated when a boron nitride salt bridge is used instead of the alumina. Boron nitride salt bridges could not be used easily, however, since they frequently disintegrated in the melt. The two steps then, at 1 and 1.2v, are associated with the reduction of the fluotantalate to tantalum metal. The most interesting properties to elucidate regarding the kinetics of this reduction are the electron change for each step, the rate-controlling process, and the nature of the reactants and products of the reactions. The easiest to establish is the final product, tantalum metal, which may be identified on the electrodes and which on a macroscopic scale is produced at 100% current efficiency (calculated on an over-all 5-electron reduction) at the cathode under a wide range of operating conditions.

The nature of the first step.—In a diffusion-controlled reaction (8)

$$i\tau^{1/2} = \frac{1}{2} nCD^{1/2} F\pi^{1/2} \qquad [1]$$

where i is the current density, τ the transition time, n the number of electrons in the reduction, C the concentration of the reacting species, D the diffusion coefficient of the reacting species, and F the Faraday constant.

Table III. Transition time ratios for various values of n

τ_2/τ_1	n_1	n_2
0.56	4	1
1.8	3	2
5.3	2	3
24.0	1	4

This requires that the transition time constant, $i\tau^{1/2}/C$, be independent of current density and concentration, and that $i\tau^{1/2}$ plotted against C be linear and extrapolate to zero at zero concentration. Examination of Fig. 4 and Table I confirms that these requirements are all met. The independence of current density, although implied, is not explicitly shown, but it is demonstrated without qualification in the data of the 81 runs from which Table I and Fig. 4 were prepared. It is, therefore, reasonable to presume that the first step is diffusion controlled and that the n in Eq. [1] represents the over-all number of electrons in the first reduction and D the diffusion coefficient of the reacting species of the first step.

The reactant for the first step is easily definable. It is undoubtedly an ion containing the pentavalent tantalum which is added to the bath. The valence of the tantalum in the operating solution has never been found to be other than 5.0, and thus it is established that no lower valence states are significant. Finally, it has been established by J. S. Fordyce, of our laboratory, that the tantalum exists in the melt as the $[TaF_7]^{-2}$ ion and that this ion is exceptionally stable under the conditions of operation. The studies of the infrared spectra of the tantalum plating systems on which this conclusion is based will be published separately. It may be concluded, then, that the reducible species which is the reactant in the first step is the heptafluotantalate (V) ion. There remains to be established the intermediate which is the product of the first step. This can be done by determining the value of n for the first step. There are two ways by which this can be accomplished.

(*A*) In stepwise, diffusion-controlled reductions such as occur in this case, it has been shown that (8)

$$\frac{\tau_2}{\tau_1} = \frac{2n_2}{n_1} + \left(\frac{n_2}{n_1}\right)^2 \qquad [2]$$

where τ_2 and τ_1 are transition times for the second and first step, respectively, and n_2 and n_1 are the corresponding electron numbers for each step. In Table III are shown the values of the ratio τ_2/τ_1 for the various possible values of n_2 and n_1 considering that $n_1 + n_2$ equals 5. The measured average value of $\tau_2/\tau_1 = 1.8 \pm 0.7$ for the 43 chronopotentiograms listed in Table II. The imprecision results largely from the variation in the value of τ_2 and is associated with some departure from diffusion control conditions for the second step of the reaction. However, the electron numbers suggested by this data are 3 and 2, for the first and second step, respectively. The close agreement of the τ_2/τ_1 ratio with the theoretical value must nevertheless be considered fortuitous since Eq. [2] applies strictly only when both steps are diffusion controlled.

(*B*) A method of obtaining the n number for a chronopotentiometric reduction which is independent of the second step depends on the shape of the potential-time curve of the first step only. It has been shown that when the reactants and products of a reversible reaction are soluble substances (8, 9)

$$E = E'_0 + \frac{RT}{nF} \ln \frac{\tau^{1/2} - t^{1/2}}{t^{1/2}} \qquad [3]$$

so that a plot of E *vs.* log $[\tau^{1/2} - t^{1/2}]/t^{1/2}$ is a straight line of slope 2.3 RT/nF where n is the desired electron number, and E, the potential at time t in the chronopotentiogram. If the product is an insoluble substance

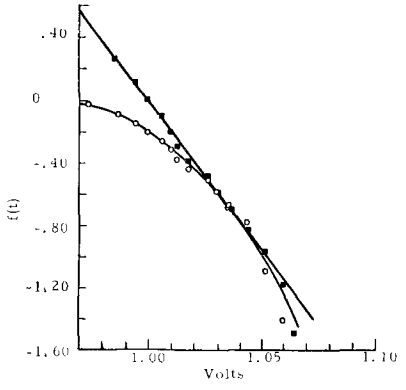

Fig. 7. Instantaneous cathode potential as a function of time during a chronopotentiometric run: ■, E vs. log $(\tau^{1/2} - t^{1/2})/t^{1/2}$; ○, E vs. log $(\tau^{1/2} - t^{1/2})$. Concentration, 5.9 x 10^{-5} mole/cm^3; current density, 0.045 amp/cm^2; temp, 750°C.

deposited on the cathode, the appropriate relation is (9)

$$E = E'_0 + \frac{RT}{nF} \ln (\tau^{1/2} - t^{1/2}) + \text{constant} \qquad [4]$$

and a linear plot of E *vs.* log $(\tau^{1/2} - t^{1/2})$ results. In Fig. 7 both these plots are shown for a typical chronopotentiogram of the first step of the reduction. It is evident that Eq. [3] applies. The slopes of the lines obtained by plotting 38 chronopotentiograms according to Eq. [3] gave an average value for n of 3.3 with a standard deviation of 0.8. Again the precision is insufficient to establish unequivocally $n = 3$, but in both cases $n = 3$ seems to be favored, and when this is coupled with the fact that occasionally sludges containing insoluble divalent tantalum fluorides are found in the operating solutions, there is good reason to believe that the first reduction step is a three-electron reduction to produce a divalent tantalum species.

There is some question regarding the nature of this divalent species. The linearity of the plot of Eq. [3] and the invariance of $E_{1/4}$ with concentration point to the divalent material as a soluble product. However, if it were soluble $\tau_{anode}/\tau_{cathode}$ in Fig. 6 should be 0.33 (9). It is found to be 0.83 at 9.64 ma/cm^2, 0.88 at 45.4 ma/cm^2, and 0.90 at 79.5 ma/cm^2. For a totally insoluble product the ratio of anodic to cathodic transition times should be unity since all that is cathodically produced at the electrode remains there to be oxidized in the anodic cycle (9). This would indicate that the product of the first reduction is only slightly soluble, that some of it dissolves and diffuses away, but that the faster the cathodic reduction is accomplished the less of it escapes from the electrode before the reoxidation step. This is confirmed by the occasional presence of an insoluble sludge consisting mostly of divalent tantalum fluorides in macroscopic electrolyzed solutions. The behavior of the E *vs.* t relationship and the constancy of $E_{1/4}$ can be explained by suggesting that through most of the time, τ, and certainly well beyond $\tau_{1/4}$, one is dissolving the product in the cathode layer, and only near the end of time, τ, is saturation reached. The departure of the last two points from the straight line of Fig. 7 may be a result of this saturation effect. The anodic cycle then oxidizes what is finally deposited as a solid on the electrode as well as whatever is available of the material in solution. It appears, therefore, that the final product of the first reduction step is slightly soluble TaF_2 and the first reduction step may be written

$$[TaF_7]^{-2} + 3e \rightarrow TaF_2(s) + 5F^-$$

The rate of the reaction is controlled by the rate of diffusion of the fluotantalate ion in the mixed alkali fluoride solvent.

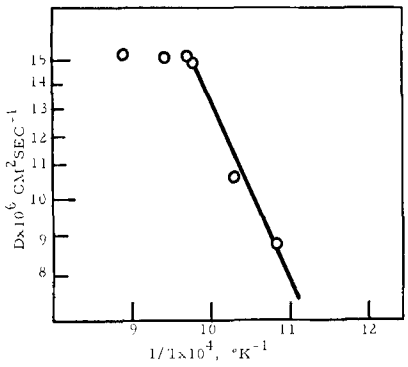

Fig. 8. Activation energy for diffusion of fluotantalate ion in molten Flinak.

Once one has established the electron number, n, as 3, one may use Eq. [1] to calculate the diffusion coefficient of the reacting species. This was done at various temperatures, and the results are shown in Fig. 8. The plot is linear between 650° and 800°C and corresponds to an activation energy for diffusion of 8.5 kcal/mole. The departure from linearity which is observed above 800°C occurs near the upper temperature limit for satisfactory plating (10). It may result from the thermal decomposition of the reacting species at this temperature with resultant decrease in its concentration, or may be an effect of increasing cathode surface area due to the unsatisfactory nature of the deposit at this temperature.

The activation energy may be compared with those obtained chronopotentiometrically by Thalmayer, Bruckenstein, and Gruen (11) who found an activation energy of 5.8 kcal/mole for diffusion of Ag^+ in molten KCl-LiCl; Cd^{2+}, 6.5; Pb^{2+}, 7.9; Bi^{3+}, 9.8; and U^{4+}, 7.72 kcal/mole. Senderoff, Klopp, and Kronenberg (3) measured diffusion coefficients by tracer diffusion from a capillary and reported 6.9 kcal/mole for Ag^+ in molten KCl-LiCl and 5.8 kcal/mole for sulfate ion in the same solvent.

The diffusion coefficient of the pentavalent tantalum species at 750°C is 1.5 x 10^{-5} cm^2/sec. This compares with 7.6 x 10^{-5} for Ag^+ in KCl-LiCl (3) at the same temperature. If one extrapolates the values in Fig. 8 to 400°C one obtains a diffusion coefficient of 1.2 x 10^{-6} which compares with those of Thalmayer *et al.* (11), for the same temperature of 24.7 x 10^{-6} for Ag^+, 12.1 x 10^{-6} for Cd^{2+}, 8.9 x 10^{-6} for Pb^{2+}, 7.2 x 10^{-6} for Bi^{3+}, and 4.89 x 10^{-6} for U^{4+} in molten KCl-LiCl.

The decreasing diffusion coefficient and increasing activation energy for diffusion with increasing valence is probably a result of the increasing complexity and size of the diffusing species as suggested by Laitinen and Ferguson (12). That the Ta^{5+} species falls well into line on this basis is additional corroboration that a highly complexed ion such as $[TaF_7]^{-2}$ is the active species at the cathode. At 750°C the diffusion coefficient is 1/5th of that measured for Ag^+ in KCl-LiCl which suggests a high degree of coordination of the transported tantalum ion since the viscosity of the fluoride melt is only twice that of the chloride melt at this temperature.

The nature of the second step.—The product of the second step has been shown to be tantalum metal. The reactant for this step is the product of the first one and is almost certainly solid TaF_2 or a saturated solution of this compound in molten Flinak. The reaction is not diffusion controlled as is shown by the decrease of $i\tau_2^{1/2}/C$ with increasing concentration. The study of the details of the kinetics of this reduction is made difficult by the imprecision of the data for this step. It is believed that the lack of reproducibility results from varying degrees of saturation of the electrolyte around the cathode and from uncontrollable partition of the current between the solid and dissolved species.

It is probable that potentiostatic measurements may be more suitable than chronopotentiometric studies for the elucidation of the mechanism of the final reduction step. Further, while Fig. 6 shows that the first step is highly reversible, cathodic-anodic chronopotentiometry on the second step shows a wide divergence between the anodic and cathodic potentials. This probably indicates additional electrochemical complications requiring further study.

Macroscopic observations which emphasize the importance of the sparingly soluble intermediate, TaF_2, are (*a*) tantalum metal is essentially unattacked in contact with K_2TaF_7 in molten Flinak between 650° and 850°C; this is in contradistinction to the rapid attack on niobium metal in contact with K_2NbF_7 in the same solvent. (*b*) the solution of fluotantalate in contact with the metal or after electrolysis always has an apparent valence of 5.0, while that of fluoniobate has a valence less than 5.0 and after prolonged electrolysis it approaches 4.0. This demonstrates the existence of a soluble reduced niobium fluoride and shows that the tantalum is inert in its pentavalent salt only because it is protected by the insoluble difluoride.

Summary

The electrodeposition of tantalum from K_2TaF_7 dissolved in a molten alkali fluoride solvent occurs in two steps. The first may be written

$$[TaF_7]^{-2} + 3e \rightarrow TaF_2(s) + 5F^-$$

and the second

$$TaF_2(s) + 2e \rightarrow Ta + 2F^-$$

The first step is a diffusion controlled, highly reversible reaction and the diffusion coefficient of the pentavalent tantalum species is 1.5×10^{-5} cm²/sec at 750°C. The activation energy for diffusion between 650° and 800°C is 8.5 kcal/mole. The low value of diffusion coefficient and high activation energy are consistent with a highly coordinated reducible species such as the $[TaF_7]^{-2}$ ion. The second step is not diffusion controlled and only poorly understood. Its kinetics probably involve the reduction of both solid and dissolved TaF_2 and it is highly irreversible.

Acknowledgment

Automation of the Measurement and Processing of Voltammetric Data

M. W. Breiter

Research Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

An assembly for the measurement of voltammetric current-potential curves and of the ohmic and capacitive components of the impedance of the interphase electrode/solution by voltammetry with superimposed a-c voltage is described. The analog to digital recording equipment which records the electrochemical data on paper tape is discussed. The main features of three computer programs required for the data processing by computer are outlined. The time for data processing is reduced to about a tenth of the value of the usual procedures, thus allowing time to evaluate more experimental points than previously. The feasibility of the set-up is demonstrated by two examples.

Information on the electrochemical formation or removal of adsorbed layers (1-3) and oxides (4) at solid electrodes, on the adsorption of ions (5, 6) or organic molecules (7), and on the kinetics of electrode reactions with adsorbed species (8, 9) may be obtained by voltammetric measurements. Two different types of measurements have been used successfully. (*a*) Potentiostatic current-potential curves: either a periodic voltage of triangular shape (1, 3) or a single ramp (2) are applied to the test electrode at different sweep rates, and the current is recorded as a function of potential; (*b*) voltammetry with superimposed alternative current: the ohmic and capacitive component of the interfacial impedance are measured (6) as a function of potential for a given frequency at small and intermediate sweep rates up to 100 mv/sec.

While the taking and recording of voltammetric data are automated the processing of the data has been cumbersome since a large number of experimental points has been involved in most cases. So far the experimental curves have been recorded by recorders or photographed from the screen of oscilloscopes. Any evaluation of the data required the tedious job of determining them manually point by point from the graphs or enlargements of films. Then the data were converted mainly by slide rules into the correct units and plotted immediately or put together

in a table for further computations, perhaps by computer. The time for data processing has been cut considerably in many fields of science by the use of high-speed computers. It appeared desirable to apply similar techniques in order to eliminate the manual procedure of determining voltammetric data from graphs or films. Now these data are printed out in table form and plotted, if requested, for any potential scale with constant increments in the potential range of the measurements. The time for processing is reduced to about a tenth of the value of the manual procedure. A larger number of experimental points may be evaluated than previously. In addition, the smoothing of experimental data by simplified least square procedures is easily carried out. Instrumentation and programming are described subsequently.

Assembly for Electrochemical Measurements

The assembly for which a block diagram is presented in Fig. 1 is an improved version of a set-up reported previously (6). It consists of a potentiostatic circuit for the application of the potential sweep and a galvanostatic circuit for the impedance measurements. Both circuits are connected to a cell of conventional design. All the electrodes are in the same solution and at the same temperature. Pretreatment of the electrodes and purification were as discussed (10).

The potentiostatic circuit is shielded by a suitable choke L from the a-c circuit. It allows sweep rates from about 3 mv/sec to 300 mv/sec. The range of the function generator was extended to lower frequencies by internal alterations. The voltage of triangular shape between K and ground is applied between test electrode and a large hydrogen electrode (platinized Pt-foil). The large hydrogen electrode is polarized little by cathodic currents up to 100 ma. It was dimensioned such that anodic currents up to 10 ma do not produce a noticeable polarization. If larger currents than 1 ma are required, a d-c power supply modified into an amplifier with small output impedance is inserted at point K. The decade resistor R_4 serves for the measurement of the current. The electrode potential is measured between A and B.

The a-c current generated by a low-frequency oscillator flows through three parallel branches. Resistors R_1, R_2, and R_3 are chosen such that each of them is at least 300 times larger than any other impedance in the respective branch. A voltage of 10 mv_{eff} is maintained across the 10 ohm resistor between A and E. Reference voltages for the resolved component indicators are produced from this voltage. The a-c current which flows between a platinum wire spiral and the test electrode is equal to R_3/R_1 in ma_{eff}. The resistor, R_2, is taken such that the voltage between A and D becomes equal to the ohmic potential drop across the electrolytic resistance R_{El} which is measured as part of the ohmic component of the interfacial impedance in a series circuit. A method of determining R_{El} was developed (6) and verified (9) for platinum electrodes. The a-c voltage between B and D ($\tilde{U}_{signal}$) is kept smaller than 2.5 mv_{eff}. The ohmic and capacitive part of $\tilde{U}_{signal}$ are measured separately by two resolved component indicators by connecting G to D and H to B. The two reference voltages ($\tilde{U}_{reference}$) have a phase shift of 90° against each other. They are made nearly equal by selecting appropriate values of C_2. The a-c assembly is calibrated and corrected for small phase shifts at each frequency before the actual measurements by connecting H to F and G to A. The phase shift is compensated by adjusting the dial of one of the analyzers slightly until the reading of the capacitive component on the meter is zero. The reading of the ohmic component achieves a maximum when the phase shift is zero. Then it corresponds to 2.5 mv_{eff}. The meters are disconnected during the actual measurements since their response time is slow. The measurements of $\tilde{I}$ and $\tilde{U}_{signal}$ are made with the same analyzer (input G and H). Different connections are established by a suitable switch.

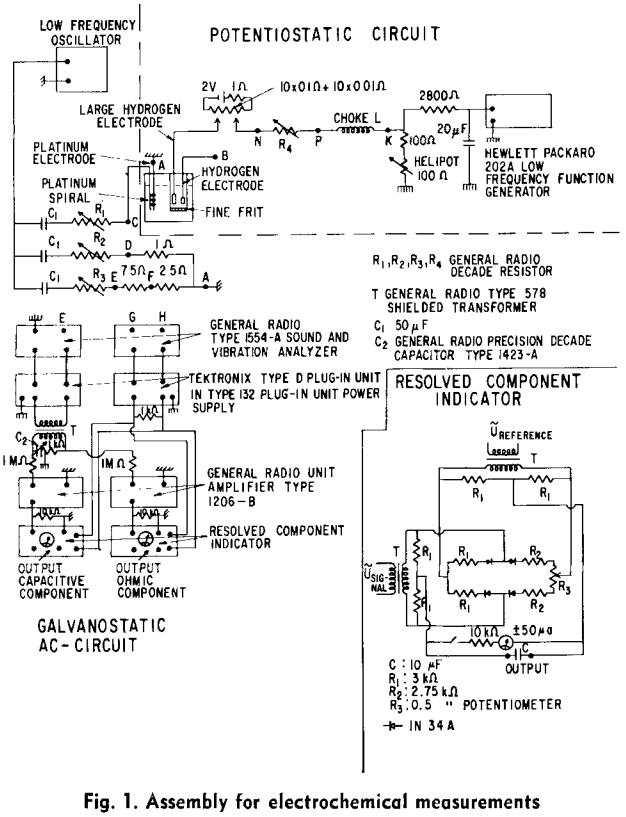

Fig. 1. Assembly for electrochemical measurements

A discussion of the circuit of the indicator (see Fig. 1) and a mathematical treatment was given by Geyger (11). The indicator is balanced at $\tilde{U}_{signal} = 0$ for zero output by the potentiometer R_3. The long-time stability of this adjustment was improved considerably over the previous design (6) by introducing the transformer T. Impedance measurements were made between 100 and 20,000 cps with transformers type 578-A. An extension to 20 cps is planned with type 578-B. The reference voltage has to be much larger than the signal voltage that the d-c voltage across the capacitor C is independent of the reference voltage and proportional to the ohmic or capacitive part, respectively, of $\tilde{U}_{signal}$. A ratio of ten was satisfactory here. The accuracy of the readings of the ohmic and capacitive component is 1% of full-scale value.

Analog to Digital Recording Equipment

A high-speed computer requires a rapid feeding of the data to be processed. Since voltammetric measurements at small and intermediate sweep rates are slow, the experimental data are punched on paper tape in digital form by the recording unit. When sufficient data are accumulated, they are transferred to magnetic tape by the tape reader in a format suitable for programming in Fortran. Finally, they are read into the computer from magnetic tape and processed. The G.E. 225 computer and tape reader were used.

The analog to digital recording equipment was designed and constructed by the Design Engineering and Instrumentation Unit of the General Electric Research Laboratory in collaboration with Dr. T. W. Hickmott, Research Laboratory, and the author. Essentially it is a multichannel recorder. Up to ten signals may be recorded independently. The signal fed to the input of channel 1 is recorded first, then the signal of channel 2, etc. One complete cycle of input readings requires 18 msec times the number of channels being used. In the "one cycle" mode the sequence stops after the last of the input channels has been recorded. Another cycle is initiated by the trigger signal of the

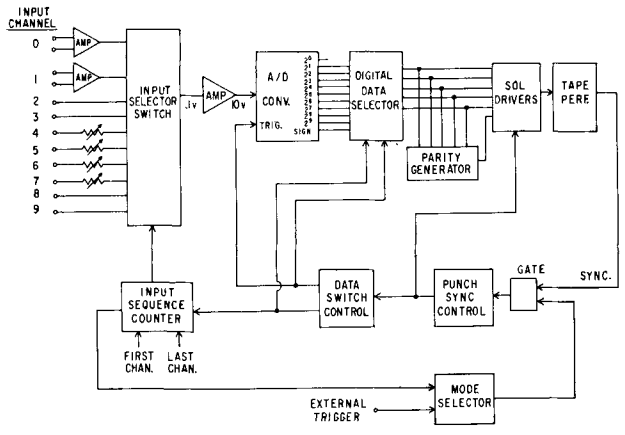

Fig. 2. Block diagram of the analog to digital recording equipment

external generator. The maximum rate of recording per channel corresponds to 55/(number of channels) data per second and may be used continuously in the "continuous" mode. In the one step mode the first external trigger leads to the recording of channel 1, the second trigger to that of channel 2, etc.

A functional block diagram is shown in Fig. 2. There are 10 d-c voltage inputs available. Two of these inputs lead to differential d-c amplifiers with input scaling switches to cover the range 1 mv to 10v full scale in 9 steps. Four of the other inputs are supplied with divider networks covering the range 100 mv to 300v full scale in eight steps. Four of the inputs are direct to the input selector switch at 100 mv full scale. The input selector switch connects the inputs one at a time to the common amplifier which raises the level to 10v full scale for the analog to digital converter. The output of the converter is ten binary bits and sign. These digital data are punched by the tape perforator in two punch cycles (6 bits per cycle). The code used is unique to this equipment. Odd parity is generated for each punch cycle. Manual settings allow any number of input channels to be sequenced, beginning with any selected channel.

The time sequence of events for one cycle of input readings is as follows. External trigger opens gate. Next synchronous pulse from perforator triggers synchronizing control. Data switch control is set to first half of data at the digital data selector and A/D converter is triggered. A conversion is performed in 100 μsec giving 10 binary bits and sign. The solenoid drivers are gated on for 4.5 msec to record the first half of data. Synchronous pulses from the perforator are at 9 msec intervals. The second synchronous pulse sets the data switch control for second half of data and input sequence counter is advanced to the next channel. The solenoid drivers are gated on for 4.5 msec to record the second half of data. The third synchronous pulse from the perforator returns data switch control to the first half of data and triggers the A/D converter to convert the input voltage of the second channel. This cycling continues according to the mode chosen.

Three rotary switches allow the insertion of a coding in the first block on the paper tape to identify up to 199 run numbers by supplying different negative voltages to the converter in the "Run Number" position of the selector switch. The run number is punched as many times in the first block as channels are used. A network for the automatic recording of the range settings of the six channels with divider network is connected to the range setting switches of the respective channels. Different positive voltages are given to the converter and recorded as binary numbers that are interpreted by the program as scale factors. If the scale factors are not changed during one run it is sufficient to record them once in the second block on paper tape. If the scale factors have to be changed during the measurements, up to four scale factors may be recorded during each cycle of input readings in the one cycle or continuous mode by the use of the four channels without divider network. Provisions are made on the rear of the chassis panel for this arrangement. The sequence of the recording of the current-potential measurements described subsequently was as follows: potential, current, scale factor potential, scale factor current. A similar sequence was utilized for the impedance measurements. The measurements of the electrochemical variables can be considered simultaneous for sweep rates below 100 mv/sec.

On the paper tape a single punch in punch position 8 of the perforator represents the "end of block" character. The introduction of such a character allows the program to find synchronization errors. The end block character may be recorded after 2^N blocks of data by the use of the "End of Block Spacing" control. The inputs without divider network may also serve to trim d-c output voltages of many standard laboratory instruments with the aid of voltage dividers to a full scale of 100 mv for an extension of the recording system. A voltage is created and connected to the inputs of all channels when the input selector switch is in the "Test" position. After conversion the following data bits are punched: sign, 2^8, 2^6, 2^4, 2^2 and a code bit in the same perforator channel as 2^6 to designate the simple test pattern. Since the bit 2^1 represents 0.2% of full scale an increase of 0.2% will cause a punch of the bit 2^1 and also of the parity bit. At a decrease of 0.2% the bit 2^2 will not be punched and the bit 2^1 will be punched. The voltage for the test pattern is taken from the same source as that for the run numbers. Thus a correct pattern is evidence that the A/D converter is correct within $\pm$ 0.2% and that the run number should be recorded properly.

The output of the common amplifier is connected to a panel meter which allows a 1% reading of voltages which are constant or slowly changing. The state of the input sequence counter is indicated as an aid for the initial setting by four lamps. This counter may also be advanced manually by a button to connect any input to the system so that an indication is seen on the panel meter. The output of the converter may be read from ten small lamps corresponding to 2^0, 2^1, — — — 2^9 and two sign lamps on the panel.

The accuracy of the recording unit was found to be 0.4% of full-scale values for the eight inputs which are ground referenced. It is 1% for the differential amplifiers for full-scale values equal or larger to 100 mv. At smaller values it is about 3%. In the case of voltammetric data the accuracy of the potential measurement determines the meaningful spacing of the cycles of input readings. A frequency of 5 cps was chosen for the triggering signal at a sweep rate of 30 mv/sec.

Programming

Three programs in Fortran were written for the processing of voltammetric data. The first program is always required for the transfer of the data from paper tape to magnetic tape as fixed point numbers. The second program handles the processing of I-U data from magnetic tape. The third program processes the impedance measurements. Since these programs are long and unique for the recording unit and the specific measurements, only their main features will be discussed here. The computer programs will be made available to readers on request.

Program 1 looks first for the run number and then the numbers representing scale factors. It is necessary that this information appears in this order. The number of channels is determined from the first block on paper tape. The number of characters between end blocks is counted by the tape reader and compared to the number of channels being used. Any block of data containing the wrong count is not recorded on magnetic tape, and a diagnostic is printed out. The first record on magnetic tape contains the following information: run number, number of

blocks in one record on magnetic tape. The number of blocks per record varies with the number of channels and is derived by program 1 in such a way as to maintain the same Fortran format on the tape (126 words/record). If required, the same dummy number is filled in several times at the end of a record. The run number is the first word in any record besides the last one which consists only of the dummy words and designates the end of a run. The scale factor numbers are recorded in the second record. Data are in the subsequent records which are counted and numbered. The record number is the second piece of information on the records with data. The total number of records with data in one experimental run is printed out at the end. The tape reader interprets about two inches of blank paper tape as the end of a run. Program 1 is applicable whether the scale factors are recorded only once in the second block on paper tape or are recorded together with the electrochemical data.

Programs 2 and 3 for the processing of data from magnetic tape differ somewhat whether the scale factors are variable or constant during the measurements. Both programs create the scale factors in the beginning and assign them during the execution to the scale factor numbers picked up from magnetic tape. One data card is read for each run with additional information. For program 2 these are: electrode area, temperature, increment for the potential scale chosen, number of increments, first value of potential scale, maximum permissible increment between two subsequent measurements of potential, positive or negative fixed point number deciding for or against plotting of data. In addition there are on the data card in the case of program 3: frequency, electrolytic resistance R_{El}(R_{El} = 0 if correction is not required), R_3/R_1 instead of R_4, a second fixed point number determining if the impedance is considered as a series or parallel circuit of resistance and capacitance. The electrochemical data in each record are converted into the correct units successively. If two subsequent measurements of potential differ more than the permissible value prescribed on the data card, all the electrochemical variables pertaining to the second potential reading are discarded. Such a precaution is necessary since errors occur by chance during the taking of hundreds

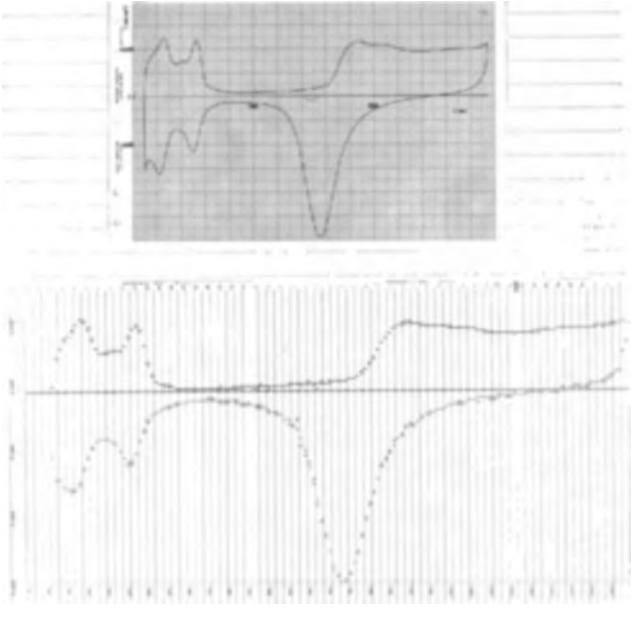

Fig. 3. Upper I-U curve on platinum in N H_2SO_4 is recorded by X-Y recorder; Lower I-U curve is plotted by printer. 1,3: interpolated values of current density. 2,4: smoothened values of current density.

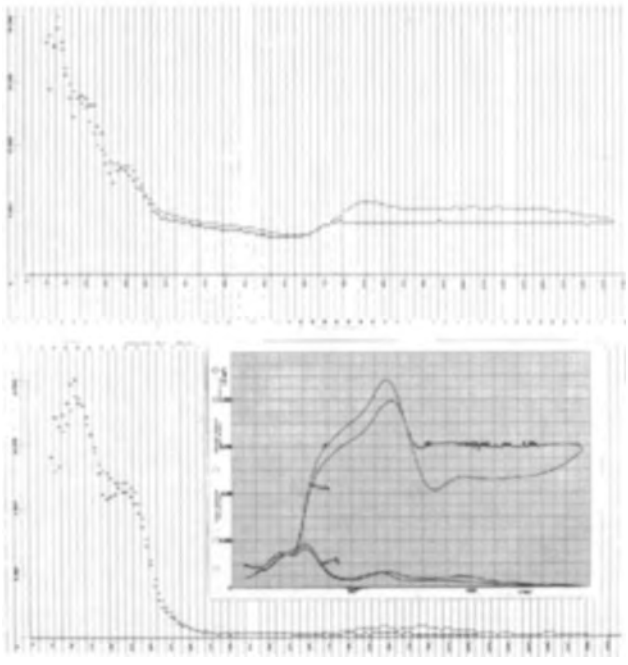

Fig. 4. Ohmic and capacitive components of the impedance on platinum in N H_2SO_4 are recorded by X-Y recorder on graph paper in a series circuit. Upper computer plot: capacitive component in parallel circuit; Lower computer plot: ohmic component in parallel circuit. 1: anodic sweep; 2: cathodic sweep.

of points. An arbitrary potential scale with constant increments as requested by the data card is established for the potential range of the measurements. The programs compute either the values of the current density or those of the ohmic and capacitive components according to this potential scale by linear interpolation from the experimental data and store them in memory, distinguishing between anodic and cathodic sweep. The capacity is derived from the capacitive component by program 3. Each of the interpolated values is smoothened by a simplified least square procedure (12) involving seven points in its vicinity. The values of the electrochemical variables are printed out subsequently according to the potential scale for the anodic and cathodic sweep. Interpolated and smoothened values are given. If requested on the data card, a plot is produced by the high-speed printer. The choice between a series or a parallel analog circuit for the impedance in program 3 simplifies the interpretation of these measurements which can only be made in a series circuit (see Fig. 1). The first data recorded in the case of impedance measurements correspond to 2.5 mv_{eff} applied during the calibration procedure for the resolved component indicators. Program 3 averages and computes the calibration factor.

It is simple to add program extensions, for instance the integration of parts of the I-U curves, as subroutines to programs 2 or 3. Similarly, the data tabulated may be obtained easily on punch cards in a format suitable to further computations. However, direct further processing is not considered since an intermediate judgement of the experimental data by the scientist is thought necessary.

Examples

A current-potential curve on smooth platinum in N H_2SO_4 at 30 mv/sec and 30°C with its typical shape (1, 3) is shown twice in Fig. 3. The quiescent solution was saturated with helium before the measurements. The upper curve was recorded with the Varian F80 X-Y recorder. The lower curve was plotted by the printer of the G.E. 225 computer, the

scales being adjusted by program 2. During the anodic sweep the symbol 1 stands for the values of the current density which were obtained by interpolation from the measured values while the symbol 2 represents the results of the smoothening of the interpolated values. The same statements hold for symbols 3 and 4 during the cathodic sweep. Values derived by interpolation and subsequent smoothing coincide if only one symbol appears. It is clear from a comparison that the accuracy of the recording unit is equivalent to that of the X-Y recorder. The data plotted in the lower curve were also printed out in a table which, however, is omitted here to avoid duplication.

The ohmic and capacitive component of the interfacial impedance of smooth platinum were measured in N H_2SO_4 at 10,000 cps in a series circuit. The sweep rate was 30 mv/sec. R_{El} was compensated. The curves as obtained in successive runs and recorded by the X-Y recorder are shown on the graph paper in Fig. 4. A discussion of their shape was given elsewhere (6). The upper and lower plots made by the printer represent the capacitive and ohmic component respectively of the impedance in a parallel circuit. The capacative component is proportional to the capacity here. Both components reflect (9) the heterogeneity of the platinum surface with respect to the Volmer reaction in the potential range of hydrogen adsorption. The impedance is practically capacitive above 0.5v in the so-called double layer region and oxygen region.

Oxygen Overvoltage Measurements on Bright Platinum in Acid Solutions

III. Nitric Acid-Passivated Bright Platinum

James P. Hoare

Research Laboratories, General Motors Corporation, Warren, Michigan

ABSTRACT

Oxygen overvoltage measurements were made on platinum electrodes which had been passivated in nitric acid. It was demonstrated that the reversible oxygen electrode may be obtained. Apparently, the treatment with HNO_3 significantly changes the nature of the platinum surface, and it is suggested that the Pt surface is converted to a Pt-O alloy. The Pt-O-alloy surface not only is a better peroxide decomposing catalyst than Pt, but also accelerates the adsorption of oxygen and the electron transfer step. Although the overvoltage is independent of the partial pressure of oxygen for large values of P_{O_2}, the rate-determining step is considered to be the discharge step

$$(O_2)_{ads} + e \rightleftharpoons (O_2^-)_{ads}$$

The rate of reduction of oxygen is increased by two orders of magnitude on Pt-O-alloy electrodes from that on Pt electrodes, and the overvoltage is reduced by at least 200 mv.

In a previous report (1) it was suggested that the reversible oxygen potential, 1.229v (2), was not observed because platinum is not inert to the reactants of the electrode reaction. As a result, the Pt/O_2 electrode is a polyelectrode (3), and since the system is always polarized by a local cell current, it never reaches equilibrium but only a steady state. The steady-state potential is a mixed potential (4). It was further suggested (1) that, if the electrically conducting layer of adsorbed oxygen on the platinum surface could be maintained complete, the reversible potential should be observed. Effectively, this is accomplished at high polarization, as shown by the fact that the extrapolated Tafel curves for anodic and cathodic overvoltage cross at the reversible oxygen potential (5-7).

It was shown in a second report (8) that a complete layer of adsorbed oxygen, which is electronically conducting and chemically inert, can be produced on a Pt surface by treatment with concentrated nitric acid. The reversible potential was observed for periods of time exceeding 24 hr.

In this report the polarization data taken on HNO_3 passivated Pt electrodes are presented.

Experimental

As before (8), small beads (0.02-0.03 in. in diameter melted at the end of platinum (99.99% pure) wires were passivated in concentrated HNO_3 in a Teflon cell for at least 72 hr. Afterwards, the beads were washed in triply distilled water and mounted in the right-hand side of a dual Teflon cell (1)

filled with $2N$ H_2SO_4 solution. The use of polyethylene was avoided, since HNO_3 attacks it. An α-Pd-H reference electrode (9) was used in the left-hand compartment of the cell. All cell and electrode preparations and all purification techniques were the same as those described before (1, 7, 8). The electrodes were polarized and the overvoltage determined in the same manner as that described in the previous report (7). All measurements were made at 25° ± 1°C and at a P_{O_2} of 1 atm (except the data shown in Fig. 6).

Results

Two systems are to be distinguished; type I, in which the HNO_3 passivated platinum electrode exhibits the reversible oxygen potential, and type II, in which it exhibits a potential from 100 to 150 mv less noble than the reversible potential. Type II electrodes are produced from type I electrodes when such electrodes have been strongly cathodized or anodized.

In Fig. 1, the polarization data taken at low current densities are presented for a type I electrode and in Fig. 2, for a type II electrode. The cathodic overvoltage curves for both types of electrodes are given in Fig. 3. Anodic overvoltage data for a type I electrode are plotted in Fig. 4 and for a type II electrode in Fig. 5. The dependence of the overvoltage on the partial pressure of oxygen (P_{O_2}) is presented in Fig. 6 for a type II electrode.

The data presented in Fig. 1 give a slope of 700 ohms which is nearly two orders of magnitude different from that (6 x 10^4 ohms) obtained on untreated bright platinum (7). These points were the average of at least three cycles of increasing and decreasing polarization over the current density range indicated and could be reproduced within ±2 mv. It is of interest to note that the linear curve

passes through the reversible oxygen potential at open circuit without a change in slope.

When a type I electrode is cathodically polarized beyond the current density range given in Fig. 1, the curve is not retraced on the decreasing part of the polarization cycle as indicated in Fig. 3 by the arrows. If the circuit is opened and the system permitted to come to a steady state (indicated by the dashed part of the curve in Fig. 3), a second polarization curve may be obtained which is displaced from the first by about 50 mv. Both of these curves exhibit

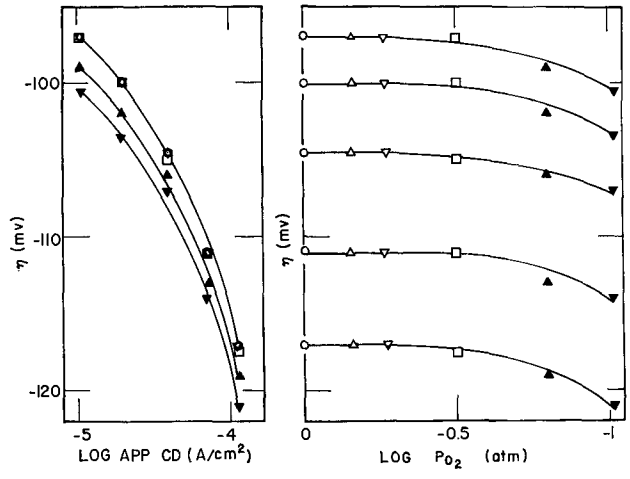

Fig. 6. Oxygen overvoltage as a function of P_{O_2} on a Pt-O-alloy electrode. P_{O_2} values are: ○, 1; △, 0.71; ▽, 0.54; □, 0.32; ▲, 0.16; ▼, 0.091. Data for the η-log P_{O_2} curves were taken from the η-log apparent current density curves.

a slope of about 0.045 with a break at about 10^{-4} amp/cm² and a change of slope to much higher values (>0.200) at the higher current densities. Now, if the system is polarized through several cycles without opening the circuit, a reproducible curve (indicated by double headed arrows) is obtained. The points on this curve are the average of three cycles with the greatest deviation from the mean being ±5 mv. It is to be noted that the slope of 0.045 cannot be detected and that all of the curves run together at high current densities with the very high Tafel slope of 0.266. A limiting current is reached near 10^{-2} amp/cm² and the system goes to hydrogen ion discharge. It is interesting to compare these results with those obtained on untreated Pt (7). The limiting current density is increased by an order of magnitude, and the overvoltage at a given current density, say 10^{-4} amp/cm², is decreased by 250 mv by the treatment of a Pt bead electrode with HNO_3.

When the circuit is opened, the steady rest potential is about 100-150 mv less noble than the reversible potential. It is seen, then, that a type I electrode has been converted to a type II electrode by cathodic polarization. Such an electrode, brought to the hydrogen potential (—50 mv *vs.* α-Pd-H) by replacing the O_2-stirring with H_2-stirring or by cathodizing for 2 min, or both, still gave the same type of polarization curves for the type II electrode (Fig. 3) instead of those for bright Pt [Fig. 2 of ref. (7)]. The i_o for the first cycle of polarization (type I electrode) in Fig. 3 is 1.8 x 10^{-6} amp/cm², three orders of magnitude greater than the i_o for untreated Pt (1.3 x 10^{-9} amp/cm²). However, the slope of 0.266 found on the type II electrode gives an i_o of 7.2 x 10^{-5} amp/cm². This higher reactivity is reflected in the low value (290 ohms) of the slope of the low current density curve given in Fig. 2.

When a type I electrode is polarized anodically, reproducible points may be obtained up to a point about 100 mv more noble than the rest potential. Above this point, the potential drifts to more noble values as shown by the dashed curve in Fig. 4. Succeeding cycles of polarization produce curves with the same slope, but with a hysteresis as shown. When this system is open circuited, the potential falls to the rest potential of a type II electrode within 2 hr. It may be seen that a type I electrode is converted to a type II electrode by anodic polarization also.

The anodic overvoltage of type II electrode is given in Fig. 5. For increasing polarization, the points are not steady, but drift with time toward more noble values. At the highest current density studied, the electrode was polarized until a steady potential was obtained. This behavior is described by the dashed curve. Now, a reproducible curve (solid lines) may be obtained. The points are the average of four cycles of polarization and deviate within ±4 mv of the mean. This curve exhibits two slopes, a lower one of 0.125 and a higher one of 0.082. The lower slope gives an i_o of 1.7 x 10^{-9} amp/cm².

In all cases, the platinum electrodes before and after a run were smooth and mirror bright.

It is interesting that the cathodic overvoltage of a type II electrode is independent of P_{O_2} for large values of P_{O_2} (1-0.3 atm). For P_{O_2} values below about 0.3 atm, the overvoltage becomes dependent on the P_{O_2} with a coefficient of about 5-10 mv/log P_{O_2} (see Fig. 6).

Discussion

Although treatment with concentrated HNO_3 is assumed to produce a chemically inert, electronically conducting layer of adsorbed oxygen, a more deep-seated change in the platinum surface apparently takes place. From double layer capacity measurements made on treated and untreated Pt electrodes (10), it appears that a certain amount of oxygen is more intimately associated with the platinum than the oxygen adsorbed in the monolayer of Pt-O. This oxygen cannot be removed easily by reduction in H_2 nor by cathodization, but only by heating in an H_2 flame to white heat. It is proposed that this oxygen actually dissolves in the surface layers of the platinum metal to form a Pt-oxygen alloy. It has been found (11) that oxygen will dissolve in massive Pt. Such an alloy could have the properties of a metal, be difficult to reduce in H_2 or by cathodic polarization, and lose oxygen by heating to a white heat. Since the solution of oxygen may require molecular or atomic rearrangements, the process would be quite slow. Such a mechanism could explain why Pt must be in contact with concentrated HNO_3 for at least 72 hr to form a complete passivating layer (8).

Basically, the treatment of Pt with HNO_3 produces an electrode material different from that of the original untreated Pt metal. In addition to producing a different electrode surface, the HNO_3 treatment also forms a complete layer of electronically conducting adsorbed oxygen as shown by the reversible characteristics of the data presented in Fig. 1. This com-

plete layer is unstable in acid solutions (8), however, and degenerates to an incomplete layer. Then the rest potential is no longer a reversible potential but a mixed potential. As demonstrated in Fig. 3 and 4, strong anodic or cathodic polarization destroys this complete protective film. In this case the exposed sites are not bare Pt sites as those in the untreated Pt case but are Pt-O-alloy sites. Therefore, a type I electrode is a Pt-O-alloy surface covered by a complete layer of adsorbed oxygen while a type II electrode is a Pt-O-alloy surface covered by an incomplete layer of adsorbed oxygen. Most likely, these layers are not much thicker than a monolayer.

Apparently, the Pt-O-alloy is a better catalyst for the oxygen reaction than is the pure Pt. Supporting data for this concept are found in the data of Fig. 2 in which the slope is much lower than that for the corresponding data [see Fig. 1 of ref. (7)] of the untreated Pt. Frumkin (12) has shown that the slope, $-di/d\eta$, of the linear curve at low current densities may be taken as the rate of the over-all electrode reaction. Using this concept, it is seen that the rate of the oxygen reaction on the treated Pt surface, 3.4 x 10^{-3} mho, is about two orders of magnitude greater than that on the untreated Pt surface, 1.7 x 10^{-5} mho. This higher reactivity is reflected in the considerably lower oxygen overvoltage on a Pt-O-alloy cathode than on a Pt cathode [compare Fig. 3 with Fig. 2 of ref. (7)].

It is interesting to note that the anodic overvoltage curve on a Pt-O-alloy electrode, Fig. 5, is nearly the same as that found on the Pt electrode [Fig. 3 of ref. (7)]. One outstanding difference is the fact that, in the low current density range (below 10^{-5} amp/cm^2), the overvoltage curve bends downward below the extrapolated Tafel line on the Pt-O-alloy electrode (Fig. 5) but flattens out above the extrapolated Tafel line on the Pt electrode [Fig. 3 of ref. (7)]. If the anodic reaction occurs on a complete layer of platinum oxide, as suggested before (7), one would expect to observe the same kinetic parameters for both kinds of electrodes, since the basis metal is no longer the catalyst for the electrochemical reaction.

Because the greatest difference in electrochemical properties of a Pt and a Pt-O-alloy electrode appears in the cathodic reduction of oxygen, it is possible that the Pt-O-alloy surface is a much better peroxide decomposing catalyst. This concept may be used to explain the difference in the anodic polarization at very low current densities on these electrodes. In the Pt-O-alloy case, as open-circuit conditions are approached, the metal peroxide linkages such as PtO_2 are quickly broken, and the system returns to the partial monolayer of Pt-O. Here, the data would fall below the extrapolated Tafel line. In the Pt case, this does not happen as quickly, and the metal peroxides formed in the anodic process maintain the potential at the more noble values. Under these conditions, one would expect the data to remain above the extrapolated Tafel line. As a check on this suggestion, a Pt-O-alloy electrode was cathodized at about 1 ma/cm^2 for 7.25 hr. The overvoltage value was steady at —292 mv for the final 6 hr. At the end of the polarization run, a sample of solution was tested for the presence of H_2O_2 with $TiSO_4$ reagent (13). Since the test was negative, this means that the concentration of peroxides was below 10^{-6}M. On a Pt electrode cathodized under similar conditions, peroxide is easily detected. These data support the contention that a Pt-O-alloy surface is a much better peroxide decomposing catalyst than a Pt surface.

The rest potential on a Pt-O-alloy electrode is higher ($E_m \sim 1100$ mv) than on a Pt electrode ($E_m \sim 1060$). This should be expected because the data of Fig. 2 and 3 show that the polarization is much lower on a Pt-O-alloy electrode. Considering the mixed potential diagram of Fig. 6, ref. (7), the O_2/H_2O reaction would be much flatter in the case of a Pt-O-alloy electrode and the Pt/Pt-O curve would cut it at a point, E_m, closer to E_o'. Consequently, a greater cathodic current density range should be found on a Pt-O-alloy electrode over which the boundary condition (7)

$$RT/F < |(E - E_o')| \text{ or } |(E - E_o'')|$$

and the linear relationship hold, as shown by Fig. 2. A calculation of the local cell current density i_m, using Eq. [21] of ref. (7) and a value of $-di/dp = 3.4 \times 10^{-3}$ from Fig. 2, gives the value of 8.7×10^{-5} amp/cm^2. The higher corrosion current agrees with the picture of a more active surface in the Pt-O-alloy case. When the system is polarized anodically, the system comes under the control of the Pt/Pt-O reaction quickly, which is even nearer to a limiting current condition than on the Pt electrode (7). As seen in Fig. 2, the anodic branch of the curve is quite short, and the potential rises quickly with increasing anodic current density. An interesting point is the fact that at the high anodic current densities (Fig. 5)) there is a change in slope from 0.125 to 0.082. This behavior implies a change of mechanism. Contrary to what is generally found in most electrochemical systems, the slope changes to a lower value. This may mean that the surface has become a better catalyst for the electrode reaction. Such an observation is not incompatible with the findings that metal peroxide linkages such as PtO_2 are detected in this potential range (14) and that such electrodes make more reversible indicator electrodes than those not preanodized (15, 16).

The observation that the overvoltage was independent of the partial pressure of oxygen at the higher values of P_{O_2} was unexpected. Suppose that the reduction of oxygen proceeds through the following steps. The dissolved oxygen in solution which is in equilibrium with the P_{O_2} above the solution is first adsorbed on the electrode surface.

$$(O_2)_{aq} \rightleftharpoons (O_2)_{ads} \quad [1]$$

An electron is transferred

$$(O_2)_{ads} + e \rightleftharpoons (O_2^-)_{ads} \quad [2]$$

followed by the reaction with a hydrated hydrogen ion

$$(O_2^-)_{ads} + H^+ \rightleftharpoons (HO_2)_{ads} \quad [3]$$

A second electron is transferred

$$(HO_2)_{ads} + e \rightleftharpoons (HO_2^-)_{ads} \quad [4]$$

and reaction with a second hydrogen ion follows

$$(HO_2^-)_{ads} + H^+ \rightleftharpoons (H_2O_2)_{ads} \quad [5]$$

The adsorbed peroxide may desorb into solution or undergo catalytic decomposition to H_2O and O_2

$$2(H_2O_2)_{ads} \overset{cat}{\rightleftharpoons} H_2O + (O_2)_{ads} \quad [6]$$

Reaction [6] is not a simple step and may go by an electrochemical mechanism (17) or by a purely chemical decomposition path. In any event, the liberated oxygen can then undergo steps [2] to [5] so that, effectively, four electrons may be liberated.

In the untreated Pt case (7), the experimental evidence indicates that step two is rate-controlling and that the H_2O_2 (ads) desorbs into solution until the concentration becomes about 10^{-5}M in H_2O_2. Yet, in the Pt-O-alloy case, step two may still be rate-controlling even though the overvoltage is independent of P_{O_2} for the following reason. According to the polarization data, the Pt-O-alloy surface is quite reactive to oxygen, and the surfaces could very well be saturated with adsorbed oxygen even at values of P_{O_2} down to 0.2 atm. Although the layer of adsorbed oxygen is in equilibrium with the partial pressure of oxygen above the solution, the rate could not be increased by increasing P_{O_2} above 0.2 atm because the surface cannot adsorb any more oxygen. In effect, a limiting current

with respect to P_{O_2} has been reached at 0.2 atm. Below a P_{O_2} value of 0.2 atm, the surface is no longer saturated with adsorbed oxygen and the rate becomes dependent on the P_{O_2}. In addition, reaction [6] occurs so fast on Pt-O-alloy surfaces that the peroxide concentration in solution cannot build up to a detectable amount. If the P_{O_2} becomes low enough, a point may be reached where enough oxygen cannot get to the surface to support the demanded current density. In this case, step one begins to influence the rate and may become rate-determining. This change in the rate-determining step may be seen in the P_{O_2} data of Fig. 5b of ref. (7) for an untreated platinum electrode. Here, the slope of the η-log P_{O_2} curve deviates from a 58-mv value to lower ones at low values of P_{O_2}.

Most likely the hysteresis effects noted in the first cycles of polarization reflect the results of changes in the system produced by the polarization procedure. After a time, the system comes to a steady state and reproducible overvoltage curves may be obtained. For the anodic curves the change is caused chiefly by the formation of a complete layer of adsorbed oxygen much of which is in the form of PtO_2. On the other hand, the chief cause for hysteresis effects in the cathodic curves is the building up of a steady-state concentration of peroxide in the solution. It was shown (1) that the rest potential was lowered by small changes in the peroxide concentration in the low concentration range. This would lower the first part of the cathodic curve, as observed.

These data support the conclusion that the treatment of Pt with HNO_3 produces a significant change in the nature of the metal surface. It is suggested that this change takes the form of a Pt-O alloy. The Pt-O-alloy surface not only is a much better peroxide decomposing catalyst than Pt, but also it greatly facilitates the adsorption of oxygen from solution and the electron transfer to the adsorbed oxygen. This is reflected in the observation that the rate of the oxygen reaction is two orders of magnitude greater, that the overvoltage is significantly lowered on Pt-O-alloy electrodes, and that the overvoltage is independent of the P_{O_2} for large values of P_{O_2}.

Acknowledgments

The author wishes to express his gratitude to Professor Paul Delahay of the Louisiana State University and to Dr. Raymond Thacker and Dr. John L. Griffin of the General Motors Research Laboratories for their interesting comments and suggestions.

Potential of a Platinum Electrode at Low Partial Pressures of Hydrogen or Oxygen

Theodore B. Warner and Sigmund Schuldiner

U. S. Naval Research Laboratory, Washington, D. C.

ABSTRACT

The open-circuit potential on bright platinum in 1M H_2SO_4 was measured as a function of oxygen or hydrogen partial pressure from 10^{-2} to 10^{-7} atm. The very low rates of H_2 or O_2 flow which were required were produced by a special gas generator. Potentials predicted by the Nernst equation for the H^+/H_2 couple were not observed below 10^{-4} atm H_2 partial pressure. A Nernst relation with a slope of 0.06 v/decade of oxygen partial pressure was found. The oxygen leak into the closed system used was found to be about 10^{-7} atm. Based on the assumption that the resultant dissolved O_2 decreases the dissolved H_2 concentration in the solution at the electrode surface, an equation was developed for obtaining the effective H_2 partial pressure.

The Nernst equation relating hydrogen partial pressure and potential of a platinum electrode in acid solution has been experimentally verified previously for hydrogen partial pressures ranging from hundreds of atmospheres down to 0.01 atm (1). It is often assumed to be valid at much lower hydrogen pressures. One purpose of this study was to check this assumption and to determine the conditions under which normal Nernst behavior prevails. The potential behavior of platinum in acid solutions equilibrated with oxygen at partial pressures ranging down to less than 10^{-6} atm was also determined.

Previous work at this Laboratory (2, 3) had shown that substantial amounts of oxygen and hydrogen could dissolve in the "skin" of a Pt electrode and affect its catalytic activity (and also appear as an unexpected participant in chemical reactions). We differentiate here between solution of a gas into the bulk of the metal in the usual sense of the word "solution," and a kind of rapid selective absorption of gas atoms into a relatively few atomic layers of metal immediately below the surface atomic layer. This layer immediately below the surface we shall call the "derma" of the metal, by analogy to biological usage. This type of absorption can then be termed "dermasorption." These experiments were designed to give additional information on the ways gases absorb in platinum, particularly on the time required to sorb

and desorb them, and the effects of sorbed gases on open-circuit potentials.

For meaningful measurements in electrochemical systems having small exchange current densities, conditions inside the cell must be rigorously controlled. The system utilizing Pyrex pipe recently built in this Laboratory (4-6) gave such control. Being gas-tight, it permitted effective exclusion of air and other atmospheric contaminants.

Experimental

Apparatus.—The electrochemical cell (6) contained a miniature glass reference electrode, a Pt bead electrode of about 0.17 cm^2 apparent area, a Pt wire electrode 5 cm long with a 0.064 cm diameter, and a Pt gauze electrode of very large area. The surface-to-volume ratios of the bead, wire, and gauze were 26, 62, and 450 cm^{-1}, respectively. The electrolyte was 1M H_2SO_4 maintained at 25° ± 1°C. The helium purification train was identical with that described previously (5) except that an improved electrolytic H_2/O_2 generator replaced the conventional design previously used. Hydrogen was treated as before in a Serfass Hydrogen Purifier, saturated with water, and introduced into the gas train between the H_2/O_2 generator and the cell. Kern High Vacuum Greaseless stopcocks (Viton A diaphragm) at the ends of a T-connection between the helium and hydrogen lines were used to block the flow of either gas. The hydrogen line was always back-flushed (from cell to Serfass) with helium and left filled with pure He when not in use.

The H_2/O_2 generator[1] shown in Fig. 1 was used to generate pure H_2 or O_2 at low rates. We shall describe this device as an H_2 generator with the understanding that the same principles also apply to the oxygen case. For our purposes, it was important that H_2 added to the helium stream not be contaminated with trace amounts of O_2, so the generator used was designed to avoid crossdiffusion of electrode products while retaining the advantages of electrolytically generated gas.[2] Crossdiffusion is impeded in four ways: (*a*) a very long path, including a glass frit, separates the two compartments; (*b*) buffer compartments act very much like plates in a conventional condenser, hydrogen diffusing downward from the working electrode is stripped by the incoming pure He, while in the upper chamber, the He + H_2 stream coming from the electrochemical cell creates an H_2-rich region below the oxygen-rich counter electrode compartment; (*c*) hydrogen-rich gas bubbles flowing over the Pd-tube counter electrode impede oxygen bubble formation; and (*d*) H_2 gas introduced on the inside (*i.e.*, the room side) of the Pd tube dissolves into the Pd and the anodic reaction is largely $H \rightarrow H^+ + e$ (7). In practice, visible bubble formation at the counter electrode is only seen at currents in excess of 20-50 ma. Hydrostatic pressure difference between the two chambers automatically compensates for the pressure drop through the cell and associated bubblers.

[1] Figure 1 shows an improved design and differs from the generator employed in this study in one respect; instead of using the circular disks shown, baffles in the lower buffer compartments were formed by pushing in the sides of the glass walls as is commonly done in vapor condensers.

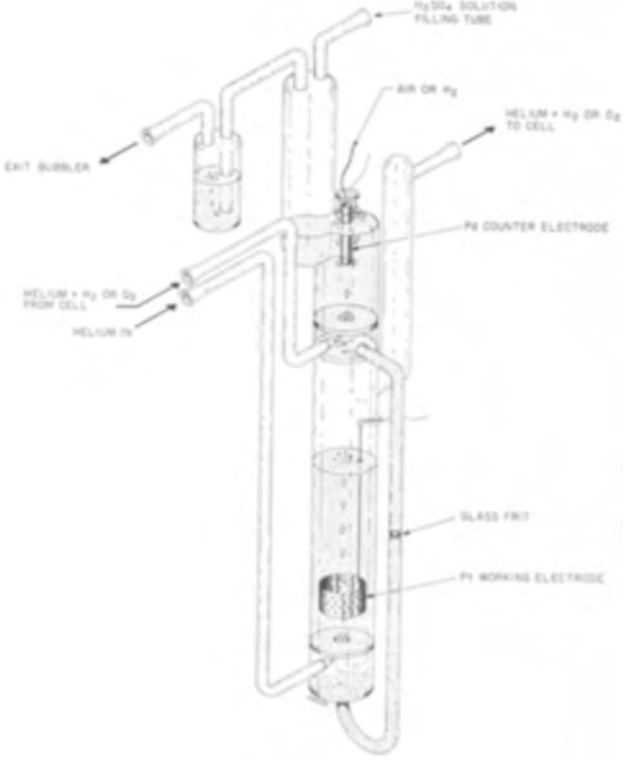

Fig. 1. Electrolytic H_2 or O_2 generator

Perhaps the greatest advantage of this design is that at very low H_2 or O_2 generation rates no gas is formed at the counter electrode at all. The anodic reaction at the counter electrode is the oxidation of H (dissolved in Pd) to H^+; a steady supply of H(dissolved) is provided by H_2 introduced inside the tube. The cathodic reaction at the counter electrode is the reduction of H^+ to H, this hydrogen dissolves in the Pd tube, diffuses to the inside surface and reacts with the oxygen there (in this case the inside of the Pd tube is open to air) to form H_2O.

Procedure.—Glassware was cleaned with boiling HNO_3 followed by 12-15 rinses with triply distilled water and/or by heating to the annealing temperature. Preliminary solution pre-electrolysis and calibration of the glass reference electrode in 1 atm of H_2 were carried out as before (6), the H_2 line was backflushed and filled with He, and the desired partial pressure of H_2 or O_2 in He (known to ±5%) was obtained by generating gas at the required rate. Helium flow was always 88 ± 4 cc/min, pressure within the cell was 13 Torr over atmospheric, and open circuit potentials of the three electrodes were measured with a Keithley 603 electrometer and reported *vs.* the normal hydrogen electrode (NHE), as before (6).

Although the experimental system was gas tight, there is no question but that a minute amount of leakage of oxygen from air[3] took place by diffusion through Viton-A O-rings connecting the various sections of glass pipe. This leakage was unimportant as long as the partial pressure of oxygen or hydrogen was more than 10^{-5} atm. However, at partial pressures of these gases approaching 10^{-6} atm and lower, the leak rate of O_2 from the air was significant and was taken into account. Since the He flow was constant, for convenience leak rates will be discussed frequently in terms of the net partial pressure of gas resulting.

Results and Discussion

Experimental results.—The experimental results are shown in Fig. 2. Values were obtained with increasing and decreasing gas partial pressures and were accepted after a steady state potential had been attained at an electrode (usually within ±10 mv). Results for oxygen pressures above 10^{-4} atm confirm previous work from this Laboratory (6). Potentials under H_2 at partial pressures $<10^{-4}$ atm deviate markedly from those predicted for the reversible H^+/H_2 couple by the Nernst potential equation. Before interpreting these data, however, the response time, extent, and probable effects of O_2 leaking into the system from its surroundings must be considered.

[2] A conventional H-cell generator cannot be used for partial pressures below 10^{-4} to 10^{-5} atm because of effects due to crossdiffusion of the gases produced.

[3] It should be pointed out that the air in the laboratory was purified by constant recirculation through an absolute filter to remove aerosols and through a carbon bed to remove gases and vapors. Smoking was not permitted in the laboratory.

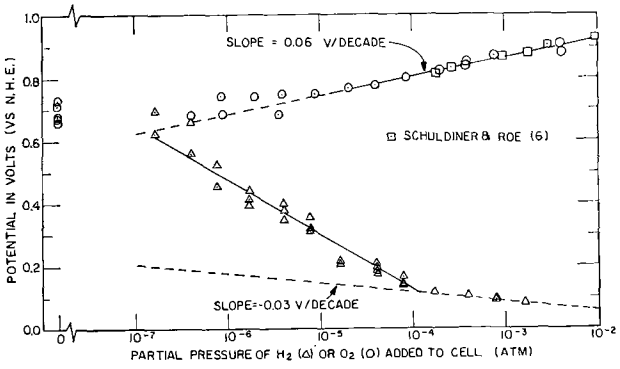

Fig. 2. Effects of H_2 and O_2 partial pressure on platinum rest potentials. The points are experimental results. In the hydrogen region, the dashed line gives reversible H^+/H_2 potentials as predicted by the Nernst equation. In the oxygen region, the dashed line is an extrapolation of the linear region found at higher pressures.

Response time.—The time required to come to a true steady state was variable, depending on the H_2 or O_2 partial pressure, the previous gas partial pressure at which the electrode was equilibrated, and the surface-to-volume ratio of the electrode. The time increased as the surface/volume ratio decreased, as partial pressure decreased, and as the change from previous pressure increased. Periods of several days were required at the lowest pressures and three or more days for open circuit potentials under pure helium (*i.e.*, helium containing only that oxygen leaking into the system). False, apparently steady state, potentials were often observed for many hours. They were always between the last potential obtained and the new one being approached.

The above behavior could consistently be interpreted by assuming that for an open-circuit potential to represent truly steady state conditions, the amount of H_2 or O_2 dissolved in the platinum must be allowed to come to equilibrium with the amount at the surface. The long times required for this, and the surface/volume effect, imply that the partition must ultimately be between gas dissolved in the bulk of the metal and gas on the surface. If sufficient time was allowed, all three electrodes invariably came to the same mean potential within 5 mv. These results, then, coupled with earlier results (2), suggest that dermasorbed gases can exchange relatively rapidly with the surface, and that gases dissolved in the bulk of the metal must exchange slowly with the dermasorbed layer (and thus with the surface).

Effect of oxygen leakage.—For the case of O_2 added to the He, any O_2 leak adds to the partial pressure of O_2 actually in the system. The case of O_2 leaking into a system to which H_2 is being added is more complex. Very little is known about the effects of trace amounts of O_2 in H_2 on the potential of a Pt electrode, but an estimate may be made by assuming that any O_2 at the Pt surface will react with H_2 until only an effective net excess of H_2 remains. Since reaction of H_2 with O_2 could take place only at the platinum surface, the H_2 concentration would be reduced only at or very near to the platinum-solution interface. An "effective" H_2 partial pressure, *i.e.*, the pressure that would result in the same electrode potential in the absence of a leak, was calculated by assuming Henry's law and complete reaction of O_2 and H_2 present in solution at the interface. The net excess concentration of H_2 in solution was used to calculate the pressure of H_2 in the gas phase that would be in equilibrium with it in the absence of any leak, and this pressure was used as the effective H_2 partial pressure.

$$(P_{H_2})_{\text{effective}} = \frac{\alpha_H (P_{H_2})_{\text{added}} - 2\alpha_O (P_{O_2})_{\text{leak}}}{\alpha_H} \quad [1]$$

Table I. Polarization of the hydrogen electrode by oxygen

P_{O_2}[a] in gas phase, atm	(P_{H_2})[b] effective calculated, atm	E (mv *vs.* NHE) Exp.	Calc.[c]

[a] Lorch (9), mixture with hydrogen, total pressure 1 atm.
[b] Calculated using Eq. [1].
[c] Calculated from the Nernst equation, $E = -0.0295 \log (P_{H_2})_{\text{effective}}$.

where α_H and α_O are the solubilities of H_2 and O_2 in 1M H_2SO_4 at 25°C, taken as 0.0149 and 0.023 std. cc/ml H_2SO_4, respectively (8). (At H_2 generation rates lower than the O_2 leak rate a net excess of O_2 resulted.)

Lorch (9) studied chemical polarization of the hydrogen electrode by oxygen, and his experimental data were used to check the assumptions implicit in Eq. [1]. The results, given in Table I, show agreement within 0.5 mv for H_2 partial pressures near 1 atm. In the next section we assume that this model also applies at very low partial pressures of both O_2 and H_2.

Extent of oxygen leakage.—The potential behavior of the platinum electrode was a sensitive indicator of the background O_2 concentration. The fact that addition of H_2 to the He stream sufficient to give a partial pressure of 4×10^{-7} atm H_2 caused the potential to drop ~0.1v indicated that the P_{O_2} could not have been much larger than this. Furthermore, plotting effective H_2 pressures *vs.* observed potential under the assumption of O_2 leaks of 10^{-6} and 10^{-7} atm (Fig. 3 and 4) gives an unreasonable picture when 10^{-6} atm[4] is as-

[4] For example, the corrections made in Fig. 3 compress potential values between 0.45 and 0.75v into the range of partial pressures between 0.85 and 1.00×10^{-6} atm. In this region the individual points should have been erratic, but in fact, they were very steady and fairly reproducible as shown in Fig. 2.

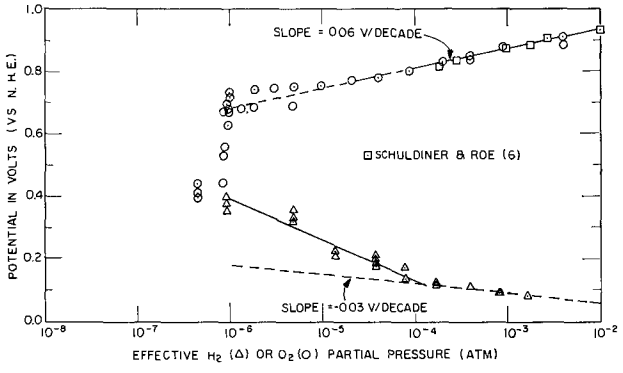

Fig. 3. Platinum rest potentials *vs.* H_2 or O_2 partial pressures corrected for an assumed oxygen leak of 1×10^{-6} atm using Eq. [1].

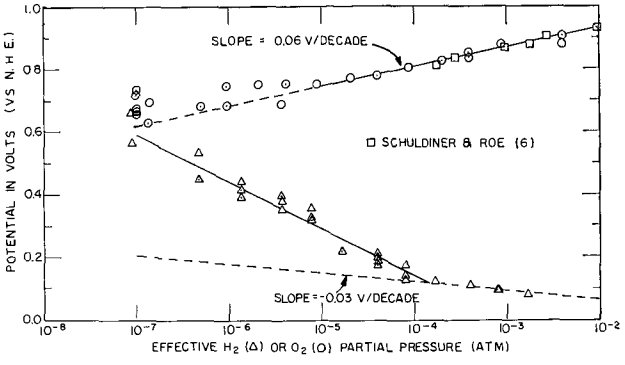

Fig. 4. Platinum rest potentials *vs.* H_2 or O_2 partial pressures corrected for an assumed oxygen leak of 1×10^{-7} atm using Eq. [1].

sumed and organizes the data coherently when 10^{-7} atm is assumed.

The above estimate based on electrochemical evidence is in reasonable agreement with the 10^{-6}-10^{-8} atm oxygen partial pressure due to leaks that would be estimated *a priori* within such a flowing system, since Viton-A O-rings are suitable for use in vacuum systems operating in the 10^{-6} Torr region. It was also confirmed by analyses using a modified CED 21-103c Mass Spectrometer that indicated that O_2 concentration in the nominally pure He flowing through our system was less than 1 ppm.[5]

Platinum rest potentials vs. P_{H_2} or P_{O_2}.—The preceding discussion indicates that Fig. 4 most closely represents the potential behavior of these systems. Clearly, a reversible H^+/H_2 couple cannot control electrode potential below 10^{-4} atm hydrogen. What does control potential is, at present, a moot question. It seems quite unlikely that an oxygen leak of the order of 10^{-7} atm could be responsible for this potential behavior at hydrogen partial pressures several orders of magnitude larger, providing that at this low partial pressure all of the oxygen which gets to the Pt surface does react readily with hydrogen.

Schuldiner (10) showed that the relationship between exchange current density i_o and P_{H_2} was

$$i_o = 1.43 \times 10^{-3} P_{H_2}(1-\theta_o)^2 \qquad [2]$$

where θ_o is the fraction of available Pt surface covered with atomic hydrogen at P_{H_2}. At low hydrogen partial pressures, θ_o will undoubtedly be very small compared to unity and for all practical purposes $(1-\theta_o)^2$ will approach one. Hence, at $P_{H_2} = 10^{-4}$ atm, $i_o \approx 1.4 \times 10^{-7}$ a/cm^2, and at $P_{H_2} = 10^{-7}$ atm, $i_o \approx 1.4 \times 10^{-10}$ a/cm^2. If a mixed potential involving H^+/H_2 and, say, the O_2/HO_2 (7) reactions were potential determining, i_o for the O_2/HO_2 reaction would have to be of the same order of magnitude as the H^+/H_2 reaction. It is very unlikely that the O_2/HO_2 or any other possible potential-determining reaction involving O_2 at 10^{-7} atm would have an i_o comparable to the H^+/H_2 reaction. All literature indications are that any equilibrium reactions on Pt involving O_2 at 1 atm have i_o values of not more than 10^{-10} a/cm^2.

It is also unlikely that these potentials are caused by polarization by the electrometer (10^{14} ohms shunted by 10 $\mu\mu F$), for then one would expect an even more marked effect on the presumably more easily polarized Pt/O_2 system. In addition, electrometer measurements were the same for electrodes which were not permanently connected and for which potential measurements were made in a few minutes after connecting the electrometer circuit.

It should be stressed that the unexpected relation between potential and hydrogen partial pressure below 10^{-4} atm is an experimental fact and does not depend on any assumptions about how hydrogen may interact with oxygen. The same kind of behavior would be expected in any real system from which oxygen is imperfectly excluded. It is believed that the deviation from Nernst behavior may be due to the rather complex sorption of hydrogen on platinum (5), where even at 1 atm of H_2 there are only a relatively small number of weakly bonded H atoms which are in rapid equilibrium with H_2 and H^+ (10, 11).

It is interesting that the Pt/O_2 system fits a Nernst relation at substantially lower O_2 partial pressures than does Pt/H_2. The oxygen rest potential follows the same Nernst relation previously obtained at this Laboratory (6). These results similarly indicate a potential-determining equilibrium

$$O_2 + H^+ + e = HO_2 \qquad [3]$$

assuming a constant activity of HO_2 adsorbed on the Pt surface.

The open circuit potentials for "pure" He, *i.e.*, at 10^{-7} atm O_2 in Fig. 4, are somewhat scattered. This may be the result of an extremely long time being required for establishment of true equilibrium between absorbed, dermasorbed, and chemisorbed O_2 at such low partial pressures. Also, small variations in the O_2 leak from time to time are possible. These values differ from the previously reported values of 0.2-0.4v (6). The reason for the discrepancy may be that in the previous work a Pd tube electrode at about 50 mv (NHE) was present in the cell. We have observed that at very low oxygen partial pressures such a Pd electrode will cause the Pt electrode to become less positive. The Pd may have either contributed a small amount of H_2 to the cell or acted as an effective O_2 getter to give O_2 partial pressures virtually equal to zero. A combination of these two effects is also possible. The effect of hydrogen-containing Pd at very low O_2 partial pressures requires further investigation.

[5] Such a concentration is at or below the lower detection limit of the instrument. The amount of O_2 was determined from repeated measurements and blanks, with due consideration of wall effects. Interestingly, the mass spectrometer data giving an N_2/O_2 ratio of about three supported the view that O_2 entering the system did so by diffusion through the Viton O-rings, where unequal diffusion rates of N_2 and O_2 are reasonable. The N_2/O_2 ratio in the helium as received was about six, and inadequate helium purification would have given at least that value. If a gross leak existed, the ratio would have been four or larger.

Acknowledgments

We gratefully acknowledge the assistance of Dr. F. E. Saalfeld, who carried out the mass spectrometer analyses, and Mr. G. J. Bergen, who fabricated much of the glassware, including the H_2/O_2 generator.

Manuscript received Jan. 8, 1965; revised manuscript received April 5, 1965. This paper was presented at the San Francisco Meeting, May 9-13, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

Electrical Conductance in Acidic, Aqueous Solutions

R. A. Horne

Arthur D. Little Inc., Cambridge, Massachusetts

ABSTRACT

Protonic conduction occurs by the Grotthuss mechanism. Below about 0.001M HCl, the lengths of the Grotthuss chains are determined by the temperature, but over the range of 0.001M to about 0.5M, the chains are principally disrupted by other protons. In this range the chain length and the equivalent conductance depend on the cube root of the concentration. An Arrhenius-type equation is developed for describing the concentration dependence of the conductance which yields values in agreement with experiment to within 1% over the range 5°-65°C and up to 0.4M. The activation energy which appears in the chain-terminating terms of this equation is that of "hole" formation in the solvent water.

Elsewhere (1, 2), we have pointed out that the Onsager-Fuoss (3) and similar equations for the concentration dependence of the electrical conductivity of ionic solutions based on consideration of the electrophoretic and relaxation effects may not be applicable to acidic, aqueous solutions or any other systems in which the Grotthuss mechanism makes a conductive contribution (4). The purpose of the present study is to indicate some of the directions which the derivation of a conductivity equation applicable to protonic conduction might take.

Throughout this discussion, we will be concerned with only the Grotthuss component of protonic conduction. Although the Grotthuss mechanism dominates protonic conduction, protons also conduct by the "normal" process of hole formation and this latter process may account for as much as 20% of the total conductance at 1 atm and 25°C.

Viscosity

At 1 atm rotation of water molecules is the rate-determining step of the Grotthuss mechanism (5, 6). Although its value is less, the activation energy of protonic conduction in aqueous solutions above 10°C varies in the same way with temperature as does that for the electrical conductivity of strong 1:1 salts such as KCl, thereby suggesting that energetically "hole" formation in water and rotation of water molecules are similar processes. The velocity of the translational movement for a sphere of radius, a, in a medium of viscosity η is given by Stokes' law

$$v = F/6\pi\eta a \qquad [1]$$

where F is the applied force, while the angular velocity, ω, of a sphere rotating in a viscous medium is given by

$$\omega = \tau/8\pi\eta a^3 \qquad [2]$$

where τ is the applied torque. Notice that the translational movement depends on the first power of the radius whereas the rotational movement depends on the third power. The application of hydrostatic pressure breaks up the order in liquid water and reduces the effective radius of hydrated ions in aqueous solution (7-9). Consequently, one expects the pressure dependence of the relative conductance to be greater for HCl solutions than for KCl solutions. Figure 1 shows such to be the case. In fact, HCl shows a greater pressure dependence than anticipated. The explanation of this is discussed later.

Both Eq. [1] and [2] contain the first power of the viscosity of the medium. Pressure, but not temperature, alters the sizes of hydrated ions (see above) and this may give rise to an apparent higher power dependence on viscosity, but as long as the solution is sufficiently dilute so that the ions do not have to compete for waters of solvation, changing the concentration of the electrolyte should not affect the sizes of the hydrated ions.

The dielectric relaxation time of water decreases with increasing electrolyte concentration (10, 11). If the speed of rotation of water molecules, the rate-determining step of the Grotthuss mechanism, behaves in like manner, then protonic equivalent conductance should increase with increasing concentration which is contrary to observation.

The introduction of ions alters the extent of structure in liquid water and gives rise to changes in the macroscopic viscosity. The proton has a positive viscosity B-coefficient (see Eq. [3]) of 0.070, indicating that it is a structure-forming ion (12). Qualitatively then, one might expect it to order the solvent, hinder the rotation of water molecules, and thus impede Grotthuss conduction as observed. An obvious attack on the present problem of deriving an expression for the concentration-dependence of protonic conductivity is to express the conductance as some function of the limiting conductance and the viscosity as given by the relation of Jones and Dole (13).

$$\eta = \eta^0 (1 + A\sqrt{C} + BC) \qquad [3]$$

where η^0 is the viscosity of pure water, C the concentration of electrolyte, and A and B are constants. Unfortunately, the effect of electrolyte concentration on viscosity is much too small to account for the observed effect on the equivalent conductance. Thus for 0.01M HCl, the relative viscosity at 25°C is only 1.0008, while the reciprocal of the relative equivalent con-

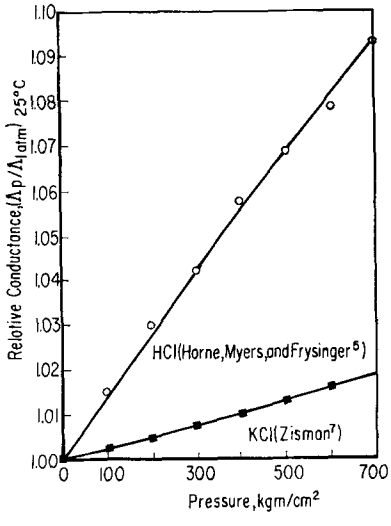

Fig. 1. Pressure dependence of the relative electrical conductances of aqueous acid and salt solutions.

Table I. Thermal termination of Grotthuss chains and structural parameters

Temp, °C	$(\Lambda^\circ/\Lambda^\circ_{0°C})^{-1}$	Λ°/Λ^*	$\eta/\eta_{0°C}$	$H/H_{0°C}$	$S/S_{0°C}$
0	1.00	—	1.00	1.00	1.00
18	0.84	—	0.65	0.88	0.66
25	0.63	0.99	0.58	0.86	0.57
35	0.54	0.99	0.50	0.82	0.47

ductance $(\Lambda/\Lambda^\circ)^{-1}$ is 1.03. In other words, the viscosity changes by only 0.08%, whereas the conductance changes by more than 3%.

In summary, the approach of estimating the retardation of water rotation from structural changes in liquid water as reflected by the macroscopic viscosity does not appear to be an attractive one.

While the concentration of electrolyte has much less effect on the macroscopic viscosity than on the conductance, the reverse is true in the case of temperature as illustrated by Table I which compares conductance ratios (based on "International Critical Tables" data) for HCl with the relative viscosity.

The above conclusion should not be taken to mean that conductivity, viscosity, and the degree of structure in liquid water are unrelated. On the contrary, Table I illustrates that they all have similar temperature dependencies (14). This table compares the reciprocal of the limiting conductance relative to 0°C, the ratio of the limiting conductance Λ°, to that, Λ^*, obtained by the extrapolation Λ *vs.* $C^{1/3}$ to 0°C; the relative viscosity $\eta/\eta_{0°C}$; the relative number of unbroken hydrogen bonds, $H/H_{0°C}$; and the relative size of the water clusters, $S/S_{0°C}$.

The latter two parameters are calculated from the estimates of Nemethy and Scheraga (15). This table indicates that the changes in the structural parameters are much larger than the changes in Λ°/Λ^*. Notice, however, the good parallel between the relative viscosity and the relative cluster size.

Grotthuss Chain Termination

Electrical conduction by the Grotthuss mechanism occurs only in the interstitial or "free" water between the fluctuating clusters in liquid water (16). This is not an unreasonable assumption inasmuch as (*a*) water molecules within the clusters are less free to rotate; (*b*) a cluster represents a closed Grotthuss propagative circuit; and (c) the only entity undergoing dipole orientation in water is the simple H_2O molecule and not polymeric forms (17). Also, the formation of small water polymers is not favored (15, 18).

If the protonic conductance involves only the "free" or monomeric water molecules, then the equivalent conductance should be proportional to the monomer concentration. Figure 2 shows such to be the case.

The proton flips propagate along transient chains of H-bonded water molecules in the free solvent. In pure water or in very dilute solutions, the length of these chains will depend for the most part on temperature; this is normal or thermal chain termination (TCT). The introduction of a second proton into a chain will be dependent on the concentration and as the concentration increases should become the dominant chain-terminating factor (CCT). Let the concentration of protons in a unit cube be C; let us assume for the sake of simplicity that a proton is "proceeding" along a chain along the edge of the unit cube,[1] then the distance which it can "move" without encountering a second proton will depend on $C^{-1/3}$. This distance is the "lattice length" discussed by Frank and Thompson (19), and they note that "it makes no particular difference what kind of a lattice is assumed —it is the $C^{1/3}$ dependence that counts." Protonic conduction should depend on the cube root of the proton concentration.

Figure 3, based on the data of Owen and Sweeton (20), exhibits the concentration-dependence of the equivalent conductance of aqueous HCl solutions at different temperatures and, indeed, Λ_{HCl} *vs.* $C^{1/3}$ is linear over a broad concentration range, roughly 0.001 to 0.5M. The departure from linearity above 0.5M is not surprising, for this represents a concentrated solution. Of greater significance are the departures below 0.001M.

In very dilute HCl solutions (below 0.001M) the conductance depends on $C^{1/2}$ (21). On the basis of this experimental finding the conductance at infinite dilution can be estimated by an extrapolation of a plot of Λ *vs.* $C^{1/2}$ to $C = 0$, without making any commitment as to the correctness of various theories of conductance which predict a $C^{1/2}$ dependence. Hence

[1] When the electrical potential is applied, the direction of a proton's apparent movement ceases to be random.

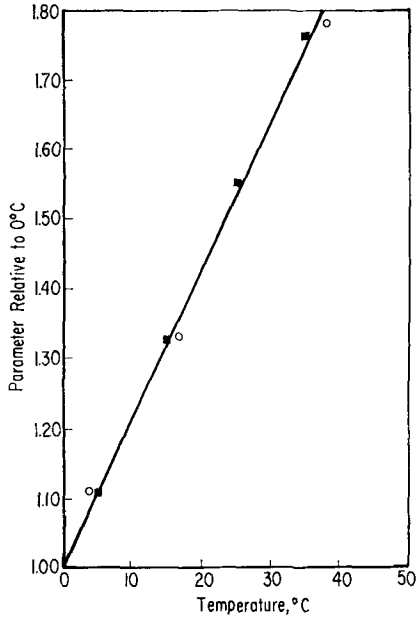

Fig. 2. Relation between proton conductance and water-monomer concentration. Parameters: ○, fraction of monomeric water relative to 0°C, $N_T/N_{0°C}$ where N is the number of monomers per 100 water molecules [I. R. Rao, Proc. Roy Soc. London, 145A, 489 (1934)]; ■, protonic limiting equivalent conductance relative to 0°C, $\Lambda^\circ_T/\Lambda^\circ_{0°C}$ [Robinson and Stokes (17)].

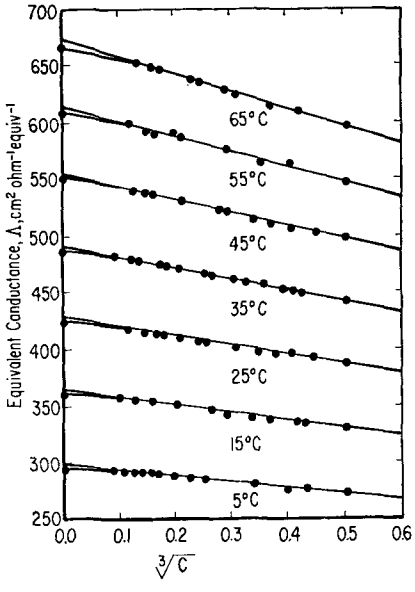

Fig. 3. Concentration dependence of the conductivity of aqueous HCl solutions [based on data of Owen and Sweeton (20)].

Table II. Properties of the Λ vs. $C^{1/3}$ plots

Temp, °C	Limit equiv. cond. (17), $\Lambda°$, cm²-ohm⁻¹ equiv⁻¹	Λ^*, cm²-ohm⁻¹ equiv⁻¹	$\Lambda^*-\Lambda°$, cm²-ohm⁻¹ equiv⁻¹	Slope
5	297.6	300	2.4	53
15	362.1	365	3	68
25	426.2	430	3.6	82
35	489.2	493	4	98
45	550.3	555	5	117
55	609.5	615	6	134
65	666.8	675	7	157

the conductances at infinite dilutions are taken to be the limiting conductances, $\Lambda°$, as given by Owen and Sweeton (20). The introduction of the concept of limiting conductance as commonly defined is of interest because physical significance can be assigned to the difference between

$$\Lambda^* = \lim_{C\to 0} \Lambda \text{ vs. } \sqrt[3]{C} \text{ and } \Lambda° = \lim_{C\to 0} \Lambda \text{ vs. } \sqrt{C}$$

If the linear segments of the curves in Fig. 3 are extrapolated down to infinite dilution of electrolyte, the values obtained, Λ^*, are greater than the limiting conductances, $\Lambda°$. Λ^* may be interpreted as the conductance corresponding to indefinitely long Grotthuss chains. But in this low proton concentration region, the chains are not indefinitely long. They are thermally terminated. The lengths of the chains decrease with increasing temperature, thus the difference between Λ^* and $\Lambda°$ should increase with increasing temperature. Table II shows such to be the case. The differences and slopes in Table II are obtained from replots (not shown) of Fig. 3 on a much-expanded scale. The conductance may be represented by an equation of the form

$$\Lambda_{T,C} = \Lambda^* - \text{TCT} - \text{CCT} \qquad [4]$$

where TCT and CCT are thermal chain termination and concentration chain termination terms respectively. The former term is related to the difference $\Lambda° - \Lambda^*$. If the logarithm of this difference is plotted *vs.* the reciprocal of the absolute temperature (Fig. 4), a reasonably linear Arrhenius plot is obtained. There is some deviation from linearity below 25°C, but the deviation amounts to only about 10% of the value of $\Lambda° - \Lambda^*$ even at 5°C. The activation energy calculated from the slope of the linear part of this curve (25°-65°C) by the integrated form of the Arrhenius equation is 3.53 kcal/mole. Figure 4 also shows an Arrhenius plot of the limiting conductance of aqueous KCl solutions from data quoted

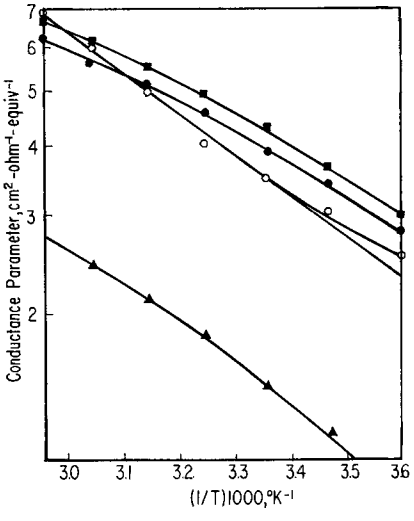

Fig. 4. Arrhenius plots of conductance parameters: ○, $\Lambda^*_{T,\,0,\,HCl} - \Lambda°_{HCl}$; ■, $\Lambda_{0.5M\ HCl}/100$; ●, $\Lambda^*_{T,\,0,\,HCl}/100$; ▲, $\Lambda°_{KCl}/100$.

by Robinson and Stokes (17). The curve is not linear, indicating that the activation energy of conductance, E_a, is temperature dependent. Over the temperature range 5°-65°C, its value varies from 3.02 to 3.77 kcal/mole. The rate-controlling step of normal conduction in aqueous solutions involves the formation of a hole in the solvent (22). Thermal rupture of a Grotthuss chain is equivalent to the formation of a one-dimensional hole, therefore one finds that E_a for thermal chain termination is nearly the same as for hole formation (that is to say for normal ionic conduction).

The slopes of Λ *vs.* $C^{1/3}$ in the linear part of the curves in Fig. 4 are also temperature dependent (Table II) and an Arrhenius plot of these slopes is linear over the entire temperature range 5°-65°C and its slope corresponds to an activation energy of 3.38 kcal/mole, the same value as for normal conduction as expected. Thus Eq. [4] becomes

$$\Lambda_{T,C} = \Lambda^*_{T,0} - \phi\, 1.32 \times 10^3 e - 3530/RT - 2.39 \times 10^4 e - 3380/RT \sqrt[3]{C} \qquad [5]$$

where T is the absolute temperature. The term ϕ has been introduced because as concentration chain termination becomes more frequent, the probability of a chain being thermally terminated decreases. The value of ϕ is given by

$$\phi = (1.32 \times 10^3 e^{-3530/RT}) / (1.32 \times 10^3 e^{-3530/RT} + 2.39 \times 10^4 e^{-3380/RT} \sqrt[3]{C}) \qquad [6]$$

The constants in Eq. [5] and the activation energies have been calculated from the data of Owen and Sweeton (20). The numerical difference between the E_a's is small; in actuality they probably should be the same value. This enables Eq. [5] to be rewritten in the form

$$\Lambda_{T,C} = K_1 e^{-E_{a,r}/RT} - (\phi K_2 + K_3 \sqrt[3]{C})\, e^{-E_{a,h}/RT}$$

where the K's are constants and $E_{a,r}$ and $E_{a,h}$ are the activation energies for the rotation of water molecules and hole formation in water, respectively.

An Arrhenius plot of Λ^* is shown in Fig. 4. Inspection shows that it parallels that of $\Lambda_{0.5M\ HCl}$ and that its value is less than for normal conduction. Again this is to be expected for the rate-determining step in protonic conduction involves the rotation of water molecules (5), and E_a for this process is less than that for hole formation.

Values of conductance, calculated from values of Λ^* given in Table II and from Eq. [5] are given in Table III along with the experimental values of Owen and Sweeton (20). The agreement is satisfactory (less than 1% deviation) over a very wide temperature and concentration range.

Returning now to Fig. 1, a_{KCl} represents the hydrated radii of K^+ and Cl^- and its value decreases with increasing pressure; however, the interpretation of a_{HCl} is less clear. The species rotating are single water molecules (see above), not clusters; hence pressure cannot alter their size significantly. The pressure dependence of the relative conductance of HCl solutions (Fig. 1), therefore, cannot be explained in terms of the a^3 term in Eq. [2]. Protonic conduction is confined to the free water. The application of pressure increases the ratio of free to clustered water, and this effect gives rise to the observed increase in conductivity by increasing the relative amount of the conductive medium.

Salt Electrolytes

We have shown above that, due to the operancy of a special conductive mechanism, over the concentration range 0.001 to nearly 0.5M the conductance of HCl solutions depends on the cube root of the concentration of electrolyte. A puzzling difficulty now arises, namely, the conductance of a great many 1:1 salts (and their diffusion coefficients and log $f\pm$ as

well) also exhibit a linear dependence on $C^{1/3}$ (19) even although, as we have seen, their conductance mechanism is entirely different from that of acids. However, data quoted by Robinson and Stokes (17), shows that KCl departs far more from linearity than does HCl. Normal ionic conduction depends on successive hole-formation determining the ion's path through the medium whereas protonic conduction depends on successive rotations of water molecules. A second ion may obstruct the former process as well as the latter. At 25°C the slope of the linear part of Λ *vs.* $C^{1/3}$ is very nearly the same and has a value of −50 for NaCl, KCl, and LiCl (19), while the corresponding value of HCl is −92, or nearly twice as great. If we compare the concentration dependence of the relative conductance of HCl and KCl solutions, we see that the latter falls off more rapidly with concentration. Apparently it is more difficult for successive hole-formations to circumvent an obstructing ion than it is for successive water rotations, a conclusion compatible with the observation that the activation energy of electrical conduction of KCl is higher than that for HCl (5).

Electrochemical Studies of NO^+ and NO_2^+ in Concentrated H_2SO_4

L. E. Topol, R. A. Osteryoung, and J. H. Christie[1]

North American Aviation Science Center, Thousand Oaks, California

ABSTRACT

Linear sweep voltammetric and chronopotentiometric studies were made on solutions of NO_2^-, NO_3^-, NO, and $NO_2(N_2O_4)$ in 18*F* sulfuric acid. It was found that the electroactive species in both NO_2^- and NO solutions is NO^+ and the NO-H_2SO_4 reaction is slow. In contrast the NO_2-H_2SO_4 reaction to yield NO_2^+ is extremely rapid. The NO-NO^+ couple appears to be reversible on clean Pt or Au but the NO_2-NO_2^+ couple is not. Some anodization results with Pt and Au in H_2SO_4 are also described.

Raman spectroscopy (1, 2, 3) has been used to demonstrate that the nitrosonium ion NO^+ and the nitronium (nitryl) ion NO_2^+ are formed by dissolution of nitrite and nitrate, respectively, in concentrated H_2SO_4

$$NO_2^- + 3H_2SO_4 \rightarrow NO^+ + 3HSO_4^- + H_3O^+ \quad [1]$$

$$NO_3^- + 3H_2SO_4 \rightarrow NO_2^+ + 3HSO_4^- + H_3O^+ \quad [2]$$

Both these species are formed by the reaction of NO_2 (or N_2O_4) with concentrated H_2SO_4

$$2NO_2 + 3H_2SO_4 \rightarrow NO_2^+ + NO^+ + 3HSO_4^- + H_3O^+ \quad [3]$$

It has been reported that NO also reacts with concentrated H_2SO_4 but there has been disagreement about the products of the reaction (4,5).

Although it is known that NO_2^+, and probably NO^+ also, play important roles in the dissolution of metals in HNO_3 and that NO^+ and NO_2^+ are attacking electrophiles in organic nitrosations, deaminations, and nitrations, the electrochemical behavior of these species has been the subject of only two polarographic studies (6, 7). Only one report on the electrochemical behavior of nitrogen oxides dissolved in H_2SO_4 has appeared (8).

In the present work linear sweep voltammetry and chronopotentiometry with Pt and Au electrodes have been applied to the study of solutions on NO_2^-, NO_3^-, NO, and NO_2 in 18*F* H_2SO_4. Solutions of NO_2^- and NO_3^- with H_2SO_4 < 15*F* are unstable and evolve oxides of nitrogen (6).

Experimental

Baker and Adamson reagent grade H_2SO_4 (96%), $NaNO_2$, and $NaNO_3$, and Matheson NO (99% pure) and NO_2 (99.5% pure) were used without further purification.

The current-voltage curves were obtained with the potential sweep apparatus described previously (9). The chronopotentiometric setup, using a John Fluke Model 351A constant current supply, was conventional. The linear sweep voltammetric and chronopotentiometric curves were recorded on a Moseley Model 2D X-Y recorder or a Tektronix Type 564 storage oscilloscope.

The Pyrex cell consisted of three compartments with the outer two connected to the center one by coarse-porosity fritted disks. The reference half-cell was Hg/Hg_2SO_4 (satd.), H_2SO_4 (18*F*) [saturated mercuric sulfate electrode (SMSE)] which has a potential of +0.22v *vs.* the saturated calomel electrode (10). The counter electrode was Pt. The Au and Pt wire or foil indicator electrodes were cleaned mechanically or by cathodization in H_2SO_4. It was found that reproducible waves in NO^+ solutions resulted after such treatment. The solutions were deaerated in the usual manner by passing argon gas through them; Ar was also bubbled through the solution between measurements to destroy concentration gradients. Chronopotentiometric transition times were measured by the method of Voorhies and Furman (11).

[1] Present address: Chemistry Department, California Institute of Technology, Pasadena, California.

Results

The Nitrosonium ion.—Voltage sweeps on clean Pt or Au electrodes taken in solutions prepared either by dissolving $NaNO_2$ or NO in 96% H_2SO_4 appear to be identical. One cathodic peak at +60-80 mv *vs.* SMSE and one anodic peak at +125-150 mv were observed (Fig. 1). The average peak separation of 65 mv is in reasonable agreement with the theoretical value of 56 mv for a reversible one-electron process (12). Since it is known that the stable N(III) species in 96% H_2SO_4 is NO^+, the reduction process must be

$$NO^+ + e \rightarrow NO \quad [4]$$

and the oxidation process, the reverse. The single electron reduction is in agreement with the results of

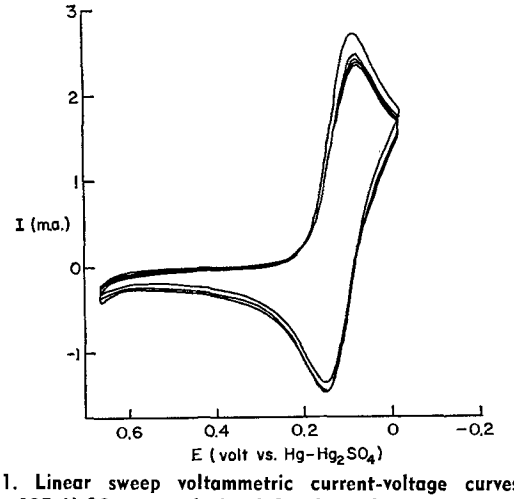

Fig. 1. Linear sweep voltammetric current-voltage curves of NO^+ in 18*F* H_2SO_4 on cathodized Pt electrode.

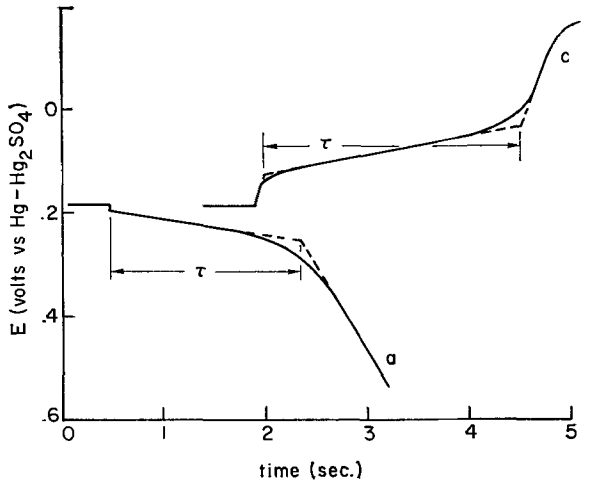

Fig. 2. Chronopotentiometric waves showing transition times τ for NO and NO^+ in H_2SO_4. (a) NO — e → NO^+, anodic (for NO)-current = 0.200 ma; (c) NO^+ + e → NO, cathodic (for NO^+)-current = 1.200 ma.

Masek (6, 7) for 18*F* H_2SO_4. If the linear potential sweep is cycled between 0.0 and +0.4v, a steady state is approached in which the ratio of the cathodic peak current to the anodic peak current is slightly greater than unity but is independent of sweep rate.

Chronopotentiometry with clean Pt or Au electrodes in solutions of nitrite or nitric oxide gave similar cathodic waves (Fig. 2, curve c). Values of $i\tau^{1/2}$ for these waves were fairly constant over a wide range of current density for both NO and NO_2^- solutions (Table I). The slight increase of $i\tau^{1/2}$ with τ may be due to the effects of nonlinear diffusion and/or convection (13). For $NaNO_2$ solutions $i\tau^{1/2}/C$ was constant over a concentration range of 2 to 30 m*F* $NaNO_2$. Plots of E *vs.* log $[(\tau/t)^{1/2} - 1]$ were linear for both NO_2^- and NO solutions with a slope of 53-60 mv, corresponding to a reversible one-electron process, and with $E_{1/4} = +0.110$-0.120v *vs.* SMSE. Current-reversal chronopotentiometry for $NaNO_2$ solutions (Fig. 3) yielded ratios of the forward electrolysis time t_f to the reverse (anodic) transition time τ_r which varied from the theoretical ratio $t_f/\tau_r = 3$, the ratio increasing with increasing t_f (Table II). If an anodic chronopotentiogram was taken immediately after bubbling NO through the solution in the cell, an oxidation wave, identical to that observed on current reversal after the NO^+ reduction wave is found (Fig. 2, curve a). This wave must correspond to the reverse of reaction [4].

It was noted that the current-voltage curves observed after the Pt electrode had been anodized at potentials more anodic than +1.4v *vs.* the SMSE differed markedly from those observed on "clean"

* Forward wave is cathodic.

(cathodized) electrodes (see Fig. 4). The most striking difference was the great decrease of the anodic peak. Upon cycling the potential between 0 and +0.4v, the anodic peak grew in slowly while the cathodic peak decayed rapidly. The cathodic peak was also broader than with previously cathodized electrodes.

Chronopotentiometry with a previously anodized electrode showed little difference in the cathodic wave, but only a very small wave, if any, was observed on current reversal. Similar experiments with anodized Au electrodes showed similar results, but the differences were not so striking as with Pt electrodes.

It appears that the reduction of NO^+ to NO occurs on anodized as well as on cathodized electrodes but that the subsequent reoxidation of NO does not readily take place on anodized electrodes. It was thought that this might be due to a blockage of the surface for the NO oxidation by anodically formed oxide on the surface of the electrode.

The anodic behavior of Pt and Au electrodes in pure 18*F* H_2SO_4 was studied to find out whether there was an anodically formed oxide which was not removed at potentials at which NO oxidation should take place.

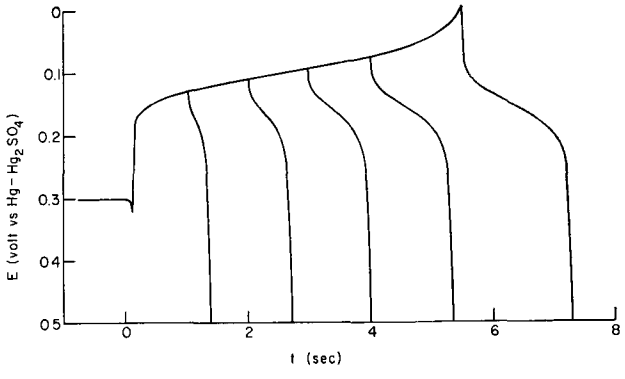

Fig. 3. Current-reversal chronopotentiometric waves for NO^+ solutions. (Forward wave is cathodic.)

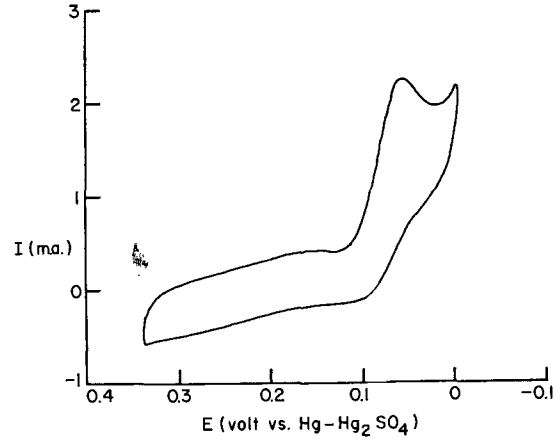

Fig. 4. Linear sweep voltammetric current-voltage curve for NO^+ in H_2SO_4 on anodized Pt electrode.

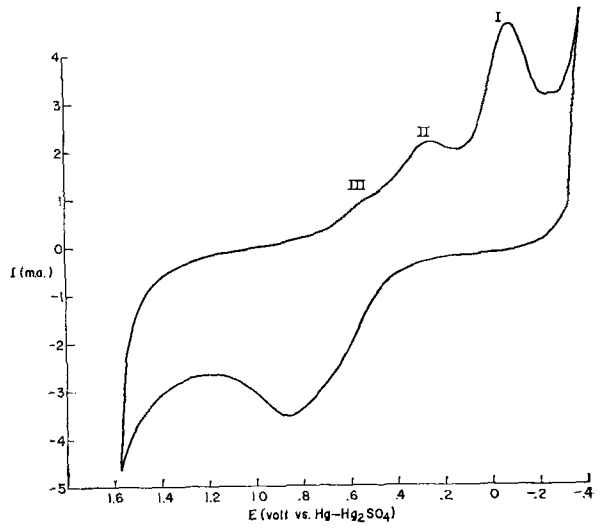

Fig. 5. Linear sweep voltammetric current-voltage curve of 18F H_2SO_4 on anodized Pt.

Figure 5 shows the current-potential behavior of a Pt electrode in pure H_2SO_4. There is only one broad anodic peak (at ~ +0.85v *vs.* SMSE) before depolarization by the solvent at +1.6v. Three cathodic peaks at +0.50(III), +0.25(II), and −0.10v(I) are apparent; these peaks also occur if the solution is stirred during the experiment, indicating that they are due to the reduction of material on the surface of the electrode.

A clean Pt electrode was then potentiostated at various anodic potentials for 30 sec and swept cathodic. After anodization at +0.68v only peak I is apparent, but with successive anodizations at increasingly anodic potentials, peaks II and III appear and finally after anodization at the most anodic potentials (>1.4v), peaks I and II coalesce to form one broad peak.

After this procedure the electrode was cleaned by cathodization and again anodized in 18*F* H_2SO_4 as above. After anodization the electrode was transferred to a 6 m*F* $NaNO_2$ solution and current-voltage curves were taken (+0.4-0.0v). The current-voltage curves were "normal" if the electrode had been subjected to anodization conditions less severe than +1.6v for 120 sec, and even in this case the behavior returned to normal within a few cycles. In contrast, anodization at +1.6v for 30 sec in the nitrite solution itself results in a complete absence of the NO oxidation peak and a large broadening of the NO^+ peak.

The voltage sweep behavior of Au in 18*F* H_2SO_4 is shown in Fig. 6. Peak I in Fig. 6 appears to be due to

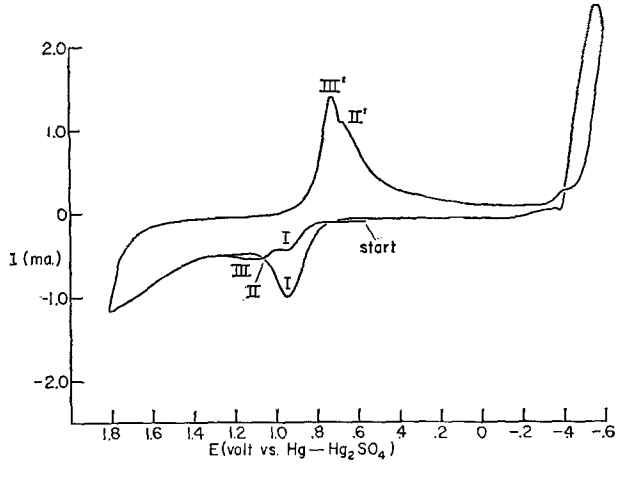

Fig. 6. Linear sweep voltammetric current-voltage curve for 18F H_2SO_4 on Au.

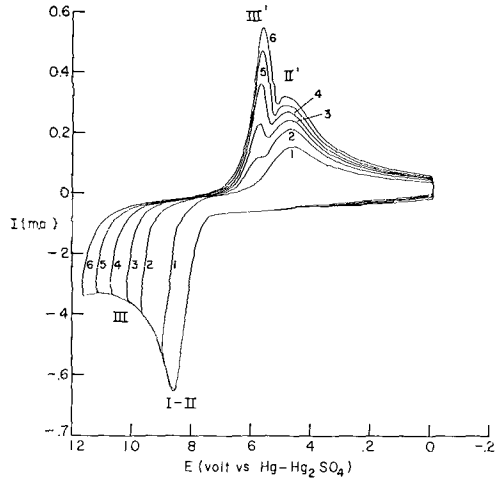

Fig. 7. Cyclic voltammetry of 18M H_2SO_4 between 0 and 1.2v (*vs.* Hg-Hg_2SO_4) on Au.

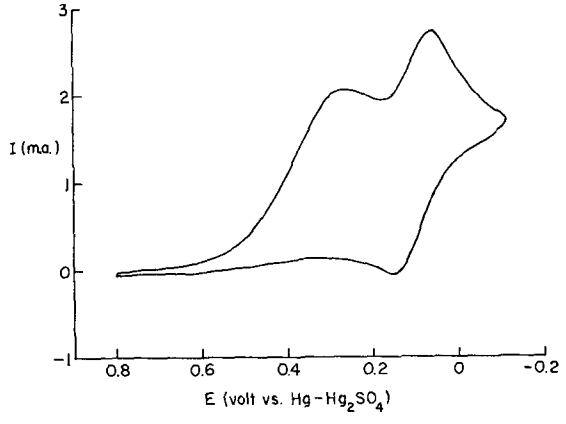

Fig. 8. Linear sweep voltammetric current-voltage curve of NO_2^+ in H_2SO_4. Potential span velocity is 0.9 v/sec.

the oxidation of material formed in the cathodic solvent decomposition. The reduction peaks II′ and III′ are associated with the anodic peak II and the region III (Fig. 7). If the solution is stirred while the experiment is being carried out, peak II′ is absent but peak III′ still occurs.

The nitronium ion.—Solution of both $NaNO_3$ and NO_2 in 18*F* H_2SO_4 yield similar linear sweep voltammograms (Fig. 8). Two cathodic peaks are present, the second corresponding to reaction [4] found in NO^+ solutions. There is only one anodic wave which occurs at the same potential as the oxidation of NO. There is no anodic wave corresponding to the reoxidation of the product of the first reduction wave. In addition, no anodic peak corresponding to the oxidation of NO_2 is found even immediately after NO_2 gas is bubbled through the solution.

Chronopotentiometry of NO_2^+ solutions at both Pt and Au electrodes yields two reduction waves, the second of which corresponds to that for NO^+ reduction. If the current is reversed after the second wave, only the wave corresponding to NO oxidation is found. The product $i\tau_1^{1/2}$ for the first wave as well as $i(\tau_1 + \tau_2)^{1/2}$ are approximately constant over a wide range of current density. In addition, the ratio of the transition time τ_2 for the second wave to the transition time τ_1 for the first has the value $\tau_2/\tau_1 = 1.5$-1.7. The ratio of the transition times for a two electron process followed by a one electron process should be 1.25 (14).

The rest potential of an electrode standing in contact with an NO_2^+ solution drifts anodic with time and an electrode that has been in contact with the solution for several minutes gives cathodic chronopotentiograms which are more poorly defined and which have

longer transition times than those obtained immediately after the electrode is put into the solution. It is apparent that the electrode is attacked chemically by the NO_2^+, presumably with the formation of oxides on the surface.

Linear sweep voltammetric curves of the above solutions for sweep rates of 25 to 1000 mv/sec were reproducible and yielded essentially linear plots of peak current *vs.* (sweep rate)$^{1/2}$ for both waves. The potential of the peaks did not vary to any extent with sweep rate.

Discussion

The similarity of electrochemical behavior between solutions formed by dissolving $NaNO_2$ and NO in H_2SO_4 indicates that the NO must react to give NO^+ as a product. The reaction is

$$2NO + 5H_2SO_4 \rightarrow 2NO^+ + SO_2 + 2H_3O^+ + 4HSO_4^- \quad [5]$$

as has been verified by subsequent studies in this laboratory (15) The ocurrence of this reaction would suggest that the reduction of NO^+ should be catalytic, *i.e.*, the NO formed should react with the solvent to regenerate NO^+. The electrochemical results do not indicate that this is the case. (The slight increase of $i\tau^{1/2}$ with $\tau^{1/2}$ in Table I for the reduction of NO^+ is probably due to nonlinear diffusion.) If the forward rate of reaction [5] is very slow, no catalytic effect will be observed. The fact that NO remains in solution for several minutes after exposure of the solution to NO gas indicates that the reaction is indeed slow. Preliminary kinetic studies (15) have yielded results consistent with second-order kinetics with a rate constant of 0.22 liter/mole-sec. This rate would give an effect on the transition time well within the experimental error.

The reaction of NO_2 with H_2SO_4 is very rapid as can be verified by exposing H_2SO_4 to NO_2 gas at a known pressure and observing the very rapid decrease in pressure. The chronopotentiometry of NO_2^+ solutions indicates that the first process is a two electron reduction of NO_2^+ to NO^+, followed by the one electron reduction [4]. Masek (6) has proposed the following mechanism for this process

$$2(N(V) + e \rightarrow N(IV)) \quad [6a]$$

$$2N(IV) \rightarrow N(III) + N(V) \quad [6b]$$

$$N(III) + e \rightarrow N(II) \quad [6c]$$

The chronopotentiometric behavior for such a second order disproportionation following the electrochemical reaction has been treated by Feldberg and Auerbach (16). If the disproportionation reaction is sufficiently fast, the over-all process would simply appear to be

$$N(V) \xrightarrow{2e} N(III) \xrightarrow{e} N(II) \quad [7]$$

It is therefore impossible to tell from our data whether the first reduction proceeds by Masek's mechanism or by a direct two-electron reduction to NO^+.

Bianchi *et al.* (8) recently have reported polarization curves for Pt electrodes in 45-85% H_2SO_4 (approximately 6-12*F*) through which nitrogen oxides were passed. Their results are in disagreement with Masek's results (6, 7), of which they seem to be unaware, as well as ours. Bianchi reports two reduction waves.

$$NO^+ + e \rightarrow NO \quad [8]$$

and

$$2NO + 2H^+ + 2e \rightarrow H_2N_2O_2 \quad [9]$$

Masek has shown that the final reduction product is hydroxylamine and that this reduction occurs cathodic to the potential for H_2 evolution on Pt.

Bianchi *et al.* also report three oxidation waves which they attribute to the processes

$$NO - e \rightarrow NO^+ \quad [10]$$

$$2NO^+ + 2H_2O - 2e \rightarrow N_2O_4 + 4H^+ \quad [11]$$

$$N_2O_4 + H_2O - 2e \rightarrow N_2O_5 + 2H^+ \quad [12]$$

The last two waves were found to be absent in $H_2SO_4 < 73\%$ and this was attributed to the disproportionation of N_2O_4 in the more dilute acid to give NO^+ and HNO_3. We find that it is impossible to oxidize NO^+ in 96% acid and that the disproportionation of NO_2 (or N_2O_4) is very rapid. It seems unlikely that the disproportionation of N_2O_4 should take place in 96% acid and with acid less than 73% but not at intermediate concentrations. An attempt to observe reaction [11] in an 80% H_2SO_4 solution containing $NaNO_2$ also failed. No explanation for the discrepancies between our results and those of Bianchi seems to be available.

The Preparation and Thermodynamic Properties of a Palladium-Hydrogen Electrode

M. J. Vasile and C. G. Enke

Frick Chemical Laboratory, Princeton University, Princeton, New Jersey

ABSTRACT

The potential of a palladium-hydrogen electrode prepared by electrolytic methods was studied as a function of the composition of the electrode, temperature, and pH. The objective of these studies was to prepare a palladium hydrogen reference electrode which can be used in hydrogen free solutions. The potential was found to be a function of the electrode composition in the α phase, and β phase, and independent of composition in the $\alpha + \beta$ phase region. Equations were derived starting from fundamental thermodynamics which fit the potential *vs.* composition data in the α phase, and in the $\alpha + \beta$ phase region, as well as the temperature dependence for such an electrode. The procedure for preparing a palladium hydrogen reference electrode by electrolytic methods is given.

The absorption of gaseous hydrogen from aqueous solutions by palladium and the subsequent potential of the Pd-H/H_2 system has been studied extensively in recent years (1-4). Reference electrodes based on the Pd-H system have been used by several workers (5-7). Ives and Janz (8) have reviewed the literature on the palladium-hydrogen system up to 1961. At that time, differences in the experimental results and their interpretation were apparent; these differences still persist. One of the main points in contention is the potential determining mechanism for the observed +50 mv plateau of the Pd-H electrode.

Hoare (1) found that palladium will absorb hydrogen from aqueous acid solutions up to the atom ratio H/Pd = 0.03, or approximately to the limit of the α-phase.[1] He attributes the steady potential of +50 mv to the (Pd-H)α mixture. To explain the continuity of the +50 mv potential up to the concentration H/Pd = 0.36, a mixed potential was postulated due to the simultaneous presence of the α and β phases, with the α phases predominating (1). Equations were derived to show that the +50 mv plateau is due to the pure α phase at its maximum concentration, H/Pd $\cong$ 0.03.

Flanagan and Lewis (2) have found that the absorption of hydrogen from acid solutions does not stop at the α phase limit, but proceeds on the $\alpha + \beta$ region, and finally to the pure β phase [later work by Hoare (9) also confirms this fact]. They attribute the +50 mv plateau to the presence of the two-phase region, and the subsequent drop to zero volts to the pure β phase. The drop in potential from the initial value to the +50 mv plateau is attributed to the presence of the pure α phase. Both Flanagan and Lewis and Hoare and coworkers used relative resistance measurements to determine the H/Pd ratio.

Cathodically charged palladium-hydrogen electrodes have been studied by several workers (10-12). Their general conclusions or implications are that the potential remains constant over the entire two-phase ($\alpha + \beta$) region, and is a function of composition in the pure α and pure β regions. More recent work on the palladium-hydrogen system has been done by Aben and Burger (3) using polycrystalline x-ray diffraction to detect the phase present at the surface of the palladium after absorption of H_2 from aqueous acid solutions. Their work supports the view that the potential is dependent on composition in the pure α and β phases, but is independent of composition in the mixed $\alpha + \beta$ phase region.

[1] The phases of the palladium-hydrogen alloy are determined by the amount of distention in the lattice parameter of pure palladium. The lattice parameter of pure Pd is 3.883Å, while that of the α phase is 3.886Å, and that of the β phase is 4.032Å.

The pressure *vs.* composition isotherms and heats of solution for hydrogen gas in equilibrium with palladium metal have been determined most reliably by Gillespie and coworkers (13, 14). A successful theoretical treatment of this system which supports the idea that hydrogen forms a homogeneous solid solution with palladium has been given by Lacher (15).

The object of the following study was to prepare a palladium hydrogen reference electrode by cathodic occlusion of hydrogen. Such reference electrodes have been prepared by absorption of gaseous hydrogen from acid solutions, and were given the name α-Pd reference electrodes (5, 16). The attempts to prepare such an electrode electrolytically led to a re-examination of the potential *vs.* composition relationship for this system. In this study a gas chromatograph was used to analyze for the hydrogen content in the palladium. The work was then extended to include potential *vs.* temperature measurements for palladium-hydrogen alloys produced by cathodic charging, and also by absorption of gaseous hydrogen from acid solutions.

Apparatus

The cell used was a simple H-type cell with the two compartments separated by a fine porosity glass frit. Nitrogen or helium was supplied both above and below the solution level in the compartment that contained the Pd test electrode. A presaturator for the hydrogen supplied to the H_2/Pt reference electrode was used. The entire apparatus was immersed in a thermostatically controlled temperature bath at 24.8° ± 0.1°C. The electrolyte was 1*N* perchloric acid, made up with water from a Barnstead high-purity distillation apparatus and 70% perchloric acid (G. F. Smith and Company). For potential *vs.* composition measurements, the palladium electrodes were made using 0.0125 in. diameter wire (Engelhard Industries) spot welded to platinum leads of 0.025 in. diameter at both ends. These platinum leads were then inserted through a rubber septum (injection gasket) up to the Pt to Pd spot welds, giving a palladium loop electrode with two contacts. The septum was then force fitted into the end of a glass sleeve which contained the lead that connected the palladium electrode to the testing apparatus. For the temperature dependence measurements and reference electrode experiments, a palladium wire approximately 4 cm long and 0.0125 in. in diameter was spot welded to a platinum lead at one end. The platinum lead was then sealed in soft glass, up to, and just including, the spot weld. The straight, exposed palladium wire was then sheathed in a glass capillary which could serve as a luggin capillary.

The measuring instruments used were as follows: for potential difference measurements, a Keithley elec-

trometer (±0.5 mv) as well as a potentiometer capable of reading ±0.1 mv; for quantity of hydrogen in palladium an Aerograph A-90-P2 gas chromatograph capable of detecting less than 1 μl of gaseous H_2 in a carrier stream of nitrogen. The palladium in the loop electrodes was weighed to the nearest tenth milligram on a Mettler grammatic balance. A constant-current source was made by using a Philbrick R100B power supply (+300v, —300v) in series with precision resistors.

Procedure

Potential vs. composition measurements.—The palladium loop electrodes were charged with hydrogen by cathodizing them at a constant current of either 30 or 150 μa (current densities of approximately 60 and 300 μa/cm^2). Between 60% and 90% of the hydrogen liberated by this cathodization was occluded in the palladium lattice. The potential of the electrode thus charged was measured in nitrogen swept solution *vs.* a normal hydrogen electrode. After the potential was tested, the electrode was removed from the cell, rinsed in distilled water as rapidly as possible, and the septum holding the Pd loop was then pried out of the glass sleeve. The septum was then inserted in a specially made injection port on the gas chromatograph, and 6v a.c. was applied across the platinum leads after they had been lowered sufficiently to avoid heating the septum. The 6v a.c. was enough to cause the palladium loop to glow red and eject its hydrogen into the carrier gas stream.

Various methods of pretreatment of the palladium electrodes were tried. They included annealing in a gas-air flame, annealing by electrical heating, immersion in boiling concentrated nitric acid, and anodization.

It has been observed that charging the palladium electrodes electrolytically leads to higher concentrations of hydrogen at the surface than in the bulk (2). To minimize this possibility, low current densities were used, and an anodization procedure was developed which depends on the diffusion of the bulk hydrogen to the surface to relieve concentration gradients. The anodization procedure simply involves reversing the current for a short time interval followed by a measurement of the rest potential. This process was repeated until no change in potential occurred with the anodization.

Temperature dependence measurements were carried out by first getting an electrode to exhibit the +50 mv plateau, at 25°C, and then raising or lowering the bath temperature in 5°C steps. The system was allowed to remain at each temperature at least ½ hr after achieving a steady potential. The temperature bath was thermostatically controlled at all values to ±0.1°C. The stability of the electrode was tested prior to variations in the temperature by leaving the electrode on open circuit in solutions swept with inert gases for periods of 8-10 hr. After the whole temperature range from 25° to 50°C and from 25° to 0°C was examined, the temperature was returned to 25°C, and the potential and hence stability of the electrode were again checked. The temperature dependence of the plateau potential was also measured for electrodes of the configuration described previously, while absorbing gaseous hydrogen from solution at pressure equal to 1 atm. In these investigations, no long-term stability tests were made prior to variation of the temperature. The electrode potential was allowed to reach a steady state with hydrogen gas at 1 atm pressure, and temperature variations were started promptly.

To test the electrode response to solutions at different hydrogen ion concentrations the electrode was removed from the cell (capillary included) and the electrolyte in the cell was thoroughly flushed out and replaced with electrolyte of different hydrogen ion concentration. While the electrolyte in the cell was being changed, the palladium-hydrogen electrode was rinsed thoroughly with and stored in the new solution.

Platinization of the Pt/H_2 reference electrode was carried out according to a procedure described by Ives and Janz (8). The current density used for platinization was approximately 15 ma/cm^2. Palladization of the palladium electrodes, when done, was carried out at current densities of approximately 30 ma/cm^2. Palladizing solution was prepared according to a procedure given by Bates (17).

Discussion and Experimental Results

The potential of +50 mv for a Pd-H electrode in the two-phase region requires a thermodynamic explanation. It is held in the presence of dissolved hydrogen ($P = 1$ atm) and in the absence of dissolved hydrogen. It is evident that the Pd-H alloy supplies its own hydrogen for the potential determining reaction at the activity prescribed by the phase or phases present.

Flanagan and Lewis (2) propose the following half reactions for the system when absorbing hydrogen from solution.

$$x\mathrm{H}{:}y\mathrm{Pd} + \mathrm{H}^+ + e^- \rightarrow (\mathrm{x}+1)\mathrm{H}{:}y\mathrm{Pd}\ \text{Pd electrode} \quad [1]$$

$$1/2\ \mathrm{H_2} \rightarrow \mathrm{H}^+ + e^-\ \text{Pt electrode} \quad [2]$$

They give as the net reaction, the sum of these two half reactions.

$$x\mathrm{H}{:}y\mathrm{Pd} + 1/2\ \mathrm{H_2} \rightarrow (x+1)\mathrm{H}{:}y\mathrm{Pd} \quad [3]$$

They then go on to compare the free energies for the net reaction with the free energy change calculated from the equilibrium gas phase isothermal data of Gillespie (13, 14). However, the equilibrium pressure of hydrogen gas in contact with palladium at 25°C is 0.0202 atm, and the only term that involves hydrogen gas in Eq. [3] is that which derives from the hydrogen reference electrode, which is at P = 1 atm. The connection between ΔG as calculated from the gas phase data of Gillespie and the net reaction Eq. [3] given by Flanagan and Lewis is not quite clear.

An alternate, and more precise method of treating this system is to arrive at a Nernst equation based on Eq. [3]. This equation will be accepted as the potential determining mechanism, regardless of the phase or phases present at the surface of the Pd-H alloy.

For the net reaction, Eq. [3], ΔG may be written

$$\Delta G = (x+1)\mu_{\mathrm{H}}{}^{(m)} + y\mu_{\mathrm{Pd}}{}^{(m)} - \tfrac{1}{2}\mu_{\mathrm{H_2}}{}^{(g)} - y\mu_{\mathrm{Pd}}{}^{(m)} - x\mu_{\mathrm{H}}{}^{(m)} \quad [4]$$

according to $\Delta G = \Sigma n_i\mu_i$ prod. $- \Sigma n_j\mu_j$ react. The symbols are: $\mu_{\mathrm{H}}{}^{(m)}$ = chemical potential of H atoms in the Pd lattice; μ_{Pd} = chemical potential of Pd atoms; and $\mu_{\mathrm{H_2}}{}^{(g)}$ = chemical potential of H_2 in the gas phase. Upon subtracting terms

$$\Delta G = \mu_{\mathrm{H}}{}^{(m)} - \frac{1}{2}\mu_{\mathrm{H_2}}{}^{(g)} \quad [5]$$

which clearly indicates the H atoms in the Pd lattice as a part of the potential determining mechanism. It remains to find an expression for $\mu_{\mathrm{H}}{}^{(m)}$. There is good reason to believe that a reaction of the type

$$y\mathrm{Pd}{:}x\mathrm{H} = y\mathrm{Pd}{:}(x-2)\mathrm{H} + 2\mathrm{H}$$
$$2\mathrm{H} = \mathrm{H_2}$$

takes place at the surface of the Pd-H alloy (18). The Pd-H alloy would then be in equilibrium with H_2 only when the pressure of hydrogen is given by the isotherms determined by Gillespie. These facts lead to an expression for $\mu_{\mathrm{H}}{}^{(m)}$ since by conditions for equilibrium the following relationships must be satisfied

$$\mu_{\mathrm{H}}{}^{(m)} = \mu_{\mathrm{H}}{}^{(g)} \quad [6]$$

where $\mu_{\mathrm{H}}{}^{(g)}$ = chemical potential of hydrogen atoms in the hydrogen gas in equilibrium with the Pd-H alloy.

$$\mu_{\mathrm{H}}{}^{(g)} = \tfrac{1}{2}\mu_{\mathrm{H_2}}{}^{(g)} \quad [7]$$

and $\mu_{H_2}^{(g)}$ is the chemical potential of hydrogen gas at the equilibrium pressure, $P = P'_{H_2}$. This pressure is 1 atm only when the atom ratio H/Pd = 0.69.

Now

$$\mu_{H_2}^{(g)} = \mu_{H_2}^{o} + RT\ln P'_{H_2} \quad [8]$$

Therefore, by equating Eq. [6] and Eq. [7]

$$\mu_H^{(m)} = \tfrac{1}{2}\mu_{H_2}^{(g)} \quad [9]$$

and finally, by substituting Eq. [8] in Eq. [9],

$$\mu_H^{(m)} = \frac{\mu^o_{H_2}}{2} + \frac{RT}{2}\ln P'_{H_2} \quad [10]$$

For the net reaction, ΔG may now be written explicitly

$$\Delta G = \frac{\mu^o_{H_2}}{2} + \frac{RT}{2}\ln P'_{H_2} - \frac{\mu_{H_2}^o}{2} - \frac{RT}{2}\ln P_{H_2} \quad [11]$$

or

$$\Delta G = \frac{RT}{2}\ln (P'_{H_2}) - \frac{RT}{2}\ln P_{H_2} \quad [12]$$

The last term in Eq. [12] refers to the normal hydrogen reference electrode. When corrected for the partial pressure of water, Eq. [12] reads

$$\Delta G = \frac{RT}{2}\ln (P'_{H_2}) - \frac{RT}{2}\ln\left(\frac{P_{BAR} - P'_{H_2O}}{760}\right) \quad [13]$$

where P_{BAR} is the barometric pressure, and P'_{H_2O} is the partial pressure of water, both in mm Hg.

Since $\Delta G = -nFE$, we get the Nernst equation

$$E = -\frac{RT}{2F}\ln P'_{H_2} + \frac{RT}{2F}\ln\left(\frac{P_{BAR} - P'_{H_2O}}{760}\right) \quad [14]$$

or alternately written

$$E = -\frac{RT}{F}\ln (P'_{H_2})^{1/2} + \frac{RT}{F}\ln\left(\frac{P_{BAR} - P'_{H_2O}}{760}\right)^{1/2} \quad [15]$$

where E refers to the potential difference between the palladium-hydrogen electrode and the normal hydrogen reference electrode. In this derivation, the gas-solid equilibrium data were used only as a means to calculate an expression for $\mu_H^{(m)}$. Gas-solid equilibrium does not exist in the experimental conditions employed in this study, or in other studies, except when the H/Pd ratio reaches 0.69, at a hydrogen pressure of 1 atm. The establishment of the steady potential relies upon the exchange of hydrogen atoms in the lattice with hydrogen ions in solution, according to Eq. [1]. The activity of the hydrogen in the palladium, as derived by the preceding thermodynamic route, was found to be a constant in the two phase region.

From Eq. [15] it is possible to derive equations predicting the temperature dependence of the plateau potential and the dependence of the potential on composition of the electrode in the α phase at a given temperature. These equations are developed in the following sections and are compared with experimental results.

Potential as a function of composition.—Figure 1 shows the potential *vs.* composition curve for a palladium-hydrogen electrode in the pure α region at 25°C. The potential is decidedly a function of the atom ratio, H/Pd, and approaches a value of + 52 to + 53 mv, as the limit of the α phase is reached. Previous methods of measuring the atom ratio were not capable of such accuracy, presumably because the lifetime of the α phase is so short when the palladium is charged by absorption of gaseous hydrogen. X-ray analysis (3) has established the presence of the α phase during the descent to +50 mv, but the bulk H/Pd ratio was not obtained by this method.

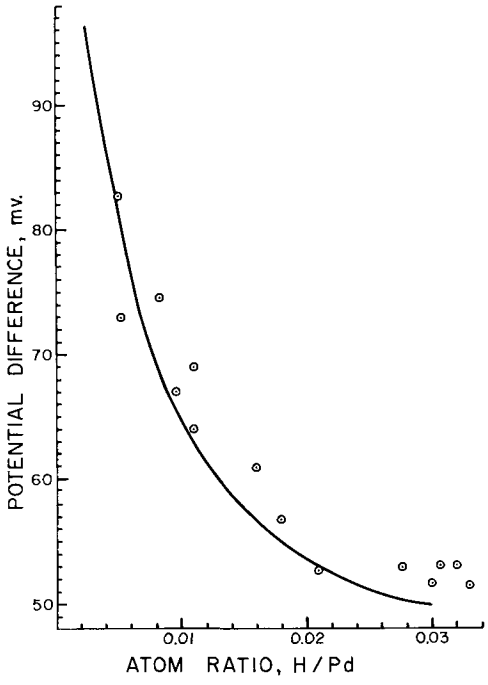

Fig. 1. Potential difference between a normal hydrogen electrode and a palladium-hydrogen electrode as a function of composition, to the limit of the α phase. ○, Experimental points; solid line predicted by Eq. [22] (temperature, 25°C).

The atom ratio was calculated as the bulk H/Pd ratio, with a propagated relative error of ±1.5%, at worst. The samples used in determining this segment of the curve were charged at a current density of ~ 60μ amp/cm^2 which should ensure a small concentration gradient between the surface and the interior of the metal.

Equation [15] can be expanded to show the potential as a function of composition if one knows how the pressure varies as a function of composition in the α phase. Tables of equilibrium hydrogen pressure as a function of composition at 30°C are given by Gillespie and Hall (13), but Moon (19) gives a phenomenological treatment which allows one to calculate the equilibrium pressure as a function of temperature and composition. These equations, which are valid only in the α phase region, are

$$\log\left(\frac{P^{1/2}}{r}\right) = -\log K + \beta r \quad [17]$$

$$\log K = -4.200 + 521.9/T \quad [18]$$

$$\beta = -926/(T - 215) \quad [19]$$

K is the equilibrium constant for the reaction

$$\tfrac{1}{2}H_2^{(g)} + \left(\frac{1}{r}\right)Pd^{(s)} = Pd_{(1/r)}\,H^{(s,\alpha)}$$

where P = equilibrium pressure of hydrogen, in mm Hg, and r = atom ratio, H/Pd. Converting to pressure in atmospheres yields

$$\log K_{atm} = -2.760 + 521.9/T \quad [20]$$

By substituting Eq. [19] and [20] into Eq. [17], an equation for the equilibrium pressure of hydrogen results. For $T = 298$°K

$$\log P^{1/2}{}_{atm} = 1.009 - 11.15\,r + \log r \quad [21]$$

Equation [21] may now be substituted into Eq. [15], the right-hand side of Eq. [21] replacing the term $\ln (P'_{H_2})^{1/2}$ in Eq. [15], after changing the base of the logarithm in the latter term. The resulting equation is

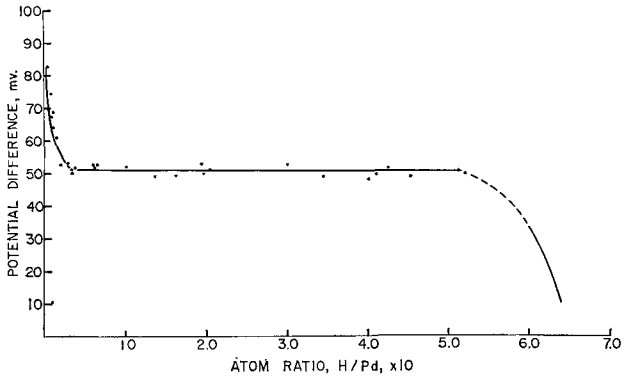

Fig. 2. Complete potential vs. composition curve for a palladium-hydrogen electrode (temperature, 25°C).

$$E = -0.05916(1.009\text{-}11.15\,r + \log r) + 0.5916 \log \left(\frac{P_{BAR} - P'_{H2O}}{760} \right)^{1/2} \quad [22]$$

for $T = 298°K$. In Fig. 1, the solid curve is the plot of Eq. [22] for values of r in the interval 0.0025 to 0.03.

The agreement between the observed values and those predicted by Eq. [22] is good, and provides substance to the thermodynamic arguments advanced. At the limit of the α phase Eq. [22] predicts a value of $E = +49.8$ mv. The value for E in the two-phase region calculated by using Eq. [15] is also + 49.8 mv. Thus, the two equations predict the same value of E at the point where the physical situation demands that their mathematical descriptions coincide.

The complete potential-composition curve is shown in Fig. 2. The potential was found to be constant in the two-phase region up to the concentration H/Pd = 0.52. The tolerance in the potential values was taken to be 50 ± 2 mv, in accord with previous workers (2, 3).

Equation [15] predicts a constant potential over the entire two phase ($\alpha + \beta$) region. At constant temperature, the only variable to appear in this equation is P'_{H_2}, which was found to be constant in the two-phase region by Gillespie and Hall (13). The pressure of hydrogen gas in equilibrium with a palladium-hydrogen alloy in the two-phase region at 25°C can be found from Eq. [23], due to Gillespie. Substitution of this value of the equilibrium pressure into Eq. [15] yields a value of + 49.8 mv as the potential in the two-phase region at 25°C.

For some experimental points beyond the ratio H/Pd = 0.4 it was necessary to anodize the electrodes to remove excess surface hydrogen. The anodization was done for convenience, since, if one is willing to wait long enough, the simultaneous process of inward diffusion of hydrogen, and diffusion of hydrogen into the electrolyte will result in a surface concentration which is very close to the bulk concentration. In order to achieve H/Pd ratios of 0.4 or greater, the current density was increased to 300 $\mu a/cm^2$.

To justify quantitatively the anodization technique, solutions for the diffusion of hydrogen in palladium were worked out. The boundary conditions contain the assumption that the anodization removed all the hydrogen from the metal to a radius consistent with the total number of anodic coulombs passed. A diffusion equation for the system, and the diffusion coefficient for hydrogen in palladium may be readily found (20). A solution of the equation for a typical case yielded the time necessary for the surface concentration to reach 99% of the bulk concentration to be of the order of magnitude of 10^{-1} sec. Thus, the anodization procedure can be justified on the grounds that the bulk H/Pd ratio establishes itself very rapidly at the surface after the cessation of anodic current.

The breaking point for the two phase limit was not determined, but points which lie in the pure β phase were found. In Fig. 2, the last point found in the two-phase region (H/Pd = 0.52) was joined by a smoothly descending curve (shown by the dotted line) with the three points found in the β phase only for the sake of continuity. It was found to be difficult to charge samples to a H/Pd ratio greater than 0.64 at the current densities employed. A probable explanation for this fact is that hydrogen in the metal is lost during the time interval between cessation of the cathodic current and analysis of the sample. The anodization technique was not used when studying the β phase potential behavior.

In these experiments the solution in which the palladium electrode was tested was constantly swept with nitrogen. There was effectively no means of preventing hydrogen dissolved in the palladium from establishing its equilibrium concentration in the electrolyte solution. This process manifested itself in a very slow rise in potential with time for electrodes that were in the β phase. Therefore, it is not necessary to invoke reasons for β phase instability in cathodically charged palladium hydrogen when no hydrogen is dissolved in the solution, since transport processes are sufficient to explain the loss of hydrogen.

The general conclusions drawn from the potential-composition data are that the potential is dependent upon the composition of the electrode in the pure α and pure β phase, and independent of composition in the $\alpha + \beta$ region. These conclusions agree with those of other workers, most recently Aben and Burger (3), and Flanagen and Lewis (2).

Potential as a function of temperature.—Figure 3 shows the temperature dependence of the cathodically charged palladium hydrogen electrodes. The experimental behavior is very close to being linear, with a slope of — 0.65 mv/°C. The data of Ratchford and Castellan (21) are included in Fig. 3. Their temperature dependence measurements were performed while the palladium was absorbing hydrogen from solution, and the temperature range studied was from 20° to 60°C. By use of their empirical equation $E = 0.06309 - 0.0005057(T\text{-}273.16)$ their values may be extended to 0°C.

It is evident that the slopes of the two different determinations do not agree. To test the possibility that electrode construction may have been responsible for this difference in slope, gas-phase absorption experiments in aqueous solution were carried out. Results

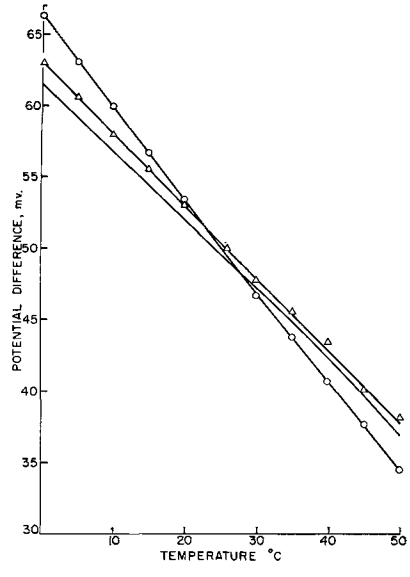

Fig. 3. Potential as a function of temperature for a palladium hydrogen electrode. ○, Experimental, electrolytically charged; △, data of Ratchford and Castellan; solid line predicted by Eq. [24].

are shown in Fig. 4. The slopes of the straight lines are in good agreement, and the potential values at any given temperature are within 1 mv of the predicted curve.

The temperature dependence of the potential of a two-phase palladium hydrogen electrode can be derived from Eq. [15]. Gillespie and Galstaun (14) give an equation which fits the two-phase equilibrium pressures for the palladium hydrogen system as a function of temperature.

$$\log P_{atm} = 4.6018 - 1877.82/T \qquad [23]$$

Substitution of this expression into Eq. [15] yields

$$E = -\frac{2.303\,RT}{2F}(4.6018 - 1877.82/T) + \frac{RT}{2F}\ln\left(\frac{P_{BAR} - P'_{H_2O}|}{760}\right) \qquad [24]$$

Inspection shows that this is a linear equation in T, with the exception of the term that involves the partial pressure of water.

Values calculated from Eq. [24] are plotted in Fig. 3 as a comparison with the various experiments. In the range $25° < T < 50°C$, the agreement between Eq. [24] and experiment is quite good for the case where palladium was absorbing hydrogen dissolved in solution. The agreement between Eq. [24] and the data of Ratchford and Castellan gets poorer as the temperature progresses to 0°C. According to Gillespie and Galstaun, the equation that gives the equilibrium pressure of hydrogen in the two-phase region is in error below 30°C. The error becomes larger as the temperature gets lower since their straight line approximates a curve in this region. The equilibrium pressure equation predicts 4.05 mm Hg for 0°C, and the observed equilibrium pressure was 3.56 mm Hg. If this experimentally observed pressure is substituted into Eq. [15]. the predicted value of E is + 63.14 mv. Ratchford and Castellan's empirical equation has + 63.09 mv as its 0°C value. The agreement here is excellent.

The thermodynamic arguments advanced have been remarkably successful in accounting for the temperature dependence of the palladium-hydrogen electrode while it is absorbing gaseous hydrogen. The agreement between theory and experiment is not quite as good for the case of cathodically charged palladium-hydrogen electrodes, although it is far from a failure. It is quite probable that the discrepancies between the two experimental situations are due to nonreversibility in the desorption process which must take place in order to have the cathodically charged electrodes establish a potential. Phenomena such as rift occlusion of hydrogen and hysteresis effects in the pressure *vs.* temperature relationship of the palladium-hydrogen alloy are possible sources of nonreversible behavior (22) which may alter the temperature dependence of the potential for cathodically charged electrodes. These phenomena would have a less pronounced effect for an electrode that is absorbing hydrogen from the gas phase.

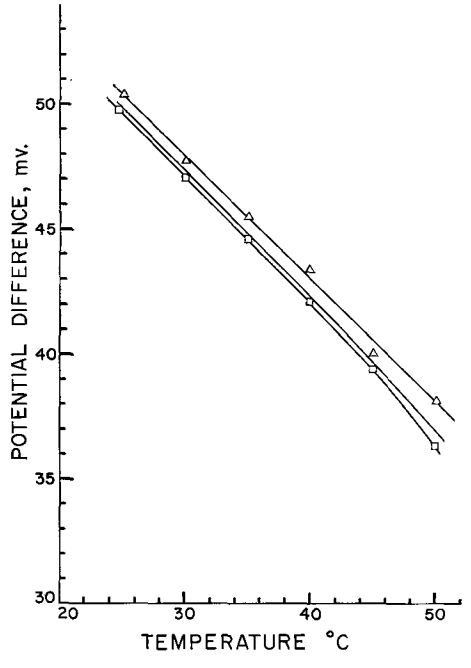

Fig. 4. Potential as a function of temperature for a palladium-hydrogen electrode while absorbing hydrogen from a solution. □, This study; △, data of Ratchford and Castellan; solid line predicted by Eq. [24].

No *p*H dependence could be found for two-phase palladium hydrogen electrodes when tested against a hydrogen electrode. Electrolytes that were tested were 2*N*, 1*N*, 0.1*N*, and 0.001*N* perchloric acid.

The Palladium-Hydrogen Reference Electrode

The preceding work was done with the object of developing a palladium-hydrogen reference electrode by electrochemical means. Other workers (5, 16) have made such an electrode by gas charging methods. It has been called the α-palladium reference electrode, since the +50 mv potential is characteristic of the concentration limit of the α phase. In practice, the "α-palladium" reference electrode actually has a composition in the two-phase region where the potential is essentially independent of the H/Pd ratio.

The electrode was constructed exactly the same way as those used for the temperature dependence measurements. Hydrogen was supplied to the palladium by constant current electrolysis of current density 75 μa/cm^2. These electrodes were palladized at a current density of 15 ma/cm^2 for 2 min, prior to charging with hydrogen.

If the electrodes displayed potentials lower than +50 mv after charging for a period of time necessary to give a H/Pd ratio of 0.5 (based on current-sorption efficiency of 60%), they were anodized according to the procedure described previously. Anodization, if necessary, re-established the +50 mv plateau potential, and the electrode was then inserted into a capillary sheath to minimize the loss of hydrogen by diffusion.

Such an electrode could be kept for periods of 24 hr in nitrogen swept solutions with only negligible changes in potential. For longer periods of time the potential was found to drift one or 2 mv but it could be restored to +50 mv by cathodization at the same current density required for charging.

Two disadvantages of the palladium hydrogen reference electrode as described here are:

1. Preparation: long electrolysis times are necessary due to such low currents.

2. Imprecision in the potential value. (Some workers have reported a value of +49.5 mv, and others a value of +50.4 mv.) For work that does not require such great accuracy, the potential may be taken as 50 ± 1 mv. It is also necessary to check the initial potential value against a normal hydrogen electrode, or some suitable reference electrode.

The prime advantage of this electrode is that it has the same *p*H response as a Pt/H_2 electrode, but may be used in hydrogen free solutions. There are several experimental situations where dissolved molecular hydrogen must be kept out of a test electrode compartment and elaborate methods and apparatus design are usually necessary to accomplish this. The use of a two-phase palladium-hydrogen electrode in a luggin capillary would eliminate the need of separating the reference electrode compartment from the test electrode compartment, and therefore greatly simplify cell designs.

Technical Notes

A Potentiometric Determination of Sodium in Amalgams

J. A. LeDuc, C. Lurie, and J. Kourilo

Electrochemical Research Section, Research and Development Department, M. W. Kellogg Company, New Market, New Jersey

The need for a rapid, accurate method for determining sodium concentration in a flowing amalgam stream was realized during a recent investigation of the ability of the sodium amalgam-oxygen fuel cell to recover power consumed during electrolysis of brine in mercury cells. A potentiometric method was decided on and involved measuring the potential between an amalgam half cell and a Hg/HgO reference cell

$$Na(Hg), Na^+ \,|\, NaOH(50\%) \,|\, HgO, Hg \qquad [1]$$

The relationship between cell potential and sodium concentration was determined at 20°C using a series of amalgam samples containing 0.01-0.53 w/o (weight per cent) sodium. The measuring system used is depicted in Fig. 1. The amalgam to be measured was admitted to the measuring cell H through the stopcock at G. After the potential across the system was read the amalgam was drained from the measuring cell H through a stopcock and another sample introduced through G. Reagent grade sodium metal and mercury purified in a laboratory-designed fractionating still were used. Sodium concentration was determined by reacting the amalgam with an aliquot of hot hydrochloric acid of known concentration and titrating the excess acid. The potentiometric measurements were made with a Gray Instrument Company Model E-3040-H potentiometer. The curve in Fig. 2 was fitted by the method of least squares. Analysis of the data reveals that the curve can be expressed as two linear relationships

$$\log [Na] = (E - 1.662)/0.105 \quad \text{for } E > 1.559v \qquad [2]$$

$$\log [Na] = (E - 1.624)/0.0636 \quad \text{for } E < 1.559v \qquad [3]$$

where E is the potential across [1]. The break in the Nernst equation plot is believed to be real within experimental uncertainty. Solution of Eq. [2] and [3] indicates that the sodium concentration at that point corresponds to $NaHg_{114}$.

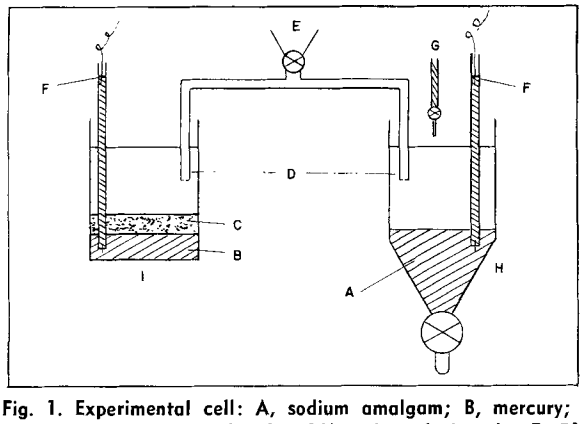

Fig. 1. Experimental cell: A, sodium amalgam; B, mercury; C, mercury and mercuric oxide; D, 50% sodium hydroxide; E, 50% sodium hydroxide salt bridge; F, leads to potentiometer; G, amalgam source; H, measuring cell, I, reference cell.

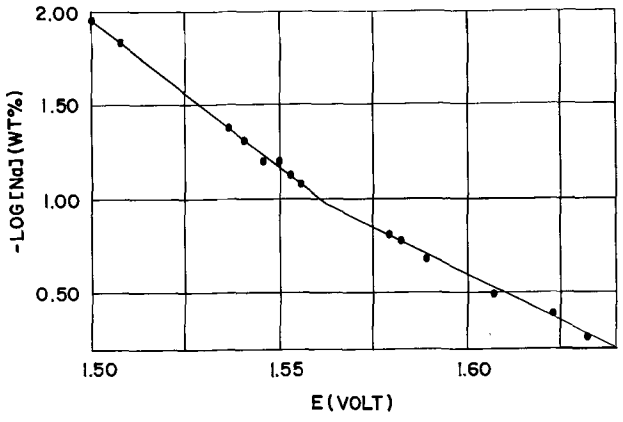

Fig. 2. Concentration-potential calibration curve

Measurements made with amalgams containing less than 0.01 w/o sodium were not reproducible. This uncertainty may be explained in terms of the reaction of the sodium in the amalgam with the electrolyte, *e.g.*, sodium corrosion. Sodium corrosion appears to be greater in more concentrated amalgams; however, the slope of the cell potential-sodium concentration curve near the origin must be considered. The rate at which the sodium corrosion decreases with decreasing sodium concentration is less than the rate at which the slope of the cell potential-sodium concentration curve increases. The Nernst equation shows that for very low sodium concentrations the slope is very steep and that

$$\left.\frac{dE}{d[\mathrm{Na}]}\right|_{\mathrm{Na}=0} = \infty$$

Sodium corrosion may be expressed as

$$\left.\frac{d[\mathrm{Na}]}{dt}\right|_{\mathrm{Na}=0} = 0$$

where t is time. For very low values of sodium concentration

$$\frac{d}{d[\mathrm{Na}]}E >> \frac{d}{d[\mathrm{Na}]}\frac{d[\mathrm{Na}]}{dt}$$

The conclusion is drawn that the effect of sodium corrosion on the cell potential is significant at very low sodium concentrations and that this technique is not suitable for determinations in that range. This method can be used for continuous evaluation of sodium concentration in flowing amalgam streams subject to the concentration limit indicated.

Notes on the Chemical Polishing of Gallium Arsenide Surfaces

R. D. Packard

Honeywell Radiation Center, Boston, Massachusetts

In chemical etching and polishing of semiconductors, the surface undergoes a chemical change. Only those reactions which do not deposit insoluble impurities on the surface are generally useful. Such etches are usually aqueous solutions containing reagents which react with the semiconductor to form reaction products which are soluble. Occasionally, one reagent will serve the two purposes of reactant and solvent. Gaseous and molten salt etchants are also employed, but will not be considered here.

When compound semiconductors are chemically polished, a combination of etchants is generally necessary. Gallium arsenide is such a compound. Most of the commonly used etches contain either nitric acid or hydrogen peroxide as an oxidant for the arsenic. For polishing, HF or HCl is generally added, with or without extra water (1-5). Strong oxidizing agents act on arsenides to form a soluble arsenic acid, rather than an insoluble oxide as in the case of antimonides.

Gallium is rather reactive, being close to zinc and iron in the electromotive series, and is converted in acid solution to the soluble nitrate or fluoride. Sulfuric acid has been added as a complexing agent and to increase the viscosity of the etchant solution for chemical polishing (6). Nitric acid alone has been used; however, Kyser and Millea (7) show some disadvantages in this etch. Sullivan and Kolb (8) obtained highly polished surfaces in bromine-methanol solutions.

A brief discussion of etching solution viscosity is useful. A stagnant liquid film always exists immediately adjacent to the semiconductor, its thickness dependent on the degree of agitation of the solution. If the viscosity of the solution is increased, the diffusion rates of the reactant etch solution and product molecules across the film decrease since

$$\frac{dN}{d\theta} = -DA\frac{dC}{dX}$$

where N is moles diffused; θ, is time, sec; D, diffusion coefficient of the species concerned in the media, cm^2/sec; A, area through which diffusion occurs, cm^2; C, concentration, $moles/cm^3$; and, X, distance in the direction of diffusion, cm. Rearranging, $D = \dfrac{-dN/d\theta}{A(dC/dX)}$, the negative sign indicating that diffusion occurs in the direction of decreasing concentration. Increasing the solution viscosity increases the shear resistance which the diffusing component must overcome in order to travel through the film and thus decreases $dN/d\theta$ and the diffusion coefficient. The viscosity of the liquid is an index of its resistance to flow and diffusion.

High-viscosity etchants are preferred for chemical polishing because the reaction with the semiconductor tends to be concentrated at the high points (projections) on the surface. The etchant forms stagnant pools in the low regions (valleys) where in-diffusion of reactant acid molecules and out-diffusion of etch products occur very slowly because of the small concentration gradient due to the thick stagnant layer. Thus, the reaction rate increases at high points and decreases at low points, which eventually results in a smooth surface. High etch solution viscosity drops the etch rate in valleys to nearly zero.

At 70°F, the viscosity of 60% aqueous H_2SO_4 is 6 cp (centipoises), while that of 98% H_2SO_4 is 22 cp (9). By contrast, pure glycerine has a viscosity of 1375 cp at 70°F (10). As glycerine is added to an aqueous etching solution, the solution viscosity may rise ultimately to over 1000 cp at room temperature. The etch-acid concentrations simultaneously decrease, creating a very slow etchant.

Experimental work reported here consists of etching GaAs samples in various solutions of aqueous HCl and HNO_3 and glycerine. The acids were "Baker analyzed"

analytical reagents, 38% HCl and 70% HNO_3, respectively.[1]

The most satisfactory polishing etches were composed of approximately 1:1 volumetric mixtures of HCl and HNO_3, with relatively large amounts of glycerine.

Kyser and Millea (7) found that nitric acid etching of GaAs resulted, under certain circumstances, in a precipitation of foreign material on the GaAs surface. These precipitates were identified as As_2O_3 by x-ray diffraction and were explained as follows. Nitric acid dissolves the GaAs by oxidizing the As and forming a soluble Ga compound. As_2O_3 is not soluble in concentrated HNO_3 but is soluble in water to the extent of 2g per 1000 ml at room temperature. Thus, diluted HNO_3 is necessary to keep the As_2O_3 in solution. Excess glycerine, therefore, serves two purposes: that of increasing the viscosity of the etching solution, and keeping the nitric acid concentration sufficiently low so that the arsenic trioxide dissolves in the etchant rather than precipitates on the semiconductor surface.

Specifically, a mixture of 5 parts HCl, 5 parts HNO_3, and 40 parts glycerine, by volume, gave a highly polished, bright GaAs surface with an etch rate of 0.37 mg/cm^2/min. It is preferable to suspend the GaAs in the etchant solution and to agitate just enough to avoid retention of bubbles on the semiconductor surface. The Monsanto GaAs used in the experimental work had a {111} crystal orientation. It was 0.13 ohm cm n-type.

Since gallium chloride is soluble in benzene, an etching solution consisting of small volumes of HCl and HNO_3, benzene, and glycol or alcohol to make the components miscible is also effective as a chemical polishing agent. The highly polar HCl, however, is limited in solubility in the higher molecular weight glycols/alcohols, so care must be exercised to keep the mixture homogenous throughout the etching cycle. Glycol, in contrast with an alcohol, increases the etchant viscosity.

To summarize, etching solutions possessing higher viscosities than water are useful to produce highly polished GaAs surfaces. They function by slowing the rate of material removal, particularly in surface valleys, which exist only on nonflat surfaces, allowing microscopic surface projections to be brought down level with a minimal total semiconductor loss.

[1] The acids used for etching were low in copper content (0.0003 and 0.0001%, respectively) to avoid thermal conversion in GaAs during subsequent heat treatment.

Etching and Crystal Growth in the GaAs-Sn System

M. F. Millea and W. R. Wilcox

Electronics Research Laboratory, Aerospace Corporation, El Segundo, California

The absence of a center of symmetry in the crystal structure of III-V compounds has been found to result in a large number of polarity effects (1). Minamoto and Malafi (2) have investigated the significance of crystallographic polarity on the alloy etching of GaSb by Sn. They found that the p-n junction formed by alloying on Sb{111} faces was planar, while the alloy junction on Ga{111} faces was curved. Better tunnel diodes were obtained when the alloying was performed on the Sb{111} face. Grimmeiss and Scholz (3) observed superior GaP diodes when Sn was alloyed to the P{111} face. The p-n junction obtained by alloying Sn to the P{111} of GaP was planar and parallel to the crystal surface.

The purpose of the present investigation is to develop an understanding of the effect of polarity on alloy etching and subsequent regrowth of GaAs by Sn. Because of similar polarity effects reported on the GaSb-Sn and GaP-Sn systems, one might expect the alloy etching and regrowth of all III-V compounds with Sn to be similar.

Experimental Procedure

Three techniques were used in this investigation. Most of our experiments were performed by alloying small cubes of Sn to mechanically polished As{111} and Ga{111} surfaces under an argon atmosphere. Various heating and cooling rates were used. The metallic region after alloying was chemically removed with dilute HCl and the morphology of the surface examined with an optical microscope.

The relative dissolution rates of the Ga{111} and As{111} were determined by dissolving both surfaces of a {111} wafer in pure Sn. In this experiment the GaAs wafer was placed in 10g of Sn at slightly above its melting point. The wafer was rotated at 1 cps with the direction of rotation being reversed every 30 sec and the bath was heated at 3°C/min. At 500°C the GaAs wafer was withdrawn from the molten Sn, and the metal adhering to the wafer was chemically removed with dilute HCl. The Ga{111} and As{111} surfaces were examined microscopically and the relative rates of dissolution observed.

The relative regrowth rates on the Ga{111} and As{111} faces were measured as follows. Ten grams of Sn were saturated with GaAs in a quartz tube. The solution was quenched, and a p-type {111}GaAs wafer and then a quartz rod were inserted into the tube. The solution was heated to slightly above its melting point, the GaAs wafer was submerged in it by the quartz rod, and the quartz tube was sealed off under vacuum. This ampoule was then heated to 600°C in an electric furnace and cooled to room temperature at 2°C/hr while being held in a vertical position. The GaAs was removed from the Sn, and the relative rates of regrowth on the Ga{111} and As{111} surfaces were determined by angle-lapping and staining.

Experimental Results

Dissolution.—When small cubes of Sn were alloyed on the As{111} of GaAs under a rapid-heating, rapid-

cooling cycle,[1] a planar alloy interface was observed. The same morphology was observed when Sn was alloyed to As{111} under a slow-heating, rapid-cooling cycle. This was identical to observation by others (2, 3). They reported that, when Sn is alloyed to the (111) face of p-type GaSb and GaP, a planar p-n junction results.

The morphology of the alloy interface on the Ga{111} is dependent on the heating rate. When small cubes of Sn were alloyed to the Ga{111} under rapid-heating, rapid-cooling conditions, a rounded noncrystallographic alloy interface was formed. This observation is similar to that of Minamoto and Malafi (2) on the alloy interface on the Ga{111} of GaSb. When Sn is alloyed to the Ga{111} under slow-heating, rapid-cooling conditions, triangular alloy pits were observed, as shown in Fig. 1a. The alloyed Ga{111} surface shown in Fig. 1a was etched for 5 min in 1 part HNO_3, 2 parts HgO to reveal dislocations (4). The result is reproduced in Fig. 1b. As can be seen in this microphotograph, a chemical-etch pit occurred at the center of each alloy-etch pit.

The relative dissolution rates of the As{111} and Ga{111} were determined by the second experimental procedure described in Experimental Procedure. The thickness of the dissolved region on the As{111} was 50×10^{-4} cm, while on the Ga{111} the thickness was 15×10^{-4} cm, except in the alloy etch pits. The distance from the original surface to the bottom of the alloy etch pits on the Ga{111} was approximately 50×10^{-4} cm. This experiment indicates that the dissolution rate of the As{111} is greater than that of the Ga{111}.

Regrowth.—The regrowth of GaAs from a Sn-GaAs solution also shows a polarity effect. When small cubes of Sn were alloyed to the Ga{111} under a rapid-heating, slow-cooling cycle, the interface reproduced in Fig. 2a was observed. Slow cooling rates were used to promote regrowth on the GaAs wafer. The regrowth on the As{111} alloyed under similar conditions is illustrated in Fig. 2b. It can be seen in Fig. 2b that the regrowth on the As{111} proceeds in a lateral manner starting from the sides of the dissolved depression. Both lateral and perpendicular regrowth are observed on the Ga{111}.

The As{111} regrowth morphology illustrated in Fig. 2b is similar to the dissolution morphology of the As{111}.

The regrowth rates were determined with the third experimental procedure described in the preceding section. In this experiment the starting GaAs wafer

[1] The rapid cooling rate served to avoid regrowth on the GaAs wafer.

Fig. 1a. Photomicrograph of pits formed on Ga {111} surfaces of GaAs during dissolution by Sn under conditions of slow heating. Wafer quenched to prevent regrowth.

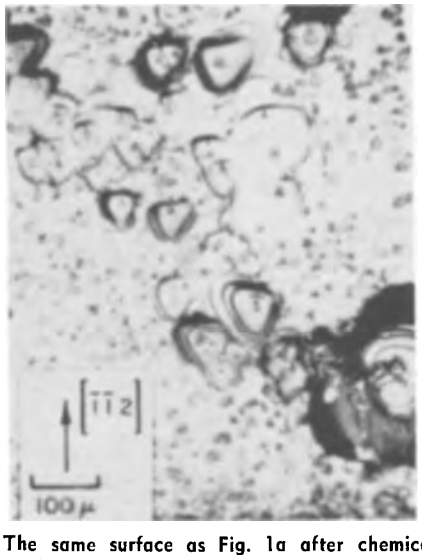

Fig. 1b. The same surface as Fig. 1a after chemical etching to produce dislocation etch pits. Note coincidence of some of these with Sn pits.

Fig. 2a. Photomicrograph of regrowth pyramids on Ga {111} surface of GaAs in Sn by slow cooling. Edge of dissolution hole in upper left hand corner showing lateral regrowth.

Fig. 2b. Photomicrograph of lateral regrowth from undissolved islands on As {111} surface.

was p-type so that the thickness of the regrowth layer (n-type) could be measured by conventional angle-lapping and staining techniques. The GaAs was submerged in the Sn solution to minimize lateral regrowth. If the specimen were not submerged, the regrowth on the As{111} proceeded in a lateral manner starting from the solid-liquid-vapor interface. It was determined from this experiment that the n-type region on the Ga{111} was twice as thick as on the As{111}. Several large growth hillocks were observed on the As{111}.

Discussion

The etching process in which a small mass of Sn is alloyed to GaAs is fundamentally identical to internal dissolution experiments (5, 6) and to the formation of "negative crystals" (7). In those experiments a cavity in a crystal is filled with solvent, and dissolution is permitted to occur. If the dissolution proceeds slowly, the shape of the cavity becomes faceted and approaches the equilibrium shape identical to that expected for the ordinary slow convex crystal growth of the same material in the same solution. The internal dissolution experiments and the present alloying experiments possess the common feature of increasing crystal surface area with time, in contrast to ordinary external (convex) dissolution in which the surface continually decreases.

Therefore our result that the morphology of the As{111} alloy interface is independent of heating rate indicates that the As{111} is a singular plane at equilibrium. That is, the prime determinant of the morphology of the As{111} alloy interface is probably the surface energy *vs.* orientation function, As{111} being located at a cusped minimum (8). The macroscopic morphology of the Ga{111} alloy interface indicates that the Ga{111} is not located at a cusp on the Wulff plot, *i.e.*, it is diffuse. Crystal growth experiments using a variety of techniques showed the same results and so tend to support these conclusions (9, 11).

The different rates of dissolution and regrowth on the As{111} and Ga{111} can be explained by considering the rate-controlling step in dissolution and growth. Experimentally it has been observed that the dissolution rate of the As{111} is faster than the dissolution rate of the Ga{111}. On the other hand, the rate of regrowth perpendicular to the Ga{111} is greater than the regrowth perpendicular to the As{111}. It should be noted that the Ga{111} is also reported to grow faster than the As{111} in crystal growth from the melt (9-11) and from the vapor (12-15). In the case of growth perpendicular to the {111}, the rate-limiting step is the addition of atoms of opposite type from those triply-bonded to the face (1), *i.e.*, Ga to As(111) and As to Ga(111). The rate-limiting step in dissolution would be the removal of the triply-bonded atom, *i.e.*, arsenic from As{111} and gallium from Ga{111}. Arsenic would be expected to add or dissolve more easily than gallium since arsenic is present in solution predominately as molecules (16-18) and gallium is present only as atoms. Hence an As_4 molecule could easily deposit on the Ga{111} surface, as suggested by Pizzarello for epitaxial vapor growth (19). In dissolution, As_4 molecules could be removed from the As{111}, or groups of arsenic atoms in solution could combine with an arsenic atom in the crystal surface to aid in its removal. One could therefore expect the As{111} dissolution rate to be greater than the Ga{111} dissolution rate and the Ga{111} perpendicular regrowth rate to be greater than the corresponding As{111} rate. Similar results would be expected for other III-V compounds containing P or Sb, since these atoms also are associated in solution and in the vapor (16, 17).

The alloy-etch pits observed on the Ga{111} during slow alloy etching (Fig. 1) are believed to be due to dislocations. This indicates, in agreement with the preceding paragraphs, that the gallium surface is attacked slowly and that a particular type or array of dislocations allows dissolution to proceed more rapidly in their vicinity. Higher over-all dissolution rates produce no alloy-etch pits, as would be expected.

Three-Point Probe Calibration for GaAs

M. H. Norwood[1]

Texas Instruments Incorporated, Dallas, Texas

The three-point probe is a useful and necessary instrument for determining properties of p on p+ or n on n+ layers of semiconductor materials. Brownson (1) described the technique and showed calibration curves for breakdown voltage, V_B, as a function of resistivity for n-type silicon. Dobbs and Kovacs (2) also show details of equipment and calibration curves for silicon. Gardner, Hallenback, and Schumann (3) compared the performance of the three-point probe with the spreading resistance technique and the control slice method and concluded that the latter two were inferior to the three-point method.

This note describes similar data for both p-type and n-type GaAs for free carrier concentrations between 10^{15} cm^{-3} and 10^{19} cm^{-3}. This quantity is more closely related to breakdown voltage than the resistivity when mobility varies from sample to sample. Actually, breakdown depends more fundamentally on the difference between donor and acceptor concentrations. If shallow levels are assumed, the free carrier concentrations are a measure of this difference.

The probe tip used in this work was ground to a 30° angle from a ⅛ in. diameter tungsten carbide rod. A diamond wheel was used for rough grinding, and the tip was polished to shape on a glass plate with a fine grinding compound by rotating the rod in a ¼ in. hand drill. This tip has been in use more than a year and more than 30,000 breakdown measurements. Tungsten wire tips are not nearly so durable. The radius of the tip is 9 mils, and the probe force is about 200 dynes. This force is reproduced by using an ohmmeter to determine first contact, then compressing a spring of known compliance a known distance.

A high current pulse generator with a 60 cycle repetition rate and a 5% duty cycle was used rather than an a-c source for biasing the point diode in order to avoid heating effects. Breakdown is observed from the voltage-time display on the scope instead of the I-V curve. Pulse shape is not a critical factor.

Conventional six-contact Hall bar samples were used as calibration standards. Relatively homogeneous bars were chosen by comparing the two longitudinal resistance values and the two transverse Hall voltages. If the two comparable measurements differed by more than 10%, the bar was rejected. All breakdown measurements were performed in the rectangular area between the side contacts of the Hall bar. The surfaces were etched to a smooth finish.

Figure 1 shows the values of V_B as a function of free carrier concentration for 5 p-type and 17 n-type samples. The error bars show the range (considerably larger than the standard deviation) of 10 breakdown measurements, and the dots are average values. To some extent, the range correlates with degree of inhomogeneity, indicating that the probe is somewhat more repeatable than it first appears. Profiles of angle lapped epitaxial layers and bulk samples have been made with very fine increments (10μ), and these indicate considerable inhomogeneity within small areas. Therefore, part of the scatter in the data is attributable to the samples rather than to the instrument.

Occasional highly compensated samples do not fit the data pattern, possibly because of the more complicated dependence of free carrier concentration on donor and acceptor concentrations with the presence of appreciable numbers of deep levels. The data shown are therefore not representative of all GaAs samples, but have been useful and reliable in most cases. For epitaxial layers, apparent differences between Hall and three-point probe measurements of carrier concentration have been explained by profiling the angle-lapped incline. In some cases the carrier concentration varies enough through the layer to cause considerable differences between a surface measurement and an averaged bulk measurement, such as the Hall technique.

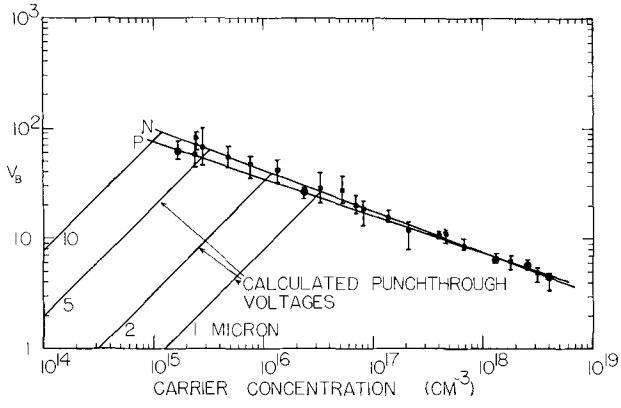

Fig. 1. Values of point contact breakdown voltage as a function of free carrier concentration for p- and n-type samples of GaAs; ■, n-type; ●, p-type.

The p-type and n-type data have been fitted by a least squares line. The results are

$$V_{Bn} = 100\ (n/10^{15})^{-0.372}$$

$$V_{Bp} = 75\ (p/10^{15})^{-0.338}$$

The exponents are smaller than for silicon (1) or for GaAs p-n junctions (4, 5). This may indicate that breakdown mechanisms other than avalanche are occurring. No attempt is made to explain these smaller exponents.

Figure 1 also shows calculated curves for voltages at which the depletion region thickness is equal to layer thickness. This effect, called "punchthrough," was described by Brownson (1). In the present work, most layers were too thick or highly doped to observe this alternate phenomenon, so none were observed.

Hall Mobilities in Heavily Doped N-Type Gallium Arsenide

Forrest V. Williams

Monsanto Company, Saint Louis, Missouri

The amphoteric nature of the group IV elements as impurities in the III-V compounds has been fairly well documented. Germanium and silicon in gallium arsenide (1-5) and tin in gallium phosphide (6) have been studied in detail. As expected, the group IV element may substitute on either a group III lattice site or a group V lattice site and behave as a donor or an acceptor, respectively. The distribution of a given group IV element between the two sites in a III-V compound has been treated thermodynamically by Scott and Fredericks (7). It was concluded that covalent bond energies, strain energies, and equilibrium vapor pressures of the elements of the III-V compound are the chief factors determining the distribution.

It might be anticipated that the group VI elements, such as selenium and tellurium, would behave as normal donors in the III-V compounds. In this case, a donor level would be introduced for each group VI atom which is incorporated into the III-V lattice at a group V site. Actually, the experimental evidence which has been obtained suggests that the behavior of group VI elements in III-V compounds is complex, especially at high dopant concentrations. The behavior of selenium in Bridgman grown crystals of GaAs has been studied by Vieland and Kudman (8) By comparing the results of chemical analyses and Hall coefficient measurements, these workers showed that above a concentration of about 4×10^{18} at./cm^3 a considerable fraction of the Se dissolved in the crystal must be either un-ionized or electrically compensated. By comparison of the mobilities of the heavily selenium doped crystals with the mobilities of silicon doped crystals (compensated), it was concluded that compensation was not a factor and that selenium introduced no acceptor levels in GaAs. Their data were interpreted as evidence for a neutral gallium vacancy-selenium complex, $[V_{Ga}Se_3]$.

Electrical measurements on GaAs doped with selenium and with tellurium have been reported recently by Black and Lublin (9). These workers, in agreement with Vieland and Kudman, noted free carrier concentrations for both selenium and tellurium far below those expected from the chemically analyzed doping levels. In addition, Trumbore and co-workers (10) concluded that selenium is either compensated or electrically neutral in heavily doped crystals of solution grown GaP.

Two important points are evident in the results reported by Black and Lublin (who reported that their results were in agreement with those of Vieland and Kudman). First, the mobilities of their heavily doped selenium crystals of GaAs are not in complete agreement with the values reported by Vieland and Kudman for crystals with the same net carrier concentration. Second, there was a significant difference in the mobilities of single crystals doped to the same level with selenium and with tellurium, although Black and Lublin did not point out this difference.

It is the purpose of this communication to report some electrical properties which have been measured on epitaxial layers of GaAs which have been heavily doped with selenium, tellurium, and tin.

The preparative technique by which these epitaxial layers were grown has been described in detail (11). Briefly, the method utilizes the vapor transport of GaAs with HCl in a flow system. The reactions which are involved are

$$GaAs + HCl \rightleftarrows GaCl + \tfrac{1}{4}As_4 + \tfrac{1}{2}H_2$$

$$3GaCl + \tfrac{1}{2}As_4 \rightleftarrows 2GaAs + GaCl_3$$

The epitaxial layers were doped by the use of a separate reservoir of the doping element in the vapor transport system. As has been reported earlier (12), it is possible to obtain single crystal epitaxial layers of GaAs with net carrier concentrations greater than 1×10^{19} at./cm^3. All of the layers were grown on high resistivity ($>10^3$ ohm-cm) substrate oriented on the <100> plane. Owing to the insulating nature of the substrate, resistivities and Hall coefficients of the epitaxial layers could be measured directly. All measurements were made at room temperature. The Hall effect was measured at magnetic field strengths of 5000G, and the free-carrier concentration was calculated from the relation $n = 1/R_H e$. Owing to the small quantity of epitaxial material (most layers were on the order of 15-25μ thick) on the substrate, it was not possible to determine the total concentration of dopant in the epitaxial layers.

The results of this investigation, along with some pertinent data from the work of Vieland and Kudman (8) and Black and Lublin (9), are shown in Table I. The data reported in this work and the data reported by Vieland and Kudman for selenium doped crystals are plotted in Fig. 1.

Several points are evident from these tabulated results. It will be observed that the mobility values obtained in this investigation for tin doped crystals of GaAs are about 40% lower than the mobility values of crystals of GaAs doped with tellurium to the same net carrier concentration. This would indicate that a considerable portion of the tin substitutes for arsenic when in solid solution in GaAs. Trumbore and co-workers (6) have reported that about 25% of the tin in solid solution in GaP is substituted at the phosphorus lattice sites. Considering the tetrahedral covalent radii of the phosphorus and arsenic, a higher distribution of tin on group V lattice sites might be expected in the case of GaAs.

The mobility values obtained in this investigation for the tellurium doped crystals of GaAs are in excellent agreement with the single published value of Black and Lublin for crystals doped to the same carrier concentration. However, the mobility values obtained both in this study and by Black and Lublin for the selenium doped crystals are slightly lower than the values reported by Vieland and Kudman.

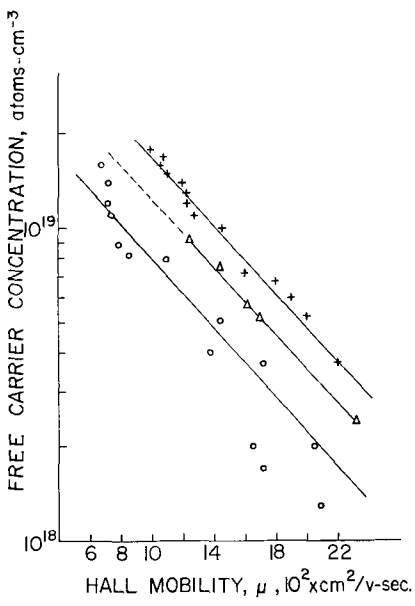

Fig. 1. Data for selenium and tellurium doped crystals: △, selenium doped Bridgmann crystals (5); ○, selenium doped epitaxial crystals, this work; +, tellurium doped epitaxial crystals, this work.

The interesting feature of the results obtained in this study, and confirmed by the data of Black and Lublin, is the difference in mobility between tellurium and selenium doped crystals of GaAs. The same effect is noted, to a greater degree, in the mobilities of Czochralski single crystals doped with sulfur and with tellurium. These mobility differences tend to disappear at doping levels below about 10^{18} at./cc The same phenomenon has been observed for selenium and tellurium dissolved in gallium antimonide (13). It was concluded that the character of the donor impurities, in addition to the two band model for GaSb, plays an important role in determining the electrical properties of n-type GaSb. The Hall mobilities of both germanium (14) and silicon (15) doped with phosphorus, arsenic, and antimony have been reported. As in the case of both GaAs and GaSb, the highest mobility values were obtained with the donor impurity with the largest atomic weight. However, the mobility values of phosphorus doped silicon and germanium are intermediate between those of arsenic and antimony doped samples. This result may seem surprising since the donor impurities with the smallest atomic weights have tetrahedral covalent radii which more nearly match the radii of the group IV or group V lattice site. It may be significant that the order of the effect in GaAs appears to be S > Se > Te.

No detailed explanations have been given for any of these observed differences in the electrical behavior of donor impurities at high concentrations. Holonyak *et al.* (15) have discussed the effect for the case of Ge in terms of modification of the conduction band, the degree of modification depending on the impurity involved. Strauss (13) speculated that the effect, in GaSb, may be due to impurity conduction. Regardless of the interpretation, evidence is accumulating that specification of the kind of impurity is necessary when discussing the electrical properties of heavily doped semiconductors.

Acknowledgment

The author wishes to thank Dr. M. A. Gilleo of this laboratory for many helpful discussions.

Crystallographic Dependence of SiP Precipitates in Diffused Silicon

T. W. O'Keeffe, P. F. Schmidt,[1] and R. Stickler

Westinghouse Research and Development Center, Pittsburgh, Pennsylvania

The formation of SiP precipitates in the surface layers of silicon diffused from doped anodic oxide films has been reported before (1). The existence of SiP precipitates was suggested by tracer data utilizing the P^{32} isotope and was confirmed on {110} oriented diffused silicon by transmission electron microscopy and by electron diffraction.

These tracer data showed the loss of a large fraction of the total phosphorus incorporated into the silicon by diffusion, when the silicon was subsequently anodized in nontracer solution for diffusion profile determination by the Tannenbaum method (2). The silicon samples used in the previous experiments were flat oblong bars cut along the length of the ingot, the large surface of the bar being {110} oriented.

It has now been shown by tracer evidence that no precipitates are found on {111} surfaces for diffusion times of about 1 hr or longer at 1200°C, the diffusion source being a doped anodic oxide film, *i.e.*, not an infinite source. For short diffusion times the precipitates are also found on the {111} surfaces if the initial phosphorus content of the oxide source is high enough. A striking difference in the behavior of the different surfaces is thus observed only for longer diffusion times. On the {110} surfaces the precipitates were still present after 16 hr of diffusion at 1175°C.

Whereas substitutional phosphorus is not lost to the anodizing solution but is incorporated into the oxide formed by anodization, both SiP and elemental phosphorus would be removed by anodization. Silicon phosphide also hydrolyzes in contact with acids, producing phosphine gas, PH_3, whereas elemental phosphorus is inert to nonoxidizing acids. The formation of PH_3 when the sample is in contact with HF solution can therefore be taken as an indication for the presence of silicon phosphide, but does not rule out the simultaneous presence of elemental phosphorus.

Experimental

Table I presents the data for 2-hr diffusion runs at 1200°C for two {111} oriented disks and for {110} oriented bars. As in the previous experiments (1), the samples were etched in CP-8 prior to anodization to remove all mechanical damage. Columns 2, 3, and 4 specify the diffusion conditions. "Clad" means that a nondoped anodic oxide film, 600Å thick, had been grown in potassium nitrite-tetrahydrofurfuryl alcohol solution (3) on top of the doped oxide in order to eliminate out-diffusion of phosphorus. The doped oxide film had been grown to 150v at constant voltage and was therefore approximately 900Å thick (4).

Column 5 of Table I gives the prediffusion concentration of phosphorus in the doped oxide source Column 6 gives the amount of phosphorus lost from the diffused sample when removing the source oxide by a quick dip in cold HF, column 7 the amount of phosphorus recovered when evaporating this HF solution to dryness; the latter two values refer to the concentration of phosphorus averaged over the combined thickness of source oxide plus oxide cladding. Column 8 gives the percentage of the total prediffusion phosphorus that was found in the silicon after stripping the oxide source in HF. Thereafter the silicon was anodized in a nontracer solution, and column 9 gives the loss to the anodizing solution during this first anodizing step. Columns 10 and 11 give the surface concentration of phosphorus in the silicon, either extrapolated from the tracer profile or calculated from the electrical resistivity profile.

In the case of the {111} surfaces the full amount of phosphorus lost from the disks when the oxide source is dissolved in HF, is recovered in the HF solution.[2] This can be taken as good evidence that no SiP precipitates were present, since these would hydrolyze to some extent when in contact with HF, and the phosphine gas evolved would not be recovered when evaporating the HF solution to dryness. This behavior is indeed shown by the bar type samples in the lower two columns. The

[1] Present address: Bell Telephone Laboratories, Inc., Allentown, Pennsylvania.

[2] The apparent discrepancy that on disks 3 and 4 more phosphorus is recovered from the HF solution than was lost from the Si sample during etching in HF is due to the fact that the counting in these two cases had to be carried out under completely different geometrical conditions. The discrepancy therefore reflects mostly the uncertainty in the conversion factors employed to convert the two counts to absolute amounts of phosphorus.

zero loss to the anodizing solution in the case of the {111} surfaces may therefore be safely attributed to the absence of SiP precipitates. The bar-type samples, on the other hand, show an enormous loss to the anodizing solution during the very first anodization step, 76-81% of the total phosphorus present in the silicon.

Table II is laid out in the same manner as Table I, but refers to 20-min diffusions at 1200° or 1175°C. It can be seen that there must now be SiP precipitates also on the {111} surfaces, as indicated by the loss to the anodizing solution. Electron transmission micrographs on these {111} oriented disks confirmed the existence of precipitates, but these were too small for identification by electron diffraction. It is noteworthy that the loss to the anodizing solution of the bar-type samples, diffused for 20 min at 1175°C, is distinctly less than the loss from the bar-type samples, diffused for 120 min at 1200°C. It seems that high temperature and long diffusion times favor the formation of SiP precipitates on the bar type samples.

In examining the data two facts were noted: (*A*) the extrapolated surface concentration of the tracer diffusion profile, as established by multiple anodizations, was always significantly higher on the {111} oriented disks, as compared to the bar-type samples, even though the prediffusion concentration of phosphorus in the doped oxide was the same. Apparently the phosphorus bound in the SiP precipitates on the {110} surfaces is not as available for diffusion even at the diffusion temperature of 1200°C. (*B*) All bars tested had been cut from the same 2 ohm-cm p-type silicon ingot (float-zoned), on which no dislocation count had been carried out.

In order to check the possible effect of dislocations preexistent in the silicon crystal on the formation and stabilization of SiP precipitates, two extreme conditions were compared and are shown in Table III. Bar BB had a dislocation count of 350/cm^2, and was accurately {110} oriented (the other bars were ± two degrees off their nominal orientation, as evidenced by x-ray diffraction). Disk 7, {111} oriented, was only mechanically but not chemically polished; its surface was therefore badly dislocated. It can be seen that some SiP precipitates are now present on the {111} surface even after a 2-hr diffusion at 1200°C, whereas relatively few precipitates have persisted on the {110} surface.

Bar DD is included in Table III to show that for short diffusion times high surface concentrations can be reached also on surfaces other than {111}. Both bar DD and disk 5 showed some anomalous behavior, and the results obtained on these two samples are questionable.

Table IV shows once more the surface concentration on all samples for which the electrical data are available [on bar F these were falsified by accidental contamination with sodium ions which were incorporated into the anodic oxide and had then diffused in the silicon (3)]. Column 5 shows again the C_o extrapolated from the tracer profile, column 6 the C_o calculated from the surface conductivity profile obtained during multiple anodizations assuming a mobility of 80 cm^2/v sec. Column 7 gives C_o values calculated from sheet resistance and junction depth when assuming a Gaussian phosphorus distribution, and column 8 when assuming a complementary error function distribution (5). The junction depths in microns are given in column 9. It can be seen that there is a tendency for the junction depths to be greatest when SiP precipitates are absent. The tendency for samples with SiP precipitates to show a relatively high C_o value, as calculated from sheet resistance and junction depth, while at the same time showing a small junction depth, may be due to deviations of the diffusion profile from a Gaussian or erfc distribution. There is no obvious explanation for the unusually great junction depth on bar BB.

Errors

Most of the data presented are based on the activity of the P^{32} enriched phosphorus incorporated into the samples. Where absolute values of the phosphorus concentration are quoted, an error associated with the uncertainty of the absolute activity of the original tracer, as received, is involved (±3%). The various conversion factors necessary to extract the absolute phosphorus concentration from the raw count data involve possibly another 10%. It might be mentioned that for all the data tabulated the statistical errors associated with the radioactivity phenomenon itself were always made insignificant by sufficiently long counting times. The most serious errors in the results for comparative purposes are purely experimental. In the case of the counts taken from the samples themselves (columns 5 through 10, excluding 7), the exact replacement of the sample in the same position was most important.

This source of error led to uncertainties of ±2% for the disk-shaped samples and ±1.2% for the bar-shaped samples. Counts from trays containing nonvolatile remains of dissolved oxides after evaporation were only reproducible to within ±10%, presumably due to uneven distribution of the material in the bottom of the trays.[3]

Most of the columns in the tables were actually obtained from counting rate difference values so that the increase in error involved in such procedure is large. A list of the errors involved in each of the columns follows (excluding those involved in determining the absolute phosphorus content):

Column	5, %	6, %	7, %	8 & 9, %	10, %
Error on disk	2	6	10	±3	6* (Disks 3 & 4; 50% disks 1 & 2)
Error on bar	1.2	6	10	±2	50

* Disks 3 and 4 were investigated in great detail; the statistical error on disks 1 and 2, and on the bars is much larger because too few measurements were taken.

Column 11 involves the surface conductance data and probably is accurate to ±20% assuming the value of 80 cm^2/v sec taken as the average electron mobility for a layer 0.1μ thick at the surface. Column 12 is the result for x_j, ρ_s measurements using Irvin's curves assuming a Gaussian distribution and involves the usual uncertainties inherent in such determinations.

Discussion

The data indicate that several factors are affecting the nucleation, growth, and stabilization of SiP. Crystal orientation and perfection appear as the most important factors, but conditions of heat-treatment, cooling rate, etc., may also be involved.

In the previous study (1) it was found that SiP precipitated in {110} oriented Si bars in the form of flat rods, lying in the {111} planes and elongated along <110 directions> (6). In {110} oriented samples the SiP particles are thus formed predominantly parallel to the sample surface, the Si/SiO_2 interface being the most likely location for the precipitates because conditions at the interface are favorable for the development of large crystals.[4] It is significant that {110} oriented, phosphorus diffused samples showed a large loss of phosphorus in the form of PH_3, due to the hydrolysis of SiP, when the doped oxide was removed in HF after diffusion treatment. Unless the SiP crystals are located directly at the interface, such a large loss of phosphorus would not be likely to occur during a short exposure to cold HF. The orientation relationship indicated above predicts that the rod-shaped SiP particles in diffused {111} oriented wafers would intersect {111} surface at larger angles so that only the small cross section of the rods would be exposed at the surface. The observation that SiP particles remain small in {111} oriented samples of normal crystal perfection can be explained as presumably due to unfavorable growth conditions.

[3] There is also another possible but less likely explanation: if the phosphorus incorporated into the oxide by anodization did not occur in the highest valence only (+5), then on dissolution of the oxide in HF and heating of the HF solution, the phosphorus present in a lower valence state would disproportion to give phosphoric acid and phosphine gas; the latter would be lost from the trays.

[4] One could also think of a stabilization of the SiP crystals by an increased oxygen content if they are located directly at the Si/SiO_2 interface.

In a low dislocation crystal, vacancy clusters or small dislocation loops were observed in germanium (7, 8) and were found to lie in {110} planes. It was found that heat-treatment and impurity concentration are very critical for the formation of the loops. It might be expected, therefore, that these parameters are also sensitive factors for the nucleation of SiP in silicon.

Another possibility for the creation of nucleation sites close to the wafer surface was recently pointed out by Barson *et al.* (9). According to these authors a fast oxidation treatment at somewhat lower temperatures can cause pile-up of phosphorus from the bulk of the (phosphorus doped) sample resulting in formation of vacancy loops near the oxide/silicon interface. These loops, then, can act as nucleation sites for the precipitates. The results with the mechanically polished, {111} oriented disk 7 shows that dislocations can also act as nucleation sites for SiP precipitates. From the tracer data it could be deduced that SiP precipitates must be present on this sample, and subsequent transmission electron microscopy did indeed confirm their presence. On this mechanically damaged (10) sample, the SiP precipitates had grown to micron size.

It is known that thick oxide layers formed on silicon surfaces can create high stresses which then are relieved by plastic strain (11). The slip dislocation formed in this way will intersect the crystal surface along the intersection of the slip plane, for instance, for {111} surfaces along <110> directions. In this case the particles precipitating during a diffusion treatment might be expected to be concentrated along these slip traces.

Acknowledgment

The authors are indebted to Mr. N. Roney for his meticulous care in the performance of the tracer experiments. This work was jointly sponsored by the Electronic Technology Laboratory, Aeronautical Systems Division, Wright-Patterson Air Force Base, Ohio, under contract AF 33-(657)-9897, and by Westinghouse Electric Corporation.

Preferential Vaporization of Carbon from Hafnium Carbide

R. L. Hansler

Lamp Research Laboratory, General Electric Company, Nela Park, Cleveland, Ohio

It has been reported (1) that when hafnium carbide vaporizes it loses carbon and hafnium at the same rate. This is in disagreement with an experiment reported here in which hafnium carbide, most certainly nearer to stoichiometric than the hafnium carbide studied by the previous authors, clearly lost carbon preferentially. In this work, it has also been shown that electrical resistivity is a more sensitive indicator of composition changes in hafnium carbide than is lattice constant.

For nearly stoichiometric HfC the rate of loss of carbon increases with temperature and with the amount of carbon in the carbide. A filament of hafnium carbide was prepared by heating hafnium to approximately 2800°K in an atmosphere of argon (99.9%) containing about 5 Torr of methane (99.9%). A steady-state condition was ultimately obtained. The hafnium carbide lost carbon at a rate equal to the rate at which it gained carbon by decomposition of the methane.

It was then heated to approximately 2800°K in pure argon at constant voltage (31v) for 2 min during which time the current dropped from 7.05 to 6.67 amp. The resistance of the wire at room temperature before and after this treatment was 1.95 and 2.75 ohm, respectively. When the same filament was recarburized by heating in methane and argon as had been done previously, the hot and cold resistance both returned to the previous values. This experiment shows clearly that carbon was preferentially lost from the hafnium carbide prepared, as described, for this study.

The room temperature resistance of hafnium carbide changes rather rapidly with composition near stoichiometry, but the lattice constant (2) changes comparatively slowly. Comparable resistance and lattice data are tabulated for four filaments of the same size which were carburized to different degrees by heating in different argon methane mixtures. Because of the small sample size no chemical analyses were possible. The lattice constants were determined in the usual fashion by x-ray diffraction.[1]

Page Charge Adopted for the JOURNAL

Increased costs of publication have made it necessary for The Electrochemical Society to institute a per page charge for publication in the JOURNAL.

At the Meeting of the Board of Directors held in New York on September 29, 1963 a charge of $35.00 per printed page was established by the Board of Directors, on recommendation of the Publication and Finance Committees, for papers published in the JOURNAL. This action becomes effective for papers received after February 1, 1964.

A 10% reduction in the page charge will apply to papers authored by one or more members of The Electrochemical Society and/or by one or more employees of Patron or Sustaining Members of the Society.

Papers are accepted for publication on the basis of merit by established practices of review. Acceptance of future papers for publication will not be dependent on payment of this invoice. Where funds are not available for payment of this charge it will be waived by The Electrochemical Society.

Discharge and Recuperation of the Vanadium Pentoxide Electrode

Naola V. Watson and Allen B. Scott

Department of Chemistry, Oregon State University, Corvallis, Oregon

ABSTRACT

The pH dependence of the potential of V_2O_5 electrodes, at 25°C, was found to be 0.0602 v/pH unit. Only those cathode reactions yielding an insoluble oxide or oxyhydroxide are consistent with this result. Polarization was assumed to result from solid solution of the product in V_2O_5. A theory of recovery previously applied to MnO_2, involving the diffusion of the product into the solid oxide electrode, was applied with qualitative agreement in a limited region of pH and current density. The theory appears to be in need of modification to account quantitatively for the behavior of V_2O_5.

Vanadium pentoxide bears a resemblance to manganese dioxide as a cathode in electrochemical cells. The oxide is a semiconductor and is easily reduced in aqueous solution. We have found that a moderate polarization occurs during cathodic discharge; after a partial discharge a gradual recuperation occurs so that the potential returns in time to a value nearly that of the oxide before discharge. These similarities between MnO_2 and V_2O_5 have led us to believe that the mechanisms of discharge and recuperation in the two oxides may be much the same. Vanadium pentoxide has some distinct advantages over MnO_2 as research material. It is low melting (670°C), can be cast in any desired massive form, and single crystals can be prepared. Further, it is transparent in the orange and red, so that some indication of impurity or imperfection content may be given by optical measurements in the region of the fundamental absorption edge.

This paper describes the first of several investigations into the electrochemical properties of V_2O_5. In addition to providing some understanding of the behavior of this oxide, which itself has some promise as a cathode material (1), we expect the results to be of interest in the study of MnO_2 and oxide cathodes in general.

Coleman (2) proposed that the polarization of MnO_2, at least in certain regions of current density and electrolyte pH, resulted from an accumulation of oxyhydroxide on the surface, with recuperation taking place as the oxyhydroxide diffused into the solid MnO_2. He suggested that the diffusing species was the proton, accompanied by electrons moving through conduction levels of the crystal. This view was also adopted by Scott (3), who showed that the form of the polarization and recuperation curves, *e.g.*, those of Ferrell and Vosburgh (4), for MnO_2 could be satisfactorily accounted for by means of equations based on the diffusion equation for continuous flux on the surface of a semi-infinite solid, followed by a period of zero flux. Kornfeil (5) showed that the shape of the recuperation curve can be calculated from constants derived from the polarization curve, at a solution pH of 7.5, and an apparent current density of 0.15 ma/cm^2 and less.

Here we attempt to show that the product of the electrode reaction in V_2O_5 is an insoluble oxide or oxyhydroxide, and to account for the polarization and recovery on the basis of the theory applied to MnO_2.

Experimental

Preparation of the electrodes.—To form the electrodes, reagent grade vanadium pentoxide was melted around a strip of platinum foil in a Pyrex tube. The tube was then cooled, and the glass was broken away from the solid. The resulting cylindrical electrode had an apparent surface area of about 2.8 cm^2.

Analysis of the discharge product.—Electrodes were made the cathode for periods up to 72 hr in solutions saturated at pH 2 with V_2O_5 (about 4 x 10^{-3} mole V_2O_5/liter), to which was added about 0.1 mole/liter NH_4Cl to increase the conductivity. The pH was adjusted to values between 1 and 8 by additions of HCl and NH_3. At pH > 2 the solutions were no longer saturated with respect to V_2O_5, but dissolution of the electrodes was extremely slow. Currents ranged from 1.5 to 30 ma. The extent of reduction of the electrode and of material in solution around the electrodes was determined by potentiometric titration with ceric ammonium sulfate. The electrodes were dissolved in 100 ml of 2*N* H_2SO_4 for analysis.

X-ray powder diffraction patterns for the original electrode materials and for the electrode material after discharge were obtained by means of a North American Philips Company diffraction spectrometer.

Effect of pH on electrode potential.—Solutions used were McIlvaine's standard buffer solutions, saturated at 25°C with V_2O_5. The pH of each solution was measured by means of a Beckman Model G pH meter, and the potential of a V_2O_5 electrode immersed in the solution was measured, with reference to the saturated calomel electrode, by means of a Varian Model G 14 recording potentiometer. The temperature was 25° ±0.2°C.

Two types of electrodes were used in these experiments. The first type consisted of freshly prepared electrodes which had been allowed to stand in a saturated vanadium pentoxide solution until all the electrodes had attained the same potential. The other type consisted of electrodes which had been discharged for several hours. These latter electrodes were then allowed to stand in the discharge solution for 2 to 3 hr until they all attained the same potential.

Polarization and recuperation measurements.—The electrodes were discharged in well-stirred 0.5M KCl solutions saturated with V_2O_5, having pH's between 2 and 5. An external source of emf was used, and platinum foil was used as an anode. The apparent current density was in the range 0.12-0.35 ma/cm^2. A saturated calomel electrode was used as the reference, with the vanadium pentoxide cathode placed in direct contact with the tip of the reference electrode tube. A recording potentiometer automatically traced the polarization and recovery of the V_2O_5 potential. Polarization, or recovery, occurring within 10^{-2} sec after making, or breaking, the circuit was taken as the height of an apparently vertical voltage step on the trace of a Tektronix Type 502 oscilloscope having a frequency response of 1 Mc and using a sweep rate of 0.5 cm/sec. This polarization, about 10 mv, was essentially of the same magnitude on either making or breaking the circuit and was thought to be largely ohmic; it was sub-

tracted in all cases from the recorded polarization to give the slowly occurring and recovering component.

Results and Discussion

Product of the discharge.—The product, or products, of the electrolytic reduction of V_2O_5 is unknown. The number of oxides and oxyhydroxides, in which the oxidation number of vanadium is less than +5, is large. Anderson (6) identified 11 oxides of definite composition ranging from that of VO to that of V_2O_5. The following oxyhydroxides are known: VO(OH) (montroseite), $VO(OH)_2$ (duttonite), a second modification of $VO(OH)_2$ (7), and $V_3O_5(OH)_4$ (7). In addition, a mineral believed to have the formula $V_2O_3(OH)$ has been described (8). Dissolved ions which may result from the discharge include VO^{2+}, $HV_2O_5^-$, HVO_2^+, V^{3+}, VOH^{2+}, and VO^+. Of these, $HV_2O_5^-$ and HVO_2^+ occur only in solutions of pH > 5.3.

On discharge, the electrodes changed from purple or brown to jet black. The site of reduction was clearly seen, on sectioning discharged electrodes, to be at the solution-V_2O_5 interface rather than at the Pt-V_2O_5 interface, establishing the fact that charge transport through the V_2O_5 is electronic. It was impossible to separate mechanically the black material from the remaining V_2O_5 in the neighborhood of the surface. Many of the reduced oxides and oxyhydroxides, particularly those of oxidation state near +4, are reported to be black or blue-black.

The x-ray diffraction pattern of the surface material of an electrode discharged at an apparent current density $i = 7$ ma/cm^2 for 5 hr was compared with that of reagent grade V_2O_5 which had been melted, cooled, and crushed in a mortar. The pattern of the latter was identical to that of the original V_2O_5 powder, except for a difference in the intensity of several lines, arising undoubtedly from a preferential orientation of certain planes in the masses of small needle-shaped crystals which were still present in the frozen crushed sample.

Table I gives the result of the diffraction analysis. The pattern of the discharged electrode material was nearly the same as that of the undischarged V_2O_5, there being some differences in line intensities, some slight displacements, and three weak new lines. The product evidently was present either in solid solution, or in a proportion insufficient to give a distinct powder pattern, or in both. An estimate of the proportion of reduced form can be made on the basis of chemical analysis provided a formula for the product is assumed. In electrodes reduced to the extent of 35 ma hr cm^{-2}, it was found by titration of the electrode material with ceric ammonium sulfate that the proportion of product, based on the entire mass of the electrode, was generally in excess of 20%, if the formula of the product was assumed to be $V_3O_5(OH)_4$, or in excess of 5%, if the formula was assumed to be VO_2. Since only the surface portions were removed for x-ray analysis, it then appears likely that the product is present in a proportion considerably higher than 5%. The new lines could not be matched with the powder patterns of any of the 13 lower oxides or oxyhydroxides reported in the "X-Ray Powder Data File." We cannot yet draw any conclusions regarding the formula of the reduction product, but it appears probable that the product forms a solid solution with V_2O_5, whose diffraction pattern is thereupon only slightly modified.

Dependence of electrode potential on p*H.*—The cathodic discharge of V_2O_5 may occur according to one or more of the following types of reactions:

1. Solid reactant + ne + $n'H^+$ + pH_2O = solid product + qH_2O where either p or q = 0 and where n and n' are equal. This type of reaction is exemplified by the equations

$$V_2O_5 + 2e + 2H^+ + H_2O = 2VO(OH)_2 \quad (a)$$

$$V_2O_5 + 2e + 2H^+ = V_2O_4 + H_2O \quad (b)$$

2. Solid reactant + ne + $n'H^+$ = soluble ion + qH_2O where $n \neq n'$. This type of reaction is illustrated by

$$V_2O_5 + 6H^+ + 2e = 2VO^{2+} + 3H_2O \quad (c)$$

3. Soluble ion + ne + $n'H^+$ = soluble ion + qH_2O where $n = n'$. This is illustrated by

$$H_3V_2O_7^- + 2H^+ + 2e = HV_2O_5^- + 2H_2O \quad (d)$$

4. Soluble ion + ne + $n'H^+$ = soluble ion + qH_2O where $n \neq n'$, such as

$$VO_2^+ + 2H^+ + e = VO^{2+} + H_2O \quad (e)$$

According to the Nernst equation, the electrode potential is given by

$$E = E_o - \frac{RT}{nF} \ln \frac{(a_{\text{prod.}})^b (a_{H_2O})^q}{a_{\text{react.}} (a_{H_2O})^p (a_{H^+})^{n'}} \quad [1]$$

where $a_{\text{react.}}$ is the activity of solid vanadium pentoxide or its soluble ion, $a_{\text{prod.}}$ is the activity of the reduced form, and b is its coefficient.

If the activity of the water is taken as the activity of pure water, and if the activity ratio of the reactant and product vanadium compounds does not change as the p*H* is changed, then at 25°C

$$E = E_o' - \frac{n'}{n} (0.0591)\, p\text{H}$$

E_o' includes constant terms in addition to E_o. The slope of the curve of electrode potential *vs.* p*H* is just $-0.0591\ (n'/n)$.

Since reaction (d), above, is the only known reaction between ions in solution in which the ratio of electrons to hydrogen ions is unity, and this reaction occurs only at pH > 5.3, the dependence of electrode potential on p*H* in the range p*H* 2 to p*H* 5 will differentiate between a reaction involving two solids and reactions involving one or more vanadium ions in solution. The reaction must be one between two solids if $n = n'$ and if the assumption made concerning the activities of the vanadium compounds is valid. If the solids are present as pure phases, the validity of the assumption is assured. If they exist as a solid solution, equilibration with solutions of variable p*H* might conceivably alter the solid concentration ratio. However, in these experiments, the V_2O_5 was present in large excess so that its concentration could not be much affected by changes in solubility, and, further, the electrodes were allowed to come to equilibrium in solutions of low p*H* and then placed in solutions of increasing p*H* for the measurements. The solubility of the discharge product was found, by chemical analysis, to decrease with increasing p*H*, so that its activity in a solid solution should also have been unaffected by the change in p*H*.

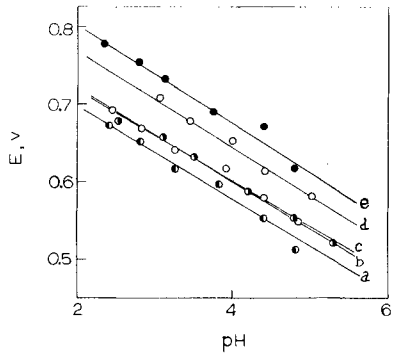

Fig. 1. Dependence of V_2O_5 electrode potential (with respect to the standard hydrogen electrode) on pH. Open and half-shaded circles, partially reduced V_2O_5; solid circles, V_2O_5.

Figure 1 gives the results of five different determinations of the dependence of the electrode potential on the solution pH. Curve e is for the pure vanadium pentoxide electrodes which were allowed to stand in the various buffer solutions for 30 min. Curves a, c, and d are for the partially reduced vanadium pentoxide electrodes which were allowed to stand in the buffer solutions 30, 60, and 60 min, respectively. Curve b is for partially reduced electrodes which were allowed to stand for 15 min in buffer solutions, which had been saturated with both vanadium pentoxide and the discharge product. The average slope of the curves was —0.0607v per pH unit; this value is nearly the theoretical slope for the case $n = n'$, indicating that both the reactant and product of discharge are solids.

Polarization and recuperation.—The foregoing results have led us to postulate that the cathodic polarization of V_2O_5 is due to an accumulation of a reduced compound in solid solution, which lowers the activity of V_2O_5 on the electrode surface. Recuperation may be the result of one or more of the following processes: (*a*) dissolution of the product, (*b*) diffusion of the product into the body of the electrode material, or (c) oxidation of the product by oxygen present in solution.

No special attempt was made to eliminate oxygen so that as yet we can make no statement concerning the role of direct oxidation in recuperation. We can, however, provide some indication of the importance of processes (*a*) and (*b*).

In Fig. 2 are shown typical curves of the polarization of the V_2O_5 electrode in solutions of varying acidity at 25°C. The apparent current density was in all cases about 0.25 ma/cm². After 10 min, the current was broken and the electrode potential recovered. The extent of polarization at 10 min clearly increases with increasing pH. So also does the polarization remaining at 20 min. Since chemical analysis showed the solubility of the reduced form to increase with decreasing pH, it is reasonable to conclude that at least a portion of the depolarization and recovery which occurs at low pH is the result of dissolution.

On the other hand, even at pH 7.7, the recovery was still remarkably rapid and leads us to the supposition that diffusion of the product into the solid oxide is the chief cause of recovery.

We now attempt to apply to theory previously given for MnO_2.

At constant pH, Eq. [1] reduces to

$$E = E_o'' - \frac{RT}{nF} \ln \frac{(a_{\text{prod.}})^b}{a_{V_2O_5}}$$

where the activities are those characteristic of the electrode surface, and E_o'' is the potential when $(a_{\text{prod.}})^b = a_{V_2O_5}$. If $b = 1$, if the activities are taken to be the respective concentrations, and if the concentration of vanadium atoms remains constant, the equation given by Kornfeil (5) applies, namely

$$E = E_o'' + k \log \left(\frac{A}{t^{1/2} - (t - T)^{1/2}} - 1 \right) \quad [2]$$

Here k should be 2.3 RT/F; A involves the rate of formation of product per unit surface area, the initial surface concentration of the oxidized form, and the diffusion coefficient for the product in the solid electrode; t is the time following the start of discharge at constant current; and T is the time at which discharge stops and recovery begins. The constants A and k may be obtained from the discharge portion of the curve, taking $t - T = 0$. For MnO_2, the recovery portion, calculated using constants so obtained, agrees well with observation (5).

If $b \neq 1$, Eq. [2] requires modification. In view of our limited knowledge of the electrode reaction, it does not seem worthwhile to test a variety of modifications based on assumed values of b, although in principle this may provide a means of discerning which of several processes may actually occur.

Instead, we have attempted to apply Eq. [2] to a series of discharges at varying current density, all at pH 3 and 25°C. The results are shown in Fig. 3. The constants used are given in Table II. Kornfeil (5)

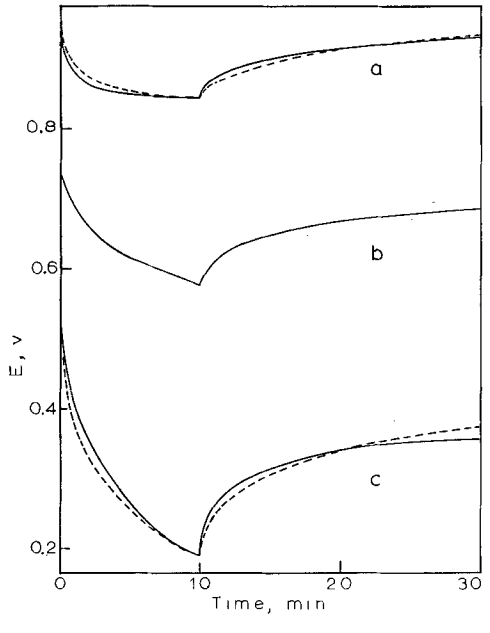

Fig. 2. Discharge and recovery of V_2O_5 electrodes at current density 0.25 ma/cm². pH: a, 1.5; b, 3.0; c, 7.7; E given with respect to the standard hydrogen electrode; solid lines, observed; broken lines, calculated (see Table II).

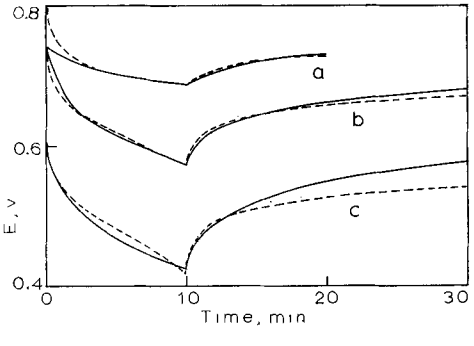

Fig. 3. Discharge and recovery of V_2O_5 electrodes at pH 3.0. Current density, ma/cm²: a, 0.12; b, 0.25; c, 0.35. Add 0.10v to ordinates of curve c. E given with respect to the standard hydrogen electrode; solid lines, observed; broken lines, calculated (see Table II).

Table II. Constants of Eq. [2] and [2']

Curve	pH	Current density, ma/cm²	E_o, v	k, v	A, min$^{1/2}$	c, v/min
Fig. 3, a	3	0.12	0.622	0.10	12.0	
b	3	0.25	0.634	0.10	4.2	
c	3	0.35	0.602	0.10	3.6	
Fig. 2, a	1.5	0.25	0.798	0.10	8.4	0.002
c	7.7	0.25	0.090	0.30	10.0	

found A and k from the slope of the discharge curve at two values of t; however, we found this process to be unsuccessful since, even at best, Eq. [2] fits the discharge portion only in the later stages where the slope is nearly constant. Rather, a single value of k, which should be current-density independent, was chosen such that all the curves could be roughly fit, both in the discharge and recovery portion by a suitable choice of the constant A. For these curves, k = 0.10v; best values of A and E_o were then found at each current density by trial.

At the two lower current densities, agreement between the observed curves (full lines) and those calculated from Eq. [2] (broken lines) was satisfactory. At the highest current density, with k = 0.10v, even the best value of A gave poor agreement with the observed curve. The value of k was significantly higher than the Nernst equation value, and, while the constant A decreased with increasing current density as it should, it was not inversely proportional to the current density. For MnO_2, k was found to be 0.068v at 25°C, and A varied inversely with current density (5).

Returning to the results obtained in solutions of variable pH, Fig. 2, we attempt again to apply Eq. [2].

Difficulties are to be anticipated here, since variations in pH affect not only the solubilities of the reactant and product, but may also alter the electrode reaction. In this regard, it must be emphasized that Eq. [2] has been applied successfully to MnO_2 only in a narrow range both of pH and current density.

At pH 7.7, qualitative agreement only was obtained, using k = 0.30v. This value is inconsistent with any conceivable polarization process which operates reversibly via activity changes in the reactants and products. At pH 1.5, no agreement between Eq. [2] and the observed curve could be obtained. However, if a term linear in the time was included, so that

$$E = E_o'' + k \log\left(\frac{A}{t^{1/2} - (t - T)^{1/2}} - 1\right) + ct \quad [2']$$

where c is a constant, a fair fit was obtained, using the constants given in Table II. The linear term in [2'] clearly tends to reproduce the effect of dissolution on polarization and recovery.

The variation of E_o'' with pH is considerably greater than 0.059 v/pH unit, which suggests that the reduction reaction may change between pH 1.5 and pH 3.0, and again between pH 3.0 and pH 7.7.

It may be concluded that, while the polarization and recovery of the V_2O_5 electrode is qualitatively similar to that of MnO_2 and rough agreement with the diffusion theory, applied successfully to MnO_2, was found at pH 3 and current density of 0.25 ma/cm² and less, the analogy with MnO_2 is far from perfect. The high value required for k and the failure of the inverse proportionality between A and current density at pH 3 may arise from any of several causes, including among other possibilities (a) dissolution of the product, (b) failure of the condition b = 1, and (c) oxidation of the product by dissolved oxygen.

Theory of Organic Corrosion Inhibitors

Adsorption and Linear Free Energy Relationships

Francis M. Donahue and Ken Nobe

Department of Engineering, University of California, Los Angeles, California

ABSTRACT

By considering adsorption processes of organic compounds as being determined by the electronic distribution in the "anchoring" group of an adsorbate, a correlation has been derived between adsorption measurements and Hammett-like substituent constants through the use of Linear Free Energy Relations (LFER). The analysis is extended to corrosion inhibitors by assuming that the mechanism of inhibition by organic molecules is chemisorption and that the energetics of the corrosion process *per se* are unaffected by the addition of substituents on the parent compound.

In a series of reviews and experimental papers Hackerman and co-workers (1-8) have discussed the effects of structural changes in organic compounds on corrosion inhibition. Each of the experimental papers (5-8) was a systematic study of the "structure-inhibition" relationship found among nitrogen-containing organics. In two reviews (3, 4) a strong implication was present that the key to the metal-organic interaction might be found using a physical organic approach. The present paper is an extension of this thought which endeavors to determine to what extent Linear Free Energy Relationships (LFER) may be used to correlate adsorption phenomena in general and corrosion inhibition in particular.

Theory.—Kinetic and equilibrium processes in organic chemistry have been found to fit an empirical equation proposed by Hammett (9) and discussed and extended by Jaffe (10) and Taft (11). The family of relationships thus obtained is a form of LFER usually designated as the Hammett relation and is given by

$$\log k/k_0 \text{ or } \log K/K_0 = \rho\sigma \quad [1]$$

where the k's are rate constants, K's are equilibrium constants, the zero subscripts refer to parent or reference compounds and the ρ and σ are the reaction and substituent constants which will be discussed below. The origin of the relation is derived from the observed regularity of the reactivity of substituted benzoic acids when compared with their respective pK's, *i.e.*

$$\log k = m(pK) + \text{const} \quad [2]$$

When the expression for benzoic acid itself was used as a reference (denoted with a zero subscript), the relation became

$$\log k/k_0 = m(pK - pK_0) \quad [3]$$

By setting the slope, m, equal to $+1.000$, for the ionization of substituted benzoic acids, the relation was further simplified to yield

$$\log k/k_0 = (pK_0 - pK) = \log K/K_0 = \sigma \quad [4]$$

This equation is then taken as the definition of the substituent constant, σ, *i.e.*, a substituent is given a numerical value which is dependent on its effect on the pK of the substituted benzoic acid compared to benzoic acid. From this definition, H has a σ of 0.00. Those substituents which increase ionization (*i.e.*, weaken the O-H bond) have positive values of σ, and those which decrease ionization (*i.e.*, strengthen the O-H bond) have negative values. From a simple electrostatic picture, substituents promoting ionization should attract electrons from the reaction center which in this case is the oxygen atom bonded to the acidic hydrogen. This result is borne out from qualitative experience in organic processes. By the same reasoning and experience, negative values of σ are associated with electron providing substituents. Electron withdrawal is a term introduced by the organic chemist to explain a decrease in the electronic charge density at an atom in a molecule due to the addition of a substituent. Likewise, electron provision is a term used to explain an increase in the electronic charge density at an atom due to the addition of a substituent.

Therefore, σ is a measure of the electron density or distribution at an atom. This measure of the electron density or distribution at a specific atom, in the molecule, is justified on the basis of quantum-mechanical calculations of electron charge density (q_i) of individual atoms within a molecular orbital structure [for example, see ref. (12), p. 58, and an application of this approach to nucleophilic and electrophilic substitution at azulene, *ibid.*, p. 94]. Such a concept should be very useful in studies where the electron density plays a dominant role. However, one must keep in mind the assumptions implicit in the Hammett treatment. The original approach assumed that all entropy effects were absent or so small as to be considered absent. However, Leffler (13) has shown that this stipulation is not necessary and that a linear relationship between enthalpy and entropy still gives the desired relationship. Steric effects have not been considered since Hammett correlated only meta and para substituents. The failure of the theory to describe the behavior of ortho substituents and aliphatic systems caused Taft to develop the σ^* scale (11). Further refinements of the technique have been developed and are discussed in review articles (10, 11, 14), but will not be treated here. In general these lead to rate or equilibrium equations which are due to structural changes

$$\log K/K_0 \text{ or } \log k/k_0 = [\rho\sigma] \quad [5]$$

where the brackets denote "the appropriate choice of parameter σ." By this it is meant that for aliphatic compounds or ortho-substituted ring compounds, the Taft constant σ^* would be appropriate and not, for example, the Hammett constant. Other substituent constants for particular molecular types have been devised and may be found in the aforementioned reviews.

From this discussion it is seen that ρ is an empirical constant, *i.e.*, it is the slope of the log rate or equilibrium-σ plot. The sign of ρ indicates whether a process is stimulated or inhibited by either electron withdrawal or electron providing at the reaction center.[1] The magnitude of ρ is a relative measure of the sensitivity of the process under study to electronic effects.

The applicability of the Hammett relation to purely organic processes has been demonstrated frequently (9-11, 14). The application to systems of electrochemical import has recently been shown (15, 17). From adsorption studies on alumina from pentane the free energy of adsorption of a number of compounds related to corrosion inhibitors has been correlated with the Hammett constant (18).

Consider an adsorption process

$$\mathrm{R\,Y} + \mathrm{M} \rightleftarrows \mathrm{R\,Y\text{------}M} \quad [6]$$

where R is some organic substituent group, Y is some organic functional group, M is a surface site, and R Y------M represents a chemisorbed species with some sort of electronic interaction between the functional group and the surface site. As a first approximation, the nature of the surface site has not been considered. In addition the electronic interaction has been scrupulously localized to M and Y and no suggestion is made as to which species functions as the Lewis base (electron donor). The process has an equilibrium constant K_a such that

$$K_a = \frac{\theta}{1-\theta} \quad [7]$$

which is related to the free energy of adsorption in the usual manner. The quantity θ is the fraction of the surface covered by the chemisorbed species. By an analogous treatment, the adsorption process of "reference substituent group," R_o, with equilibrium constant, K_{ao}, and surface coverage, θ_o, may be described. The effect of structure on the adsorption process is revealed by the relative change in the free energies

$$\Delta\Delta G_a^\circ = \Delta G_a^\circ - (\Delta G_a^\circ)_o = -RT \ln (K_a/K_{a,o}) \quad [8]$$

where the ΔG_a°'s are the standard free energies of adsorption. Comparing Eq. [8] and [5]

$$\Delta\Delta G_a^\circ = -[\rho'\sigma] \quad [9a]$$

where

$$\rho' = 2.303\,RT\,\rho \quad [9b]$$

Equations [9a], [8], and [7] lead to

$$[\rho'\sigma] = \log \frac{\theta(1-\theta_o)}{\theta_o(1-\theta)} \quad [9c]$$

From Eq. [9a] it is seen that the free energy of adsorption should exhibit a linear dependence with the appropriate σ. The parameter ρ should exhibit a temperature dependence (13). Although the derivation was for an adsorption process, the analysis would be similar for other changes of a physical parameter related to a comparable free energy change; for example, correlations with polarographic half-wave potentials should be anticipated, etc.

In substance, Eq. [9a] and [9c] show that the relative coverages in a hypothetical competitive chemisorption process will depend on the electronic distribution at the adsorption (reaction) center in the or-

[1] Reaction center is defined as that part of an organic molecule which is directly participating in the reaction. In the case of adsorption it is that part (adsorption center) which interacts with the surface.

ganic molecules. An alternate approach to viewing the phenomenon is to note that the relationship shows the relative tendency of one adsorbed species to be displaced (desorbed) when a second adsorbable species is present.

If one considers the kinetics of any surface reaction occurring with simultaneous adsorption of an inactive species, the rate is given by

$$r = \kappa\,(1 - \theta')\,\exp\,[-\Delta G^{\ddagger}/RT] \qquad [10]$$

where r is the rate of the reaction, κ is a constant, θ' is the surface coverage of the inactive (inhibiting) species, and $\Delta G^{\ddagger}$ is the free energy of activation. If one considers a family of organic compounds, where the functional group is held constant and the substituent is varied, the rate of the surface reaction in the presence of any member of this family compared to that of the parent compound is

$$\frac{r}{r_o} = \frac{1 - \theta'}{1 - \theta'_o}\quad \exp -\left[\frac{\Delta G^{\ddagger} - \Delta G_o^{\ddagger}}{RT}\right] \qquad [11]$$

In order to correlate the rates with the previously derived adsorption relationship, a simplifying assumption must be made.

$$\log\frac{1 - \theta}{1 - \theta_o} \cong \log\frac{1 - \theta'}{1 - \theta'_o} \qquad [12]$$

That is, the ratio of the surfaces not covered by the organic compounds is approximately the same whether considering a "purely" adsorption or an inhibiting process. Therefore, taking the log of [11], substituting [12] and [9] and rearranging

$$\log\frac{r}{r_o} = -\,[\rho\sigma] + \log\frac{\theta}{\theta_o} - \left[\frac{\Delta G^{\ddagger} - \Delta G_o^{\ddagger}}{2.3\,RT}\right] \qquad [13]$$

If the activation process for the reaction is unaffected by changing substituents on the organic compound (this assumes that the organic compounds alter the reaction rate solely by blocking the surface and not by "deactivating" other neighboring surface sites), Eq. [13] reduces to

$$\log\left(\frac{r}{r_o}\right) = -\,[\rho\sigma] + \log\frac{\theta}{\theta_o} \qquad [14]$$

When the relative coverages for the "pure adsorption" process are such that $\log\,(\theta/\theta_o) < [\rho\sigma]$,[2] a Hammett relation

$$\log\left(\frac{r}{r_o}\right) = -\,[\rho\sigma] \qquad [15a]$$

is obtained. This result indicates that the relative rate of the inhibited reaction is dependent on the electronic properties of the adsorbate.

Most corrosion inhibition data are given in the form of corrosivity (inhibited rate/uninhibited rate) or in per cent protection, I'. The corrosivity is $(1 - I)$ where $I = I'/100$. Equation [15] expressed in terms of the more familiar corrosion parameter, corrosivity then becomes

$$\log\frac{(1 - I)}{(1 - I)_o} = -\,[\rho\sigma] \qquad [15b]$$

In the foregoing no restriction has been made as to whether the adsorption is from solution or the gas phase or whether the surface reaction is on a solid or a liquid. Therefore, the treatment should be entirely general, and, more significantly, it suggests that gas phase adsorption measurements may be correlated with aqueous corrosion inhibition [this suggestion was implicit in the recent papers by Yao (20)] or electrocapillary data may be correlated with corrosion inhibition as suggested by Blomgren and Bockris (21).

Since Eq. [15a] is derived directly from Eq. [9c], a comparison of Eq. [15a] and [9a] where the ρ's are correlated by Eq. [9b] yields

$$\Delta\Delta G_a^{o} = 2.3\,RT\log\frac{r}{r_o} \qquad [16]$$

However, correlations of adsorption and corrosion inhibition data with the substituent constants, σ, shown later in this paper indicate that the ρ's are not equal. Therefore, subscripts "a" and "i" are used to identify the ρ's determined from adsorption and inhibition measurements, respectively. Equations [9a], [9c], and [15a] lead to relations which enable the direct correlation of adsorption and inhibition data

$$\Delta\Delta G_a^{o} = \frac{\rho'_a}{\rho_i}\log\frac{r}{r_o} \qquad [17]$$

and

$$\log\frac{\theta(1 - \theta_o)}{\theta_o(1 - \theta)} = -\frac{\rho_a}{\rho_i}\log\frac{r}{r_o} \qquad [18]$$

Although the aim of this paper is toward corrosion inhibition, other forms of inhibition of surface reactions are not precluded.

Discussion

Two simplifying assumptions are made in the present work, *viz.*, that one atom in the molecule may be considered as the "anchoring group" and that the electron density at that atom uniquely determines the adsorbability of the molecule as a whole. In the light of both experience and intuition, the assumptions oversimplify the problem. The former assumption constrains the researcher to focus on a single functional group during the course of a structure-inhibition evaluation. Such a practice was indeed followed in past inhibition studies, (5-8) and, hence, has been a traditional first approximation. The assumption that the electron density at the "anchoring group" uniquely determines the adsorbability still allows the possibility of π-interactions provided that such interactions are assumed to vary in the same qualitative manner as the electron density at the functional group under consideration. The reasonableness of this assumption cannot be determined *a priori*, but may be ascertained from experimental data (see below).

The theory herein derived offers a starting point for the consideration of a semi-quantitative approach to the structure-adsorption relationship of organic compounds on metals. By utilizing Hammett-like substituent constants, the problem of ascribing electronic charge densities determined from solutions of the LCAO-MO (Linear Combination of Atomic Orbitals-Molecular Orbital) method (12) is circumvented, and the experimentalist may, even with a limited organic chemistry background, use the tabulated "σ" values (10, 11, 14) in correlations.

Snyder (18) has calculated the free energy of adsorption of a number of organic chemicals which are structurally related to corrosion inhibitors by a technique based on experimental chromatographic retention volume measurements (see Eq. [2] in ref. 18). With a second technique, he calculated the free energy of adsorption by assuming a "localization" of the adsorbate-adsorbent interaction (see Eq. [5] in ref. 18). These latter calculations were shown to correlate well with the Hammett constant for "nonortho" substituents on pyridine, aniline, indole, and quinoline.

Figure 1 is a plot of the free energies of adsorption of a number of substituted pyridines calculated from the retention volume measurements of Snyder (18) against Hammett-like substituent constants. The free energies plotted are actually the differences between a substituted molecule and the parent compound, pyridine. Hammett σ values were used for the 3- and 4-substi-

[2] Hackerman and Cook (19) have shown that the amount of chemisorption does not vary much when the substituent is changed. There are, however, differences (as suggested by Eq. [9c]). These differences are suppressed by the scale which those authors used to represent their total adsorption data.

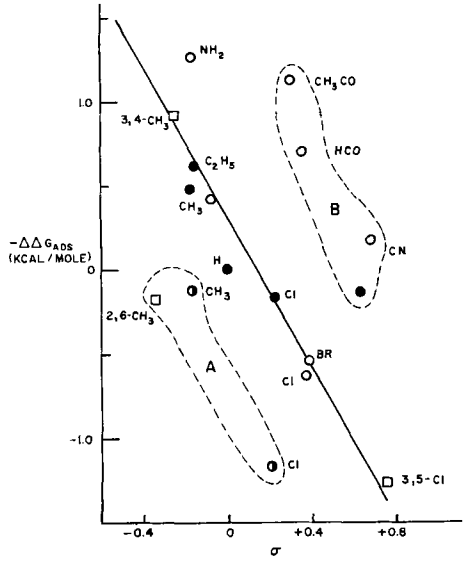

Fig. 1. Free energy of adsorption of substituted pyridines (18) compared to a Hammett-like substituent constant: solid circles represent substitution in the 4-position; open circles, in the 3-position; half-filled, in the 2-position; and squares, as shown.

tuted molecules, Taft σ^* values for the 2-substituted, and the sum of the appropriate σ's for multiple substituted molecules. The solid line is a least squares fit of all points (excluding those denoted by regions A and B). The correlation coefficient of this line was 0.95. The points making up the fit have a similar characteristic in terms of their contribution to the π-system. All of the substituents tend to donate electrons in resonance, *i.e.*, enrich the charge density of the π-system (22). On the basis of this observation, it would seem that the species which donate electrons in resonance do not affect the fit of the simple theory. However, such an observation is not universally true. The most interesting aspect of Fig. 1 is the failure of the substituents in region B to give a fit. These substituents tend to attract electrons in resonance and, thereby, decrease the electron density of the π-system. From the slope, *i.e.*, ρ' in Eq. [9a] of the observed fit, adsorption is increased by electron provision to the nitrogen on pyridine. However, on the basis of the substituents in region B, a diminution of electron density of the π-system gives a more favorable condition for adsorption for a given value of σ. It would have been instructive to use the Taft-Lewis treatment (17) to ascertain whether the observed effect was primarily due to resonance or inductive effects. However, insufficient data were available from the reference (18) for such an analysis.

The region denoted as A should not yield a correlation since the substituents are ortho to the reaction center, and consequently, can contribute a steric effect not allowed for in the simple Hammett treatment. The "ortho" substituents are quite well behaved, *i.e.*, they demonstrate that for a given electronic contribution the steric contribution is sufficient to diminish the tendency toward adsorption. The presence of a steric effect would tend to rule out a completely π-interaction as the mode of adsorption since an orientation of the molecule parallel to the substrate surface would be indifferent, sterically, to the location of the substituent. In summary, the correlation predicted by Eq. [9a], although not as all inclusive as would be desired, is satisfactory.

Ayers and Hackerman (8) have studied the inhibition of methyl pyridines on iron. Their results may be used to test Eq. [15b]. The methyl pyridines do not allow a test of the anomalies observed in Fig. 1 since the alkyl groups tend to donate electrons in resonance. However, an opportunity presents itself to note the effect of steric interactions in the vicinity of the nitrogen in the pyridine skeleton. Figure 2 shows a plot

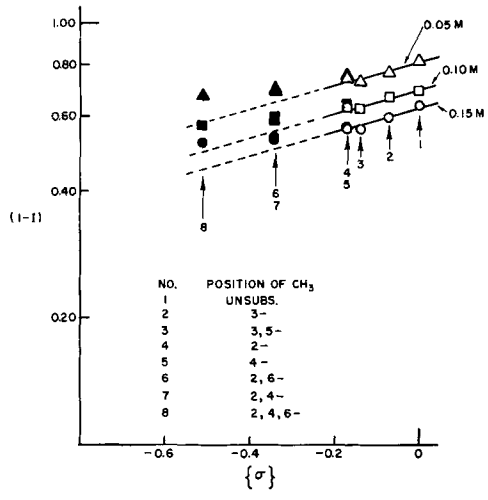

Fig. 2. Relative corrosivity of methyl-substituted pyridines (8) compared to Hammett-like substituent constants: open points should be collinear; filled points should not; position of the methyl group and concentration of the inhibitors are as shown.

of the data according to [15b]. For the 2-substituted pyridines, the Taft σ^* constant was used. The remainder of the σ's were the Hammett constants, and the σ's used for multiple substituents were the sum of the appropriate σ's. On the basis of the theory herein derived the open points, *i.e.*, those devoid of steric complications, should be collinear which indeed they seem to be. However, a single substitution in a 2-position fits the data just as well. The 2,4-disubstituted product shows a lesser deviation than that for the 2, 6-product and suggests that steric effects were really acting. However, the difference between the two corrosivities is not very great. Therefore, the observation made concerning the orientation of the molecules on alumina cannot be made in the inhibition work since the results are inconclusive. The qualitative correlation by Ayers and Hackerman between inhibition and ionization potential is in qualitative agreement with the approach developed in the present work since ionization potential and σ are qualitatively related.

A further test of theory is the fit of Eq. [17] shown in Fig. 3. Here five compounds which were included in the studies of both Snyder (18) and Ayers and Hackerman (8) may be examined. From the foregoing, three of the compounds (open symbols) should be collinear

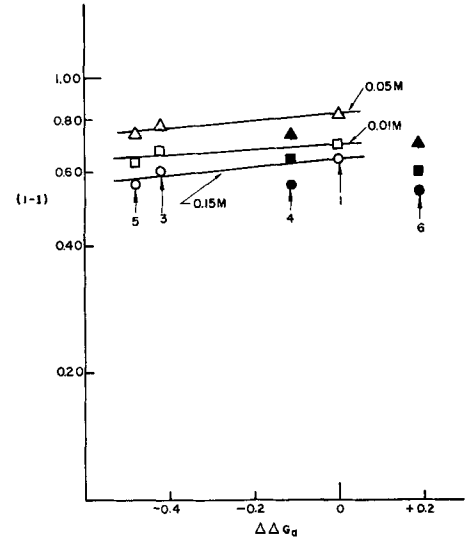

Fig. 3. Relative corrosivity data compared to adsorption measurements for substituted pyridines: open points should give a fit by Eq. [17]; filled points should not; concentrations of the inhibitors are as shown. For the identity of the compounds, see Fig. 2.

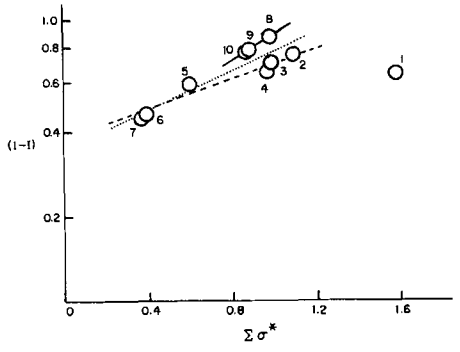

Fig. 4. Corrosivity of alkyl and alkyl-aryl amines (7) *vs.* Taft substituent constants: solid line joins alkyl amines; dashed line, alkyl-aryl amines. 1, aniline; 2, N-methyl aniline; 3, N-ethyl - -; 4, N-n-propyl - -; 5, N,N-dimethyl - -; 6, N,N-diethyl - -; 7, N,N-di-n-propyl - -; 8, methylamine; 9, ethylamine; 10, n-propylamine.

while the other two (filled symbols) should show varying degrees of deviation from the fit. The results substantiate the premise that direct comparison can be made between seemingly unrelated phenomena by an analysis based on LFER.

Alkyl and aryl-alkyl amines, *i.e.*, N-alkyl substituted anilines, have been studied by Kaesche and Hackerman (7). They have reported data on the maximum inhibition achieved by twelve such compounds. Figure 4 shows ten of these compounds plotted in terms of the sum of the Taft substituent constant (11). The other two, *viz.*, toluidines, were ring substituents and were not, therefore, amenable to the particular approach being used here. At the present level of sophistication it is not known whether the theory is actually applicable to the direct comparison of primary alkyl amines with secondary and tertiary alkyl-aryl amines (note the dotted line). Therefore, the internal correlations of alkyl amines (solid line) and the aryl-alkyl amines (dashed line) are shown as well. The lone point is that for aniline (a primary aryl amine) suggesting that substitution on the nitrogen changes the energetics of the adsorption process to such an extent that the internal correlations mentioned are probably a better representation of the fit. This conclusion derives from the observation that the removal of a methyl group from N-methylaniline causes a decrease in the corrosivity well below that predicted by the dashed-line correlation. This tends to suggest a steric interaction resulting on N-substituted anilines. In addition, the alkyl primary amines do not correlate at all with the aryl primary amine (aniline). From studies of amine-boron addition compounds, Taft has shown that secondary and tertiary amines have much larger steric strains than corresponding primary amines (23). Therefore, intuition suggests that the proximity of the primary alkyl amines to the aryl-alkyl amines is fortuitous and should not be taken seriously at this time. Indeed, the apparent fit of the secondary and tertiary amines may also be fortuitous.

The present analysis and the demonstration of its applicability has been somewhat hampered by insufficient data in the literature. Ring-substituted anilines have been studied both in terms of adsorption (18) and corrosion inhibition (24) quite extensively. Although a good correlation has been effected between oxidation potentials and Brown-Okamoto substituent constants (17), Snyder's "experimental" data for the adsorption of substituted anilines (18) were not as well behaved. Besides the -R groups which had failed to fit the simple theory (see above), the halo-substituents showed a nearly constant value of the free energy of adsorption independent of position or nature of the halogen. A comparison of the data of Every and Riggs (24) with that of Fox *et al.* (17) shows a displacement from the anticipated straight line (where oxidation potentials replace free energies of adsorption in Eq. [17]) for most of the halo-substituents. A similar trend is noted when the inhibition data (24) are plotted against the Hammett σ (assuming, that in the absence of substituent complications, [15b] is obeyed by such substituents as H, CH_3, and NH_2, which will be denoted as "inactive" substituents, *i.e.*, those which introduce no new resonance or inductive effects for substituted anilines). This is an area of investigation which is quite well suited to the Taft-Lewis treatment [see ref. (17) and the references therein] to discriminate between inductive and resonance contributions to electron density at a functional group. An extremely interesting group of compounds is the substituted benzenethiols which, although scarcely reported, show better inhibitive powers than the corresponding substituted anilines (24, 25). In addition, they have a ρ value of opposite sign from that of the anilines (26) suggesting a drastically different mechanism of inhibition and adsorption, as noted previously (25).

Summary

A theory has been advanced which now makes tractable the systematic study of the structure-inhibition relationships for organic compounds. The system is based on the electronic effects of substituents on the adsorption (reaction) center of an organic compound. A quantitative scale of values may be ascribed to substituents in terms of the appropriate Hammett-like substituent constant [see ref (9)-(11), (14)]. In addition, a correlation has been shown between adsorption measurements and corrosion inhibition through the substituent constant.

At present, the theory has had only token examination. It remains to ascertain the scope of the applicability by further, more detailed experimentation. For a complete analysis of a family of compounds [*e.g.*, see ref. (17)], meta and para-substituents must both be studied. In particular, "inactive" substituents, *e.g.*, alkyl groups, should be studied as well as cross-referencing, *i.e.*, if halogen substituents are used, then a number of experiments using halogen functional groups should be performed, etc.

Chemically Deposited Cobalt-Phosphorus Films for Magnetic Recording

Y. Moradzadeh

Systems Development Division, Development Laboratory,

International Business Machines Corporation, San Jose, California

ABSTRACT

Thin magnetic films of cobalt-phosphorus chemically deposited from a modified Brenner bath are reported in this paper. Detailed data are presented to demonstrate the role of deposition conditions on thickness, phosphorus content, and magnetic properties of the films. The films are much thinner than have been reported previously and exhibit a coercivity range of approximately 80 to 900 oe with a coercivity-thickness relation $H_c = At^{-2/5}$. This is similar to that reported by Fisher and Chilton for much thicker films. Some of the variables which control the magnetic properties of the deposited film are shown to be: film thickness, bath *p*H, hypophosphite concentration, and bath temperature; the first two are the dominant factors and overshadow any influence that the codeposited phosphorus may have. An account of the apparatus used for precise and automatic control of the bath *p*H is given. Well-adherent mirror-like films which are suited for conventional high-density magnetic recording, as well as Kerr magneto optical readouts, are obtained

Thin metallic films of cobalt-phosphorus, chemically deposited on the surface of a properly treated substrate, offer a wide range of controllable magnetic properties. These properties are suitable for conventional recording applications which require improved magnetic media (1). They are particularly suited for high-density recording due to their high coercivity and relative low film thickness. If the films are properly deposited on a glass substrate, they also provide a desirable medium for Kerr magneto-optical readouts (2).

The method of preparing cobalt-phosphorus film on Mylar, along with the influence of many variables on its magnetic properties, is described in this paper. The bath used in this investigation is similar to the one suggested by Brenner (3). Although Brenner reports the appearance of the deposit to be "dull," for this particular composition, very bright films are obtained by slight modification of this bath and also by depositing thinner films.

Pretreatment of the Mylar substrate is also simplified to a great extent from that reported by Fisher and Chilton (1), *i.e.*, no adhesive layer is applied to the Mylar surface. Although there is a good deal of agreement between this investigation and the work of Fisher and Chilton (1), it must be stressed that the bath composition used by them is somewhat different from the one reported here. In addition bath variables such as *p*H, temperature, and hypophosphite concentration are dealt with in greater detail. Furthermore, the deposited films are much thinner than those reported by Fisher and Chilton, hence resulting in higher obtainable coercivity ranges.

Experimental Procedures

Film preparation.—Mylar (du Pont type D) was used as the substrate throughout this investigation. The substrate was rendered hydrophilic by immersing it in a hot (95°C) solution of 25% NaOH which contained a few drops of a surface active agent (Tergitol 08, $C_4H_9CH(C_2H_5)CH_2SO_4Na$). After a 5-min immersion, the Mylar sample was rinsed with de-ionized water followed by a hot (80°C) rinsing in de-ionized water to remove all the sodium hydroxide. Alkali etching proved to be a desirable means of surface preparation; it not only created the necessary hydrophilic surface, but further increased the eventual cobalt-phosphorus film-to-Mylar adhesion without causing surface roughness. After the alkali treatment, the sample was immersed in an acidic solution of stannous chloride: $SnCl_2 \cdot 2H_2O$ (Mallinckrodt grade), 30g; HCl (concentrated), 50 ml; water (de-ionized), 1000 ml. Length of the immersion time was 30 sec. This process (sensitization) was followed by dipping the sample in hot de-ionized water (80°C) and immediately immersing for 30 sec in a palladium chloride bath having the following composition: $PdCl_2$ 0.1g; concentrated HCl, 10 ml; de-ionized water, 1000 ml.

The Mylar, thus treated, was then immersed in the deposition bath. The composition of the bath, unless otherwise indicated, was as follows

Cobalt chloride, $CoCl_2 \cdot 6H_2O = 27.1$ g/l

Sodium hypophosphite, $NaH_2PO_2 \cdot H_2O = 9$ g/l

Sodium citrate, $Na_3C_6H_5O_7 \cdot 2H_2O = 90$ g/l

Ammonium chloride, $NH_4Cl = 45.3$ g/l

Alkali for *p*H adjustment = NH_4OH

All of the materials were reagent grade. The bath temperature was kept constant to ±0.5°C; most of the experiments were conducted at 75°C, except when the temperature was a variable. The bath *p*H, as will be seen, played a critical role and therefore was controlled to within ±0.02 *p*H. Such control over the bath *p*H was made possible by using plating apparatus with

automatic pH recorder-controller. The pH of the bath is detected by an expanded-scale pH meter through a high-temperature glass and reference (AgCl, KCl) electrode. All the pH readings in this paper should be interpreted at the designated temperature. The pH meter was standardized with Beckman Buffer No. 14049 at 75°C. The pH of this buffer varies with temperature in the following manner;

Temperature, °C	pH
25	9.18
70	8.92
90	8.85

A decrease as small as 0.02 pH causes the controller to open the solenoid valve through a relay, permitting the release of enough ammonium hydroxide to readjust the pH to a preset level. This on-off pH-control process is monitored by a recorder. No thermal compensator is used since bath temperature is kept constant. The bath container is a conventional Pyrex reaction vessel; the lid is modified to hold in position the glass and reference electrodes, a thermometer, condenser, and a sample holder. It also provides entrance for ammonium hydroxide.

The bath was not agitated in this investigation. Bath volume was kept at 1100 cc; the size of the Mylar sample was 10 x 2 cm and 7.62 x 10^{-3} cm thick (3 mil). All water used for preparation and rinsing purposes was de-ionized, having a resistivity greater than 1 megohm-cm. Samples, thus prepared, were air dried and cut into ¼ x 2½ in. pieces for magnetic measurements, thickness measurements, and chemical analysis.

Magnetic measurements.—Samples (¼ x 2½ in.) were placed vertically into the center of the sensing coil of a 60-cycle B-H loop tracer having a maximum driving field of approximately 1400 oe. From the hysteresis loop displayed on the cathode ray tube of a Tektronix Type RM-503 oscilloscope, coercivity (H_c), squareness ratio (B_r/B_m), and retentivity (B_r) were calculated. Reproducibility of the coercivity readings is 1% for higher coercivities and 5% for lower coercivities (of the order of 100 oersteds).

Thickness measurements.—Two methods were applied: (*A*) determination of amount of cobalt and phosphorus by polarography and spectrophotometry, respectively. By assuming a bulk density of 8.9 and also surface uniformity, film thickness with 5% expected accuracy was obtained. (*B*) Standard two-beam interferometric method (4); the interference tester in conjunction with the "Reicharts Universal Camera Microscope MeF" was used; special masking and dissolution was applied to create a sharp step. The thickness measurement was reproduced to within ±0.5 μin. by this method.

Phosphorus analysis.—Phosphorus content was determined spectrophotometrically, using the heteropoly blue method (5). Total errors for phosphorus content was about 2%.

Experimental Results

Effect of deposition time.—The influence of deposition time on the film thickness is illustrated in Fig. 1, where an almost linear relation is observed. The slope is pH dependent. As will be seen later, this relationship is temperature and hypophosphite dependent also. The dependence of film coercivity on the deposition time is illustrated in Fig. 2. Here we see that film thickness (deposition time) has significant influence on the coercivity of the deposited film, particularly at higher pH ranges. A plot of log H_c *vs.* log thickness results in a straight line (Fig. 3) with a slope of 0.4. Hence, $H_c = At^{-2/5}$.

Another noteworthy influence of increased deposition time or film thickness is a decrease in the phosphorus content of the deposit (Fig. 4). It appears that a good portion of the phosphorus is codeposited in the initial stages of the reaction. The phosphorus content for the majority of the samples reported in this paper ranged up to about 4%.

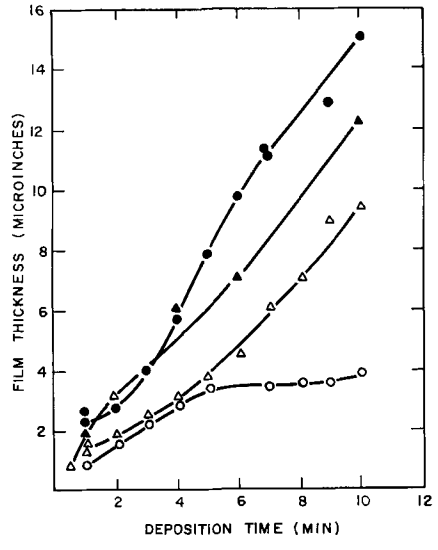

Fig. 1. Film thickness of cobalt-phosphorus *vs.* deposition time at various pH: ●, 8.42; △, 8.37; △, 8.20; ○, 7.66; bath temperature, 75°C.

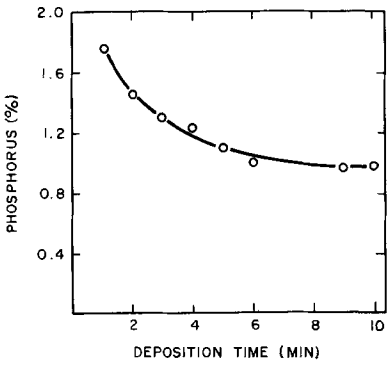

Fig. 4. Per cent phosphorus vs. deposition time for chemically deposited cobalt-phosphorus films; bath temperature, 75°C; pH, 8.42; thickness, 2.2-15 μin.

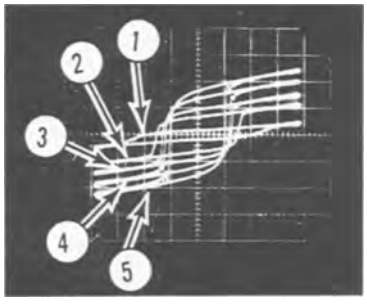

Fig. 5. Effect of deposition time at constant pH 8.2; temperature, 75°C: 1, 1 min; 2, 4 min; 3, 6 min; 4, 8 min; 5, 10 min.

The effect of deposition time on the shape of superimposed hysteresis loops is seen in Fig. 5 in which the decrease in H_c with simultaneous increase in B_m is observed. Squareness ratios ranging from 0.75 to 0.95, with B_r values from 7 to 10 kilogauss (also occasional higher and lower values) were observed.

Effect of bath pH.—Bath pH provides another significant tool in controlling the magnetic properties of cobalt-phosphorus films. Increasing the bath pH (in the alkaline range) increases the speed of deposition to a limit. This not only increases the thickness of the deposit, as seen in Fig. 6, but it apparently causes some structural changes which influence the magnetic properties. According to Fig. 6, a film thickness of 2 to about 14 μin. is obtained as the pH is varied from 7.7 to 8.3 at constant deposition time (10 min). The influence of pH on film coercivity is illustrated in Fig. 7.

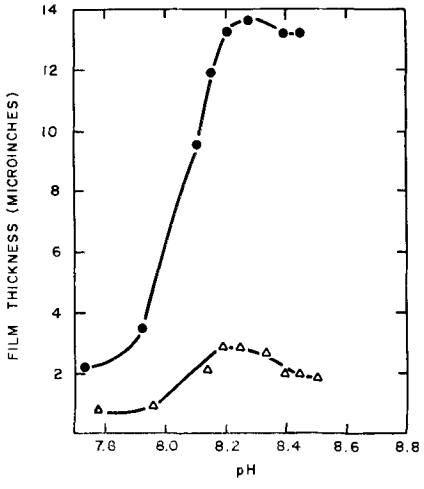

Fig. 6. Thickness of cobalt-phosphorus films vs. bath pH for various deposition times: ●, 10 min; △, 2 min; bath temperature, 75°C.

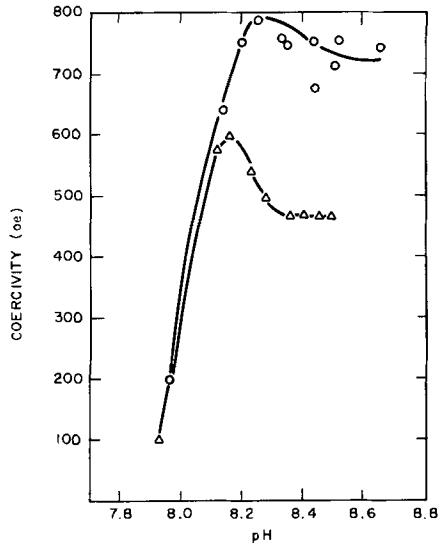

Fig. 7. Coercivity of cobalt-phosphorus films vs. bath pH for various deposition times: ○, 2 min; △, 10 min; bath temperature, 75°C.

Observe that as the pH increases there is a sudden initial increase in H_c, followed by a maximum and, finally, a reversal of the trend. This trend was also observed in Fig. 2, which is the result of a different set of experiments.

Table I helps to explain Fig. 7. The pH and thickness effects are separated in Table I, clearly demonstrating the H_c-pH dependence at constant film thicknesses of 2 and 4 μin. A gradual increase in pH causes sharp increases in coercivity, creating an order-of-magnitude increase in coercivity as the pH is increased by approximately 0.8. Therefore, the initial and sudden H_c increase of Fig. 7 is due solely to the increasing pH of the bath overshadowing the increasing thickness effect. The phosphorus content of the deposited film in general appears to decrease with increasing bath pH, as is illustrated in Table II.

The superimposed hysteresis loops pertaining to the pH effect are shown in Fig. 8. Note again the dominating effect of pH on coercivity in Fig. 8, where deposition time (film thickness) has been kept small. No definite correlation seems to exist between B_r and bath pH. The B_r/B_m does show a tendency to increase as the bath pH increases (see Fig. 9).

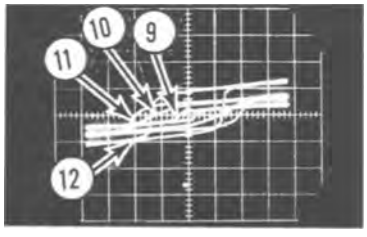

Fig. 8b. Effect of bath *p*H at 2-min deposition time: 9, *p*H 7.97; 10, 8.22; 11, 8.41; 12, 8.65.

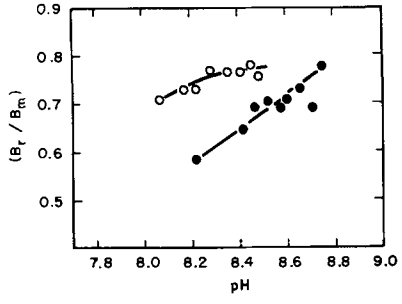

Fig. 9. Squareness ratio *vs.* bath *p*H for cobalt-phosphorus films: ●, 5 min; ○, 10 min; bath temperature 75°C.

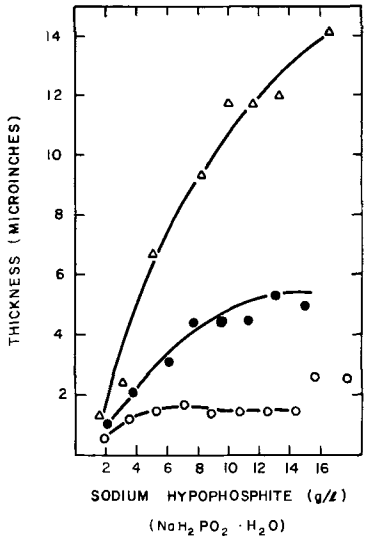

Fig. 10. Film thickness of cobalt-phosphorus *vs.* sodium hypophosphite: *p*H: △, 8.5; ●, 8.13; ○, 7.78; bath temperature, 75°C; deposition time, 5 min.

Effect of sodium hypophosphite.—Sodium hypophosphite is an essential component of the bath in that it reduces the cobalt ion to metallic cobalt.

Aside from its part as a reducing agent, sodium hypophosphite influences the speed of deposition. This effect is shown in Fig. 10, where deposition time and temperature were kept constant. Note that at a higher *p*H level (8.45) an increase in the sodium hypophosphite content of the bath from 2 to 14 g/l causes an increase of 12 μin. in the film thickness. Such an increase is less pronounced when the bath *p*H is kept at lower levels (7.78).

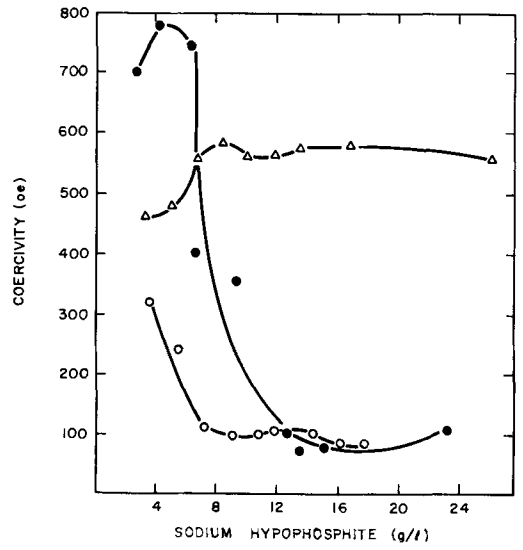

Fig. 11. Coercivity of cobalt-phosphorus films *vs.* sodium hypophosphite at various bath *p*H: △, 8.45; ●, 8.13; ○, 7.78; bath temperature, 75°C; deposition time, 5 min.

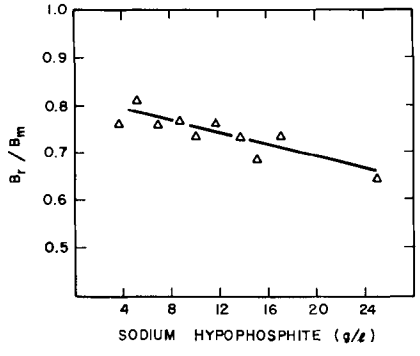

Fig. 12. Squareness ratio of cobalt-phosphorus film *vs.* sodium hypophosphite content of the bath: △, *p*H, 8.45; bath temperature, 75°C; deposition time, 5 min.

The influence of sodium hypophosphite content on the film coercivity is illustrated in Fig. 11. At low and moderate *p*H an increase in sodium hypophosphite causes a reduction in coercivity; at higher *p*H no sharp changes are observed. Fig. 11, in reality, represents three different effects: *p*H, film thickness, and sodium hypophosphite. The *p*H effect is separated from the other two by conducting three isolated experiments, keeping *p*H levels constant. Therefore, changes of film coercivity shown in Fig. 11 seem to be the result of an increase in the film thickness which is caused by sodium hypophosphite. Thus, the true influence of sodium hypophosphite is masked by the thickness effect.

Sodium hypophosphite content of the bath seems to have a negative influence on the B_r/B_m ratio of the deposition. In one particular case, as shown in Fig. 12, the B_r/B_m value drops from 0.8 to 0.65 as the sodium hypophosphite content is increased about 20 g/l.

Effect of bath temperature.—A strong dependency of film thickness and coercivity on bath temperature was observed as the bath temperature was changed from 70° to 95°C. Deposition took place at temperatures as low as 57°C, and, although this is a convenient temperature, the deposition rate is too slow for practical consideration.

The relation between bath temperature and film thickness is illustrated in Fig. 13 for two different *p*H levels. The amount of the deposit nearly doubles as

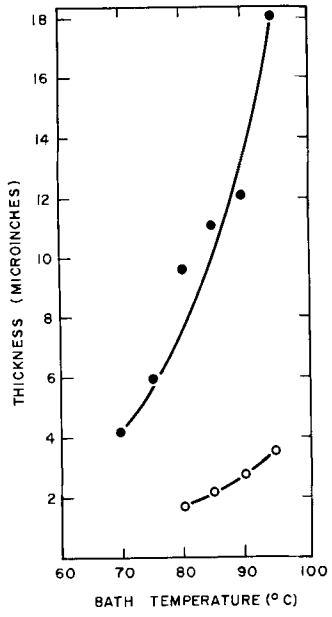

Fig. 13. Thickness of cobalt-phosphorus films *vs.* bath temperature; deposition time, 5 min; ○, *p*H 7.45; ●, *p*H 8.02.

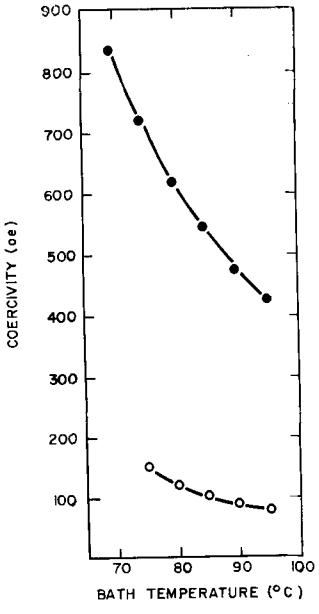

Fig. 14. Coercivity of cobalt-phosphorus deposition *vs.* bath temperature; deposition time, 5 min; ○, *p*H 7.45; ●, *p*H 8.02.

the temperature is increased from 70° to 80°C. As the temperature is raised to 95°C, film thickness increases to 18 μin. for a deposition time of 5 min. This tendency is *p*H dependent as is evident from Fig. 13.

The influence of bath temperature on the magnetic properties of deposition is illustrated in Fig. 14. A careful analysis of this figure shows that the reduction of H_c as a function of temperature is truly due to the increase in the film thickness which is caused by the increase in bath temperature (Fig. 13). Briefly, it appears to be the thickness which governs the coercivity rather than temperature. To demonstrate precisely the effect of the temperature, independent of film thickness, a new set of experiments is needed in which the thickness of the deposit is kept constant.

The magnitude of B_r/B_m for this series was within the range of 0.75-0.9; this range seems to be representative for most cobalt-phosphorus deposition.

Discussion

The pretreatment and posttreatment conditions play a significant part in the nature of the deposited film and its adhesion to the Mylar substrate. The alkali etching treatment proved to be much more satisfactory than a sodium dichromate-sulfuric acid treatment. The latter caused microscopic cracking of the substrate. The alkali etching approach suggested here should be a much more desirable method of rendering Mylar surface hydrophilic than the use of an adhesive as suggested by Fisher and Chilton (1). A more acidic sensitizer bath (compared to the activator bath) proved significant to a more uniform and consistent deposition. A few minutes heating cycle at 110°C after the deposition step causes a large increase in the adhesion value of Co-P to the Mylar surface.

The coercivity of the deposit which appears to be one of the most structure-sensitive characteristics, can be conveniently controlled by deposition time. Further control of coercivity, particularly for higher ranges, is achieved by the *p*H element or hypophosphite concentration.

The dependence of coercivity on film thickness is not new; it was first predicted by Néel (6) to be

$$H_c = At^{-4/3}$$

Fisher and Chilton (1) report a value of —1/3 for the exponent which agrees well with the empirical relation $H_c = At^{-2/5}$ reported in this paper. It should be noted, however, that the thickness-coercivity dependency can be overshadowed if other factors are not kept constant. Bath *p*H, for example, affects film coercivity noticeably even at the same film thicknesses (Table I); hence the above empirical relation is valid only when all other bath variables have been kept constant. It is very likely that the increase in bath alkalinity brings about some structural changes, as well as changes in the internal stresses, of the deposit; the latter is known to affect the coercivity of electro-deposited cobalt films (7).

The influence of phosphorus content on the magnetic property of the film is not clear. In one set of experiments, a linear increase in H_c as a function of per cent phosphorus was observed; however, the film thickness effect obscures any definite conclusion. In a second case, where *p*H is the main variable (Table II), a trend between per cent phosphorus and H_c is observed, which again is overshadowed by strong H_c-*p*H dependency. There is a need for more intensive investigation to determine the true influence of codeposited phosphorus.

The effect of hypophosphite is noticeable at low and moderate *p*H; bath temperature provides another tool for controlling the thickness, hence affecting the coercivity. In order to produce a film with desired film thickness and coercivity the four major factors, *i.e.*, deposition time, bath *p*H, temperature, and hypophosphite concentration, must be taken into consideration simultaneously.

Although the B_r/B_m ratio is not as sensitive to various changes it does increase with increasing film thickness and bath *p*H. Sodium hypophosphite, on the other hand, seems to have a decreasing effect on B_r/B_m.

The B_r values for the majority of the experiments remained between 7 to 10 kilogauss with occasional lower and higher values.

In conclusion the results of the study have served to provide the means for preparing thin, optically reflective magnetic recording media with a wide range of magnetic properties. These properties are suited particularly for high-density magnetic recording and Kerr magneto-optical readout.

Acknowledgments

The author wishes to acknowledge Mr. E. B. Moore, R. J. Cappell, and Dr. I. Barlow for their excellent assistance in thickness measurements, chemical analysis, and x-ray work, respectively. Thanks are also due to Dr.

J. T. Smith, and Mr. O. Kornei for their continued interest in this work, to Mr. N. Erez for his assistance in performing the experiments, to Mr. F. Stryker for earlier help in the substrate etching, and to Dr. J. R. Werning, Dr. G. Bate, and Mr. J. Judge for their comments in reviewing this paper.

Manuscript received Dec. 21, 1964; revised manuscript received May 19, 1965. (Work completed in 1962.)

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

Determination of the Density and Dielectric Constant of Thin Ta_2O_5 Films

Julius Klerer

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

The density of anodically formed Ta_2O_5 thin films on sputtered tantalum has been measured *in situ*. The method used is the measurement of the average density of the assemblage tantalum-tantalum oxide and subsequent separation of the contributions of each component to this measured density. From a knowledge of the stoichiometry of the reaction, both the thickness and the angstrom per volt values (thickness of oxide formed per volt) can be determined for the oxide. Application of the capacitance formula for a parallel-plate capacitor leads to a value for ϵ. The values obtained are: Density; 8.00 g/cm^3 ± 2.4%; anodization constant, 16.0Å/v ±3.2%; dielectric constant, 21 ± 3.3% at 1 kcps.

The use of anodic Ta_2O_5 films for capacitor fabrication can be aided by a precise knowledge of the density and dielectric constant of these films. Reported densities have ranged from 7.93 g/cm^3 (1) to 8.74 g/cm^3 (2), and dielectric constant values reported range from 22 to 27.6 (3). Most of the values of these constants have been obtained from bulk oxides or from anodized tantalum foil.

This study represents an attempt to determine these values for the oxide anodically formed on sputtered tantalum. The density of the oxide is measured *in situ* by an independent method. From this value of density, the thickness of the film is obtained by a determination of the anodization constant (Å/v). The dielectric constant can then be evaluated by application of the ordinary formula for capacity.

Theoretical

Density.—The average density of the assemblage, tantalum-tantalum oxide can be defined as

$$D = \frac{\overline{M}}{\overline{V}} \qquad [1]$$

where $\overline{M}$ is total mass and $\overline{V}$ total volume.
Now by definition

$\overline{M}$ = mass of tantalum remaining (m_{Ta}) after anodization + mass of oxide formed during (m_o) anodization

$\overline{V}$ = volume of tantalum (v_{Ta}) after anodization + volume of oxide (v_o) formed during anodization.

The average density can then be redefined as

$$\overline{D} = \frac{m_{Ta} + m_o}{v_{Ta} + v_o}$$

By definition

$$V_{Ta} = \frac{m_{Ta}}{d_{Ta}};\ v_o = \frac{m_o}{d_o}$$

where d_{Ta} is the density of tantalum and d_o the density of tantalum pentoxide. Substituting for v_{Ta} and v_o and rearranging the equation to solve for d_o produces the expression

$$d_o = \frac{\overline{D} d_{Ta} m_o}{d_{Ta}(m_{Ta} + m_o) - D m_{Ta}} \qquad [2]$$

During the anodization process, two moles of tantalum are required for each mole of Ta_2O_5 formed. In order that stoichiometry be preserved, the mass of tantalum consumed (Δm_{Ta}) to form m_o grams of Ta_2O_5 is

$$\Delta m_{Ta} = m_o \frac{2M_{Ta}}{M_{Ta_2O_5}}$$

where M_{Ta} equals the atomic weight of tantalum and $M_{Ta_2O_5}$ equals the molecular weight of tantalum pentoxide. Thus, the original mass (P) of the tantalum before anodization is

$$P = m_{Ta} + m_o \cdot \frac{2M_{Ta}}{M_{Ta_2O_5}} \qquad [3]$$

By a previous definition

$$\overline{M} = m_{Ta} + m_o \qquad [4]$$

Solving Eq. [3] and [4] for m_o and m_{Ta} and placing the values of the atomic weight of tantalum and the molecular weight of Ta_2O_5 in the equations results in the following

$$m_o = 5.524\ \Delta M \qquad [5]$$

$$m_{Ta} = \overline{M} - 5.524\ \Delta M \qquad [6]$$

where $\Delta M = \overline{M} - P$

Combining Eq. [5], [6], and [2], a final working equation is obtained

$$d_o = \frac{5.524 \overline{D} d_{Ta} \Delta M}{M(d_{Ta} - D) + 5.524 D \Delta M} \qquad [7]$$

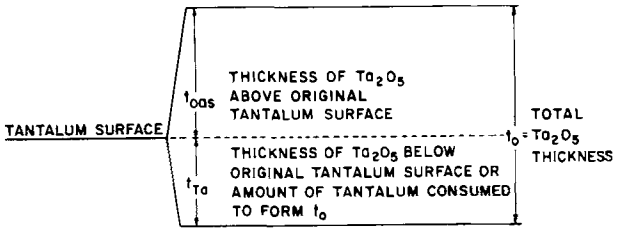

Fig. 1. Schematic structure of oxide film growth by anodization

All of the quantities on the right-hand side of this equation can be determined experimentally. The density of tantalum is taken as 16.6 g/cm³ (7).

Determination of the anodization constant.—As tantalum is anodized, the oxide grows above and below the original surface of the tantalum to give rise to the schematic structure shown in Fig. 1 where the volume of the oxide is greater than the volume of the metal displaced.

By definition

$$t_o = t_{oas} + t_{Ta} \qquad [8]$$

and assuming, for the moment, that the thickness is proportional to the applied field

$$t_o = k_1 V \qquad [8a]$$

$$t_{oas} = k_2 V \qquad [8b]$$

$$t_{Ta} = k_3 V \qquad [8c]$$

where V is the voltage applied and k the respective anodization constants. The t_{Ta} consumed to form t_o can be related by the ratio of densities

$$\frac{t_{Ta}}{t_o} = \frac{(2)\ (M_{Ta})\ (d_o)}{(M_{Ta_2O_5})\ (d_{Ta})} = B$$

or

$$t_{Ta} = Bt_o \qquad [9]$$

Substituting Eq. [9] into Eq. [8] and rearranging

$$t_o = \frac{t_{oas}}{(1 - B)} \qquad [10]$$

Eq. [8a], [8b], and [10] produce

$$k_1 = \frac{k_2}{1 - B} \qquad [11]$$

From Eq. [8b], a plot of t_{oas} *vs.* the applied voltage, V, yields a straight line whose slope equals k_2. Placing this value of k_2 in Eq. [11] determines k_1 and since $k_1 = k_2 + k_3$, the value of k_3 is likewise determined. The constant B is dependent on the determination of the density of the Ta_2O_5.

Determination of the dielectric constant of Ta_2O_5.—The capacitance of a parallel plate capacitor is defined as

$$C = \frac{0.0885A\epsilon}{t_o} \qquad [12]$$

where ϵ is the dielectric constant, A the area (cm²), t_o the thickness (cm), and C the capacitance (pf).

The thickness, t_o of the Ta_2O_5 film formed is proportional to the anodization voltage from Eq. [8a] and substituting into Eq. [12] produces

$$C = \frac{0.0885\epsilon A}{k_1 V}$$

If C is plotted as a function of $1/V$, a straight line is obtained with the slope $= (0.0885\epsilon A)/k_1$. On rearrangement

$$\epsilon = \frac{(\text{slope})\ (k_1)}{0.0885A} \qquad [13]$$

The value of the dielectric constant rests on the determination of k_1 from the previous section. The geometrical area can be measured directly.

Experimental

The tantalum utilized was sputtered through a mask to define a definite area onto Corning No. 7059 1 x 3 in. glass slides. The cathode was separated a distance of 5.25 cm from the work. At an argon pressure of 20 x 10^{-3} Torr and a potential of 4 kv, the current density was maintained at 0.35 ma/cm². The deposition rate was approximately 110 Å/min. Anodization of these slides was carried out at room temperature in aqueous 0.01% citric acid solution as follows: The current was maintained at a current density of 1 ma/cm² until the desired constant voltage was attained. Anodization was continued at the desired formation voltage for an additional hour. Capacitors were fabricated by the vacuum evaporation of gold counterelectrodes, the other contact being the underlying tantalum.

Weighing of the slides was performed on a Mettler type M5 Microbalance with a precision of ± 0.001 mg. Area determinations both for counterelectrode area and the area involved in the volume determinations were made with the Nikon Model 6 Shadowgraph with a precision of ± 0.001 cm².

Density determination.—Table I contains a summary of the data utilized for the density determination. $\bar{D}$ is obtained from the weight of the tantalum and tantalum oxide after anodization ($\bar{M}$) and measurement of the volume ($\bar{V}$) of the tantalum and tantalum oxide. The geometrical area is defined by the masked sputtered area and the thickness was obtained by Talysurf[1] measurements of the height of the tantalum and tantalum oxide. The use of the Talysurf measurements is more clearly illustrated in the next section.

$\bar{D}$ can be used as a measure of the ratio of tantalum to tantalum oxide. In order to vary this ratio, the formation voltage was changed to detect any influence upon the sensitivity of the method used for the density determination. The low value obtained for d_o for slide 2 in Table I is attributed to its being chipped during anodization. The density values obtained were computed using Eq. [7] and an average density and average error were calculated to be 8.00 g/cm³ ± 2.4%.

Determination of the anodization constant.—Figure 2 is a plot of the height of the oxide above the original tantalum surface (t_{oas}) as a function of the voltage. The height was determined by Talysurf measurements and the curve fitted by the method of least squares. The slope was computed to be 9.67 Å/v with a probable error of ± 2.2%

[1] Taylor-Hobson Ltd. Model 3 Talysurf with a straight line datum attachment.

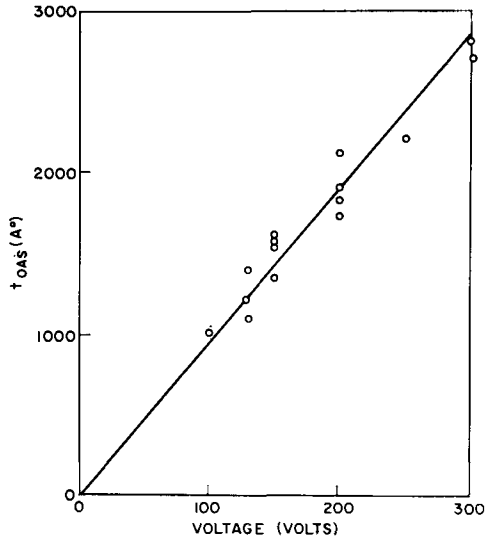

Fig. 2. Height of tantalum oxide film above original tantalum surface (t_{oas}) as a function of voltage; slope equals 9.67 Å/v.

Utilizing the formulas [8] to [11], the following values were determined

$$t_{Ta} = 0.3948\, t_{oxide}$$

Anodization constant (k_1)
= 16.0 Å/v ± 3.2% for Ta_2O_5

Anodization constant (k_3)
= 6.3 Å/v ± 3.2% for tantalum

Determination of the dielectric constant.—Sputtered tantalum slides were anodized as previously described to voltages between 100 and 300v and gold counterelectrodes were vacuum evaporated and the capacitance measured at 1 kc on a parallel capacitance bridge with a maximum error of ±0.5%. Figure 3 shows the curve obtained by plotting capacitance *vs.* reciprocal voltage. Each point represents the average of approximately 90 capacitors at each voltage. The curve was fitted by the method of least squares and the slope calculated to be 1.40 x 10^6 with a probable error of ±0.2%. From this value, the value of k_1, (16.0 Å/v) and the measured counterelectrode area (0.121 cm^2) the dielectric constant was calculated by application of Eq. [13]. The

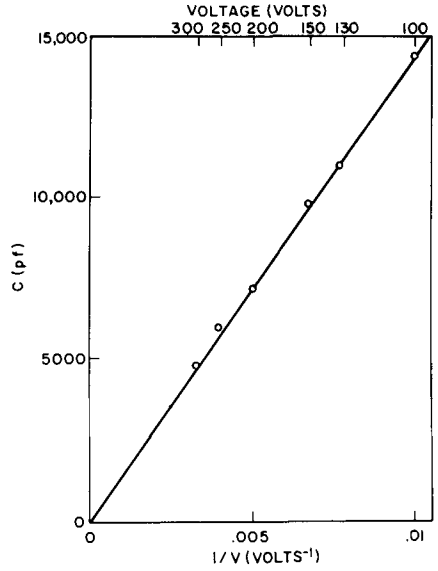

Fig. 3. Capacitance of tantalum oxide films as a function of voltage^{-1}; slope equals 1.40x10^6.

dielectric constant determined was ϵ = 21.2 with a maximum error of 3.3%.

Discussion

The determination of the density, anodization constants, and dielectric constant presented in this work, as well as in other papers to be cited, rests on the validity of several assumptions. One is that the density of the sputtered tantalum film is known and is constant throughout the film. Foreign gases in the field should change the density as has been shown in gas doping experiments (9).

The films utilized in this work were sputtered with no known addition of foreign gas. Talysurf measurements of the thickness of some of these sputtered tantalum films, combined with the geometrical area and weight, resulted in values of density of 16.5 g/cm^3. This agrees closely with reported values for bulk density, 16.6 g/cm^3. Resistivity measurements of the films used in this work also indicate that the tantalum was comparable to that normally obtained by sputtering. The question as to whether the resistivity of the tantalum as a function of thickness remains constant throughout the film is still debatable. It is believed, in general, that there is a graduation in resistivity in the sputtered tantalum film, particularly if a shutter is not utilized for presputtering. This gradation in resistivity has not, as yet, been shown to affect the density of the tantalum.

Another assumption is that the anodization reaction is 100% efficient. This has been confirmed by Vermilyea (6) and Young (3). Basic to this determination is the fact that the oxide formed is Ta_2O_5 and that the oxide is stoichiometric. These conditions appear to be realized within the limits of experimental error. In the present case, the determination of the density of the oxide did not seem to depend on the ratio of oxide to tantalum thickness nor on the resistivity of the tantalum, again implying that the density of the oxide was constant throughout and that stoichiometry was preserved.

The density of bulk Ta_2O_5 is reported to be 8.74 g/cm^3 in the Handbook of Chemistry and Physics (1). Reisman *et al.* report the density of the low-temperature crystalline form as 8.18 g/cm^3 and that of the high-temperature form to be 8.37 g/cm^3 (4). King *et al.* determined densities of 8.41 g/cm^3 and 8.63 g/cm^3 for the low- and high-temperature forms, respectively (5). All of the above values have been determined from bulk tantalum pentoxide, and it might be expected that these values would differ from the density obtained for a thin film of Ta_2O_5 on sputtered tantalum.

Young (1) determined the density of thin anodic films of Ta_2O_5 formed in 1% H_2SO_4 on chemically polished foil by the Archemedian displacement method to be 7.93 g/cm^3 ± 3%. This agrees closely with the present determination of a density of 8.00 + 2.4% for anodically formed Ta_2O_5 on sputtered tantalum. The validity of the newly proposed measurement technique devised is also supported.

This measurement technique requires that a large number of samples be used since the average surface area for the individual sample is ≅ 15 cm^2. The maximum error expected from a consideration of the probable errors in the variables was of the order of 4%. However, careful technique and probable cancellation of some of the expected errors occurs leading to the average error obtained. The reproducibility of the individual determination is low, as can be seen in Table I.

In contrast is the determination of the density of the oxide formed on sintered tantalum anode sets with a combined surface area of ~ 1600 cm^2 by the utilization of only three separate samples (7). A greater accuracy was expected and reported. The values obtained for the density were 8.039 ± 0.005 g/cm^3 for films formed in 0.01% HNO_3; 7.87 ± 0.01 g/cm^3 for films formed in 50% H_2SO_4; and 8.03 ± 0.04 g/cm^3

for films formed in 0.1% H_3PO_4. The accuracy of these values in leading to the speculation that the forming electrolyte has an influence on the density merits further confirmation. A more important point to be gathered from this study and the other determinations of density is that the oxide anodically formed on sintered tantalum, tantalum foil, and sputtered tantalum has essentially the same density.

Vermilyea (6) computed the anodization constant for Ta_2O_5 films on tantalum foil to be 14.95 Å/v using weight measurements and 15.27 Å/v using Faraday's law. The thickness of the oxide was measured by a calibrated color step gauge, and the density value for Ta_2O_5 was assumed to be 8.74 g/cm^3. If the density value determined in this work is used to recalculate Vermilyea's results, the anodization constant for Ta_2O_5 becomes 16.29 Å/v and 16.64 Å/v, respectively. This is to be compared with the value obtained experimentally in this work, 16.0 Å/v for the oxide. Vermilyea anodized his films in 1% Na_2SO_4 at an initial current density of 2 ma/cm^2 and held them at constant voltage until a current density of 0.1 ma/cm^2 was reached.

Patterson and White (8) using ellipsometric techniques determined the anodization constant of the oxide to be 14.1 Å/v for sputtered tantalum films on glass substrates and 16.6 Å/v on glazed alumina. The anodization was carried out in a phosphoric acid, water, and ethylene glycol solution. The voltage was raised at a rate of 2 v/min to a constant voltage and held till a current of 25 μma was reached. The difference in anodization constant on the two substrates was attributed to either a "secondary substrate" effect influencing the tantalum surface or to differences in the tantalum film, since separate sputtering runs were used for each substrate.

All of the values obtained correspond closely. The difference that might be present can possibly be attributed to the anodization techniques and/or film quality. The techniques used in this work measures gross effects and are not as dependent on the uniformity of the film. The measurements reported in the present work have only the error involved in the individual Talysurf measurements which appear to be small when the data has been compensated for in the least squares determination of the curve of t_{oas} *vs.* voltage.

The value of 21.2 at 1 kcps obtained for the dielectric constant is lower than has been reported. Young (9) reports values of dielectric constant from 23 to 25 for tantalum oxide anodically formed on tantalum foil previous to his own determination which is 27.6 ± 5% at 1 kcps (2). The differences in the dielectric constant might be attributable to the type of tantalum utilized and/or the anodization conditions utilized. The point has been made that electrolyte species can be incorporated into the growing oxide (7), and quite possibly an influence on the dielectric constant might be expected.

Conclusions and Summary

In this study, the sputtered tantalum used has been assumed to be as pure as can be produced at the present state of the art. The homogeneity of the oxide appears to be such that the validity of the determined density can be used with assurance. The derived values of the other constants, within error, appear to be valid. The theoretical derivations and the techniques utilized have been justified and can be used as a general technique for the study of the growth of oxide films. The limitation of these techniques lies in the fact that the stoichiometry of the oxide formed must be known.

In summary, the values obtained from this study are

$$d_o = 8.00 \pm 2.4\%$$
$$t_{Ta} = 0.3948\, t_{oxide}$$
Anodization constant (Ta_2O_5) = 16.0 Å/v ± 3.2%
Anodization constant (Ta) = 6.3 Å/v ± 3.2%
Dielectric constant (Ta_2O_5) = 21.2 ± 3.3%

Acknowledgment

The assistance of Miss Dolores Farrell in some of these experiments and the Talysurf measurements of the film thicknesses by R. Brown are greatly appreciated.

Inversion of Oxidized Silicon Surfaces by Alkali Metals

J. R. Mathews, W. A. Griffin, and K. H. Olson

Bell Telephone Laboratories, Incorporated, Laureldale, Pennsylvania

ABSTRACT

The effects of alkali-metals on the behavior of the oxide protected silicon surfaces has been investigated using a p-n structure. Examination of diode characteristics and photoresponses on controlled samples revealed the manner of alkali-metal electrolysis through the oxide and the formation of donor-type surface states at the $Si-SiO_2$ interface.

Investigations have been performed to determine the effects of alkali-metals on oxide protected semiconductor surfaces. The emission of glass modifiers, among them the alkalies, has been observed from glass to metal seals in semiconductor device packages (1). Since the use of such seals is a widespread practice in the semiconductor industry, knowledge of the behavior of alkalies and their effects on semiconductor surfaces is of importance. Figures 1 and 2 illustrate the degradation of aging stability and radiation resistance caused by alkali contamination of diodes. The figures represent data from diodes sealed in miniature glass packages

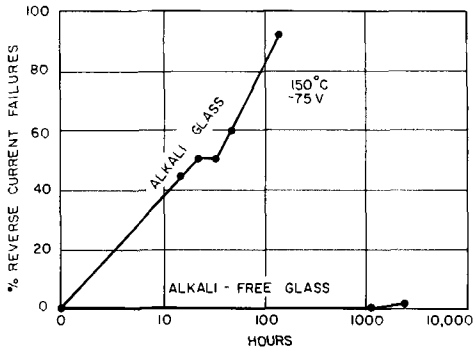

Fig. 1. Temperature-reverse voltage aging data

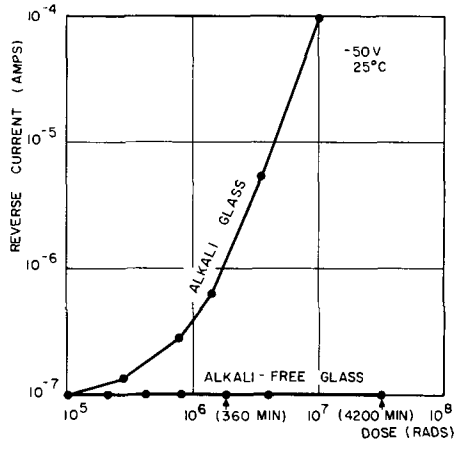

Fig. 2. Gamma irradiation-reverse voltage aging data

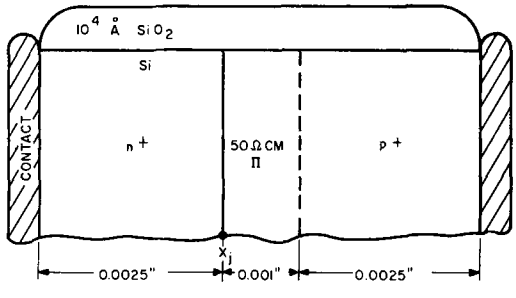

Fig. 3. Test wafer used during the investigation

using both alkali-containing and alkali-free glass cylinders.

Experimentation and Results

The structure used in the investigation was a silicon pπn diode with a high-pressure steam-grown SiO_2 protective film shown in Fig. 3. The gold-doped chip was 23 mils square with a 50 ohm-cm π layer. The encapsulation used as a source for alkali-metal contamination in some of the experimentation was the simple cylindrical structure shown in Fig. 4. Contamination of unpackaged device structures was obtained using the apparatus of Fig. 5. With the devices at room temperature, the metallic sodium was heated with a burner, and a small amount of O_2 was introduced. This procedure deposited a very fine sodium peroxide dust on the wafers down stream.

Surface effects on the contaminated devices were observed after the following treatments: (i) heating the devices for a few seconds in the range 600° to 700°C and above; (ii) reverse biasing the devices at temperatures between 100° and 200°C for times as short as a few hours; (iii) Irradiating the devices with gamma rays at room temperature with reverse bias for dosages as low as 2×10^5 rads.

When heated above the range 600°-700°C the contaminated devices became unstable and ambient sensitive. When reverse biased either at elevated temperature or under irradiation the devices exhibited characteristics of the types shown in Fig. 6. Excess reverse currents ranged from a few hundred nanoamperes to several milliamperes. Those devices whose excess reverse current began at zero bias were designated A. Those which exhibited no excess current below some threshold voltage were designated B. The threshold voltage of B devices was always less than the aging reverse bias. Double, occasional triple B, and combinations of A and B devices were observed.

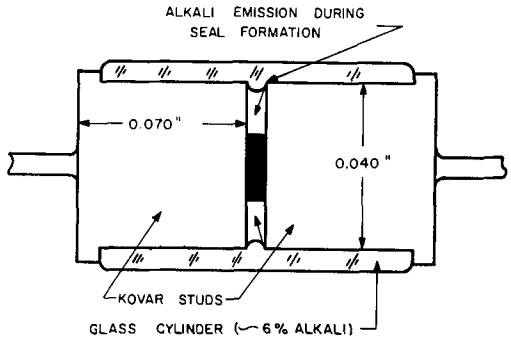

Fig. 4. Encapsulation used as the contamination source

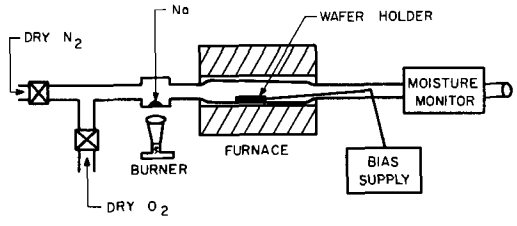

Fig. 5. Sodium contamination apparatus

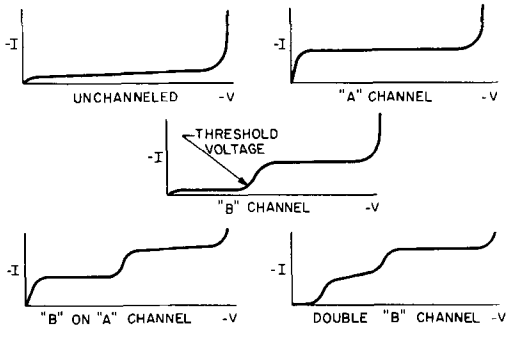

Fig. 6. Typical inverted diode characteristics

Reverse characteristics of these types are normally called channels and are associated with surface inversion. Etching and light-probe measurements were performed to determine the extent and nature of the inverted region. The protective oxide on inverted devices was etched in stages to determine the location of the surface states in the oxide. Device excess currents disappeared only when the last of the oxide had been removed.

The photoresponses were measured on devices which exhibited the various V-I characteristics shown in Fig. 7 and 8. By comparison with the uncontaminated diode, it can be seen in Fig. 7 that the B diode exhibited no excess reverse current below a voltage of about 25v. Above 25v a positive curvature exists and then the typical reverse characteristic of a channeled diode. Diodes b and d exhibited excess current starting at zero voltage as can be seen from the low-voltage insert. Notice that curve d exhibited the characteristic positive curvature of a B diode at low voltages. Those devices which exhibited excess reverse current starting at zero voltage also exhibited excess forward current as shown in Fig. 8, whereas the threshold voltage devices did not.

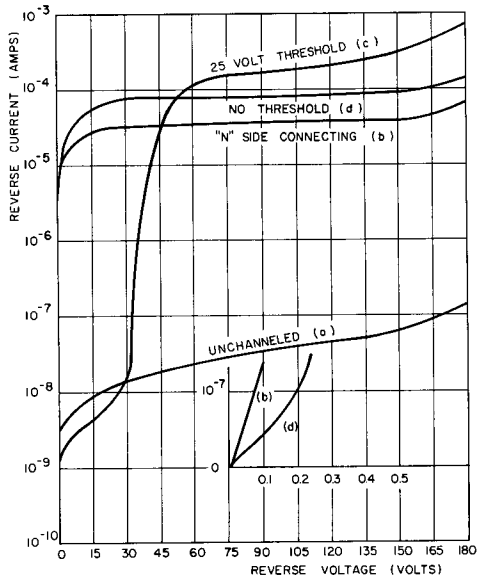

Fig. 7. Reverse characteristics

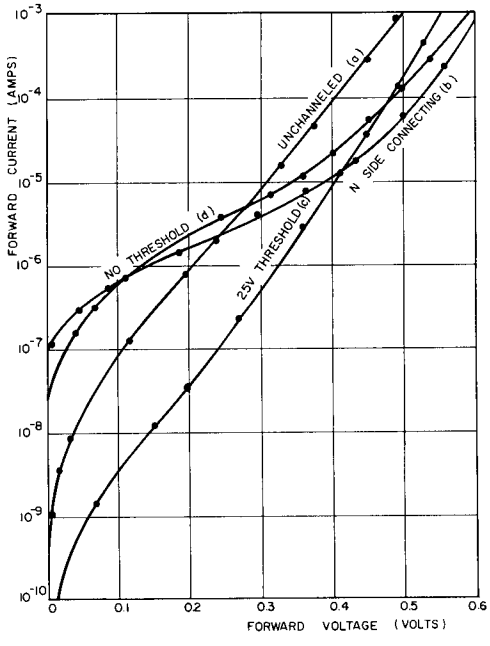

Fig. 8. Forward characteristics

A metallurgical microscope and a battery-operated electrometer were used for the photoresponse measurements. An aperture was mounted in a holder which fitted in the illuminator filter slot such that it was located at the objective image plane. This way both the sample and the light spot were in focus simultaneously. The spot size obtained with a 50μ aperture was approximately 8μ. Since the π layer width was approximately 30μ, the 8μ spot was sufficient to give adequate detail.

The photoresponse curves corresponding to the devices of Fig. 7 are shown in Fig. 9. The predominant characteristics of these curves are:

1. Diode b did not exhibit the large photoresponse peak at the p-n junction.
2. The peak in diode d was significantly smaller than the peak of diode a or c.
3. Diodes b, c, and d, exhibited a plateau in the photo response over the π layer.
4. No plateau existed in the noninverted device.

Inversion of the device π region after contamination from the glass-metal seal under conditions of elevated

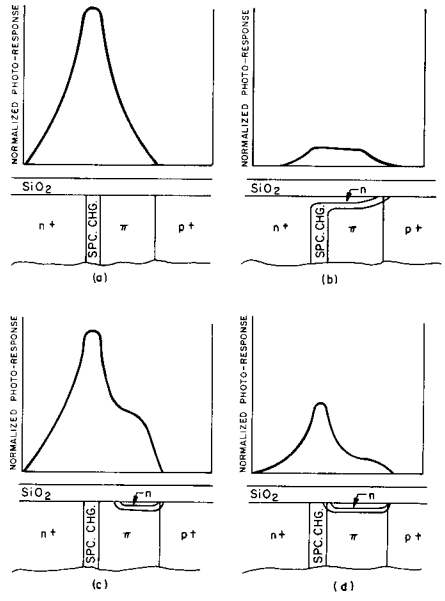

Fig. 9. Photoresponse of inverted diodes

temperature and reverse bias was observed to be delayed by more than an order of magnitude in time when a thin film of P_2O_5 or B_2O_3 glass was deposited over the SiO_2 protective film.

Discussion

The degrading effects of alkali metal contamination on oxide protected devices can be explained by two processes:

1. At temperatures in the range 600°-700°C and above, the alkali metals react visibly with the protective SiO_2 to form regions of alkali glass and devitrification. On cooling, differences in expansion coefficients cause cracking around the reacted area (1).
2. When alkali-metal contamination of the SiO_2 occurs at temperatures below approximately 600°C no visible reaction occurs. However, under conditions of either temperature or irradiation with reverse bias, electrolysis of the alkalies through the protective SiO_2 film occurs.

A model of this latter process for the pπn structure can be proposed with the aid of Fig. 10. Alkali ions are electrolyzed from the oxide surface to the interface along the fringing field lines and are deposited on the π side immediately adjacent to the expanded p-n junction depletion layer. They can then migrate down the interface covering the π region. As the inversion layer grows to the right, it accepts a portion of the diode bias depriving the junction depletion region of that voltage and causing it to recede near the surface. Actually, the depletion region in the vicinity of the p-n junction depletion-layer edge may remain the same, but the portion which is supported by the p-n junction recedes while the portion supported by the increased (positive) ionized charge-density of the surface states expands. The charge in the depletion region to the right of line a-a in Fig. 10 is compensated by the ionized surface donor states, that portion to the left is compensated by the ionized bulk donors of the p-n junction. The result is the establishment of short electric field lines to the left, as illustrated in Fig. 10. In this way the inversion layer can grow to the left, and the distance grown to the left will depend, for the most part, on the π layer resistivity and width, the alkali concentration, and electrolysis and migration rates.

When the diode is removed from the aging conditions, the p-n junction depletion layer recedes to its zero bias width. It may leave behind a noninverted region of the π layer surface (see Fig. 11). On reapplication of reverse bias, no excess current will flow until

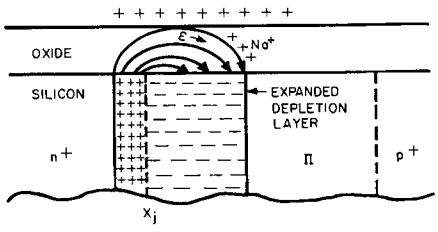

Fig. 10. Schematic representation of initiation and growth of an inversion layer by the process of alkali electrolysis: 10a. Initial stage of electrolysis.

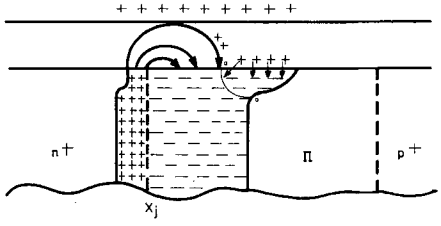

Fig. 10b. Initial stage of surface depletion

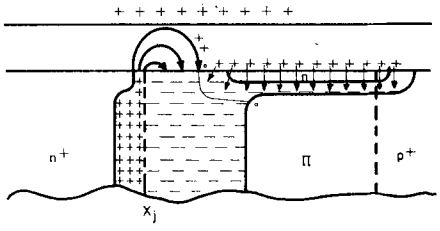

Fig. 10c. Final stage of surface inversion

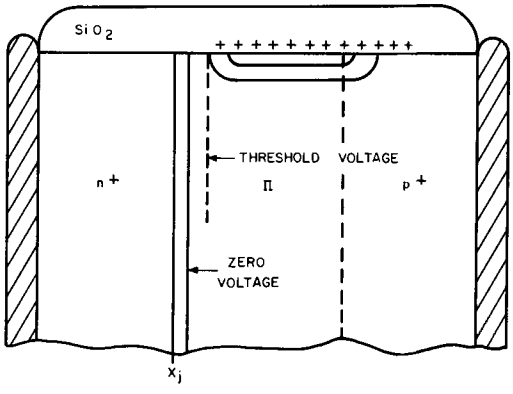

Fig. 11. "B" inversion layer geometry

a threshold voltage where the depletion region contacts the channel completing a current path. There is no reason to expect the noninverted π layer width to be uniform around the wafer perimeter. If the expanding depletion layer contacts the inversion layer in two isolated positions at different voltages, a double B characteristic would result. It is easy to see from this model how triple B and combinations of A and B devices could be created.

This surface inversion process explains why the device threshold voltages were always below the aging voltage and why the B devices exhibited no excess current in the forward direction. The device of curve d in Fig. 7 and 8 was one in which the inversion layer had grown sufficiently close to the p-n junction that it contacted the p-n junction depletion layer at zero reverse voltage but did not extend all the way to the p-n junction. Hence the model predicts that this device should be expected to exhibit the observed positive curvature at very low reverse voltages, and excess current at low forward voltages. Device b in Fig. 7 and 8 possessed an inversion layer which had contacted the metallurgical p-n junction thus creating a connection between the inversion layer and the diode's n side. This device should not be expected to exhibit positive curvature at low reverse voltage but should possess excess current at low forward voltage. Device c, the threshold device, possesses an inversion layer which does not contact the p-n junction depletion layer at zero bias and should not, therefore, possess excess current in the forward characteristic.

The photoresponse curves of Fig. 9 clearly reveal the inversion layer geometries of the various devices. The plateau in the photoresponses of all except the noninverted device locates the inversion layer on the π layer surface. The existence of the large photo-voltage peak in devices a, c, and d reveal the emergence of the p-n junction depletion layer at the surface, indicating that the inversion region did not connect with the diode's n side isolating the junction depletion layer from the surface as occurred with device b which shows no photo-voltage peak. Partial isolation of the junction depletion layer is indicated by the subdued peak in the photo response of diode d.

Electrolysis of the alkalies through the SiO_2 film is indicated by the resulting inversion layer geometries and the fact that the surface states were located at the Si-oxide interface as revealed by successively etching the oxide.

By depositing a thin film of P_2O_5 or B_2O_3 glass over the SiO_2 layer, the rate of inversion layer formation was drastically reduced. Extensive measurements were not performed on this system. The explanation, at present, appears to be a low alkali electrolysis rate in the P_2O_5 and B_2O_3 films.

Conclusion

Surface degradation of semiconductor devices from alkali-metal contamination is of importance in the semiconductor industry since glasses containing alkalies are used for surface passivation and for insulators in device packages where direct seals are made to metal parts.

Degradation of oxide protected alkali-metal contaminated pπn diodes can be attributed to:

1. Formation of alkali-glass and devitrification regions in the oxide at temperatures in the range 600°-700°C and above with subsequent cracking during cooling.
2. Surface inversion of the π layer caused by electrolysis of the alkalies through the protective oxide under conditions of (*a*) elevated temperature and reverse bias, and (*b*) irradiation and reverse bias.

The Controlled Sublimation Technique and Its Utilization for the Crystal Growth of Hexamine

G. E. Gottlieb

RCA Laboratories, Princeton, New Jersey

ABSTRACT

A technique has been developed for the growth of large single crystals of hexamine from the vapor. The method is based on sublimation, with modifications that allow stringent control over the process. A single nucleation is induced at a localized cold spot, produced by a fine tipped temperature-controlled copper rod, in contact with the wall of the growth ampoule. Another modification is the presence of four separate temperature zones. Single crystals of hexamine $\sim$ 2 cm^3 in volume were produced. The as-grown crystals exhibited considerable strain because they were in contact with quartz during growth. A significant improvement in the mechanical and electrooptic properties was observed after annealing the crystals. The best electrooptic coefficient (r_{41}) obtained was 4.18 x 10^{-10} cm/v; this corresponds to a half-wave voltage ($V_{\lambda/2}$) of 15 kv (width/length). The technique described here should be applicable for the crystal growth of many other materials. It could be extended to low vapor pressure materials by utilizing chemical transport instead of sublimation.

As a result of the advent of lasers, and the consequent effort to develop optical communication systems having bandwidths of thousands of megacycles, a need has arisen for wideband laser modulators and demodulators. The materials used for this purpose have been potassium dihydrogen phosphate and ammonium dihydrogen phosphate, along with cuprous chloride, which exhibit the electrooptic effect found in crystals that do not possess a center of symmetry. A good electrooptic material should have low loss tangent, large electrooptic coefficient, transparency over a wide spectral range, and a transverse as well as longitudinal electrooptic effect. The above mentioned materials lack some of these desirable properties. The molecular crystal hexamine (hexamethylenetetramine), a body-centered cubic possesses a linear electrooptic coefficient, a low loss tangent, and is transparent over a large spectral range. A comparison of electrooptic materials (1), manifests some of the advantages of hexamine for certain electrooptic applications.

Often with electronic materials, the utilization of a particular physical phenomenon has awaited the development of a technique for the preparation of large single crystals of the required perfection. The interesting electrooptic properties of hexamine, and the absence of a method of growing large single crystals has given impetus to the present work. Hexamine melts at 263°C; however the rapid decomposition encountered at this temperature precludes the utilization of melt techniques for the crystal growth of this material. Hexamine is very soluble in water, alcohol, and acetone, so that solution growth has been used to produce crystals. However, trapped solvent is usually included in these crystals. This leaves growth from the vapor as the most applicable crystal growth technique. Fortunately, hexamine has a high enough vapor pressure to make vapor growth or controlled sublimation a practicality (2).

Honigmann and Heyer (3) grew crystals of hexamine from the vapor, using a copper thermostat in an oven. Elaborate temperature controls were required in order to maintain conditions at the most desirable temperature (100°C). Veigele (4) reports a vapor growth technique in which a copper plate attached to a copper rod makes contact with a sealed ampoule in a beaker of boiling water. Nucleation occurs in the area in contact with the copper plate. The method to be discussed here is based on controlled sublimation, and can be used to grow large single crystals of hexamine.

Growth from the Vapor

For vapor growth of crystals, a source of vapor and a growth area are required. In the process of sublimation, an evaporating source at temperature T_1 may produce many nucleations in an area at a lower temperature T_2. In order to grow large single crystals, the number of nucleations in area T_2 must be limited. To avoid extensive nucleation, low supersaturation ratios are used. This means that small differences in temperature between the source and growth areas must be utilized.

The use of as high an average temperature as practical is desirable for several reasons: the rate of growth increases with the absolute vapor pressure at the growing surface; the crystallinity is also improved at higher temperatures, due to the higher surface mobility. Therefore crystals grown at high temperatures tend to be more perfect, and also growth can proceed at a reasonable rate.

The fact that the growth of single crystals from the vapor as described is essentially sublimation under controlled conditions explains why very pure crystals can be obtained by this technique. Of course, substances that have similar vapor pressures, cannot be removed by sublimation.

Experimental Procedure

The technique reported in this paper is characterized by four temperature zones denoted T_1, T_2, T_3, and T_4, respectively, as shown in Fig. 1; material vaporizes in region T_1, becomes supersaturated in region T_2, nucle-

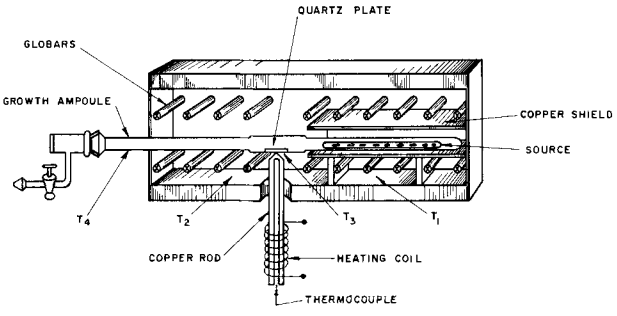

Fig. 1. Controlled sublimation apparatus with the four temperature regions: T_1, source temperature; T_2, growth zone temperature; T_3, temperature at tip of copper rod; T_4, ambient temperature.

ates and grows at localized cold spot T_3 with the excess crystallizing in region T_4. The ampoule itself extends through the furnace into the surrounding ambient. A copper rod, with a thermocouple extending to within an eighth of an inch of its bottom, rests on a flat area of the ampoule, in the colder temperature zone. This provides a localized cold spot. A heater wound directly on the copper rod controls the heat flow through the rod, and therefore the temperature of the cold spot. In order to produce a uniform temperature distribution, the source area is encased in a copper sleeve.

The growth ampoule containing hexamine powder is pumped down to a vacuum of 10^{-6} mm Hg and placed in the furnace; the cold zone and the copper rod, resting on the ampoule, are brought to the growth temperature. The hot zone, containing the source material, is then raised to the growth temperature. Hot zone temperatures of 100°-110°C, producing a vapor pressure of approximately 0.2 mm, were usually utilized (2). Cold zone temperatures 5°-10°C less than the hot zone were found to be satisfactory. The temperature of the copper rod is decreased until nucleation occurs in the area immediately under the rod. The temperature of the rod is then raised several degrees, to prevent the growth from proceeding too rapidly. This is necessary because greater supersaturation ratios are required for nucleation than for growth. The rod temperatures utilized were usually 65°-75°C. The reason for the apparently large temperature difference between the rod and T_2 is that heat must be conducted through two thicknesses of quartz. It is therefore probable that the actual temperature at the nucleation/growth area above the rod is only 2°-3°C below the cold zone temperature.

Growth onto a seed has also been utilized. In this case a flat quartz plate, with a small, well-formed hexamine crystal on it, is placed in the growth ampoule. The copper rod is then placed in contact with the flat area above or below the seed, and growth conditions rather than nucleating conditions are established.

When the crystal has grown to a usable size, it must be cooled. The cooling procedure is complicated by the relatively high vapor pressure of hexamine, and by the sensitivity to thermal shock which manifests itself in the extreme case by cracking the crystal, and more commonly by introducing varying amounts of strain. Because strain rotates the plane of polarization of the light entering the crystal, it seriously limits the usefulness of the material as an electrooptic modulator. In order to minimize the strain, a very slow rate of cooling must be used. However, the high vapor pressure, coupled with the long cooling time, would tend to sublime away part of the crystal during cooling. To eliminate this problem, the source area is kept 5° hotter than the crystal area during the cooling process. The source thereby provides sufficient vapor pressure to prevent sublimation of the crystal; the temperature difference between source and substrate is small enough so that no observable new growth occurs during cooling. The copper rod is also removed prior to cooling, so that the crystal is no longer a local cold spot. A cooling rate of 5°-10°C/hr, with the above conditions, has produced crack-free crystals.

In order to produce a crystal useful for electrooptic modulation, residual strain must be removed. It was found that this can be done by annealing the crystals after growth. Crystals were removed from the plates on which they were grown, and were sealed into an ampoule packed with hexamine powder. The ampoule was heated at 105°C for 3 hr and was then cooled slowly. Examination of the crystals with polarized light indicated that the strain originally present in the crystals was almost completely removed. This finding was corroborated by an increased electrooptic effect after annealing. This is shown in Table I. Crystals grown on quartz and on polyethylene, which originally had widely differing amounts of strain (polyethylene grown had less strain than quartz grown crystals) were both found to have little or no strain after annealing.

Table I. Electrooptic data

Crystal No.	Max. effect, % (I/I_o, 10 kv)	$V_{\lambda/2}$, kv (W/L)	r_{41}, cm/v	Crystal dimensions (mm) Width	Length
RH2	40	60	1.3×10^{-10}	$1.7 \times 1.9 \times 4.9$	
RH3	48	81	0.96×10^{-10}	$1.5 \times 1.9 \times 5.8$	
RH7	45	45	1.7×10^{-10}	$4.1 \times 4.1 \times 8.6$	
RH7 (after annealing)	59	37	2.1×10^{-10}	$4.1 \times 4.1 \times 8.6$	
RH10	—	15	4.18×10^{-10}	$3.2 \times 3.2 \times 2.7$	
RH37 (annealed)	60	41	1.9×10^{-10}	$2.6 \times 2.5 \times 5.9$	
RH38 (annealed)	40	30	2.6×10^{-10}	$1.9 \times 2.4 \times 11.5$	
RH39	27	57	1.36×10^{-10}	$5 \times 10 \times 10$	
RH40 (annealed)	45	32	2.66×10^{-10}	$10 \times 5 \times 15$	

RH7 and RH39 are cut from the same crystal. RH37, 38 and 40 are cut from the same crystal. Measurements were made at 6328Å, with a He-Ne gas laser source. I = Transmitted intensity (crossed polarizers) for a 10 kv field. I_o = Transmitted light intensity (parallel polarizers) for zero field. W = width. L = length.

Results

Spontaneous nucleation.—Large single crystals of 2 cm^3 volume have been obtained by allowing the hexamine to nucleate on a controlled cold spot on a flat wall of an ampoule. In order to obtain a useful, well-formed crystal, nucleation must occur very slowly; irregularities or malformations cannot be tolerated in this initial nucleation. The crystals produced from defect-free nucleations were hemispheric in appearance, approximately 1 in. in diameter with 6-8 flat faces evident. These faces were found to be [110], by Laue patterns. A representative crystal is shown in Fig. 2. The crystals produced are clear, with only a few inclusions. In order to produce such material, an extremely slow growth rate is required (0.1-0.2 g/day). Rapid growth produces imperfections, defects, and ultimately polycrystallinity.

As crystal growth proceeds, it becomes exceedingly difficult to retain the flat faces; the crystal tends to become completely hemispherical. However, the faces can be retained if the copper rods are changed periodically in order to always have a copper rod equal to or slightly smaller in diameter than the growing crystal.

Growth onto a seed.—(i) *Seed mounted on a quartz plate.*—A well-formed hexamine crystal approximately

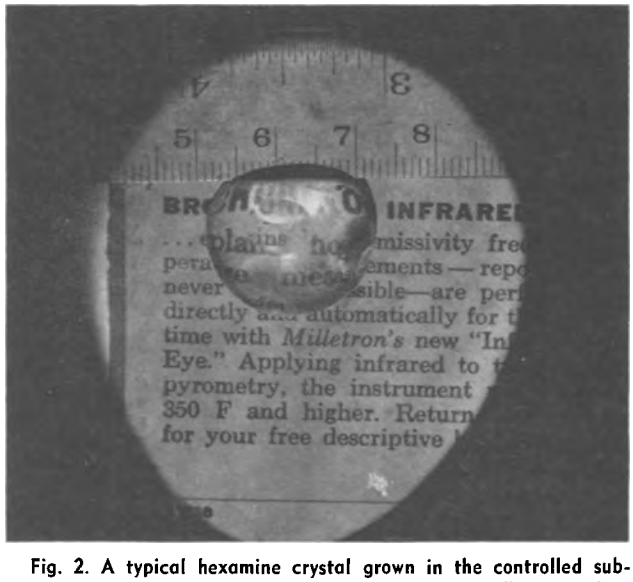

Fig. 2. A typical hexamine crystal grown in the controlled sublimation apparatus. The flat faces or "growth flats" are evident as nondistorted regions. The distortion in the crystals is due to the rounded surface.

1 mm on edge is placed on a quartz plate, and held in place with a small amount of "Torrseal," a high vacuum resin. The plate is then placed against the flat area of the ampoule, using silicone grease as the adhesive. Large single crystals, comparable to those previously described, were obtained by this technique. No unusual growth effects were observed. (ii) *Seed mounted on a polyethylene sheet.*—Crystals grown on quartz, either by seeding or by direct nucleation exhibit considerable strain. This strain was present regardless of the cooling cycle utilized. It is probably due to the large mismatch between the thermal expansion coefficient of hexamine and quartz. Therefore a thin sheet of polyethylene was mounted on a quartz plate with stopcock grease, and a seed was mounted on the polyethylene with the resin previously mentioned. Crystals produced in this manner exhibited reduced strain, compared to crystals grown on quartz. However, it was found that growth on polyethylene is more difficult than growth on quartz. This is due to the low surface energy of the polyethylene, resulting in low energy nucleation sites. The problem was resolved by initiating the growth process extremely slowly, using very small temperature differences.

Effect of vacuum bake.—In order to investigate the effects of volatile impurities on the growth process, several ampoules were baked at 85°C for several hours at 10^{-5} mm Hg prior to growth. The remainder of the growth procedure was similar to that described previously. The baked material sublimed at a slower rate than nonbaked material, necessitating source temperatures of 120°-130°C (10°-20°C higher than normal) in order to obtain a usable growth rate. The above facts indicate that baking removes a volatile impurity, possibly water vapor or alcohol.

Occasional growth defects were observed in the crystals. Microscopic examination showed these defects to be rectangular holes or voids. It was suspected that these defects were due to the presence of water vapor, but they were also encountered in the baked material. Therefore, the cause of these voids is not clear.

Electrical properties.—The electrooptic data obtained from representative crystals produced in this study, are presented in Table I. The electrooptic measurements were made by placing the crystals between crossed polarizers, and applying at 10 kv field. A He-Ne gas laser with an output at 6328Å was used for the light source. The change in the transmitted light intensity (I/I_o) was then measured, and the electrooptic coefficient was calculated using the following equation

$$I/I_o = \sin^2 \frac{\Gamma}{2}$$

where the retardation Γ is given by

$$\Gamma = \frac{2\pi l n_o^3 r_{41} E}{\lambda}$$

in which l is the path length of the light, n_o is the index of refraction, r_{41} is the electrooptic coefficient, E is the applied transverse field, and λ is the wavelength.

The half-wave voltage $V_{\lambda/2}$ is related to the electrooptic coefficient by the equation

$$V_{\lambda/2} = \lambda/2\, n_o^3\, r_{41}$$

The best experimental electrooptic coefficient (r_{41}) was 4.18 x 10^{-10} cm/v; this compares with a theoretical value (1) of 13.2 x 10^{-10} cm/v, and an experimental value of 7.3 x 10^{-10} cm/v, determined by McQuaid (5) on solution grown hexamine. However, recent work (6) indicates a half-wave voltage of 93 ± 9 kv for material prepared by a technique similar to McQuaid's. The difference between the experimental and theoretical values reported here is probably due to crystal imperfection, *i.e.*, inclusions, impurities, misorientation, and strain. Table I also manifests a size effect: the smaller crystals possess better properties than the larger ones. This is especially noticeable when small and large sections cut from the same boule are compared. This size effect is due to the imperfections mentioned above, and also apparently to crystal inhomogeneity. Table I also illustrates the considerable improvement in the electrooptic effect usually produced by the annealing process.

Discussion

The method described here differs from those previously described in the literature in several important respects. First, the ampoule projects into the room temperature ambient, providing an extra temperature zone. Second, the copper rod allows growth to occur only at a localized cold spot, and third, a pregrown seed can be mounted in the apparatus, thereby eliminating the difficult and time consuming nucleation process.

By allowing the ampoule to project through the furnace into the room temperature ambient a zone T_4 at a considerably lower temperature than the growing crystal is obtained and therefore any excess material above that required by the equilibrium conditions of the growing crystal continues to the coldest area. It was found that approximately 50% of the vaporized source material grew into single crystals, with the other 50% condensing at T_4. This is in contrast to a two-zoned situation in which the source temperature is extremely critical because of the control it exercises over the growing crystal. (Single crystals could not be grown in a two-zoned apparatus.) The degree of control inherent in this technique is demonstrated by the fact that spontaneous nucleation does not occur with temperature differences as large as 30°C; (supersaturation ratios of approximately 10).

The advantage of the copper rod, and its separate heater is that growth is limited to a localized cold spot, thereby eliminating multiple nucleations and also increasing the over-all control over the crystal growth parameters.

The use of pregrown seeds eliminates the tedious nucleation process. The seeds used were usually small, well-formed crystals that nucleate spontaneously in the cooler regions of the growth ampoules. The advantage of seeding is the additional control, and the over-all simplification that results.

The crystals grown under differing supersaturation conditions were examined via Laue patterns, and all were found to be of the cubic system; however, those grown with extremely high supersaturation ratios were needle-like ~ 3 mm on edge and 2 cm long. Crystals grown under more moderate conditions were circular and platelike as described previously. This is in agreement with the work of Ibuki (7), who found that the crystal habit of CdS varied with the supersaturation ratio.

The flat faces of the hexamine crystals were in all cases found to be [110]. This indicates that the nucleation process remains constant under differing conditions.

Conclusions

A technique for crystal growth via controlled sublimation has been developed. The process, characterized by four separate temperature zones, has been utilized to produce large crystals of hexamine for electrooptic modulation. In order to maximize the electrooptic effect, crystalline strain must be minimized by annealing the crystals after growth. The best electrooptic coefficient (r_{41}) obtained experimentally was 4.18 x 10^{-10} cm/v; this corresponds to a half-wave voltage ($V_{\lambda/2}$) of 15 kv (width/length). The effect of several parameters on the growth process were also studied. The technique should be applicable for the crystal growth of many materials, especially those possessing vapor pressures >0.1 mm at reasonable temperatures.

Solid Solution in the GeTe-InTe System

J. C. Woolley

Physics Department, University of Ottawa, Ottawa, Ontario, Canada

ABSTRACT

Standard x-ray powder photograph techniques have been used to investigate the phases occurring in alloys of the GeTe-InTe section and also in some general alloys of the ternary systems Ge-In-Te which lie in the composition range bounded by GeTe-In_2Te_3-InTe-Ge. The conditions when the alloys are water quenched from the melt and when annealed to equilibrium at 400°C have been investigated. In the GeTe-InTe section, the water-quenched alloys show a single-phase condition in the range 0-75 mole % InTe, this phase having a rock salt-type structure over the range 8-75 mole % InTe and the GeTe-type structure at lower InTe content. The lattice parameter variation of this phase is compared with that for the similar PbTe-InTe and SnTe-InTe systems and correlated with the occupation by the indium atoms of octahedrally and tetrahedrally coordinated interstices in the tellurium lattice. When the alloys are annealed at 400°C, this long composition range for single phase behavior is lost, and in the region of the ternary diagram investigated, three three-phase fields have been determined.

Although the compound InTe has the B37 type structure (1), extensive solid solubilities of InTe in both of the rock salt-structure compounds PbTe and SnTe have been observed (2). It is found (2) that the limiting mole fractions x of the solute in the rock salt-type a phase have the values $x \sim 0.35$ and $x \sim 0.53$ for the $(PbTe)_{1-x}(InTe)_x$ and $(SnTe)_{1-x}(InTe)_x$ systems, respectively. This relatively large solubility of InTe in the rock salt structure can be correlated with the fact that a form of InTe with this structure [InTe(II)] can be produced by the effects of high pressure (3). InTe(II) is metastable at room temperature and atmospheric pressure and has a lattice parameter a_o of 6.154Å. In the systems $(PbTe)_{1-x}(InTe)_x$ and $(SnTe)_{1-x}(InTe)_x$, the lattice parameter is found to vary linearly with x and extrapolation to $x = 1$ [*i.e.*, to InTe(II)] gives values of 6.24 and 6.21Å, respectively, for the PbTe and SnTe alloys. The difference in these three values for a_o can be attributed to the fact that in the alloys some of the indium atoms occupy sites which are tetrahedrally coordinated by tellurium atoms (*i.e.*, sites equivalent to those in a zinc blende structure) rather than replace lead (or tin) atoms in sites octahedrally coordinated by tellurium. This results in the alloy in a lattice parameter larger than that which would occur if all indium atoms occupied octahedrally coordinated sites by substitution. From this lattice parameter data, and assuming a lattice parameter of a hypothetical zinc blende crystal of InTe as 6.38Å (from the atomic radii of tetrahedrally coordinated indium and tellurium), Rosenberg and Wald (4) have estimated that for the PbTe alloys about one third of the indium atoms enter the tetrahedral sites, and two thirds replace lead atoms substitutionally. A similar calculation for the SnTe alloys indicates that in that case a little less than a quarter of the indium atoms occupy tetrahedral sites in the rock salt lattice.

In the case of GeTe, this compound shows a rhombohedrally distorted rock salt structure at room temperature with $a_o = 5.973$Å and $\alpha = 88° 16'$ (5). However with increased temperature the rhombohedral distortion is reduced, and above 430°C (6) the cubic rock salt structure is observed. Since both GeTe and InTe can show the rock salt structure under suitable conditions, it was of interest to observe the solid solubility of InTe in GeTe. This study led to a consideration of ternary alloys of the Ge-In-Te diagram away from the GeTe-InTe section.

Experimental Procedures

All specimens were prepared from elements of 99.999% purity. For those lying in the GeTe-InTe section, the compounds GeTe and InTe were prepared first and then the ternary alloys prepared from these compounds. The other ternary alloys were prepared directly from the elements. The samples were sealed in evacuated quartz tubes and melted. They were held at 1100°C (*i.e.*, at a temperature well above the liquidus value for any alloy) for approximately 30 min, being agitated continually to give good mixing, and were then quenched in water. X-ray powder photographs were taken to establish the quenched condition. The specimens were then resealed and annealed at an appropriate temperature (normally 400°C) until an equilibrium condition was attained, as indicated by x-ray powder photographs. In all cases annealing for four days was found to be sufficient, and in the final work a standard four day annealing time was used.

Results

It should be noted here that the x-ray data obtained for the quenched samples need not in general represent any equilibrium state of the alloys. However data on the quenched condition are useful in that, as is shown below, metastable single phase solid solution is obtained, and the behavior of this metastable phase could be of interest in studies of semiconductivity and superconductivity of intermetallic alloys. The quenched

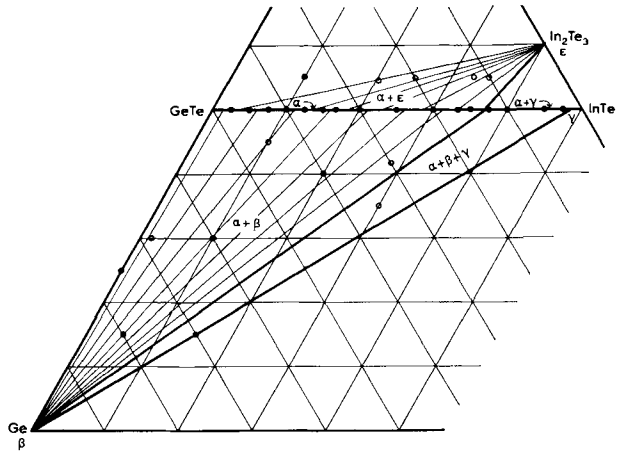

Fig. 2. Diagram showing conditions of alloys water quenched from the melt.

conditions have therefore been considered in some detail. The data on the annealed samples give, of course, a standard 400°C isothermal section of the phase diagram.

The GeTe-InTe *section.*—It was found that over a considerable range of composition the quenched specimens were single phase with a rock salt-type structure, although for alloys near the limit of the single phase range, *i.e.*, 60-75 mole % InTe, the higher angle x-ray lines were blurred. The alloy with 95 mole % GeTe content showed the rhombohedral GeTe-type structure rather than the rock salt structure even with the most rapid quench from the melt, *i.e.*, as with GeTe itself it was impossible to quench in at room temperature the high-temperature cubic phase. However the 95 mole % GeTe alloy had lattice parameter a_0 slightly larger than that of GeTe and lattice angle α nearer to 90°, *i.e.*, showing a transition toward a cubic form with increased InTe content. Figure 1 shows the variation of the rock salt-type lattice parameter a_0 as a function of composition, the point for GeTe itself being the extrapolated room temperature value from data by Mazelsky *et al.* (7). The graph shows a typical pseudobinary behavior, with the limit of single phase solid solution in the rock salt-type structure at 74-75 mole % InTe. The alloys containing 80, 90, and 95 mole % InTe show a second phase of an InTe type. However the lattice parameter of this phase is slightly smaller than that for InTe, showing a limited solid solution of GeTe in the InTe structure. Since in the 95 mole % InTe alloy, the rock salt-type lines are still visible, this range of solid solution must be less than 5 mole % GeTe, but no attempt has been made to determine this value more accurately.

When these alloys were annealed at 400°C, the pseudobinary behavior was no longer observed, and general three-phase conditions were found to apply. These results therefore are discussed below together with those for alloys not on the GeTe-InTe section.

Ge-In-Te *diagram.*—The alloys investigated were limited to those of composition inside the region GeTe-In_2Te_3-InTe-Ge. The diagram giving the quenched condition of the alloys is shown in Fig. 2. As indicated above, this is not an isothermal section of a ternary diagram, but gives a convenient method of presenting the conditions of the alloys in the quenched state. All alloys investigated showed the rock salt-type phase α (or the equivalent GeTe-type phase at large GeTe concentrations). Two two-phase fields ($\alpha + \beta$) and ($\alpha + \epsilon$) are observed where β is germanium and ϵ is In_2Te_3, and a three-phase field ($\alpha + \beta + \gamma$) where γ is the limiting InTe phase discussed above. Lattice parameter measurements confirmed that in the two-phase fields the tie lines ran as shown in the figure. The small region of the diagram between InTe and In_2Te_3 was not investigated.

When the alloys were annealed at 400°C, the pseudobinary behavior of the GeTe-InTe section and the resulting two-phase fields were lost. Specimens in the range 10-67 mole % InTe became three phase, the phases present being germanium (β), In_2Te_3(ϵ), and a rock salt-type phase (α). Comparison of the lattice parameter of the α phase with the data in Fig. 1 gave a value of approximately 92 mole % GeTe-8 mole % InTe as the composition of the phase. An accurate determination of this composition from lattice parameter data is difficult because of the small variation in lattice parameter with composition in this range. However the equilibrium α phase had a lattice parameter slightly smaller than the quenched 10 mole % InTe alloy, while the 5 mole % InTe alloy showed a rhombohedral GeTe-type structure after annealing, thus confirming that the equilibrium α phase lies between these two compositions. Thus the range of solid solution in the GeTe-InTe section is reduced to 0-8 mole % InTe, and for alloys in this range, when annealed at 400°C and then x-rayed at room temperature, there is a transition with increased InTe content from the rhombohedral pseudocubic GeTe structure to a cubic rock salt-type structure.

For well annealed specimens in the ($\alpha + \beta + \epsilon$) field, ordering lines were observed corresponding to the ordered structure of In_2Te_3.

The x-ray photograph of the annealed 30 mole % GeTe-70 mole % InTe alloys showed a very complicated pattern of lines, but in which the lines of none of the phases GeTe, InTe, In_2Te_3 or germanium could be observed. GeTe-InTe alloys in the composition range 75-95 mole % InTe showed this pattern of lines plus InTe lines, and the results for alloys off the GeTe-InTe section are consistent with there being a new δ phase very close to the 70 mole % InTe alloy. In the diagram shown here this new phase has been assumed to be at 70 mole % InTe. The InTe (γ) phase has the same lattice parameter as in the quenched state, indicating the retention of some limited solid solution (less than 5 mole %) of GeTe in the InTe structure.

The 400°C isothermal section is shown in Fig. 3. As indicated, there is a narrow two-phase field ($\alpha + \beta$) close to the Ge-Te boundary and three three-phase fields ($\alpha + \beta + \epsilon$), ($\beta + \delta + \epsilon$), and ($\beta + \gamma + \delta$). Again the region between In_2Te_3 and InTe was not investigated.

The transition temperatures at which the rock salt-type phase becomes unstable have not been determined accurately. The blurring of the high angle x-ray lines for quenched specimens containing 60-75 mole % InTe perhaps would indicate that the transition temperature is higher for these than for alloys of lower InTe content. For specimens in the range 30-50 mole %

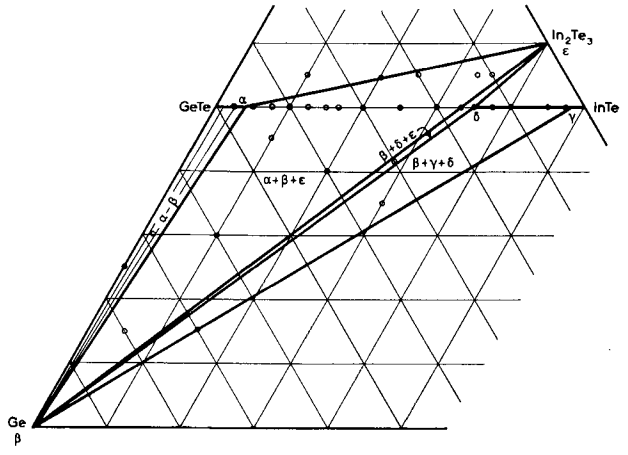

Fig. 3. Diagram showing 400°C isothermal section

InTe, the annealing results indicate a transition temperature in the vicinity of 450°C.

Discussion

Although neither GeTe or InTe show the rock salt-type structure in their equilibrium room temperature states, the quenched alloys of the GeTe-InTe section show a rock salt-type structure (although metastable) over a larger composition range than that for the corresponding PbTe-InTe and SnTe-InTe alloys. While however the lattice parameter varies linearly with composition in the two latter cases, Fig. 1 shows that this is not the case for the GeTe-InTe alloys. Hence here, an extrapolation to determine the effective rock salt-type parameter for InTe is difficult. In Fig. 1, the extrapolated values from the PbTe-InTe and SnTe-InTe systems are shown together with the value for InTe(II) given by Banus *et al.* (3). The extrapolation of the GeTe-InTe data appears to be closer to the other extrapolated values than to the InTe(II) result. As indicated at the beginning of this paper, this implies once again that some of the indium atoms are occupying tetrahedrally coordinated sites in the tellurium sublattice. However, the curvature of the a_o *vs.* composition line would indicate that here the ratio of tetrahedrally coordinated to octahedrally coordinated indium atoms is not constant with indium content. Thus in the range 0-20 mole % InTe it would appear that all of the indium atoms are in octahedrally coordinated sites. However if the value of lattice parameter for the hypothetical zinc blende InTe as given by Rosenberg and Wald (4) is assumed, the slope of the a_o *vs.* composition line at 70 mole % InTe indicates that three out of every four added indium atoms are entering tetrahedrally coordinated sites at this composition. The limit of single phase solid solution at 74 mole % InTe is thus not unexpected.

The Depth of Mechanical Damage in Gallium Arsenide

Charlie E. Jones and A. Ray Hilton

Texas Instruments, Incorporated, Dallas, Texas

ABSTRACT

A technique for the determination of the depth of damage induced into the surface of doped n-type gallium arsenide by sawing, grinding, and polishing is described. The infrared reflectivity in the 20-60μ region was used for this measurement. The relationship between the optical constants of GaAs and reflectivity is reviewed briefly. The extent of the damage is shown to be about equal to the diameter of the final grinding particles. The mechanical treatments produce defect states in the surface which serve as electron traps. This technique is not applicable in the study of p-type or undoped material.

The condition of the surface of semiconductors has taken on added significance with the advent of epitaxial techniques. The surface of a substrate on which an epitaxial layer is to be deposited should be as much like the bulk of that substrate as possible. Mechanical treatment of a substrate can produce damage which is propagated into a deposited layer (1). There is also evidence that defect states can be mechanically induced (2, 3).

Reflection and optical constants.—The normal incident reflectivity, the ratio of reflected radiation to incident radiation, is dependent on the optical constants (4)

$$R = \frac{(n-1)^2 + k^2}{(n+1)^2 + k^2} \qquad [1]$$

where n and k are the real and imaginary parts, respectively, of the complex index of refraction. The absorption coefficient, α, is related to k by (5)

$$\alpha = 4\pi k/\lambda \qquad [2]$$

The surface layers may be assumed to be very similar to the bulk when the measured reflectivity is the same as the reflectivity calculated from the optical constants of the bulk.

There are two absorption processes that cause significant changes in the reflection spectrum, at wavelengths greater than the band edge, of III-V compounds. They are lattice absorption and free carrier absorption. These absorption processes have been studied by many investigators (6-9). The calculated

curves presented in this report, Fig. 1, 2, 3, and 9, were derived using equations given by Lyden (8).

$$n^2 - k^2 = \epsilon_\infty - \frac{Ne^2}{m_c\epsilon_0\omega^2}\frac{\omega^2\langle\tau\rangle^2}{(1+\omega^2\langle\tau\rangle^2)} + \left[\frac{\epsilon_\infty+2}{3}\right]^2\frac{N_lQ^2}{M\epsilon_0}\left[\frac{(\omega_t^2-\omega^2)\tau_l^2}{\omega^2+(\omega_t^2-\omega^2)^2\tau_l^2}\right] \quad [3]$$

$$2nk = \frac{Ne^2}{m_c\epsilon_0\omega^2}\frac{\omega\langle\tau\rangle}{(1+\omega^2\langle\tau\rangle^2)} + \left[\frac{\epsilon_\infty+2}{3}\right]^2\frac{N_lQ^2}{M\epsilon_0}\left[\frac{\omega\tau_l}{\omega^2+(\omega_t^2-\omega^2)^2\tau_l^2}\right] \quad [4]$$

where ϵ_∞ is the relative dielectric constant of the medium in the absence of any contribution from free carriers at very high frequencies; N the free carrier concentration; e the electronic charge; m_c the conductivity effective mass; ϵ_0 the permittivity of free space; ω the angular frequency of the infrared radiation; $\langle\tau\rangle$ the relaxation time averaged over all the free current carriers; N_l the concentration of atom pairs AB; Q the effective charge; M the reduced atomic mass; τ_l the relaxation time related to the damping of the lattice vibration; ω_t the angular frequency of the traverse lattice vibration. The equations were programmed in Fortran IV on the IBM 7040 and the resultant curves were plotted using a Calcomp plotter.

Lattice absorption in GaAs.—A strong absorption band, at long wavelengths, occurs in GaAs due to the resonant vibration between the gallium and arsenic atoms. This absorption gives rise to high values of k (Equation [1]) and causes the reflectivity to rise and peak at about 36μ. This peak in reflectivity is referred to as the Reststrahlen band and is common in diatomic crystals. The optical constants and reflectivity of undoped GaAs in the region of the lattice absorption are shown in Fig. 1. The parameters specific to GaAs, used in calculating curves 1, 2, 3, and 9, were obtained from Hass (10), Moss (4), and Burstein (9).

The absorption process begins to cause significant changes in the optical constants at about 30μ. The real part of the index of refraction (n) first decreases, then rises to a maximum at a wavelength just past the resonant frequency, and finally levels off to a near constant value. The imaginary part (k) rises rapidly as the absorption process increases, reaches a maximum then rapidly drops to very small values. The reflection spectrum shows a minimum at 34μ, the Reststrahlen band peaking at 36μ, and constant values at wavelengths well past the absorption band.

Free carrier absorption in GaAs.—The free carrier absorption process has been thoroughly analyzed by Moss (6). Radiation, which has a wavelength greater than the absorption edge, may be absorbed by interaction with free carriers in the material under study. These free carriers may be supplied by the n-type dopant in GaAs. Figure 2 shows the effect on the optical constants and reflectivity of free carrier absorption (and free carrier alone) in doped 1 x 10^{18} cm^{-3} GaAs in the 20-60μ range. As the energy is absorbed by the free carriers, the value of n decreases to a minimum around 35μ, then slowly increases. The value of k increases as the absorption increases. The reflection spectrum shows a minimum at 27μ and rises smoothly to a maximum which is maintained at larger wavelength.

Lattice and free carrier absorptions actually occur at the same time, therefore, both effects must be considered together. The reflectivity of GaAs with various carrier concentrations is plotted in Fig. 3. The reflection minimum moves to shorter wavelength as the carrier concentration increases. The maximum stays about the same, and the long wavelength reflection increases. The position of the minimum is actually a good measure of the carrier concentration of the material being measured. Figure 4 is a plot of carrier concentration *vs.* position of the minimum in the reflection spectrum. The curve was drawn from experimental points taken in our laboratory. Values from Spitzer and Whelan (11) as well as calculated values are included for com-

parison. The relationship is linear over the range 5 x 10^{17} to 6 x 10^{18} cm^{-3} carriers. The calculated curves, Fig. 3, can be used to ascertain when measured reflection curves are the result of a surface that has the same optical constants that the bulk carrier concentration level demands.

Experimental Procedure and Results

The work described in this paper was carried out using n-type GaAs, Te doped $\approx$ 1.7 x 10^{18} cm^{-3} grown in the <111> direction, sliced parallel to the (111) plane. The reflection was measured from the B face. The study was carried out in this sequence: treat the surface mechanically, weigh, measure the reflectivity in the 20-60μ region, etch away an increment from the surface, weigh, measure reflectivity, etch away another increment, weigh, measure reflectivity, etc. This sequence was repeated until no significant change occurred in the reflection spectrum as more sample was etched away. The measured reflectivity was also compared to the theoretical reflectivity to be sure the final surface was actually about 1.7 x 10^{18} cm^{-3} GaAs. A H_2SO_4:H_2O_2:H_2O B face etch was used. The thickness removed by each etch was calculated from the sample weight loss, the surface area, and the density of GaAs. The area under the curve was used as a measure of the sample's over-all reflectivity. The result of one such sequence may be seen in Fig. 5. The polishing compound used in this case was 1200 grit (particle diameter $\approx$ 10μ). The reflectivity of the sample after it had been polished with the 1200 grit abrasive is marked with the solid dots. The reflectivity increased as the damaged layers were removed. At the end of the fourth etch a total of 13μ had been removed from the surface of the sample and the reflectivity (marked with open triangles) had reached a maximum. The reflection spectrum does not change as more surface is etched away and is equivalent to the reflectivity of a bulk

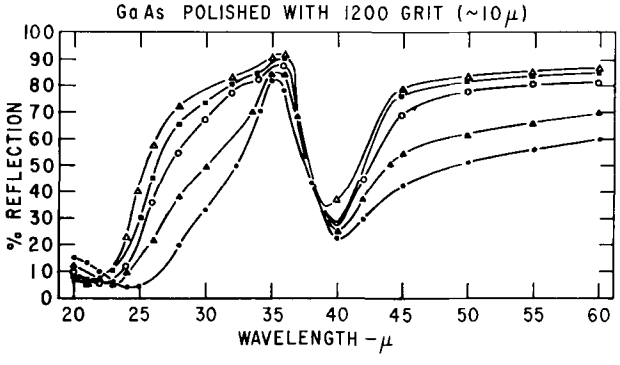

Fig. 5. GaAs polished with 1200 grit (~ 10μ). μ Removed: △, 13.0, 18.0, 25.0; ■, 5.8; ○, 2.2; ▲, 0.9; •, 0.0.

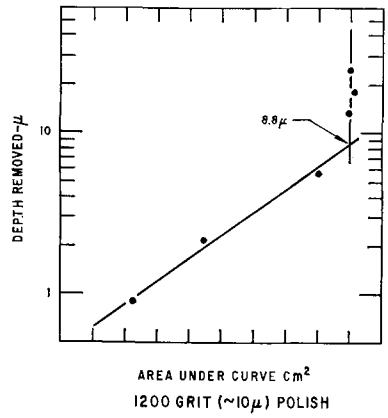

Fig. 6. 1200 grit polish

sample with a carrier concentration of 1.6 x 10^{18} cm^{-3}. This is in reasonable agreement with the estimated carrier concentration, 1.7 x 10^{18} cm^{-3}. Figure 6 is a plot of the observed relationship between the area under each reflection curve and the depth of the material removed. The area under the curve increases as more surface is removed until the surface shows the same optical constants as the bulk. No change occurs after the damaged layers have been removed because the layers being removed are just like the bulk. The curve changes slope at about 9μ. We then conclude that the 10μ particles damaged the surface to a depth of about 9μ.

Surfaces that were abraded by lapping compounds which had particle diameters of 3, 50, and 65μ were also treated in the same manner as described above. The results from the grinding and polishing part of this study are shown in Fig 7. The damage depth is approximately equal to the diameter of the abrasive particle. The results of Warekois, Lavine, and Gatos (12), using an x-ray technique, are included for comparison.

The grinding and polishing results agree satisfactorily with Warekois *et al.* (12) in the region of small particle damage, but do differ in the large particle region. Since the area of interest is the damage by small particles, no effort has been made to reconcile the differences in the large particle region.

The depth of the damage induced by sawing can also be measured by this technique. Figure 8 shows that a surface is damaged only about 8μ deep with a Hamco Dia-Saw.

Discussion

The described infrared reflection technique serves acceptably as a measure of the depth of damage in-

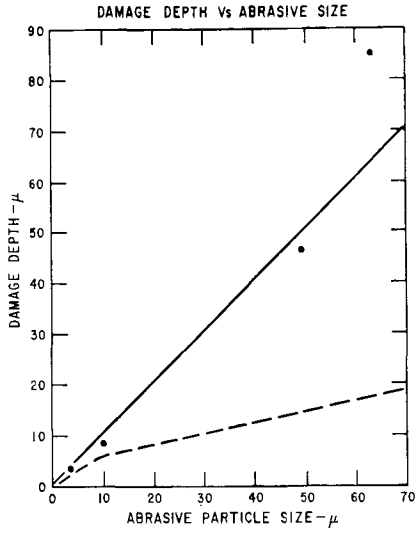

Fig. 7. Damage depth and abrasive size

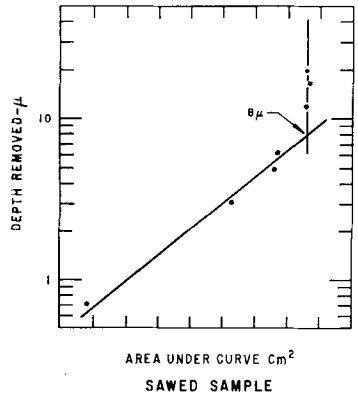

Fig. 8. Sawed sample

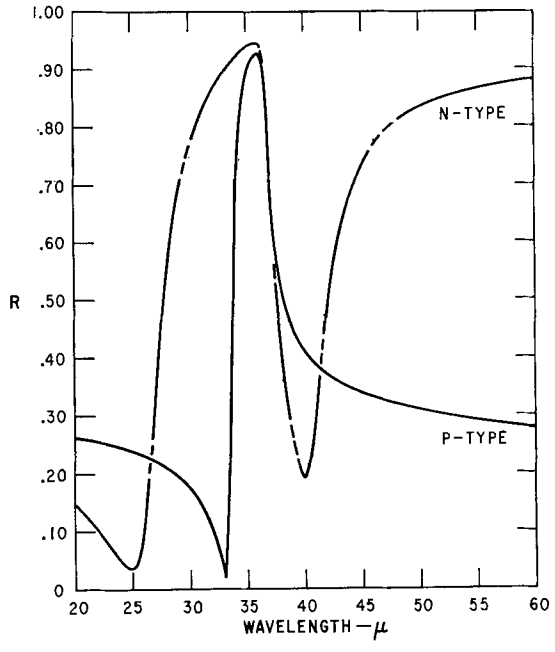

Fig. 9. Reflectivity: n-type (1 x 10^{18}) and p-type (1 x 10^{18}) GaAs

duced into doped n-type GaAs by mechanical treatment. When the surface has the same optical properties as the bulk, the damaged layers have been removed.

The data also lead to a better understanding of the type of damage produced by the saw and fine grit polishes. In Fig. 5 it should be noted that the point of minimum reflection moves to shorter wavelength as the damaged layers are removed. This suggests that the defects are serving as electron traps and lowering the number of free carriers available to absorb radiation. The free carriers are lower by about 10^{18} cm^{-3}; therefore, the concentration of defects must be at least the same order of magnitude.

The described method was not found to be useful, in the wavelength range of this report, for p-type GaAs with carriers 10^{18} cm^{-3} or less. It is evident from Fig. 9 that the effects due to free holes in p-type GaAs does not have the significance of the free carrier effects in n-type. This is true because of the effective mass of the hole is much larger than that of the electron. The effective mass value enters, as a squared term, into the denominator of free carrier equation (8).

Conclusions

The reflection technique described can be used to determine the depth of mechanically induced damage in doped n-type GaAs. GaAs is damaged by mechanical polishing to a depth about equal to the diameter of the abrasive particle. The damage produced by sawing and polishing appears to serve as electron traps causing the surface to contain fewer free carriers than the bulk material.

Acknowledgments

The authors wish to thank Dr. George Cronin for supplying the material used in this study, Mrs. Marilyn White for her efforts on the computer program, and Mr. Jim Parker for making the reflection measurements.

Effect of Fast Cooling on Diffusion-Induced Imperfections in Silicon

M. L. Joshi

Systems Development Division, International Business Machines Corporation, Poughkeepsie, New York

ABSTRACT

Misfit dislocations in phosphorus-diffused silicon are shown to suffer rearrangement on fast cooling. These dislocations extend in specific directions and act as centers of phosphorus precipitates. There are also other areas of precipitation where the particles are of irregular shape and size. The motion of dislocation network in the depths of the diffusion profile is mainly by glide, although a less dominant climb motion is observed.

The generation of misfit dislocations in silicon by solute concentration gradients imposed by diffusion of large dopant concentration has been demonstrated by the observation of etch pits (1) and slip lines revealed by chemical etching (2), x-ray microscopy (3), and the electron probe (4). Formation of dislocation networks on (111) orientation Si was reported by Jaccodine (5) and was later supported by the authors (6) in more detailed study through the technique of transmission electron microscopy. Thomas *et al.* (7) observed square grid of dislocations on (100) orientation through the same technique.

The study of phosphorus-induced imperfections (6) as a function of the depth in the diffusion profile shows that the dislocation network on (111) oriented wafer, with 2μ junction depth, exists only up to about $1/3\mu$ depth in the diffused layer. Penetration of the network in the diffusion profile was shown to have occurred from glide on the {111} planes inclined to the (111) plane of the wafer. Impurity precipitates, believed to be phosphorus precipitates, were also found throughout the diffusion profile in the same study. The detailed analysis of thin phosphorus-diffused layers in p-type silicon by Tannenbaum (8) shows that with high concentration of phosphorus ($>10^{20}/cm^3$) there is a significant difference between the profile determined by sheet resistivity and that by radiotracer measurements. This difference was interpreted to mean that part of the phosphorus might be in the form of precipitates. The actual detection of these precipitates (6, 9) corroborated the precipitation model.

Tannenbaum's diffusion data analysis (8) also indicated the importance of the rate of cooling down from the diffusion temperature. Precipitates of irregular size and shape were observed in a sample dropped from the furnace into an oil bath, in contrast to well-developed crystalline precipitates observed (6, 9) in a sample pulled from the diffusion furnace and allowed to cool slowly in air on a quartz platform. Dislocations generated during diffusion are also shown to be sites of enhanced precipitation. Rapid cooling may also cause basic dislocations in the silicon lattice, corresponding to {111} <110> slip, to extend in specific directions, due to the introduction of uniform stress field. Dislocation interactions are shown to be highly influenced by the energy processes that pull the dislocations into <110> alignment. Dislocation movement by "climb" is also shown to exist, although it may not be the dominant mechanism.

Experimental

Diffusion and quenching.—Three 10-mil thick and 1-in. diameter wafers were cut parallel to (111) from a Czochralski-grown Sb-doped (10^{15} cm^{-3}) silicon crystal. The wafers were lapped on both sides and chemically polished to remove any surface damage. The dislocation density of one of the wafers was found to be less than $10^3/cm^2$ by the etch pit technique. Two of the wafers were symmetrically diffused with phosphorus (junction depth 2μ) at a temperature of 1150°C with the P_2O_5 source held at 300°C. The surface concentration of phosphorus measured with a four-point probe was found to be 3×10^{21} at./cc. The wafers were removed from the furnace and quenched in oil. The significant rate of quenching is that which occurs during the first 400°C (approximately) where the process of diffusion can affect the precipitation. This significant rate could not be measured. However, the estimated average quenching rate (from 1150°C to room temperature) is about 0.5×10^3°C/sec.

The third wafer was not diffused and was used as a test wafer for the quenching process. The wafer was quenched from 1150°C in the same way (as in the case of the diffused wafer) to check whether any plastic deformation had occurred from the thermal stresses during the necessarily inhomogeneous cooling (12).

Specimen preparation.—One of the wafers was used for determination of the junction depth which was found to be 2μ. The other was cut into strips about ⅛ in. wide; these were subjected to anodic oxidation on the side to be studied. The appropriate depth in the solute profile was reached by successive removal of the oxide layers through HF. The thickness of the removed silicon layer through sectioning was determined from a comparison of the silicon oxide color to a standard film thickness gauge. Each strip was cut into ⅛ x ⅛ in. samples to be observed in a Philips electron microscope (100B), using a standard specimen holder with a slightly enlarged specimen receptacle.

The procedure for thinning the sample to obtain transparency to the electron beam is essentially the same as described in an earlier paper (6).

Experimental Observations

No significant generation of dislocations could be observed by the etching pit technique or by transmission electron microscopy in the test wafer. Occasionally regular, but mostly irregular, dislocation networks are found on the surface of the (111) oriented phosphorus diffused samples quenched in oil, Fig 1, in accordance with previous findings (5, 6). The dislocations are considered to be generated by the lattice parameter mismatch caused by the impurity gradient. Unlike the dislocations in the strictly hexagonal grids with <112> alignment (pure edge characteristic), we see many parallel dislocations whose axes are oriented in <110> directions, Fig. 2. These dislocations seem to lie almost entirely on the plane of the foil which is also the most active glide plane. They are 60° Read dislocations possessing a screw character in part. These long dislocations also show jogs. Such jogs are related to the quenching process which is expected to give rise to climb forces due to nonequilibrium concentrations of interstitials or vacancies. The jogged dislocations were found near the surface only (0μ depth). About 0.13μ deep in the diffused sample we find interactions between the dislocations, Fig. 3 and 4. Again, dislocation axes

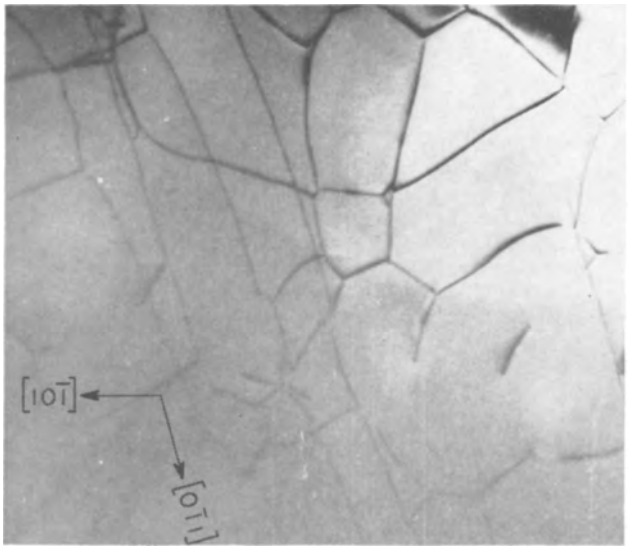

Fig. 1. Misfit dislocation network on the surface (0μ depth). Magnification approximately 17,330X.

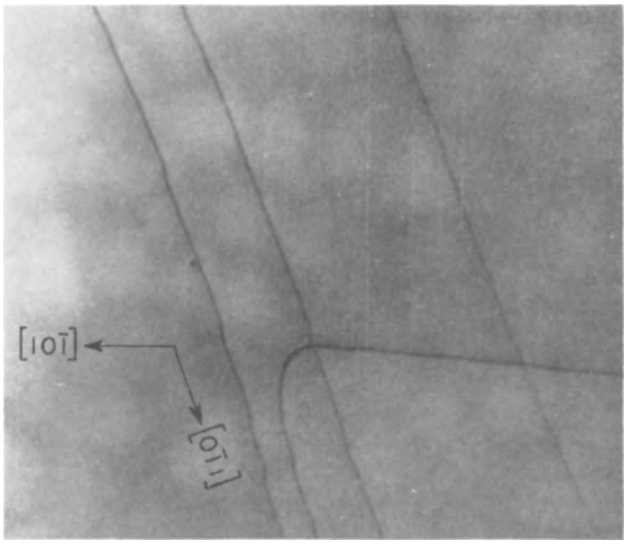

Fig. 2. Rectilinear dislocations in <110> directions with jogs in the surface (0μ depth). Note the elbow dislocation. Magnification approximately 17,330X.

in these figures are all in <110> directions and lie in the foil plane. Figure 5, however, indicates that all the dislocations are not on the same glide planes. Consequently a threefold node would not have 120° angles among its dislocations. This phenomenon also signifies that the transfer of dislocations to this depth on the film plane has occurred by glide. A possible reaction (Fig. 5) could be written as

$$\tfrac{1}{2}[011] + \tfrac{1}{2}[\bar{1}\bar{1}0] = \tfrac{1}{2}[\bar{1}01]$$

$$\text{on}(\bar{1}\bar{1}1) \quad \text{on}(\bar{1}11) \quad \text{on}(111)\text{—(plane of the film)}$$

The possible reaction for the dislocations in Fig. 3 and 4 could be written on the basis that they all have the same glide plane

$$\tfrac{1}{2}[\bar{1}10] + \tfrac{1}{2}[0\bar{1}1] = \tfrac{1}{2}[\bar{1}01]\text{—(all on the foil surface)}$$

The threefold nodes in these reactions should have their angles between interacting dislocations, rearranged to balance tension. However, we see 60°T joints at O and P in Fig. 3b (idealized diagram of Fig. 3 or 4), indicating that either the glide plane of intersections C and L may not be the same as that of the other dislocations, or that there exists processes which keep the dislocations in <110> alignment and lower their

configuration energy. Since these dislocations are misfit dislocations, it is reasonable to assume the latter case, which requires dislocations to have their Burgers vectors lie in the same plane as the diffusion plane. T joints and elbows have been observed in germanium under tension tests (13). The polygonal dislocations are shown also to exist in the quenched specimen, Fig. 6. Formation of an elbow is shown in Fig. 2. This is indicative of reduction of the line energy while maintaining <110> alignment. Impurity segregation along

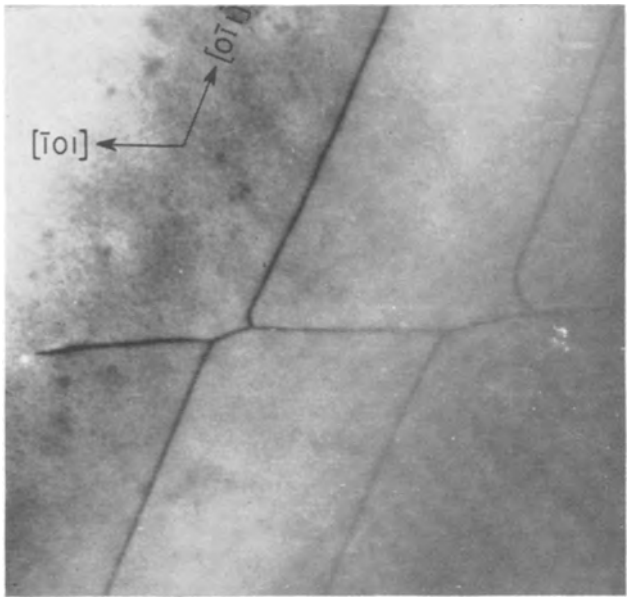

Fig. 4. The same as Fig. 3a except that the dislocation segments generated at the nodes after interaction are longer and the plane of observation is at 0.3μ. Magnification approximately 17,330X.

the dislocation lines is seen in Fig. 6. We also see there a diffused spotty contrast which can be attributed to general precipitation. Dark field imaging shows that the spots are structurally inherent to silicon. No well-developed crystalline hexagonal or square shapes were observed in the quenched specimen throughout the examined profile. The density of dislocations was reduced substantially ($<10^6$ cm/cm^3) below 0.4μ depth of the diffusion profile, which is in agreement with previous findings.

Discussion

An inhomogeneous temperature gradient is always accompanied by stresses which, if they are large, could cause plastic flow by relieving part of the stresses at the cost of the formation of a number of dislocations in the material in excess of those introduced by the impurity gradient (12). The failure to observe significant dislocation in the quench test wafer indicates that the majority of the dislocations observed in the diffused samples owe their origin to the diffusion gradient of phosphorus.

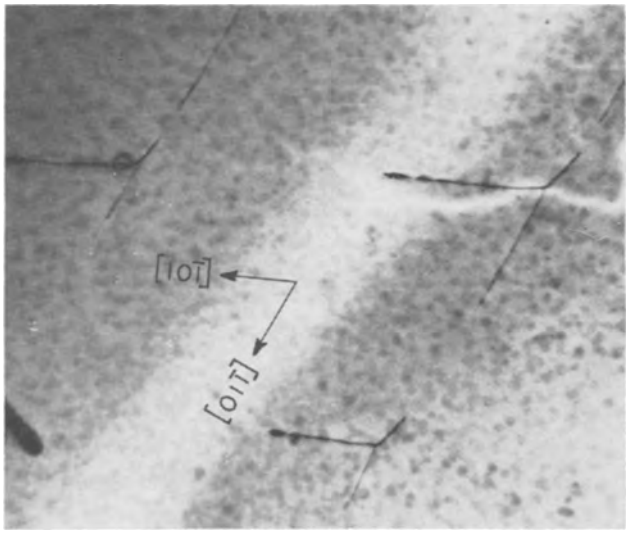

Fig. 5. Threefold nodal interaction of dislocations, all of which are not in the foil plane. The diffused spots are impurity clusters, and the plane observation is 0.13μ deep in the sample. Magnification approximately 17,330X.

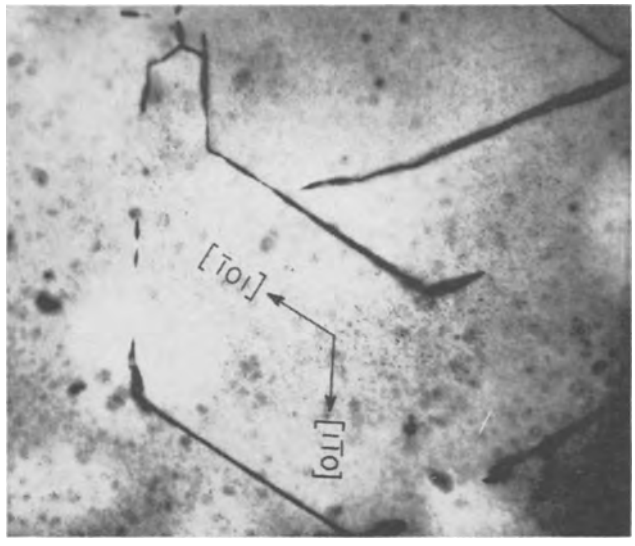

Fig. 6. Polygonal dislocations and the impurity atmosphere at 0.13μ depth. Magnification approximately 17,330X.

It is generally assumed that in cooling rapidly from diffusion temperature to room temperature a supercooled solution is obtained with substantially all the phosphorus frozen into substitutional positions. At high concentrations, however, precipitation can occur on cooling from diffusion temperatures, depending on the rate of cooling. It is also found that basic dislocation types corresponding to {111} <110> slip extend in specific directions if they are produced during uniform stress applications (10, 13).

Tannenbaum's (8) analysis of her diffusion data indicating the existence of phosphorus precipitates was supported by the observation of well developed crystallites believed to be phosphorus precipitates in the sample slowly cooled down from diffusion temperature. In the present experiment, no such precipitates were observed. The quenching, however, seems to have given rise to diffuse impurity precipitation in the matrix with some enhancement of impurity along dislocation lines. This again corroborates the precipitation model in the case of large amounts of phosphorus diffusion. The impurity segregation along dislocation lines could be due to both the Cottrell atmosphere (involving reduction in elastic energy) and the negative charge of dislocation lines (in n-type semiconductors) having coulombic attraction for positively charged impurities. One of the important consequences of these impurities would be the pinning of the dislocations. Even with very pure semiconductors, there are enough impurity atoms to saturate the dislocations present. The density of locking sites (14) in pulled crystals would be about $10^4/4 \times 10^{-8} \approx 10^{11}$/cm^3, where the numerator is the dislocation density and the denominator is the Burgers vector. The impurities in our experimental example could surely contribute this number of locking sites. The Cottrell model is known to be applicable in the case of Si (14-16).

A majority of the dislocation axes in the electron micrographs are oriented in <110> directions. Since the relief of the strain on the diffusion plane implies that the Burgers vectors should lie on the (111) plane of the wafer, these dislocations are 60° Read dislocations. The rectilinearity seems to have been caused by the uniform stresses probably produced during the rapid cooling. The <110> alignment of the dislocations has been shown to be inexplicable on the basis of anisotropy of elastic constants (17, 18). Hassen (19), however, has pointed out that the bonds opposite an extra half plane in the 60° dislocation are severely strained and, from consideration of the yield stress, it may be that they are broken, *i.e.*, there is a crack on the edge of the extra half-plane. The stress necessary to set the dislocation in motion must also be sufficient to move

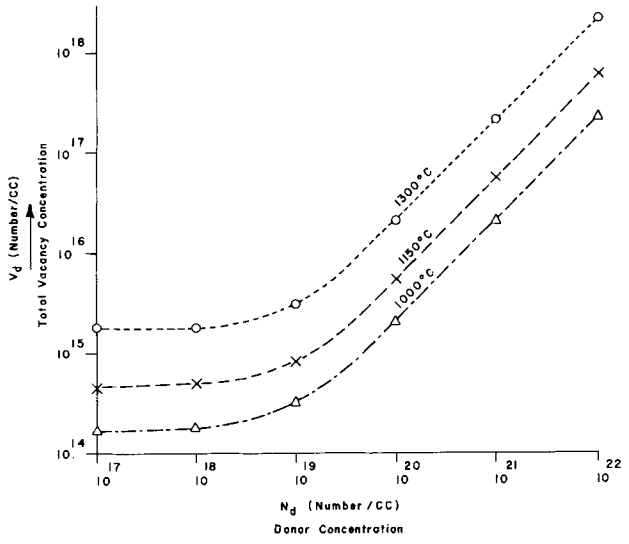

Fig. 7. Total vacancy concentration vs. donor concentration at different temperatures.

the broken bonds, *i.e.*, the cracks, along with it by diffusion. In other words, the 60° dislocation has a high Peirels-Nabarro friction arising from the periodic nature of the lattice and the breaking and remaking of new bonds as it moves.

The jogs in the wall aligned <110> dislocations will cause the mean dislocation line not to lie in the exact <110> crystallographic direction. These jogs could be formed either by tension or compression forces parallel to the foil plane (which is also a slip plane) or by climb. The climb mechanism, however, seems to be a reasonable explanation, in the light of the quenching treatment of the sample. The total vacancy concentration (*i.e.*, the sum of the neutral and the charged vacancies) estimated for $10^{21}/cm^3$ donor concentration at 1150°C is about $10^{18}/cm^3$ (see Appendix and Fig. 7). From the diffusion profile analysis (8), however we know that impurity atoms in the order of $10^{20}/cm^3$ exist in sites other than substitutional. The jogs, then, may be considered primarily due to the nonequilibrium concentration of the interstitials, giving rise to the climbing forces.

The double nature of the (111) extra half-planes requires the absorption or rejection of pairs of interstitials or vacancies. The movement of dislocations by jogs is energetically expensive. The dominant process of the transfer of dislocations to equalize strains in the diffusion profile is the glide process on the {111}<110> slip system, as illustrated in Fig. 5. Our own work (6) on (111) orientation and that of Washburn *et al.* (7) had postulated this mechanism, for which we have obtained herein the necessary evidence. The dislocation interactions in Fig. 3a and 4 are informative from the point of view of the junction reactions. Figure 3b idealizes the dislocation configurations in Fig. 3a. In Fig. 3b, A and L are in <110> direction, and junction dislocations C and D follow the same course of A and L without substantial attempt to balance the tensions at the threefold nodes, o and p. The study of triple nodes at equilibrium provides a measurement of line tensions. One can check in this way whether the line tension measure $K\mu b^2$ $(1 - \nu \cos^2 \alpha)$ is a sufficient criterion, where K is a numerical constant, μ the modulus of elasticity, ν Poisson ratio, and α is the angle between the dislocation line and Burgers vector. Knowing that the Fig. 3b-2- configuration is the result of the interaction in the sets of dislocations both lying in <110> direction and in the plane of the foil, it is imperative for the equilibrium condition that the dislocations at node O rearrange with 120° angles between them, as shown in Fig. 3c. Evidently the resultant reaction is the low energy configuration. Assuming isotropic line tensions and neglecting long-range interactions between dislocations, the change in elastic energy involved between these two configurations can be calculated. The decrease in energy (ΔE) involved in pulling OA from the —1— configuration into the —2— configuration, can be shown by a simple calculation to be

$$\frac{\Delta E}{E} \approx 0.5$$

where E is the isotropic line tension. For stability of the 60°T joint at O, then ΔE is the energy that must be derived from some energy-lowering source that maintains <110> alignment of the dislocations even after interaction with others. The source of this energy can be conceived to be the Peierls-Nabarro trough for a 60° Read dislocation and the pinning points, provided by impurity atoms. Another possibility is that, if we interpret the dislocation reaction with assumption that A is a screw dislocation, then the short segments C and L might not have the same glide plane as the foil plane has. If the intersected dislocations with Burgers vector CD are on the foil plane BCD and the intersecting screw dislocation on plane ABC with Burgers vector AC, then the interaction is AC + CD = AD (Fig. 3d). The resulting dislocation lying in the direction CB is capable of gliding on the (100) plane only. This is the undissociated Cottrell-Lomer lock (LC in Fig. 3d). Since this is sessile and cannot glide in the plane of the foil, it lies in the <110> direction, and it should appear as a straight line on the micrograph (20). This is in agreement with what is observed. The same interpretation has been given by Jenkinson and Lang for similar interactions among dislocations in floating-zone grown silicon (21). However, whether C and L are Cotrell locks, it cannot be said with certainty.

Conclusions

This study has shown that quenching produces precipitates of irregular size and shape, in contradistinction to the well-developed crystalline precipitates observed in slow cooling from the diffusion temperature. The dislocations act as centers of extra precipitation. The motion of the dislocation network in the depths of the diffusion profile is by glide, although a less dominant climb motion seems to exist.

Acknowledgments

The author is pleased to thank Professor G. Thomas, Department of Mineral Technology, University of California, and Dr. B. H. Kear of the Pratt-Whitney Research Laboratories, New Haven, Connecticut, for very helpful comments in the interpretation of this work. He also wishes to thank E. S. Wajda, J. N. Ramsey, J. G. Christ, and F. Wilhelm for their valuable help and encouragement and are grateful to S. Mader for help in experimental and theoretical matters. Thanks are due to W. J. Armstrong for carefully reviewing the manuscript and giving critical comments.

APPENDIX

Let us calculate the equilibrium concentration of vacancies in a highly doped n-type silicon crystal, following the line of argument given by Millea (22).

A fraction of the vacancies will be negatively charged since they are electron acceptors. The concentration of filled acceptor sites may be determined by Fermi-Dirac statistics. Therefore, we have, at a given temperature, the total number of vacancies in an intrinsic crystal

$$V_i = V^o + V^- \qquad [1]$$

where V^o is the number of neutral vacancies and V^- the number of charged vacancies. We will assume V^o to be constant, on the basis that the part of V^o converted to V^- at a given temperature will be replenished to its original concentration by diffusion of vacancies into the crystal from the crystal surface and from the dislocations. Then it is easy to see that a change in electron concentration introduces a proportional change in V^- and, consequently, a simple manipulation will show that the ratio (to a first approximation) of vacancies in a crystal doped with donors V_d, to the vacancies in an intrinsic crystal, V_i, is

$$\frac{V_d}{V_i} = \frac{n_d}{n_i} \qquad [2]$$

where n_d and n_i refer to electron concentrations in a doped and in an intrinsic crystal. The concentration of electrons as a function of doping can be found from the usual charge balance relation:

$$N_d + \frac{n_i^2}{n_d} = N_a + n_d \qquad [3]$$

where N_d is the number of donors, N_a the number of acceptors, and n_d the electron concentration in the conduction band. Combining [2] and [3], we obtain for predominant donor doping

$$\frac{V_d}{V_i} = \frac{N_d + (N_d^2 + 4n_i^2)^{1/2}}{2n_i} \qquad [4]$$

where

$$V_i = V^o\{1 + 2\exp[(E_{Fi} - E_A)]/kT\} \qquad [5]$$

where, again, E_{Fi} is the intrinsic Fermi level, E_A the energy level of the fraction of negatively charged vacancies which act as acceptors, T is temperature (absolute units), and k is Boltzmann's constant. For silicon, we use the figures given by Swalin (23, 24) $E_{Fi} = 0.545$ ev; $E_A = 0.16$ ev (below conduction band) and the enthalpy of formation of neutral vacancy, $\Delta H_v = 2.32$ ev. Figure 7 gives the calculated curves of total vacancy concentration as a function of donor concentration at different temperatures. The phosphorus surface concentration measured with four-point probe in our experimental wafer is about 3×10^{21} at./cc. The actual concentration of phosphorus, however, as measured by tracer technique (25) in a similar case has been shown to be about 10^{22} at./cc in the surface layer which is thinner than 1000Å. This indicates that the total vacancy concentration at 1150°C prior to quenching is about 10^{18} at./cc, or a little less.

The Oxidation Mechanism of Pure Uranium in Carbon Dioxide Between 350° and 650°C

J. J. Stobbs

Materials Division, Berkeley Nuclear Laboratories,

Central Electricity Generating Board, Berkeley, Gloucestershire, England

ABSTRACT

Weight gain/time curves obtained on a thermobalance are related to metallographic observations of the oxide. It is found that the oxide is initially protective, but as a result of nonuniform oxidation and cracking the oxidation rate accelerates until finally a linear rate law is obeyed. In the early stages of oxidation a separate layer of oxide grows at the oxide-gas interface, but soon attains a limiting thickness of a few thousand Angstroms and does not influence the over-all oxidation behavior. Carbon monoxide formed from the reaction between uranium and carbon dioxide reacts further in the cracks in the oxide.

The oxidation behavior of uranium in carbon monoxide and carbon dioxide is important when considering the consequences of can leaks in the current British and French type of gas-cooled nuclear power reactors. A large amount of empirical data relating to the behavior of reactor grade uranium in carbon dioxide of various purities has been obtained, although with few exceptions little success in understanding the scientific aspects of the system has been achieved. Recent work at the Berkeley Nuclear Laboratories of the Central Electricity Generating Board on the examination of failed fuel elements (1) and the development of an oxidation resistant coating for uranium fuel bars (2, 3) has indicated the need for a more fundamental understanding of the reactions between uranium and carbon monoxide and dioxide.

The work described here is part of a systematic investigation to determine the oxidation mechanism of uranium in these gases under a comprehensive range of experimental conditions.

Experimental

Specimens.—Uranium was obtained from the Centre d'Etudes Nucléaires de Saclay in ingot form and contained the following impurities (in ppm): Ag, < 0.5; Al, < 10; B, < 0.1; Be, < 0.5; C, 12; Cd, < 0.5; Cr, 6; Cu < 10; Fe, 19; H, < 1; K, < 20; Li, < 2; Mg, < 10; Mn, < 1; Na, 5; Ni, < 3; O, 13; P, ≤ 50; Pd, < 3; and Si, 15. The levels of the impurities are thus considerably lower than in British reactor grade uranium which contains 600-1000 ppm C, ~ 700 ppm Al and ~ 250 ppm Fe as its major impurities. Specimens 14 x 13 x 2 mm thick were used to investigate oxidation kinetics, and small pieces 5 x 5 x 2 mm thick were used to follow oxidation metallographically. All specimens were vacuum annealed at 950°C for 4 hr and then 660°C for 5 hr to give a stable α grain structure before oxidation. Kinetic specimens were mechanically polished to a ¼μ diamond finish on all faces; those for the qualitative metallographic studies were polished only on one face.

Oxidation.—Carbon dioxide was purified by passing it through successive columns of copper (prepared by the hydrogen reduction of wire form cupric oxide) at 350°C, magnesium perchlorate and phosphorus pentoxide. The purified gas contained ≤ 7 vpm oxygen and ≤ 3 vpm water vapor, nitrogen (~ 50 vpm) and carbon monoxide (≤ 25 vpm) being the only other impurities detected.

Rates of oxidation were measured in carbon dioxide at 1 atm pressure flowing at 50 cc/min on a Stanton "Massflow" vacuum thermobalance (Model MF — L5). During oxidation, each specimen was suspended inside an alumina crucible on a platinum wire. The specimen was brought to temperature (and cooled) in flowing carbon dioxide, this process taking between 25 and 35 min depending on the oxidation temperature. Oxidations were carried out at 350°, 450°, 550°, and 650°C (to ± 5°C), the temperature being measured with a chromel-alumel thermocouple in the gas stream adjacent to the specimen.

Both adherent and nonadherent oxide were analyzed for carbon and their structures determined by x-ray powder diffraction.

The metallographic features of oxidation were mainly followed by oxidizing specimens in a simple tube furnace with an observation port in one side so that the polished face could be examined with a binocular microscope (maximum magnification about 60X) during oxidation. At suitable intervals the furnace was cooled and the specimens removed for more detailed examination at higher magnifications.

Results

Weight gain measurements.—The oxidation rate at 350°C was too slow to be measured with the present apparatus. Weight gain/time curves typical of the other temperatures investigated are shown in Fig. 1-3; the original geometrical surface area of the specimens

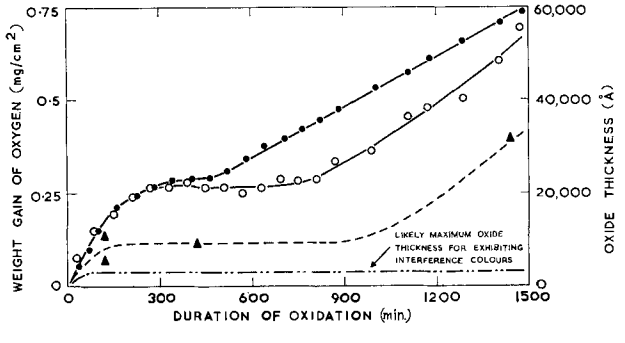

Fig. 1. Early stages of oxidation at 400° and 450°C. Weight gain data: •, run a; ○, run b (both present work, 450°C); ▲, Hayfield et al., 400°C (5). Oxide thickness data: — - - — Hayfield et al., 400°C (5).

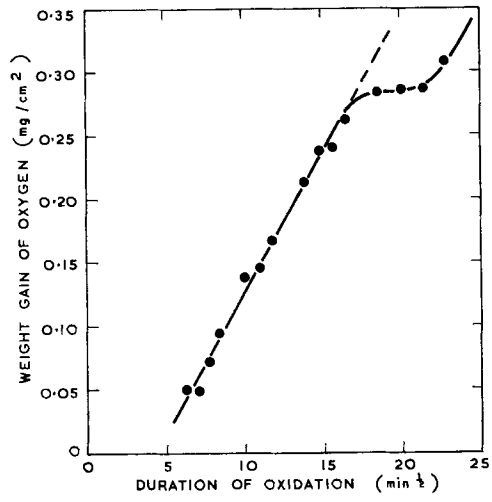

Fig. 2. Parabolic plot of the early stages of oxidation at 450°C

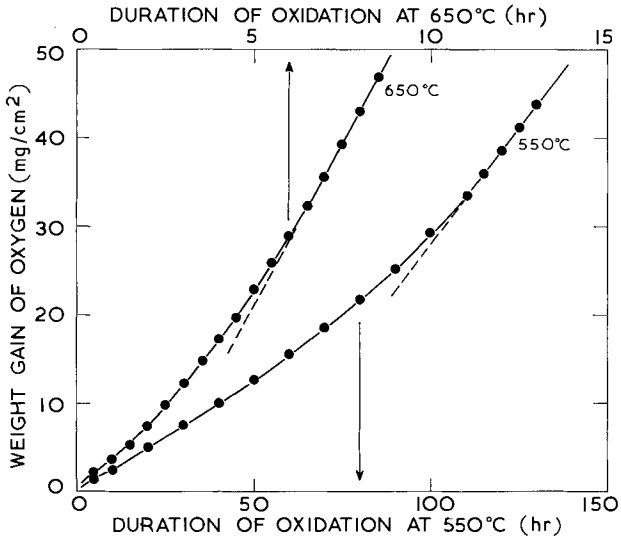

Fig. 3. Long-term oxidation behavior at 550° and 650°C

was used to calculate the weight gain per unit area.

It was evident that the oxidation behavior could be divided into four stages, the importance of which was influenced by temperature. The stages were:

(i). The parabolic growth of a uniform oxide layer to a thickness of ~ 2μ at 450°C and ~ 10μ at 550°C (a weight gain of 1.0 mg/cm² corresponds to an 8μ thick layer of crack-free UO_2); at 650°C it was not possible to decide if a parabolic rate law was obeyed since the form of the rapid initial oxide growth was obscured by the heat-up period.

(ii). A period when the oxidation rate remained very low, varying from 120 to 540 min at 450°C, to ~30 min at 550°C, and to zero time at 650°C.

Table I. Data relating to parabolic oxidation

Oxidation temperature, °C	Time to completion of parabolic oxidation, min	Weight gain at end of parabolic oxidation, mg/cm²	Parabolic rate constant, mg²/cm⁴ min
450(a)	256	0.28	4.8×10^{-4}
450(b)	256	0.27	4.2×10^{-4}
550(a)	182	1.37	2.8×10^{-2}
550(b)	180	1.25	2.2×10^{-2}
650(a)*	20	1.50	—
650(b)*	20	1.50	—

* Data refers to end of period when rate decreased with time.

Table II. Data relating to linear oxidation

Oxidation temperature, °C	Time to onset of linear oxidation, hr	Weight gain at onset of linear oxidation, mg/cm²	Linear rate constant, mg/cm² hr
450(a)*	>120	>3	>0.018
450(b)*	>300	>5	>0.018
550(a)	90	31	0.56
550(b)	110	33	0.51
650(a)	6.9	35	7.63
650(b)	6.6	30	7.11

* Linear oxidation rates were not attained in the times studied.

(iii). A gradual acceleration in the oxidation rate that increased with temperature.

(iv). A final linear oxidation rate that was attained sooner and was faster the higher the temperature.

Tables I and II summarize details of parabolic and linear oxidation.

Metallographic studies.—Several orders of interference colors appeared in rapid succession, individual grains showing different shades or different colors as a result of some dependence of the oxidation rate on the orientation of the underlying metal. The disparity in the thickness between thicker and thinner oxides became more marked with time, and a locally thicker oxide often appeared around surface discontinuities such as twin bands, scratches, and grain boundaries.

On further oxidation the thicker oxide spread laterally to cover the entire surface (Fig. 4). At the same time cracks appeared on the surface of the thicker oxide, and the whole surface eventually became a network of cracked oxide (Fig. 5). The cracks increased in size with time and, although small pieces of the outer layers of oxide often broke away, the oxide was generally adherent (see Table III).

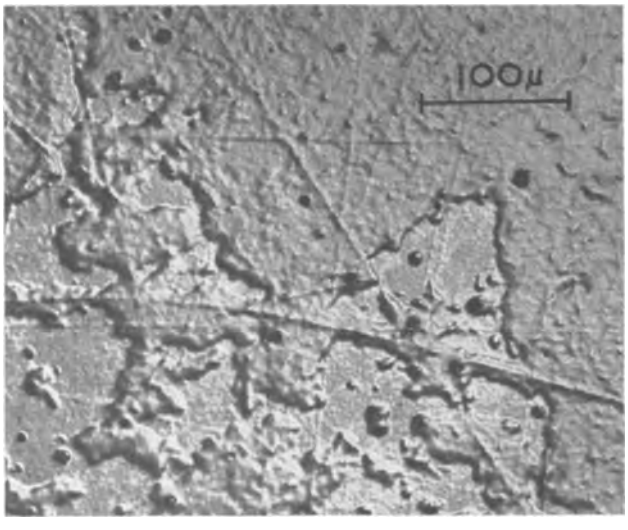

Fig. 4. Lateral growth of thicker oxide over the surface after 350 hr at 350°C.

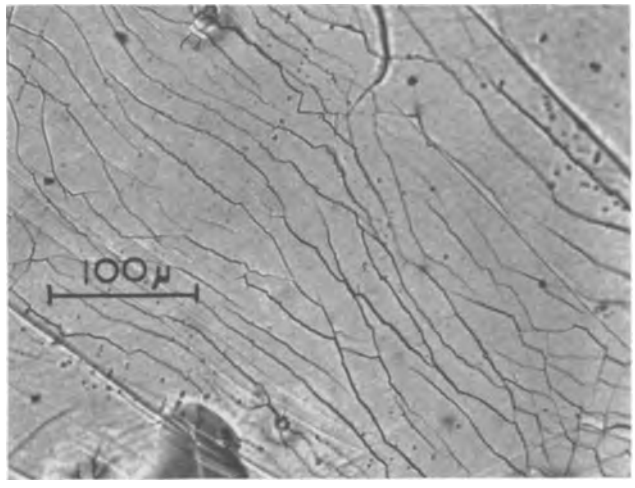

Fig. 5. Cracked oxide after 145 hr at 450°C

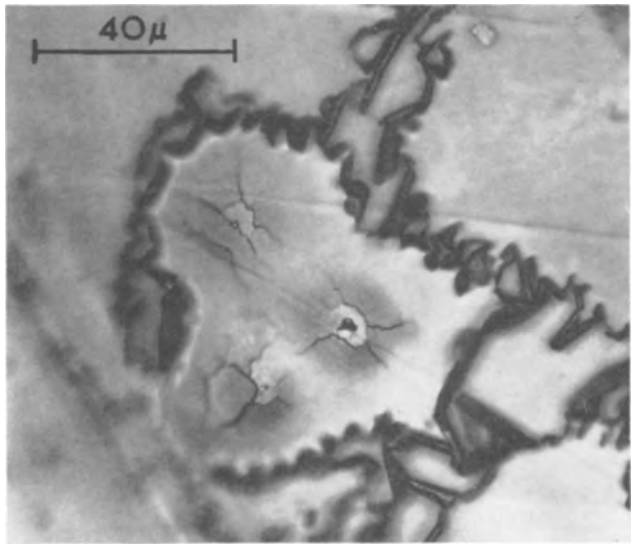

Fig. 6. Coiled thin layers of oxide on the surface after 7 hr at 550°C.

In some regions, prior to thicker oxide growth and cracking, very thin layers of oxide became partly detached and curled up on the surface (Fig. 6).

Cross sections of the oxides also showed the extensive cracking at the oxide-gas interface, but, although these cracks extended almost to the metal-oxide interface in many places, there was always a continuous layer of compact oxide next to the metal (Fig. 7 and 8).

A second phase was clearly visible at 550°C and in even greater amounts at 650°C, located near cracks in the oxide (*e.g.*, Fig. 8). Supplementary oxidation experiments were made at 650°C in static carbon dioxide in a sealed system (volume 500 cc) starting at 1 atm pressure, where the carbon monoxide produced

Table III. Data from the kinetic specimens relating to the form and composition of the oxide

Oxidation temperature, °C	Duration of oxidation, hr	Form of the adherent oxide	Form of the nonadherent oxide	% of nonadherent oxide*	Carbon content of the oxide (ppm by weight ±25%) Nonadherent	Adherent
450(a)	118	Thin, adherent, shiny, purple/gray film	Powder	1.4	—	—
450(b)	312	Thin, adherent, shiny, purple/gray film	Small flakes	10.4	1200	—
550(a)	123	Undulating, fairly adherent, shiny gray film	Small flakes	1.4	1400	2800
550(b)	140	Undulating, fairly adherent, shiny gray film	Small flakes	1.0	1700	—
650(a)	9	Undulating, cracked but fairly adherent, shiny gray film	Small flakes + powder	4.5	1300	—
650(b)	11	Undulating, cracked but fairly adherent, shiny gray film	Small flakes + powder	1.3	1600	2500

* The majority of loose oxide came from the edges of the specimens.

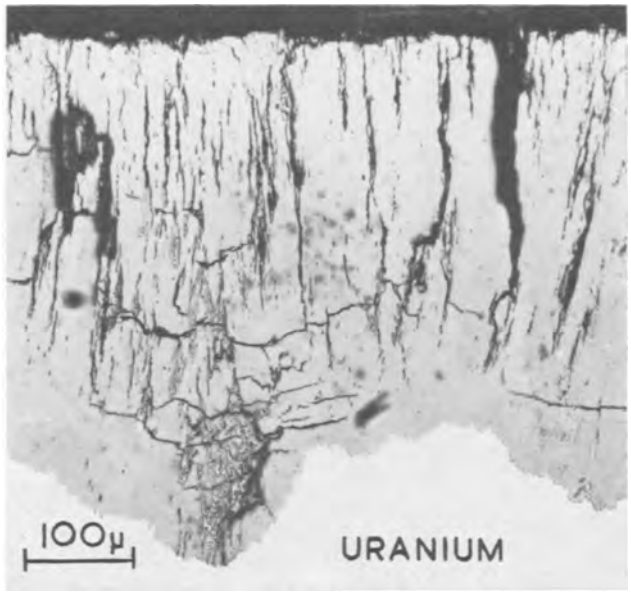

Fig. 7. Cross section of the oxide formed after 140 hr at 550°C

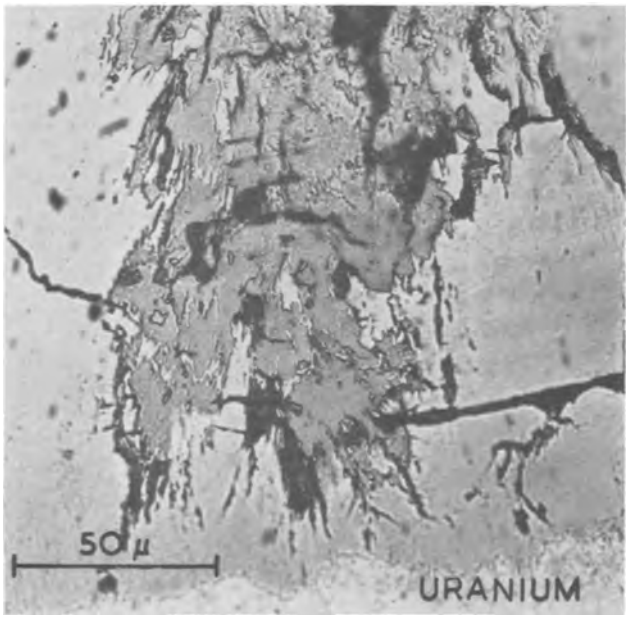

Fig. 8. Cross section of the oxide formed after 9¼ hr at 650°C showing the continuous oxide layer and the association of the second phase with cracks.

from the uranium-carbon dioxide reaction could accumulate and react with the uranium. It was evident that reaction with carbon monoxide led to a marked increase in the amount of the second phase. Further, if oxide formed at 650°C in flowing carbon dioxide was vacuum annealed at 800°C for several hours, the amount of this second phase could be increased by at least 50%.

X-ray diffraction.—At 550° and 650°C lines for uranium dioxide only were observed. At 450°C, in addition to uranium dioxide, traces of U_3O_8 were just detectable.

The room temperature lattice parameters of the oxides formed at 550° and 650°C were equivalent to that of stoichiometric UO_2 within the limits of experimental error, *i.e.*, 5.4705 ± 0.0005Å compared with a value of 5.4705Å derived by Lynds, Young, Mohl, and Libowitz (4). The extremely diffuse nature of the lines at 450°C precluded lattice parameter measurements at this temperature.

Carbon analysis.—Since the uranium contained only 12 ppm carbon, carbon analyses of the oxides listed in Table III indicate that significant quantities of carbon were incorporated from the gas stream. However, since even the highest carbon level corresponded to < 1% of the weight gain no correction need be made to the weight gain measurements. The amount of carbon incorporated from the gas appeared to be independent of temperature over the range investigated.

Discussion

It is evident from both the metallographic and kinetic results that oxidation can be broadly divided into an initial period when a crack-free protective oxide is formed, stages (i) and (ii), and a subsequent period when nonuniform oxidation and cracking of the oxide occurs, (stages (iii) and (iv).

Uniform oxidation.—At temperatures in the range 350°-550°C, qualitative oxide thickness assessments from interference colors (present investigation) and using the Drude-Tronstad polarimeter (5) show that a thin uniform oxide film rapidly builds up to a thickness of a few thousand Angstroms and thereafter thickens at a very slow rate (*e.g.*, Fig. 1). On the other hand, the weight gain studies suggest that the oxide continues thickening for a significantly longer period of time and attains a much greater thickness. Since the level of gaseous impurities in all experiments was similar, and the influence of any minor differences in surface preparation would be slight (6), i would seem that the two approaches have measured different quantities, and two layers of oxide must have been formed, the optical techniques measuring a thin outer layer of oxide. The observation of the thin curled up films of oxide (Fig. 6) is direct evidence for this.

By analogy with the low-temperature (<300°C) oxidation of uranium dioxide in oxygen (7, 8) it seems likely that the layers are of higher oxide such as UO_{2+x} or U_3O_7. As these oxides are structurally similar to the dioxide their detection is not simple. Thus from the present experiments the composition of the outer layers remains uncertain.

It is probable that the over-all growth of the uniform oxide is controlled by inward diffusion of O^{--} ions through uranium dioxide, since the activation energy for oxidation derived from the parabolic rate constants (45 kcal/mole, Fig. 9) falls within the range of that for the diffusion of O^{--} ions through slightly nonstoichiometric uranium dioxide and is significantly lower than the value for U^{4+} ion diffusion (9). This is consistent with data from inert marker and other techniques (10, 11).

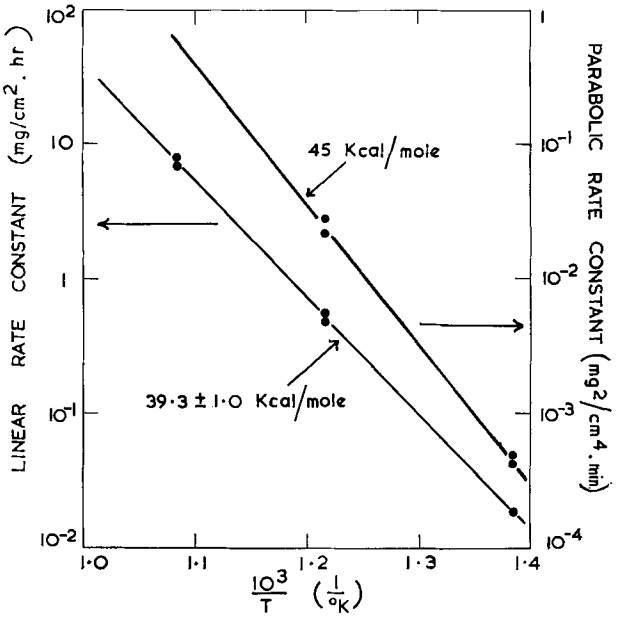

Fig. 9. Arrhenius plot of the parabolic and linear rate constants

Nonuniform oxidation.—The accelerating oxidation rate occurring in stage (iii) is due initially to the incidence of localized oxidation at grain boundaries, etc., then to the lateral growth of thicker oxide and the accompanying cracking.

This lateral growth must be the result of the high volume ratio of UO_2: U of 1.98. If the oxide were not restrained by the underlying metal it would cover a larger area, and is consequently under considerable compressive stress. At the thick oxide-thin oxide boundary the thick oxide will grow in a lateral direction where there is least resistance, to reduce the compressive stresses, and this will occur when the oxide step becomes sufficiently great, causing cracking in the adjacent thin oxide region. As the driving force for the process (the high stress in the oxide) is always maintained, the thicker oxide continues to propagate over the surface. The cracking of these thicker oxides is also a result of the compressive stresses in the oxide.

As oxidation proceeds the cracks propagate through the oxide until a linear oxidation rate is established [stage (iv)]. The activation energy for oxidation derived from the linear rate constants was 39.3 ± 1.0 kcal/mole which is very close to the value existing during uniform oxidation (Fig. 9), indicating that rate control remained by the diffusion of O^{--} ions through uranium dioxide. Thus linear oxidation must correspond to the state when the rate of crack propagation through the oxide equals the rate of oxide growth at the metal-oxide interface, with the oxidation rate controlled by diffusion across the thin compact layer of oxide between the tips of the cracks and the metal surface. Since it is not possible to measure the thickness of this layer, it is not possible to decide if the increase in linear rate with temperature is due entirely to faster diffusion rates or whether the uncracked oxide thickness also varied with temperature.

The weight gain at the onset of linear oxidation is similar at 550° and 650°C and significantly greater than the likely value at 450°C. This supports the x-ray evidence (more diffuse patterns at 450°C) and particle size measurements of Lyons and Popple (12) for there being some change in the physical properties of the oxide between 450° and 550°C.

This type of paralinear oxidation behavior where the oxide is initially protective, but breaks down to form porous outer layers of oxide, is well established for uranium in oxygen at low temperatures [*e.g.*, (13), (14)] and in many other systems (15). However, previous representations of the oxidation behavior of impure grades of uranium in carbon dioxide have almost always been in terms of one or more linear rates, frequently from zero time [*e.g.*, (16), (17)], although in most instances data could be as easily represented by an accelerating rate usually leading to a single final linear rate. The present interpretation enables the results to be more simply explained since theories based on multiple linear rate behavior are difficult to justify.

Carbon deposition.—It is evident from the carbon analyses of the oxides that the reaction occurring between uranium and carbon dioxide cannot be completely represented by the over-all equation

$$U + 2CO_2 \rightarrow UO_2 + 2CO \quad [1]$$

as also shown by Feron (18). The latter obtained similar carbon levels which were also independent of temperature. However, his assumption that carbon deposition results from the reaction

$$U + CO_2 \rightarrow UO_2 + C \quad [2]$$

is not wholly justified on the experimental evidence, and it seems more likely that the reaction leading to carbon deposition is

$$U + 2CO \rightarrow UO_2 + 2C \quad [3]$$

from the carbon monoxide produced by reaction [1]. As deposition of carbon on uranium dioxide from carbon monoxide only occurs when the carbon dioxide content of the gas is $< 1\%$ (19), the most likely site for reaction [3] will be within the cracks in the oxide, which constitute stagnant regions where the carbon dioxide content will be low; the association of the second phase (which has been shown to be directly connected with the carbon monoxide reaction) with cracks in the oxide supports this view. And the existence of a lower carbon content in the nonadherent oxide is also consistent since this oxide would consist of the outer layers that were near the widest parts of the cracks where the carbon dioxide content of the gas would be higher and the carbon deposition rate consequently low. Further, as cracking of the oxide became more extensive the carbon content should increase with time; this appears to be verified by the present results (Table III).

Although none of the known carbon containing uranium compounds were detected after oxidation in carbon dioxide, in agreement with the majority of previous workers, it seems possible from a comparison with oxidation in carbon monoxide (18) that the second phase corresponds to the compound UC_2, but is present in quantities too small for detection in the present experiments. An alternative explanation is that at the oxidation temperature some of the deposited carbon is taken into solution in the uranium dioxide. On cooling to room temperature the dissolved carbon in excess of the room temperature solubility limit (which may be zero), precipitates as free carbon in the oxide and appears as the second phase (oxide + precipitated carbon). The fact that the amount of the second phase can be increased by vacuum annealing the oxide as more free carbon is taken up from the cracks supports either mechanism.

Conclusions

1. The oxide initially formed on pure uranium in pure carbon dioxide in the temperature range 350°-650°C is protective, and nonuniform oxidation and cracking then occur leading to a gradual acceleration of the oxidation rate until eventually linear kinetics are obeyed. At this stage the rate of crack propagation through the oxide equals the rate of oxide growth, and the rate of oxidation remains controlled by the diffusion of O^{--} ions through a thin layer of uncracked uranium dioxide of constant thickness next to the metal.

2. Comparison with optical techniques for measuring oxide growth rate has shown that in the early stages of oxidation at 450° and 550°C a separate layer, probably of some higher oxide, grows at the oxide-gas interface, but soon attains a limiting thickness of a few thousand Angstroms and does not influence the over-all oxidation behavior.

3. Carbon monoxide produced from the reaction

$$U + 2CO_2 \rightarrow UO_2 + 2CO$$

reacts according to the equation

$$U + 2CO \rightarrow UO_2 + 2C$$

This latter reaction probably exclusively occurs in the cracks in the oxide, some of the deposited carbon either forming UC_2 or going into solution in the oxide.

A New Assemblage for Hydrogen Electrodes

G. Bianchi, A. Barosi, G. Faita, and T. Mussini

Laboratory of Electrochemistry and Metallurgy, University of Milan, Milan, Italy

ABSTRACT

A new assemblage for hydrogen electrodes is presented which makes use of a support of porous graphite activated with platinum-black catalyst and which does not require a continuous flowing of hydrogen. At 25°C its exchange current measured in different environments is in the range of 11 to 30 ma/cm^2; bias potential is 0.03 mv; stability is better than 0.01 mv when the electrode is aged for some days. These essential characteristics render such an electrode convenient for precision measurements; moreover, in many cases this electrode enables one to avoid difficulties which arise from liquid junction potentials verified with some commonly used reference electrodes.

From the first simplest Hildebrand electrode (1) until the more recent types, the hydrogen electrode has undergone considerable modifications (2) to improve its performances for accurate measurements in the area of the electrochemical thermodynamics and kinetics (3).

Quite recently, Giner (5) presented a "polarized" hydrogen electrode, having a number of advantages when used for kinetic studies on strongly acid or alkaline environments, and Zaitsev and Bulgakova (6) applied a hydrogen electrode assemblage to determinations of partial pressures of hydrogen in inert gas mixtures.

New opportunities are now provided by the use of activated porous electrodes (7).

This investigation concerns the obtainment of a new hydrogen electrode assemblage, which is reasonably simple and at the same time satisfies the requirements of stability, reproducibility, and so on, by making use of a support consisting of porous graphite activated with noble metal catalysts.

Experimental

Figure 1 shows in detail the structure of the hydrogen electrode according to the present realization. The triple contact electrode-solution-gas occurs at the upper part of porous graphite disk A, covered by a thin layer of platinum black catalyst (see also enlarged detail in Fig. 1) and immersed in the solution up to about 2/3 of its thickness. The solution moves upward through the pores of the graphite disk by capillarity and moistens the catalyst layer. A thin network of sintered Teflon drops (TD) protects the catalyst from mechanical crumblings (7) and prevents the formation (during operation) of a gauze of solution on the activated surface of the electrode, without screening the catalyst itself. This way, the contact electrode-solution-gas is highly satisfactory, and neither the solution level nor the porosity degree of graphite are critical parameters. The catalyst is platinum-black Johnson & Matthey whose specific surface is 9.8 m^2/g.

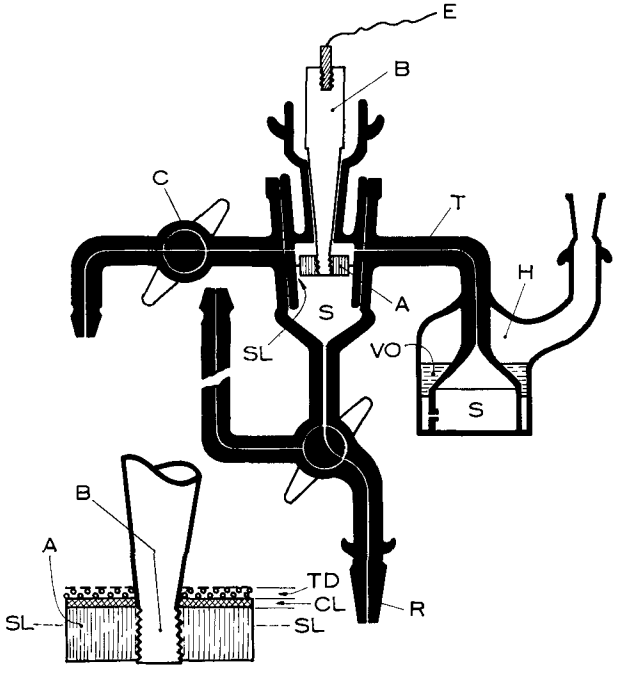

Fig. 1. Structure of the hydrogen electrode: A, porous graphite disk; B, screw stem of impermeabilized graphite; C, gas inlet stopcock; CL, catalyst layer; E, electrical connection; H, hydraulic seal; R, to second half-cell; S, solution; SL, solution level; T, tube connecting to hydraulic seal; TD, Teflon drop network; VO, vacuum oil layer on solution.

The porous graphite disk A is of the type PC 57 H Stackpole Carbon Company; it is 0.5 cm thick, 1.5 cm in diameter. The rate of applied catalyst is about 10 mg/cm^2. The real working surface is actually about 900 fold the geometrical surface, as it was determined according to the method of Laitinen and Enke (13).

A type-30 du Pont Teflon dispersion has been used to get sintered-drop networks on the catalyst layer, according to the technique described by Bianchi (7) and derived from that previously indicated by Elmore and Tanner (8). The porous graphite disk is kept in position by means of a screw stem (B) made of impermeabilized graphite which also acts as a support for electrical connections. The form of the glass vessel is such that the volume of gas and solution is reduced to a minimum; thus, equilibrium between solution and gas phase is more quickly reached and both temperature and pressure response are improved. The gas and vapor dilatations which occur following changes of temperature are compensated by a little hydraulic seal (H). This hydraulic trap obviously serves to keep the inside of the electrode at atmospheric pressure at any temperature and to prevent the entrance of air and foreign gases. In view of this purpose it is filled up to about half its volume with the same solution as in the porous electrode compartment: between this solution and external atmosphere a floating layer of high vacuum silicone oil is interposed (VO). The solution in this trap serves to quickly reach the vapor saturation in the tube (T) connecting the trap with the electrode compartment, when temperature must undergo any change.

If a graphite disk has been freshly activated and assembled as previously described, it is recommendable to keep it at a temperature in the order of 60°-70°C for about half a day under a moderate circulation of hydrogen, once for all; this way the last traces of adsorbed and dissolved gases are removed. In fact, the correct electrode behavior can be affected by nitrogen because it lowers the hydrogen partial pressure, while the last adsorbed oxygen traces are unimportant due to the rapid catalytic combination with hydrogen. If these points are considered in setting up the electrode, by a previous filling of the vessel and a deaeration of solution with hydrogen, the best satisfactory electrode behavior is obtained.

When preliminary operations have been carried out one can stop the hydrogen inlet with the appropriate stopcock (C) and now the hydrogen electrode is ready for use. Such as it is, it can be used at various temperatures, obviously taking into account appropriate corrections for vapor pressure of the solution.

No further hydrogen circulation is necessary during many weeks, and such an electrode can be easily handled as the most usual and popular reference electrodes.

Reversible emf measurements have been carried out with the aid of a type K3 L & N potentiometer with a type 610 B Keithley electronic millivoltmeter as a null-point detector, the input-impedance of the latter being higher than 10^{14} ohms. Accuracy of emf measurements is within ± 0.01 mv. The highest input impedance of such null-point detector enabled us to measure emf's keeping the stopcock connecting the two half-cells in the closed position.

Solutions were made up with doubly distilled water and Merck products, reagent grade. Hydrogen was used with total oxygen less than 5 ppm. Analysis and checking of solutions and other substances were done according to the conventional technique. Temperature of the cell was regulated to ± 0.01°C by means of an air thermostat.

Table I. Exchange currents according to Eq. [2]

Environment	Exchange current, ma/cm^2 at 25°C
1*M* HCl	16.2
6.06*M* HCl (=20% azeotropic HCl)	30.3
0.5*M* H_2SO_4	12.8
3.75*M* H_2SO_4	26.5
1*M* $HClO_4$	11.2

Results and Discussion

Stability.—The stability of the hydrogen electrode just described has been tested at 25° and 40°C by coupling it with an electrolytic-type silver-chloride electrode and taking reversible emf measurements of the resulting cell

$$\text{Pt/graphite-Pt black/}(H_2\ 1\ \text{atm})\text{/HCl}(1\ M)\text{/AgCl/Ag/Pt} \qquad [1]$$

all characteristics concerning the silver-chloride half-cell being already known accurately as outlined in the recent and exhaustive review by Ives and Janz (9). Cell 1 was controlled thermostatically at the appropriate temperature for twenty days, and emf measurements were made at intervals of about 12 hr. Both at 25° and at 40°C the emf of such cells verified a 0.03 mv total shift during the first eight days, but kept its value constant during the remaining twelve days of the experiment: this constant value in both cases was 0.01 mv less than the value which results from taking into account activity coefficients of HCl (11, 12) and correction to 760 mm Hg pressure of hydrogen. With regard to the activity coefficients of HCl, it is to be pointed out that the effect of AgCl solubility in HCl solutions is quite negligible when the HCl concentration is lower than 3*M*, as indicated by the data of Akerlöf and Teare (4). Besides, since we worked with 1*M* HCl and we kept the stopcock closed between the two half-cells any danger of hydrogen electrode poisoning by diffusing AgCl was avoided.

Since electrolytic-type silver-chloride electrodes are characterized by bias potentials in the range of 0.02 mv and generally constant to ± 0.005 mv (9) the stability of the present hydrogen electrode is 0.03 mv when the electrode is freshly prepared, being better than 0.01 mv when the electrode is 8 days old.

Bias potentials.—The intercomparison potential was determined on 5 identically prepared electrodes; one of them was characterized by a 22-day aging and was chosen as the basis for comparison, a second one had a 10-day aging, the others being freshly prepared. Measurements were taken at 25°C during 15 days: the resulting bias potential was 0.03 mv for newly prepared electrodes, but it reduced to 0.01 mv for aged electrodes.

Reversibility.—The reversibility of the present hydrogen electrode has been tested by evaluating exchange currents in polarization experiments. Exchange current actually is an important and critical parameter for reference electrodes, as has been pointed out adequately elsewhere (10). In the present case exchange currents have been determined by considering polarization curves related to cathodic discharge and to anodic ionization of hydrogen in various media. An identical hydrogen electrode was used as a reference electrode: thus, liquid junction potentials were avoided. These curves, at the lowest overpotentials (less than 10 mv) clearly showed a linear relationship between overpotential and current, so that exchange currents have been evaluated graphically according to the equation

$$i_o = \frac{RT}{2F}\frac{di}{d\eta} \qquad [2]$$

where i_o is exchange current, i is polarizing current, and η is the overpotential.

Exchange currents at 25°C, determined according to Eq. [2] and related to the apparent geometrical area of the electrode, are given in Table I.

From the order of magnitude of exchange currents in Table I it is apparent that this hydrogen electrode presents a high degree of reversibility.

Conclusions

A new and convenient assemblage for the hydrogen electrode has been presented which is easy to handle and widely applicable for measurements concerning electrochemical thermodynamics and kinetics.

Such an electrode is characterized by a high degree of reversibility, as shown by the range of exchange currents measured in different environments (11-30 ma/cm^2 at 25°C). Bias potential is 0.03 mv at 25°C. Stability tests against a Ag/AgCl/HCl electrode have been made at 25° and 40°C: thus, the stability of the present hydrogen electrode has been shown to be better than 0.01 mv when working with electrodes aged for some days.

The reference electrode may be realized with solutions of different compositions, and in many cases it helps overcome difficulties arising from liquid junction potentials observed with usual reference electrodes connecting to concentrated acid solutions.

The Bubbling Gas Electrode

I. Instrumentation and Applications

Wayne J. Subcasky

Aeronutronic Division, Philco Corporation, Newport Beach, California

ABSTRACT

The bubbling gas electrode technique for studying electrochemical reactions at solid electrodes is described. This technique gave reproducible concentration gradients at the electrode surface by intermittently stirring the electrolyte in the vicinity of the electrode by means of electronically pulsed gas bubbles. Under the proper conditions current-voltage curves could be recorded automatically with a polarograph and interpreted in a manner similar to polarograms. The method has been found to be controlled by semi-infinite linear diffusion. Analytical applications and studies of catalyzed electrochemical reactions involving oxygen are discussed.

The use of solid electrodes for electrochemical systems has been reviewed by Adams (1). One of the major problems associated with solid electrodes has been the variation in manner and rate at which material is transported to and from the electrode. One solution to this problem uses a "dipping" electrode in which an inert gas is bubbled around the tip of a solid electrode. Such an electrode was first described by Lyalikov and Karmazin for use in fused salts (2). Flengas (3) used this technique in molten nitrates. Hills and co-workers (4) described a similar system for use in various solvent systems. The bubbling gas electrode (BGE) as herein described is an extension of the dipping electrode to aqueous solutions with electronic control of the rate of bubbling.

Experimental

In the BGE technique an electronically pulsed gas bubble was used to stir the solution intermittently in the immediate vicinity of the electrode. In this manner, the interval between stirring was accurately and reproducibly controlled, and the electrode was isolated from the solution only momentarily.

Figure 1 is a block diagram of the experimental arrangement used for these BGE studies. The function generator (Hewlett-Packard 202A) produced a square wave whose period could be varied from about 1 sec to 100 sec. This square wave controlled the bubble monitor circuit which in turn produced pulses of a few millisecond duration at intervals determined by the period of the function generator. The pulses produced by the bubble monitor circuit actuated the solenoid valve in the gas supply and allowed a small volume of gas to flow to the mantle surrounding the electrode in the cell. This gas stirred the electrolyte in the

immediate vicinity of the test electrode. The current-potential curve of the solid test electrode was automatically recorded by the polarograph (Sargent Model XV).

Figure 2 is a schematic diagram of the bubble monitor circuit. The square wave from the function generator actuated relay L_1. The contacts of this relay alternately charged the condensers, C, from the batteries, V, and then discharged the condensers through the coil of the second relay, L_2. Actuation of L_2 momentarily closed the circuit to supply power to the solenoid valve. With this bubble monitor circuit, the interval between pulses and hence the interval between bubbles (the bubble time, τ) was determined by the period of the function generator. The length of the pulses was determined by the combination of the voltage used to charge the condensers, the size of the condensers, and by the effective resistance of the relay coil and parallel resistor, R. With the particular components used in this study the pulse width could be varied from about 30 msec to one-half of the pulse period.

Figure 3 shows the electrolytic cell and mantle bubble tube used in this study. An external saturated calomel electrode could be electrolytically connected to the test solution through an agar-KCl salt bridge. A mantle which surrounded the test electrode was used to disturb the concentration gradient. The pulse of gas released by the solenoid valve forced electrolyte down away from the electrode and out of the mantle. A small bleeder valve in the gas supply line to the mantle permitted the return of the electrolyte when the solenoid valve closed. This mantle bubble tube was easy to assemble and gave reproducible results.

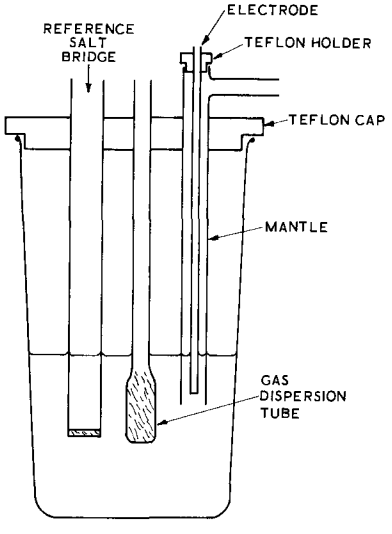

Fig. 3. Electrolytic cell

Various electrodes with different geometries were used. These are shown in Fig. 4. The graphite electrodes were prepared from spectrographic rods (United Carbon Company, Bay City, Michigan) and have a nominal diameter of 0.120 in. All graphite electrodes were first impregnated with molten paraffin to reduce the porosity. The two types of planar electrodes differed only in the manner of insulation. Some electrodes after impregnation with paraffin were given a heavier coating of wax. Before use a cross section of the graphite was exposed by abrasion with fine emery paper followed by polishing with bond paper. Other planar electrodes were insulated by covering the wax impregnated electrode with a heat shrinkable plastic sleeve (Ray Chemical Corporation, Redwood City, California). The lower part was polished as before. This latter method of sealing was preferable because the electrodes could be handled without danger of breaking of the wax coating.

Graphite cylindrical electrodes were prepared by completely covering a wax impregnated graphite rod with the heat shrinkable plastic. While the plastic was still warm the lower end was pinched together to form a tight seal. After the plastic was cooled, a narrow portion was cut away to expose a definite amount of the graphite. Platinum cylindrical electrodes were prepared by sealing B & S Gauge No. 20 platinum wire in soft glass and applying a bead of glass to the lower end.

Reduction of Copper

The supporting electrolyte for all studies with copper was approximately 1*M* NH_4Cl-1*M* NH_4OH. The supporting electrolyte was deaerated with nitrogen before any current-potential curves were determined. The nitrogen was first passed through a prebubbler containing the supporting electrolyte to minimize changes in the ammonia concentration. During the experimental runs the supporting electrolyte was blanketed with nitrogen. The electrodes were given a precathodic treatment at about —1.5v (SCE) to remove any oxides and/or adsorbed oxygen which might be present on the electrode. The pretreatment was particularly important with the graphite electrodes because of the large amount of adsorbed oxygen.

A large area saturated calomel electrode connected to the electrolysis cell through an agar-KCl salt bridge was used as the reference electrode. The voltage span of the polarograph was 0 to —1.0v, and the scan rate was 100 mv/min unless otherwise noted. In these preliminary studies no attempts were made to thermostat the cell, although the temperature of the supporting electrolyte varied less than 0.5°C during any particular experiment.

Residual current curves were always run to determine the completeness of removal of dissolved and adsorbed oxygen. These curves were run at the same sensitivity as the curves where copper was present. All curves run with the BGE technique used nitrogen

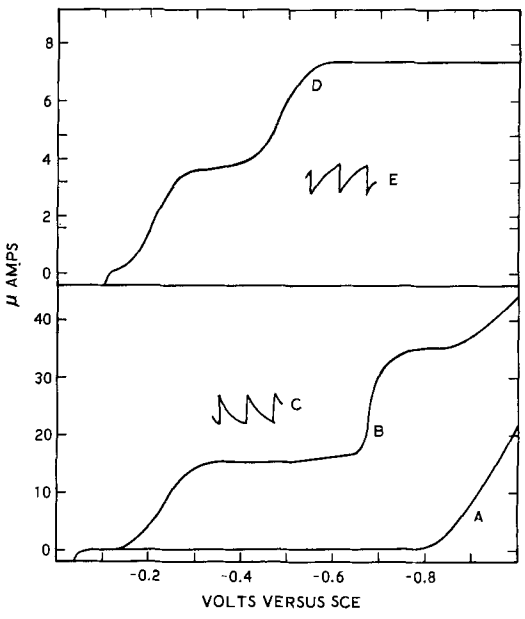

Fig. 5. Comparison of BGE and DME. Reduction of 1.04 *m*M Cu(II) in approx. 1*M* NH_4OH-1*M* NH_4Cl. BGE characteristics Pt cylindrical electrode, 0.205 cm^2, bubble time 4.06 sec. Curve A, residual current; B, in the presence of Cu(II); C, current-time behavior between individual bubbles. as the stirring gas. A bubble time of 4.06 sec was used for most of the curves. Copper was added to the deaerated supporting electrolyte as definite volumes of a stock solution containing a known amount of copper in the supporting electrolyte.

Figure 5 shows a comparison of the current-potential and current-time curves for the BGE and the DME. The solution used was 1.04 m*M* $CuSO_4$ in 1*M* NH_4OH-1*M* NH_4Cl. The characteristics of the DME were m = 1.702 mg/sec and t = 5.37 sec at —0.70v (SCE). The polarogram shows the typical two equal wave structure characteristic of the reduction of copper (II) in this supporting electrolyte. The first wave represents the one electron reduction of $Cu(NH_3)_4^{+2}$ to $Cu(NH_3)_2^{+}$ and the second wave the one electron reduction of $Cu(NH_3)_2^{+}$ to copper amalgam. The maximum in the current-time curve occurs at the end of each drop of mercury. The current increases as each mercury drop grows because the increase in area and the expansion of the Hg drop into the concentration gradient of the electrolyte more than compensates for the increasing thickness of the diffusion layer.

The current-potential curve for the BGE was obtained in the same solution as that used for the polarogram. The characteristics of the BGE were a platinum cylindrical electrode with a geometric area of 0.204 cm^2 and a bubble time of 4.06 sec. The first wave had the same shape and occurred at the same potentials for both the DME and the BGE. The second wave with the BGE occurred at more negative values and showed a sharp increase in current at the start of the wave rather than the S-shaped curve characteristic of polarograms. Both of these differences were due to the nature of the product of the second wave. With the DME, the product was copper amalgam. Hence the copper was deposited at less than unit activity, and the deposition occurred at less negative potentials. Also the activity of copper in the amalgam was constantly varying thereby giving a curvature to the lower portion of the wave (Heyrovsky-Ilkovic behavior). With the BGE the reduction product of the second wave was metallic copper at unit activity. As a result the deposition occurred at more negative potentials. As soon as a monomolecular layer of copper was present, the activity of copper did not vary and consequently the current increased rapidly with potential (Kolthoff-Lingane behavior). Similar curves were obtained with the various graphite electrodes with the exception that no hydrogen evolution was observed even at —1.0v (SCE). The geometry of the electrode did not seem to affect the shape of the curves. The only differences were in the magnitudes of the currents observed. These differences were proportional to the various areas for electrodes of different geometry. No statistically significant difference was found for currents recorded with linearly increasing potentials and for currents measured by holding the electrode at various constant potentials.

The reduction of $Cu(NH_3)_4^{+2}$ to $Cu(NH_3)_2^{+}$ was found to be reversible on both platinum and graphite. Figure 6 shows the plot of potential *vs.* log $i/(i_d - i)$ for a platinum cylindrical electrode. The slope as determined by the method of least squares was found to be 60.7 mv as compared to a theoretical valve of 59.1 mv at 25°C. A "*t*" test at the 95% confidence limit showed no significant difference between these two values. The half-wave potential was found to be —0.225v (SCE) as compared to a value of —0.24v normally reported for a 1*M* NH_4OH-1*M* NH_4Cl supporting electrolyte. The difference is probably due to a slightly lower concentration of ammonia in the supporting electrolyte.

No log plot was made to determine the reversibility of the second wave for reduction of $Cu(NH_3)_2^{+}$ to Cu^0. Deposition of metallic copper on the electrode changes the electrode area and makes interpretation of the log plot difficult. However when the direction of the potential scan was reversed no displacement along the potential axis was noted when the current passed from cathodic to anodic values due to the anodic stripping of the copper. This is commonly accepted as a sign that the couple is reversible.

With the BGE, the current decreased with time and reached a minimum just before the solution was stirred by a bubble (see Fig. 5). This was to be expected for diffusion to a stationary electrode. The theory for semi-infinite linear diffusion predicts that the diffusion limited current should decrease with the square root of time, *i.e.*, the product of the current and the square root of the time should be a constant. Table I shows this current-time product for the first wave in the reduction of copper on a graphite planar electrode. The currents listed are the averages of at least ten determination at each bubble time. The geometric area of the electrode was 7.30×10^{-2} cm^2 and the solution was 1.20 m*M* in Cu(II). The lack of constancy in the $i\tau^{1/2}$ product for small τ's was found to be due principally to the slow response time (10 sec for full-scale travel) of the polarograph recorder. Other experiments, with a faster recorder or an oscilloscope, showed that the constancy extended to bubble times as short as 1 sec in most cases.

To substantiate further the conclusion that the BGE with a planar electrode was a linear diffusion electrode the value of $i\tau^{1/2}$ was calculated from the known concentration of Cu(II) present, the measured geometric area, and the diffusion coefficient as measured by po-

larographic techniques (5). The calculated value was 14.9 μa-sec$^{1/2}$ as compared with an experimental value of 17.15 μa-sec$^{1/2}$. The agreement is considered to be good considering the uncertainties present in determining the area of a solid electrode which might be somewhat porous.

The analytical possibilities of the BGE were determined by measuring the diffusion limited current as a function of the amount of Cu(II) added. Figure 7 shows this current-concentration relationship for a planar, graphite electrode. The current for the first wave was measured at —0.5v (SCE) and for the second wave at —0.9v (SCE). The points on the curve are the averages of at least three determinations. The curve shown for the second wave was determined from the total wave height. The proportionality constant for the second wave was slightly larger than twice that of the first wave because the electrode area had been increased slightly by deposition of metallic copper. The values of the constant, i/C, were found to be 7.50 $\pm$ 0.34 and 16.12 $\pm$ 0.52 μa/mM for the first and second waves, respectively.

For analytical applications of the BGE, determination of concentrations by the method of standard addition or by the method of a pilot ion might be simpler and more accurate. Either of these methods would minimize difficulties associated with changes in temperature, electrode area, bubble time, and extent of stirring which might occur from one determination to another.

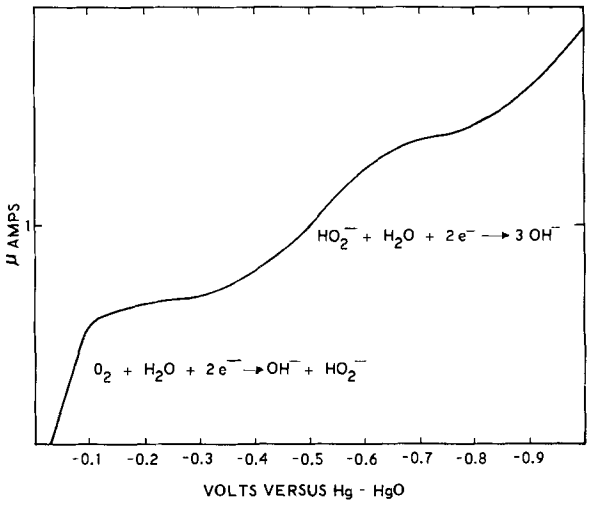

Fig. 8. Reduction of oxygen on uncatalyzed graphite. 25% by weight NaOH; graphite planar electrode, area 7.30 x 10^{-2} cm^2, bubble time 4.00 sec.

Reduction of Oxygen

The BGE technique was also used to study the reduction of oxygen at graphite electrodes in alkaline solution. For this work the supporting electrolyte was 25% by weight sodium hydroxide with oxygen as the bubbling gas. Solutions were not deaerated except where a residual current curve was desired. The graphite electrodes were precathodized for 1 min at —0.7v *vs.* the Hg pool to remove oxygen initially adsorbed on the electrode. If the precathodization step was eliminated, the current decreased with time even on the diffusion limited portion of the current voltage curve. An internal mercury pool was used as the reference and auxiliary electrode. The potential of the mercury pool in this alkaline solution was within a few millivolts of that of the normal hydrogen electrode.

The current-potential curve for the reduction of oxygen on an uncatalyzed graphite electrode is shown in Fig. 8. The curve is similar in shape to that obtained with a dropping mercury electrode. Two distinct waves are evident before the final current rise due to hydrogen evolution. The first wave corresponds to the nearly reversible two electron reduction of oxygen to hydrogen peroxide ions

$$O_2 + H_2O + 2e^- \rightarrow OH^- + HO_2^-$$

and the second wave to the totally irreversible reduction of hydrogen peroxide ions to hydroxide ions

$$HO_2^- + H_2O + 2e^- \rightarrow 3\ OH^-$$

The current of the first wave was slightly larger than that of the second. Even a so-called uncatalyzed graphite electrode caused some decomposition of the hydrogen peroxide ions

$$2HO_2^- \rightarrow 2\ OH^- + O_2$$

The oxygen produced by this catalytic decomposition enhances the height of the first wave. The first wave then corresponds to slightly greater than a two electron reduction and the second wave to slightly less than two electrons.

The effect of catalyzing the graphite electrode is shown in Fig. 9 and 10. The silver catalyzed electrode was prepared by electrodeposition of silver from a nitrate solution. The enhanced decomposition of hydrogen peroxide ions is readily apparent in the increased height of the first wave at the expense of the second wave. It was found experimentally that by increasing

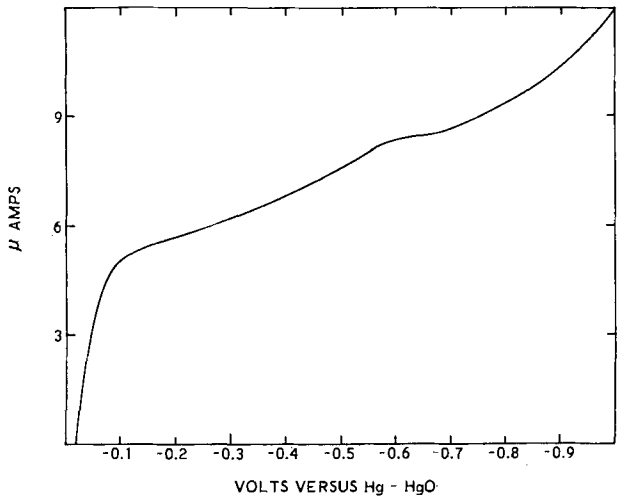

Fig. 9. Reduction of oxygen on silver catalyzed graphite. 25% by weight NaOH; graphite planar electrode plated with silver from $AgNO_3$, bubble time 4.00 sec.

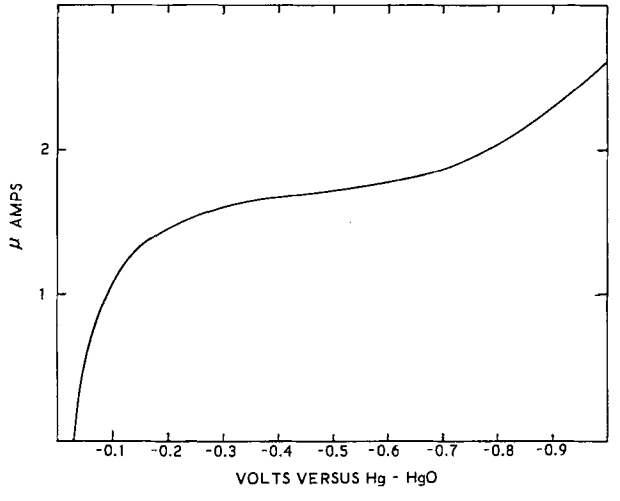

Fig. 10. Reduction of oxygen on spinel-type catalyzed graphite. 25% by weight NaOH; spinel formed by thermal decomposition of Co and Al nitrates, bubble time 4.00 sec.

the amount of silver on the electrode either by longer electrodeposition times or by thermal decomposition of silver nitrate deposited on the graphite electrode, the second wave could be made to disappear altogether indicating complete catalytic decomposition of the hydrogen peroxide ions.

In many experiments a high current peak was observed at potentials considerably positive to that observed for the reduction of oxygen. However, this current decreased rapidly with time when the electrode was held at constant potential. This decaying current at a potential of approximately +0.20v *vs.* NHE suggested that it was due to the electrochemical reduction of silver (I) oxide formed chemically by the reaction between silver and oxygen in the alkaline solution

$$2Ag + \tfrac{1}{2} O_2 \rightarrow Ag_2O$$

$$Ag_2O + H_2O + 2e^- \rightarrow Ag + 2\,OH^-$$

In some instances an apparent correlation was found between the area under the current peak and the length of time the electrode had been exposed to the alkaline solution containing oxygen. With the method used to deposit silver, the chemical oxidation of silver by dissolved oxygen was much slower than the electrochemical reduction of silver oxide and hence the current decayed with time.

Figure 10 shows the reduction of oxygen on a graphite electrode catalyzed with a cobalt-aluminum spinel type of material. The electrode was prepared by evaporation of a solution of cobalt and aluminum nitrates of the stoichiometric proportions and then thermally decomposing the nitrates at a red heat. This catalyst was sufficiently active that no second wave appeared. The decomposition of hydrogen peroxide ions was complete enough that no electrochemical reduction of peroxide ion was evident. A similar type of behavior has been reported for the reduction of oxygen on platinum (6).

Conclusion

The BGE technique has been found to be a rapid and simple method for studying electrochemical reactions at solid electrodes. Intermittent stirring of the electrolyte in the vicinity of the electrode by electronically pulsed gas bubbles gave reproducible concentration gradients so that the system appeared to be controlled by semi-infinite linear diffusion. Analytical applications are possible, particularly in potential regions where a mercury electrode would undergo anodic oxidation. The method has been used to study the effect of various catalysts upon the reduction of oxygen in alkaline solutions. Qualitative information concerning the mechanism and rate of the catalytic activity has been rapidly obtained.

The Effect of Electrode Pretreatment on the Oxygen Reduction on Platinum in Perchloric Acid

Y. L. Sandler and E. A. Pantier

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

The effect of pretreatment of a platinum electrode on the electrochemical reduction of oxygen and of hydrogen peroxide in perchloric acid was studied at room temperature. Hydrogen and oxygen pretreatments affect the oxygen reduction in a manner similar to cathodic and anodic pretreatments, respectively. An interpretation of various electrode characteristics is given on the basis of this parallelism. Removal of strongly bound oxygen by hydrogen pretreatment or cathodization accelerates the decomposition of hydrogen peroxide and increases the open-circuit potential and the rate of the oxygen reduction in solutions containing 10^{-5} to $10^{-7}M$ peroxide. Decay rates from a high anodic potential provide a sensitive measure for peroxide concentrations in the electrolyte.

One of the main difficulties in studying the electrochemical oxygen reduction reaction on platinum in acid solution is the lack of reproducibility under varying conditions. This is due to differences in impurity content, the peroxide concentration of the solution, and the physical characteristics of the electrode. This report deals mainly with the influence of the latter on the characteristics of the electrode reaction.

Hydrogen peroxide is either an intermediate (1) or a by-product (2, 3) in the reduction reaction of oxygen. In practice, therefore, it is always present when a cathodic current is drawn, as, for example, in fuel cells.

In clean solutions and at very low peroxide concentrations, open-circuit potentials (OCP) of close to 1.23v *vs.* a hydrogen electrode in the same medium have been obtained in the past by special pretreatments (2-4). The potentials were assumed to be true reversible potentials, corresponding to a four-electron reduction of oxygen to water. The potential cannot be reproduced after a cathodic current is drawn.

At high peroxide concentrations, above 10^{-4} mole per liter, a potential of about 0.84v (5) is set up which is characteristic of the peroxide electrode and is independent of the ambient atmosphere and the peroxide concentration. For the oxygen reduction reaction OCP's usually lie between 0.8 and 1.1v. The oxygen coverage is below one monolayer (6).

In a previous study (7) of the oxygen adsorption on platinum and silver in a dry system, different types of chemisorptions were found varying in binding energy. The activity of the surface for the reaction $O^{16}{}_2 + O^{18}{}_2 \rightarrow 2O^{16}O^{18}$ was found to be affected by the presence of firmly bound oxygen adsorbed at high temperatures and by the presence of hydrogen in the surface.

In the present study the effect of the high-temperature pretreatment of the platinum electrode with oxygen and with hydrogen on the characteristics of the oxygen electrode in perchloric acid solutions was studied. A reproducible effect of gas pretreatment was found and was compared with the effect of electrochemical prehistory. This method of comparison was used to study the influence of the nature of the adsorbed oxygen on the electrochemical characteristics of the electrode.

Experimental

The Cell.—The cell consisted of a flanged 5-in. diameter Pyrex vessel closed by a lid and a Teflon gasket. The electrodes were introduced through the lid via ground joints fitted with Teflon sleeves. The counter-electrode tube and the Luggin capillary tube contained fritted glass disks separating the corresponding electrodes from the main body which contained the test electrode and the oxygen bubbler. A platinized platinum coil served as hydrogen electrode which was frequently checked against a second hydrogen electrode.

Gases.—Commercial electrolytic oxygen was purified by passage through hot copper, Dryerite, Ascarite, and a molecular sieve at dry ice temperature. Hydrogen was also an electrolytically produced commercial product. It was passed over hot palladium asbestos, Dryerite and molecular sieve at liquid nitrogen temperature.

The electrolyte.—Reagent grade perchloric acid was used. It was diluted with water distilled from alkaline permanganate and then double distilled in a quartz still.

The electrodes.—Platinum foils of 99.999% purity were used in form of a square, ½ in. each side. After degreasing in hot 20% KOH, the foils were treated in hot 50% nitric acid and carefully washed in triple distilled water and in condensing steam.

Heat pretreatment.—The foils having platinum lead wires spot welded to them were cleaned, mounted in their quartz electrode holders and fitted into a quartz furnace tube. The foils were treated in a flow of oxygen at increasing temperature with at least 2 hr at 700°C. The tubes were then plugged and transferred to a glove box flushed with pure oxygen. Inside the box the electrode holder and foil were transferred to the cell.

In the case of "hydrogen pretreated foils" the same procedure was adopted except that after the oxygen treatment at 700°C the oxygen was displaced by helium and the foil was treated for 2 hr with hydrogen at 600°C. The foils were then cooled in helium and again exposed to oxygen at a temperature below 100°C for at least ½ hr. Oxygen was bubbled over the electrode, except where stated otherwise.

Instrumentation.—Potentials were read with a Keithley model 660 differential voltmeter. Open-circuit potentials were read at infinite input impedance using the Kelvin-Varley divider on the instrument. A Varian recorder was used only when the lower input impedance of the direct reading device (about 10^7 ohm) was considered not disturbing. Approximately constant currents were obtained by means of mercury batteries giving 28v and a set of fixed and variable resistors in series with the cell. Currents were measured by means of a Keithley electrometer, model 200B, and current shunt.

Results

Reduction of oxygen.—The following experiments are examples of the effect of the electrochemical pretreatment of solution and electrode on the current-voltage characteristics. Measurements shown in Fig. 1 were carried out in 1/10*N* perchloric acid which was pre-electrolyzed for 60 hr at 10 ma with oxygen bubbling through it. Two platinum pre-electrolysis

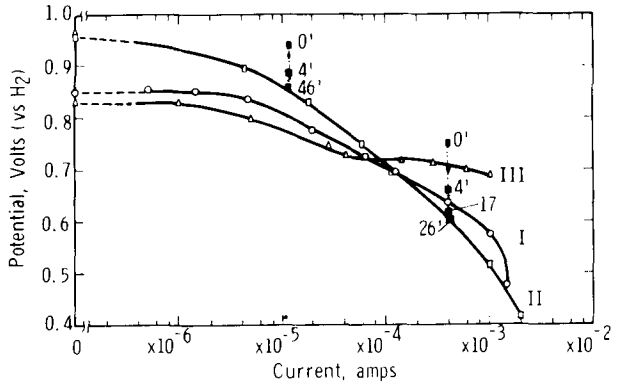

Fig. 1. Cathodic polarization curves of a chemically pretreated electrode; I, first polarization curve; II, after 10^{-4} amp/cm² overnight (■, overshoot on decreasing current); III, after anodization at 1.8v.

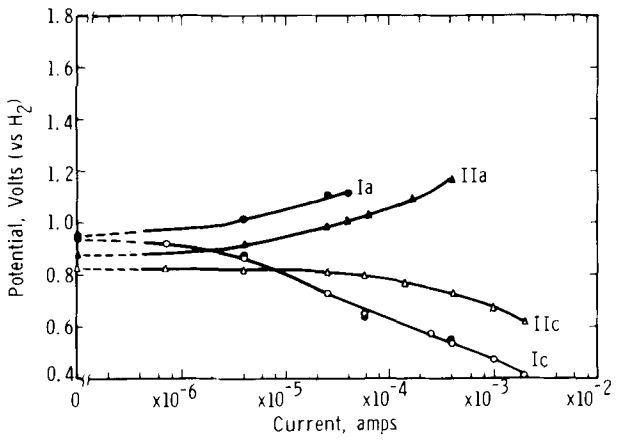

Fig. 2. Polarization curves after thermal gas pretreatments of electrodes: 1, after hydrogen pretreatment; 2, after oxygen pretreatment; c, cathodic, a, anodic.

electrodes of about 1 cm² area were in the main compartment of the cell which was later occupied by the test electrode. This type of pretreatment purifies the solution but generates hydrogen peroxide. The test electrode was dipped for 20 min in hot 50% nitric acid, washed and steamed before use, but was not treated thermally. The open-circuit potential, *vs.* hydrogen in the same medium, varied from 0.80v at a high oxygen bubble rate to 0.88v when the oxygen was shut off. The rise in potential, described in the literature (8), is due to the catalytic destruction of the peroxide at the electrode as is discussed later. The points shown in all figures were taken after 4 min at constant current. Only the open-circuit potentials (OCP) will be given as obtained 30-60 min after immersing the electrode or interrupting the current.

Curve 1 gives the cathodic galvanostatic polarization curve for increasing current settings. An overshoot at first occurred with each new current setting increasing to 25 mv at 10^{-3} amp. The potential then rose and became stationary within the given time. Currents were always cut off when strong fluctuations started indicating approach of the limiting current before drop to low potentials in the hydrogen evolution region. On decreasing the current a stronger overshoot occurred. The overshoot with increasing cathodic polarization is believed to be due to removal, on increasing the current, of strongly bound oxygen which decreases the activity of the electrode, as discussed later. On decreasing the polarization the reverse process occurs.

After leaving the current at 1 x 10^{-4} overnight, the OCP was higher, having risen to 0.962v. Another cathodic sweep then taken is shown in Fig. 1, curve 2. While the polarization was now lower at low currents it was higher at high currents. No good Tafel region was found; the approximate slope was 160 mv between 10^{-5} and 5 x 10^{-4} amp, while it was 115 mv in curve 1. The overshoot on the return curve as a function of time is indicated in Fig. 1 by the points at 4 x 10^{-4} and 1.3 x 10^{-5} amp.

After anodizing the foil several times in the same solution to about 1.8v (to determine the decay rate, as described below) the open-circuit voltage was found to be low, *viz.*, 0.835v. A cathodic curve then taken is shown as curve 3 in Fig. 1. The potential was now relatively low at low currents and high at high currents. The described behavior was qualitatively well reproducible: cathodizing at high current gave a relatively high open-current potential and a steep slope while anodizing gave a low potential at open circuit, but a small decrease in potential with increasing current.

The rate of decay measured after charging the foil anodically to 1.8v was measured oscillographically; it indicated peroxide concentration of the order of 10^{-4} mole/liter (see below).

In Fig. 2 curves obtained after different gas pretreatments of the electrode are presented. Curve 1 was obtained after the hydrogen pretreatment described in the Experimental Section. The initial open-circuit potential was 0.97v. On the following day the OCP was 0.94v. A cathodic sweep for increasing and decreasing current was taken which is shown in Fig. 2, curve Ic. The high open-circuit potential and the steep slope of 160 mv are very similar to what was obtained after cathodizing in Fig. 1. After anodizing, again a low open-circuit potential, 0.83v, and a flat characteristic was obtained (not shown). Curve 2 in the same figure shows the results after thermal oxygen pretreatment of another foil in a new solution. The open-circuit potential was low immediately, 0.85v, and the slope of the cathodic curve was small. This is similar to what was previously obtained after anodizing (Fig. 1).

Several experiments were made with gas pretreated electrodes in which the solution was only anodically pre-electrolyzed (3) for 20 hr at 5 ma. In these experiments the main cell compartment, later used for the test electrode, contained an auxiliary electrode serving as an anode, while the counter electrode was used as the cathode. This resulted in a lower peroxide concentration. Figure 3 shows two sets of curves in which the anodic sweeps were taken first, in 1*N* perchloric acid. Anodic potential values rose steadily and were taken after 4 min. It may be seen that the initial values for the hydrogen pretreated electrode are higher again, 75 mv at open circuit. In the present case this even holds for the cathodic sweeps taken after anodization although this was not always found. The potential

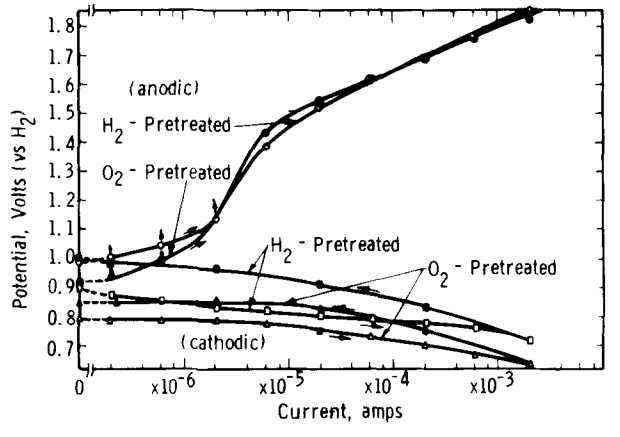

Fig. 3. Polarization curves with oxygen and with hydrogen pretreated foils in anodically pre-electrolyzed 1*N* perchloric acid. Anodic curves taken first. Cathodic curves shown for increasing and decreasing currents.

for an electrode which was not thermally pretreated was intermediate between the values found for oxygen and for hydrogen pretreated electrodes. Similar differences were also obtained when the cathodic sweeps were taken first, giving OCP's of 1.02 and 0.94v, respectively. The peroxide concentration in these experiments was of the order of 10^{-7} mole/liter.

Estimation of the peroxide concentration.—The peroxide concentrations were estimated in two ways, (i) from the anodic limiting current, (ii) from the rate of decay from a given high potential. In Fig. 3 the rate of rise to the oxygen evolution potential (1.45v) became appreciable below 10^{-6} amp/cm^2. The limiting current i_L is related to the diffusion coefficient, D, by the relation

$$i_L = \frac{2FD}{\delta} c$$

Winkelmann's (9) experimental results can be presented by the simple approximate relation

$$i_L(\text{amp/cm}^2) \approx c(\text{mole/liter})$$

Therefore the peroxide concentration in the present case was below 10^{-6} mole/liter.

Figure 4 shows a set of decay curves obtained with different added peroxide concentrations after charging the oxygen electrode to 1.8v. The decay rate may be seen to be a function of the peroxide concentration. A corrosion-like reaction apparently takes place involving the reduction of unstable surface oxygen and the simultaneous oxidation of peroxide. The approximate concentration of 10^{-7} mole/liter was found for the examples given in the previous paragraph by comparing the measured decay curves to the given set of standard curves.

In peroxide-free solutions, the decay (11) of the polarization would give a slope of only about 120 mv. The method, therefore, can be extended to even lower peroxide concentration and by far exceeds the sensitivity limit of chemical tests.

Reduction of peroxide.—The reduction of peroxide in 1*N* perchloric acid in helium-saturated solutions was also studied and compared to the oxygen reduction in the same electrolyte.

In Fig. 5, curves a and b show cathodic polarization curves at a concentration of added peroxide of 10^{-3} mole/liter, as obtained with a hydrogen pretreated electrode in helium and oxygen saturated solutions, respectively. Curves c and d were similarly obtained with a peroxide concentration of 10^{-4} mole/liter. It may be seen that the curves obtained with oxygen and with helium are practically identical up to the sharp potential drop in the helium-saturated solutions when the limiting current for the given peroxide concentration is approached at 10^{-3} and 10^{-4} amp/cm^2, respectively.

Curve e was obtained with an oxygen-pretreated electrode in a 10^{-4}M helium-saturated peroxide solution. In all cases the OCP on immersion was about 0.90v (±25 mv); for all hydrogen pretreated electrodes it decayed to 0.85v within 30 min, while for two oxygen pretreated electrodes the OCP was only 5-10 mv lower. On the other hand, an oxygen pretreated electrode which was exposed to laboratory air for 1 min gave an OCP as low as 0.80v.

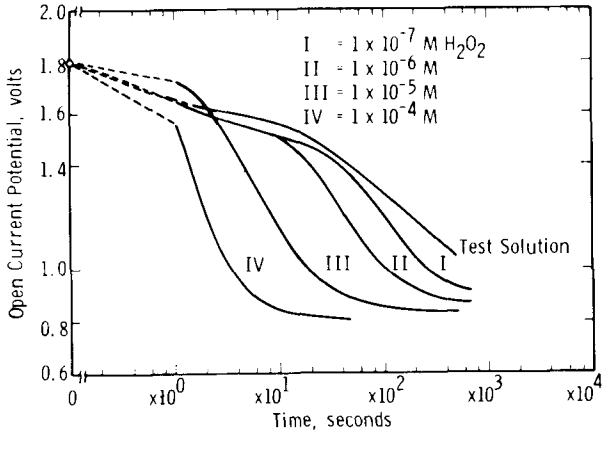

Fig. 4. Decay curves at varying peroxide concentrations

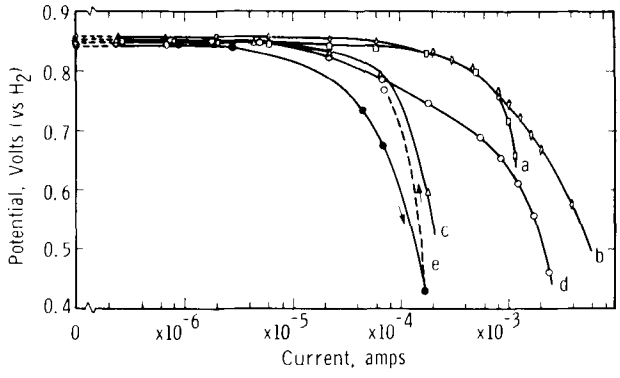

Fig. 5. Cathodic polarization curves at various added concentrations of peroxide: I. Hydrogen pretreated electrode: (a) 10^{-3}M H_2O_2, He-saturated solution; (b) 10^{-3}M, O_2 in solution; (c) 10^{-4}M H_2O_2, He; (d) 10^{-4}M H_2O_2, O_2. II. Oxygen pretreated electrode: (e) 10^{-4}M H_2O_2, He.

In 10^{-5}M peroxide solutions the oxygen reduction curve lies clearly above the peroxide reduction curve, as seen from Fig. 6. Again a hydrogen pretreated foil was used. (The cathodic limiting current was relatively high, about 10^{-4} instead of the 10^{-5} amp/cm^2 expected, presumably due to incomplete oxygen removal from the solution.)

In all cases again a distinct overshoot was found when decreasing the cathodic polarization. It amounted to between 30 and 80 mv on opening the circuit and returned to within 10 mv of the original OCP within about 30 min. Also a small stirring effect on the OCP was found at all peroxide concentrations. The potential in unstirred solutions was about 15 mv higher than at high stirring rates.

Catalytic decomposition of peroxide by platinum.—The higher OCP of the hydrogen pretreated or cathodized platinum electrodes at low peroxide concentrations may be explained by a higher decomposition rate of the peroxide. To test this possibility the catalytic decomposition by differently pretreated electrodes was studied.

Two electrodes which were stored after use in the preceding experiments in triple-distilled water were first used in qualitative tests. An oxygen pretreated electrode stored for one week formed practically no bubbles on the electrode surface when dipped into a 1% aqueous peroxide solution, while a hydrogen-pre-

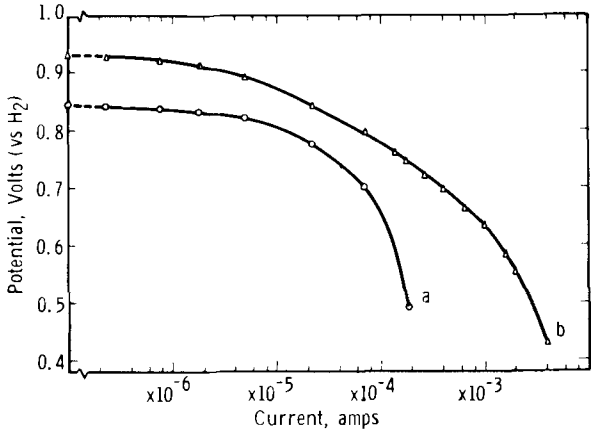

Fig. 6. Cathodic polarization curves at 10^{-5}M H_2O_2: a, He; b, O_2 atmosphere.

treated electrode stored for two weeks rapidly covered itself with oxygen bubbles.

In a more quantitative experiment, a new platinum foil was oxygen pretreated and then dropped into a 1% peroxide solution in perchloric acid. The gas evolved was collected in an inverted buret. A gas evolution rate of 0.01 cc/min of oxygen was measured. The rate gradually decreased to 1/3 in the course of 16 hr.

The experiment was repeated with the same foil after hydrogen pretreatment. After the usual exposure to oxygen at room temperature (see Experimental Section) the oxygen evolution rate in the solution was measured and found to be 0.10 cc/min., *i.e.*, 10 times larger than in the previous experiment.

Discussion

According to Gerischer (10) and Winkelmann (9) the catalytic decomposition of hydrogen peroxide is the result of an over-all anodic process

$$H_2O_2 \rightarrow O_2 + 2H^+ + 2e^- \quad [1]$$

and an over-all cathodic process

$$H_2O_2 + 2H^+ + 2e \rightarrow 2H_2O \quad [2]$$

proceeding at equal rates when no current is flowing. The OCP at, or above, 10^{-4}M peroxide is 0.85v; it is a mixed potential set up by the two given reactions.

Since the gas pretreatment did not change the peroxide potential appreciably, we conclude that the rates of the two reactions, [1] and [2], are about equally affected by the pretreatment. On the other hand, the drop in OCP, found for an electrode poisoned by exposure to the contaminations of laboratory air, is to be explained by a larger decrease in the rate of step [2]. The reduction of peroxide may be expected to be more sensitive to poisoning of the metal surface because, contrary to step [1], step [2] involves the complete dissociation of an oxygen-oxygen bond.

The dependence of the decomposition rate of hydrogen peroxide on the pretreatment suggests a simple explanation for the dependence of the open-circuit potential of the oxygen electrode on pretreatment. At relatively low peroxide concentrations (10^{-5} to 10^{-7} mole/liter), when the peroxide reduction is slower than the oxygen reduction, the O_2/H_2O_2 couple may mainly determine the open-circuit potential, as is often assumed for alkaline solutions (11). (At even higher potentials other equilibria such as oxygen chemisorption may also be of importance or the reduction of oxygen may be balanced by other anodic reactions, such as the oxidation of impurities.) The standard potential of the O_2/H_2O_2 couple is 0.68v (12) and, according to the Nernst equation, the potential rises by 2.30 x $RT/2F$ = 30 mv with each decade of decreasing H_2O_2 concentration. In view of the catalytic activity of the electrode no true equilibrium is established with the bulk of the solution. The rise in OCP after hydrogen pretreatment or cathodization then is a consequence of the increased activity of the electrode which lowers the concentration of peroxide in the diffusion layer. Similarly, the dependence on the gas flow can be explained by a change in convective transport: the concentration of peroxide at the electrode further diminishes as the flow rate decreases. Thus in a stirred solution having a peroxide concentration of roughly 5 x 10^{-8}M (Fig. 3), the peroxide concentration at the oxygen-pretreated electrode (OCP = 0.92v) would be about 10^{-8}M, while at the hydrogen-pretreated electrode (OCP = 0.99v) it would be about 10^{-10}M.

Under current drain, it was also found that in all cases the potential at a given oxygen reduction rate depended on the electrode pretreatment. At low peroxide concentrations, the polarization for hydrogen-pretreated electrodes was smaller than for the oxygen-pretreated electrodes throughout the cathodic range up to the diffusion-limited current (Fig. 3).

The overshoot found on changing the current may also be explained by a change in catalytic activity as the oxygen content of the surface changes. Breiter (13), from a study of periodic sweeps taken at a much faster rate, suggested that adsorbed oxygen hindered the oxygen reduction reaction. The long lasting effects observed in our work show that the change in activity is due to oxygen strongly embedded in the surface (7). The oxygen changes the activity of the surface but does not directly enter into the reaction. The similarity of the effect on the potential of cathodic pretreatment and thermal hydrogen pretreatment seem to confirm this explanation.

In the initial experiments, carried out at higher peroxide concentrations (Fig. 1 and 2), the slope found for the hydrogen or cathodically pretreated electrodes was considerably higher than for the oxygen pretreated electrodes and at higher currents the former showed the larger polarization. No definite conclusions can be drawn on the basis of the present experiments. The electrolyte in the early experiments may not only have contained a higher peroxide concentration but may also have differed in impurity content as a result of the different preelectrolysis procedure used. We are inclined to believe that the greater inhibition of the oxygen reduction for the surface containing the electropositive hydrogen may have been caused by a stronger adsorption of impurity anions (possibly Cl^-). The latter were more thoroughly removed by the anodic preelectrolysis used in the later experiments.

The experiments show the difficulty involved in predicting or analyzing the long-term polarization behavior of the oxygen electrode. The oxygen content of the surface changes with potential and time and thus the activity for the intermediate steps should change in a manner difficult to predict. Similarly, experiments in a dry system (7) have shown that the nature of the adsorbed oxygen tends to change with time; it changes to a more stable form which decreases the catalytic activity. It thus may be expected that a slow deactivation of the platinum electrode would be observed even in absence of impurities.

The Indous Ion: An Intermediate in the Electrochemical Oxidation of Indium Metal

R. E. Visco

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

It has been demonstrated that in a stirred acidic noncomplexing medium, the In(I) ion is an important intermediate in the electrochemical oxidation of either indium metal or its amalgam to the In(III) ion. The In(I) ion formed during anodization can be swept away from the electrode surface and can be detected polarographically in the bulk of the solution. The current efficiency in stirred solutions for In(I) production is about 2% in the case of dilute indium amalgams. For indium metal anodes, the current efficiency for In(I) production under the same conditions is at least 75% and is dependent on anodic current density. The effects of mass transport conditions during electrochemical oxidation and of added complexing agents on the quantity of In(I) formed have also been investigated. Based on overpotential decay curves, the polarographic behavior of In(I) and In(III), and coulometric experiments, an electrochemical mechanism is proposed which postulates that the In(I)/In(O) couple is at equilibrium, that the interfacial concentration of In(I) is not vanishingly small, and that an irreversible electrochemical step is associated with the further oxidation of In(I) to In(III).

The aqueous electrochemistry of the higher atomic weight group IIIB elements has been the subject of much scientific interest. For all these elements, the +3 oxidation state is stable in aqueous solution. Vetter (1) has studied both the oxidation and reduction processes for the two-electron Tl(III)/Tl(I) system. Bockris and Enyo (2, 3) have studied the oxidation and reduction processes for the Ga(III)/Ga(O) couple with gallium metal as either a liquid or solid electrode. The In(III)/In(O) couple has been studied using amalgam electrodes by several workers (4-7). In addition to these studies on stationary electrodes, usually made under steady-state conditions, a large body of information, particularly on indium, is available from studies using dropping mercury and dropping amalgam electrodes (8-12).

For the cases of gallium and indium, the over-all electrochemical oxidation is a three-electron process. This multi-electron transfer presents the possibility that during the electrochemical process there may exist detectable quantities of two intermediate oxidation states. Corbett (13) has recently demonstrated that Ga(I) does exist in measurable quantities during the electrochemical oxidation of gallium metal. Hurlen (14, 15) recently reported an extensive study of the oxidation of liquid gallium metal and concluded that lower valent gallium species are formed and can be swept away from the electrode surface.

This paper is a report on a search for In(I) as an intermediate during the electrochemical oxidation of either indium metal or its amalgam. Epelloin (16) has presented coulometric data which suggests that lower valent In(I) species are formed during electropolishing of indium metal in either acetic acid or ethyl alcohol. Losev and co-workers (4-6) have reported on electrochemical and radiochemical studies of the In(III)/In(O) couple using amalgam electrodes. These workers have ascribed a transitory existence to lower valent indium oxidation states and imply that In(III) and In(O) are the only indium oxidation states that can exist during anodization at anything but infinitesimal concentrations. On the other hand there exists a body of information on equilibration of In(O) with solutions of In(III) (17-20) which suggests that at least In(I) can exist at a finite concentration.

Experimental

All chemicals used in this study were reagent grade meeting ACS specification, except those listed below. Indium metal, obtained as shot or rod from American Smelting and Refining Company, South Plainfield, New Jersey, was of 99.999+% purity. The mercury used was triply distilled. Indium amalgams were prepared by determinate weighing of the constituents. Sodium perchlorate was prepared by quantitative neutralization of Na_2CO_3 with $HClO_4$. All solutions were tested for any halide ion by recording the polarographic residual current at potentials anodic of 0v *vs.* saturated calomel electrode (SCE). Residual currents recorded in $NaClO_4$ solutions were identical to those of the $HClO_4$ used, and no wave prior to the oxidation of mercury to Hg^{++} was observed.

The reaction vessel was a thermostatted cell (volume *ca.* 70 ml) similar in design to that sold by Brinkman Instruments. Nitrogen, which was passed through two vanadium (II) wash towers and a water wash, was continuously passed into or above the solution to purge O_2. The amalgam was held in a Riley electrode (Sargent No. S-30438) giving a surface area of 1 cm^2. Indium metal anodes were 0.25 in. in diameter rods. The dropping mercury electrode used was of a conventional design. In addition to the dropping mercury and indium electrodes, a reference and a counterelectrode were also employed; both were saturated calomel electrodes. Each SCE was isolated from the solution by a perchloric acid-silica salt bridge which was similar in composition to the sulfuric acid-silica bridges described by Vinal (21).

The polarograph was a Sargent Model XV modified to have a 1-sec pen response. A Sargent Model IV coulometric current source was employed. Voltage-time curves for the indium electrodes were recorded in several ways. A Keithley Model 610A electrometer and a L&N K-3 potentiometer were used to make steady-state potential measurements. Potential-time transients were recorded using a locally fabricated high-impedance voltage follower (22) and either a Sargent MR Recorder or a Tektronix 565 Oscilloscope with 2A63 preamplifiers. Temperature control was achieved using a thermistor temperature controller so that bath temperature could be controlled to $\pm$ 0.05°C. Micrometer driven syringe burets were used to deliver small quantities of solutions into the glass cell.

Stirring was provided by a Teflon or glass-coated magnetic stirring bar. For a given series of experiments reproducible mass transport conditions in the

cell were maintained by controlling the position and the speed of the stirring bar.

The experimental procedure employed for the analysis of In(III) solutions is described below. To an aliquot of anolyte a quantity of HCl was added to the In(III) solution such that the Cl^- concentration after quantitative dilution became 0.20M. A polarogram was recorded of the In(III) solution and the limiting current at —0.65v *vs.* SCE measured. At this potential and chloride concentration, the polarographic limiting current is diffusion controlled and proportional to the In(III) concentration. Known solutions of In(III) were prepared by determinate weighing of indium metal. The diffusion current constant, *I*, evaluated from the simple Ilkovic equation was found to be 5.20 with a coefficient of variation of 0.6%. The numerical constant used in the Ilkovic equation was 706 since an underdamped current measuring device was employed.

Results

General.—It will be shown that, during anodization of either indium metal or its amalgam, In(I) is an important intermediate in the oxidation. The existence and importance of In(I) can be demonstrated by the detection of In(I) carried by mass transport to the bulk of the solution. The In(I) can be detected at an electrode independent of that used for its generation. To demonstrate the existence and importance of an intermediate in an over-all multi-electron process, the above procedure is preferred to the calculation and subsequent comparison with experiment of a set of current-voltage curves for the case where the interfacial concentration of an intermediate is not vanishingly small.

Polarography of In(I).—Using the dropping mercury electrode as a probe, it is observed that after electrochemical oxidation in stirred solutions of 0.70M $HClO_4$ with anodes of either indium metal or indium amalgam, the anolyte contains a soluble species which can be both oxidized and reduced, Fig. 1 of ref. (20). When corrections are made for the homogeneous decay of the electroactive species (*vide infra*), both the anodic and cathodic process at the dropping electrode are found to be diffusion controlled. For both processes, the limiting current is proportional to the square root of the height of the mercury column and extrapolation to zero column height gives zero current (23). At any given time after termination of the electrolysis, the ratio of the anodic current (—0.20v) to the cathodic current (—0.65v) at the dropping electrode is 2.0, Fig. 2 of ref. (20).

The anodic and cathodic currents decay with time. Plots of log current *vs.* time are linear for at least 4 half-lives. Anodic currents decay completely; after complete decay, the polarogram at potentials more positive than —0.70v *vs.* SCE is identical to the residual current of $HClO_4$. The irreversible reduction of the aquo-indic ion becomes important at potentials more negative than —0.75v. The decrease in polarographic current after anodization results from a homogeneous rather than heterogeneous decay of the electroactive species. This is true since polarograms are recorded in quiet solutions, and because the decay rate is unaffected by periodic stirring. Polarograms recorded with intervening 1-min periods of vigorous stirring show no enhancement in the rate of In(I) disappearance. The intentional addition of In(III) and the build-up of products from repeated anodization experiments do not affect the rate of polarographic current decay.

Based on the above experimentally observed ratios of diffusion-controlled polarographic currents and the potentiometry at indium metal electrodes (*vide infra*), the lower oxidation state of indium present in solution after anodization must be In(I). The electrochemical oxidation process occurring at the dropping electrode therefore is

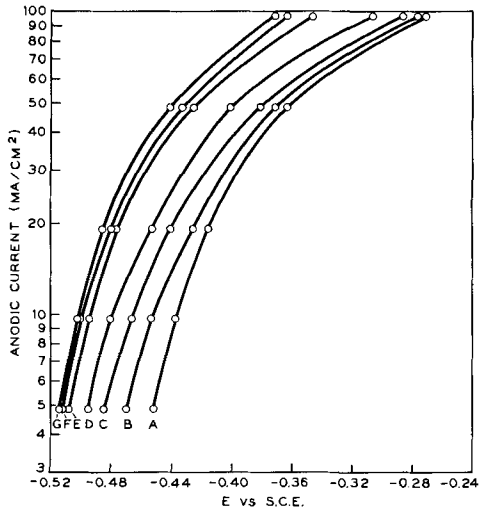

Fig. 1. Current density *vs.* potential for 2 mole % indium amalgam at 20°C as a function of added Cl^- in well stirred 0.70M $HClO_4$ with In(III) of 5 x 10^{-3}M: A, 0; B, 0.016; C, 0.031; D. 0.057; E, 0.091; F, 0.123; G, 0.153.

$$In(I) - 2e^- \rightarrow In(III) \quad [1]$$

while the reduction process is

$$In(I) + 1e^- \rightarrow In(Hg) \quad [2]$$

Homogeneous disappearance of In(I).—The indous ion is observed to decay by a first-order chemical reaction in acidic solution, Fig. 2 of ref. (20). In 0.70M $HClO_4$ solution, the pseudo first-order rate constant at 20°C is 5.28 x 10^{-3} sec^{-1}. This constant decreases linearly with decreasing acidity. A detailed description of the solution chemistry of the indous ion is given elsewhere (20).

Anodization experiments on indium metal and indium amalgam electrodes.—For the stirred solutions and at the high currents used in this study, a plot of log current density *vs.* potential for a 2 mole % amalgam electrode is nonlinear and is shown in Fig. 1, where results for Cl^- containing solutions are also shown. These curves are independent of stirring at the high stirring rates employed. If, during an anodization experiment, stirring is terminated, the electrode potential drifts anodic by about 25 mv. Experiments performed in quiet solutions thus give plots which are similar but displaced with respect to those obtained using stirred solutions. In stirred solutions regardless of the magnitude of the applied current, the potential of the working anode varies by no more than 2 mv during a typical 10-min anodization experiment. The slopes of these Tafel plots at the lowest current densities studied approach 40 mv/decade. Anodization experiments were not carried to current densities below 5 ma/cm^2, and the curvature in Fig. 1 is probably due to amalgam concentration polarization and iR drop. The limiting current density for the 2% amalgam used is somewhat less than 200 ma/cm^2. These data, therefore, place only an upper limit on the Tafel slope. Several workers have already reported on the Tafel experiments at lower current densities, and a value of 27 mv/decade is typical (5-7).

Since in stirred solutions In(I) is observed polarographically in the bulk of solution, it must be either the final product of the anodization or an electrochemical intermediate swept away from the electrode surface. In order to investigate this point further, the efficiency for In(I) formation and escape to the bulk was investigated at both metal and amalgam electrodes. The efficiency for the escape of In(I) from the electrode surface during anodization can be evaluated in two ways. Concentration of In(I) after

anodization and the average valence of indium going into solution are both measures of this efficiency.

During anodization, the steady-state concentration of In(I) is reached in a time equal to 5 half-lives for the decay of In(I), or about 10 min in 0.70M $HClO_4$ at 20°C. The concentration of In(I) as a function of time for the approach to the steady state can be calculated using expressions for the rate of decay of In(I) by the chemical reaction with H^+ (20) and the electrochemical formation rate at the anode. These expressions are given below

$$R_{decay} = k_1[In(I)] \quad [3]$$

$$R_{escape} = k_2(E) \quad [4]$$

and

$$\frac{d[In(I)]}{dt} = k_2(E) - k_1[In(I)] \quad [5]$$

The constant k_1 has been previously defined. The term $k_2(E)$ is a constant describing the rate of formation and escape of In(I) to the bulk; such a constant is surely dependent on the anode potential, E, and the mass transport conditions prevailing in the cell during the experiment.

The solution to Eq. [5] with the initial condition that $[In(I)]_{t=0} = 0$ is

$$In(I) = \frac{k_2(E)}{k_1}(1-e^{-k_1t}) \quad [6]$$

The concentration of In(I) can be evaluated from the polarographic limiting current provided the diffusion coefficient is known. The diffusion coefficient of In(I) is unknown, but it should be very similar to that of Tl(I), 17.9×10^{-6} cm^2 sec^{-1} (24). If only comparisons are of interest, the variation of $k_2(E)$ with anode current and, therefore, anode potential should be independent of the value of the diffusion coefficient for In(I). A comparison of the efficiency for formation and escape of In(I) as a function of potential is therefore meaningful even if the exact value of the diffusion coefficient of In(I) is unknown.

Relevant experimental data for amalgam electrodes are shown in Table I, while the data for solid indium electrodes are given in Tables II and III. Several anode current levels were investigated, and experiments were performed at different times prior to the attainment of the steady-state concentration of In(I). The observed polarographic currents for each type of electrode divided by $(1-e^{-k_1t})$, where t is the length of anodization in seconds, yields a constant value which corresponds to the polarographic diffusion current for the oxidation of In(I) to In(III) when the concentration of In(I) has reached a steady state. The limiting anodic current for the amalgam electrode is less than 200 ma/cm^2, thus, in a potential region where concentration polarization of the amalgam is important, significant quantities of In(I) are observed to escape from the electrode surface to the bulk of the solution.

Since In(I) is observed away from the electrode surface, at least one mass-transport step is required to distribute the product of the anodization throughout the solution. To test the importance of this mass transport step on the quantity of In(I) observed, experiments designed to measure the In(I) concentrations were carried out at several different stirring rates. Data for an amalgam anode are given in Table IV. It is seen that stirring is, indeed, important in determining the quantity of In(I) observed in the bulk. It was observed in other experiments with amalgam electrodes that, at a fixed stirring rate, anodization current and anodization time, the concentration of In(I) reached during that time (< 10 min) was constant. Comparisons within a series of experiments performed in the same solution are, therefore, quantitative, but because of differences in the relative positions of anode, stirrer, and salt bridges, changes in mass transport conditions occur. Thus, comparison of data obtained with different solutions on different days can be only qualitative. These geometry restrictions appear to be less severe for solid anodes. The reproducibility of $\bar{n}$, the average number of electrons transferred per atom of indium dissolved, calculated using Eq. [7], for two different solutions at the same cur-

rent density appears satisfactory (Tables II and III).

It is possible to translate the calculated $k_2(E)$ [subject to the assumption of an In(I) diffusion coefficient] into $\bar{n}$ by the equation

$$\bar{n} = \frac{3k}{2k_2(E) + k} \qquad [7]$$

The quantity k in Eq. [7] is the number of equivalents of charge passed per second per liter of anolyte, Tables I, II, and III.

The second method for evaluation of the efficiency of the formation and escape of In(I) during anodic dissolution is the determination of the average number of electrons transferred per atom of indium dissolved, n, by a coulometric technique. Experiments of this type require an analytical method for total dissolved indium. It has been shown (20) that in acidic solutions In(I) is oxidized by H^+ to In(III); therefore, a determination of In(III), provided sufficient time is allowed for In(I) decay, is a satisfactory method of analysis.

Results of the experiment described above for both metal and amalgam anodes are shown in Table V. Experiments of this type should be dependent on mass transport conditions prevailing in the cell during anodization; therefore, quantitative interpretation of the departure from an n value of 3 is difficult. Qualitatively, it can be seen that for amalgam electrodes $\bar{n}$ approaches 3 only at the highest current density employed.

The $\bar{n}$ data for solid electrodes were taken sequentially in the same solution with In(III) samples removed after each anodization. The corresponding polarographic currents for the In(I) ion appear in Table III as the first three entries. The data allow a direct comparison between the two methods of evaluating the importance of In(I).

Agreement between the two methods is quite good. The corresponding values for the same experiment are 1.17 *vs.* 1.25, 1.21 *vs.* 1.31, and 1.24 *vs.* 1.30. These small differences in the two methods of calculating $\bar{n}$ can be rationalized by either (or both) of two explanations. The diffusion coefficient of 17.9×10^{-6} cm² sec^{-1} assumed for In(I) is about 15% high and a value of 15.5×10^{-6} cm² sec^{-1} is correct. The alternate explanation is that since at the anode surface during generation the concentration of In(I) is about tenfold larger than in the bulk, the rate of the reaction with H^+ is also a factor of 10 larger, thus consuming In(I) close to the interface before it can be distributed to the bulk. An approximate tenfold difference in concentration can be shown to exist based on the open-circuit potential curves discussed in the next section.

Open-circuit potentials on indium metal electrodes. —The open-circuit potential of an indium metal electrode was followed as a function of time after anodization. Potential-time curves in stirred and unstirred solutions are shown in Fig. 2 and 3. If the electrolysis carried out in a stirred solution is sufficiently long to build up the In(I) ion concentration to above 10^{-5}M (for example, 150 sec at 14.4 ma/cm²), the decay of

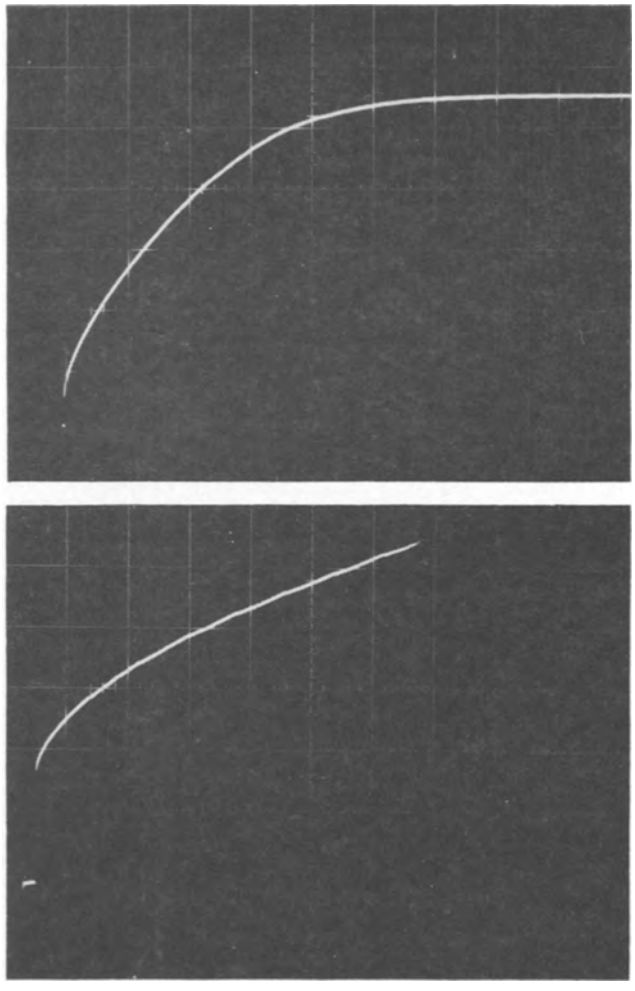

Fig. 2A and 2B. Overpotential decay curves for solid electrodes in stirred solutions of 0.70M $HClO_4$ at 20°C, anodized at 13 ma/cm²; upper curve (Fig. 2A) 20 mv/cm and 0.5 sec/cm; lower curve (Fig. 2B) 5 mv/cm and 20 msec/cm.

open-circuit potential on an indium metal electrode is linear with time for at least 4 min, Fig. 3, curve A. For a short electrolysis (~5 sec at 14.4 ma/cm²) in a stirred solution, the return to the open-circuit rest potential is more rapid, and no linear potential decay is observed, Fig. 3, curve B.

During anodization in a quiet solution, In(I) exists only at or very close to the electrode surface and is not distributed throughout the bulk of solution. When the anodization is terminated, the value of the open-circuit potential for a quiet solution is a few millivolts more positive than that for a stirred solution. It is also observed that the open-circuit potential decays more rapidly for the quiet solution than for a stirred solution. The latter will be true since diffusion of In(I) away from the electrode, as well as oxidation of In(I) by H^+, remove In(I) from the solution volume adjacent to the electrode surface, curves A and C, Fig. 3. For a quiet solution stirred during the measurement of potential decay, Fig. 3, curve D, the potential almost immediately returns (< 10 sec) to the stirred, open-circuit rest potential. The relatively small quantity of In(I) existing close to the electrode surface during anodization in a quiet solution is now distributed by the subsequent stirring through the entire solution. After stirring, the electrode thus sees a solution very little different from that if there had been no anodization at all.

Based on this and the polarographic evidence given earlier, this potential-time behavior of an indium metal electrode depends on the In(I) ion concentration. Two couples involving In(I) are possible

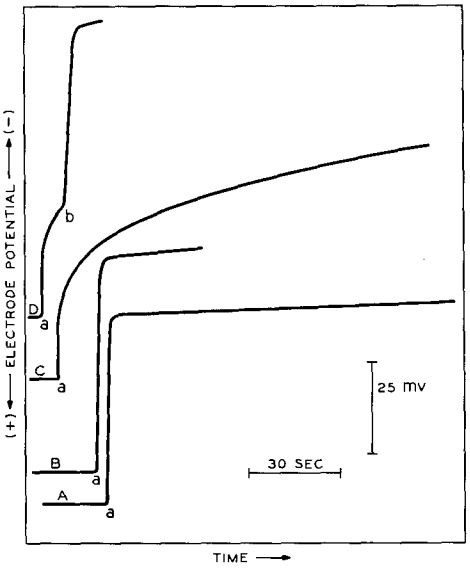

Fig. 3. Open-circuit potential-time curves for an indium metal electrode in 0.70M $HClO_4$ at 20°C with 5 x 10^{-3}M In(III). For each curve the anodization was discontinued at point "a". Curve A, electrode anodized for 150 sec at 14.4 ma/cm^2 in well-stirred solution; curve B, electrode anodized for 5 sec at 14.4 ma/cm^2 in a well stirred solution; curve C, electrode anodized for 150 sec at 14.4 ma in an unstirred solution; curve D, anodization carried out as in C, but during potential decay stirring was commenced at point "b".

$$In(I) + 1e^- \leftrightarrows In(0) \quad [8]$$

and

$$In(III) + 2e^- \leftrightarrows In(I) \quad [9]$$

Because the In(I) ion is unstable with respect to oxidation by H^+, the potential of an electrode responding to In(I) should vary with time. The electrode potential should become more oxidizing if the electrode responds to the In(III)/In(I) couple, but it should become more reducing if it responds to the In(I)/In(0) couple. On open circuit, the potential of the indium metal electrode becomes more reducing; the electrode is, therefore, responding to the In(I)/In(0) couple. The time dependence of the potential can be calculated from the Nernst equation for reaction [8] and the known (20) rate law for the decay of In(I) by the homogeneous reaction with H^+

$$E = E^{0'}_{In(I)/In(0)} + \frac{2.3\,RT}{F}\log[In(I)^0] - \frac{2.3\,RT}{F}k_1 t \quad [10]$$

In Eq. [10], $E^{0'}_{In(I)/In(0)}$ is the formal potential for the In(I)/In(0) couple, $[In(I)^0]$ is the zero time value of the bulk In(I) concentration, and k_1 has already been defined in Eq. [3]. For the initial 4-min linear portion, the observed rate of decay of open-circuit potential is —8.0 mv/min, while the calculated value for the In(I)/In(0) couple, using the k_1 value, at 20°C in 0.70M H^+ is —8.05 mv/min. After the initial 4-min portion, the rate of potential change decreases and, in about 12 min the open-circuit rest potential is reached.

The decay of overpotential recorded on a millisecond time scale is given in Fig. 2B. It can be seen that at 13 ma/cm^2, there is about 8 mv of iR drop. On a slightly longer time scale, Fig. 2A, two distinct segments of overvoltage decay can be seen. The second segment corresponds to that calculated using Eq. [10]. The initial, more rapidly changing portion can be viewed as that brought about by stirring which distributes the high concentration of In(I) in the Nernst diffusion layer throughout the bulk of the solution. The potential difference between the extrapolated zero time value of the potential decay curve changing at 8 mv/min and the initial open-circuit potential (corrected for iR), Fig. 2, is about 60 mv. Such a potential difference for a reversible 1 electron couple corresponds to a concentration difference of a factor of 10 between the electrode interface and the bulk of the solution.

The value of the open-circuit rest potential for indium metal in perchloric acid is dependent on both stirring and the In(III) concentration. For a given In(III) concentration, the rest potential is 10 mv more cathodic in a well-stirred solution than in a quiet solution. If stirring is terminated, the rest potential reaches the value for a quiet solution in less than 2 min, while if a quiet solution is stirred, the potential shifts in less than 10 sec.

The effect of stirring on rest potentials and on open-circuit decay curves is consistent with the metal electrode responding to changes in In(I) ion concentration. The rest potential in a stirred solution is more cathodic than in a quiet solution because In(I) is being swept away from the electrode surface. A finite concentration of In(I) is maintained at the surface in the absence of external current by a cathodic process. The irreversible hydrogen evolution reaction on indium metal (25) is the most likely cathodic process, but the irreversible reduction of In(III) is also possible (4).

Effects of added Cl^- *on the quantity of* In(I) *formed at metal and amalgam electrodes.*—An examination of the quantity of In(I) generated as a function of added Cl^- in experiments performed at the same anodic current for equal times using amalgam electrodes is instructive. Tafel curves for the relevent current densities and Cl^- concentrations are given in Fig. 1. When the solution is made 3.9 × 10^{-3}M in Cl^-, the concentration of indous ion after anodization is half that when no Cl^- is present. It was also observed that the rate of decay of In(I) is unaffected by the addition of Cl^- up to the highest concentration investigated (8.0 × 10^{-3}M). This observation of a decreased efficiency for formation and escape of In(I) is consistent with the change observed in the position and slope of the Tafel plots shown in Fig. 1. The effect of added Cl^- on the quantity of In(I) generated during oxidation of indium metal electrodes is given in Table III. The quantity of In(I) generated at 8 × 10^{-3}M Cl^- is still significant, but is fivefold less than in the absence of added chloride ion.

Discussion

The electrochemical oxidation in noncomplexing media of either indium metal or its amalgam in well-stirred solutions leads to a measurable quantity of In(I) ion in solution. Based on the coulometric and polarographic data from experiments with indium metal electrodes, at least 75% of the current goes to In(I) which escapes to the bulk of solution. For several mole per cent indium amalgams, the polarographic results indicate about 2% of the current goes to In(I) which can be detected at the dropping electrode. Higher but probably less reliable data for In(I) escape are obtained by the coulometric technique for amalgam electrodes.

If only successive one-electron transfers are considered, the slowest electron-transfer step for the oxidation of both the metal and its amalgam must be after the initial formation of In(I). At low current density, a Tafel slope of 27 mv/decade for the oxidation of the amalgam is consistent with the slow step being the oxidation of In(II) to In(III) for which values of between 20 to 30 mv/decade are expected. Further, the polarographic reduction of In(III) in noncomplexing media suggests that the first-electron transfer is the slowest, since the cathodic transfer coefficient is about 0.5.

The early cycling experiments of Heyrovsky (26) at dropping electrodes for In(III) in a $SO_4^=$ media may now be explained by considering the behavior of In(I) produced as an intermediate in the indium amalgam oxidation. Heyrovsky observed no cathodic "kink" or potential arrest, but only an anodic kink on the first

complete voltage cycle. The irreversible reduction of In(III) would produce no obvious kink on the first cycle, but the oxidation of In(0) to In(I) would produce a kink on the first anodic sweep. Heyrovsky also observed that a "warming-up makes the cathodic kinks sharper" on successive cycles. This would be true if the In(I) formed during the previous anodic half-cycle is reduced on the next cathodic half-cycle. The large voltage sweeps of 1-2v employed by Heyrovsky are well suited for such observations.

A mechanism proposed previously (4, 5, 7) for the electrochemical oxidation of indium amalgam is consistent with the data presented here and is given below

$$\mathrm{In(0)} \underset{v_{-1}}{\overset{v_{+1}}{\rightleftarrows}} \mathrm{In(I)} + 1e^-, \quad \text{fast} \qquad [11]$$

$$\mathrm{In(I)} \underset{v_{-2}}{\overset{v_{+2}}{\rightleftarrows}} \mathrm{In(II)} + 1e^-, \quad \text{fast} \qquad [12]$$

and

$$\mathrm{In(II)} \underset{v_{-3}}{\overset{v_{+3}}{\rightleftarrows}} \mathrm{In(III)} + 1e^-, \quad \text{slow} \qquad [13]$$

The previous treatments of this problem have assumed that transport of In(I) and In(II) to the bulk is unimportant; this is equivalent to the assumption that the interfacial concentrations of these intermediates are vanishingly small. Based on the data presented here for both amalgam and metal electrodes, the interfacial concentration of In(I) is not vanishingly small, and, therefore, some account must be taken of its transport to the bulk of solution. Consideration of the rate expressions for reactions [11] to [13] when transport of In(I) is important leads to the following expression for anodic current in the potential region when the cathodic back reaction is no longer important

$$\frac{i}{A} = F\,\mathrm{In(0)} \left\{ 3\,\frac{k_{+3}k_{+2}k_{+1}}{k_{-2}k_{-1}}\, e^{(2+\beta_3)F\Delta\phi/RT} + m\,\frac{k_{+1}}{k_{-1}} e^{F\Delta\phi/RT} \right\} \qquad [14]$$

The several k's are the rate constant for the unit steps in the oxidizing (+) and reducing (—) direction when $\Delta\phi = 0$. The mass transfer coefficient, m, for In(I) can be written D/δ where δ is the Nernst diffusion layer thickness. On examination of Eq. [14], it is clear that as $\Delta\phi$ becomes more positive, the fraction of the current going to In(I) which escapes should decrease, a fact substantiated by the data presented in Tables I, II, IV, and V.

The electrochemical mechanism suggested by Losev (4, 5) is that given above where both the In(I) and In(II) interfacial concentrations are vanishingly small. At the current densities investigated here, several per cent of the current goes to the formation of In(I). Losev suggested that In(I) does exist, but did not consider its interfacial concentration to be important. At the current densities he used, larger fractions of the current should go to In(I) formation than that indicated at the current densities reported here.

It has been reported (27, 28) that metallic indium anodes on electrochemical oxidation disintegrate to give a suspension of finely divided particles of indium metal. Straumanis (27) states that, at current densities greater than 70 ma/cm^2, such particles can be observed. Current densities used with metal anodes in this investigation were at least five times less than the observed lower limit for particulate formation. After oxidation, the electrodes used in this investigation were bright, and some faceting of the polycrystal rods could be seen, but no particles could be observed during or after dissolution.

The system In(0), In(I), and In(III) in acidic solutions where In(I) appears to have a finite chemical lifetime as well as a finite interfacial concentration should be an interesting system to study using one of the newer electrochemical techniques. An impedance method similar to that described by Sluyters-Rehback and Sluyters (29), or the method of faradaic rectification Section to be published in the June 1966 JOURNAL.

Manuscript received Feb. 10, 1965. This paper was presented at the Toronto Meeting, May 3-7, 1964.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

The Effect of Cathodic Prepolarization on Capacity Curves of Germanium Electrodes

Christof C. Krischer and Robert A. Osteryoung

North American Aviation Science Center, Thousand Oaks, California

ABSTRACT

Rapid potentiostatic capacity-potential measurements were carried out at Ge electrodes in solutions of pH 1, 7, and 12. Two distinct capacity curves were observed. If cathodic current flow was excluded, capacity-potential curves were measured which are in agreement with results reported in literature. The measuring parameters could be varied within a wide range without affecting the results. These capacity curves occur on an oxidized OH covered surface. Another capacity curve was measured by utilizing a galvanostatic pulse method in order to prepolarize the electrode cathodically prior to the measurement. The capacity curve measured with sufficient prepolarization is shifted 300 to 500 mv cathodic with respect to the curve measured in the absence of prepolarization. These curves correspond to the reduced surface.

The electrochemical behavior of germanium electrodes differs from that of metal electrodes because Ge is a semiconductor. As a consequence of the low electron and (or) hole concentrations there exists a space charge layer on the semiconductor side of the interface. The capacity of this space charge layer is up to three orders of magnitude smaller than the capacity of the Helmholtz double layer in concentrated electrolytes. Both capacitors are considered to be in series (1). The smaller capacitor of the semiconductor determines the measured capacitance of the interface.

The capacity of the space charge layer as a function of potential was calculated by Bohnenkamp and Engell (2) using the Poisson equation and a Boltzmann distribution of the carriers. A semilogarithmic plot of the capacity-potential curves gives V-shaped curves with a rounded minimum which occurs for intrinsic germanium at zero space charge potential difference or "flat band potential" (1). The capacity curves that were measured with a standard a-c bridge technique (2) were in poor agreement with the calculated curves. They were too broad and the minima were at higher capacity values than calculated. With the introduction of a fast pulse technique Brattain and Boddy (3) were able to measure capacity curves in agreement with theory.

It was found experimentally that the potential of the capacity minimum depends on the pH of the solution (2) as well as on the "history" of the electrode (3). Obviously the position of the flat band potential depends on the chemical properties of the surface. Detailed studies of the pH effect (4, 5) yielded the result that the capacity minimum shifts by —58 mv per pH unit at 25°C. This observation and other experimental evidence led to the assumption that the germanium surface is covered with a homopolar bound layer of OH groups (1). The dissociation of the OH groups was made responsible for the observed shift of the curves with pH. Hofmann-Perez and Gerischer (4) called it a "dissociation double layer." The second effect, the dependence of the capacity curves on the "history" of the electrode is reported by Brattain and Boddy in two papers (3, 5). The authors find that the higher the anodic current density prior to the measurement the more anodic was the potential of the minimum. The data (3) show that the potential shift of the capacity minimum is a little over 100 mv per decade of anodic current density, provided the current density does not exceed 50 $\mu a/cm^2$. Later, Boddy and Sundburg (6) published capacity curves which were obtained with a dynamic current sweep method. The minimum measured with a decreasing anodic current density was 180 mv more anodic than the one measured with increasing anodic current density.

The objective of this paper is to show that an electrochemical surface reaction rather than dipole rearrangements are responsible for changes in the capacity curves caused by various pretreatments. A galvanostatic pulse method, which is described elsewhere (7), is used for quantitative prepolarization.

Gerischer and Beck (8) showed that germanium is a corroding electrode. The process can be described by the corrosion theory of Wagner and Traud (9). According to these authors the corrosion process can be separated into two independent partial reactions, one anodic and the other cathodic. In the absence of an external applied potential both reactions proceed at the same rate which is characterized electrochemically in terms of the "corrosion current density." With an external polarizing circuit and a given large overvoltage, one of the reactions prevails and the other can be neglected. Both reactions become comparable in magnitude at external current densities which are close to the corrosion current density (9). It is felt that in the case of Ge electrodes the product of the cathodic partial reaction causes (*a*) the increase in capacity observed with steady-state measurements and (*b*) the cathodic shift and broadening of the capacity curves.

The experimental study of the influence of both partial reactions is possible because the capacity minimum occurs in the potential region of small anodic dissolution currents (6). In the first series of experiments reported here, the capacity potential curves at an anodically polarized electrode are examined with a potentiostatic sweep method (7). The capacity curves are measured dynamically under various conditions. Anodic polarization is, however, maintained throughout these capacity measurements. In a second series of experiments the influence of the cathodic partial reaction on the capacity-potential curves is studied. The electrode is kept at a potential of high anodic dissolution rate. Immediately prior to recording the capacity curve, a constant cathodic current of varying duration is impressed on the electrode. The charge consumption during the capacity measurement, where usually anodic current flows, is kept small by using a fast sweep. Therefore the state of the surface that was created by cathodic charging remains practically unchanged.

Experimental

The measurements were carried out in a cylindrical Pyrex glass cell. The counter electrode consisted of a platinum wire. All potentials are referred to the saturated calomel electrode. Purified argon served as inert gas atmosphere. Solutions were made up of triple distilled water and "reagent" purity chemicals. Na_2SO_4 served as supporting electrolyte, H_3BO_3, H_3PO_4, and

acetic acid, all 0.1M, served as buffer [Prideaux, Ward (10)]. The temperature was at ambient and was close to 25°C.

Germanium rotating disk electrodes were used. Cut from single crystal material in approximately <111> orientation, the Ge was soldered to a rod and imbedded in low melting polyethylene. The electrodes could be rotated from 0 to 3000 rpm.

Results

No Cathodic Prepolarization

Capacity-potential measurements.—In a first series of experiments method (C) of ref. (7) was employed. The germanium electrode is potentiostated at a steady-state potential where the electrode dissolves (E_{dc}). The capacity potential curve is measured by applying a cathodic sweep $E_s = E_{dc} - \nu t$, $\nu = dE/dt$ with superimposed short duration square wave pulses (E_r). In these experiments the transistor (7) was shorted out.

The pulse amplitude E_r was varied from 30 to 100 mv. Positive and negative pulses were used. The measured capacity potential curves were, within the limits of experimental error, the same.

The rate of potential change $\nu = dE/dt$ could be varied from 1 to 300 v/sec without changing the capacity potential curve if E_{dc} was not more than 200 mv anodic to the potential of the capacity minimum. The data are in good agreement with the calculated capacity curve (2), as can be seen in Fig. 1. If E_{dc} was chosen more anodic than the limit specified above, *i.e.*, at high dissolution current densities, best agreement with the calculated curves was obtained if ν was small ($\sim$ 1 v/sec). Higher values of ν yield a vertical shift of the capacity curves toward larger capacity values.

Contrary to the data of Brattain and Boddy (3) results presented here indicate that the potential of the capacity minimum is within wide limits independent of the time required to measure the capacity curve. (Some reservation must be attached to this comparison, however, as the time scales in their work and this work are quite different.) The potential of the minimum in these buffered solutions does not depend on the anodic state of polarization that exists immediately prior to the measurement.

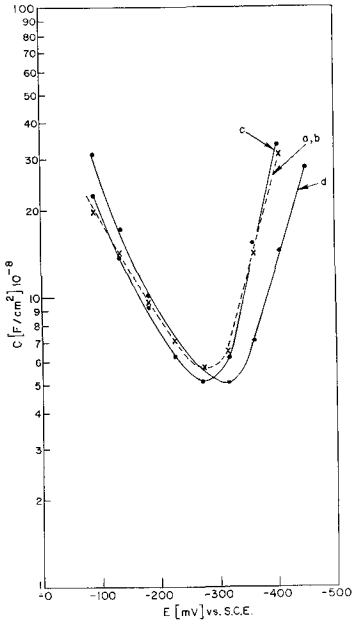

Fig. 1. Dynamically measured capacity potential curves at 10 ohm-cm p-Ge in 0.5 M Na_2SO_4, 0.1M buffer pH 7, unstirred. Curve a (dashed) was measured with —1 v/sec (cathodic going); Curve b which coincides with curve a was measured with a +1 v/sec, anodic going sweep which was started at —500 mv, immediately after the electrode had been potentiostated anodically; curve c was measured like b, but the electrode rested at 0 current for 3.3 sec before sweeping; curve d was measured like b but without the use of the transistor; therefore a short cathodic current spike had prepolarized the electrode. The curves agree favorably with the calculated capacity curve (2). Curve d matches it exactly.

The measurement of the capacity-potential curve with an anodic sweep with approximately the same "history" as the measurements outlined above is described as method A_2 in ref. (7). With the cell potentiostated anodically at E_{dc}, as above, a negative step, $-E_{st}$, makes the potential slightly negative to the potential of the capacity minimum and the capacity potential curve is measured with a positive sweep: $E_s = E_{dc} - E_{st} + \nu t$.

From Fig. 1d it is seen that the capacity curve obtained in this way is shifted 50 mv cathodic with respect to the one obtained employing a cathodic sweep. The corresponding current potential trace, however, showed that there was a short cathodic current spike before the minimum was reached.

To see if exclusion of cathodic charge flow before reaching the minimum could yield the same capacity curve as obtained with the cathodic sweep, method A_1 of ref. (7) was used. A transistor with its reverse bias in the cathodic direction is placed in series with the cell. The cathodic current flow is then, at zero base current, limited to the value of the reverse limiting current which is $\sim$ 1 μa. To make the resistance of the transistor small during the sweep, the gate of the "delayed sweep generator" of the oscilloscope also serves to inject a base current, via E_o. For details see ref. (7). Curve b is obtained in this fashion. As this method excludes major cathodic current flow prior to the sweep we investigated the effect of time that the electrode rests at $\sim$ 0 current prior to the capacity measuring sweep. Curve c is measured after the electrode had been kept for 3.3 sec at $\sim$ 0 current. Coincidence of curves a and b shows that changes of the potential of the minimum during the sweep are negligible. Comparison of curves b and c shows that no significant changes of the surface properties took place when the electrode rested for 3.3 sec at $\sim$ 0 current prior to the sweep.

Cathodic Prepolarization

Charging curves.—In these experiments a transistor was placed in series with the cell. Superposition of a sufficiently high cathodic step $-E_p$ on E_{dc} switched the transistor into its reverse limiting current region [see ref. (7)]. A steady base current was supplied to the transistor via a battery potentiometer. The cathodic limiting current which prepolarizes the electrode during the interval when $-E_p$ is applied could be varied by changing the magnitude of this impressed base current. The consequence of the negative prepolarizing step $-E_p$ is the immediate flow of a constant cathodic current, *i.e.*, a current step. During this galvanostatic period, the potential of the indicator electrode, which is measured differentially between the reference electrode (output of the follower) and the emitter of the transistor, (Fig. 5) of ref. (7), is steadily increasing in the cathodic direction.

In the initial phase of the current step, the increase in cathodic overvoltage is very large. The change in potential at longer times is much less pronounced. Figure 2 gives an example of a charging process measured in alkaline solutions. The individual curves are recorded with various sweep rates of the oscilloscopic trace. As the sweep rate increments are chosen to differ by a factor of 10, intersections of the potential time curves with parallels to the ordinate represent logarithmic time intervals of the charging curve. In Fig. 3, the intersections with parallels to the ordinate at div 1 and 4 are plotted against the corresponding time at which the potential is read. The points of the resulting plot of E *vs.* log t scatter around a straight line with the slope of —100 mv per decade of time.

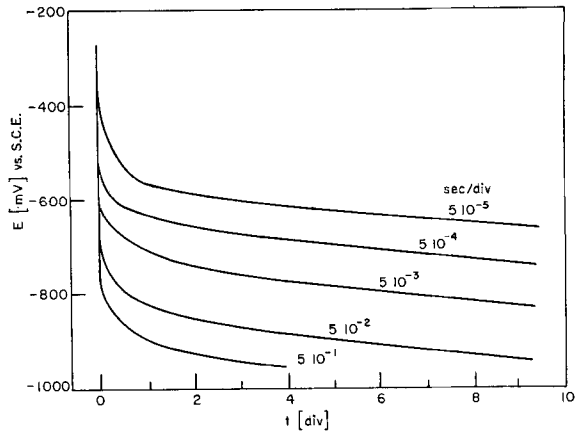

Fig. 2. Buildup of cathodic potential by application of a 0.36 ma/cm² cathodic current step at a 10 ohm-cm n-Ge electrode in 0.5M Na_2SO_4, 0.1M buffer pH 12 solution. Before the step was applied anodic steady-state current of 0.36 ma/cm² was flowing. The corresponding sweep rate of the oscilloscope is marked at each individual curve.

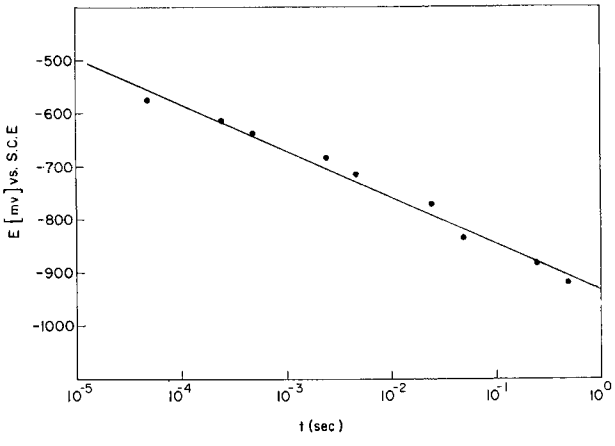

Fig. 3. Potential at div 1 and 4 of Fig. 2 plotted vs. the corresponding time.

Part of the scatter may be caused by the fact that for each individual curve the charging process had to be repeated. This initial E-log t behavior was observed in all charging experiments, both at n- and p-type germanium, in alkaline as well as in neutral and acid solutions. The slope of the E-log t curves (studied in some detail in alkaline solutions at p-Ge) was constant for a given current density. If, however, the current density was varied, the slope also varied. The slope [mv/decade] increased somewhat with increasing current density.

Whereas the potential shift in the beginning of the charging process followed a linear E-log t relationship in solutions of all pH values that were studied, a marked difference in the curves at longer times could be observed at different pH values: in alkaline solutions the curves showed no break (Fig. 2) whereas in acid solutions the curves contained a break, both at n- and at p-Ge. Figure 4, lower curve, gives a typical example. It is seen that the break occurs after the passage of $\sim$ 400 μa sec/cm². To investigate the nature of the break in the cathodic charging curve further, the current density was varied. The time required to reach the break will be called a transition time τ. It was seen that the product of $i\tau$, where i is the current density, was a constant of approximately 400 μa sec/cm². Rotating the electrode with 3000 rpm brought only a slight change in shape of the charging curve which may be attributed to traces of oxygen contamination. These results indicate that the transition time observed in neutral and acid solutions is not caused

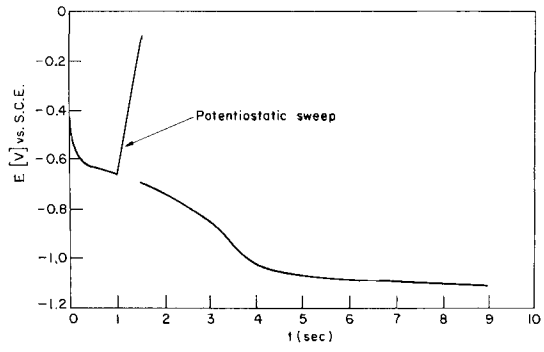

Fig. 4. Potential time behavior for a galvanostatic step (lower curve is the charging curve), interrupted by a potentiostatic sweep (straight line). The electrode was 10 ohm-cm p-Ge in 0.5M Na_2SO_4, 0.1M buffer pH 1. It was rotated at 650 rpm; cathodic current density 0.14 ma/cm²; sweep +1.2 v/sec (anodic going); preceding anodic current density by 0.14 ma/cm².

by exhaustion of a diffusing species. If the latter was the case, the product of $i\tau$ at various values of i should not be a constant [Delahay (11)] and it should be sensitive to stirring. The data presented here are in quantitative agreement with the findings of Turner (12), who attributed the charge required to reach the break to the reduction of the surface hydroxide to a surface hydride.

Capacity-potential measurements.—Capacity measurements with varying cathodic prepolarization were carried out as follows [method PA of ref. (7)]: starting from anodic potentials at which the electrode is rapidly dissolving the cathodic step, $-E_p$, causes a constant cathodic current flow across the electrode interface. At any desired time after the beginning of the pulse, $-E_p$, (which caused a constant current to flow) a positive pulse E_{st} is applied which adjusts the potential to the value that was reached during the charging process. The simultaneous initiation of the anodic sweep $E_s = dE/dt$ (with superimposed short duration pulses) provides a means of measuring the capacity curve in that potential region. Simultaneous injection of a constant base current minimizes the error in the capacity value that is introduced by the transistor (7). Figure 4 represents a typical potential-

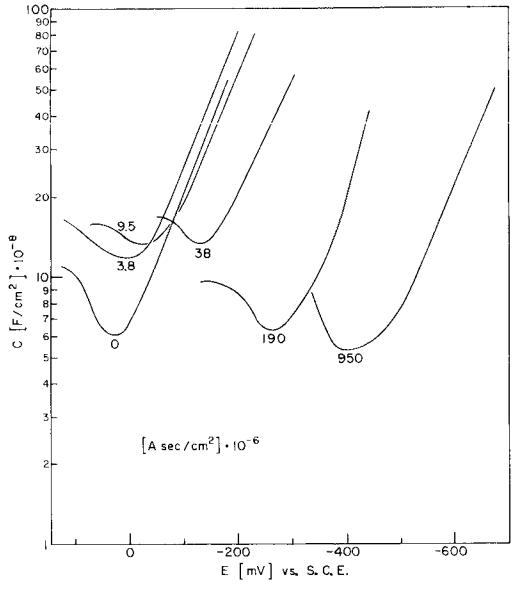

Fig. 5. Dynamically measured capacity potential curves at 40 ohm-cm n-Ge in 0.5M Na_2SO_4, 0.1M buffer pH 1. Electrode was rotated at 900 rpm. Prepolarizing charges are marked at the curves. The sweeps, 100 v/sec, anodic going, were started at the potential of the charging curve.

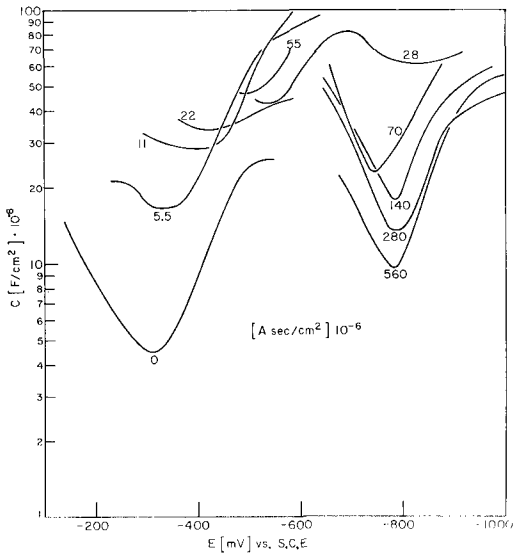

Fig. 6. Dynamically measured capacity potential curves at 10 ohm-cm p-Ge in 0.5M Na_4SO_2, 0.1M buffer pH 7. Electrode was rotated at 900 rpm; sweep, 100 v/sec (anodic going); starting potential coincided with charging curve. Cathodic prepolarization coulombs are marked in figure.

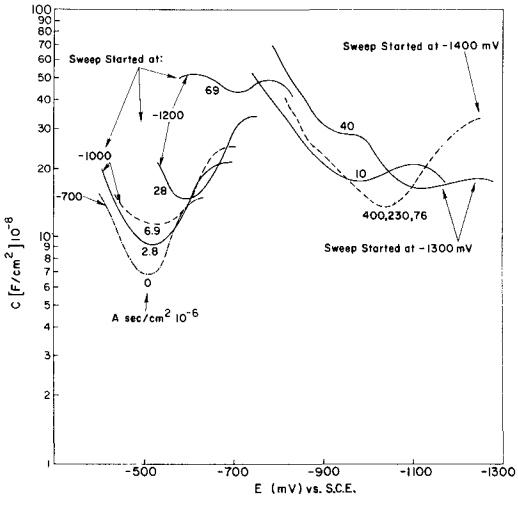

Fig. 7. Dynamically measured capacity potential curves at 10 ohm-cm p-Ge in 0.5M Na_2SO_4 0.1M buffer pH 12, unstirred. Curves to the left +7.2 v/sec (anodic going); dashed curve to the left +2.5 v/sec; solid curves to the right +7 v/sec. Cathodic prepolarization and starting potential are marked in figure.

time trace of these experiments (the short duration pulses cannot be resolved). For the charging curve (lower curve) the electrode is polarized galvanostatically whereas during the sweep the operation is potentiostatic.

Capacity-potential curves obtained in this manner in solutions of pH 1, 7, and 12 are shown in Fig. 5, 6, and 7, respectively. It is seen that at small prepolarization the minimum of capacity increases with increasing prepolarizing charge and the potential of the minimum shifts cathodic. For many of the curves the shift is a little over 100 mv per decade of prepolarizing charge. A maximum increase in capacity is observed at prepolarizations of 70 ± 30 μa sec/cm^2. At sufficiently large prepolarization the minimum decreases again.

Further experiments were carried out in order to examine other parameters. In cases of prepolarizations in the order of 50 μa sec/cm^2 and high enough sweep amplitudes two shallow minima could be observed on one current-potential trace. The corresponding current-potential curves, however, contained characteristic transients indicating that the surface was highly unstable. The current potential curves that correspond to prepolarizations larger than 100 μa sec/cm^2 did not have these transients and were quite reproducible.

The choice of the sweep starting potential E_{st} was of prime importance. If E_{st} is properly chosen, the current level stays approximately constant until the minimum is reached. If E_{st} deviates from this value in the cathodic or anodic direction, a current spike of the same polarity (cathodic or anodic) is observed. This current spike tends to change the capacity curve in the same way as it was described in the experiments with no prepolarization.

Provided E_{st} is properly chosen the sweep rate, $v = dE/dt$, could be varied from 1 to 100 v/sec without a significant change of the capacity curves. Sweep rates larger than 100 v/sec were not employed because the current potential curve showed rapid transients which prevented the evaluation of the capacity curves from the superimposed, short duration current transients that were caused by the pulses (7). Integration of the current as a function of time during such fast sweeps yielded charges in the order of 1 μa sec/cm^2. In most cases this charge represents only a very small fraction of the prepolarizing charge.

The capacity measurement with a cathodic going sweep [method PC of ref. (7)] was studied briefly. This method is less convenient than the one employing an anodic sweep because the exponential nature of the current potential curve in the region of the capacity minimum makes the choice of E_{st} critical. Qualitatively, the same influence of the prepolarization is observed.

Variation of E_{dc} in such a manner that the steady-state anodic dissolution current varied from 700 to 35 μa/cm^2 had no influence on the capacity potential curves.

Discussion

The capacity measurements without cathodic prepolarization showed that when cathodic current flow is excluded and the measurement is carried out rapidly the minimum of capacity lies at one particular potential. The sweep rate and sweep direction may be varied within a wide range without causing a change of the capacity potential curves. In the measurements of Brattain and Boddy (3) the potential of the capacity minimum shifted anodic with increasing steady-state current density prior to the measurement. In the data of ref. (3), Fig. 8, a narrowing of the curves (toward those calculated) takes place coupled with an anodic shift of the capacity minimum. This may be taken as an indication that their method of measurement is quasistationary. The time required to determine an individual experimental point was sufficiently long so

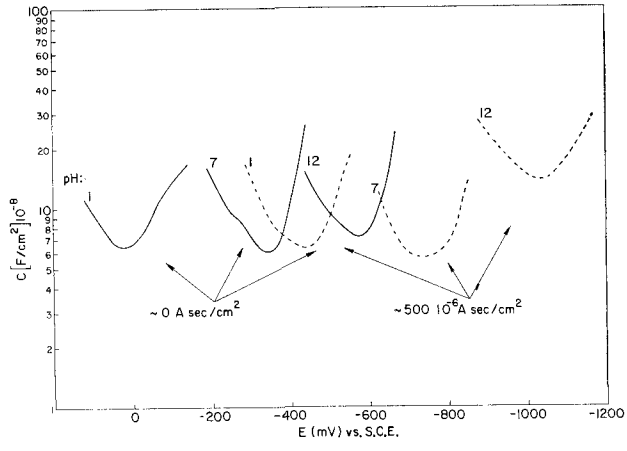

Fig. 8. Collection of dynamically measured capacity potential curves at 10 ohm-cm p-Ge in 0.5M Na_2SO_4, 0.1M buffer, pH marked at curves. Solid curves are measured without cathodic prepolarization, dashed curves after cathodic pretreatment of approximately 500 μcoulomb cm^2.

that at small preceding steady-state current densities the cathodic partial reaction effected the results, as will be discussed below.

Measurements with cathodic pretreatment showed that small amounts of cathodic charge are sufficient to change the potential of the minimum as well as the magnitude of the capacity potential curve. From Fig. 8 it appears that the Ge surface can exist in two different states. The anodic state is well-known and extensively studied (1). The other, the cathodic state of the surface, lies 300 to 500 mv more negative and can be obtained only after considerable cathodic charge has polarized the electrode. The capacity potential curves of the two different surfaces (they may be called oxidized and reduced surfaces) fit, at least in acid solutions and after certain prepolarizations, closely the curves which were calculated on the basis of the Poisson-Boltzmann equation (2).

In the equivalent circuit for a metal (or semiconductor) electrolyte interface a nonohmic resistance, R_p, that corresponds to the faradaic current must be considered to be in parallel with the interface capacitor (11). The applied voltage causes both a faradaic current flow and changes of the space charge capacitor. The occurrence of two different capacity curves at Ge electrodes hence implies that there should also be two d-c current voltage curves. This is indeed what is found experimentally. Figure 9 gives an example of a current voltage curve obtained with a continuous running triangular wave. For comparison, the two capacity curves are also shown in Fig. 9. [Gobrecht and Meinhardt *et al.* reported similar dynamic current voltage curves (13). Their publication, however, does not contain any capacity curves. In another series of papers (14) steady-state capacity curves are published that have more than one minimum of capacity. The authors, however, did not use the result of the dynamically measured current voltage curves to explain the occurrence of more than one capacity minimum in the steady-state measurements.]

The capacity curves that lie in the potential region between the curves measured at the oxidized and reduced surface are characterized by considerably increased capacity minima. An increase in capacity over the calculated value generally is attributed to surface states (1). In the electrical equivalent circuit for the Ge interface the surface states are represented by an additional capacitor in parallel with the space charge capacitor (1). From Fig. 5 to 7 it appears that prepolarization with small amounts of cathodic charge of an OH-covered (oxidized) surface act as surface states. At charges between 70 ± 30 μa sec/cm^2, which corresponds to somewhat less than one unit charge per

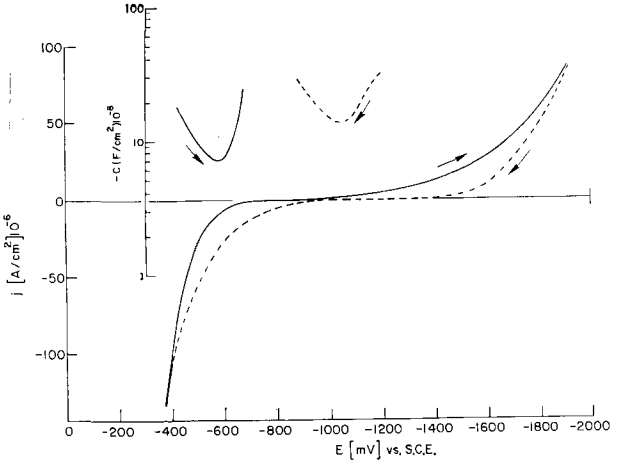

Fig. 9. Dynamically measured current potential curve at 10 ohm-p-Ge in 0.5M Na_2SO_4, 0.1 M buffer pH 12. Free running triangular wave of ±0.73 v/sec; for comparison, the figure contains the simultaneously measured capacity potential curves.

surface atom (12) the additional capacitor has its maximum value. On the other hand, deficiencies from the cathodic charge required to reach the totally reduced surface (hydride surface in acid solutions) also form surface states, as can be seen from the family of cathodic curves in Fig. 6. The experimental results would indicate that at small prepolarizations chemisorbed hydrogen creates surface states on the OH-covered surface whereas at larger prepolarizations empty hydrogen sites act as surface states.

The charging experiments show that in all solutions in the initial phase of the charging process the potential is a linear function of the logarithm of the time. Frumkin (15) also observed logarithmic potential changes with time in connection with his studies of the hydrogen ion discharge at metal electrodes. He showed that this logarithmic relationship is caused by the charging of the double layer or a chemical capacitor (at Pd) via an activation controlled current path. Even though the electrochemical properties of Ge differ considerably from that of typical metal electrodes, the hydrogen overvoltage at Ge is quite similar (1). The experimentally observed slope of the E-log t plot for the charging curve at Ge is 100 mv per decade of time. This is close to the usual values for the slope of an activation controlled current voltage curve (slope of a "Tafel" plot), which holds for both metal and Ge electrodes (1).

The potential shift of the capacity curves with increasing prepolarization indicates that the reaction product of the faradaic reaction is stored at the surface and determines the potential. Without this assumption one could not explain the increase in the value of the capacity at the minimum and the cathodic shift even though the prepolarization has ceased.

The charging curves at longer times, however, give some evidence that the faradaic reactions are different in acid and alkaline solutions. The data in neutral solutions seem to have an intermediate position. In acid solutions Ge hydride is the reaction product (12). The reaction after the break represents hydrogen evolution (12). The capacity curve measured at the hydride surface (Fig. 5) is very close to the calculated curve (compare Fig. 1). In alkaline solutions no break in the charging curve is observed. This can be interpreted in two ways: (*a*) the two possible reactions, surface oxide reduction and water electrolysis occur simultaneously, or (b) the suface hydroxide is not reduced and only water electrolysis takes place. Since the OH groups at the Ge surface are partially dissociated (4, 5) one can attribute some stability to the negative surface in so far as the negative charge of the O^- group may be shared in a mesomeric and tautomeric manner with the germanium and the undissociated OH groups. The arrangement would be analogous to the anion of carboxylic acids. Those anions, too, are in alkaline solutions much more difficult to reduce than in acid solutions. In case (*a*) and (*b*), however, hydrogen ions (or water) are discharged. The increase in the capacity minimum indicates the presence of surface states which may be adsorbed hydrogen. The shift of the capacity curve proves that a potential determining product is stored at the surface.

A recent paper by Hurd and Hackerman (16) involving capacity measurements at the silicon/electrolyte interface has several features in general agreement with the work reported here. There are, however, marked differences in the electrochemical behavior of silicon and germanium. A direct comparison of the two papers is therefore not justified.

The anomalies observed in previously published capacity measurements can now be given an electrochemical explanation.

1. Steady-state measurements yielded capacity curves which were too broad and the minimum of capacity too large. The minimum of capacity lies in a potential region of small current densities, compare Fig. 9. In this region, the two partial reactions of the

corroding Ge electrode are comparable in magnitude. Due to the tendency of Ge to store the charge of the cathodic partial reaction, one therefore observes a cathodic potential shift and an increase of the differential capacity if longer times are required to measure the capacity curves. As the cathodic charging that is responsible for the shift of the curves proceeds during the measurements, the curves appear broader and the minimum larger than calculated (2). Brattain and Boddy (3) were the first authors to publish capacity curves that were in agreement with theory. These authors measured the capacity curves with a pulse method and with an anodic pretreatment of the electrode. The reason for the good agreement of the experimental and calculated curves measured by these authors and in this publication, Fig. 1, is that the dissolution removes the cathodic charge that is generally stored on the electrode if the electrode is allowed to rest a certain length of time at the rest potential. The pulsed capacity measurements are fast enough to exclude storage of cathodic charge.

2. The storage of cathodic charge created by corrosion also explains the shift in the potential of the minimum of the capacity at the dynamically measured capacity curves reported by Boddy and Sundburg (6).

3. In previous investigations of the pH dependence of the potential of the minimum of capacity, it was found that at the extremes of pH the minimum was larger and shifted cathodic with respect to the values that one would expect from the pH dependence observed at intermediate pH values (5) Fig. 4 and (4) Fig. 5. Due to the coupling of anodic and cathodic partial reaction of a corroding electrode (9) both reactions will proceed faster at extremes of pH. In extreme alkaline solutions germanium dissolves readily. The rate of dissolution at a given overvoltage is higher in alkaline than in neutral and acid solutions (17). The anodic partial reaction is the driving force. On the other hand, the hydrogen ion discharge will proceed easily in acid solutions due to the abundance of hydrogen ion. The storage of the reaction product of the cathodic partial reaction causes potential shift and increase of the minimum of the capacity.

Instrumentation for the Measurement of the Electrical Double Layer Capacitance at Solid Electrodes

Louis Ramaley[1] and C. G. Enke[2]

Frick Laboratory, Princeton University, Princeton, New Jersey

ABSTRACT

Two methods of measurement of double layer capacitance used by the authors are described. One method, involving the application of a rectangular current waveform, is convenient for obtaining qualitative information on the frequency dispersion of the double layer capacitance. The other, involving the application of a small sinusoidally varying potential of constant amplitude, is capable of an accurate and very rapid determination of capacitance over a wide potential range.

The double layer capacitance present at a metal electrode-electrolyte interface is of great interest because of its relation to the chemical and physical properties of the interface. The measurement of this capacitance has presented certain problems due to its nonideality, the effect of solution components and contaminants on it, and the presence of the solution resistance connected with it.

Several different methods of capacitance measurement have been employed. Several authors have used direct current or pulse current charging methods (1-5). Armstrong and Butler (6) proposed the method of current interruption for measurement during a faradaic reaction. Wagner (7) has used a potential step technique. Several authors have applied a controlled sinusoidal potential or current waveform in capacitance studies (8-10). An impedance bridge is often used when high accuracy is desired (11-13).

In general the constant current, current pulse, and potential step methods measure the average capacitance over the region of potential change. Average capacitance may be defined as $C_a = (q_2-q_1)/(E_2-E_1) = \Delta q/\Delta E$. The differential capacitance is obtained from

[1] Present address: Department of Chemistry, University of Arizona, Tucson, Arizona.

[2] Alfred P. Sloan Research Fellow.

the slope of the potential-time curve in the controlled current methods. All the techniques employing sinusoidal waveforms measure the differential capacitance directly if the amplitude of the waveform is kept small.

Capacitance measurements on solid electrodes are complicated by the fact that the electrode surface can become contaminated rapidly with an adsorbed impurity and by the fact that the actual electrode area is not reproducible or exactly measurable. Thus a measurement technique of high accuracy and long measurement time, such as the impedance bridge, probably would not be a good choice. Since the differential capacitance is usually the parameter of interest, a method of direct measurement would be preferred.

The use of a sinusoidal potential of constant amplitude as described below is capable of reasonable accuracy and high measurement speed. In high resistance solutions or for qualitative data on frequency dispersion, the rectangular current pulse technique described below is useful.

Measurements Using a Rectangular Current Waveform

Theory.—In the absence of a faradaic reaction the portion of an electrochemical cell between the reference electrode (or the tip of the Luggin capillary leading to the reference compartment) and the test electrode may be thought of as a resistor in series with a capacitor. The resistor corresponds to the solution resistance and the capacitor to the electrode capacitance. If a current pulse of constant amplitude I is applied through this series network, at time $t = 0$ a discontinuity in the potential across the network will appear corresponding to the IR drop across the resistor. At times greater than $t = 0$ the potential will be a linear function of time according to

$$E = IR_sA + it/C_d \qquad [1]$$

If the current is reversed in sign but held constant in magnitude when the potential reaches E_1, another discontinuity occurs and the slope of the potential reverses. If the current is again reversed at a potential E_2, the same discontinuity appears and the slope of the potential equals the original slope. A triangular shaped waveform as shown in Fig. 1 results. The average capacitance is calculated using

$$C_a = i(t_2 - t_1)/(E_2 - E_1) \qquad [2]$$

where the potential discontinuity due to IR drop is not included in either E_2 or E_1. The differential capacitance is calculated using

$$C_d = idt/dE \qquad [3]$$

The double layer capacitance itself is nonideal, since it is dependent on electrode potential. The change of capacitance with potential is quite gradual in most potential regions in the absence of a strongly adsorbed material. Thus capacitance may be considered independent of electrode potential if small potential increments are used in the measurements.

Finally, nonideality may be caused by a dependence of electrode capacitance on frequency. The curvature imparted to the potential-time waveform by this effect may be explained in the following way: A current pulse may be considered to be a superimposition of sinusoidal currents of different frequencies. The higher frequencies may be looked upon as having the largest effect at the beginning of the pulse and the lower frequencies become more prominent as the pulse lengthens. A change in capacitance with frequency will thus cause a change in the slope of the potential-time waveform during the duration of the pulse.

Elimination of the other causes of nonideality allows a qualitative but extremely rapid determination of the frequency dependence of the double layer capacitance. A study of this dispersion of capacitance may be carried out as a function of potential or time of electrode contact with solution. As a general method of capacitance measurement this technique suffers from inaccuracies in determination of the slope of the potential-time curve. It is reasonably rapid, though not as rapid as the other technique to be described. It does offer the advantage of direct subtraction of the effect of solution resistance in determination of the average capacitance and elimination of this effect on differential capacitance calculation. This can be quite important in high resistance solutions.

Operation.—The block diagram of the apparatus is shown in Fig. 2. Amplifier SF is a stabilized voltage follower and amplifier SX is a stabilized operational amplifier. George A. Philbrick K2-X and K2-P amplifiers were used throughout as the operational units. The voltage follower matches the impedance of the reference electrode to that of the measuring device. Amplifier SX maintains the test electrode at ground potential and adjusts the potential of the counter electrode so that all the current flowing into the summing point of the amplifier flows through the cell.

The reversing current generator RCG supplies the pulses of constant current to the summing point of amplifier SX. The signal that causes reversal of the current is fed into RCG from SF. The wiring diagram for RCG is shown in Fig. 3. The MOD. X amplifier is the same as a G. A. Philbrick K2-X except that a 22K 2W resistor has been placed in the plate circuit of the output cathode follower. This prevents dam-

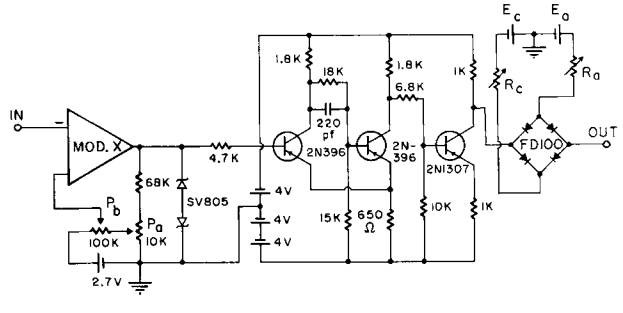

Fig. 3. Wiring diagram of the reversing current generator (RCG).

age to the 6AN8 output tube of the amplifier by preventing an excessive amount of current from flowing through the SV805 zener diodes. A schmidt trigger consisting of the 2N396 transistors squares the output waveform of the MOD. X amplifier. The 2N1307 transistor is an inverter which drives the diode bridge which in turn supplies the current pulses to the cell. The cathodic current is determined by the values of R_c and E_c, the anodic current by R_a and E_a. These values may be varied over a wide range as long as R_c and R_a are much larger than the forward resistance of the diodes, and the current capabilities of amplifier SX and transistor 2N1307 are not exceeded. The current capabilities may be altered by changing the amplifier or the transistor. The potentials, E_1 and E_2, at which the current reverses are determined by the settings of the potentiometers P_a and P_b. The setting of P_a determines the waveform amplitude $(E_1 - E_2)$ and the setting of P_b determines the average potential of the waveform ($E_{avg} = [E_1 + E_2]/2$).

The 1 μf capacitor in the circuit of Fig. 2 detects the presence of a faradaic current flowing in the cell. If no charge crosses the electrode-solution interface, no long term net current will be observed. A faradaic reaction will cause a net direct current. If switch S is open, the direct current must charge the 1 μf capacitor. The presence of such a current is detected by a long term change in the output potential of amplifier SX.

The circuit as described has a current capability of 1 ma and a frequency limit of about 1000 cps (cycles per second). The minimum amplitude $(E_1 - E_2)$ attainable is about 20 mv at 1000 cps and depends to some extent on the cell resistance (or cell geometry) and the frequency of measurement, decreasing somewhat as the frequency decreases. Others have applied square wave currents to capacitance determination (2, 3). The mechanics of the method presented here differs somewhat from the previously reported methods. These methods use a square wave generator to supply symmetrical square current pulses to the test electrode and an auxiliary means to determine the potential of the test electrode. The repetition rate of the wave is determined by the square wave generator and the amplitude of the observed potential-time waveform is determined by the capacitance and resistance of the cell.

The reversing current generator described above supplies the current alternations and also determines the electrode potential. The amplitude of the waveform is determined by the generator, and the repetition rate of the waveform is a function of the cell resistance and capacitance. It is sometimes advantageous to be able to carry out all measurements over the same potential span $(E_1 - E_2)$. The reversing current generator has no low frequency limit, as do ordinary square wave generators, and the current output is genuinely constant and can be made as large as desired by suitable choice of the electronic components. Square wave generators are usually limited to low currents, the lower the current, the more accurate the current control. However, the performance of square wave generators at very high frequencies is superior to that of the generator described above.

Results.—A typical waveform obtained with the reversing current generator is shown in Fig. 4. The results obtained using this method on silver electrodes are published in another article (14).

Use in other areas.—Application of a rectangular current pulse waveform has been discussed with regard to obtaining information on the double layer capacitance. It may be used more widely to obtain information on any process effected by a cyclic reversal of current. For example the circuit in Fig. 2 could be readily used to obtain data on electrochemical

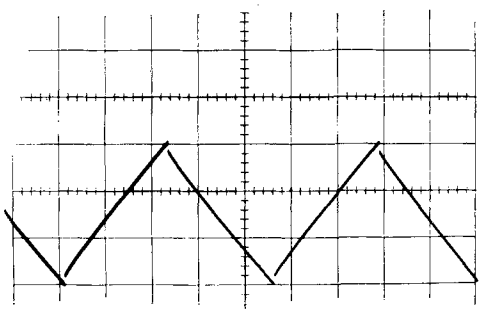

Fig. 4. Potential-time waveform obtained at a silver electrode in molar sodium perchlorate solution. Average potential, minus 340 mv vs. NHE; potential sensitivity, 10 mv/cm; sweep speed 1 ms/cm; current density, 1.7 ma/sq cm.

reactions by cyclic chromopotentiometry (15-17). Herman and Bard (15) describe a circuit for a rectangular current wave generator which employs mechanical switching. The circuit of the generator described above employs electronic switching and is capable of smoother and faster operation.

Measurements Using a Controlled Potential and Constant Frequency

Theory.—If a small sinusoidal potential of constant amplitude is applied across the electrode-solution interface and the sinusoidal current and phase angle are measured, the double layer capacitance can be calculated from

$$C_d = \left(\frac{I_{ac}}{2\pi f A E_{ac}}\right)\sqrt{1/\tan^2\phi + 1} \qquad [4]$$

If the solution resistance is quite small compared to the double layer impedance, $1/\tan^2\phi$ will be small compared to one and Eq. [4] simplifies to

$$C_d = I_{ac}/2\pi f A E_{ac} \qquad [5]$$

The phase angle may be $-76°$ ($-90°$ represents pure capacitive reactance) before a 3% error is made by using the simplified equation.

When Eq. [5] does not apply, the sinusoidal current and phase angle may be measured at one potential and used to calculate the cell resistance R_s. This value of R_s may then be used to calculate the double layer capacitance at all other potentials according to

$$C_d = \frac{1}{2\pi f A}\left[\left(\frac{E_{ac}}{I_{ac}}\right) - R_s^2\right]^{-1/2} \qquad [6]$$

This eliminates the necessity of determining the phase angle at every measurement potential.

An a-c voltmeter or oscilloscope may be used to detect the sinusoidal current directly. The oscilloscope or phase angle meter can be used to determine the phase angle. The sinusoidal current may be rectified and recorded by a servo recorder.

If the sinusoidal potential is superimposed on a linear potential sweep, the capacitance as a function of potential may be obtained. The use of an oscilloscope as the readout device enables sweep speeds of a volt per second or more to be achieved, allowing very rapid determinations of capacitance to be carried out. The linear potential sweep may be cycled between two potential limits, thus providing a recording of capacitance as a function of both potential and time. This technique has been applied by Breiter (10) to double layer measurements on platinum.

This method may be employed in capacitance measurements at an electrode at which a faradaic reaction is proceeding if the measurement frequency is high and the faradaic reaction is kinetically slow.

Operation.—Several types of instrumentation are available for this particular technique. Walker *et al.*

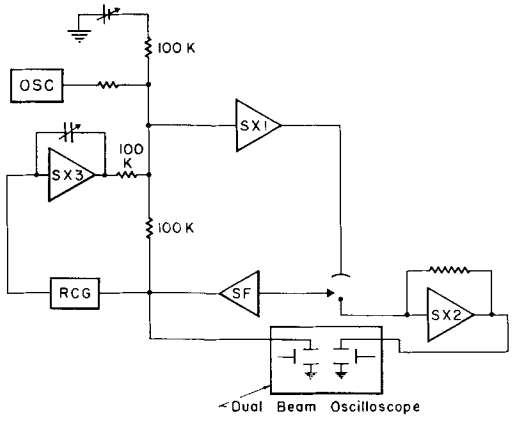

Fig. 5. Block diagram of the apparatus for capacitance measurement with a sinusoidal potential of controlled amplitude and frequency.

(18) used a modified d-c recording polarograph to perform a-c voltammetry at solid electrodes. The sweep speed of this instrument is limited by the polarograph. Breiter (10) replaced the polarograph with an electronic triangular wave generator and oscilloscope, thus greatly increasing the sweep speed.

The circuit used by the authors is shown in Fig. 5. It differs from those previously mentioned in the same way a potentiostatic polarograph differs from an ordinary or two electrode polarograph, thus eliminating or reducing the effect of solution resistance in the same way the potentiostatic polarograph reduces the effect of solution resistance. The circuit is similar to that used by Smith (19) for a-c polarography.

Amplifier SX1 establishes the required potential between the reference electrode and test electrode and amplifier SX2 holds the test electrode at ground potential and provides an output potential proportional to the current through the cell. OSC represents a sine wave generator and RCG and amplifier SX3 combine to provide a triangular sweep generator. The sinusoidal cell current and the potential difference between the test and reference electrodes are displayed simultaneously on a dual beam oscilloscope. A typical display is shown in Fig. 6. The envelope represents the peak-to-peak sinusoidal cell current which is proportional to the capacitance. The other trace represents the potential of the test electrode-reference electrode combination. The phase angle can be determined at a given potential by displaying the sinusoidal potential and current simultaneously on the dual beam oscilloscope and noting the time relationship of one to the other.

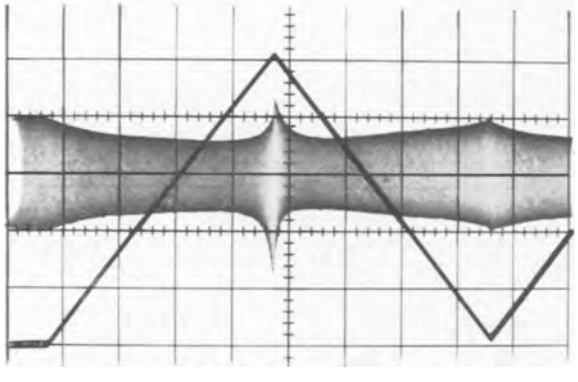

Fig. 6. Potential-time and current-time waveforms obtained at a silver electrode in molar sodium perchlorate solution using a controlled sinusoidal potential. See the text for an explanation. Potential sensitivity, 200 mv/cm; current sensitivity, 0.100 ma/cm; sweep limits, minus 430 mv to plus 570 mv vs. NHE; sweep speed, 200 ms/cm; applied sinusoidal potential, 10 mv peak to peak; electrode area, 0.0401 sq cm.

The frequency limits of the system are determined by the amplifiers. Accuracy begins to fall off rapidly above 2000 cps. The use of higher speed amplifiers could raise this limit. The lower limit of the amplitude of the potential wave form is determined by the signal-to-noise ratio of the instrument. It was found convenient to use a 10 mv peak-to-peak signal, but this could have been made much smaller if tuned amplifiers had been used to suppress the line frequency noise (19). The use of tuned amplifiers would necessitate some sacrifice in measurement speed.

The authors chose to control the sinusoidal potential rather than the sinusoidal current so that a linear potential sweep could be applied, and so that the potential amplitude would not vary with capacitance, causing a change in "resolution" with capacitance. Breiter (9) has used a system that employs a controlled current superimposed on a linear potential sweep which is limited to slower sweep speeds than that described above.

The use of the controlled potential device for the measurement of the double layer capacitance of silver is published in another article (14).

Summary

Speed and ease of measurement, and not extreme accuracy, are important factors in determination of a method of double layer capacitance measurement on solids. Very rapid measurement and good accuracy are obtained with a controlled sinusoidal potential technique. If the cell resistance is small compared with the double layer impedance, the cell capacitance is measured directly by this technique. Kinetically slow reactions do not interfere in the measurements.

With high resistance solutions a constant or pulsed d-c technique has advantages. In the presence of a kinetically rapid reaction a current interruptor method of measurement offers a good solution.

The Double Layer Capacitance of Silver in Perchlorate Solution

Louis Ramaley[1] and C. G. Enke[2]

Frick Laboratory, Princeton University, Princeton, New Jersey

ABSTRACT

The electrical double layer capacitance of silver was studied in 1N sodium perchlorate solutions as a function of pH, method of surface preparation, and electrode potential. The results suggest that the double layer structure on silver and mercury may be very similar. A model explaining the frequency dispersion of the double layer capacitance on solid electrodes is proposed, and qualitative substantiating evidence is given.

Many studies of the electrical double layer capacitance of silver have been carried out in aqueous solution (1-7). The agreement among the values of the capacitance observed in these studies is very poor. This is in part due to the use of different electrolytes over different concentration ranges. However, if the Gouy-Chapman-Stern treatment of the double layer structure is valid for silver, the large differences observed cannot be explained by variations in the type and concentration of electrolyte alone.

Differences in manner of surface preparation and solution purity have probably been the major causes for the discrepancies. Often the surfaces have been mechanically polished or subjected to long and complicated chemical cleansings. The surface state was generally unknown and varied from worker to worker. In the early literature insufficient care was taken to remove adsorbable impurities from solution. These have a dramatic effect on the double layer capacitance.

A frequency dispersion of the double layer capacitance has often been observed (7-15), most notably on solids. Several explanations of this effect have been given (7, 12, 16), but none of these explain all the observed phenomena satisfactorily. Thus it seemed worthwhile to undertake an investigation of the double layer capacitance of silver employing techniques which avoid damaging surface treatments and adsorption of impurities from solution. Information as to the cause of frequency dispersion of the double layer capacitance was also sought.

Experimental

Materials.—Solutions 1M in perchlorate ion were prepared with triply distilled water over a pH range from 0-13 by the mixture of appropriate amounts of Baker and Adamson Reagent Special Grade NaOH and G. F. Smith doubly distilled lead-free 70% $HClO_4$. These solutions were pre-electrolyzed for at least 18 hr using a mercury cathode and platinum anode, and immediately before use were filtered through purified activated charcoal to remove adsorbable impurities. The silver employed was 99.99% pure wire of two sizes, 0.063 and 0.020 cm in diameter. All mercury used was purified by washing with dilute nitric acid followed by vacuum distillation.

Electrode preparation.—Silver electrodes were prepared from wire cleaned in an alcohol solution of KOH, etched in concentrated HNO_3, and suspended in a quartz tube. The tip of the wire was melted and allowed to form a sphere. The size of the sphere was controlled by the amount of wire melted. A stream of pure helium was passed through a liquid nitrogen trap and then through the quartz tube at all times. Hydrogen was not used for this purpose since it has been observed that exposure to hydrogen affects the double layer capacitance of silver (2). The electrodes prepared from the smaller wire were transferred immediately to the electrochemical cell. The electrodes prepared from the larger wire were electropolished in 60% perchloric acid solution for several minutes and then transferred to the cell. The surfaces of both types of electrodes were observed to be bright and specular under the optical microscope.

Hanging mercury drop electrodes were prepared by mercury-coating the tip of a small platinum wire sealed in glass using the method described by Ramaley *et al.* (17). The drops that were hung on this electrode were obtained from a Manostat microburet filled with mercury. These electrodes were used as checks of technique and solution purity.

Electrochemical cell.—A three-electrode system, consisting of the test electrode, a large cylindrical platinum foil counter electrode, and a hydrogen reference electrode, was employed. The counter electrode and test electrode, positioned in a geometrically concentric manner, occupied the main cell compartment. The reference compartment was connected to the main compartment with a Luggin capillary. An atmosphere of nitrogen, passed through a liquid nitrogen trap containing activated charcoal on glass wool and through a presaturator, was maintained in the main cell compartment at all times. Hydrogen, treated in the same manner, was bubbled slowly into the reference compartment. All potentials were measured *vs.* the hydrogen reference electrode in the test solution, and are given here *vs.* the normal hydrogen electrode (NHE).

The cell itself was constructed completely of glass. At no time after the solution had been filtered through activated charcoal did it contact any organic matter, including Teflon. Since silver does not readily seal in glass, the electrodes were suspended from above and allowed to dip into solution.

Methods of measurement.—Double layer capacitance was measured using a small amplitude sinusoidal potential superimposed on a fast linear potential sweep. The electrode was held at a cathodic potential just below hydrogen evolution before the sweep was begun. Experiment demonstrated that adsorbable impurities had less effect at a cathodic potential. The potential was then swept quite rapidly in an anodic direction and then back. Sweep rates of a volt per second were used to minimize completely the effect of

the adsorption of impurities. The frequency of the applied sinusoidal potential was 1000 cps and the amplitude was 10 mv peak to peak.

A rectangular current pulse waveform was employed in capacitance measurements where the object was to determine the extent of frequency dispersion in a qualitative manner. The curvature in the slope of the measured potential-time waveform was taken as a qualitative measure of the extent of frequency dispersion. These measurements were carried out as function of time and potential.

A detailed description of both techniques is given in another article (18).

Results and Discussion

Capacitance-potential data.—The results obtained for mercury using the hanging mercury drop are given in Fig. 1. The effect of pH is as expected and the data agree well with the work of Grahame (19). The wide spread in the curves was caused primarily by background noise on the amplifiers. The signals from the measurements on mercury were small enough so that the signal to noise ratio was unfavorable. In the case of silver, the signal was much greater, and this problem was not encountered. No measurable change in capacitance over periods of 20 min or longer was noted, indicating high solution purity.

The results for silver were much less reproducible than those for mercury. This is in part caused by an uncertainty in the actual area of the electrode. The geometrical area of the silver spheres was calculated from values of their diameters measured with a micrometer. Some error was introduced here due to imperfect sphericity of the electrodes, especially in the case of the electropolished electrodes. The capacitance data are all given in terms of the calculated geometrical area. For a solid, the calculated area will always be smaller than the real area, and from electrode to electrode there is probably no direct proportionality between real area and calculated area. This leads to nonreproducibility in measurements.

Reproducibility was also found to be affected by the manner of electrode preparation. The electropolished electrodes gave the more reproducible values of capacitance which changed very little with time. The electrodes used immediately after cooling of the molten drop (nonelectropolished) gave capacitance-potential curves which contained nonreproducible peaks. The capacitance of these electrodes changed with time over a period of 15 min, becoming higher and approaching the capacitance-potential curves for electropolished electrodes. This behavior is shown in Fig. 2.

In transferring the nonelectropolished electrodes to the electrochemical cell, a brief contact (several seconds) with the atmosphere was necessary. Such a direct contact was not made with the electropolished electrodes. Thus it was assumed that some impurity had adsorbed on electrodes exposed to the atmosphere, and that this impurity slowly desorbed in solution, allowing the behavior of one type of electrode to approach that of the other. A mercury electrode was deliberately exposed to the atmosphere and its capacitance recorded as a function of time. It behaved in exactly the same manner, showing anomalous peaks and an increase in capacitance with time toward the accepted value. Therefore, the capacitance-potential curves of electropolished silver electrodes were taken to be more representative of a clean silver surface.

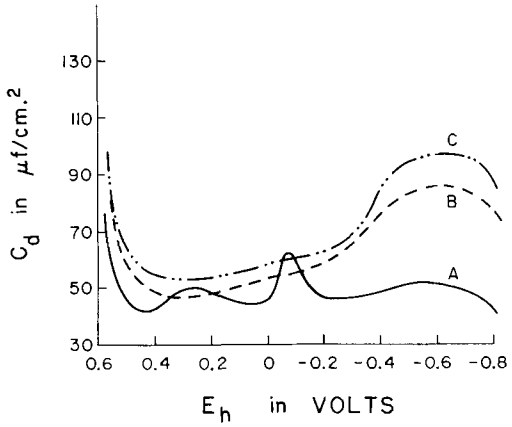

Fig. 2. Capacitance potential behavior of two silver electrodes in 1M $NaClO_4$ at pH 4. Curve A, nonelectropolished silver electrode immediately after immersion in solution; curve B, the same electrode 15 min later; curve C, electropolished silver electrode showing no change in capacitance with time.

Figure 3 describes the results obtained for silver as a function of pH, measurements being made at pH 13, 9.5, 4, 1, and 0. The two large envelopes contain the capacitance-potential curves for thirty-eight electrodes prepared in the two manners previously noted. The values for the nonelectropolished electrodes were taken after their capacitance had increased and the curves had become similar to the electropolished electrodes. The large bandwidth is caused by the nonreproducibility of area mentioned above. The large increase in capacitance at anodic potentials for pH 13 is most probably attributed to the adsorption of hydroxide ion. Similar behavior is observed on mercury in Fig. 1. The values of capacitance for the electrodes run in neutral or acid solution were normalized by assuming that the average value of 65 μf/cm^2 at 0.00v *vs.* NHE is the actual value at this potential. All capacitance values were corrected to 65 μf/cm^2 at 0.00v and the correction factor was used to normalize the capacitance values at all other potentials. All values fell within

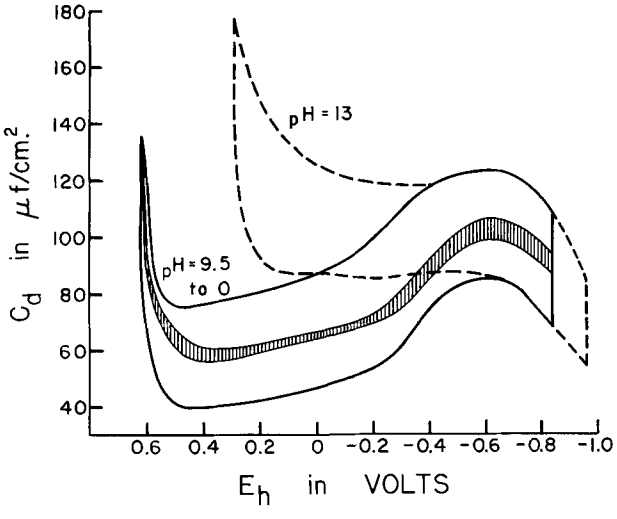

Fig. 3. Variation of the capacitance of silver in 1M perchlorate solutions with pH and potential. Shaded portion normalized at 0v to compensate for varying and unknown surface roughness.

the shaded area in Fig. 3. The width of this band is consistent with about a ±5% measurement error.

The normalization demonstrates the reproducibility of the curve shape. However, it does not give a more accurate measure of the actual double layer capacitance per unit area because the roughness factor is still unknown.

The shape of the curves in Fig. 3 is very interesting in that it resembles the shape of the curves obtained for mercury with the silver curve shifted toward more negative values of potential. For a direct comparison of the curves, the zero point of charge (zpc) of both metals must be known. According to Grahame (19) the zpc for mercury in 1M perchlorate solution occurs within 25 mv of the small capacitance peak shown at 0.30v in Fig. 1. Several values of the zpc have been given for silver, 0.51v (NHE) (20), 0.046v (NHE) (2), and —0.70 ± 0.05v (NHE) (5). If either of the first two values is correct, there is little similarity between the curves for silver and mercury. However, if the zpc for silver is at or near the potential of the capacitance maximum, as would be the case if the third and most recent value is correct, then the double layer structure for the two metals can be assumed to be very similar. A confirmation of the value of —0.70 ± 0.05v should be carried out before any definite statement can be made.

Frequency dispersion.—Several models explaining the variation of capacitance with measurement frequency have been proposed. McMullen and Hackerman (7) have suggested that the change in measured capacitance with frequency is caused not by a frequency dispersion of the double layer, but by a faradaic current due to small amounts of impurities present in solution. Bockris and Conway (12) have proposed that, due to strong adsorptive forces, the water molecules in the inner Helmholtz layer are unable to follow the applied field, resulting in a capacitance dispersion. Frumkin (16) has postulated that for solids, the dispersion is caused by the presence of unevenness and cracks in the electrode surface. This would create paths of differing resistance to different areas of the electrode. These different areas would then have different time constants and a frequency dispersion would result. A shielding of any part of the test electrode surface has the same effect. Grahame (9) has shown that shielding gives rise to dispersion on mercury electrodes.

Any model which attempts to explain the dispersion effect must explain several observed facts: The dispersion is always observed to be much greater on solid electrodes than on liquid electrodes, the measured capacitance always decreases with increasing frequency, the dispersion is potential dependent, the dispersion is observed at low frequencies, and the dispersion increases as the solution conductivity decreases.

The faradaic reaction model fails to explain the increase in dispersion with decreasing electrolyte concentration. It would be expected that the lower the electrolyte concentration, the lower the impurity level, and thus the lower the dispersion.

Experiments were performed in this laboratory by observing both the potential-time waveform and the faradaic current flowing when a rectangular current pulse waveform was applied to the test electrode (18). The curvature of the potential-time waveform (see Fig. 4, curve B) was taken as a qualitative estimate of the frequency dispersion of the double layer capacitance. No relationship between dispersion and faradaic current was observed as long as the faradaic current was a small fraction of the total cell current. The faradaic current, equal to or less than 0.2% of the total current, tended to increase as the potential became more cathodic while the dispersion tended to decrease.

The inner layer relaxation model, as pointed out by Grahame (21), does not explain the dependence of dispersion on solution concentration. It also predicts

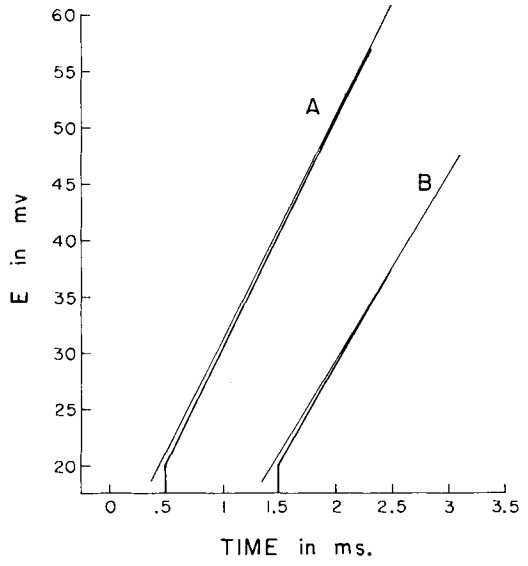

Fig. 4. Curve A, plot of potential vs. time for a constant current according to Eq. [1]; curve B, reproduction of a photograph of an oscillographic potential-time trace for a silver electrode.

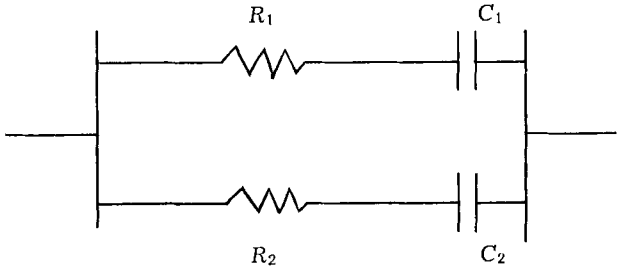
that the dispersion of capacitance is noticeable at about 100 megacycles on mercury. If the double layer structures on mercury and solid electrodes are similar, the dispersion on solids should be noted only at high frequencies. Dispersion is easily observable at frequencies of 100 cycles and less on solids.

The cell configuration used in this work was symmetrical and avoided shielding effects, so that all resistance paths to the test electrode should have been equivalent. It was felt that the method of electrode preparation, especially that of electropolishing, avoided the difficulty of uneven and cracked surfaces. Even so dispersion of capacitance with frequency was still observed. No dispersion was noticeable on mercury under the same conditions. If a nonequivalence of resistance paths to different sections of the electrode causes the frequency dispersion, then the potential dependence of the dispersion should be the same as the potential dependence of capacitance. This results because the time constant of the system, which is a function of frequency, changes only as the capacitance changes. A dependence of dispersion on potential was observed, but it was in no way related to the dependence of capacitance on potential. The capacitance is maximum at —0.60v and minimum at +0.45v in neutral or acid solution. The dispersion shows no maximum or minimum, but gradually increases with increasingly anodic potential. Thus the nonequivalent resistance path model does not explain the observed data.

A dispersion of capacitance with frequency will result if various areas of the electrode display different capacitances. The results are the same as for nonequivalent resistance paths to the electrode, but the cause is different. A simple model for this type of behavior can be drawn



where R_1 and R_2 represent resistant paths to the different parts of the electrode having the different ca-

pacitance values C_1 and C_2. The equation, derived by the method of nodal analysis (22), for the potential across this network as a function of time when a constant current pulse is applied at $t = 0$ is

$$E = \frac{it}{C_1 + C_2} + \frac{iR_1R_2}{R_1 + R_2} + \frac{i(R_1C_1 - R_2C_2)^2}{(R_1 + R_2)(C_1 + C_2)^2}\left[1 - \exp - \frac{(C_1 + C_2)t}{C_1C_2(R_1 + R_2)}\right] \quad [1]$$

Figure 4, curve A shows a plot of this equation assuming an electrode of 1 cm^2 having a capacitance of 60 μf for half its area and a capacitance of 40 μf for the other half. The solution resistance to the electrode is assumed to be 10 ohms and the current is assumed to be 2 ma. Figure 4, curve B shows the actual curve for a silver electrode measured at —0.20v in a solution of pH 13. The current density was 1.8 ma cm^2 and the calculated capacitance was 105 mf cm^2. The curves are quite similar. The majority of electrodes showed less deviation from a linear slope, and thus less dispersion, than did that depicted in Fig. 4, but some showed a greater dispersion.

The network and equation shown above also represent the nonequivalent resistance path model. No choice as to the correct model can be made on the shape of the curves alone. Other information must be obtained before the choice is made. The network shown above is only a very simple approximation of a more complicated system. On a polycrystalline electrode, there must be some variation in the resistance of the solution adjacent to surfaces of various curvature and there are very likely differences in double-layer capacitance among various surfaces of the electrode. The complete network would contain n resistances and capacitances. The point to be made is that in many cases, the variation of C may be much greater than that of R and therefore could be the principal cause of dispersion. Equation [1] is used to show that capacitance variation would result in the observed trends, but it is too simple a model to justify fitting it to the data quantitatively.

The model proposed predicts the decrease of measured capacitance with frequency and the increase in dispersion with increasing solution resistance. (According to the equation as R_1 and R_2 increase, the curvature of the E *vs.* t curve increases, and thus there is an increase in frequency dispersion.) It explains the fact that dispersion is higher on solids than on liquids. Solids present more than one crystal face to the solution, and the crystal faces can have different capacitances (23). Grain boundaries and other imperfections would not show the same capacitance as a more perfect crystal face. There is a probability that an impurity can be preferentially adsorbed on one crystal face, thus drastically changing its capacitance. Finally it can explain the potential dependence of dispersion. The areas of different capacitance may show capacitance-potential behaviors which are not alike, and thus a potential dependent dispersion results. This dispersion need not show any obvious relation to the total measured capacitance-potential behavior of the electrode.

As mentioned above, measurements in this laboratory indicated a potential dependence of dispersion which was not related to the measured capacitance-potential dependence in any obvious way. Another set of measurements was made on a silver electrode in a solution which had not been highly purified. The capacitance of the electrode decreased slowly with time as impurities adsorbed on it. This dispersion was also observed to decrease with time at approximately the same rate. This indicated that as the electrode became contaminated, the adsorbant tended to decrease the nonuniformity of the surface and the dispersion decreased.

Further evidence in support of this model is given by Tsa and Jofa (13). They observed that frequency dispersion decreased when a monocrystalline electrode was used instead of a polycrystalline electrode. This eliminates much of the nonuniformity in the capacitance values of different sections of the electrode.

Summary

Capacitance-potential curves obtained in 1M perchlorate solutions on silver surfaces prepared in two manners without mechanical or extensive chemical treatment indicate the need to avoid any atmospheric contact of the freshly prepared surfaces. After desorption of impurities, the capacitance-potential behavior of the nonelectropolished surfaces approached that of the electropolished surfaces. Since the data on the two types of surfaces agree, the potential dependence of capacitance measured is assumed to be that of a clean silver surface. The data also indicate a similarity between the double layer structure on mercury and silver.

The dispersion of the measured capacitance with frequency is explained on the basis of different portions of the silver electrodes possessing varying capacitance values. This model explains the observed facts concerning the frequency dispersion of the double layer for solids more satisfactorily than those previously proposed.

The Effect of Electrode Separation in Microcells

R. N. O'Brien[1] and K. Kinoshita

College of Chemistry, University of California, Berkeley, California

ABSTRACT

An interferometry cell has been designed with movable electrodes. Interferograms were taken in three cell orientations, shallow vertical, deep vertical, and horizontal cathode-over-anode at various current densities in a 0.1*N* solution of $CuSO_4$, *p*H 4-5. Anomalous maxima and minima were found in concentration gradient change with separation of electrodes and current density in all orientations. Similarly the impressed voltage to maintain a constant current density with increasing electrode separation went through at least one minimum which has been attributed to changes in the convection system in the vertical electrodes and tentatively to migration and field effects in the horizontal orientation. No quantitative interpretation seems possible at this stage.

The thin cell chronopotentiometric work of Anson *et al.* (1) and the recent interest in thin layer ion-exchange electrolytes for fuel cells and electrolytic machining has focussed attention on the effects of having two electrodes very close together.

The authors' interest concerns the very considerable effect of geometry on the transport processes in microcells. It has already been shown (2) that the effect of the orientation of the electrodes is profound varying from pure diffusion (and electromigration) in the cathode-over-anode configuration to almost pure convection in the anode-over-cathode position. All vertical electrodes in cells whose electrolyte depth is greater than 0.2 mm produce natural convection (2), and hence diffusion is limited to some portion of the so-called diffusion layer (3, 4).

It is possible to obtain concentration gradients between working electrodes by the optical means of Schlieren patterns (5) and interferometry (2, 6-8). Interferometry is perhaps the most convenient and is here employed. Since the concentration is directly proportional to the refractive index for all but the most concentrated solutions, the slope of a fringe can be measured to give $\partial c/\partial x$ or the rate of change of concentration with distance from the electrode.

It would be desirable to have a movable probe electrode as well as the ability to move the polarizing electrodes, but since the space limitations are so stringent this was not possible so in all cases the voltages shown are those impressed across the cell, as the distance between the electrodes was varied.

Experimental

The circuit used was a transistorized source, decade resistance boxes of about 100,000 ohms, and the cell of about 200 ohms, whose resistance varies with conditions of electrolysis. The circuit is therefore essentially a constant current circuit.

The interferograms were recorded with an Exacta 35 mm camera using Ilford HPS film.

The cell used was a specially modified one similar to that recently described (9). The Teflon cylinder with coated glass-flat ends had slits for the entry of long slabs of copper which were the movable electrodes. These electrodes were coated with TFE fluorocarbon spray to make them easier to move and so that they would be hydrophobic and thus help prevent leaks around the electrodes. All other parts and manipulations were the same as previously described (4).

The current passing was measured with a multirange microammeter, the impressed voltage with a Simpson Multimeter. The interferograms were taken at 3 min after a desired electrolysis current began to pass. The slope of the fringes were measured as close to the electrode as possible with a straight edge on a light box.

[1] Chemistry Department, University of Alberta; Visiting Scholar, College of Chemistry, University of California, Berkeley, California.

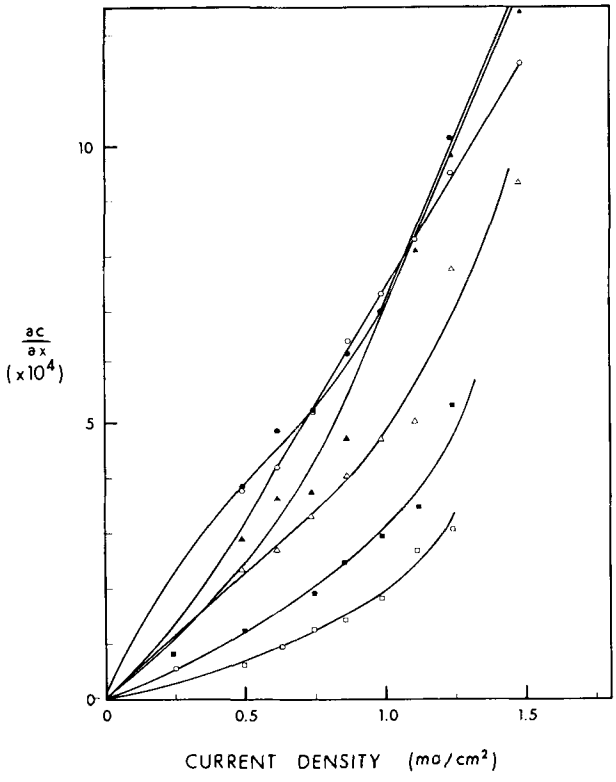

Fig. 1. Concentration gradient *vs.* current density for three different electrode separations, shallow vertical orientation. The separations are: • cathode, ○ anode, 0.0365 cm; ▲ cathode, △ anode, 0.516 cm; ■ cathode, □ anode, 1.115 cm.

Results

Current density, impressed voltage, and interferograms were taken for electrode separations of about 0.4, 0.6, 0.75, 1.0, 2.25, 3.3, 4.2, 5.2, 7.0, 9.5, and 11.0 mm. At each separation 3 orientations of the cell were used and about 10 C.D.'s ranging from about 0.3 ma/cm^2 to about 1.5 ma/cm^2. The range of C.D.'s was dictated by the resolution of the interferometer. At C.D.'s higher than 1.5 ma/cm^2 the fringes lie so close together that they are not measureable with this light-path difference. A thinner cell would of course permit higher current density interferograms. A number of interferograms with similar characteristics to those obtained in this work have been previously published (2, 7-9); therefore none are included here.

Figure 1 is a plot of concentration gradient *vs.* current density at three representative separations in what will be called the shallow vertical position (S/V). This means that the electrodes which were 2 mm by 25.4 mm on the working face were oriented so that

the cell (and hence electrodes and electrolyte as well) was 2 mm deep. The two shortest distances have very steeply increasing gradients with C.D. and the widest separation much less so. Figure 2 shows the same variable plotted for the deep vertical position (D/V) where the electrodes are now 25.4 mm deep and 2 mm wide. A similar relationship obtains.

Since convection is known to occur at all vertical electrodes, the results of Fig. 1 and 2 could be interpreted to mean that convection is a less efficient transport mechanism up to a distance of about 2.3 mm in the S/V and about 7 mm (with one previous change) in D/V and with the possibility of some effect of electromigration and electrode field. But considering Fig. 3 which shows the results for $\partial c/\partial x$ *vs.* C. D. in the cathode-over-anode position (C/A), the fact that the rate of change of $\partial c/\partial x$ with C.D. is constant, although the values of $\partial c/\partial x$ for a given C.D. are different and lower for the two widest separations and have a lower rate of change, suggests that field effects must be important since there is no convection in this position. The change to a constant slope is first noticeable at 2.3 mm separation and a C.D. limitation of about 0.67 ma/cm^2 (impressed voltage 50 mv) and at progressively higher C.D.'s and impressed voltages until, at 4.30 mm separation, there is only slight suggestion of a change (increase) of slope at the highest C.D.'s used.

These effects can be more clearly seen in plots of $\partial c/\partial x$ *vs.* electrode separation at constant current density. Figure 4 is the plot for the S/V orientation. It shows peaks at 1 mm and about 3.5 increasing to just over 4.0 mm at higher C.D.'s and valleys at just under 0.5 mm increasing to 0.6 mm, and at 2.3 mm as well as anomalous variations between the two electrodes at the smallest separations. The first peak is thought to represent the most favorable separation for one convective whorl, the second peak that for two with over and underflow (10) with field effects superimposed.

Figure 5 shows $\partial c/\partial x$ *vs.* electrode separation at constant C.D. for the D/V position. Rapidly dropping values of $\partial c/\partial x$ are evident for low C.D.'s and small separations, but at high C.D.'s there are two peaks at about 0.75 mm and about 4.5 mm. These are also thought to be due mainly to one and two whorl convective flows.

In Figure 6 for the C/A position, $\partial c/\partial x$ values show sharp drops at small separations at all C.D.'s where it was possible to make measurements close to the electrodes. One peak persists from about 1 mm separation

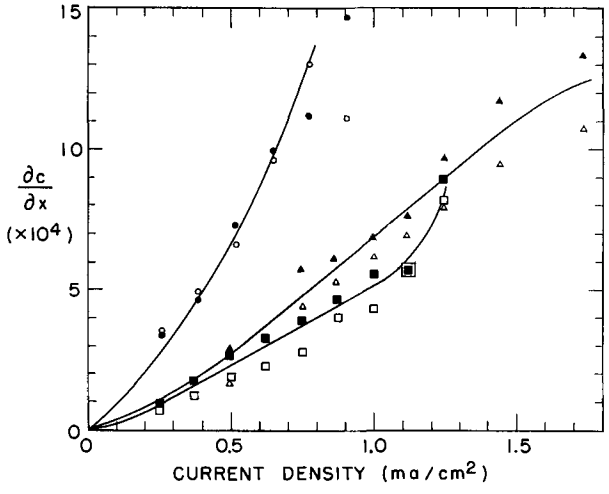

Fig. 2. Concentration gradient *vs.* current density for three different electrode separations, deep vertical orientation. The separations are: • cathode, ○ anode, 0.0245 cm; ▲ cathode, △ anode, 0.532 cm; ■ cathode, □ anode, 1.088 cm.

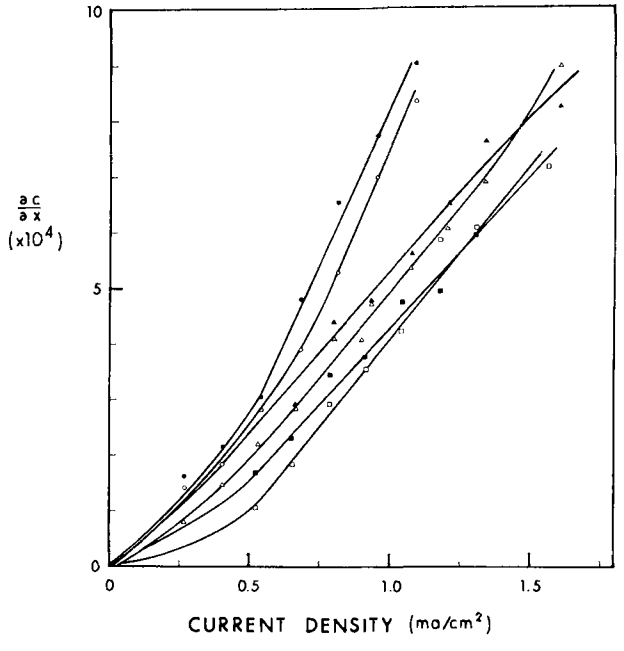

Fig. 3. Concentration gradient *vs.* current density for three different electrode separations, horizontal, cathode-over-anode orientation. The separations are: • cathode, ○ anode, 0.042 cm; ▲ cathode, △ anode, 0.526 cm; ■ cathode, □ anode, 1.112 cm.

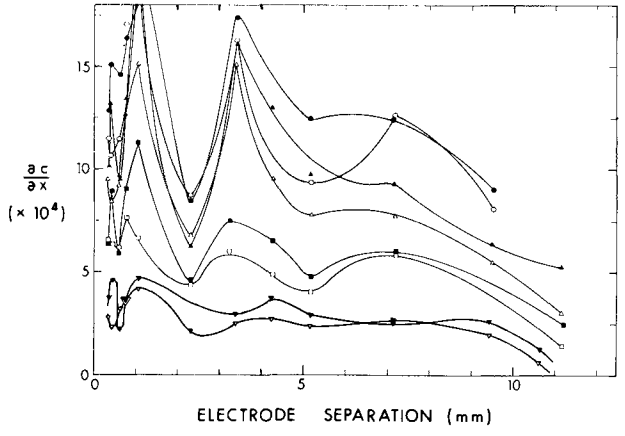

Fig. 4. Concentration gradient *vs.* electrode separation for four different current densities, shallow vertical orientation. The current densities are: • cathode, ○ anode, 1.48 ma/cm^2; ▲ cathode, △ anode, 1.23 ma/cm^2; ■ cathode, □ anode, 0.86 ma/cm^2; ▼ cathode, ▽ anode, 0.49 ma/cm^2.

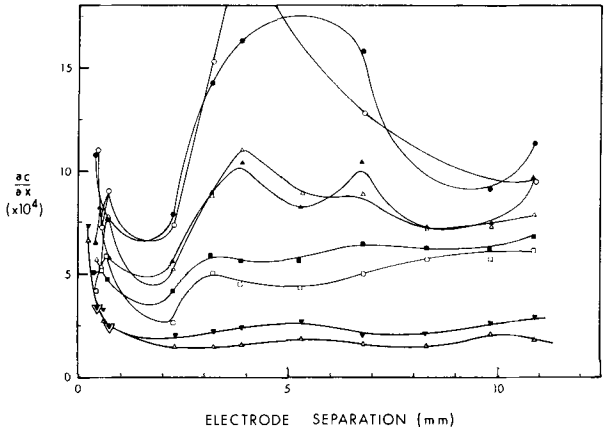

Fig. 5. Concentration gradient *vs.* electrode separation for four different current densities, deep vertical orientation. The current densities are: • cathode, ○ anode, 1.51 ma/cm^2; ▲ cathode, △ anode, 1.26 ma/cm^2; ■ cathode, □ anode, 1.01 ma/cm^2; ▼ cathode, ▽ anode, 0.51 ma/cm^2.

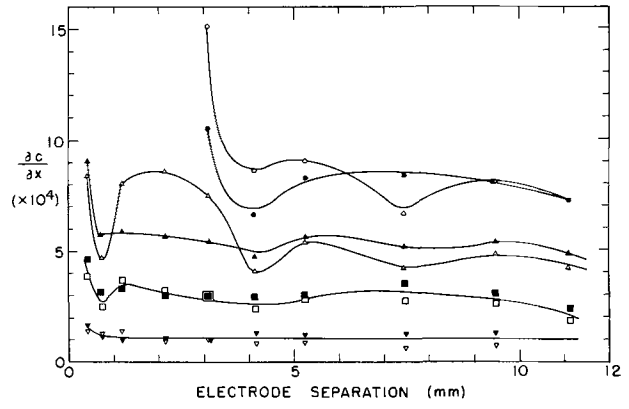

Fig. 6. Concentration gradient *vs.* electrode separation for four different current densities, horizontal, cathode-over-anode orientation. The current densities are: ● cathode, ○ anode, 1.58 ma/cm^2; ▲ cathode, △ anode, 1.07 ma/cm^2; ■ cathode, □ anode, 0.67 ma/cm^2; ▼ cathode, ▽ anode, 0.27 ma/cm^2.

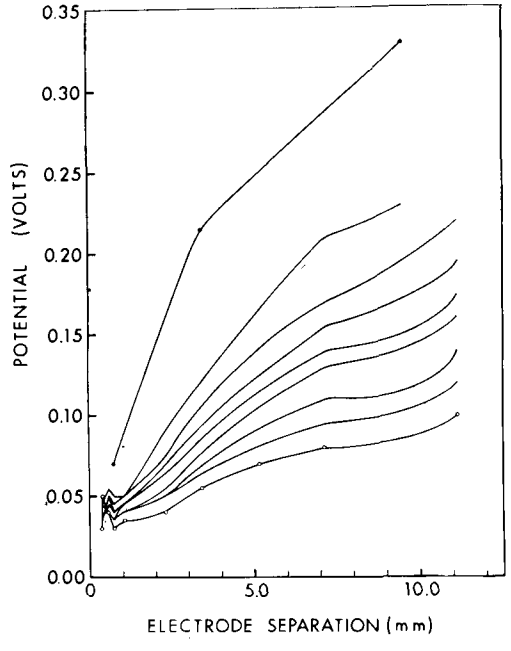

Fig. 7. Impressed voltage to maintain a constant current density at various electrode separations in the S/V orientation. Current densities successively from the top of the plot are: 2.22, 1.48, 1.23, 1.11, 0.99, 0.86, 0.74, 0.62, 0.43 ma/cm^2. Only data points at 2.22 and 0.43 ma/cm^2 are shown to avoid clutter.

up to about 1 ma/cm^2 when the peak begins to broaden. Other minor perturbations to the plot at greater distances persist above 0.5 ma/cm^2.

A plot of the impressed voltage to maintain constant current density should show these anomalous changes in the change in concentration gradient, if they are real. Figure 7 gives the impressed voltage at constant C.D. and various separations for the S/V position. A very sharp drop in required potential has occurred at 0.4 mm electrode separation, the potential then reaches a peak varying from about 0.4 mm to 0.6 mm, increasing with increasing C.D., then again suddenly drops at 0.75 mm to rise again more slowly at greater separations. Up to about 10 mm separation there is no indication that a constant increase in potential with distance will maintain a constant C.D. in this orientation. Figure 8 is the same plot for the D/V position. It again shows a rapidly decreasing potential below 0.4 mm, a peak at about 0.65 mm and a minimum at about 0.80 mm, these distances remaining reasonably constant with C.D. At the greatest current densities and separations the potential is approximately proportional to the separation for constant C.D.

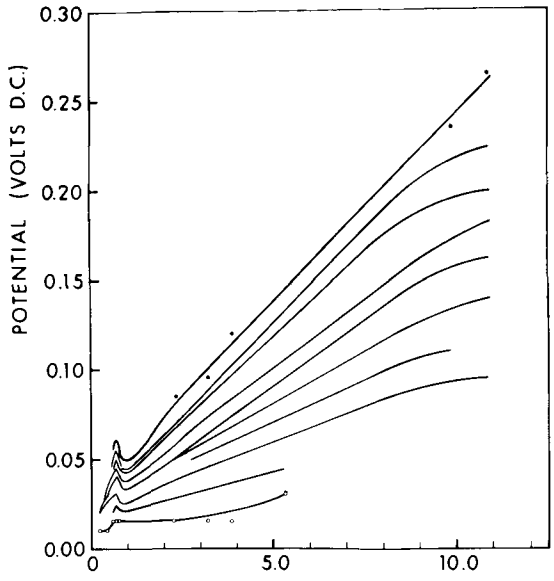

Fig. 8 Impressed voltage to maintain a constant current density at various electrode separations in the D/V orientation. Current densities successively from the top of the plot are: 1.51, 1.26, 1.14, 1.01, 0.88, 0.76, 0.63, 0.51, 0.38, 0.25 ma/cm^2. Only data points at 1.51 and 0.25 ma/cm^2 are shown to avoid clutter.

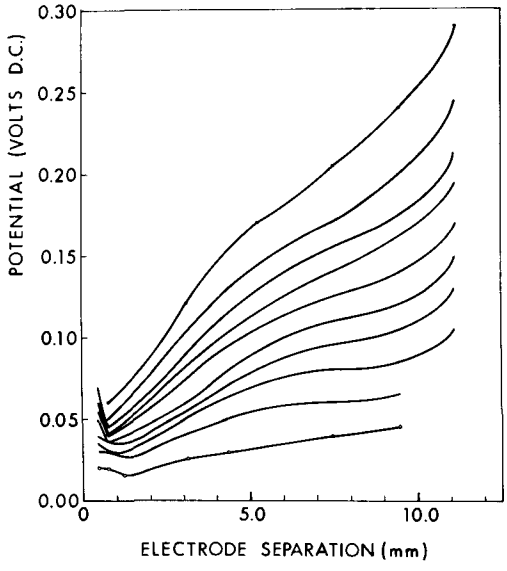

Fig. 9. Impressed voltage to maintain a constant current density at various electrode separations in the C/A orientation. Current densities successively from the top of the plot are: 1.58, 1.33, 1.20, 1.07, 0.94, 0.80, 0.67, 0.53, 0.41, 0.27 ma/cm^2. Only data points at 1.58 and 0.27 ma/cm^2 are shown to avoid clutter.

Figure 9 is the plot for the C/A position. At all C.D.'s the potential to maintain a constant C.D. is increasing with decreasing separation from about 0.75 mm up to about 0.4 mm which is the closest approach that could be measured with this cell. The authors have no doubt that this trend would be reversed at still smaller electrode separation, but they did not find it so. The minima in the family of curves occurred at constantly decreasing separations as the C.D. increased. No further obvious features occurred except that the potential was not proportional to the distance and enough variation at 4.5 mm and 10 mm is present to support the existence of the peaks seen in Fig. 6 at these distances.

Close comparison of Fig. 1, 2, and 3 shows that at the greatest electrode separation ($\sim$ 1.1 cm) and 0.3 ma/cm^2 all three orientations have equal concentration gradients. This is presumably the point at which convection just becomes effective in altering the concentration gradient in this geometry of cell.

Conclusions

The evidence in the presented data for convection when electrodes are oriented vertically is really only reinforcement for already existing evidence. However the anomalies in the plots of $\partial c/\partial x$ *vs.* C.D., $\partial c/\partial x$ *vs.* electrode separation, and impressed voltage *vs.* electrode separation in the C/A orientation clearly indicate the presence of electromigration and field effects. Obviously any quantitative characterization of these effects will require further careful work with a redesigned cell at smaller electrode separation in the C/A position. Preliminary work in the same cell at different concentrations and temperatures shows similar general behavior. This agrees in principle with the findings of Anson who has shown that thin layer chronopotentiometry where his electrolyte layers were 0.01 mm to 0.1 mm thick required less voltage than normal diffusion chronopotentiometry. It should be possible to predict the onset of effective convection in any geometry of cell with further work.

Technical Notes

Detection of Striae in GaAs by Chemical Etching

T. S. Plaskett and A. H. Parsons

IBM Watson Research Center, Yorktown Heights, New York

Striations in GaAs pulled from the melt in a sealed magnetic puller have been observed by Pilkuhn and Rupprecht (1) by anodic etching of bulk material and by chemical etching of p-n junctions that have been produced by diffusion. Striae have also been observed by Drougard and Gunn (2) by infrared transmission and by LeMay (3) in Te doped GaAs by chemical etching with HNO_3 etch. It has been postulated (4) that the striae in GaAs are associated with segregation of the solute during growth of the crystal, as has been observed in the case of Ge and Si [see review article by Dikhoff (5)] and InSb (6), and result from a variation in the rate of growth (7, 8). In the present investigation a chemical etching technique is described for revealing striations in both the heavily doped, conducting GaAs that is used for the fabrication of injection lasers, and the semi-insulating GaAs that is used for insulating substrate for the epitaxial growth of Ge. The laser material was n-type, selenium or tin doped. The semi-insulating material was obtained by doping with chromium. Striations were clearly evident by infrared examination in the conducting crystals, but could not be detected by this means in the insulating crystal.

The etching solution that was used was $3HNO_3$:1HF:$4H_2O$. Etching was carried out at room temperature for about 2 min on either chemically or mechanically polished surfaces. The striation pattern on a section cut parallel to the growth axis for a 3 x 10^{18} at./cc Sn doped crystal is shown in Fig. 1a. The striation spacing is not constant, but over the distance shown in the photomicrograph it is about 20μ. The spacing calculated from the f/ω relationship where f is the rate of growth of the crystal and ω is the rotation rate is 9μ. As was shown previously (4), agreement with this relationship for a sealed Czochralski system is not good because of an erratic pulling rate characteristic of this type of puller where the pulling mechanism involves magnetic coupling. This etching technique does not detect the finer striation structure reported by Gatos *et al.* (6) to occur between the coarse striae.

A longitudinal section taken from a Se doped crystal (1.5 x 10^{18} at./cc) was given a similar etching treatment as above. Initially, no striae were detected in this material by etching even though the infrared examination indicated that the sample was striated. When, however, the sample was etched under tungsten illumination the striae were clearly visible as shown in Fig. 1b. The etchant only revealed striae on the side of the sample which was closest to a {111} Ga face and was most effective when the surface parallel to the growth axis was a $\{\bar{2}11\}$ (all crystals examined were grown in <111>). For the Sn doped crystal there was no orientation or polarity dependence.

It was found that striae were not detected in the semi-insulating, Cr doped crystal unless the etching was carried out under illumination and on a surface having the same crystal orientation and polarity as required for the Se doped material. The Cr doped crystal showed no striae pattern when examined by infrared transmission but, as shown in Fig. 1c a striation structure is revealed by the chemical etching technique. The Cr level was about 2.8 x 10^{17} as determined by emission spectroscopy; the Se and Sn levels were

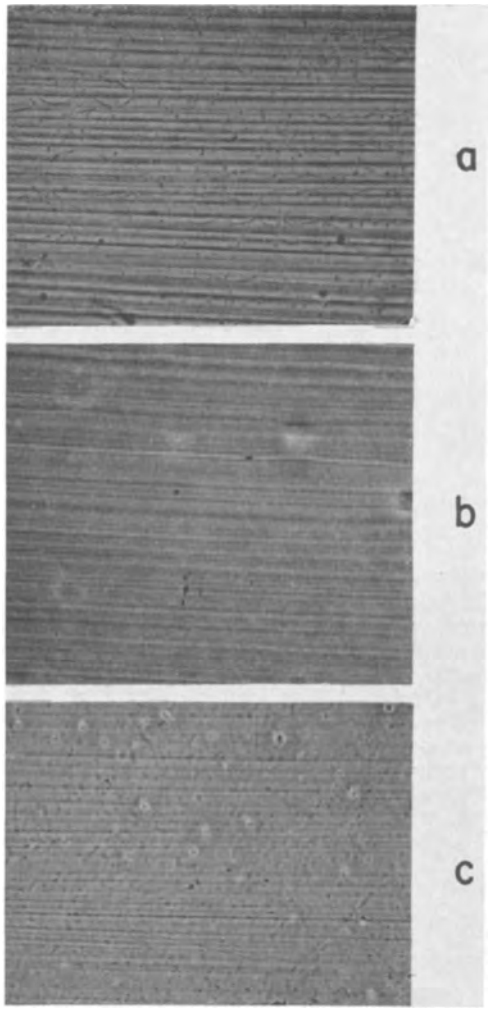

Fig. 1. Striation structures revealed by chemical etching. Sections shown were cut parallel to the growth axis. (a) Sn doped; (b) Se doped; (c) Cr doped. Magnification approximately 45X.

determined by Hall effect measurements. The measured striation spacing for the Se and Cr doped samples was 10 and 15μ, respectively. The calculated spacing from f/ω relationship for the Se was 3μ and for Cr 52μ. The agreement with f/ω relationship is not good and for the same reason as suggested for the Sn doped crystal.

The chemical etching technique with the additional requirement of etching under illumination provides a sensitive means of detecting inhomogeneities in GaAs crystals. The effect of the illumination is to make the etch preferential. The illumination probably injects holes at the surface by some photo process, such as photoconductivity, and makes the surface more reactive. Inhomogeneities in the crystals would affect the amount of the injection of holes and thus give rise to the striated pattern. Semi-insulating GaAs is known to be photoconductive (9), and therefore the striations in this case could be explained by Cr segregation. Similarly the Se doped material had the same etching requirements which would also suggest that the striae represent a chemical segregation pattern. However, for the Sn doped crystal no special etching requirements were needed and thus the striae could represent some other type of crystalline defect such as dislocation loops. The fact that the atomic size mismatch between Sn and Ga or As is much greater than for the other dopants would support a crystalline defect model.

Chemical Etching of Silicon Carbide with Hydrogen

T. L. Chu and R. B. Campbell

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

Silicon carbide has a large energy gap and is useful for the fabrication of active devices operable at high temperatures. Chemical etching can be used for the preparation of silicon carbide surfaces in the fabrication process; however, the number of etchants is limited due to its chemical inertness. Molten salts, such as sodium peroxide, sodium carbonate, etc., have been used to reveal structural imperfections in silicon carbide (1). Mixtures of chlorine and oxygen have also been used for the etching of silicon carbide at 900°C or above (2). The (0001) and (000$\bar{1}$) faces of hexagonal silicon carbide exhibit different etching behaviors due to the slightly ionic character of the Si-C bond. Using molten sodium peroxide, for example, one face (hereafter face A) remains smooth after etching while the other (face B) becomes "wormy" in appearance with a considerably lower etch rate. However, face B is more readily attacked by mixtures of chlorine and oxygen. No unambiguous conclusions on the nature of these two faces have been reached.

The use of gaseous etchants is more advantageous in certain processes. In the epitaxial growth process, for instance, the substrate surface condition is a very important factor determining the crystal perfection of the grown layer, and the etching of substrates in the reaction tube immediately prior to the growth process is often employed. The chemical reactivity of carbon toward hydrogen at high temperatures suggests that hydrogen could be used as an *in situ* etchant for silicon carbide. We have found that at temperatures above 1600°C, hexagonal silicon carbide crystals are etched at measureable rates yielding smooth surfaces. The results are summarized in this note.

The reaction of carbon with hydrogen proceeds rapidly at high temperatures producing hydrocarbons. At 2000°K, for example, the free energies of forma-

tion of acetylene and methane are 27.97 and 31.19 kcal/mole, respectively (3). The reaction between silicon carbide and hydrogen thus yields a mixture of silicon vapor and hydrocarbons. The use of hydrogen in a flow system shifts the chemical equilibrium toward the formation of gaseous silicon and hydrocarbons, and reasonable etch rates can be obtained. It should be noted that the vapor pressures of the silicon carbide species are very low in the temperature range under consideration. At 2149°K, for example, the principal gaseous species above silicon carbide are Si, SiC_2, and Si_2C, and their partial pressures are 2.1×10^{-5}, 1.9×10^{-6}, and 1.4×10^{-6} atm, respectively (4). Thus, the evaporation of silicon carbide in an inert atmosphere at this temperature or below would not be appreciable.

The etching experiments were carried out in a flow system, using a horizontal, water-cooled quartz tube of 2.5 cm ID with gas inlet and exhaust tubes. Hydrogen was purified by diffusion through a palladium-silver alloy, and its flow rate was measured with a Matheson flowmeter. Hexagonal silicon carbide platelets with main faces of {0001} orientation grown by a sublimation technique (5), were etched in molten sodium peroxide to reveal the polarity of the faces and then mechanically polished. These crystals, usually 3-6 mm across and 0.2 mm thick, were supported on a refractory inert susceptor in the quartz tube (6), and hydrogen was introduced at a constant rate. The susceptor was then heated externally by an rf generator so that the crystals could be maintained at a desired temperature. The temperature of the crystals was measured with a microoptical pyrometer. The measured temperatures should be corrected for the emissivity of the crystals and the reflection loss at the wall of the reaction tube which would be about 100°C under the conditions used here. The etch rate was determined by measuring the thickness of the crystal before and after heating in hydrogen for a measured length of time using both optical microscopy and thickness gauges. In some cases, it was also determined from the surface area of the specimen and its decrease in weight after etching.

The etching of silicon carbide crystals with hydrogen involves such experimental variables as the polarity of the crystal surface, temperature of the crystal, and flow rate of hydrogen. Most experiments were carried out using a hydrogen flow rate of 2.5 l/min which, in our apparatus at room temperature, corresponds to a linear velocity of 8.5 cm/sec or higher. The etch rates of faces A and B of hexagonal silicon carbide in the temperature range 1600°-1750°C (meas.) are summarized in Table I, and the data shown here are believed to be accurate within ±10%. The etch rate was found to decrease with decreasing hydrogen flow rate, as expected. At a hydrogen flow rate of 0.5 l/min, for example, the etch rates at 1700°C were found to be 0.3 and 0.2 μ/min for face A and B, respectively. In all cases, the etch rate of face A by hydrogen is higher than that of face B, contrary to the etching action of chlorine-oxygen mixtures.

Table I. Etch rate of silicon carbide with hydrogen, μ/min (Hydrogen flow rate = 2.5 l/min)

Temperature, °C	Face A	Face B
1600	0.3	0.25
1650	1.5	0.8
1700	2	0.8
1750	4	2

Attempts were made to analyze the products of the silicon carbide-hydrogen reaction using a mass spectrometer, and no hydrocarbons were detected. This is due presumably to the decomposition of the hydrocarbons immediately after reaction (7), depositing carbon at lower temperature regions of the reaction tube.

The hydrogen etch appears to be nonpreferential, and the resulting surface, irrespective of polarity of the surface and growth steps initially present on the crystal, is smooth when examined with an optical microscope. The same results were obtained when the as-grown surfaces of hexagonal silicon carbide were used. A further advantage of this technique is that ultrapure hydrogen can be prepared readily to minimize the contamination of the crystal surface during the etching process. The effectiveness of the H_2 etch technique is indicated by the fact that the structural perfection of epitaxial silicon carbide films has been greatly improved by the *in situ* etching of substrates with hydrogen (6). Furthermore, the use of hydrogen etch also enabled the epitaxial deposition of silicon films of reasonable perfection on silicon carbide substrates (8).

Electrical Conductivity of Fused Potassium Nitrate

C. A. Angell[1]

Department of Metallurgy, University of Melbourne, Parkville, Victoria, Australia

Recently published electrical conductance data for KNO_3 obtained by King and Duke by means of a d-c technique (1) are in agreement, to ±0.1% over the whole temperature range, with a-c measurements made in this laboratory but published only in graphical form (2). Since King and Duke observe that their d-c data show less scatter than previous a-c measurements and as our measurements show less scatter still, it seems appropriate to report the actual conductivity values so that, jointly with those of King and Duke, they may serve as a standard for this salt. The results, together with the "activation energies" [or, preferably, "Arrhenius coefficients" (2)] for the temperature intervals between successive pairs of points are given in Table I. The consistency of activation energies calculated from points only 10°C apart constitutes a severe test of precision of conductance data, *e.g.*, an 0.1°C error in temperature at 385.4°C would be sufficient to

[1] Currently on leave at Argonne National Laboratory, Argonne, Illinois.

Table I.

T, °C	κ	E_κ

352.9	0.6749	3.59
336.0	0.6212	3.71

cause the only interruption to the otherwise regular increase of E with T seen in Table I. In view of this, we note that the regular change of activation energy with temperature reported graphically by Cowen and Axon (3) implies a particularly high precision in their measurements, which unfortunately were not tabulated.

In connection with the precision of King and Duke's measurements, it is pertinent to observe that the curvature of their log κ *vs.* $1/T$ plot for the $LiNO_3$-$NaNO_3$-KNO_3 eutectic (4) is of the form to be anticipated for a low-melting eutectic from the free volume interpretation of other molten salt data (2, 5). In fact, the plot runs almost parallel to (but slightly lower than) that for the KNO_3-$NaNO_3$-$NaNO_2$ eutectic shown in Fig. 6 of ref. (2). The curvature represents a systematic increase of E_κ from 3.1 kcal/mole at 370°C to 6.9 kcal/mole at 143°C, which is not sufficient to permit independent calculation of the free volume parameters for this melt. The data are none the less of considerable theoretical value since they cover the temperature range linking the domains of the glass-forming molten nitrate mixtures and the glass-forming aqueous nitrate solutions.

Brief Communication

Progress toward Single Crystal Silicon Films on Amorphous Substrates

J. D. Filby and S. Nielsen

Royal Radar Establishment, Malvern, England

The preparation of single crystal layers of silicon on insulating substrates has potential advantages in semiconductor technology. Some progress has been made recently toward this with the successful epitaxial deposition of silicon on crystalline quartz (1) and sapphire (2, 3) and with the recrystallization of thin films of silicon on alumina (4,5). We report here encouraging progress toward single crystal layers on fused quartz using a new technique, ultrathin alloy-zone-crystallization, U.T.A.Z.C.

U.T.A.Z.C. involves the use of an extremely thin layer of alloy on the substrate surface and must be differentiated from thin alloy-zone-crystallization, T.A.Z.C., techniques (6, 7) such as the vapor liquid solid technique (8,9). In the T.A.Z.C. technique, material diffuses through a layer of alloy to the substrate surface; in the U.T.A.Z.C. technique the alloy layer is too thin for diffusion to be an important factor and the function of the layer is apparently to alter the energetics of the nucleation and growth processes. The use of the U.T.A.Z.C. technique in the epitaxial deposition of silicon on silicon at low temperatures (10) and on single crystal alumina (11) has been described elsewhere.

When silicon is sublimed, or evaporated, on the surface of fused quartz, polycrystalline layers are obtained. The grain size increases with substrate temperature and may approach 5μ at 1100°C. However, if a very thin layer of gold is evaporated on the fused quartz surface before the silicon is deposited, the grain size is much increased. This is illustrated in Fig. 1, which shows large silicon grains on quartz previously covered with gold on the left, and small silicon grains on quartz with no gold on the right. The grain size can be as large as 300μ, and we believe that with further development even larger grains and possibly single crystal layers may be obtained.

Layers containing grains larger than 50μ, as shown in Fig. 2, were repeatedly obtained by the following procedure. The fused quartz substrate (½ x ¼ in.) was cut from a 3 x 1 in. microscope slide and washed in trichloroethylene, chromic acid, deionized water, and acetone to remove the surface contamination intro-

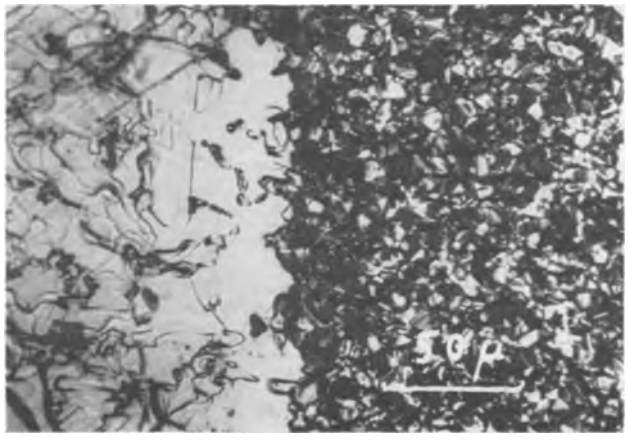

Fig. 1. Surface of evaporated silicon layer deposited on amorphous quartz (right) and on quartz covered by a 1000Å gold film (left).

Fig. 2. Typical area of the surface of a silicon layer sublimed on amorphous quartz using a thin (2000Å) gold film.

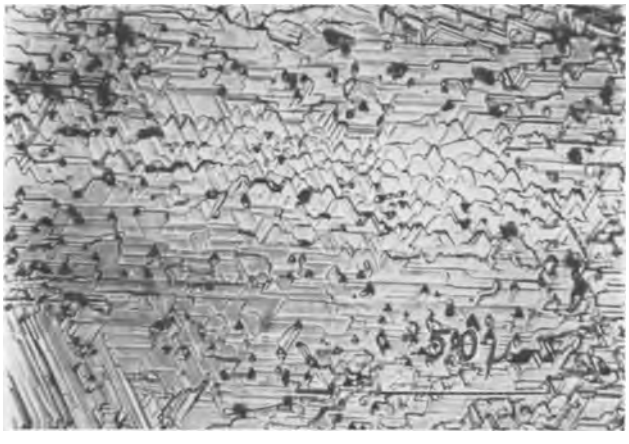

Fig. 3. Growth steps on the surface of a silicon layer deposited on amorphous quartz.

duced during the cutting process. A layer of gold 1000-3000Å thick was evaporated on one surface of the substrate, the substrate being near room temperature. The substrate was then transferred to a sublimation apparatus (7), where silicon was sublimed onto it at a rate of 2 μ/hr, the substrate temperature being in the region 700°-800°C. Layers of silicon up to 20μ in thickness were obtained in this way, but due to differential thermal contraction these were cracked into areas a millimeter or so in diameter. A high proportion of the larger grains had a (111) plane parallel to the surface of the layer, although the grains were randomly orientated with respect to each other. The (111) orientation can be easily seen in Fig. 3, which shows the growth steps on the surface of a large grain, the growth steps being typical of those observed on epitaxial silicon layers grown on (111) surfaces of silicon. Further evidence for the single crystallinity of such large grains was obtained by transmission and reflection electron diffraction, Fig. 4 being a transmission diffraction photograph.

Similar results have also been obtained using evaporation rather than sublimation. In these cases silicon was evaporated as described by Newman (12), and a Varian V120 getter-ion vacuum system used. Although a high proportion of the resultant layer consisted of grains over 50μ across, grains larger than 250μ were less numerous than for sublimed layers. Current results suggest that the grain size is decreased if either the deposition rate or the substrate temperature is too high. Layers containing large numbers of grains

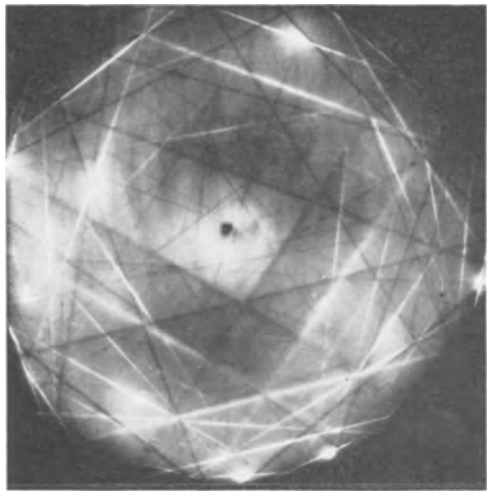

Fig. 4. Transmission electron diffraction photograph of an area of the layer shown in Fig. 2.

50μ or more in diameter were obtained by using 1000Å of gold, an evaporation rate of 50 μ/hr and a substrate temperature of 900°C.

Apart from the thickness of the gold layer, which has been varied between 1000Å and 5μ, with layers below 3000Å giving the best results, no attempt has been made to optimize the experimental conditions. Preliminary experiments using platinum, copper, silver, aluminum, tin, or indium in place of gold, suggest that gold gives the best results. No systematic variation of the experimental parameters, *e.g.*, rate of evaporation, substrate temperature, etc., has been attempted, and no attempt has been made to induce a preferred orientation to the nuclei. The results to date with the U.T.A.Z.C. technique, therefore, seem to offer good prospects of single crystal layers on amorphous substrates.

The Cathodic Reduction Mechanism of Electrolytic Manganese Dioxide in Alkaline Electrolyte

A. Kozawa and J. F. Yeager

Consumer Products Division, Research Laboratory, Union Carbide Corporation, Cleveland, Ohio

ABSTRACT

Constant-current discharge curves for electrodeposited MnO_2 on graphite showed a two-stage reduction; $MnO_{2.0}$ to $MnO_{1.5}$ and $MnO_{1.5}$ to $MnO_{1.0}$. Potential decreased continuously during the first stage and in some discharges was constant for at least half of the second. The first stage was not influenced by current density, KOH concentration, MnO_2 thickness, or a complexing agent. The constant-potential portion was observed with 9M KOH, low current density; the potential was near the standard redox potential of Mn(II) and Mn(III) species in solution as determined polarographically. The first stage is considered a homogeneous phase reduction, while the second stage involves a heterogeneous system. A new mechanism is suggested for the latter.

The cathodic reduction of electrolytic manganese dioxide (γ-MnO_2) in alkaline electrolyte has been investigated by Cahoon and Korver (1) and also recently by Bell and Huber (2) by taking discharge curves and by chemical and x-ray diffraction analyses.

Cahoon and Korver postulated the following three stages for the reduction process. The electrolytic manganese dioxide is first reduced simultaneously to $Mn(OH)_2$ and Mn_4O_7, then the Mn_4O_7 is reduced to Mn_3O_4 and $Mn(OH)_2$ in the second stage, and the Mn_3O_4 to $Mn(OH)_2$ in the final stage. Their discharge curves, however, did not show steps corresponding to those stages (see Fig. 7).

Bell and Huber postulated the following three stages based on the steps observed in their discharge curves (Fig. 7) (*i*) $MnO_{2.0} \rightarrow MnO_{1.7}$ as a homogeneous phase reduction; (*ii*) $MnO_{1.7} \rightarrow MnO_{1.47}$ as a heterogeneous system, $MnO_{1.7}$ being rhombic groutite (αMnOOH) structure and $MnO_{1.47}$ tetragonal γ-Mn_2O_3 structure; (*iii*) below $MnO_{1.47}$ as a heterogeneous system. In the first stage, the potential decreased continuously as the cathodic reduction proceeded, but in the second and third stages the potential remained practically at the characteristic steady potential values.

Contrary to Cahoon and Korver, Bell and Huber found by x-ray diffraction no $Mn(OH)_2$ as a reduction product at the beginning stage of the discharge. As they (2) pointed out, this discrepancy may be due to the difference in the current density; Cahoon and Korver discharged at about 60 ma/g of MnO_2 and Bell and Huber discharged at 0.5 ma/g of MnO_2.

In the above investigations (1, 2), the discharges of manganese dioxide were performed in the presence of a zinc electrode or even in a KOH solution containing ZnO (2). This may have introduced an additional complication in elucidating the reduction process.

In the present investigation, electrodeposited manganese dioxide on graphite rods was discharged in pure KOH solution under varying conditions of current density, KOH concentration, and thickness of the MnO_2 layer on the graphite. Also the effect of triethanolamine added to the electrolyte was examined in order to see whether $Mn(OH)_2$ is formed on the electrode surface at the beginning stage of the discharge. Triethanolamine forms a stable complex with Mn(II) and Mn(III) ions in alkaline solution; therefore, if $Mn(OH)_2$ is formed on the electrode surface, it will be removed by complexing and an influence will be shown on the discharge curve.

Electrodeposited manganese dioxide on the spectroscopic graphite rod has been extensively used (3-6) in previous studies for the discharge process in neutral or acid solutions and has given satisfactory results, mainly because the rod is porous and provides good adhesion between the manganese dioxide and graphite.

Experimental

Preparation of the MnO_2 *electrode.*—Manganese dioxide was electrodeposited on spectroscopic graphite rods (AGKSP), 7.7 cm long (except for the experiment shown in Fig. 4) and 4.5 mm diameter, from 0.5M $MnSO_4$ + 0.5M H_2SO_4 at 90° ± 1°C at 20.0 ma for 10.0 min. The electrode construction and the electrolysis bath are shown in Fig. 1. The graphite electrodes with electrodeposited manganese dioxide was taken out of the Teflon holder and washed with 0.1*N* H_2SO_4, then washed with water at room temperature for more than 48 hr, and then kept in distilled water until use. Current efficiency of the electrodeposition of manganese dioxide was almost 100% under these conditions. From chemical analysis of the manganese dioxide by the previously reported ferrous sulfate method (7), 10.6 ± 0.4 mg of MnO_2 per electrode and 1.98 ~ 1.99 for the x value in MnO_x were obtained.

Discharge experiments.—The discharge experiments were carried out at room temperature (23° ± 0.5°C) in a cell which was the same as that shown in Fig. 1, except alkaline electrolyte was employed instead of

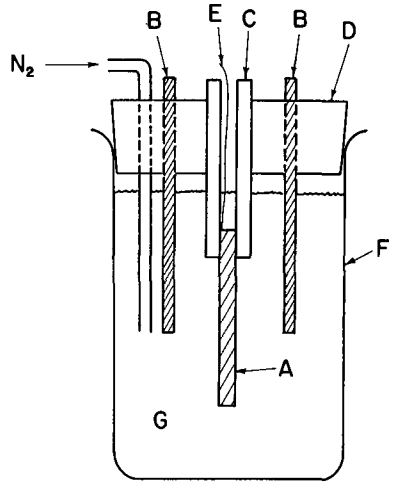

Fig. 1. Electrodeposition bath and discharge cell; N_2 gas was admitted here only when used as a discharge cell. the manganese sulfate solution. Before the discharge, nitrogen was passed through the electrolyte to eliminate dissolved oxygen. Before the discharge, the electrode was immersed in the electrolyte for 12 hr or more unless otherwise noted, and the electrolyte was not stirred during the discharge. During the discharge, the potential was recorded with reference to Hg/HgO electrodes immersed in KOH at the same concentration.

In this experimental arrangement, O_2 may be produced at the counter electrode of graphite. Migration of the O_2 to the manganese dioxide electrode and influence to the current as well as the electrochemical reaction might be considered. This point was examined by calculation as well as experiment. Based on the solubility and diffusion coefficient of oxygen in 9M KOH at 25°C, 3×10^{-5} mole/liter and 5×10^{-6} cm^2 sec^{-1}, respectively (21). The diffusion limiting current was found to be

$$i = \frac{NFDC}{\delta} = \frac{2 \times 10^5 \times 5 \times 10^{-6} \times 3 \times 10^{-8}}{0.05}$$

$$= 0.6 \times 10^{-6} \text{ amp/cm}^2 = 0.6 \ \mu\text{a/cm}^2$$

by assuming $\delta = 0.05$ cm for unstirred aqueous solutions (22). For the graphite rod used in this experiment, therefore the approximate diffusion limiting current is approximately 7μa. This point was also examined by measuring current at the graphite electrode (7.7 cm long) at —0.60v *vs.* Hg/HgO (9M KOH) in 9M KOH saturated with O_2 (1 atm) or N_2. It was found that the current attributable to the dissolved O_2 was less than 3 μa under unstirred conditions. Therefore, the error due to this fact must be very small.

The discharge curves presented in this paper were repeated at least twice, the two curves agreed with each other within 15 mv at any stage of the discharge except at the very end of the discharge curve.

Results

Effect of current density.—Figure 2 shows three discharge curves at three constant current densities; 0.11, 0.33, and 3.0 ma per electrode (apparent area: 10.8 cm^2). The lower abscissa of Fig. 2 shows the amount of electricity in ma-hr and the upper abscissa shows the x value in MnO_x calculated from the electricity drawn. We can see two distinct steps in the discharge curves. In the first step from $MnO_{2.0}$ to $MnO_{1.5}$ the potential decreased continuously and in the second step from $MnO_{1.5}$ to $MnO_{1.0}$ the potential remained practically constant [—0.40v *vs.* Hg/HgO (9M KOH)] for a considerable portion of the discharge period on the 0.11 and 0.33 ma discharges.

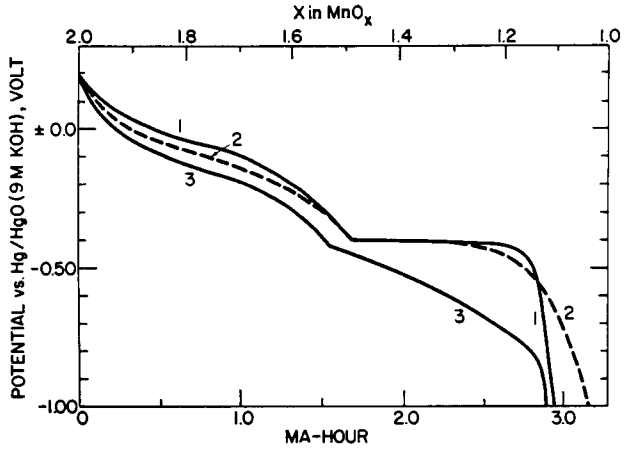

Fig. 2. Discharge curves at constant current in 9M KOH at 23°C. The x value in MnO_2 was calculated from the amount of electricity drawn. Curve 1, at 0.11 ma/electrode; curve 2, at 0.33 ma/electrode; curve 3, at 3.0 ma/electrode.

Table I. Discharge capacities of electrodeposited manganese dioxide in 9M KOH based on the curves shown in Fig. 2. Each graphite rod had 10.6 mg of MnO_2*

Discharge current per electrode, ma	Theoretical discharge time**, hr	Observed discharge time to —1.0v (Fig. 2), hr	Discharge capacity***, %
0.11	30.3	27.0	89.1
0.33	10.1	9.50	94.1
3.0	1.11	0.96	84.4

* Calculated discharge capacity to $Mn(OH)_2$ is 3.33 ma-hr.
** Assuming from MnO_2 to $Mn(OH)_2$.
*** Based on the theoretical discharge time.

Table I shows discharge capacities observed in those discharges (Fig. 2) to —1.0v. The discharge capacity in column 4 of Table I shows values ranging from 84 to 94%. Several additional electrodes prepared and discharged in the same manner as those in curve 2 in Fig. 2 exhibited discharge capacities of 95 ± 3% and the discharge curves were very reproducible.

Effect of KOH concentration.—The effect of KOH concentration was investigated at constant current (3.0 ma) discharge in 0.1, 1.0, and 9M KOH electrolytes. The results are shown in Fig. 3. In these experiments, the potential was measured against Hg/HgO electrodes in 0.1, 1.0, or 9M KOH depending on the electrolyte used in the discharge in order to eliminate the junction potential. We can see in Fig. 3 that the first step ($MnO_{2.0} \rightarrow MnO_{1.5}$) in the discharge is influenced very little by the electrolyte concentration in a range of 0.1-9M, but the second step ($MnO_{1.5} \rightarrow MnO_{1.0}$) is greatly influenced. The second step is essentially absent in 0.1 and 1.0M KOH solutions.

Effect of thickness of MnO_2 layer.—In order to prepare a manganese dioxide electrode which has a thicker MnO_2 layer, a graphite rod 1.5 cm long instead of 7.7 cm long was used for the electrodeposition at the same conditions (20 ma for 10 min at 90°C). The manganese dioxide electrode prepared in this manner had almost the same amount of MnO_2 (10.6 mg) by chemical analysis and therefore should have a MnO_2 layer approximately five times thicker. However, the graphite rod is porous (7) (porosity: 20%) and considerable deposition may have taken place in the pores.

The discharge curves at 3 ma are shown in Fig. 4, which again shows a case where the first step is influenced very little, this time by increasing the MnO_2

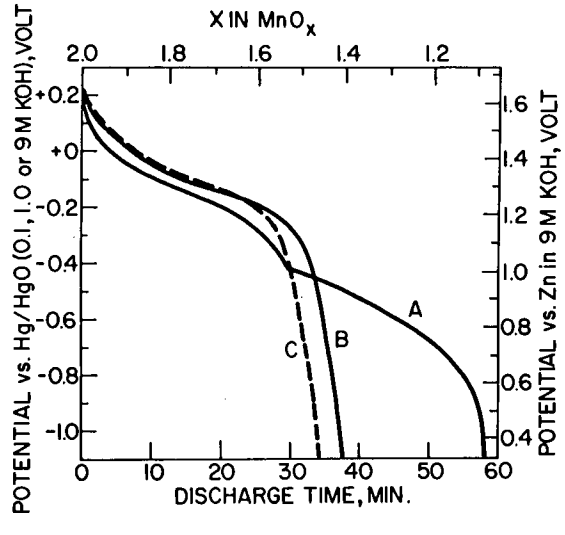

Fig. 3. Effect of KOH concentration on the discharge at a constant current of 3.0 ma. The reference electrodes of Hg/HgO used for discharges in 9, 1 and 0.1M KOH electrolyte were kept in 9 (curve A), 1 (curve B), and 0.1M (curve C), KOH, respectively.

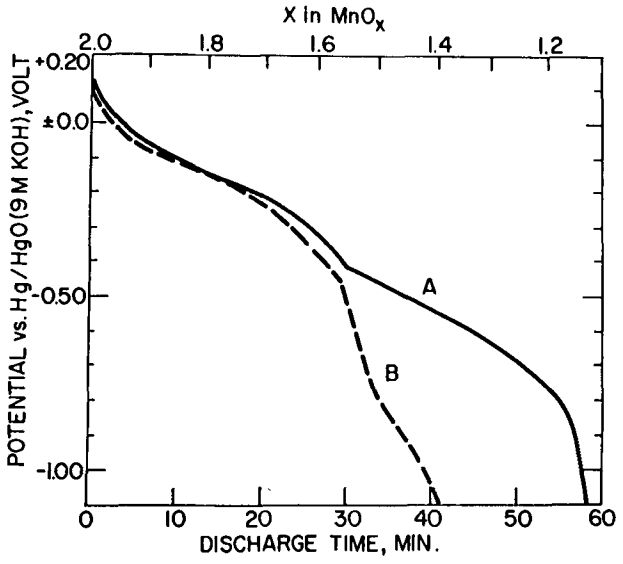

Fig. 4. Effect of thickness of manganese dioxide layer, discharged at a constant current of 3.0 ma in 9M KOH at 23°C. Curve A, MnO_2 on a 7.7 cm graphite rod; curve B, MnO_2 on a 1.5 cm graphite rod.

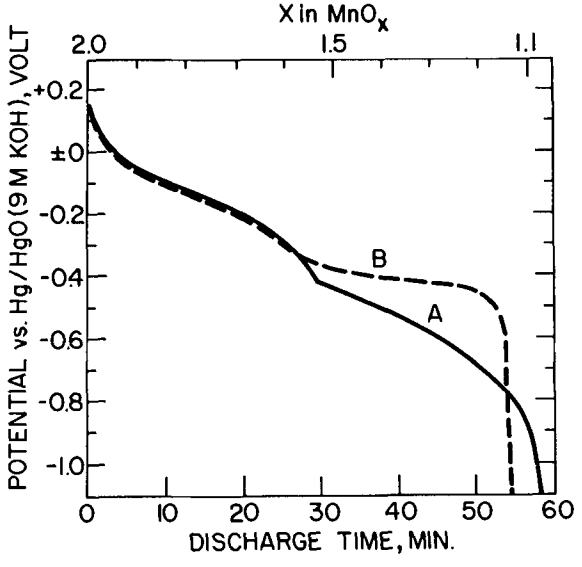

Fig. 5. Effect of triethanolamine (TEA) added to the electrolyte on the discharge at a constant current of 3.0 ma at 23°C. The x in MnO_x was calculated from the amount of electricity drawn. Curve A, 9M KOH; curve B, 9M KOH + 10% (by volume) TEA.

thickness. In the second step, the polarization is much greater with the thicker electrode.

Effect of triethanolamine added to the electrolyte.—Triethanolamine forms stable complexes in alkaline solution with divalent and trivalent metal ions such as Mn^{+++}, Mn^{++}, Fe^{+++}, and Fe^{++} (8, 9). Discharges at a constant current of 3 ma were carried out in 1.0 and 9M KOH solutions containing 10-20% triethanolamine by volume. The results are compared to the discharges in those solutions in which no triethanolamine was added. In these experiments the manganese dioxide electrodes (7.7 cm long) were immersed in the electrolyte for 5 ± 0.5 hr before the discharge. Longer immersion reduced the discharge capacity (20 hr immersion reduced its discharge capacity by about 20%); manganese dioxide was probably slowly reduced by triethanolamine. Figures 5 and 6 show the results. The addition of triethanolamine presents a third instance where the first step of discharge is influenced very little, but the second step

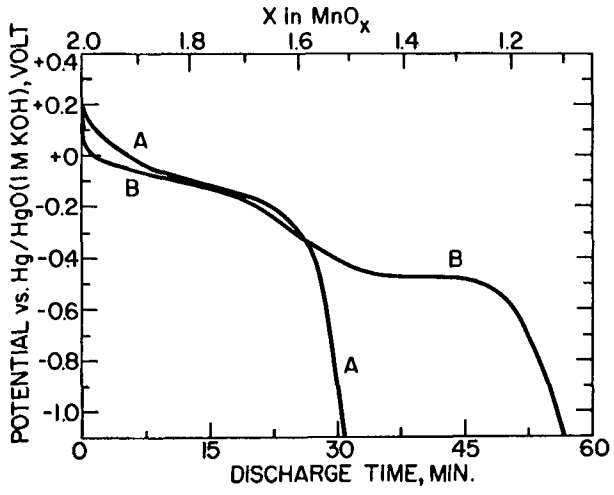

Fig. 6. Effect of triethanolamine (TEA) added to 1M KOH on the discharge at a constant current of 3.0 ma at 23°C. The x in MnO_x was calculated from the amount of electricity drawn. Curve A, 1M KOH; curve B, 1M KOH + 20% (by volume) TEA.

markedly. In the presence of triethanolamine, the second step was kept at a considerably higher and relatively constant potential in 9M KOH as shown in Fig. 5. In 1M KOH containing 10% triethanolamine, the second discharge step can be carried at a relatively high and constant potential, although without triethanolamine the second step did not appear.

Discussion

Discharge curves.—The experimental results obtained above are significantly different from the previously published results by Cahoon and Korver (1) and Bell and Huber (2). This is shown in Fig. 7 in which their results are compared on the same potential scale and also on the basis of x value. The MnO_2 electrodes used in the present investigation could be discharged almost completely to $Mn(OH)_2$ at moderate current densities (11 ~ 33 ma/g of MnO_2), while those used by the other investigators were not. This is probably due to the porous nature of the rod and good contact between the manganese dioxide and graphite, since MnOOH or α-Mn_2O_3 are very poor electronic conductors (10). The three-step reduction curve obtained by Bell and Huber may be due to the extremely slow (low current density) discharge, because under

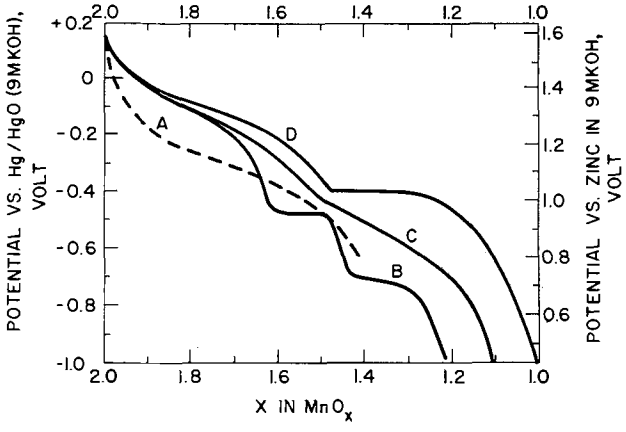

Fig. 7. Comparison of discharge curves of electrolytic manganese dioxide. Curve A, Cahoon and Korver (1), in 7.6M KOH at 30 ohm load continuous discharge (about 60 ma/g of MnO_2); curve B, Bell and Huber (2), in 9.0M KOH at 100 ohm load, 100 hr per week (about 0.5 ma/g of MnO_2); curve C, present work, in 9.0M KOH at 300 ma/g of MnO_2 constant current discharge; curve D, present work, in 9.0M KOH at 11 ~ 33 ma/g of MnO_2 constant current discharge.

such a condition the lower manganese oxide formed in the discharge seems to recrystallize. Bell and Huber cited the fact that the bobbin hardened. Absence of zinc in the present work might be a factor which might make the discharge characteristics different from the others (1, 2).

The present results can be summarized as follows. Generally speaking the discharge curves (the potential-x value in MnO_x relation) consisted of two steps, (*i*) the first step from $MnO_{2.0}$ to $MnO_{1.5}$ where the potential decreased continuously as the x value decreased, and (*ii*) the second step from $MnO_{1.5}$ to $MnO_{1.0}$ where the potential remained almost unchanged at low current densities in KOH electrolytes of high concentration or containing triethanolamine. The first step of the discharge curve was not greatly influenced by the discharge parameters such as current density (11 ~ 300 ma/g of MnO_2), electrolyte concentration (0.1 ~ 9M KOH), and thickness of MnO_2 layer (approximately $2.5 \times 10^{-4} \sim 13 \times 10^{-4}$ cm thick). The second step is greatly dependent on these discharge parameters. The presence of two steps in the reduction and oxidation between MnO_2 and $Mn(OH)_2$ can be substantiated by the charging curves which also clearly show two steps before oxygen evolution on the graphite.

Thermodynamic considerations.—Vetter (11, 12) presented a general thermodynamic theory of the electrode potential of nonstoichiometric conductive metal oxides (or hydroxides). According to this theory, if the system consists of a homogeneous phase, the potential should change in a continuous manner as the oxidation state (x value) changes. Also, according to the theory, if the oxide or hydroxide system consists of two phases (two oxide or hydroxide phases), the potential should remain unchanged as long as the two phases exist in equilibrium. In the first step of the discharge curve from $MnO_{2.0}$ to $MnO_{1.5}$ observed above, the potential decreased continuously. Therefore, this step may be a homogeneous phase discharge. In the second step from $MnO_{1.5}$ to $MnO_{1.0}$ the potential remained constant under certain discharge conditions. Therefore, this process corresponds to a heterogeneous system composed of $MnO_{1.5}$ phase and $MnO_{1.0}$ phase.

Reduction mechanism.—Although thermodynamic considerations provide an interpretation of the two discharge steps as a homogeneous phase reduction followed by a reduction process involving two oxides (or hydroxides), it cannot give or suggest any detailed mechanism. Further discussion of the mechanism for the two steps is necessary.

The first step.—For the first step from $MnO_{2.0}$ to $MnO_{1.5}$ the authors tentatively postulate an electron-proton mechanism; namely, in the discharge, electrons and protons are introduced into the γ-MnO_2 lattice and form α-MnOOH.

$$MnO_2 + H^+ + e^- \rightarrow MnOOH$$

or

$$MnO_2 + H_2O + e^+ \rightarrow MnOOH + OH^-$$

This electron-proton mechanism has been proposed and investigated by Coleman (13), Vosburgh and his co-workers (14, 15), and Scott (16) but not completely proved experimentally. The experimental results presented in this paper substantiate this mechanism. The first step is not greatly influenced by the various discharge parameters investigated such as current density, KOH concentration, MnO_2 thickness, and also addition of triethanolamine to the electrolyte. If formation of lower oxides (or hydroxides) such as $Mn(OH)_2$ at the MnO_2 solution interface in the first step and then subsequent diffusion of such a lower oxide into the MnO_2 were the actual processes, addition of triethanolamine should have an appreciable effect. Any lower oxide formed on MnO_2 surface does not diffuse into the MnO_2 at an appreciable rate (17) and probably accumulates on the surface to some extent. The electron-proton mechanism can be supported by x-ray evidence presented by Brenet (18) and Bell and Huber (2). Bell and Huber found by x-ray that the α-MnOOH structure developed as the discharge proceeded during the first step. The lattice dilation during this discharge step was observed first by Brenet (18) and confirmed by Bell and Huber (2). If the lower oxide is formed on the MnO_2 surface, the x-ray analysis should show the new diffraction lines of the lower oxide rather than the lattice dilation.

The second step.—In order to explain the flat discharge curve of the second step the author proposes here a new mechanism which is based on the appreciable solubility of Mn(II) and Mn(III) in concentrated KOH electrolyte.

The solubilities of Mn(II) and Mn(III) [or $Mn(OH)_2$ and $Mn(OH)_3$] are very small (about 4×10^{-5}M) in neutral or the usual alkaline solutions (*e.g.*, 1M) (19), but the solubility increases rapidly with increasing KOH or NaOH concentration, because of the formation of OH^- coordinated species, $[Mn(OH)_6]^{\equiv}$ and $[Mn(OH)_6]^{\equiv}$ (20). The solubility of Mn(II) and Mn(III) in 9M KOH was found to be about 0.5×10^{-3}M and 4×10^{-3}M, respectively, by a polarographic method.

In the second step in the discharge, two solid phases coexisting in equilibrium must be involved as concluded above from the thermodynamic considerations. Let us assume tentatively that α-MnOOH and $Mn(OH)_2$ are the two phases and also assume that these solid phases are in solubility equilibrium with the dissolved Mn(III) and Mn(II) species, respectively. The potential of such a system can be determined mainly by the dissolved species at an inert electrode such as graphite by the following Nernst equation

$$E = E^0 - \frac{RT}{F} \ln \frac{a_{Mn(II)}}{a_{Mn(III)}} \qquad [1]$$

which corresponds to the electrode reaction, $Mn(III) + e^- \rightleftarrows Mn(II)$. The concentrations of dissolved Mn(II) and Mn(III) are equal to their solubility values as long as the two solid phases exist. Therefore, the ratio $a_{Mn(II)}/a_{Mn(III)}$ in the above equation must be a fixed value, and consequently the potential will remain constant during the discharge at a small current density, because in such a condition the solubility equilibria (Eq. [2] and [4]) are not disturbed appreciably. In other words, we can understand the flat discharge curve if reactions [2] and [4], dissolution of α-MnOOH and precipitation of $Mn(OH)_2$, are fast or at least at a rate comparable to that of the electrochemical reduction, reaction [3].

$$\alpha\text{-MnOOH (solid)} \leftrightarrows Mn(III) \text{ (in solution)} \qquad [2]$$

$$Mn(III) + e^- \rightarrow Mn(II) \text{ (electrochemical reduction)} \qquad [3]$$

$$Mn(II) \text{ (in solution)} \leftrightarrows Mn(OH)_2 \text{ (solid)} \qquad [4]$$

One experimental approach to test the above mechanism is to compare how the potential of the flat discharge portion (Fig. 2) agrees with the potential of the Mn(II)-Mn(III) system in 9M KOH. Polarograms were taken in 9M KOH containing Mn(II) and/or Mn(III) in order to obtain the approximate standard potential of the Mn(II)-Mn(III) system in 9M KOH. Figure 8 shows the results in which we can see that the half-wave potential for the anodic process ($E\frac{1}{2} = -0.290$v) and that of the cathodic process ($E\frac{1}{2} = -0.500$v) are somewhat apart, but the mean values of −0.395v can be taken as the approximate standard potential, because the polarographic reversibility of these processes seems approximately the same from the shape of the polarograms. The potential of the flat discharge portion in Fig. 2 was −0.40v and is in good agreement with this polarographic value −0.395v. In the above comparison, the observed potential in

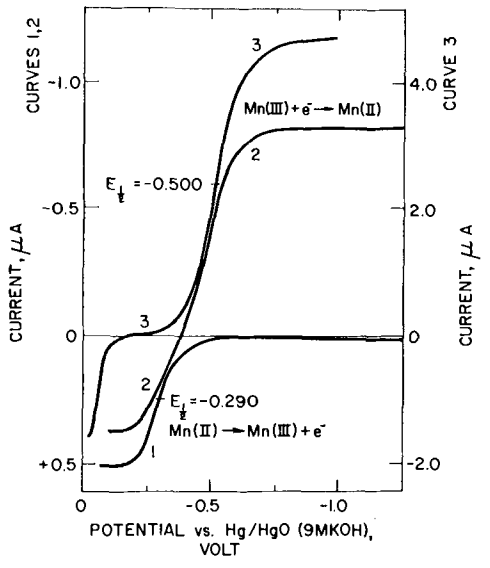

Fig. 8. Polarograms of Mn(II) and Mn(III) in 9M KOH. The curves were corrected for residual current. Polarograms were taken in N_2 saturated 9M KOH at a dropping mercury electrode (m = 1.54 mg/sec, t = 5.4 sec at open circuit in 9M KOH). Curve 1, Approximately 0.5 x 10^{-3}M $MnSO_4$ in 9M KOH, some $Mn(OH)_2$ suspended in solution; curve 2, same as 1, but some of the Mn(II) was oxidized to Mn(III) by passing O_2 gas; curve 3, approximately 2 x 10^{-3}M Mn(III) in 9M KOH. Mn(II) in 9M KOH was completely oxidized to Mn(III) by passing oxygen. Some of the Mn(III) was further oxidized to MnO_2 which was suspended in the solution.

the flat discharge curve was compared directly with the polarographic E° value. This means the logarithmic term, in the Eq. [1] was neglected. This can be justified if we realize that the ratio of the solubility values for Mn(III) and Mn(II) in 9M KOH is about 8 and the second term does not contribute more than 60 mv.

Another test of the above described mechanism is whether the α-MnOOH formed electrochemically by the reduction of γ-MnO_2 can dissolve in 9M KOH or not. During the discharge shown in Fig. 2 a reddish-violet color was observed when the electrode was wrapped with a filter paper. This is evidence that the electrochemically formed trivalent oxide can dissolve in 9M KOH, since manganous ion dissolved in 9M KOH has almost no color.

As mentioned previously the graphite rod on which manganese dioxide was electrodeposited is porous; therefore, a good portion of the manganese dioxide may be deposited on the inner walls of the pores. However, a still larger portion of the bare graphite surface on which no manganese dioxide is deposited must exist, particularly inside the pores. The manganese dioxide may be reduced by the electron-proton addition until the entire phase becomes α-MnOOH. Then further reduction takes place on the bare graphite surface through the dissolved Mn(III), according to the mechanism presented above.

The mechanism described above can explain the discharge behavior in various KOH concentrations and with addition of triethanolamine to the electrolyte, as follows: At low KOH concentrations (0.1 ~ 1M), the solubilities of Mn(II) and Mn(III) are very low; therefore, the concentration of dissolved Mn(III) cannot support the current (Fig. 3). On addition of triethanolamine, the Mn(III) complex forms. This complex is much more soluble and is reversibly reduced to the Mn(II) complex even in 0.5M NaOH (8, 9). Therefore, the discharge can proceed smoothly even in 1M KOH (Fig. 6) and also a much flatter discharge curve can be obtained as shown in Fig. 5.

Effect of Carbon and Oxygen in Iron on Stress Corrosion Cracking in Nitrate Solution

L. M. Long and H. H. Uhlig

Corrosion Laboratory, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

It was established previously that nitrogen or carbon in iron is necessary for susceptibility to stress corrosion cracking in boiling aqueous 60% $Ca(NO_3)_2$-3% NH_4NO_3. Present measurements show that oxygen in Fe at a concentration as high as 0.07% does not induce similar susceptibility. Pure iron-carbon alloys containing 0.001% N or less are susceptible as quenched from 925°C if they contain more than about 0.002% C. Below this carbon content they are resistant. However, resistant alloys become susceptible when heated subsequently for 3 hr at 550°C, including zone-refined iron containing <0.001% C and <0.0003% N. Only "floating" zone-refined iron of still higher purity is immune as quenched or when heated at 550°C. These results are interpreted in terms of crack-sensitive paths consisting of interstitial atoms associated with imperfections of the grain boundaries. Quenched-in imperfections within grains transport interstitial atoms to grain boundaries which induce susceptibility of an otherwise resistant iron.

Iron or steel stressed in tension and exposed specifically to hot aqueous solutions containing nitrate or hydroxyl ions may crack rapidly along intergranular paths. This type of failure is called stress corrosion cracking (s.c.c.). Uhlig and Sava (1) showed that interstitial carbon or nitrogen in iron is necessary for susceptibility to s.c.c. in boiling nitrate solutions and, presumably, in alkaline solutions as well, in which the mechanism of failure is thought to be similar (2). By reducing both the carbon and nitrogen contents to 0.001% or less, they found iron became essentially immune when either water-quenched from 925°C or cold-rolled to 70-85% reduction in thickness.

For higher C or N contents, the degree of susceptibility was sensitive to heat-treatment. For example, a commercial mild steel (0.06% C, 0.001% N), as quenched, cracked within less than 2 hr. Essential immunity, defined arbitrarily as resistance to cracking for 200 or more hours, was observed for mild steel first quenched from 925°C, then heat-treated at 250°-300°C for ½ hr. The steel became susceptible again if heated at higher temperatures, *e.g.*, 3 hr at 550°C or ½ hr at 700°C, and remained susceptible after long-time heat-treatment, *e.g.*, 3 weeks at 600° or 700°C.

These results were interpreted in terms of crack-sensitive paths formed by interstitial C or N atoms (or transition phase carbides and nitrides) along grain boundaries. Quenching of mild steel from the austenite region produces crack-sensitive paths, but subsequent heat-treatment at 250°-650°C for ½ hr results in resistance to s.c.c. because carbides or nitrides are precipitated which deplete grain boundaries of C or N atoms. Longer heat-treatment, *e.g.*, 3 hr at 550°C, again induces susceptibility because the imperfection structures of grain and grain boundary are altered from arrays characteristic of the material as quenched from 925°C, to arrays characteristic of lower temperatures, *e.g.*, 550°C. In other words, quenched-in imperfections tend at, *e.g.*, 550°C, to migrate from grains to grain boundaries, taking C or N atoms with them. Hence interstitial atoms reverse direction of diffusion at temperatures in the order of 450°-690°C, again entering the grain boundaries from which they originated in concentration sufficient to reinduce susceptibility to cracking. The diffusion of imperfections is slower on the whole than diffusion of interstitial atoms away from or toward grain boundaries, hence, within the intermediate temperature range, immunity precedes ultimate susceptibility.

The observed activation energy is about the same for interstitial atoms diffusing either way, the value for carbon lying within 35-40 kcal. For C atoms migrating toward the grains, the activation energy presumably corresponds to the energy required to dissociate carbon atom-imperfection atmospheres at the grain boundaries of quenched steel. Similarly for diffusion in the reverse direction, the observed value is presumably the energy required to dissociate iron carbides into interstitial carbon and ferrite (or dissociate carbon-imperfection atmospheres at the carbide-ferrite interface). The activation energies for nitrogen steel are somewhat higher, namely, 48 kcal, otherwise the qualitative conditions leading to immunity or susceptibility are similar to those for carbon steels.

It was stated in the earlier paper (1) that the critical minimum concentration of C in iron necessary for s.c.c. appears to be equivalent to the solubility of C in ferrite at 200°-350°C and for nitrogen at 150°-250°C. This was an educated guess based on the information that a quenched mild steel containing 0.06% C becomes immune within about 20 hr on heating at 200°C (¼ hr at 250°C) [Fig. 5, ref. (1)], during which time the carbon associated with grain boundaries is precipitated as carbide particles. By the same token, extrapolation to the time required to reinduce susceptibility to s.c.c. at 200°C [Fig. 7, ref. (1)] is 2900 years (71 years at 250°C). Hence any steel containing less carbon than its solubility in ferrite at 200°C, if immune as quenched, would not be expected to become susceptible if heated for long times at 200°C. It would also not become susceptible at any other temperature of heat-treatment provided crack-sensitive paths depended on a minimum interstitial concentration of carbon established by the solubility of cementite in ferrite at the given temperature. The latter supposition turned out to be not entirely correct, as data presented later show.

Heating a susceptible quenched mild steel (0.06% C) for ½ hr at temperatures up to 690°C, but not above, resulted in immunity presumably because, within the time necessary to reach the upper temperature, rapid precipitation of carbides occurs at intermediate temperatures, depleting grain boundaries of C atoms. Heating for only ½ hr at 690°C does not suffice to alter effectively the imperfection structure of the metal followed by dissociation of precipitated carbides and induced susceptibility; however, heating ½ hr at 700°C succeeds in this respect.

It could also have been assumed, of course, that rate of solution of carbides in ferrite is relatively rapid and that the critical concentration of C in ferrite for susceptibility is close to its solubility at the Ac_1 temperature. Hence heating of quenched mild steel for

½ hr at 690°C would precipitate carbides which lower the carbon content of ferrite below the supposed critical concentration needed for susceptibility. On the other hand, following the same reasoning, when the steel is heated to 700°C, even though carbides may precipitate, enough carbon remains in solution to account for susceptibility. The argument against this process, other than the high solubility of C in ferrite at 690°C (0.02%) (3), is that long time heating at a lower temperature, *e.g.*, 600°C, also produces a susceptible steel which remains susceptible, hence the solubility of C in ferrite at this temperature also suffices to produce crack-sensitive grain boundaries. Any critical concentration of C, therefore, certainly lies below the solubility of carbon in ferrite at 600°C. By the same reasoning it also lies below the value at 550°C at which temperature 3 hr are required to induce susceptibility and, similarly, below 443°C requiring 70 hr. The question remains as to just how far below 443°C the solubility of carbon in ferrite becomes too low for susceptibility to occur within any reasonable time of heat-treatment.

Parkins (4) reported that iron containing less than 0.02% C is immune to s.c.c. in nitrate solution, but Logan (5) reported cracking of iron containing only 0.01% C. Uhlig and Sava (1) reported cracking of a steel containing still less carbon, *i.e.*, 0.001% C, but which steel also contained 0.043% N. It was considered worthwhile checking the minimum concentration of carbon required for susceptibility, taking into account the important factor of heat-treatment and maintaining, at the same time, a low nitrogen content which otherwise also induces susceptibility. Information of this kind is useful to a further understanding of the mechanism of stress corrosion cracking.

Experimental

Pure iron-carbon alloys were produced in the range 0.001-0.03% C. The basis iron was electrolytic grade decarburized to 0.001% C by passing wet H_2 over it for several hours at 760°C. The melt was contained in a crucible of pure dense alumina; carbon additions were made in a vacuum furnace via a 4% carbon master alloy prepared from electrolytic iron and spectroscopically pure graphite. After the iron was melted, helium purified over titanium at 800°C and previously passed through a liquid N_2 trap was allowed to enter the furnace. Castings were then prepared by drawing the melt into 7 mm diameter Vycor tubing followed by water quenching. The castings were encapsulated in evacuated Vycor tubes and homogenized at 1050°C for 15 hr followed by furnace cooling. They were then cold rolled to 0.102 cm (0.040 in.) strip and sheared to specimens measuring 4.45 x 0.48 cm (1-3/4 x 3/16 in.). These were then heated briefly to 925°C in quartz tubes containing an argon atmosphere and water quenched. Some specimens thereafter were heat-treated at lower temperatures in a molten metal bath, the temperature of which was controlled automatically. Specimens were air cooled on removal from the metal bath. Before testing, all specimens were pickled for 4 min in 5 vol. % concentrated commercial HCl at 95°C.

For the s.c.c. tests, specimens were bent beyond the elastic limit to a span of 3.65 cm (1-7/16 in.) and held to this dimension by means of a compression spring. They were totally immersed in boiling 60% calcium nitrate, 3% ammonium nitrate solution employing apparatus described by Uhlig and Sava (1). Failure time was recorded by an electric clock. Variations of the span and corresponding change in flow stress were not found to be critical for specimens essentially immune to stress corrosion cracking. For example, specimens containing 0.0016% C, 0.001% N, bent to a normal span of 3.65 cm (1-7/16 in.) did not fail within 200 hr; they also did not fail within the same test period when bent to a span shorter by 0.65 cm (¼ in.), *i.e.*, to a final span of 3.0 cm (1-3/16 in.).

Table I. Lack of effect of oxygen on stress corrosion cracking of iron

% Oxygen in iron	% C	% N	Cracking time, hr
0.012	0.002	0.002	>200 (2 spec.)
0.066	0.001	0.002	>200 (2 spec.)

Suspected effect of oxygen.—Although it was established that C or N in Fe is necessary for occurrence of stress corrosion cracking, a possible contributing effect of oxygen in Fe also required investigation since oxygen is always present to some extent. It was especially difficult to arrive at a conclusion from analyses of melts already prepared and tested because of the unavoidable experimental variations inherent to all stress corrosion cracking tests, and also because significant amounts of C, N, and O in Fe were at the extreme limits of analytical accuracy. Special melts of iron were prepared, therefore, low in C and N, but relatively high in oxygen. Melts were prepared in vacuum as before; but prior to casting, instead of filling the furnace with the customary purified helium, a mixture of 4 parts He to 1 part O_2 was introduced at a flow rate of 5 liter/min. The He as before was freed of N_2 by passing over hot titanium. In this way, 7 mm diameter castings were obtained which varied in oxygen content, depending on length of contact of melt with the He-O_2 atmosphere, from 0.01 to 0.07% oxygen. These alloys were homogenized, cold rolled to 0.102 cm (0.04 in.), quenched from 925°C, and tested as usual in the boiling nitrate solution. Results summarized in Table I show that oxygen-iron alloys are not susceptible to s.c.c.

Quenched and heat-treated carbon-iron alloys.—Iron specimens as prepared with variable but low C content contained in the order of 0.001% N which marked the limit of usual analytical accuracy for this element. All specimens as quenched from 925°C cracked within 0.6-3 hr except those containing about 0.002% or less carbon. The latter specimens resisted cracking for 70 to 200 or more hours, indicating greater resistance or essential immunity. Data are plotted in Fig. 1.

However, when immune specimens containing 0.002% C or less were heated at 550°C for 3 hr, corresponding to conditions necessary to reinduce sus-

* Determined by internal friction. Upper value for carbon is by combustion-conductometric, and for nitrogen by vacuum fusion. The latter values are higher probably because of interstitial atoms associated with imperfections of grains and grain boundaries which do not contribute to internal friction. (Analysis by W. Rengstorff, Battelle Memorial Institute, 2nd Special Report on Analysis of High Purity Iron to Am. Iron and Steel Inst., July 11, 1963).

ceptibility of quenched mild steel, they all failed within a short time. When, in fact, zone refined iron was examined containing <0.001% C, <0.0003% N which Uhlig and Sava found to be immune as quenched, such specimens also failed on heating at 550°C for 3 hr. Failure time was as short as 1 hr. This result was at first questioned by us on the ground that failure occurred because of possible contamination of the specimens during heat-treatment. For this reason several zone-refined iron specimens were encapsulated in evacuated fused pure quartz tubes so as to minimize contamination that may have resulted from impurities in Vycor both during the quenching and heat-treatment schedules. These specimens, however, also failed by s.c.c. Quenched specimens heated at 550°C for 3 hr, then quenched from 925°C were again immune (Table II) indicating that susceptibility was not caused by contamination through heat-treatment.

The question remained, therefore, whether the very low C and N contents of zone-refined iron were actually high enough to induce the observed cracking. This matter was resolved by obtaining a further sample of pure iron of the so-called "floating" zone-refined quality prepared at Battelle Memorial Institute. This iron was purer than the zone-refined iron first used, as was determined at Battelle by sensitive analytical methods including internal friction measurements. After fabrication and pickling, the purer material was encapsulated in evacuated fused quartz tubes and quenched from 925°C, or heat treated at 550°C for 3 hr. Unlike the first zone-refined iron, specimens of the second material did not crack within 200 hr or more, either as quenched or as heat-treated at 550°C (Table II).

Hence, it can be concluded in accord with earlier conjecture that pure iron is essentially immune to s.c.c. The present results also indicate that the critical carbon content for susceptibility of heat-treated iron lies below 0.001%, which is well under the sensitivity of usual analytical methods for quantitative determinations. For iron quenched from 925°C, the critical carbon content is about 0.002%. The latter value is probably influenced by an unknown small concentration of nitrogen also present.

Discussion

The trace amounts of C in Fe needed for s.c.c. support the suggestion made by Uhlig and Sava that probably only C atoms associated with imperfections of the grain boundary are needed to form crack-sensitive paths, rather than alignment of precipitated carbides along the grain boundaries as had been proposed by other investigators. The present results also suggest that s.c.c. in ammonium nitrate solution of recrystallized iron whiskers after heating above 910°C, reported by Flis *et al.* (6) is caused by impurities in the whiskers instead of by differences, as they suggest, in free energy of iron atoms at grain boundaries and in grains. The partition of C atoms between both interstitial sites and imperfection sites within the grains, and imperfection sites of the grain boundaries corresponding to a 925°C quench, requires an over-all approximate 0.002% C in order to provide crack-sensitive grain boundaries. On the other hand, the over-all required carbon content is much less on heating iron at a lower temperature, *e.g.*, 550°C, presumably because quenched-in imperfections within the grains move at this temperature to grain boundaries accompanied by C or N atoms with which they are associated. The result of such heat-treatment is a final higher concentration of C or N at grain boundaries sufficient to induce susceptibility to s.c.c. Only if the over-all C or N content is extremely low, corresponding to floating zone-refined quality, does iron remain immune after heating in the order of 550°C. The actual lower limit of carbon concentration corresponding to immunity is not readily defined, both because of obvious analytical difficulties and also because the mechanism of sensitization implies that grain size should also be a factor. A large grain size iron with small grain boundary surface would become sensitive at a lower C and N content than would a small grain size iron of larger grain boundary surface. Probably a monolayer or less of C or N atoms along grain boundaries suffices to induce susceptibility. For example, 1 cm^3 of iron containing 1 mm diameter grains would contain about 30 cm^2 of grain boundary surface. Carbon atoms 0.77Å in radius lined up at grain boundaries as close-packed monolayers would account for a carbon content of 0.4 ppm not including C atoms contained within the grains. This value increases appreciably as grain size decreases. Less than a monolayer would perhaps suffice for susceptibility if C and N atoms were available from adjoining regions of the metal by rapid diffusion to the apex of the growing crack, diffusion being aided by plastic deformation accompanying crack growth.

The function of C and N atoms at grain boundaries, as described earlier (1), is supposedly to extend life of emerging surface imperfections of iron during plastic deformation at the tip of the crack sufficient to allow chemisorption of NO_3^- ions (or the reaction product of Fe with NO_3^-) on the imperfection arrays. If the mechanism of crack growth is basically one of surface energy reduction (stress sorption cracking), which has been suggested as a plausible mechanism (7, 8), the reduction is brought about by chemisorption of NO_3^- ions or their reaction products. Chemisorption of this kind substantially reduces affinity of adjoining Fe atoms at the tip of the growing crack, allowing Fe atoms under stress to separate and form a fissure by a mechanism similar to that causing cracking of tensionally stressed metals by specific liquid metals, *e.g.*, brass by mercury. In absence of specific anions which chemisorb, or in absence of surface imperfections of reasonable half-life on which chemisorption can occur, s.c.c. is not observed. Electrochemical action may be required indirectly to form the reaction product which chemisorbs; marked specificity of the anion probably rules out crack growth by direct electrochemical dissolution of disarrayed metal atoms. The marked differences between various anions in causing or not causing cracking are far greater than can be accounted

for on the basis of the parallel, relatively smaller differences they exert on anodic polarization or on film forming characteristics. Similarly, specificity of anion and the fact that pure metals do not fail by stress corrosion cracking make less likely the proposed mechanism of Hoar *et al.* (9) supposedly accounting for rapid electrochemical dissolution of metal at the tip of a crack because the metal undergoing active strain dissolves anodically at appreciably lower overvoltage than does unstrained metal. General incidence of s.c.c. of all metals would probably be much more pronounced were this mechanism to apply. The increase observed by Hoar *et al.* of anodic current at constant potential as a metal is strained may be a function only of the greater surface area produced by numerous cracks, as indeed is not unexpected, since the large increase of current they measured occurs specifically in environments which otherwise induce s.c.c.

The very small amount of C or N in Fe necessary for susceptibility to s.c.c. suggests that a convenient criterion of purity is to subject a stressed specimen of Fe previously heated at about 550°C to boiling nitrate solution. Large grain size Fe would be particularly sensitive to trace amounts of both C and N. Although it was established that oxygen is less effective than C or N in causing susceptibility, it is not known at present to what extent other impurities in iron such as P or S may also contribute.

The Short Time, High Temperature Oxidation of Cobalt

A. R. Reti

Dynatech Corporation, Cambridge, Massachusetts

ABSTRACT

Cobalt was oxidized at 1000°C in 0.5-4.0 atm O_2 over periods of 0.005-100 sec. The reaction rates observed in the 10-100 sec range are of the order of magnitude predicted from long time oxidation studies, checking within 50% with the parabolic constants measured by Carter and Richardson and Bridges *et al.* The reaction rates observed in the initial 0.01-10 sec of oxidation are considerably slower, indicating that cation vacancy diffusion through the CoO layer is no longer the main rate-limiting step. These short-time reaction rates were found to be strongly influenced by the surrounding O_2 partial pressure.

An extensive review of the literature for the oxidation of cobalt metal is presented by Kubaschewski and Hopkins (1). In the oxygen pressure-temperature region where only the cobaltous oxide, CoO, phase is stable, the oxidation mechanism has been explained successfully by considering a model where cation vacancy diffusion through the forming cobaltous oxide layer is the rate-limiting step for the oxidation process (2-4). The experimental oxidation rates measured for all these studies correspond to oxidation times ranging from 1 min to 60 hr, the most recent measurements (3, 4) being performed for oxidation times of 45 min to 31 hr. The corresponding oxide layer thicknesses for such experiments are of the order of 10^{-2} cm. At the initial stages of oxidation, however, the oxide layer is so thin that processes other than cation vacancy diffusion through the oxide scale may control the reaction rate.

Furthermore, for very thin oxide layers, the assumption of a uniform, parallel, and coherent oxide layer may not truly represent the geometry of the system. Because of the total lack of experimental data for the initial oxidation rates of cobalt metal at high temperatures, this investigation was undertaken in order to discover at which point, if any, the parabolic oxidation law breaks down, as well as to understand the nature of any other rate-limiting processes which may exist. The focus of this study was upon the reaction rate over the first 0.005-100 sec of reaction.

Experimental

Apparatus.—The rate of oxidation of cobalt metal was measured by following the oxygen pressure decrease within a closed container of known volume when the metal and oxygen, both at the initial reaction temperature, were suddenly brought into mutual contact. A diagram of the system used is shown in Fig. 1. The reactant cobalt metal was sealed within a Vycor vial under a vacuum of the order of 100μ Hg, and pretreated in any desired fashion. The sealed vial was placed within the pressure container, which was sealed and placed in a furnace where it was brought to the initial reaction temperature. The pressure container was then evacuated and filled with oxygen gas to the desired pressure. After thermal equilibrium was attained, the Vycor vial was broken by means of a rod which slides through a sliding seal, and the reaction rate was followed by recording a signal from a pres-

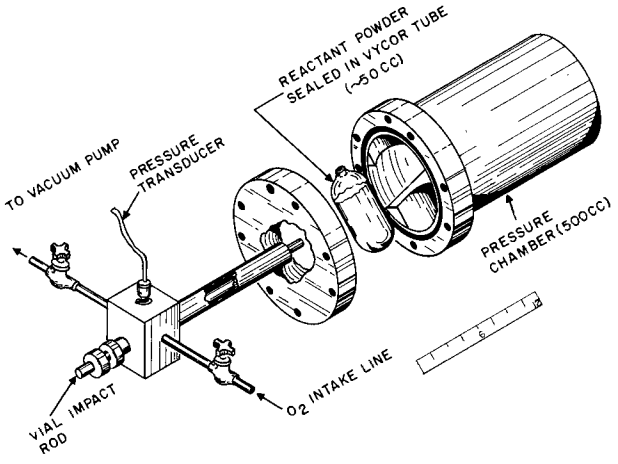

Fig. 1. Experimental apparatus

sure transducer. The entire assembly of the pressure vessel is contained within the furnace except for the end of the extension tube which contains the pressure transducer, the oxygen and vacuum lines, and the end of the vial impact rod. This assembly is maintained at room temperature by use of cooling coils. The pressure transducer used was a Dynisco strain gage transducer with a response time constant of approximately 1 msec, and the electrical signal from the transducer was recorded by a Minneapolis Honeywell Light Beam Oscillograph equipped with a high-frequency response (350 cps) galvanometer or by an Offner Dynograph high-speed recorder (125 cps frequency response). This apparatus provided a means of measuring very rapid pressure changes, and calibration runs involving empty vials indicated that time lags in the apparatus introduced no appreciable error in the reaction rates which were measured.

Oxidation runs were performed at an initial sample temperature of 1000°C under oxygen pressures varying within 0.5 and 4.0 atm.

Materials.—Two types of cobalt metal were used. For the very short time oxidation rate measurements (0.005-0.1 sec), a spectrographic grade cobalt sponge, supplied by the Johnson, Mathey & Company, Limited, was employed. This material had the following certified analysis

Element	Estimated quantity present, %
Silicon	0.0003
Aluminum	0.0001
Copper	0.0001
Iron	0.0001
Calcium, Magnesium, Silver	Each element less than 0.0001

For the longer time (0.1-100 sec) oxidation rate measurements, larger prime particle size material was necessary and had to be used in larger amounts, precluding the use of the spectrographic grade material. Purified cobalt shot, item CB 308, supplied by the Matheson Coleman & Bell Division of the Matheson Company, was employed. A typical analysis of such a material is the following:

Element	Quantity present, %
Co	99.52
Cu	0.009
Ni	0.17
Fe	0.11
S	0.006
P	0.002
C	0.010
Zn and Cd	0.008
Si	0.006
Al	0.034
Mn	0.005
Pb	0.001
H_2	0.00054

Sample preparation.—In order to prevent gas phase diffusion effects from becoming significant, the reactant material configuration must be such that all of its surface is readily accessible to the oxygen gas even at the highest possible reaction rates. Since the finely divided cobalt metal sinters appreciably at 1000°C, if the cobalt sponge were loaded directly into the vial and heated, it would result in a sintered, porous mass of the shape and dimensions of the vial. Oxidation experiments with such a material indicated that only an outside layer, a few millimeters thick, reacted over the initial stages of oxidation. The sample preparation procedure adopted consisted in presintering the cobalt sponge powder for 2.0 hr at 1000°C in an evacuated and sealed Vycor vial, after which the resulting porous sintered body was broken up into porous particles of diameters ranging between 0.5 and 1.0 mm. Such particles were reloaded into a Vycor vial, which was evacuated and sealed. B.E.T. nitrogen adsorption measurements performed on the material prior to heat-treatment, after heating at 1000°C for 2 hr, and after heating at 1000°C for 2 hr and undergoing the heat-up cycle prior to undergoing reaction, indicate that most of the sintering took place during the initial heat-treatment (the surface area decreased from 0.43 to 0.14 m^2/g), with negligible surface area changes occurring during the shorter heat-up period. This later value was used in calculating the cobalt oxidation rate per square centimeter of cobalt surface. Figure 2 shows the appearance of a porous cobalt metal particle cross section after heat-treatment. The average prime particle size, of the order of 10μ, checks well with the measured B.E.T. surface area. The B.E.T. surface measurements, checked against glass spheres (0.24 m^2/g) of known dimensions, were found to be accurate within ±5% in this range. It was found that these particles oxidized uniformly throughout and did not sinter appreciable to each other, leaving sufficiently open path for oxygen to flow into the particle envelope areas and into the internal areas.

For the longer time oxidation experiments, solid cobalt shot, 1-2 mm in diameter was used. The shot was cleaned from surface oxide by surface polishing in an inert atmosphere, after which it was charged into the vial, evacuated, sealed, and annealed at 1000°C for 2 hr. Figure 3 is a photomicrograph of a partially reacted shot, polished and etched in acetic acid, with an oxide layer (darker area) about 15μ thick. The metal grain size, of the order of 10-30μ, can be seen readily. The outside envelope area was used for all reaction rate calculations, as in ref. (3) and (4), neglecting the extent of surface roughness. This procedure is quite valid for oxide layer thicknesses of 1μ or more, where the effects of initial surface roughness will be negligible, but there may be an effect when dealing with smaller oxide thicknesses. The presintering of the pellets at 1000°C should minimize the surface roughness.

Results

Results for the longer time oxidation tests at 1000°C and 0.5-1.0 atm O_2 are summarized in Fig. 4. The oxida-

tion is essentially parabolic, with a reaction rate constant of 1.46 x 10^{-8} g^2 cm^{-4} sec^{-1}, as compared with the 2.43 x 10^{-8} value obtained by Carter and Richardson (3) and Bridges *et al.* (4). The agreement in the reaction rate constant is quite good considering that the oxidation times studied are 30-3000 times shorter, and remembering that the 0.1% Fe impurity level in the samples used for this series of tests may have an appreciable effect on the vacancy concentration and thus on the reaction rate constant (8). A typical oxide layer formed in these tests is shown in Fig. 3. The oxide-metal interface is by no means completely smooth, and there is definite evidence of preferential attack at the grain boundaries. There is a definite indication that the reaction rates are lower at oxidation times shorter than 4 sec (oxide layer thicknesses smaller than 10,000Å), showing the desirability for even shorter time oxidation data.

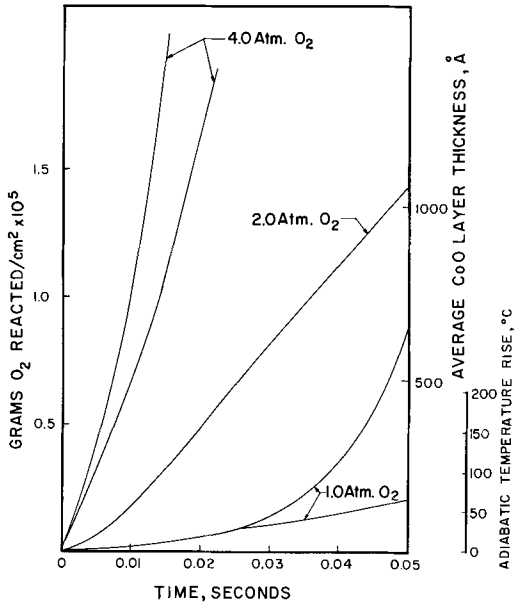

Fig. 5. Oxidation of cobalt sponge at 1000°C; initial sample temperature.

The results of the extremely short time oxidation rate measurements performed on the spectrographic grade cobalt sponge particles are shown in Fig. 5. The initial reaction temperature was 1000°C, and runs were performed at 1.0, 2.0, and 4.0 atm oxygen pressure. These initial reaction rates are highly pressure dependent, and the amount reacted after 25 msec reaction time at 1.0 atm O_2 pressure (1.0 x 10^{-6}g O_2/cm^2) is twenty-five times smaller than the amount that would be predicted from extrapolation of the parabolic reaction rate equation, $\Delta W^2 = K_G t$, obtained from the longer time oxidation studies of Carter and Richardson (3) and Bridges *et al.* (4). A summary of the reaction rate data obtained by other authors and in the present study is presented in Table I.

For the very short time oxidation measurements performed in this study, only the initial stages of the oxidation (up to 2 x 10^{-6}g O_2/cm^2 reacted) have quantitative significance. Such a rapid reaction in the short times considered takes place in an essentially adiabatic system. For this reason, the reactant materials rise rapidly in temperature as they react, since all the heat of oxidation liberated is retained by the reactants as sensible heat. A separate scale in Fig. 5 shows the corresponding adiabatic temperature rise of the reactants for proper reference. This adiabatic temperature raise may account for the autoacceleration effect observed at longer reaction times, rather than the kinetics of reaction. In fact, in runs performed with the fine cobalt sponge and large excess oxygen a decrease in reaction rate was observed as the calculated adiabatic temperature rise of the material indicated that the melting points of Co and CoO had been reached (1490 and 1800°C, respectively), as would be expected from the drastic decrease in surface area that would occur under these conditions. There is no ques-

tion, however, that the initial reaction rates, corresponding to average oxide layer thicknesses of less than 200Å, are definitely affected by pressure, increasing by a factor of 30 as the oxygen pressure is increased from 1.0 to 4.0 atm.

Conclusions

The parabolic oxidation law which describes well the oxidation behavior of cobalt metal for high oxide thicknesses breaks down at oxide layer thickness lower than 10,000Å, below which the oxidation rate is significantly slower than that which would be predicted from cation vacancy diffusion rates through a homogeneous CoO layer. The rate-limiting process below this point is strongly affected by the surrounding oxygen pressure, suggesting that either the CoO nucleation rate or the rate of growth of small, freshly formed nuclei control the oxygen uptake.

Oxidation of Manganese in CO_2-CO Mixtures

Kazuo Fueki[1] and J. B. Wagner, Jr.

Materials Research Center and Department of Materials Science, Northwestern University, Evanston, Illinois

ABSTRACT

The kinetics of oxidation of manganese have been studied in CO_2-CO mixtures at temperatures of 800°-1200°C. In most cases the oxidation was parabolic. Activation energies for parabolic oxidation in different gas mixtures were found to range from 40.5 to 45.6 kcal/mole. In a few cases where manganese specimens were oxidized below 1000°C in gas mixtures with a high content of carbon monoxide, weight gains were abnormally large and the parabolic rate law was not obeyed. In these cases carbon deposits were formed on the oxide, and cracks of the scale were observed. Marker studies revealed that manganous oxide grows by the outward migration of manganous ions. From the oxidation data, the self-diffusion coefficient of manganous ions is determined as a function of p_{CO_2}/p_{CO}, and the mechanism of oxidation is discussed.

Only a few kinetic studies have been made of the oxidation of manganese. These have been chiefly in air or in oxygen. Baldwin and his co-workers (1,2) studied oxidation in air and found that parabolic oxidation is obeyed at temperatures between 400° and 1000°C. Their microscopic observations revealed that the scales formed below 825°C consist of layers of Mn_2O_3 plus Mn_3O_4 and MnO. Those formed above 825°C consist of a thin layer of Mn_3O_4 and two layers of MnO, a compact outer one and a porous inner one. They proposed a mechanism whereby the compact layer grows by the outward diffusion of cations and the porous layer grows by the inward diffusion of anions.

Paidassi and Echeverria (3, 4) studied the oxidation of manganese in air at temperatures of 400°-1200°C. They reported that (*a*) the oxidation obeys the parabolic rate law; (*b*) above 900°C the fraction of the oxide layer which was Mn_3O_4 does not exceed several per cent of the total thickness; and (c) the Arrhenius plot of k *vs.* $1/T$ has a break point at about 950°C.

As far as the present authors know, no kinetic study of the oxidation of manganese in CO_2-CO mixtures has been made.

The purpose of the present study is to obtain diffusion data in manganous oxide from the oxidation data and also to elucidate the oxidation mechanism of manganese in CO_2-CO mixtures.

Thermodynamic Consideration

The possible reactions between manganese and CO_2-CO mixtures are discussed with the help of a thermodynamic diagram. Figure 1 shows such a diagram (5, 6) of the Mn-O system superimposed on that of the C-O system. The data were taken from Elliott and Gleisner (7). The ordinate of the diagram represents the chemical potential of oxygen, $\Delta G = RT\ln p_{O_2}$, and the abscissa gives the temperature, T. Lines 1 to 4 represent the equilibrium between two condensed phases of the Mn-O system and divide the $T - \Delta G$ plane into several regions in any one of which a specified condensed phase is most stable. Line 5 gives the equilibrium between carbon and carbon dioxide of 1 atm. A group of lines, denoted by 6, give the equilibrium between carbon and carbon monoxide at specified partial pressures. Similarly, a group of lines, denoted by 7, show the equilibrium between carbon monoxide and carbon dioxide at specified ratios of CO_2 to CO. Lines 5, 6, and 7 divide the $T - \Delta G$ plane into three regions. In a region where the chemical potential of oxygen is high, carbon dioxide is most predominant. In a region where the chemical potential of oxygen is low carbon is the most stable species. At temperatures above the triple point, carbon monoxide

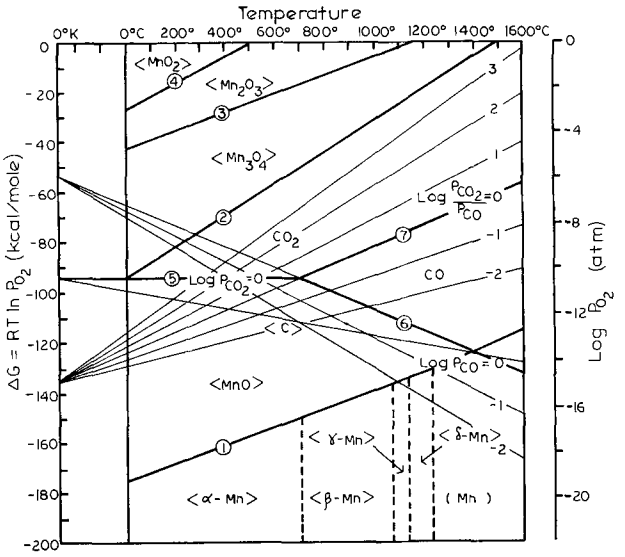

Fig. 1. Superimposed T — ΔG diagrams of the Mn-O system and of the C-O system. The symbol < > denotes a solid phase, ( ) a liquid phase, and the absence of brackets or parenthesis denotes a gas phase.

is the most predominant gas phase. It is seen that manganous oxide is the only oxide formed in CO_2-CO mixtures. When the temperature is above the triple point of the C-O system, which is determined by the partial pressures of CO_2 and CO, the possible reactions between Mn and CO_2 or CO are

$$Mn + CO_2 = MnO + CO \quad [1]$$

$$Mn + CO = MnO + C \quad [2]$$

Since the free energy change of reaction [1] is large and negative, reaction [1] would always occur. The free energy change of reaction [2] is negative only when the content of carbon monoxide is high. It increases as the temperature decreases. Therefore, reaction [2] is likely to occur when the content of carbon monoxide is high and the temperature is low. Carbon monoxide is unstable at temperatures below the triple point. Therefore, under these conditions carbon dioxide would react with manganese to form carbon and manganous oxide by the reaction

$$CO_2 + 2Mn = 2MnO + C \quad [3]$$

Moreover, carbon monoxide might decompose on MnO by the reaction

$$2CO = CO_2 + C \quad [4]$$

When carbon deposition occurs, a carbide such as Mn_7O_3 would be formed by the reaction

$$Mn + C \rightarrow \text{carbide} \quad [5]$$

The present analysis has been made at temperatures above 800°C and at low contents of carbon monoxide so that only reaction [1] could occur.

Experimental and Results

Oxidation rate measurements.—Manganese specimens were prepared from electrolytic manganese chips of 99.9% purity. The main impurities are listed in Table I. The manganese chips were polished with coarse polishing papers on a wheel and finished into coupons of rectangular shape. A typical coupon was 1 cm wide, 1.5 cm long, and 1 mm thick. Two small notches, of about ½ mm radius, were made on both sides of the specimen in order to suspend the specimen by means of a platinum wire. Then the specimens were heated for 6 hr *in vacuo* of 10^{-4} mm Hg at 500°C to remove hydrogen, polished with 2/0 and 4/0 emery

papers and then with Linde "A" alumina abrasive on a wheel, washed with water and then with acetone, and dried. An Ainsworth automatic recording balance and its accessories described by Pettit and Wagner (8) was used for the measurements. Mixtures having ratios of CO_2 to CO of 1:10, 1:3, 1:1, 3:1, 10:1, 30:1, and 100:1 at a total pressure of 1 atm were used. For all runs, a linear flow rate of 0.9 cm/sec was employed.

Figure 2 shows the parabolic plots of oxidation in various atmospheres at 1100°C. With the exception of an initial period, the parabolic law is obeyed. The run denoted by 0.05:0.05 was carried out in a mixture containing CO_2 at 0.05 atm, CO at 0.05 atm, and argon at 0.9 atm. The other runs, denoted by m:n with m and n having integer values, were conducted in CO_2-CO mixtures at a total pressure of 1 atm. Comparison of run 0.05:0.05 with run 1:1 shows that the parabolic rate constants do not depend on the partial pressures of CO_2 and CO but the pressure ratio of CO_2 to CO (mole fractions), and that the linear oxidation is not observed even in low pressures of CO_2 and CO such as run 0.05:0.05. Figure 3 shows the parabolic plots of oxidation at 900°C. The weight gains in a mixture of 1:10 are considerably larger than those in other mixtures and do not follow the parabolic law,

The dependence of parabolic constant on the ratio, p_{CO_2}/p_{CO}, is given in Fig. 4. The plots are not straight but slightly curved.

Arrhenius plots for various gas mixtures are shown in Fig. 5. A break in the Arrhenius plot such as was found by Paidassi and Echeverria for their studies of oxidation in air was not observed in the present study.

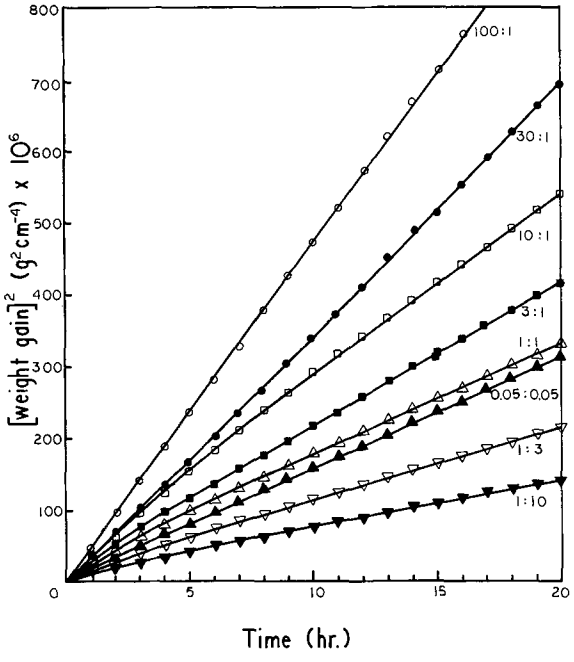

Fig. 2. Parabolic plot of oxidation in CO_2-CO mixtures at 1100°C

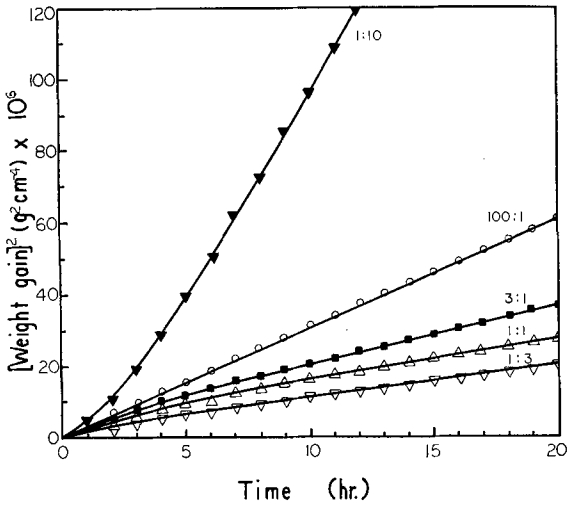

Fig. 3. Parabolic plot of oxidation in CO_2-CO mixtures at 900°C

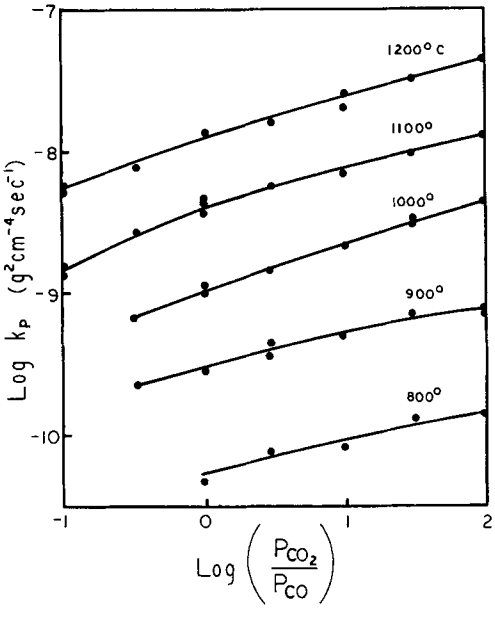

Fig. 4. Pressure dependence of the parabolic rate constant

Activation energies from the present study with errors at a confidence level of 90% are listed in Table II.

Microscopic observations.—The surfaces of oxidized specimens were examined microscopically. Figure 6 shows the surface of specimen oxidized for 24 hr at 1200°C in a CO_2-CO mixture of 5:1. Large oxide grains with growth pyramids are seen. From the fourfold symmetry of growth steps, the habit planes of manganous oxide formed in CO_2-CO mixtures are identified as {100}. This indicates that the surface reactions occur on {100} planes of manganous oxide, as was also observed in the oxidation of iron to wüstite in CO_2-CO mixtures (9).

On the surfaces of specimens which were oxidized at 800° or 900°C in gas mixtures with a high content of carbon monoxide and which exhibited very high oxidation rates, as discussed previously, black carbon deposits were observed on the oxide and cracks in the scales were observed.

The cross section of oxidized specimens that exhibited the normal parabolic behavior were also examined. As shown in Fig. 7, the scales formed in CO_2-CO mixtures were compact, homogeneous, and singly layered. In addition, a few runs were made in 1 atm oxygen, primarily for a marker study described below. The scales formed in oxygen consisted of a

on polished specimens. The specimens were heated at 1000°C for 30 min in purified argon to convert the paste into a thin platinum layer and also to fix the platinum wires on the surfaces of the specimens. The specimens were oxidized at 1100°C in a CO_2-CO mixture of 10:1 and cross-sectioned. Manganese metal after oxidation was so brittle that it fell off when the specimens were sectioned and polished. The platinum markers were found at the metal-oxide interface, as is seen in Fig. 7. The location of the markers at the interface between metal and the oxide shows that manganese ions move much faster than oxygen ions in manganous oxide. When manganese was oxidized in 1 atm oxygen, the markers were also found to be located close to the manganese metal-manganous oxide interface as shown in Fig. 8. These findings show that manganese ions play the major role of material transport in manganous oxide under the conditions reported herein.

Discussion

In a previous paper (10), the present authors proposed a method by which the self-diffusion coefficient of the most mobile ions is obtained from the oxidation data as a function of oxygen partial pressure. According to the method, the self-diffusion coefficient of manganous ions in manganous oxide is calculated from the oxidation data, under the assumption that the self-diffusion coefficient of oxygen is negligible, by the equation

$$D_1^* = \frac{1}{2}\left(\frac{M_{MnO}}{M_O \rho_{MnO}}\right)^2 \frac{dk_p}{d \ln (p_{CO_2}/p_{CO})} = 0.1436 \frac{dk_p}{d \log (p_{CO_2}/p_{CO})} \quad [7]$$

where D_1^* is the self-diffusion coefficient of manganous ions, M_{MnO} and ρ_{MnO} are the molecular weight and the density (5.45 g/cc) of manganous oxide, M_O is the atomic weight of oxygen, and k_p is the parabolic rate constant in units of $g^2\ cm^{-4}\ sec^{-1}$. Graphical differentiation of k_p with respect to log (p_{CO_2}/p_{CO}) and multiplication by the factor of 0.1436 yields the value

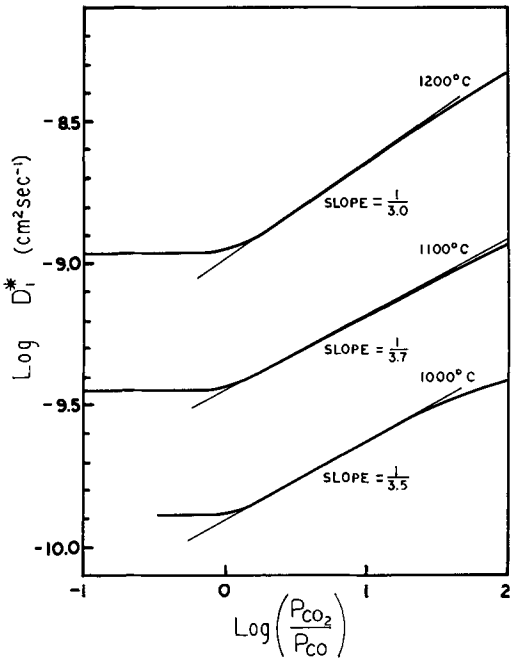

Fig. 9. Plots of log D_1^* vs. log (p_{CO_2}/p_{CO}).

of D_1^* as a function of log (p_{CO_2}/p_{CO}). Figure 8 shows the plots of log D_1^* *vs.* log (p_{CO_2}/p_{CO}) for 1000°, 1100°, and 1200°C. Above the value of log (p_{CO_2}/p_{CO}) = 0, log D_1^* increases almost linearly with the increase in log (p_{CO_2}/p_{CO}). The slope ranges from a value of 1/3.7 to 1/3.0. Cation vacancies would be created in manganous oxide mainly by a mechanism

$$CO_{2(g)} \rightleftarrows CO_{(g)} + Mn_{\square''} + 2\oplus + MnO \quad [8]$$

where $Mn_{\square''}$ is cation vacancy and $\oplus$ is an electron hole. During oxidation manganous ions diffuse via vacancies. Below a value of log (p_{CO_2}/p_{CO}) = 0, log D_1^* is independent of log (p_{CO_2}/p_{CO}).Under those conditions, presumably the intrinsic disorder predominates. Cation defects would be formed mainly by a Frenkel mechanism

$$\text{Null} \leftrightharpoons Mn_{\square''} + Mn_{O''} \quad [9]$$

or by a Schottky mechanism

$$\text{Null} \rightleftarrows Mn_{\square''} + O_{\square''} \quad [10]$$

where the symbols $Mn_{O''}$ and $O_{\square}$ denote an interstitial manganous ion and an oxygen ion vacancy, respectively.

Davies and Richardson (11) have studied the deviations from stoichiometry of manganous oxide at 1500°-1650°C, and they have found that manganous oxide has a composition from $MnO_{1.000}$ to $MnO_{1.045}$. Birchenall (12) has shown that the data of Davies and Richardson are well-explained if cation defects are assumed to be created by mechanism [9] at the stoichiometric composition and by mechanism [8] at large deviations from stoichiometry. The electrical conductivity of manganous oxide has been recently measured by Eror and Wagner (13) in the temperature range of 900°-1150°C in CO_2-CO gas mixtures. The transition of n- to p-type conduction was found to occur near the CO_2-CO ratio of 1:1. These workers (13) also found that above the ratio of 10:1, a $p_{O_2}^{1/6}$ dependence was followed, while a $p_{O_2}^{-1/6}$ dependence was obeyed below the ratio of 1:10. The present results are consistent with those of Birchenall and also with those of Eror and Wagner in the p-type region of manganous oxide.

Paidassi and Echeverria have found in their oxidation studies of manganese in air that the oxide film

formed above 900°C consists chiefly of MnO and that the activation energy above that temperature is 79.8 kcal/mole. The activation energies obtained in the present studies for MnO are much smaller than this value. Additional studies are necessary to clarify the reason for this difference.

Summary

The oxidation of manganese in CO_2-CO mixtures is controlled by the outward diffusion of manganous ions through a single layer of manganous oxide. The self-diffusion coefficient of manganous ions is independent of p_{CO_2}/p_{CO} in a region where the value of log (p_{CO_2}/p_{CO}) is less than 0. The independence is explained by a mechanism whereby intrinsic defects, Frenkel or Schottky, are more prevalent than those formed by the introduction of oxygen into the lattice according to Eq. [8]. In the region where the value of log (p_{CO_2}/p_{CO}) is larger than 0, the dependence of self-diffusion coefficient on p_{CO_2}/p_{CO} is 1/3.7 to 1/3.0. This dependence is explained if the creation of one cation vacancy and two electron holes is assumed.

Manuscript received Jan. 5, 1965; revised manuscript received July 7, 1965. This paper was presented at the Washington Meeting, Oct. 11-15, 1964. This work was supported by a grant from the Advanced Research Projects Agency through the Northwestern University Materials Research Center.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

The Reaction of Aluminum Electrodes with a Glycol Borate Electrolyte

Robert S. Alwitt and Reginald G. Hills

Engineering Laboratories, Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

Foil electrodes used in aluminum electrolytic capacitors are attacked by glycol borate electrolytes at elevated temperatures. In the work described in this paper it appeared that the dissolution rate was controlled by a reaction step involving OH^- and possibly water, but dissolution proceeded to a significant extent only because the dissolved aluminum was present as a soluble borate complex. The kinetics of electrode attack was studied by means of capacitance and weight change. Cathode foil (not anodized) dissolved at a constant rate and a film of amorphous, nonbarrier oxide was formed. Anodic Al_2O_3 initially dissolved at an approximately constant rate independent of oxide thickness, but at longer times the rate decreased and there was a dependence on thickness. Capacitance and weight loss data correlated as if uniform dissolution were the sole process, despite the fact that electron micrographs showed that the oxide had been penetrated at flaws. The anodizing electrolyte was found to affect the kinetics of dissolution, with and without an applied potential.

Most aluminum electrolytic capacitors contain a glycol borate electrolyte. A typical electrolyte would be ammonium pentaborate dissolved in ethylene glycol, which react to produce glycol borate esters and water. In a previous paper (1) it was shown that some of the common failure modes of low voltage aluminum electrolytic capacitors were the results of slow reactions between the glycol borate electrolyte and the aluminum electrodes. It was found that the primary mode of attack of anode foil was uniform dissolution of anodic oxide, upon which was superposed a more rapid attack at grain boundaries and discrete points within a grain. At these points the substrate metal was pitted and there was a new growth of nonbarrier oxide. Foil that had not been anodized (cathode foil) suffered a weight loss of metal and a gas was evolved that was qualitatively identified as hydrogen. Growth of nonbarrier oxide also occurred on cathode foil.

It was supposed that the slow step for both anode and cathode foil attack was oxide dissolution. When the thin oxide on cathode foil was reduced to its equilibrium barrier layer thickness by this reaction further dissolution was accompanied by a rapid electrochemical reaction to produce new oxide

$$2Al + 3H_2O - 6e \rightarrow Al_2O_3 + 6H^+ \qquad [1]$$

This was accompanied by the cathodic evolution of hydrogen. Oxide dissolution was balanced by formation of oxide at steady state, so the net result was dissolution of metal and production of hydrogen. Quite possibly some dissolved oxygen also was reduced, but this would not affect the qualitative aspects of this description.

Additional data on the kinetics of electrode attack are presented in this paper, as determined by capacitance and weight change both with and without applied potential. Also, the chemistry of oxide dissolution is examined in some more detail. The purpose was to construct a more complete picture of the phenomena and to answer some questions raised by the previous results (1). For example, what fraction of the surface undergoes nonuniform attack, and why was the dis-

solution rate of anodic oxide dependent on oxide thickness? Still no answer has been found to this last question.

Interpretation of anode foil weight change data is complicated by the fact that oxide dissolution is accompanied by some oxide growth, so that observed weight loss is not necessarily a true measure of the loss of anodic oxide. Also, accurate estimation of the weight of oxide deposited during anodization, without resorting to destructive testing, is not an obvious matter. In the discussion that follows on the analysis of weight data, this nomenclature will be used:

Measured quantities:

W_o = initial sample weight..
W_1 = weight after anodization.
W_2 = weight after immersion in electrolyte.
W_3 = weight after oxide stripped in CrO_3-H_3PO_4 solution.
W_4 = weight of metal in solution.
Q_e = equivalents of charge used in anodization.

Calculated quantities:

W_a = weight of anodic oxide dissolved.
W_m = weight of metal dissolved.
W_f = weight of new nonbarrier oxide.
W_{mf} = weight of metal in new nonbarrier oxide.

For cathode foil, the rate of dissolution is derived from data of W_m *vs.* time, where

$$W_m = W_o - W_3 \quad [2]$$

Properties of the corrosion product are given by

$$W_f = W_2 - W_3 \quad [3]$$

$$W_{mf} = W_o - W_3 - W_4 \quad [4]$$

For analysis of anode foil data two assumptions will be introduced. First, that all the charge passed during anodization removes aluminum from the substrate in the +3 state. This is not a stringent assumption since even for anodizations of less than 100% current efficiency it has been found to hold, so long as the anodizing voltage was low enough to prevent oxygen evolution. Under the conditions of the present study this assumption was tested and found to be valid. Second, the anodic film is assumed to be pure Al_2O_3. This is probably not true for any anodic oxide since material from the anodizing solution will be incorporated to an extent dependent on the particular conditions. In this study this was not a serious problem and the method of dealing with it will be presented later.

For anode foil, the weight of substrate metal dissolved is then

$$W_m = W_o - 9Q_e - W_3 \quad [5]$$

and the loss and gain of oxide are, respectively

$$W_a = (102/54)\ [W_4 - (W_m - W_{mf})] \quad [6]$$

$$W_f = (W_2 - W_3) - [(102/48)(W_1 - W_o) - W_a] \quad [7]$$

Unfortunately, Eq. [6] and [7] are a pair of simultaneous equations with three unknowns, W_a, W_f, and W_{mf}. To solve, W_{mf}/W_f could be assumed to be the same as found for cathode foil from Eq. [3] and [4]. If this is done, the resultant expression for W_f has a singularity when $W_{mf}/W_f = 54/102$, *i.e.*, no solution is possible when the new oxide growth is Al_2O_3 and the solution becomes more accurate the more dissimilar is the composition of the new growth from that of the anodic oxide. The best experimental determination of W_{mf}/W_f for cathode foil indicated the ratio was sufficiently close to that of Al_2O_3 to prohibit use of this technique to determine W_a and W_f.

Fortunately, upper and lower limits can be defined for W_a, and the experimental values for these limits were sufficiently close together to provide good estimates of W_a. Thus, the loss of anodic oxide is at least as great as the net observed oxide weight loss, *i.e.*

$$\underline{W_a} = (102/48)(W_1 - W_o - (W_2 - W_3) \quad [8]$$

Similarly, W_a can be no greater than the oxide equivalent to the total amount of metal found in solution, *i.e.*,

$$\overline{W_a} = (102/54)\ W_4 \quad [9]$$

No solution for W_f is possible but its magnitude can be inferred from the range in W_a.

Although aqueous phosphate solutions are the preferred electrolytes for commercial low voltage formations, they were not suitable for this investigation since anodizations in these electrolytes proceed at less than 100% current efficiency and a significant weight of phosphorus is incorporated into the film under some conditions (2). In contrast, Bernard and Cook (3) found that anodization in ethylene glycol containing 30% by weight ammonium pentaborate (E30) at 25°C proceeded at 100% current efficiency and the sole anodic product was Al_2O_3. Bernard and Randall (4) subsequently found that films formed in E30 over the voltage range 40v-150v occluded as much as 0.7% boron (equivalent to about 2% B_2O_3). This electrolyte was used in these present studies.

The first term on the right hand side of Eq. [8] represents the total weight of anodic product and must be modified to account for matter occluded during an anodization at 100% current efficiency. The weight of anodic oxide is simply 102 $Q_e/6$ and the weight gain of oxygen is $8Q_e$. The difference between the observed weight gain and $8Q_e$ represents occluded matter. The modified expression for $\underline{W_a}$ is then

$$\underline{W_a} = (102/6)\ Q_e + [(W_1 - W_o) - 8Q_e] - (W_2 - W_3) \quad [8a]$$

Experimental

Commercially etched 99.97% pure Al foil of 0.003 in. nominal thickness and with a surface roughness factor of about fifteen was used for all capacitance and weight measurements Anodized samples were of 17.6 cm^2 area and samples not anodized (cathode foil) were of 97 cm^2 area. (Areas referred to are projected areas, not true areas.) All samples were given an initial immersion at room temperature in 0.04*N* NaOH for 1 min followed by about 30 sec with gentle agitation in distilled water and then a prolonged soak in acetone. With this treatment the surface oxide was reduced to an amount undetectable by weight change in an oxide-stripping solution. Anodizations were done at constant current in E30 at 25°C. The current was maintained at 25 ma until the desired cell voltage was reached and was then decreased to 2.5 ma where it was held until the particular voltage was again obtained. Anodizations were to either 10v or 40v and the IR drop in the cell was about 0.1v at 2.5 ma.

For the 10v anodizations there were no significant differences between the observed weight gain $(W_1 - W_o)$ and the weight of oxygen calculated from the charge passed $(8Q_e)$. The weight gain in the 40v anodizations was consistently greater than $8Q_e$ by as much as 0.8 $\mu g/cm^2$, or about 2% of the weight of anodic oxide.

After initial capacitance and weight measurements foil samples were immersed in ethylene glycol containing 17% by weight ammonium pentaborate (E17) and kept at 85°C in sealed glass containers. E17 is a typical glycol borate electrolyte and was used in previous studies of electrode attack (1). The ratio of electrolyte volume to foil area was 2.3 ml/cm^2. In a preliminary experiment, only a small increase in the rate of oxide attack in E17 was observed when an anodized Al wire was rotated at several hundred revolutions per minute compared with that obtained with no rotation. In another experiment, no change in the rate of dissolution of cathode foil occurred when the electrolyte viscosity was increased 50% by the addition of a small amount of a thickening agent. These results in-

dicated the absence of significant electrolyte diffusional resistance so no attempt was made to control the natural convective conditions.

After the prescribed immersion time, capacitance and weight were again measured, oxide was stripped and the weight again determined. Between steps the foil was rinsed in distilled water followed by reagent grade acetone.

Oxide stripping was done in an aqueous solution of 2% CrO_3 and 5% H_3PO_4 at 85°C. The rate of attack of the aluminum substrate was only 1.5 $\mu g/cm^2$-min or 0.1 $\mu g/min/cm^2$ of true area, which compared with a rate of 0.2 $\mu g/cm^2$-min reported by Bernard and Randall (5) for electropolished aluminum. The attack of anodic oxide was more than fifty times as fast *e.g.*, a 10v film was completely stripped in 30 sec and a 40v film within 2 min. Samples of 17.6 cm^2 area were stripped for 30 sec, weighed and the cycle repeated until the rate of attack in an interval dropped to that of the base metal. The transition was sharp and unequivocal. The weight preceding the last was taken as the weight of oxide-free metal. The same procedure was used for the 97 cm^2 samples except that a 15 sec stripping interval was used.

Aluminum in solution was determined using a method of Sandell [procedure A in ref. (6)] based on the extraction of aluminum hydroxyquinolate by chloroform and photometry of the resulting yellow extract. For an aluminum concentration of greater than about 2.5 ppm (equivalent to 10 μg Al) the accuracy of the determination was ±5%. At lower concentrations the results were accurate to 5 μg.

All weighings were made on a microbalance accurate to within 10 μg. Capacitance readings were made in an aqueous borate electrolyte at 120 cps using a conventional capacitance bridge with a signal voltage less than 0.3v rms.

Samples for electron microscopy were prepared from 99.99% Al foil, 0.003 in. thick, electropolished in a perchloric acid-acetic anhydride bath. Anodization current densities and other conditions were the same as described for etched foil. Standard methods were used to prepare the micrograph specimens and these have been outlined elsewhere (1). Examination of surfaces was done with carbon negative replicas shadowed 15°.

Results and Discussion

Dissolution chemistry.—Before examining the data on the kinetics of dissolution it may be helpful to consider some results that shed light on the roles of the chemical species involved in the process.

Cathode foil was dissolved in E17 to the extent of 600 ppm Al in solution, with no sign of a precipitate nor decrease in dissolution rate. The solubility product of $Al(OH)_3$ in glycol is not known, but as a comparison, this concentration of Al could be attained in a simple aqueous solution only at a *p*H less than three or greater than ten (7). E17 is an almost neutral electrolyte, so the high solubility of Al appeared likely to be due to formation of complexes, either with glycol or a borate species.

E17 can be considered as a solution of various borates in a mixed solvent of composition 91% glycol + 9% water. Several nonborate solutes were dissolved in this glycol-water solvent, *e.g.*, KCl + HCl, and in each case the *p*H and conductivity were adjusted approximately to that of E17. No significant dissolution of aluminum occurred indicating that the enhanced solubility in E17 is not due to complexing with glycol.

In a saturated aqueous ammonium pentaborate (APB) solution at room temperature (*p*H 7), the concentration of dissolved Al reached 90 ppm. A concentration of less than 1 ppm would have been predicted from solubility data for aluminum hydroxide (7). It is concluded that the enhanced solubility of Al in aqueous and glycol solutions is the result of formation of borate complexes. The structure of the complex is not known, but probably involves a B-O-Al-O-B linkage.

In some simple experiments in aqueous APB solutions it was observed that the rate of weight loss of cathode foil and the rate of dissolution of anodic oxide were independent of the APB concentration, but increased as the *p*H was increased from 7 to 9. The addition of water to E17 increased the rates of attack (1), but it is not known if this was due to direct involvement of water in the rate controlling step or to the effect of water on solvent properties and the several equilibria that exist in this electrolyte. It was proposed (1) that oxide dissolution in E17 proceeded via the over-all reaction

$$Al_2O_3 + 3H_2O + 2OH^- \rightarrow Al(OH)_4^- \quad [11]$$

The results discussed here indicate this is not an accurate description. Although the dissolution rate is apparently controlled by a reaction step involving hydroxyl ion and possibly water, dissolution proceeds to a significant extent only because the dissolved aluminum is present as a soluble borate complex, and not as $Al(OH)_4^-$.

Cathode foil.—Figure 1 shows that etched aluminum foil dissolved in E17 at 85°C at a constant rate of 0.17 $\mu g/cm^2$-hr or, in terms of the equivalent weight of oxide, 0.33 μg Al_2O_3/cm^2-hr. Despite the uniform rate of metal dissolution, the growth of new oxide followed no discernible pattern. The following values of W_f were obtained at the indicated immersion times:

Time (hr)	W_f ($\mu g/cm^2$)
21	3.9, 4.0
67	0.8, 1.0
114	6.7, 6.8
168	0 , 0.3

Apparently, the fraction of dissolved aluminum that entered the oxide phase was determined by factors other than those controlled in these experiments.

No capacitance decrease ever accompanied this film growth so the new oxide was not a barrier film. An attempt was made to learn about the film composition by calculating the per cent Al in the film using the 114 hr data. These were the only data for which both W_f and W_4 were large enough for acceptable accuracy. The data and calculated results are given in Table I. The values of 48% and 52% compare with 53% for Al_2O_3 and 45% for $Al_2O_3 \cdot H_2O$.

A previous examination (1) of electron micrographs of electropolished foil after immersion in E17 showed that the oxide/air surface was similar in appearance to that of anodic oxide and the metal substrate was heavily pitted. The oxide was too thin to permit transmission micrographs. If water is added to a glycol borate electrolyte the reaction with aluminum electrodes is enhanced (1). Some typical results are given in Fig. 1 which show that with 10% water added the reaction rate with cathode foil was increased fourfold. The oxide film on an electropolished specimen immersed in E17 + 10% H_2O for 168 hr at 85°C was sufficiently thick to obtain transmisson electron micrographs. One of these is shown in Fig. 2 along with a selected area electron diffraction (SAD) pattern. The oxide and metal surfaces of this specimen had the same appearance as samples immersed in E17 to which no water had been added (1). The transmission micrograph and SAD pattern indicate that this oxide is amorphous,

Table I. Aluminum content of nonbarrier oxide

Weights in milligrams for 97 cm^2 samples				
W_0-W_3	W_4	W_f	W_{mf}	% Al
1.90	1.56	0.66	0.34	52
1.87	1.56	0.65	0.31	48

except for what appears to be a grain boundary in Fig. 2a. Despite the similarity of Al content then, this oxide cannot be $Al_2O_3 \cdot H_2O$ (boehmite), which has a crystalline structure.

Anode foil.—The change of reciprocal capacitance with time of immersion in E17 at 85°C is shown in Fig. 3 for foils anodized to 10 and 40v. Initial values of 1/C were 0.116 ± 6% (10v) and 0.490 ± 2% (40v). For about the first 100 hr Δ1/C was independent of oxide thickness and then the data for each thickness diverged. This behavior at longer times will be discussed in detail later.

The weight loss of anodic oxide during immersion in E17 at 85°C is shown in Fig. 4. Upper and lower limits for the weight loss were calculated from Eq. [9] and [8a] and are indicated in Fig. 4 by tails pointing up and down, respectively. Each point is the average of two samples. Smooth curves drawn through the lowest data points for each thickness are similar in shape to those for reciprocal capacitance in Fig. 3. The linear portion of the 40v curve represents a dissolution rate of 0.20 μg/cm²-hr, which is 2/3 the rate found for cathode foil.

If oxide dissolution proceeded uniformly over the surface, then the fractional loss of oxide calculated from the change in capacitance would equal the corresponding fractional loss in oxide weight. Corresponding points from the curves in Fig. 3 and 4 are plotted

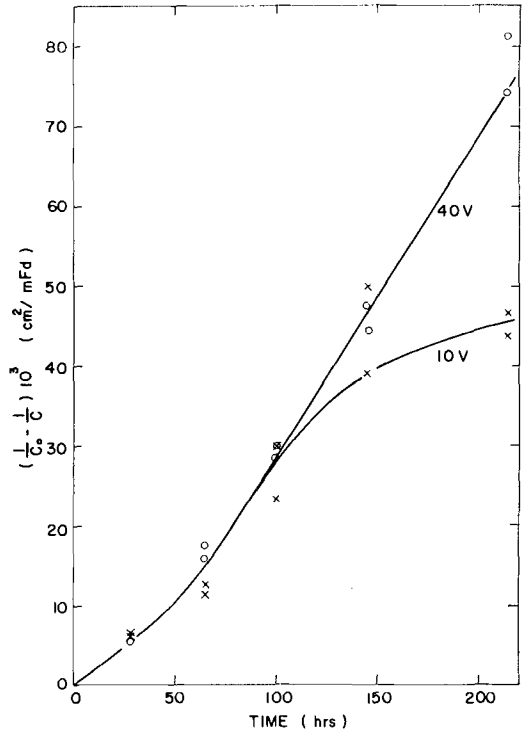

Fig. 3. Reciprocal capacitance change in E17 for two oxide thicknesses.

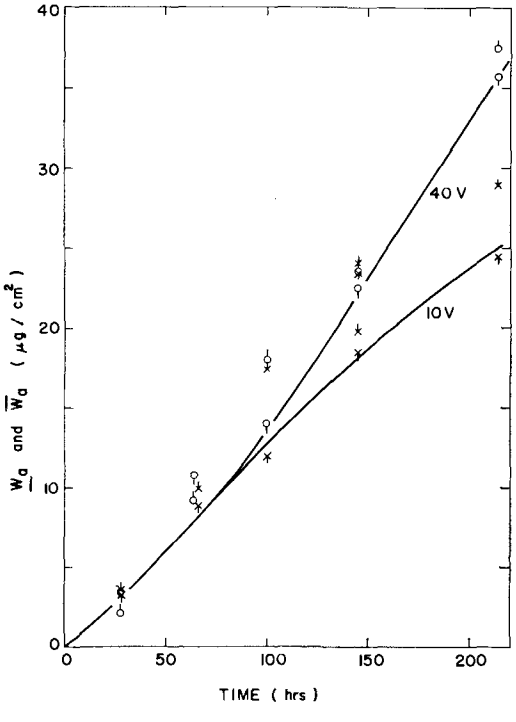

Fig. 4. Dissolution of anodic oxide in E17. (See text for explanation of symbols.)

in this fashion in Fig. 5, where W_{ao} is the initial weight of anodic film. The line is drawn with a slope of one and, except at the highest weight loss with a 10v film, the data are representative of uniform oxide dissolution. This is despite the fact that a significant amount of nonuniform attack took place, as indicated by the electron micrographs to be discussed shortly. This anomaly will be considered further at that time.

If the curves in Fig. 4 were drawn through the upper data points and values of W_a obtained from this curve were used in Fig. 5, all the points would have been below the line of unit slope. This represents a

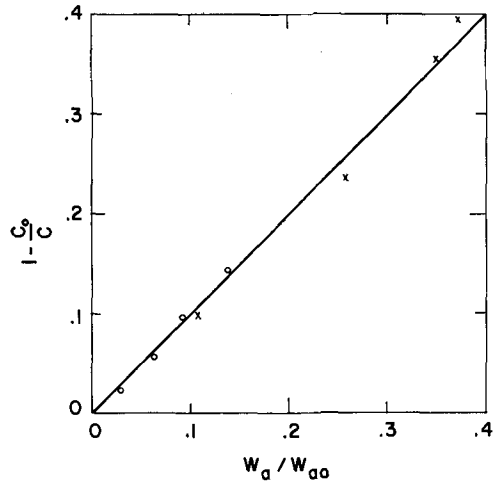

Fig. 5. Equivalence of capacitance increase and oxide weight loss; (X) 10v; (○) 40v.

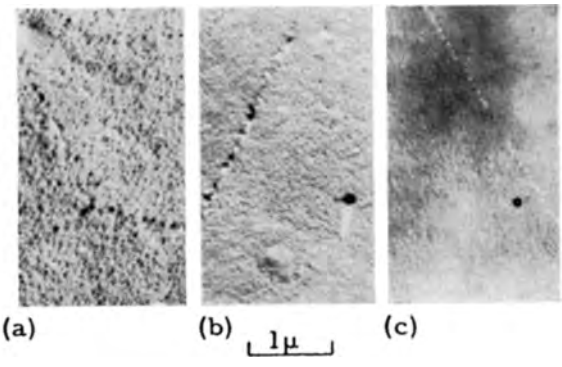

Fig. 6. Electropolished foil anodized to 10v in E30; (a) oxide/air surface; (b) metal surface at metal/oxide interface; (c) oxide film by transmission.

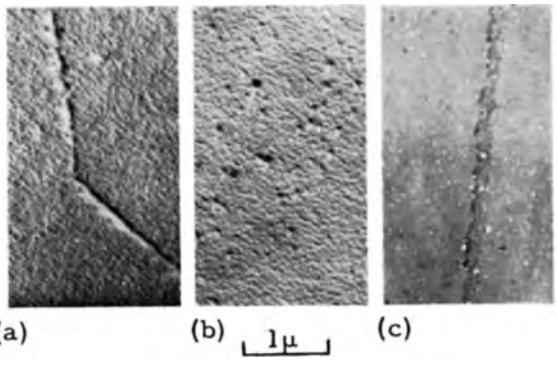

Fig. 7. 10v foil after immersion in E17 for 168 hr at 85°C; (a), (b), (c) same as in Fig. 6.

physically impossible situation since the change of reciprocal capacitance must at least be equivalent to the weight loss of barrier oxide. On this basis, Eq. [8a] probably gives a better estimate of W_a than does Eq. [9]. Since the right hand side of Eq. [8a] equals W_a-W_f, this implies that $W_f << W_a$.

The difference between $\overline{W_a}$ and W_a should be at least equal to the oxide equivalent of the substrate metal dissolved (W_m). In Fig. 4 it can be seen that this difference did not follow a regular pattern but covered a range of values up to the equivalent of 4 μg/cm^2 of dissolved metal, with an average value of 2.5 μg/cm^2. Values for W_m were also calculated from Eq. [5], and for both 10 and 40v films these increased from 2.6 μg/cm^2 at 28 hr to 5.4 μg/cm^2 at 214 hr. Although the ranges of values of W_m calculated by these

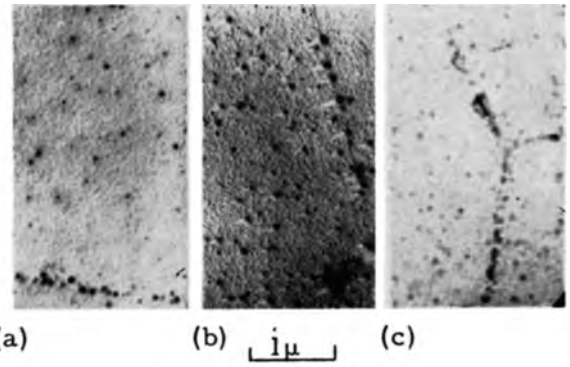

Fig. 8. 10v foil after immersion in E17 for 340 hr at 85°C; (a), (b), (c) same as in Fig. 6.

two methods overlap, those found from the difference between W_a and $\overline{W_a}$ were generally smaller.

Electron micrographs.—The rates of capacitance increase of the electropolished foils examined by electron microscopy were about the same as those of the etched foils. For example, after 168 hr in E17 at 85°C, C_0/C for 10v etched foil was 0.64 compared to 0.62 for polished foil. Examination of electron micrographs showed that significant nonuniform oxide dissolution had taken place. The extent and characteristics of the attack were the same as for polished foils anodized in aqueous phosphate solution that were previously examined (1).

The effect of immersion in E17 on a 10v film formed in E30 is shown in Fig. 6, 7, and 8. After anodization (Fig. 6) the oxide/air surface and metal surface at the metal/oxide interface exhibited uniform texture except for an occasional pit and a noticeable delineation of grain boundaries. The oxide was thinner at grain boundaries and at apparently random sites within a grain. The lower grain in Fig. 6c, in which thin spots are barely discernible, represents the most severe thinning that was observed in an anodized sample. Ten volt films formed in 1 g/liter $NH_4H_2PO_4$ did not exhibit any thin spots (1).

After 168 hr in E17 at 85°C (Fig. 7) there was no change in the oxide/air surface except for enlarged grain boundary grooves. Increased grain boundary attack was also evident at the metal surface and, in addition, numerous pits were present within the grains. The oxide was now thickened at grain boundaries and had a high density of thin spots and holes. After 340 hr in E17, C_0/C was 0.44. In Fig. 8 it is seen that pits were now evident within grains at the oxide/air interface and were more numerous in the metal substrate. Instead of holes, the oxide film now exhibited thickened areas within grains as well as at grain boundaries.

These thickened areas undoubtedly correspond to the points of attack in the substrate and represent a growth of nonbarrier oxide, perhaps similar in properties to that found on cathode foil. Alwitt and Hills (1) have found that this new growth is not too adherent to the surrounding anodic oxide and its presence or absence in a transmission micrograph is dependent on specimen preparation. It is possible that at least some of the holes in Fig. 7c were filled with oxide that was knocked out during specimen handling prior to examination. A general characteristic of the attack is that the metal substrate usually appears more pitted than the oxide/air surface. This may be because the nonbarrier oxide fills the holes in the anodic film so that shadowing of the replica of the oxide/air surface does not reveal their existence.

The pits in Fig. 7b are about 0.03-0.05μ deep and have a diameter of 0.05-0.1μ. After 340 hr immersion these dimensions were not much increased. From the pit depth and the weight loss of metal substrate the

fraction of the total area occupied by pits can be estimated. For a pit depth of 0.04μ and a metal loss of 4 $\mu g/cm^2$, this fraction is 2.5%. This should have resulted in a capacitance increase greater than could be accounted for by the weight loss on the basis of uniform dissolution. For example, assuming a 2v barrier oxide in the pits, it was estimated for a 10v film that when $W_a/W_{ao} \simeq 0.3$, the ordinate in Fig. 5 should be 10% greater and when $W_a/W_{ao} \simeq 0.1$ for a 40v film, $1-C_0/C$ should be 3 times as large. This was clearly not observed. It must be that the electrical resistance of the nonbarrier oxide in the pits was sufficiently high to prevent the capacitance of the underlying dielectric from being measured.

Weight loss and capacitance change are not always found equivalent, *e.g.*, foil anodized to 40v in a phosphate solution and immersed in E17 until $W_a/W_{ao} = 0.23$ had a value for $1-C_0/C$ of 0.32 (1). Perhaps foil anodized in E30 would have shown the same behavior if dissolution had been allowed to proceed to as great an extent.

Decreased dissolution rate at longer times.—The decrease in the rate of attack of thinner films at longer times, shown in Fig. 3 and 4, is a general characteristic of this dissolution process that has been observed previously for films formed in aqueous phosphate solutions (1). It occurred to the same extent whether the foil was left undisturbed in the E17 or removed for periodic capacitance measurements and then replaced. Periodic change of the electrolyte with fresh solution had no effect. The knee in the curve is not always reproducible, as indicated by the 145 hr 10v data in Fig. 3, where only one sample had a decreased rate of dissolution. However, the averaged results from several experiments showed that departure from the parent curve for 10v films occurred usually at about 0.035 cm^2/mfd, and for 20v and 40v films at about 0.050 and 0.085 cm^2/mfd, respectively. These are equivalent to dissolution of 30%, 21%, and 17% of the initial oxide, respectively.

The decrease in the dissolution rate is quite substantial. From the curves in Fig. 4, at 200 hr the 10v oxide was dissolving at only half the rate of the 40v oxide. The capacitance data (Fig. 3) indicates an even larger difference in rates. It is emphasized that even at the longer times when the oxides were dissolving at different rates, the capacitance and weight data behaved as if uniform dissolution was the sole process (Fig. 5). For some reason, the rate of uniform dissolution decreased at longer reaction times as a function of oxide thickness.

Randall *et al.* (8) have found that anodic films formed on tantalum and niobium consist of a layer of stoichiometric pentoxide next to the metal and an outer layer which contains matter characteristic of the anodizing electrolyte. At least in some cases the outer layer was more chemically reactive than the inner portion. At any current density, the relative amounts of the two layers remained constant, independent of the total charge passed. Randall (9) has found that anodic aluminum oxide has a similar structure.

It was thought that the decrease of dissolution rate at longer times in E17 might involve different compositions of inner and outer portions of the oxide. This was tested in the following manner. Four foil tabs were anodized in E30 to 20v, immersed in H_3PO_4-CrO_3 solution for 55 sec at 65°C and then thoroughly rinsed in distilled water. The oxide was now thinned to the thickness of about a 10v film, as determined by capacitance. Two of the tabs were "healed" in E30 at one tenth the anodizing current density until the rapid voltage rise ceased, about 9.5v. Healing produced less than a 3% capacitance decrease which indicated that uniform dissolution had occurred in the stripping solution. These films were now of about the same thickness as normal 10v films but any outer layer was much thinner than normal. If this was an important factor in the dissolution kinetics, these films should undergo a decrease in the rate of dissolution much sooner than normal 10v films. The capacitance increase in E17 of all four samples (two healed, two not healed) was determined in the usual fashion. There were no significant differences among the samples and all data essentially replicated the previous results with normal 10v films.

The agreement between normal and "thinned" 10v oxides means that the observed dependence of dissolution rate on film thickness was not a function of any compositional variations within the oxide. Moreover, lack of any difference between the healed and not healed samples shows that any space charge induced in the oxide by the formation field had no residual effect on the dissolution kinetics. In the absence of any other simple model for the oxide which suggests a thickness-dependent dissolution process, we can offer no explanation for the dissolution kinetics of these oxides.

Sites for oxide penetration.—Rapid penetration of the anodic oxide occurred at points that are probably very similar to the flaws in anodic Ta_2O_5 films discussed in detail by Vermilyea (10). Aside from infrequent gross imperfections, direct evidence of flaws in the as-formed films was found only in the micrographs of 10v E30-formed films (Fig. 6c), and these were at too low a magnification to distinguish any structural features. Inspection of Fig. 6c shows that flaws occurred at grain boundaries and at points within grains, and flaw density varied from grain to grain. These features were intensified by the immersion in E17 as seen in Fig. 7. Most flaws were circular, as inferred from the round pits produced during oxide attack, but larger flaws were sometimes of the types shown in Fig. 9. Though direct evidence is lacking, it is suspected that the annular depressions seen in Fig. 9b were present in the as-formed oxide. The deep slit in the center area was probably developed during immersion in E17. [Vermilyea (10) describes a structure like those in Fig. 9b as being due to a sequence of flaw formation, healing and new flaw formation at the same spot. In the present case, the dimensions of the flaws are too large to have been due to this cause.]

Flaws are presumably the result of surface contamination, either from impurities in the metal or from external sources, and surface roughness. Renshaw (11) has presented evidence that flaws in the oxide formed on chemically etched aluminum tend to be concentrated at the 90° step edges. The internal stresses in the oxide along the step edges would presumably be large enough to cause oxide failure and cracking. In our experiments no micrographs were made of etched foil and the capacitance/weight data were insensitive to the nonuniform dissolution, so no information on the relationship between surface roughness and flaws was obtained. It might have been expected that with foil as heavily etched as that used in these experiments, some difference in the rate of capacitance change between etched and polished foil would have been observed if surface roughness was a factor in flaw generation, but no such difference was seen.

To determine the effect of grain orientation on flaw density, several previously examined samples with

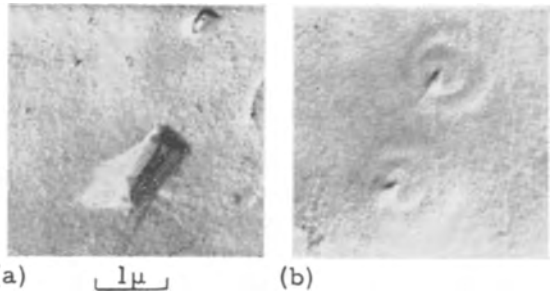

Fig. 9. Flaws in 40v film; oxide/air surface after immersion in E17 for 340 hr at 85°C.

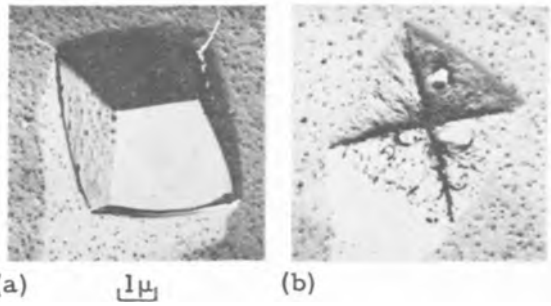

Fig. 10. Characteristic etch figures in (a) grains with high flaw density and (b) grains with low flaw density.

high flaw density were given a metallographic etch in a bath recommended by Lacombe and Beaujard (12). Subsequent examination showed that etch figures such as that in Fig. 10a were in grains with a high flaw density while etch pits such as in Fig. 10b were in grains of low flaw density. This was interpreted to mean that more flaws were present in grains with surfaces parallel to {110} planes than in grains with surfaces parallel to {100} planes. No attempt was made to determine the frequency of the differently oriented grains, nor were any measurements made throughout this study of the relative frequency of grains with high or low flaw densities other than to note that a significant amount of both was always present in a sample.

From electron micrographs, the flaw density within grains (not including grain boundaries) was estimated to be $10^9/cm^2$ for grains exhibiting significant attack, *e.g.*, the grain in Fig. 7b. The same value for flaw density was obtained from the values of pit dimensions and metal weight loss used previously to estimate the area occupied by pits. Neither the anodizing solution nor film thickness had an observable effect on flaw density. Vermilyea (10) estimated 10^7 flaws/cm^2 in oxide films on chemically polished commercial high purity tantalum foil.

Effect of anodizing electrolyte.—Ten volt films were formed at 25°C in the following electrolytes: Aqueous 1 g/l $NH_4H_2PO_4$ (ADP), *p*H 4.74; E30; aqueous 50 g/l H_3BO_3 (NH_4OH added to give *p*H 4.72). For the first two electrolytes the conditions were the same as used previously except that instead of a final current of 2.5 ma, the current was maintained at 25 ma and the anodization continued until the cell voltage was 10v plus the IR drop. The aqueous boric acid electrolyte would not support anodization at this current density so in this case the films were formed at constant voltage to a final current of 25 ma.

The capacitance increase in E17 was followed in the usual manner, with the results shown in Fig. 11. Films formed in the phosphate electrolyte dissolved at a faster rate than did films formed in electrolytes containing borate species. Moreover, the oxide formed in the aqueous borate electrolyte was more resistant to dissolution than that formed in the glycol borate electrolyte. The differences in rates were substantial. For example, the average dissolution rates for the first 24 hr were in the ratio 9:3:2, for the electrolyte order listed above.

It is characteristic of films formed in E30 that their initial dissolution rate is either constant, as in Fig. 11, or there is a period of increasing rate preceding the constant rate, as in Fig. 3. The latter behavior is thought to be due to dissolution initiating at points sufficiently separated so that until the dissolution fronts from these points merge, the attack is occurring over an increasing fraction of the area. On the other hand, films formed in aqueous ADP have never exhibited either of these characteristics, but instead dissolve at a steadily decreasing rate, even at times less than 24 hr.

Although it was shown in a preceding section that compositional differences do not explain the decrease

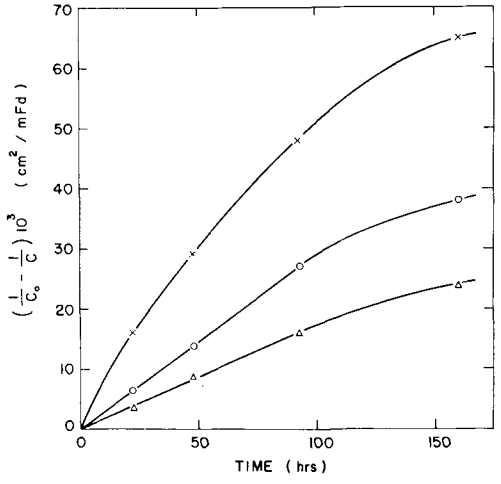

Fig. 11. Effect of anodizing electrolyte on dissolution of 10v films; (X) 1 g/liter ADP: (○) E30; (△) 50 g/liter H_3BO_3.

in dissolution rate for any one oxide, it appears likely that the differences among oxides formed in the three electrolytes are because of the species and concentration of occluded matter in each film.

Effect of applied potential.—Samples of 10v foil were maintained at several positive voltages with respect to a platinized platinum wire cathode, using a storage battery as the constant voltage source. After 96 hr in E17 at 85°C the changes in capacitance and oxide weight were measured. This was done not only with samples anodized in E30 but also with foil anodized in aqueous 1 g/liter $NH_4H_2PO_4$ (ADP). Anodizing conditions with ADP were the same as described in the preceding section. Lastly, tabs of electropolished foil, intended for electron microscopy, were anodized to 10v in E30 and maintained at positive potentials in E17 for 281 hr at 85°C.

The effect of applied potential is illustrated in Fig. 12. The ordinate for weight change is simply the oxide weight after immersion in electrolyte divided by the initial oxide weight. For reasons that will soon

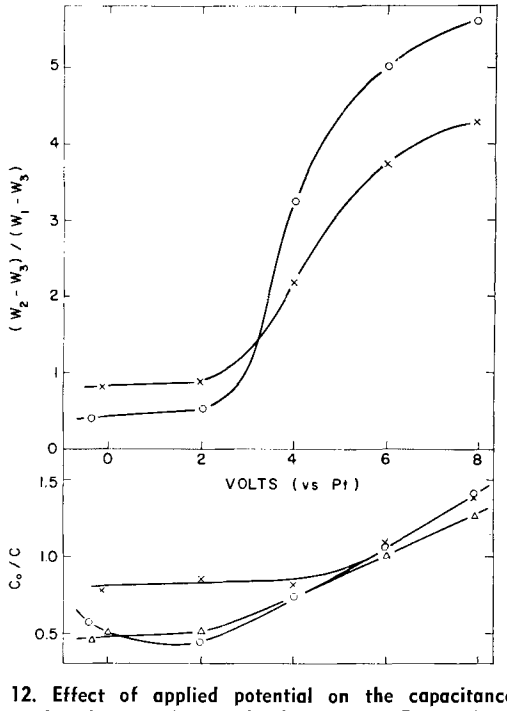

Fig. 12. Effect of applied potential on the capacitance and oxide weight change of several 10v foils in E17. (X) etched, anodized in E30, 96 hr immersion; (○) etched, anodized in 1 g/liter ADP, 96 hr immersion, (△) polished, anodized in E30, 281 hr immersion.

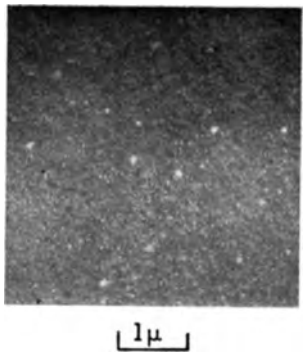

Fig. 13. Transmission micrograph of 10v film after 96 hr in E17 at 85°C with +6v applied potential.

be obvious, C_0/C was a better measure of the fraction of initial barrier oxide remaining than was the change in oxide weight. With foil anodized in E30, small positive potentials had little effect on the dissolution of barrier oxide. This would be expected for a simple chemical dissolution process. Increasing the potential decreased the effect of dissolution until at sufficiently high potentials additional barrier oxide was apparently deposited.

The change in weight of oxide agrees with this description except that the weight gain at higher potentials was far greater than could be accounted for by the capacitance decrease. For example, at 6v there was no change of capacitance but the oxide weight increased almost fourfold. This large a change could only be due to the formation of a porous oxide. To verify this, an electron micrograph was made of the oxide stripped from the electropolished foil kept at 6v. In Fig. 13 it is seen that in addition to the larger holes observed before, a fine network of pores exists throughout the oxide. Formation of porous oxide in electrolytes ordinarily used to produce barrier oxide has been observed previously by Renshaw (11) and by Hunter and Towner (13). The formation of a porous oxide apparently depends only on the relative rates of anodization and oxide dissolution. The observation that porous oxide can be formed in E17 is not of fundamental significance though it could be of importance in interpreting capacitor performance.

Foil anodized in ADP behaved differently from foil anodized in E30. Besides a greater rate of attack on open circuit, small positive potentials accelerated the dissolution, resulting in a minimum barrier thickness at about +2v. The barrier thickness would have been still thinner at higher potentials if the competing process of film formation had not become significant. The same behavior has been observed with foil commercially anodized in ADP (1).

It was thought that the dependence on potential might have been related somehow to the more extensive attack of ADP films at 96 hr compared to E30-formed samples. However, the electropolished tabs were in E17 for sufficient time to produce the same thinning of barrier oxide as the ADP-formed tabs, and yet no increasing attack with increased potential was observed. It is concluded that the different behavior with applied potential is due to a difference in the electrical properties of aluminum oxide formed in a glycol borate electrolyte from that formed in aqueous phosphate solution. In particular, the oxide formed in phosphate solution must contain a higher concentration of mobile charged species. Engell (14) has shown that the dissolution rates of several semiconducting metal oxides are dependent on electrode potential.

It is generally accepted that lattice defects are preferred sites for reaction on a solid surface. The greater dissolution rate of phosphate-formed oxide compared to E30 formed oxide can be explained as the effect of different incorporated material from the electrolyte on defect concentration and type. Phosphorus is found in films formed in aqueous phosphate solutions (2), and in E30-formed films boron, and probably carbon, is occluded (4). The concentration of defects at the surface of oxide formed in 1 g/liter ADP was apparently increased by the application of a potential too low to result in any significant ionic transport, but sufficient for the movement of electrons and/or vacancies. Since we know neither the mechanism of the dissolution reaction nor the state of the incorporated matter in the oxide, it is not possible to be more specific in the interpretation of these results.

Conclusions

1. Dissolution of aluminum and aluminum oxide occurs to a significant extent in glycol borate electrolyte only because of the formation of soluble aluminum-borate complexes.
2. Aluminum oxide is attacked preferentially at flaws that are similar to those found in anodic Ta_2O_5. Despite a significant flaw density in the anodic oxide, the weight of nonbarrier oxide grown at these sites is very small compared to the total weight of anodic oxide dissolved. The resistance of the new oxide growth is sufficiently large so that the capacitance and weight loss correlate as if only uniform dissolution occurred.
3. The dissolution rate of anodic oxide is a function of oxide thickness, but no explanation for this dependency has been found. It is not due to compositional variations within the oxide or to a defect distribution determined by the formation field.
4. Material incorporated from the anodizing electrolyte affects the dissolution kinetics not only on open circuit, but also with an applied potential. This may be a useful tool in learning more about the incorporated species and/or oxide dissolution.

Acknowledgments

The authors wish to thank Miss A. Harvin for the electron micrographs, Mr. R. Vanasse for the aluminum analyses, and Mr. S. Acello for the metallographic etch. Discussions with Drs. J. J. Randall, Jr., S. D. Ross, and D. M. Smyth were most helpful.

Manuscript received May 24, 1965. This paper was presented at the San Francisco Meeting, May 9-13, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

The Effect of Phosphor Coating Weight on the Lumen Output of Fluorescent Lamps

R. Gaines Young

Advanced Development Department, Lamp Division, Westinghouse Electric Corporation, Bloomfield, New Jersey

and E. G. F. Arnott

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

Brightness measurements have been made in partially coated lamps at both surfaces of 1-cm wide fluorescing Cool White halophosphate stripes for a wide range of coating weights per unit area. The brightness data were used in equations describing the optics of fully coated lamps and the resulting curve was successfully fitted to an experimentally obtained curve of lumens *vs.* coating weight per unit area for such lamps. The values of the differential reflection and absorption coefficients of visible emitted radiation of the coating which gave the best fit were $r = 0.43$ cm²/mg and $a = 0.0012$ cm²/mg, respectively.

It is known that an optimum thickness of phosphor coating is required to produce maximum lumen output from the fluorescent lamp (1). A coating of inadequate thickness does not utilize all the energizing u.v. radiation, whereas an excessively thick coating tends to trap the generated radiation within the lamp and increases absorption losses.

A study was made of the effects on brightness and lumen output resulting from variations in the quantity of coating, *i.e.*, weight per unit area, over a range of thirty-seven to one. These data were sought to increase our understanding of phosphor coating optics and, in particular, the effect of partial trapping of visible light with the phosphor on total output.

Procedure

Twenty-four 48 in. long, 1½ in. diameter, tubular bulbs were coated internally with Cool White halophosphate phosphor, and three more were left bare. Eight different concentrations of phosphor suspended in ethylcellulose lacquer were used on three bulbs each. The lacquer was removed by baking in air. By means of a beam transmittance arrangement, as described by Thayer (1), it was determined that the coating weight at the center of each bulb was within 2½% of the average of its set. A center section was then cut from one bulb in each set, and an analytical balance was used in determining the weight of phosphor per unit area of this section. The coating values varied from zero and 0.36 to 13.4 mg/cm². The other eighteen bulbs were used in the making of 40-w fluorescent lamps.

Other sections of the nine bulbs used in the weight determinations were next used in phosphor brightness studies. All the phosphor except a straight 1-cm wide stripe parallel to the bulb axis was removed from these sections. A G36T5 Sterilamp u.v. source was placed concentrically inside each bulb section, in turn, and the phosphor stripe was irradiated by ultraviolet, Fig. 1. Relative brightness measurements were then made of B_o, the phosphor emission through the outer side of the coating touching the glass, and of B_i, that emitted from the inner side facing the Sterilamp source. A Model UBl-½ Spectra Brightness Spot Meter[1] was used with a red filter (Wratten No. 25) to exclude nearly all of the visible radiation emitted from the mercury discharge of the Sterilamp source. The results shown in Fig. 2 are discussed below.

Total lumen output measurements were made on the eighteen completed lamps. The lumen values include radiation from the discharge, and so the curve in Fig. 3 does not quite drop to zero for zero-coating weight. The measurements were made near zero hours of burning, prior to possible changes in the optical properties of the phosphor caused by interaction with u.v. radiation and the glass bulb. The lamps were operated with a reference ballast and with the rated voltage input, in accordance with ref. (2).

Results and Discussion

The stripe geometry of Fig. 1 was chosen so that practically no radiation would reach it from other phosphor surfaces. In this way the brightnesses aris-

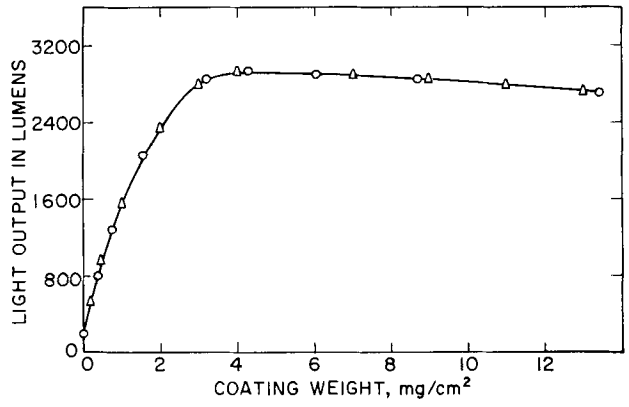

Fig. 3. Lumen output of fully coated fluorescent lamps vs. coating weight per unit area: ○—○, measured values; △—△, calculated values.

ing directly from emission generated in the coating could be studied. Consider first the sum of B_o and B_i, shown in Fig. 2, which is related to the total amount of radiation generated. There is a coating weight per unit area beyond which the amounts of ultraviolet utilized and visible radiation generated are essentially constant. This value is approximately 4 to 5 mg/cm² for the phosphor studied.

It can be seen from Fig. 2 that much of the visible radiation is generated in the layers of the coating nearest the phosphor surface exposed to the gas discharge. Of the portion of the visible radiation which is directed deeper into the phosphor coating, part is transmitted through the phosphor coating and the glass. Another part is reflected internally and passes back through the gas discharge side of the coating. A decreasing proportion of the visible radiation reaches the glass or outer side of the stripe as the coating thickness increases.

The lumen output of a fully coated lamp in Fig. 3 increases with coating weight and reaches a maximum at about the same weight per unit area as does the total brightness of the striped bulb. Because there are interreflections within the lamp and because the phosphor does not have zero optical absorptance for visible radiation, the lumen output decreases for heavier coatings.

It should be possible to use the data in Fig. 2 to predict the lumens *vs.* coating weight per unit area curve for the fully coated lamps, actually measured and given in Fig. 3. In Fig. 4 it is shown how visible light, produced by u.v. radiation striking one portion of the phosphor surface and having brightnesses B_i and B_o eventually escapes the fully coated lamp. The light flux, as it strikes another portion of the phosphor surface, is either transmitted to the outside, absorbed, or reflected to still another internal surface. The process continues until all the light is either transmitted outside or absorbed in the coating.

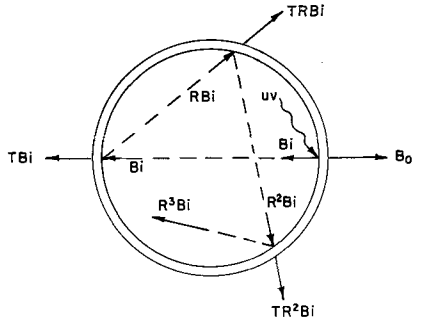

Fig. 4. Schematic cross-section view of fully coated fluorescent lamp, showing the multiple reflections of internal light.

As a result of this, the relative brightness on the outside surface of a fully coated lamp, B, is given by

$$B = B_o + TB_i + TRB_i + TR^2B_i + TR^3B_i + \ldots \quad [1]$$

$$B = B_o + TB_i(1 + R + R^2 + R^3 + \ldots) \quad [2]$$

$$B = B_o + T(1-R)^{-1}B_i \quad [3]$$

where T and R are the transmittance and reflectance of the coating for visible radiation.

The external brightness must be corrected to take into account the visible radiation of the mercury discharge. The latter has a relative brightness of B_{Hg} in an uncoated bulb, and is transmitted and reflected by a coating in the same fashion as is B_i, hence

$$B = B_o + T(1-R)^{-1}(B_i + B_{Hg}) \quad [4]$$

The values of T and R can be found by using equations given by Schuster (3) and applied to powders by others (4-7).

$$T = [\cosh(ps) + (a + r)p^{-1}\sinh(ps)]^{-1} \quad [5]$$

$$R = [\cosh(ps) + (a + r)p^{-1}\sinh(ps)]^{-1}rp^{-1}\sinh(ps) \quad [6]$$

$$T + R + A = 1 \quad [7]$$

where $p^2 = a^2 + 2ar$; s is the coating weight per unit area; a is the differential absorption coefficient of coating for visible radiation; r is the differential reflection (or scattering) coefficient of coating for visible radiation; and A is the absorptance of coating for visible radiation.

Substitution of Eq. [5] and [6] into Eq. [4] gives a final form for the outside surface relative brightness.

$$B = B_o + [\cosh(ps) + ap^{-1}\sinh(ps)]^{-1}(B_i + B_{Hg}) \quad [8]$$

The relative brightness of Eq. [8] must be multiplied by a constant to give total lamp lumens. Evaluation of this constant and of B_{Hg} was made using the measured values of B_i, B_o, and lamp lumens for those thinner coatings for which the term $[\cosh(ps) + ap^{-1}\sinh(ps)]$ of Eq. [8] was known to be nearly unity. The constant equating relative brightness to lumens was found to be 332, and B_{Hg} was 0.64.

Using these figures and the values of B_i and B_o picked for ten different values of coating weight per unit area from the smoothed curves in Fig. 2, it was found that a calculated lumen curve best fits the measured lumen curve of Fig. 3 for values $a = 0.0012$ cm²/mg, $r = 0.43$ cm²/mg, and $p = 0.032$ cm²/mg. This determination was made by the least square method, using a computer. The calculated lumen curve for these optical coefficient values is seen in Fig. 3 to fit the measured data well.

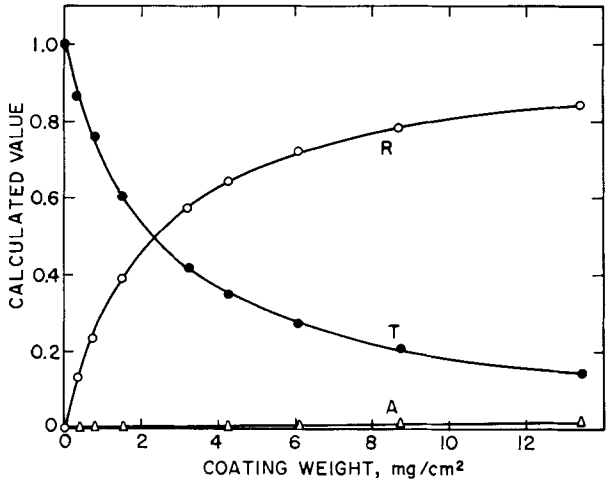

Fig. 5. Reflectance, transmittance, and absorptance calculated for $a = 0.0012$ cm²/mg and $r = 0.43$ cm²/mg vs. coating weight per unit area.

Table I. Calculated values of R and T

Author	Phosphor	R	T	A

Weinstein (9)	Halophosphate	0.55-0.65	0.28-0.40†	0.05-0.07
Young and Arnott	Halophosphate‡	~0.64	~0.35	0.005

* 1.5-2.0 mg/cm².
† Calculated by $T = 1 - R - A$.
‡ 4.0 mg/cm².

Most of the coatings used in this fit of data were sufficiently thick that their u.v. reflectances were maximum for the particular phosphor used. It is thought that the data of the one or two thinnest coatings which had lower reflectance did not affect the fit or evaluation of the coefficients.

No correction has been made for the relatively small loss of radiation at the ends of the lamp.

Calculated values for R, T, and A *vs.* s are shown in Fig. 5. The R and T values are in fairly close agreement with some given in the literature for other phosphor coatings at their normal or optimum thickness (Table I). It appears that the absorptance of visible radiation by commercial phosphors has decreased considerably from the early phosphor reported by Thayer (1).

By letting s approach infinity in Eq. [6], the relationship between the reflectance of an infinitely thick coating and the p, a, and r coefficients is

$$R_\infty = \frac{r}{p + a + r} \qquad [9]$$

Using our evaluation of the coefficients, the value of R_∞ is calculated to be 0.93. This is a very reasonable value; however, no thick-layer measurements were made on this phosphor to check agreement.

Summary

It has been shown that the lumen output of a fully coated fluorescent lamp varies with coating thickness in a manner predictable from the application of Schuster's equations to data of the measured brightness of phosphor stripes. The values obtained for the differential reflection and absorption coefficients of visible emitted radiation of the coating were $r = 0.43$ cm²/mg and $a = 0.0012$ cm²/mg, respectively. The calculated values of reflectance, transmittance, and absorptance of a coating of normal thickness agree well with those given in the recent literature.

On the Luminescent Properties of Some Rare Earth Ions in Zinc Borate as a Host

L. H. Brixner

Pigments Department, Experimental Station, E. I. du Pont de Nemours & Company, Wilmington, Delaware

ABSTRACT

Zinc borate, ZnB_2O_4, melting at 1000°C, forms a glass of high optical perfection which can be cast readily or pulled into almost any shape. Rare earths can be introduced in the cation sites with compensation by Na^{1+} to give glasses of the generic formula $Ln_xNa_xZn_{1-2x}B_2O_4$. The rare earths Sm^{3+}, Eu^{3+}, Tb^{3+}, Dy^{3+}, and Tm^{3+}, all emitting in the visible, were introduced into zinc borate and emission spectra as well as the optimum of x for fluorescent emission were determined. For a rod of the composition $Nd_{0.02}Na_{0.02}Zn_{0.96}B_2O_4$, stimulated emission was observed at room temperature with a threshold of 1500 joules. Rods containing the optimum concentration of Eu^{3+} and Tb^{3+} did not show laser action.

Although the original solid state laser experiments by Maiman (1) were based on single crystalline ruby and considerable work has been done since with other monocrystalline hosts, such as $CaWO_4$ (2), CaF_2 (3), $CaMoO_4$ (4), $Ca(NbO_3)_2$ (5), and $Ca_3(VO_4)_2$ (6), glasses (7) were soon considered as hosts and found quite useful, particularly in the case of Nd^{3+}. The advantages of glasses over single crystals such as ease of preparation, high optical perfection, low expansion coefficient, homogeneity of the dopant, mechanical strength and greater hardness are quite apparent and are only partially counteracted by some disadvantages such as lower thermal conductivity and higher threshold values. Since the fluorescent transitions occur in the shielded 4f levels of the rare earths, the fluorescent spectra differ not too much in principle between glasses and single crystals although observed halfwidth are considerably narrower in the latter. Never-

theless, glasses definitely do have their established place among the limited list of useful laser hosts.

Most of the glasses studied previously are of the silicate type with SiO_2 as the predominant constituent and at least four or five other components such as Na_2O, CaO, Al_2O_3, and Sb_2O_3. Although in appropriate proportions these constituents do form a homogeneous melt, they still represent a complicated mixture and if nothing else pose a multiple purity problem over less complicated systems. We therefore looked for a simple, well-defined, glass-forming composition with relatively low melting point such as ZnB_2O_4. This compound melts congruently at 1000°C and according to Swanson (8) crystallizes in a cubic structure with $a_o = 7.4726$Å. Rare earth ions can be introduced into the Zn^{2+} site and compensation to achieve electroneutrality can be obtained through the equivalent introduction of Na^{1+} according to $Ln_x^{3+}Na_x^{1+}Zn_{2-2x}^{2+}B_2O_4$, although such compensation may not be necessary in the amorphous glass state. Since the compound melts so low, no problem of volatilization of Na_2O exists. Glass rods can readily be cast in platinum tubes or can be pulled from a melt.

Experimental

The constituent components used in this investigation were of the best commercially available purity, usually 99.9+% pure, and were not given any further purification treatment prior to the reactions. The rare earth oxides were obtained from the Lindsay Chemical Division; ZnO, Na_2CO_3, and H_3BO_3 were Mallinckrodt analytical reagent grade chemicals.

The constituents were weighed to the nearest 0.1 mg according to the desired stoichiometry and were well mixed. In a first step, the mixture was heated to 300°C until all water from H_3BO_3 was removed. The reaction product was homogenized at this point by ball milling under acetone in a mechanical agate ball mill. After drying, 1 in. diameter pellets were pressed under 20,000-40,000 psi. These pellets were given a final heat treatment at 600°-800°C if polycrystalline powders were desired or taken directly to 1000°-1200°C if glass rods were to be cast. Generally ½ or ¾ in. diameter Pt-tubing was used to contain the castings. After a homogeneous melt was obtained, controlled cooling took place at about 1°-2°C/min to room temperature. In each case, the platinum could be readily peeled from the glass rods. Almost invariably, sound, bubble-free rods of good optical perfection were obtained from which stress or strain as indicated under polarized light could be removed by proper annealing at about 650°C, although this proved quite difficult in some cases. Castings up to 12 in. long and ¾ in. diameter were prepared in this fashion. When rods were pulled from a melt, a temperature of 900°C and pulling speeds of ½ to 1 in./sec were found most practical. The hardness of these glasses, as determined with a Reichert microhardness tester is 6.1 mohs (as converted from Knoop). Quartz, used as a standard, gave a 752 Knoop reading, which compares well with the literature (9) value of 750. Although 6.1 mohs for these glasses is considerably softer than ruby (9.0), it is better than the generally low hardness of such single crystals as $CaWO_4$ (4.5), or $CaMoO_4$ (4.3). The surfaces of the glass can readily be polished and were not affected by 100-hr exposure to demineralized water at room temperature.

Although we were primarily interested in the characteristics of the homogeneous glasses, it was of interest to find the limits of solid solubility of the two components, $Ln_{0.5}Na_{0.5}B_2O_4$ and ZnB_2O_4, of the general composition $Ln_xNa_xZn_{1-2x}B_2O_4$. First of all, the structure of $Ln_{0.5}Na_{0.5}B_2O_4$, at least for the cases where Ln = Gd, Dy, or Er, is different from that of the cubic ZnB_2O_4. It is tetragonal with $a_t = 7.304$Å and $c_t = 8.874$Å for $Dy_{0.5}Na_{0.5}B_2O_4$. The compound $Er_{0.5}Na_{0.5}B_2O_4$ with the smaller rare earth ion gave $a_t = 7.273$Å, $c_t = 8.801$Å and $Gd_{0.5}Na_{0.5}B_2O_4$ with the larger Gd^{3+} gave $a_t = 7.375$Å, $c_t = 8.947$Å. This structure could be considered as a tetragonal distortion of the 7.473Å ZnB_2O_4 cube, which is not surprising in view of the fact that the ionic radius of Zn^{2+} (0.74) deviates considerably from the mean value of 0.92 for the Na^{1+}/Dy^{3+} pair. As a result of this discrepancy, very limited solid solubility of the two phases exists in the solid polycrystalline state. The limit of single-phase glass formation was found for all rare earth compounds to be between x = 0.2 and 0.3. Above this rare earth concentration, even at 1300°C, two phases were formed and no homogeneous glasses could be obtained. The Na compensation was retained in the glasses simply to have a precise knowledge of the compositional character, although as was stated in the introduction it may not be necessary.

Fluorescence Studies

Spectra of the polycrystalline powders were obtained in a Beckman DK2 recording spectrometer with a F4T5/BL fluorescent u.v. lamp. Spectra of the glasses were excited with a filtered AH3 mercury discharge lamp (3660Å) and recorded with a Leeds & Northrup 0.5 meter Ebert mount grating spectrometer using a 1P28 photomultiplier detector. The establishment of the optimum for fluorescent emission was based on these data and Fig. 1 gives a typical plot of the concentration dependence for the Sm system. Figure 2 shows the fluorescent emission spectrum of the optimum composition $Sm_{0.05}Na_{0.05}Zn_{0.90}B_2O_4$ at room temperature. It is rather characteristic for all rare earths in this particular host that there was neither a significant shift of emission nor any noticeable narrowing of lines in going from 300° to 77°K. Half-width of the most intense lines was generally between 50-100Å as can be seen in Fig. 3-6 for the corresponding Eu, Tb, Dy, and Tm examples. The latter was a particularly interesting example, since the blue Tm emission, stemming almost exclusively from the 4500Å line, was rather intense compared to Tm in most other

hosts. Figure 7 gives the concentration *vs.* emission curve for the Tm example.

For the purpose of a comparison, a summary of the principal emission characteristics of the five rare earths emitting in the visible is given in Table I.

Here again one can see the importance of the host as far as fluorescent emission is concerned. This was pointed out previously specifically for the case of Eu^{3+} in various hosts (6). Whereas for instance, Tb^{3+} just barely emits in a $Ca_3(VO_4)_2$ host, it is by far the most intense emitter in the ZnB_2O_4 host.

Table I. Comparison of fluorescent emission of different rare earths in the $Ln_xNa_xZn_{1-2x}B_2O_4$ system

Rare earth (Ln)	Optimum x	Strongest emission at Å	Intensity at identical slit width (0.2)
Sm	0.05	5980	20 (15)
Eu	0.30	6115	68 (130)
Tb	0.20	5425	1,140 (2,100)
Dy	0.03	5750	95 (135)
Tm	0.02	4540	56 (51)

Table II. Rare earths analysis for some cast rods

Composition	% Ln_2O_3 calc.	% Ln_2O_3 found Top	Bottom	Length of rod, in.
$Ho_{0.01}Na_{0.01}Zn_{0.98}B_2O_4$	1.25	1.27	1.24	3
$Eu_{0.20}Na_{0.20}Zn_{0.60}B_2O_4$	22.02	21.89	21.92	6
$Tb_{0.10}Na_{0.10}Zn_{0.80}B_2O_4$	11.72	11.81	11.75	12
$Nd_{0.02}Na_{0.02}Zn_{0.96}B_2O_4$	2.22	2.24	2.23	2

Since the data in Table I were not corrected for the response of the photomultiplier tube in the different spectral regions, they are merely meant to serve for a qualitative comparison. The numbers in parentheses give the intensities for the corresponding cadmium compounds and it can be seen that at least for the Tb and Eu case the intensity was twice as strong. The emission characteristics of the investigated rare earths in other single phase borates, such as CaB_2O_4, CaB_4O_7 as well as the corresponding Sr and Ba analogues, were very similar to those in ZnB_2O_4.

Analyses by x-ray fluorescence techniques were carried out for a number of cast rods, mainly to demonstrate the homogeneity, which constitutes a significant advantage over practically all single crystalline hosts, where segregation is often a severe problem. Some typical analyses for the rare earth constituents only are summarized in Table II.

Absorption spectra were run for the pure host ZnB_2O_4 as well as the Eu^{3+}, Tb^{3+}, and Nd^{3+} doped glass: ZnB_2O_4 is transparent from 2460Å to 28,500Å. The spectra of the doped materials are given in Fig. 8, 9, and 10. One can see that the Eu sample exhibits much sharper absorption characteristics than Tb^{3+} and the absorption is also considerably more intense in the region of interest for pumping. The Nd absorption spectrum will be considered in the discussion section, but it can already be stated here that the last $4F_{3/2}$ absorption level is not significantly shifted from its location around 0.88μ in most other hosts. An absorption at 0.84μ would, of course, be of interest for injection laser pumping.

Laser Experiments

The three rare earths, Nd^{3+}, Eu^{3+}, and Tb^{3+}, were selected for attempts to observe stimulated emission.

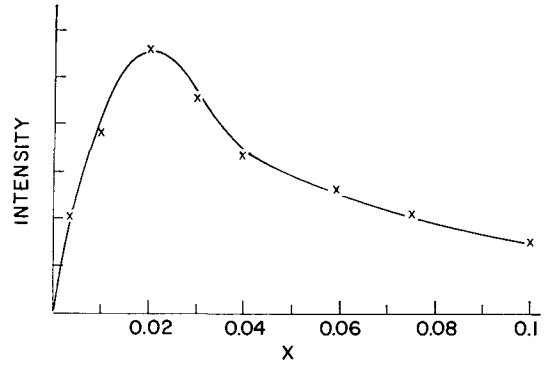

Fig. 6. Intensity of fluorescent emission as a function of x for the $Tm_xNa_xZn_{1-2x}B_2O_4$ system.

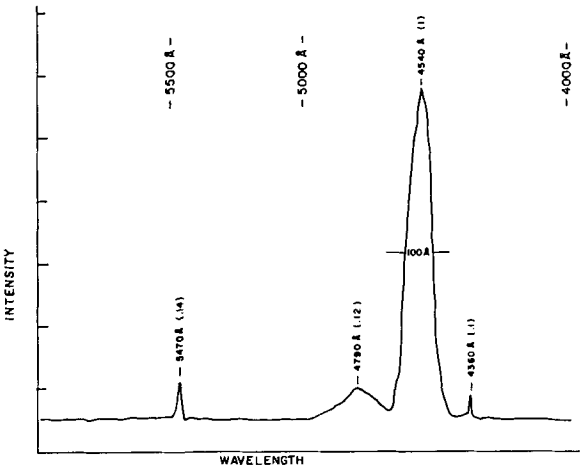

Fig. 7. Fluorescent emission spectrum of $Tm_{0.02}Na_{0.02}Zn_{0.96}B_2O_4$ at 300°K

For the Nd^{3+} case, a ½ in. long, ¼ in. diameter Fabry Perot resonator was machined by grinding and polishing. The ends had dielectric coatings for maximum reflectivity in the 1.06μ region. The composition was $Nd_{0.02}Na_{0.02}Zn_{0.96}B_2O_4$. In a Lear-Siegler LS-3 laser head with a Kemlite FT 100 B helical xenon flash lamp laser action was observed at 300°F with a threshold of 1500 joules. Due to repeated pulsing before reaching threshold, the mirror coatings were severely damaged, so that their effectiveness was probably poor. For the purpose of a comparison with an established laser material, we determined the threshold of a $CaMoO_4$: $NdNbO_4$ (1%) rod of identical size without any coatings at all. It was 500 joules. Such a rod would normally have a room temperature threshold of about 10 joules with appropriate silver or dielectric coatings. For the experiments with the visibly fluorescing composition of Eu^{3+} and Tb^{3+}, 6 in. long x ⅝ in. diameter rods were ground and polished into Fabry Perot cavities. The ends were reflectorized with dielectric coatings to give maximum reflectivity in the region of emission. The rods were placed into a Raytheon LHM-6 system, cooled to near liquid nitrogen temperature and optically pumped with 3 msec light pulses. The output from the rods was monitored at 5400Å (Tb) and 6100Å (Eu), bandwidths 60Å, with a monochrometer-photomultiplier-oscilloscope combination. Maximum storage bank energies were 24,000 joules for the Tb rod and

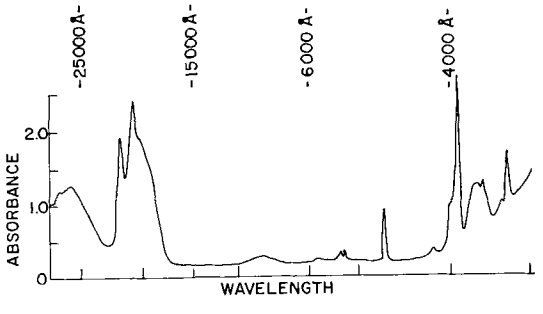

Fig. 8. Absorption spectrum of $Eu_{0.3}Na_{0.3}Zn_{0.4}B_2O_4$ at 300°K

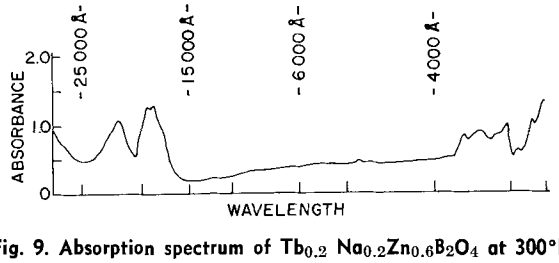

Fig. 9. Absorption spectrum of $Tb_{0.2}$ $Na_{0.2}Zn_{0.6}B_2O_4$ at 300°K

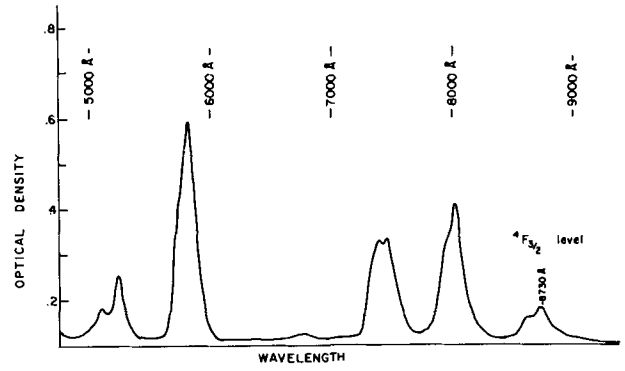

Fig. 10. Absorption spectrum of $Nd_{0.02}Na_{0.02}Zn_{0.96}B_2O_4$ at 300°K

26,100 joules for the Eu rod. In neither case was there evidence for stimulated emission.

The fluorescent signal obtained from the Tb rod was of sufficient intensity to allow an estimate of the fluorescent lifetime, which is approximately 3.3 msec at the temperature of the test.

Discussion

Rare earths in the glass-forming ZnB_2O_4 compound constitute sufficiently interesting compositions to determine as many properties as possible. Due to the isotropic nature of the glass, one can take advantage of the high Verdet constant of several rare earths and make use of the optical Faraday rotation. Since the Verdet constant increases essentially proportional to the rare earth concentration, one is only restricted by the limitation of glass formation and the relatively low density of the host. The magnetic rotation was determined for Dy^{3+} and Tb^{3+} in the compositions $Dy_{0.20}Na_{0.20}Zn_{0.60}B_2O_4$ and $Tb_{0.20}Na_{0.20}Zn_{0.60}B_2O_4$ and the results summarized in Table III. These numbers are in good agreement with those published recently by Rubinstein *et al.* (10), who studied the Faraday rotation of the rare earths in straight rare earth borate glasses. The concentrations achievable in those systems are approximately twice as high as in the ZnB_2O_4 host and therefore the Verdet constants are essentially twice the reported values here.

Thermal conductivity was measured by an absolute technique and found to be 11.5 mwatts/cm-deg which of course for laser work constitutes one of the biggest disadvantages opposite single crystalline hosts such as $CaWO_4$ or $CaMoO_4$, whose conductivities are 3 to 4 times higher. This disadvantage of low thermal conductivity may be compensated for to some degree by the low thermal expansion of about $7 \times 10^{-6}°C^{-1}$ (11). No cracking due to thermal shock was ever experienced on dropping samples directly into liquid nitrogen. The dielectric constant of the pure host was found to be 6.5 at 1 kc/sec and the refractive index, 1.64. These characteristics also compare unfavorably with most single crystalline hosts. The hardness of 6.1, however, is considerably greater than that of $CaWO_4$ (4.5) or $CaMoO_4$ (4.3) and makes polishing of these borates quite easy.

As far as the spectral characteristics of Nd^{3+} in zinc borate are concerned, we made observations similar to those of MacAvoy *et al.* (12); that is, rather intense absorption characteristics as seen in Fig. 10 coupled with quite weak fluorescence. In an attempt to

Table III. Verdet constants of Dy and Tb in ZnB_2O_4 glass

Composition	Intrinsic color of glass	Density g · ml^{-1}	Ions per ml	Verdet constants at 598 mμ min/ gauss/cm
$Dy_{0.20}Na_{0.20}Zn_{0.60}B_2O_4$	Light yellow	3.42	2.54×10^{21}	0.090
$Tb_{0.20}Na_{0.20}Zn_{0.60}B_2O_4$	Colorless	3.40	2.93×10^{21}	0.089
Barium Crown Glass (for comparison				0.022

explain this apparent anomaly, it has been suggested that some quenching process (13) intrinsically associated with the borate network is responsible. In view of the extremely small ionic radius of boron (0.23Å) the nearest Nd-Nd distance will be largely reduced in this host and a shift of the onset of concentration quenching toward lower concentrations seems likely. However, a correct assessment of the structural arrangement of the Nd and other ions in any glass is rather difficult due to the particular amorphous state of the glass, exhibiting rather random distribution of the constituent ions and only a small degree of order around ionic centers such as Nd^{3+}. A coordination number for oxygen of 8 has been suggested for Nd^{3+} in glass (12) and this should create a rather favorable situation for fluorescence. Indeed, Pearson's (14) recently observed laser oscillations in borate glasses closely related to the ones discussed in this paper, and the fact that we obtained stimulated emission in essentially a pure borate host adds another example.

Acknowledgments

The author wishes to thank Drs. P. A. Flournoy and J. C. Caris for carrying out the laser experiments.

Manuscript received May 28, 1965. This paper was presented at the San Francisco Meeting, May 9-13, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

Vapor Phase Deposition and Etching of Silicon

W. H. Shepherd

Fairchild Semiconductor, Research and Development Laboratory,

A Division of Fairchild Camera and Instrument Corporation, Palo Alto, California

ABSTRACT

A theory is developed and compared with experiment for the growth and etching of silicon in H_2, $SiCl_4$ and/or HCl mixtures. The horizontal reactor used is operated, as is usual for commercial reactors, under conditions such that the processes are mass-transport controlled. Good agreement between theory and experiment is found if it is assumed that mass transport occurs predominantly by diffusion.

The factors influencing the rate of growth of silicon by hydrogen reduction of $SiCl_4$ in an epitaxial reactor vary with the design of the reactor. In small, single wafer reactors such as described by Theuerer (1) and Tung (2) the rate of growth is found to be highly temperature dependent in the range 900°-1300°C with an apparent activation energy of 37 kcal/mole (1). A similar result has been reported for the hydrogen reduction of $SiHCl_3$, although with a smaller activation energy (3). In larger multiwafer horizontal reactors, such as have been used extensively in commercial operations, the deposition rate, at least above 1150°C, has been found to vary only slowly with temperature (4). Below 1150°C the rate becomes increasingly temperature sensitive. For example, in the reactor described in the present paper an apparent activation energy of 44 kcal/mole has been measured for the hydrogen reduction of $SiCl_4$ between 900° and 1100°C. In multiwafer reactors it appears that the characteristics of the deposition are determined at low temperatures principally by the kinetics of the surface reaction and at higher temperatures by the thermodynamic equilibria involved and by the mass-transfer properties of the gas phase.

The etching of silicon in HCl-H_2 mixtures at elevated temperatures, as shown by the present work (see Fig. 3) and by published work (5), is largely temperature insensitive in the range 1100°-1300°C, and the same conclusions may be drawn concerning the rate-controlling processes.

Theory

At least one worker in the field, Steinmeier (6), has attempted to explain the deposition of silicon from $SiCl_4$-H_2 mixtures on the basis of thermodynamics alone. Certain general characteristics dependent basically on the equilibria in the system can be described by this treatment, for example the fact that with increasing $SiCl_4$ concentrations the growth rate rises to a maximum and then decreases until etching of the silicon actually occurs. However, in order to properly understand the rate of reaction of a component of a fast moving gas stream with a surface it is necessary to take into consideration the rates of transfer of reactants and products to and from the equilibrium region at the surface. This model, *i.e.*, an equilibrium surface layer with the transfer of reactants and products into and out of the layer controlled by gas phase properties is commonly applied to many heterogeneous reactions [see for example Chapter II of ref. (7)].

Thermodynamic data are available for the chemical equilibria of interest and it is now necessary to consider a number of assumptions required to simplify a problem which in a detailed analysis is highly complex.

Under typical operating conditions (see Experimental Section) the Reynolds number for the system used in these experiments is about 20. With such a low value turbulent motions of the gas can be neglected leaving diffusion and convection as possible transport mechanisms. The diffusion coefficients for the species

of interest can be estimated to be in the range 3-10 $cm^2\ sec^{-1}$ at the reaction temperature and it is clear that diffusion must make a strong contribution to the transport process. It is much more difficult to decide if convection also should be considered. However it is assumed that diffusion is the dominant process and convection is neglected.

It is further assumed that diffusive interactions between reactant and product molecules can be ignored so that each component can be treated as if diffusing in hydrogen alone. This is a reasonable assumption for the dilute gas mixtures used. In addition, because of low reactant concentrations, high diffusion coefficients and relatively short diffusion paths, streaming corrections to the mass transport arising from net volume changes in the reactions can be ignored (8).

In the experimental reactor used the gas stream passing directly over the wafers flows through a tube of semicircular section 4 cm in diameter and 15 cm long bounded by the hot, R.F. heated wafer support and the relatively cold wall of the reactor envelope. For such a configuration, because of wall effects for example, it might be expected that across the heated surface considerable variations would exist in gas conditions, including those most responsible for influencing the rate of reaction, *i.e.*, concentrations of reactants and products, gas temperature, and gas velocity. However, it has been experimentally observed that etching and growth rates over individual wafers and over a boat load do not vary more than ±15% from the mean rate and generally only about ±10% from the mean. Still smaller variations are typical of the larger reactors designed for production operation where uniformity is a prime objective. Over-all uniformity is probably due to a delicate balance between rate controlling factors, for example the low transfer coefficients for reactants in the cold gas stream impinging on the front of the boat are balanced by the higher reactant concentrations. However, for the purposes of the treatment to follow it will be assumed that the uniformity in reaction rate implies a uniform gas pattern and reactant distribution. From this an idealized reactor can be pictured which is amenable to a very simple analysis. In such a reactor the heated susceptor and the reactor wall are infinite plane parallel surfaces, thus eliminating edge effects, and the distributions of gas velocity, temperature, and reactant concentrations are assumed to vary so little in the direction of gas flow that they can be treated as invariant. In this way the diffusion of reactants and products in the reactor need be considered only normal to the reacting surface. The simplification is not as extreme as might appear at first glance, as is discussed below.

There is some justification for assuming that the velocity profile and gas temperature in fact do not vary much along the length of the actual reactor. For isothermal flow in a tube a fully developed parabolic profile is established in a distance given by 0.05 R_e times the tube diameter where R_e is Reynold's number (9). Neglecting the non-isothermal nature of the present system and taking $R_e = 20$ suggests that the flow is fully developed in 2-4 cm and hence is stable over the great majority of the boat. As far as temperature uniformity is concerned it is observed that if the flow of hydrogen is increased from 0 to 15 liters/min (normal flow 10 liters/min) only the leading 1/5th (*i.e.*, 3 cm) of the boat is cooled by the gas stream and no effect at all is observed over the last 2/3 of the boat, indicating that the gas is substantially fully heated in the first 3-5 cm.

Derivation of Equations

Concentration gradients of diffusants.—For one-dimensional binary diffusion in the absence of thermal diffusion effects the flux toward the surface, Π, of diffusant in molecules $cm^{-2}\,sec^{-1}$ can be written (10)

$$\Pi = D(y) \cdot N(y) \frac{dx}{dy} \qquad [1]$$

where x is the mole fraction of the diffusant, $D(y)$ is the diffusion coefficient ($cm^2\,sec^{-1}$), and $N(y)$ is the gas density (molecules cm^{-3}). In the system to be considered $D(y)$ and $N(y)$ are functions of y, the distance from the surface because of the temperature gradient along the y-axis, *i.e.*, normal to the surface.

The mole fraction of diffusant, x can be replaced by p/P where p is the partial pressure of the diffusing species and P is the total gas pressure. In the system under discussion, P will be constant and equal to 1 atm so that with p expressed in atmospheres the flux can be written

$$\Pi = D(y) \cdot N(y) \frac{dp}{dy} \qquad [2]$$

Rearranging Eq. [2] and noting that, because of the assumption of one-dimensional diffusion, Π is constant at all points along the concentration gradient gives p as a function of distance from the surface of the form

$$p(y) = \Pi \int_0^y \frac{dy}{D(y) \cdot N(y)} \qquad [3]$$

For an ideal gas the density can be written

$$N(y) = \frac{N_o T_o}{T(y)}$$

where N_o is the gas density at $T_o = 273°K$. The temperature dependence of the gaseous diffusion coefficient (11) results in an expression for $D(y)$ of the form

$$D(y) = D_o \cdot \left(\frac{T(y)}{T_o}\right)^m$$

where D_o is the diffusion constant at $T_o = 273°K$ and where m normally has values between 1.75 and 2.00. The temperature $T(y)$ is that obtaining at a distance y from the surface and, as all temperatures in this paper, is expressed in °K.

Assuming a linear temperature gradient, β, and a temperature T_s at the surface gives for $T(y)$

$$T(y) = T_s + \beta \cdot y$$

where β is negative.

Substituting the above expressions for $D(y)$, $N(y)$, and $T(y)$ into Eq. [3] and carrying out the integration results in the general relationship

$$p(y) = p^* + \Pi \frac{T_o^{m-1}}{D_o N_o} \cdot \frac{(T_s + \beta y)^{2-m} - T_s^{2-m}}{\beta(2-m)} \qquad [4]$$

where p^* is the partial pressure of diffusant at the reacting surface, *i.e.*, at $y = 0$.

Material balance for the reactor.—The general material balance equation for each component is

$$R_1 - R_o = \Pi w l \qquad [5]$$

where w is the width of the susceptor and l the length, R_1 and R_o are the rates at which component molecules are swept into and out of the reactor, respectively. In computing R_1 and R_o only the reactants in the gas stream passing directly over the heated surface are considered. The fraction of the total gas stream passing over the boat is taken as the ratio of the cross-sectional area of the gas path over the boat to the total cross-sectional area of the reactor tube. In the ideal reactor described earlier the area over the boat is simply $w.a$, where a is the separation between the boat and the plane, parallel reactor wall. The value of a is chosen so that $w.a$ is equal to the area determined for the real reactor. Thus R_1 is given by

$$R_1 = F \cdot \frac{w.a.}{A} \cdot N_o \cdot p^o \qquad [6]$$

where F is the total gas flow at 0°C and 1 atm in ml/sec, A is the cross-sectional area of the reactor tube

(cm^2), and N_o is the ideal gas density at 0°C in molecules cm^{-3} atm^{-1}.

The value of R_o is obtained from

$$R_o = w \int_o^a V(y) \cdot N(y) \cdot p(y)\, dy \qquad [7]$$

where $V(y)$ is the gas velocity (cm^2/sec) at distance y cm from the surface and the other symbols are as previously described. For a parabolic gas flow between parallel plates $V(y)$ is given by

$$V(y) = \frac{6 \cdot F_m}{A\, a^2}[y(a-y)] \qquad [8]$$

where F_m is the flow rate in ml/sec at the mean gas temperature, T_m in the reactor, *i.e.*, $F_m = F\,T_m/T_o$.

The integration of Eq. [7] is laborious but straight forward and need not be elaborated on here. Substituting the result for R_o and Eq. [6] for R_1 into Eq. [5] and rearranging leads to the relationship for the flux

$$\Pi = \Psi\,(p^o - p^*) \qquad [9]$$

where the transfer coefficient Ψ is of the form

$$\Psi = N_o D_o \lambda \left[\frac{T_o^{m-1}(\Omega - \lambda\, T_s^{2-m})}{\beta\,(2-m)} + \frac{lAa^2}{6\,FT_m} \cdot D_o\right]^{-1} \qquad [10]$$

All of the symbols above have been described previously except Ω and λ which are given by the following expressions

$$\Omega = \frac{a\beta(4-m)\,(T_s^{3-m} + T_w^{3-m}) + 2(T_s^{4-m} - T_w^{4-m})}{\beta^3(2-m)\,(3-m)\,(4-m)} \qquad [11]$$

and

$$\lambda = \frac{1}{\beta^3} \cdot \left[\alpha\beta\left(T_s(\ln T_s - 1) + T_w(\ln T_w - 1)\right) + \frac{1}{2} \cdot \left(T_s^2(2 \ln T_s - 3) - T_w^2(2 \ln T_w - 3)\right)\right] \qquad [12]$$

In the above expressions T_w is the wall temperature of the reactor, hence $T_w = T_s + \beta a$.

Implicit in the above derivation of Eq. [9] is the assumption that the diffusant does not undergo reactions in the gas phase, or at least that such reactions can be neglected. Such is assumed to be the case for HCl and $SiCl_4$. However, some of the components of the system such as $SiCl_2$ and SiH_2Cl_2, which are stable in the equilibrium layer at the silicon surface, are highly unstable away from the silicon surface where the temperature is considerably lower. Such unstable products can be expected to react rapidly on the walls of the reactor or even in the gas phase. If reaction is complete within the gas phase the concentration of $SiCl_2$ falls to zero at some distance from the surface. For the purposes of the present treatment it will be assumed that the unstable product molecules diffuse away from the surface without reaction for a distance b cm where reaction then occurs so fast that the concentration becomes effectively zero. Because of the very steep temperature gradient and hence rapid decrease in the stability of the product molecules this simplification may be a good approximation to the actual situation.

If the condition that $p(y) = 0$ at $y = b$ is put into Eq. [4] the following result is obtained for the product flux away from the surface

$$\Pi = \frac{D_o N_o}{T_o^{m-1}} \cdot \frac{\beta(2-m)}{(T_s + \beta b)^{2-m} - T_s^{2-m}} \cdot p^* \qquad [13]$$

$$= \mu p^* \qquad [13a]$$

The form of transfer coefficient, μ, has been determined in this case without the need for a material balance but unlike ψ it contains an unknown quantity, b, which can be determined only by experiment.

For the conditions of etching and deposition described in this work, *i.e.*, temperatures above 1100°C and $SiCl_4$ and HCl concentrations below 1.5 mole % and 7 mole %, respectively, the only diffusants of interest are, according to data taken from the JANAF Table (12), $SiCl_4$, HCl, and $SiCl_2$. The diffusion fluxes of $SiCl_4$ and HCl are described by equations of the form of [9] while for $SiCl_2$ an equation similar to [13] has to be used. Using θ, Φ, and χ for the fluxes of $SiCl_4$, HCl, and $SiCl_2$, respectively, leads to the relationships

$$\theta = \psi_1(p_1^o - p_1^*) \qquad [14]$$

$$\Phi = \psi_2(p_2^o - p_2^*) \qquad [14a]$$

$$\chi = \mu p_3^* \qquad [14b]$$

The subscripts 1, 2, and 3 in the above and all subsequent equations refer to properties of $SiCl_4$, HCl, and $SiCl_2$, respectively.

From the condition that thermodynamic equilibrium exists at the silicon surface the surface partial pressure of $SiCl_2$, p_3^* can be written as a function of the surface pressure of HCl, p_2^*

$$p_3^* = K(p_2^*)^2 \qquad [15]$$

where K is the equilibrium constant for the reaction

$$2HCl + Si \gtrless SiCl_2 + H_2 \qquad [16]$$

A relationship exists also between the surface pressures of $SiCl_4$ and HCl, however, for the conditions of temperature and concentration used in this work, p_1^* is so small that it may be neglected entirely.

Chlorine atom balance at the silicon surface.—Here, use is made of the fact that there is no net flux of chlorine atoms at the surface. The flux of chlorine atoms toward the silicon as $SiCl_4$ molecules is 4θ, since each molecule contains four chlorine atoms. Similarly the flux as HCl is Φ and as $SiCl_2$ is -2χ. Hence from Eq. [14] through [15]

$$2\mu K p_2^{*2} - 4\Psi_1 p_1^o - \Psi_2(p_2^o - p_2^*) = 0$$

which is a quadractic in p_2^* solving to give

$$p_2^* = \frac{\Psi_2}{4K\mu}\left[\left(1 + \frac{8K\mu}{\Psi_2}\left[p_2^o + 4\frac{\Psi_1}{\Psi_2} \cdot p_1^o\right]\right)^{1/2} - 1\right] \qquad [17]$$

The total flux of silicon atoms toward the surface is simply $\theta - \chi$ hence the rate of deposition in atoms per square centimeter per second, R_D is

$$R_D = \Psi_1 p_1^o - \frac{\Psi_2^2}{16K\mu}\left[\left(1 + \frac{8K\mu}{\Psi_2}\left[p_2^o + 4\frac{\Psi_1}{\Psi_2} \cdot p_1^o\right]\right)^{1/2} - 1\right]^2 \qquad [18]$$

This equation is a general one for the rate of deposition of silicon from mixtures of both $SiCl_4$ and HCl in hydrogen. For the more normal case of growth in $SiCl_4$-H_2 mixtures, *i.e.*, $p_2^o = 0$, the result becomes

$$R_D = \Psi_1 p_1^o - \frac{\Psi_2^2}{16K\mu}\left[\left(1 + \frac{32K\mu\Psi_1}{\Psi_2^2} \cdot p_1^o\right)^{1/2} - 1\right]^2 \qquad [19]$$

For etching in HCl-H_2 mixtures, *i.e.*, $p_1^o = 0$ the result is

$$R_E = \frac{\Psi_2^2}{16K\mu}\left[\left(1 + \frac{8K\mu}{\Psi_2} \cdot p_2^o\right)^{1/2} - 1\right]^2 \qquad [20]$$

The above deposition and etching rates are in atoms cm^{-2} sec^{-1}. The multiplying factor for conversion to microns/minute is 1.2×10^{-17}.

Evaluation of equations.—To evaluate the above expressions it is necessary to know, (*a*) the equilibrium

Table I. Equilibrium constant for Eq. [16]

Temperature, °K	Equilibrium constant, K
1400	1.44
1500	1.32
1600	1.48

constant K (Eq. [16]), (*b*) the diffusion coefficients for diffusants, and (*c*) the temperature gradient in the gas.

The equilibrium constant K for Eq. [16] has been calculated using thermodynamic data obtained from the JANAF Tables (12). Values are tabulated in Table I for temperatures of interest.

The estimation of diffusion coefficients at reaction temperatures requires evaluation of D_o, the diffusion coefficient at 0°C and the parameter, m, which determines the temperature dependence of the coefficient. Figure 1 shows a plot of diffusion coefficient in hydrogen *vs.* molecular weight for a variety of organic and inorganic molecules (11). A reasonably good correlation seems to exist and this plot was used to obtain values of D_o for $SiCl_4$, HCl, and $SiCl_2$. The parameter m is quoted as having values in the range 1.75 and 2.00 (11) and, although m varies with different molecules, it will be assumed to be the same for all species considered here.

A rough estimate of the temperature gradient in the gas was obtained as follows. With the reactor evacuated the susceptor was raised to a measured temperature of about 1370°C, then, without altering the power setting of the generator, hydrogen was introduced at a typical flow rate of 11 liters/min and the new temperature (about 70°C lower) again measured. The energy radiated at each temperature was then calculated using the Stefan-Boltzmann relationship and the emissivity of molybdenum (13). The difference between the calculated and measured values was the energy conducted away in the hydrogen and using a value of 1×10^{-3} cal sec^{-1} cm^{-2} $°C^{-1}$ for the thermal conductivity of hydrogen at 1250°K (estimated mean gas temperature), the temperature gradient for a susceptor temperature of approximately 1600°K was determined to be 450°C cm^{-1} °C. For the above experiment the water-cooled susceptor support was replaced by a fused quartz holder so that the thermal environment of the susceptor was symmetrical.

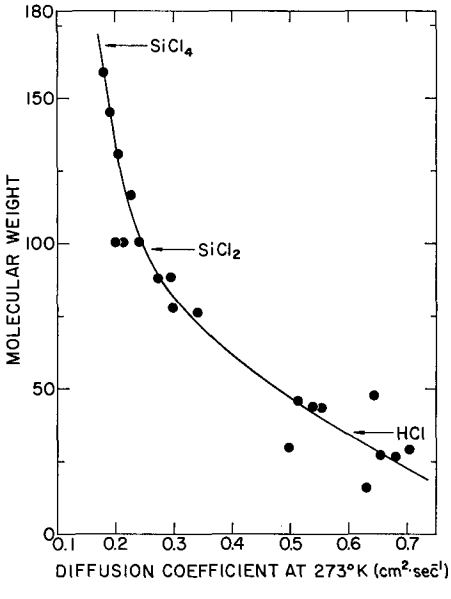

Fig. 1. Diffusion coefficient *vs.* molecular weight for a variety of organic and inorganic molecules in hydrogen at 0°C and 1 atm pressure.

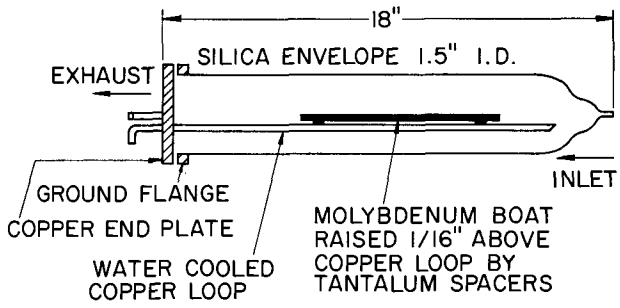

Fig. 2. Epitaxial reactor tube

Apparatus and Experimental Procedures

The reactor was of the horizontal R. F. heated type with a molybdenum susceptor 15 cm long by 3.5 cm wide on which 5-6 wafers could be placed. The essential features of the design are shown in Fig. 2. All flowmeters were calibrated using standard displacement techniques. Silicon tetrachloride was introduced into the reactor by way of a secondary hydrogen stream saturated at 0° ± 0.2°C in a stripping condenser. This arrangement was found to supply $SiCl_4$ at a rate consistent with published vapor pressure data (14) at all flows experimentally used.

For growth studies low resistivity (<0.01 ohm-cm), antimony doped, chemically polished wafers were used and deposit thicknesses were determined from infrared interference measurements. The films were 10-20 microns thick. Etching studies were made on epitaxial n-n+ wafers having 20-40 micron layers. In this way the amount removed could be determined from infrared measurements.

Experimental Results

Etching in HCl-H_2 *mixtures.*—The etching results are presented in Fig. 3 where each point represents a measurement on one wafer. Generally four runs were made at each composition, and more points are not shown because at least two wafers in each run were included for evaluation of etching quality and had no predeposited film, and other wafers gave poor infrared traces which could not be accurately interpreted.

In the temperature range investigated the etching rate is apparently not sensitive to temperature, al-

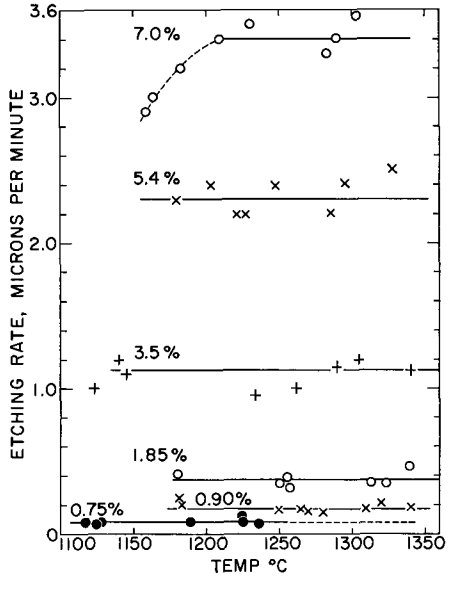

Fig. 3. Rate of etching of silicon in HCl/H_2 as a function of temperature. Numbers refer to HCl concentrations in mole %.

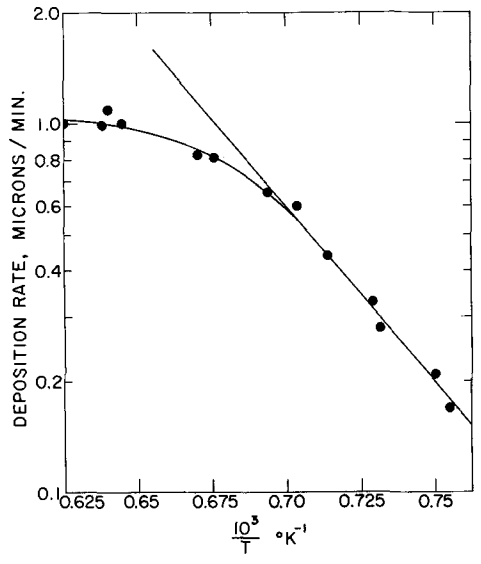

Fig. 4. Arrhenius type plot of temperature dependence of growth rate in $SiCl_4/H_2$. ΔH = 44 kcal/mole; total gas flow, 10 liters/min; $SiCl_4$ concentration, 0.48 mole %.

though the experimental uncertainty is great enough to mask a trend of perhaps 10%. At some temperatures below the lower limit in Fig. 3 a temperature sensitive region is to be expected. However, attempts to investigate this were unsuccessful due to highly preferential etching and even oxide growth which entirely eliminated etching. The oxidation was apparently due to impurities in the HCl since no visible oxide growth occurred when wafers were heated in hydrogen alone at the same temperatures, *i.e.*, 1000°-1100°C.

Growth in $SiCl_4$-H_2 *mixtures.*—Preliminary experiments were carried out to determine the temperature dependence of growth rate for the reactor. The results are shown in Fig. 4, in which the logarithm of the deposition rate is plotted against the inverse of the absolute temperature. Below about 1130°C (*i.e.*, $10^4/T \geqq 0.71$) the plot is linear and the deposition is apparently an activated process with an enthalpy of activation of 44 kcal. The enthalpy quoted by Theuerer (1) for the same reduction is 37 kcal. At higher temperatures, particularly above about 1220°C, (*i.e.*, $10^4/T \leqq 0.67$), the deposition becomes relatively insensitive to temperature. It is within this region that the theory is intended to apply and all growth data have been obtained at 1310° ± 10°C. The results of the growth rate experiments are presented in Fig. 5. Each point is a mean of values obtained on 5-6 wafers.

Growth and etching in $SiCl_4$-HCl-H_2 *mixtures.*—These measurements were made at 1300° ± 10°C. The $SiCl_4$ concentration was maintained constant at 0.40 mole % and the HCl concentration varied from 0-4 mole %. The results are shown in Fig. 6 where each point is a mean of values from 5-6 wafers.

Comparison of Theory and Experiment

For the purposes of calculation the following values are used for quantities appearing in the various equations. The reaction or surface temperature of the silicon, T_s, is taken as 1600°K and the wall temperature, T_w, as 900°K. The separation, a, between the parallel surfaces of the ideal reactor is estimated in the manner previously described as 1.6 cm, so that the temperature gradient, β, is approximately —440°C/cm. The mean gas temperature, T_m, is 1250°K, the cross-sectional area of the reactor, A, is 9 cm^2, and the gas flow at 0°C, F, is 10 liters/min (11 liters/min at 25°C).

The simplest comparison of theory and experiment can be made for growth in $SiCl_4$-H_2 mixtures. As can be seen from the experimental results in Fig. 5, the growth rate is nearly a linear function of concentration in the range investigated. This means that in Eq. [19], which expresses deposition rate as a function of $SiCl_4$ concentration, the second term is relatively insignificant and that the rate may be closely approximated by $\Psi_1 \cdot p_1^o$. Since all of the quantities which determine the magnitude of Ψ_1 are known or can be estimated independently of the experimental data a prediction of the deposition rate can be made. Taking D_o[1], the diffusion coefficient of $SiCl_4$ in hydrogen, as 0.19 cm^2 sec^{-1} (see Fig. 1) and m as 1.9, *i.e.*,

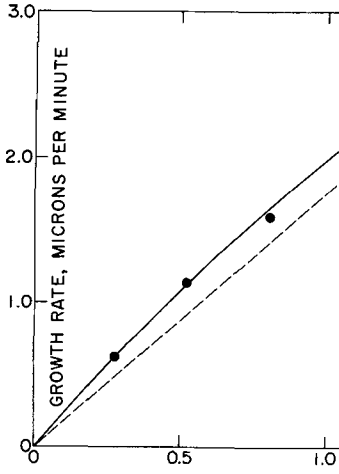

Fig. 5. Growth rate of silicon in $SiCl_4/H_2$ vs. $SiCl_4$ concentration at 1310°C (1583°K): ——, theory; •, experiment; — — —, predicted.

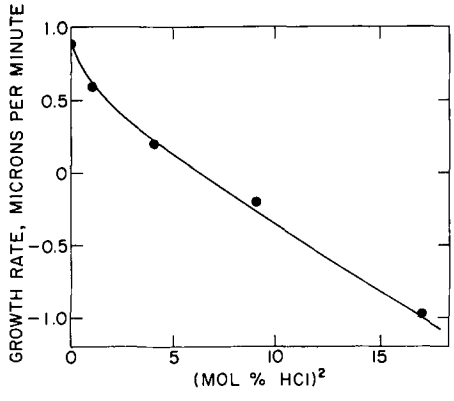

Fig. 6. Growth and etching of silicon in $SiCl_4/HCl/H_2$ at 1300°C: ——, theory; •, experiment.

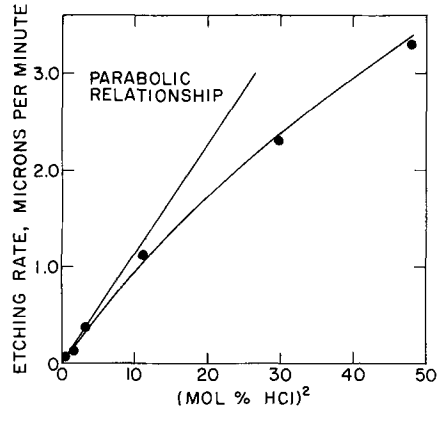

Fig. 7. Etching rate of silicon in HCl/H_2 vs. the square of the HCl concentration: ——, theory; •, experiment.

approximately the mean of the quoted range from 1.75-2.00, gives 176 microns min^{-1} atm^{-1} for Ψ_1. This result is represented by the broken line in Fig. 5, and is remarkably close to the experimental points.

A similar comparison cannot be made for etching since the relevant transfer coefficient, μ, is a function of the distance, b, which can be obtained only by experiment. However the theory can be checked by choosing μ so that a fit is obtained with experiment at one point, and observing the agreement as the etch rate is varied. The variation of etch rate with HCl concentration is sufficiently complex for this to be a good test of the form of the etching equation if not its absolute predictions. A further good test is to use the estimated value of μ to observe agreement between theory and experiment for growth and etching in $SiCl_4$-HCl-H_2 mixtures.

The coefficient μ can be obtained simply from a plot of etching rate against the square of the HCl concentration since, as can be seen from Eq. [20] as $p_2^o \rightarrow 0$, the initial slope of such a plot is $K\mu$. In Fig. 7, R_E is plotted against $(p_2^o)^2$ and the initial slope used to calculate μ is indicated.

The value of Ψ_1 to be used for further comparison of theory and experiment is taken from the initial slope of the experimental plot of growth rate *vs.* $SiCl_4$ concentration shown in Fig. 5. The transfer coefficient for HCl, Ψ_2, like Ψ_1 is described by Eq. [10]. Hence, knowing Ψ_1 it is simple to obtain Ψ_2 by substituting the diffusion coefficient of HCl, D_o^2, for that of $SiCl_4$, D_o^1, and by noting that the length, l, is now the length of etched silicon surface (always maintained at 10 cm) and not the entire heated length of the susceptor as in the case of deposition.

Using 0.60 cm^2 sec for D_o^2 the following values are obtained for the transfer coefficients: $\Psi_1 = 230$ microns min^{-1} atm^{-1}; $\Psi_2 = 507$ microns min^{-1} atm^{-1}; and $\mu = 695$ microns min^{-1} atm^{-1}. With these values, Eq. [18], [19], and [20] have been evaluated and compared with experiment. In Fig. 5 this comparison is shown for deposition in $SiCl_4$-H_2 mixtures. The good agreement observed is not surprising since the plot is only slightly sublinear and the theoretical curve is normalized to the experimental near the origin. However it is obvious that the second term in Eq. [19] is not grossly in error.

Comparison of theory and experiment for etching in HCl-H_2 mixtures is shown in Fig. 7. Again agreement is excellent and in this case more satisfying since the dependence of rate on HCl concentration is a complex one.

Theory and experiment are compared for reactions in $SiCl_4$-HCl-H_2 mixtures in Fig. 6. This, perhaps, is a better test of the equations than either of the above since now the separately determined parameters Ψ_1 and μ are both included in one equation where each has a predominant influence on the curve at different HCl concentrations, Ψ_1 at low HCl concentrations and μ at the higher ones. Again agreement is very good.

Finally now that μ has been measured it is possible to return to Eq. [13] and determine the value of b. Because of the instability of $SiCl_2$ away from the silicon surface and its expected consumption by gas phase reactions, b should be less than a, the susceptor to wall separation. In fact b is calculated to be 3 mm. Equation [13] was evaluated using $m = 2.08$ which is the value of m required to give $\Psi_1 = 230$ microns min^{-1} atm^{-1}, *i.e.*, the experimentally measured value. This is somewhat above the upper limit of 2.0 expected for m but not enough to be of great significance. The values of m for $SiCl_2$ and for HCl probably differ from the value for $SiCl_4$ but, as was pointed out earlier, it has been assumed for the purposes of simplicity that m is the same for all diffusants.

Discussion and Conclusions

It appears that for the reactor geometry and conditions investigated, and these are fundamentally similar to many that have been described, that the rates of reaction in H_2, $SiCl_4$, and/or HCl mixtures can be very satisfactorily described by the theory developed in this paper. The theory takes into account both the thermodynamic and transport aspects of the reaction processes and, since agreement with experiment is good, it is interesting to analyze the equations to determine how these two factors influence the processes.

In Eq. [19] for growth in $SiCl_4$-H_2 compositions the rate is indicated by two terms. The first term on the right hand side of the equation is the rate of transfer of silicon toward the surface as $SiCl_4$ and, apart from being proportional to pressure, is only a function of the transfer properties of the gas stream. The second term, however, contains the thermodynamic equilibrium constant, K, and hence is sensitive to the state of equilibrium at the surface. The second term increases faster than the first as the concentration of $SiCl_4$ is increased and Eq. [19] predicts a maximum in the growth rate curve and eventually a region in which etching takes place. Such behavior is in fact observed (6). However, no attempt has been made to extend Eq. [19] so far since at high reactant and product concentrations many of the assumptions of the theory are no longer valid, *e.g.*, binary diffusion.

The diffusion term for $SiCl_4$ is independent of the surface equilibrium because, under the conditions of temperature and concentration considered, the surface concentration of $SiCl_4$, although varying remains so much smaller than the inlet concentration that it can be totally ignored. At normal epitaxial deposition rates from 0-2 microns/min the second, equilibrium dependent, term in Eq. [19] can be neglected and hence it is true to state that the deposition process is mass-transport controlled since changes in temperature, gas flow rate, or other reactor variables influence the growth rate only through the transfer coefficient.

Etching in HCl-H_2 mixtures is a different situation. As has been pointed out already, Eq. [20] reduces to $R_E = K\mu(p_2^o)^2$ as the HCl concentration approaches zero, which from a practical standpoint is less than 2-3 mole %. Hence at low HCl concentrations the etching rate is proportional to the equilibrium constant, K, as well as the transfer coefficient μ. As a result the etching rate might be expected to be temperature sensitive, but, as can be seen in Table I, K is virtually constant in the temperature range of the present study, *i.e.*, 1100°-1300°C. As the HCl concentration is increased Eq. [20] predicts decreasing influence of the equilibrium constant until finally the rate is simply a function of the transfer coefficient for HCl, Ψ_2. However, as with Eq. [19], the assumptions of the present treatment invalidate predictions for high HCl concentrations.

Semiconduction in Iron Phosphate Glasses

Kent W. Hansen

Research and Development Laboratory, Corning Glass Works, Corning, New York

ABSTRACT

The electrical resistivity. (ρ), and thermoelectric power of iron phosphate glasses were measured over the temperature range 25°-400°C. The resistivity increased as the iron oxide was replaced by magnesium oxide. The resistivity also varied with the Fe^{+3}/Fe_{total} ratio in a glass containing 55% FeO-45% P_2O_5 (on mole basis); ρ passed through minimum at a Fe^{+3}/Fe_{total} ratio approximately equal to 0.5. From thermoelectric data, the glasses were determined to be p-type when the Fe^{+3}/Fe_{total} ratio was less than 0.38 and n-type at higher ratios. The results suggest that the carrier mobility is a thermally activated diffusion process similar to that proposed for crystalline transition metal oxides. The conduction activation energy pertains to mobility rather than to the formation of carriers.

Interest and activity in the field of "electronic" conduction in glassy materials have increased during the past decade. "Electronic" conduction or semiconduction is defined as electrical charge transfer by electrons (or holes) as opposed to ions.

Baynton and co-workers (1) studied the electrical resistivity of glasses in the V_2O_5-P_2O_5 system. They found that the conductivity increased with the V_2O_5 content. This was the first important work reported on semiconducting oxide glasses. The authors suggested that the conduction activation energy is the energy required to excite an electron into the conduction band. Munakata (2) measured the conductivity of vanadium-barium phosphate glasses at various V^{+4}/V_{total} ratios. He found the resistivity was a function of this ratio and that it passed through a minimum at $V^{+4}/V_{total} \approx 0.2$. The conduction mechanism was proposed to be a charge transfer between V^{+4} and V^{+5} ions, similar to the mechanism suggested for transition metal oxides such as Fe_3O_4 (3) and $Li_xNi_{1-x}O$ (4, 5).

Since then, several papers have been published on the electrical properties of semiconducting oxide glasses. Most of these suggest essentially the same mechanism as that proposed by Munakata. MacKenzie (6) has published a review that covers this work.

Very little has been done to correlate Hall effect, Seebeck coefficient, or optical data with resistivity data, to obtain a better understanding of the conduction process. This paper covers work in which a correlation is made between resistivity (ρ) and thermoelectric power (Q) in iron-phosphate glasses. Both ρ and Q were measured as a function of temperature and the ratio Fe^{+3}/Fe_{total}.

Experimental

Glasses containing 55% (FeO + MgO)-45% P_2O_5 (all percentages in this paper are on a mole basis) were melted in fused silica crucibles at 1300°C using reagent grade ferric oxide, magnesium oxide, and phosphoric acid as batch materials. The glasses were annealed between 475° and 500°C. The valence state of the iron in the 55% FeO-45% P_2O_5 glasses was adjusted by adding different amounts of dextrose to the batch. The ferric-ferrous ion concentrations were determined by dissolving glasses in HCl in an inert atmosphere, titrating for ferrous ions, then reducing ferric to ferrous, and titrating for total iron. The percentage of ferric ions, based on total iron, ranged from 4.4 to 87.6%.

X-ray diffraction patterns and transmission electron micrographs of the glasses showed no evidence of crystalline phases. It is difficult to tell from the electron micrographs whether or not a liquid-liquid separation had occurred in the glasses. If separation had occurred, at least one glassy phase is of the order of 30Å or less across.

The d-c electrical resistivity and thermoelectric power were measured as a function of temperature, ρ between 25° and 400°C, and Q between 125° and 400°C. Thermoelectric tests were limited to this temperature range because the resistivity at temperatures below 125°C was too high to obtain meaningful data, and the annealing range of the glasses was about 475°C. The thermal emf's were measured using gold as a reference, and the samples were contained in helium or air atmospheres; no differences were observed between the two ambients. The thermoelectric power was independent of temperature gradients for ΔT's up to at least 20°C.

The d-c resistance was measured across the thickness of glass plates (~2 in. × 2 in. × 3 mm). A guard-ring circuit was used to eliminate surface leakage from the measurements. Both gold and silver were used as electrode materials; essentially the same results were obtained with the two metals. The resistance between electrodes and samples was found to be negligible from data taken using a four-contact technique. Test voltages up to ~300 v/cm indicated the samples are ohmic in this region.

Results and Discussion

The specific resistivities of the glasses obey the general equation

$$\rho = \rho_0 \exp (q/kT) \qquad [1]$$

where q is conduction activation energy and ρ_0 is a constant. As can be seen in Fig. 1 and 3, there is a change in slope between 110° and 150°C. The reason for this break is not completely understood. A few possibilities include: conduction in different phases above and below the break; charge transfer between iron ions in similar positions at low temperatures, and between iron ions in different positions at higher temperatures; and predominately ionic conduction in one temperature range and electronic conduction in the other. The latter possibility is unlikely because no polarization was observed in the samples, *i.e.*, the resistance did not change with time at a constant temperature even though potentials as high as 20v D.C. were applied for 36 hr at 330°C. Under similar conditions the resistivity of a soda-lime-silica glass, Corning Code 0080 glass, increased four orders of magnitude in 64 hr.

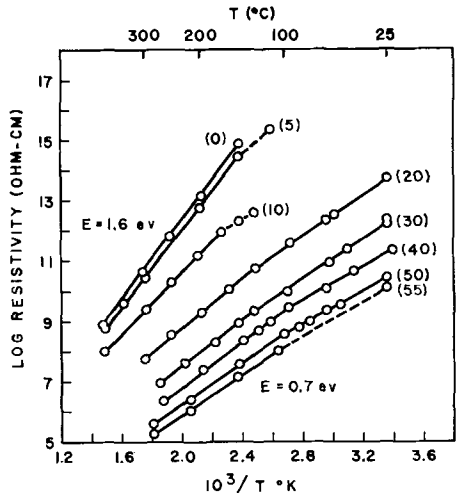

Fig. 1. Logarithm of resistivity vs. $1/T$ for glasses containing 55% (FeO + MgO)-45% P_2O_5. The numbers in parentheses are the percentages of FeO.

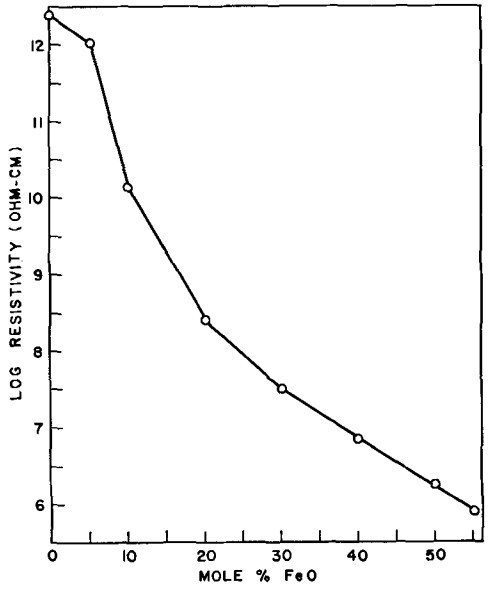

Fig. 2. Logarithm of resistivity at 200°C as function of FeO content

Figures 1 and 2 show the effect of substituting magnesium for iron at a constant P_2O_5 content. As can be seen in Fig. 2, the logarithm of resistivity varies linearly with percentage FeO, down to about 25% FeO. The activation energy is constant in the linear region and increases rapidly as FeO is decreased below 25%. The activation energy of "pure" magnesium-phosphate glass is about twice that of the 55% FeO-45% P_2O_5 glass. These results are similar to those found by Ioffe *et al.* (7) and Kitaigorodskii *et al.* (8) for V_2O_5-P_2O_5 and V_2O_5-BaO-P_2O_5 glasses, and Hansen and Cutler (9) in crystalline $Fe_{1-x}O$-MgO solid solutions. In the latter case, a sharp increase in activation energy was observed when the percentage $Fe_{1-x}O$ decreased below 14%. This was attributed to the fact that, at iron levels below 14%, there is no longer a continuous chain of iron ions by which charge transfer can occur.

The curves in Fig. 3 indicate how the resistivity varies with Fe^{+3}/Fe_{total} at a constant total iron content. This is better illustrated in Fig. 4 where the resistivities at 200°C are plotted *vs.* Fe^{+3}/Fe_{total}. The resistivity passes through a minimum similar to that found in vanadium-phosphate glasses (2). However, the minimum is at Fe^{+3}/Fe_{total} equal to 0.4-0.6 compared with a V^{+4}/V_{total} ratio of 0.2 for the vanadium containing glasses.

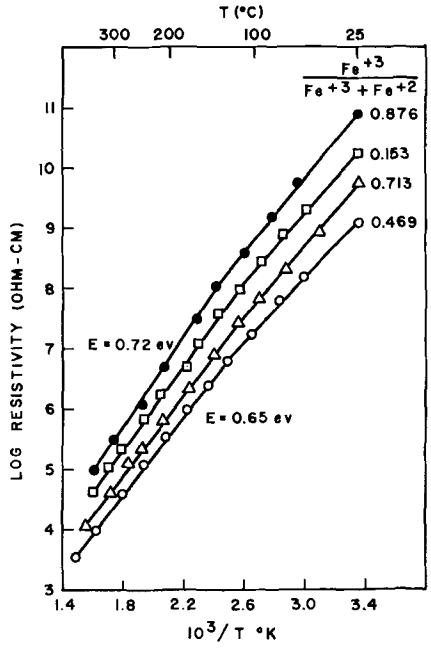

Fig. 3. Logarithm of resistivity vs. $1/T$ for representative glasses containing 55% FeO-45% P_2O_5 with various Fe^{+3}/Fe_{total} ratios.

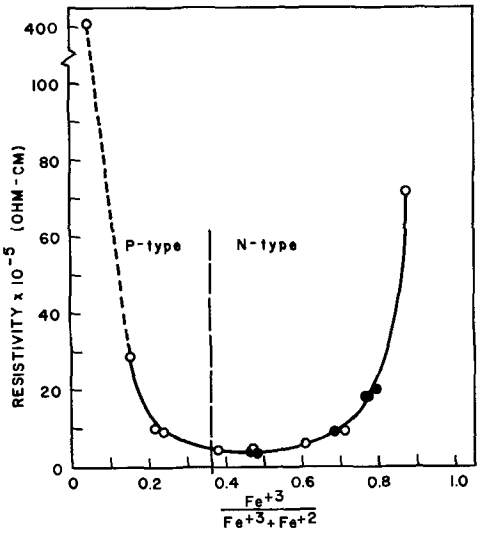

Fig. 4. The effect of Fe^{+3}/Fe_{total} on resistivity at 200°C for glasses containing 55% FeO-45% P_2O_5. • and ○ represent two different series of melts.

Like many crystalline transition metal oxides, the thermoelectric power of the glasses is essentially independent of temperature, as can be seen in Fig. 5. It has been shown in such cases that the carrier concentration (n) is insensitive to temperature (5). Then

$$n \approx N_0 \exp(-|Q|T/kT) \qquad [2]$$

where N_0 is the concentration of total available sites. Figure 6 shows how the glasses changed from n- to p-type as they were reduced, the change in sign occurring at $Fe^{+3}/Fe_{total} \approx 0.38$. Note the agreement obtained between two different sets of melts.

The results reported here and those reported for vanadium-phosphate glasses show a remarkable similarity to those found for transition metal oxides, such as the iron oxides and $Li_xNi_{1-x}O$. A conductance mechanism has been proposed by Heikes and Johnston (4) for these materials. The mechanism involves trapping of charge carriers at cation sites. The conduction mobility in this case is a thermally activated diffusion

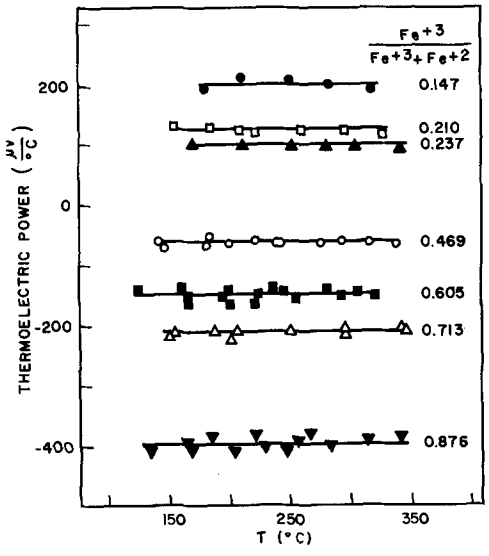

Fig. 5. Thermoelectric power vs. temperature for representative glasses containing 55% FeO-45% P_2O_5 at various Fe^{+3}/Fe_{total} levels.

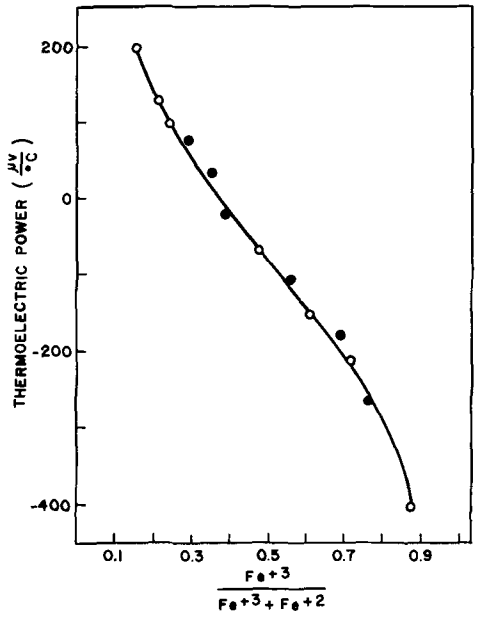

Fig. 6. Thermoelectric power vs. Fe^{+3}/Fe_{total}; 55 FeO-45 P_2O_5 at 200°C. • and ○ represent two different series of melts.

process where the activation energy pertains to the mobility. If such a mechanism occurs in the glasses, the conducting hole (or electron) must reside at a "lattice" site for a time equal to or greater than $1/\nu_0$, where ν_0 is the vibrational frequency ($\sim 10^{13}$ sec^{-1} at 400°K) of the "lattice." The mobility is then given by

$$\mu = \frac{ed^2 \nu_0 e^{-E/kT}}{kT} \quad [3]$$

where d is jump distance, E is activation energy for jump, and e is electronic charge; in this case E is the same as q in Eq. [1]. The mobilities in 55% FeO-45% P_2O_5 glasses containing 87.6 and 14.7% Fe^{+3} were calculated from the following equation

$$\sigma = ne\mu \quad [4]$$

where σ is the conductivity and n is given by Eq. [2]. N_0 was taken as the absolute difference between the ferric and ferrous concentrations. The mobilities ranged from about 10^{-10} $cm^2/v\text{-}sec$ at 400°K to 10^{-7} $cm^2/v\text{-}sec$ at 600°K. Using these mobilities and the activation energies determined from Fig. 3, vibrational frequencies at 400°K were calculated from Eq. [3]. These frequencies were 0.8×10^{13} and 1.7×10^{12} sec^{-1} for the 87.6 and 14.7% Fe^{+3} glasses, respectively. Considering that ν_0 is extremely sensitive to the conduction activation energy, the calculated frequencies are very close to the lattice vibrational frequency.

Collectively, the results are very similar to those for the crystalline transition-metal oxides. Hence, electrical conduction is probably a thermally activated diffusion process in which the electrons (or holes) migrate between Fe^{+2} and Fe^{+3} ions.

In view of the similarity between iron-containing glasses and vanadium-containing glasses, the above conduction model can probably be extended to glasses containing other transition-metal ions when the ions exist in more than one valence state.

Conclusions

1. Conductivity is proportional to the iron content in FeO-MgO-P_2O_5 glasses.
2. Resistivity is a function of the ratio Fe^{+3}/Fe_{total} in iron phosphate glasses, passing through a minimum at 0.4 to 0.6 in a 55% FeO-45% P_2O_5 glass.
3. The thermoelectric power is nearly independent of temperature in the range 125-400°C. This implies that the carrier concentration is insensitive to temperature.
4. Glasses change from n-type to p-type semiconductors as Fe^{+3}/Fe_{total} decreases below 0.38.
5. The mobilities are very low, ranging from about 10^{-10} to 10^{-7} $cm^2/v\text{-}sec$, as temperature varies from 400° to 600°K.
6. The conduction is probably a "hopping" process, *i.e.*, charge transfer between ferrous and ferric ions similar to that proposed in crystalline transition-metal oxides.

Oxygen Chemisorption Effects on Photoconductivity in Sintered Layers

Herbert Shear and Edgar A. Hilton

and Richard H. Bube

Department of Materials Science, Stanford University, Stanford, California

ABSTRACT

Processes involving the adsorption and desorption of oxygen are shown to be of basic importance for the photoconductivity properties of sintered layers of CdS-CdSe and CdSe. Annealing in the light in oxygen decreases photoconductivity and dark conductivity, whereas annealing in the dark in oxygen or in either light or dark in He increases both photoconductivity and dark conductivity. Chemisorbed oxygen decreases the dark conductivity by removing electrons from the conduction band, and decreases the photosensitivity by an effect on the free electron lifetime. The concentration of copper acceptor impurity incorporated in the layer determines the effectiveness of the adsorbed oxygen in establishing a depletion layer, particularly important in the sintered connections between individual particles.

The development of high sensitivity photoconductors of the CdS and CdSe type in single crystal form (1) led directly to the development of high sensitivity photoconductors of these materials in microcrystalline powder and sintered layer forms (2). Although the photosensitive powder differed appreciably in certain basic characteristics from the single crystals (3), the properties of the sintered layers proved to be almost completely similar to those of single crystals. The same type of impurity incorporation led to photosensitive layers, ohmic current-voltage curves could be obtained even down to the microvolt range, photovoltaic effects could be virtually eliminated, and in general the absolute sensitivity and speed of response of the layers were comparable to those of crystals. The chief differences found between sintered layers and single crystals were associated with the relative ease of incorporating high impurity concentrations in the layers; later work with high impurity concentrations in single crystals (4) re-established the close similarity of behavior. Thus in most commercial applications of photoconductors of this type, the sintered layer cell has all but dominated the field.

In spite of the close similarity between the photoelectronic properties of sintered layers and single crystals, there are several effects in the area of reproducibility and stability of the cells made from these layers, which achieve a prominence not ordinarily found in single crystals (5). These stability effects have this importance probably because of two characteristics peculiar to the sintered layers: (i) the microcrystalline or polycrystalline nature of the layers, the actual conductivity links between particles having been formed by the relatively brief sintering process; and (ii) the relatively large ratio of surface to volume as compared with single crystals.

An extensive literature exists on the adsorption of oxygen on n-type semiconductors of many different types: Ge (6-8), PbS (9-11), PbTe (12), BaO (13), ZnO (14-23), ZnS (24), CdS (25-27), and CdSe (28, 29). The significance of photoexcitation in the oxygen sorption phenomena has been investigated particularly for the last four of these compounds. Mark (27) has shown that the free electron lifetime in crystals of insulating CdS is strongly decreased by adsorbed oxygen for strongly adsorbed radiation and has substantiated a previous report (30) that a high density of electron traps can be created in certain CdS crystals by the removal of adsorbed oxygen.

Chemisorption of oxygen in such cases occurs when the oxygen accepts an electron from the crystal and becomes chemically bound in an ionic state. The result of this electronic transfer is the establishment of a depletion layer at the surface, which may reach completely across a thin insulating crystal or layer. When the conductivity path is parallel to the surface, these depletion layer effects may dominate the measured conductivity in the dark.

The results of the present investigation lead to the conclusion that such properties of sintered layer photoconductors as instability, nonreproducibility, variability through low-temperature annealing, and long-time drifts may all be attributed to the effects of adsorption or desorption of oxygen. The long-term stability of sintered layer cells is found to depend significantly on whether the cells are stored in light or dark. The room temperature properties of a sintered layer are also known to depend markedly on the exact environment of a previous low-temperature anneal (50°-250°C), *i.e.*, whether the environment involved light and oxygen or not. It is this effect of environment on the annealing of sintered layers of CdS-CdSe and CdSe that constitutes the major concern of the present investigation. It is believed that the changes that can be brought about rapidly in times of the order of 10 min by annealing at slightly elevated temperatures, are the same as the changes that occur slowly at room temperature and constitute the main source of instability and undesired change with time.

The experiments that are described in this paper demonstrate that oxygen adsorption on sintered layers of this type plays an important role in their over-all photoelectronic behavior. Even more, it is demonstrated that the "normal" sintered layer cell depends on adsorbed oxygen acting as an acceptor to achieve the high dark resistivity typical of these cells. There is at all times a two-way reaction occurring between oxygen being adsorbed on the surface and oxygen being desorbed from the surface. It is the role of the environment to cause this reaction to proceed preferentially in one direction or the other. A nonequilibrium situation at room temperature may be induced by low-temperature annealing. The slow return to the equilibrium state constitutes the observed drift of the photoconductivity with time.

A phenomenological model that considers the formation of depletion layers due to adsorbed oxygen,

particularly at the links between particles, satisfactorily describes a variety of observed phenomena.

Experimental

Apparatus.—The sintered layer to be measured was mounted in a special chamber, the atmosphere in the chamber being variable between air, oxygen, or helium, and the temperature of the layer in the chamber being rapidly variable between 25°and 250°C. The temperature of the layer could be raised from 25° to any desired temperature up to 250°C in a maximum period of about 4 min, held at that temperature for any desired time, and then quenched by water cooling of the chamber substrate to below 75°C in 15 sec.

Optical excitation of the sample was provided by a high-intensity Bausch and Lomb monochromator equipped with a 500w tungsten lamp source. The output of the monochromator was calibrated as a function of wavelength using an Eppley thermopile. The intensity of the excitation was varied over almost seven orders of magnitude, using neutral density filters Set 5A from Optics Technology and stainless steel mesh screens. All measurements were made at 25°C unless otherwise stated.

Materials.—Two types of sintered layers were investigated, one consisting of a solid solution of 45% CdS and 55% CdSe, and the other consisting of CdSe only. A mixture with $CdCl_2$ and $CuCl_2$ was sintered on a ceramic substrate by heating above the melting point of $CdCl_2$ for a short time. Although only layers prepared at hp associates are described in this paper, experience with many other layers produced by a variety of different methods and at different laboratories has established that the effects described are common to all such layers.

Ohmic electrodes of indium were evaporated onto these layers in an interdigital pattern, providing 10 individual cells in parallel, each 0.57 cm long and 0.03 cm wide. The average thickness of the layers was estimated to be about 4μ by weighing the total amount of material on several layers and determining the thickness from the weight per unit area (31).

The peak photoconductivity response for the CdS-CdSe layers at 6550Å and for the CdSe layer at 7250Å is consistent with the known bandgaps of these materials. The wavelength used in all measurement, unless otherwise specified, was 7000Å for the CdS-CdSe and 7400Å for the CdSe layers. These wavelengths were chosen to correspond to approximately homogeneous excitation of the layers, lying as they do at longer wavelengths than the absorption edge.

The layers were highly photosensitive with an electron lifetime of the order of a hundred microseconds. A photoconductivity gain of 150 was typical for 10v applied to the cell. Such data yield an electron mobility between 10 and 100 cm^2/v-sec, consistent with the results of photo-Hall measurements on similar layers (32, 33).

The starting reference for all experiments on the effect of annealing is the cell as it is received from the preparative sintering process. This means that the cell has already passed through an annealing process as it cools in air and room light after firing. By selecting cells for which the photocurrent *vs.* light intensity curve fell within certain narrow limits, however, a reliable reference could be established with which to compare the effects of later annealing. Attempts to choose a more scientifically acceptable reference condition, such as by annealing each cell in the dark at 250°C before any other treatment, proved to be less useful. Although a presumably well-defined and reproducible state of the layer could be achieved in this way, the instability of the resulting cell under normal environmental conditions at room temperature made the use of such a reference impractical.

Results

Although there are some differences in quantitative details, the over-all character of annealing effects is similar for CdS-CdSe and CdSe sintered layers. In discussing the results, therefore, the most complete data available for a given phenomenon will be presented, with comments included to indicate any difference of behavior in details with the other system.

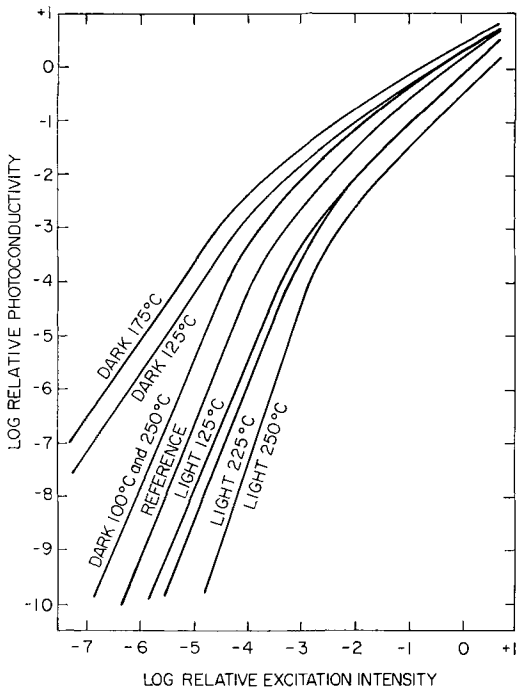

Fig. 1. Room temperature dependence of photoconductivity on light intensity after annealing at elevated temperatures in air. The illumination condition and the temperature are shown on each curve. (The light intensity used for the illumination during annealing corresponds to 0.75 on the log light intensity scale in all cases except where specified. The point 0 on the intensity scale corresponds to 1250 μw/cm^2. The point 0 on the current scale corresponds to 2.45 ma at 1.35v.)

Photoconductivity vs. excitation intensity.—The dependence of photoconductivity on excitation intensity at room temperature was one of the principal types of measurement used to determine the effects of annealing. A summary of such curves after various annealing conditions is given in Fig. 1 for CdS-CdSe layers. All annealing was done for this series of experiments in an atmosphere of air, the only variable being the presence or absence of photoexcitation.

For annealing under photoexcitation, little change occurs in a 10 min anneal until temperatures of 100°C are exceeded. For annealing at higher temperatures, the photoconductivity is reduced. The effect of increasing temperature is small between 125° and 225°C, but becomes larger again at 250°C. For annealing in the dark, quite the opposite effect is found. The photoconductivity increases with increasing annealing temperature, reaching a maximum near 175°C, and then decreases again. The effects obtained with CdSe are quite similar, except that the decrease in photoconductivity after annealing under photoexcitation is not so large.

If either CdS-CdSe or CdSe layers are annealed in He (or another inert atmosphere such as N_2) at 175°C, in either light or dark, the dark conductivity increases by many orders of magnitude and the resulting high-conductivity layer shows little change in conductivity with photoexcitation.

Reversibility of annealing effects.—The effects produced by light or dark annealing in air, as shown in Fig. 1, are completely reversible. Likewise the effects produced by annealing at a given temperature in oxygen or in helium are completely reversible. This latter reversibility is demonstrated by the dynamic curves of Fig. 2, which show the variation of conductivity under various conditions of light or dark, oxygen or

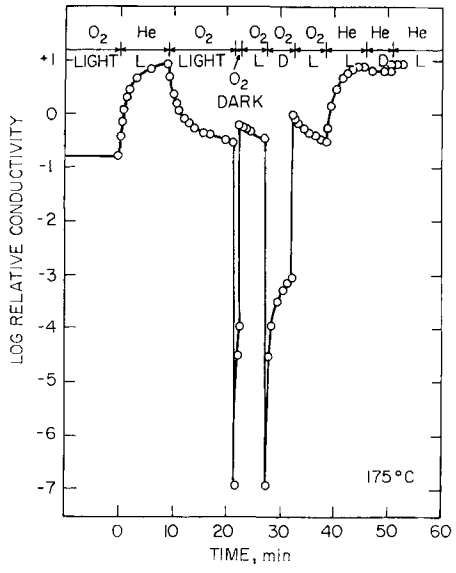

Fig. 2. Dependence of the measured current with variations in illumination and atmosphere at 175°C.

helium atmosphere, at 175°C for a CdS-CdSe layer. Quite comparable results are obtained for a CdSe layer.

The data plotted in Fig. 2 illustrate (*a*) the complete reversibility of oxygen and helium effects on the conductivity, (*b*) the effect of photoexcitation in reducing the dark conductivity of a cell in oxygen, and (*c*) the relative insensitivity of the magnitude of the conductivity in He to the presence or absence of photoexcitation.

Dark conductivity.—Although measurements of dark conductivity as a function of temperature have been made for both the CdS-CdSe and the CdSe layers, it is difficult to draw meaningful conclusions from such curves, since it is virtually impossible to separate true temperature changes of dark conductivity from temperature annealing effects. Representative data are shown in Fig. 3 for a CdS-CdSe layer. Evident from the data are the higher dark conductivity in an oxygen atmosphere produced by annealing in the dark, and also the much higher dark conductivity produced by heating in helium above 140°C. This high dark conductivity produced by a helium anneal persists practically unchanged upon cooling to room temperature in helium; at 260°C, however, the dark conductivity variations between helium and oxygen atmospheres are completely reversible, even as indicated in Fig. 2 for 175°C.

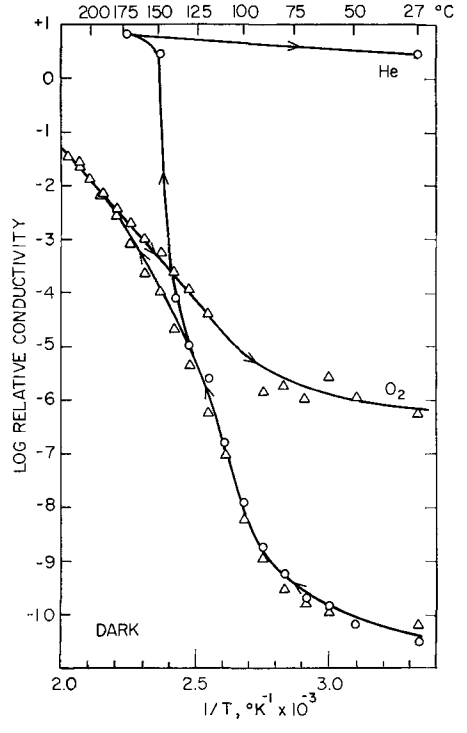

Fig. 3. Temperature dependence of the conductivity in the dark, in an atmosphere of He (○), oxygen (△).

Photoexcitation intensity effects.—The observed dependence of annealing on the intensity of photoexcitation during the annealing is shown for a typical case for a CdS-CdSe layer in Fig. 4. The results are exactly as would be expected from Fig. 1. Since annealing in the dark and in the light produces opposite changes in conductivity, there is some particular light intensity for annealing at a given temperature for which no change in photoconductivity is caused. For light intensities less than this critical intensity, the photoconductivity is increased by annealing. For light intensites greater than this intensity, the photoconductivity is decreased by annealing. For a sufficiently high intensity, the annealing effect appears to saturate.

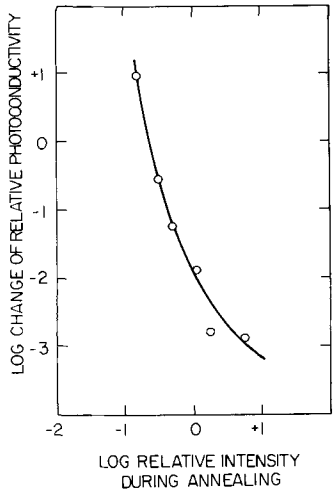

Fig. 4. Change (ratio of current after annealing to before) in the room temperature photoconductivity for a light intensity of —4.1 on the log light intensity scale, after annealing *in air* at 175°C with various intensities of illumination.

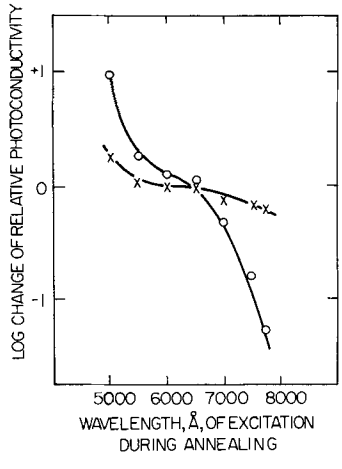

Fig. 5. Change in the room temperature photoconductivity for a light intensity of 0.15 (x) and for a light intensity of —3.6 (○) on the log light intensity scale, after annealing at 175°C in air with various wavelengths of illumination as shown. The intensity of illumination at the elevated temperature was chosen to correspond to equal photocurrent at room temperature for each wavelength.

Photoexcitation wavelength effects.—The dependence of annealing on the wavelength of the photoexcitation is shown for a typical case for a CdS-CdSe layer in Fig. 5. The magnitude of the change in the room temperature photoconductivity at two selected light intensities is plotted as a function of the wavelength used for the photoexcitation during annealing. The intensity of the light at each wavelength was adjusted to give equal photocurrents at room temperature. Wavelengths shorter than the absorption edge are less effective in producing the decrease in photoconductivity than wavelengths longer than the absorption edge. This result may be attributed to the lower efficiency of strongly absorbed light for bringing about oxygen absorption, because of the generation of holes at the surface leading to oxygen desorption as a strongly competing process.

Effects of varying copper concentration.—Additional insight into the processes involved can be obtained by examining the behavior of cells made with both less than and more than the "normal" Cu concentration (0.06 mole %). Cells were prepared of the CdS-CdSe type with 1/3, 3, and 10 times the normal Cu concentration.

Those layers prepared with 1/3 the normal Cu concentration had high dark conductivity. By annealing them in oxygen under photoexcitation, however, the conductivity could be reduced and a cell produced that had a photocurrent *vs.* light intensity curve similar to that of a normal-Cu layer. Typical curves are shown in Fig. 6.

Layers prepared with 3 and 10 times the normal Cu concentration were quite insensitive at room temperature. Their sensitivity and their dark conductivity could be increased, however, by annealing in the dark in air or in helium. Figures 7 and 8 show typical results. If the dark annealing were carried out in air, then a rather normal photocurrent *vs.* light intensity curve was obtained. If the layer were annealed in the dark in He, however, the dark conductivity increased appreciably. If the layer which had been annealed in the dark in He were allowed to stand at room temperature in the air, its properties gradually converted to a much lower conductivity, as is shown in Fig. 7. In other words, the state produced by annealing the layer with

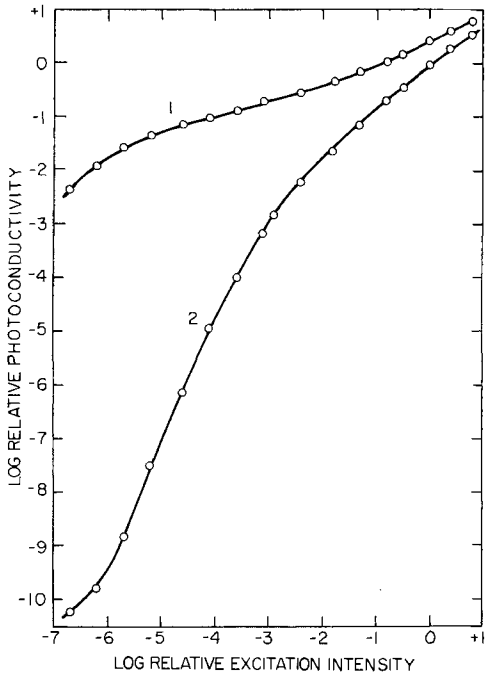

Fig. 6. Dependence of photoconductivity on light intensity at room temperature for a sintered layer of CdS-CdSe with 1/3 the normal Cu concentration, as prepared (curve 1), and after annealing under photoexcitation in air at 260°C for 12 min (curve 2).

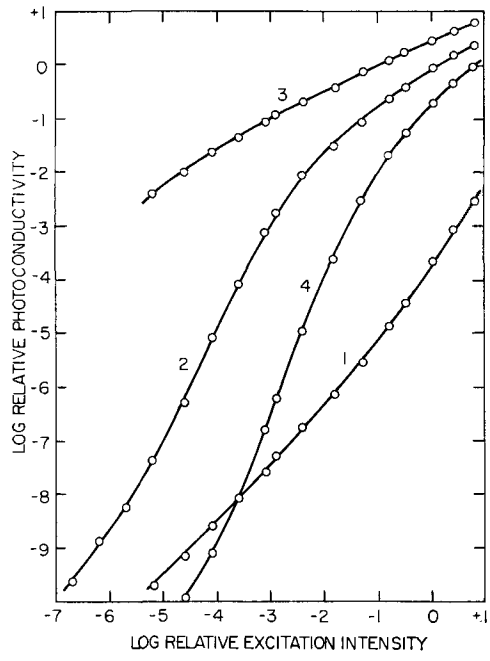

Fig. 7. Dependence of photoconductivity on light intensity at room temperature for two sintered layers of CdS-CdSe with 3 times the normal Cu concentration. The curves for both layers as prepared are given as curve 1. Curve 2 is for one layer after annealing in the dark in air at 175°C. Curve 3 is for the other layer after annealing in the dark in He at 175°C. Curve 4 is again for both layers after the passage of several days during which the cells stood in room light and air at room temperature.

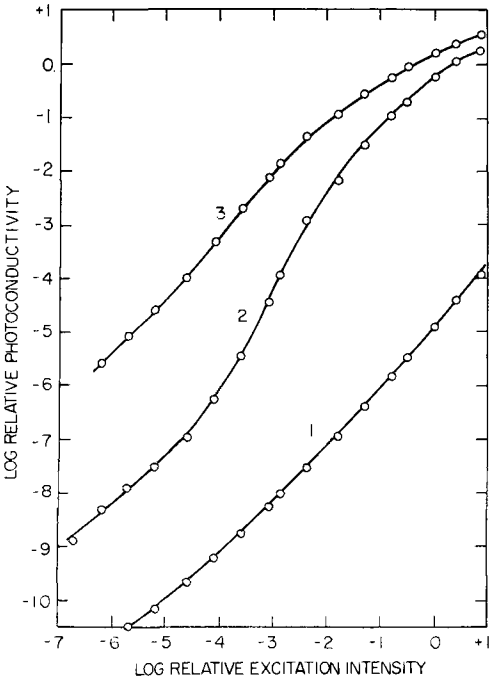

Fig. 8. Dependence of photoconductivity on light intensity at room temperature for two sintered layers of CdS-CdSe with 10 times the normal Cu concentration. Curve 1 is for both layers as prepared. Curve 2 is for one of the layers after annealing in the dark in He at 160°C. Curve 3 is for the other layer after annealing in the dark in He at 180°C.

3 times the normal Cu concentration in the dark in He was extremely unstable at room temperature in air. A curve similar to the one produced by dark annealing in air could be produced by dark annealing in He at a lower temperature than that used to produce the He curve of Fig. 7. The effect of the temperature of the

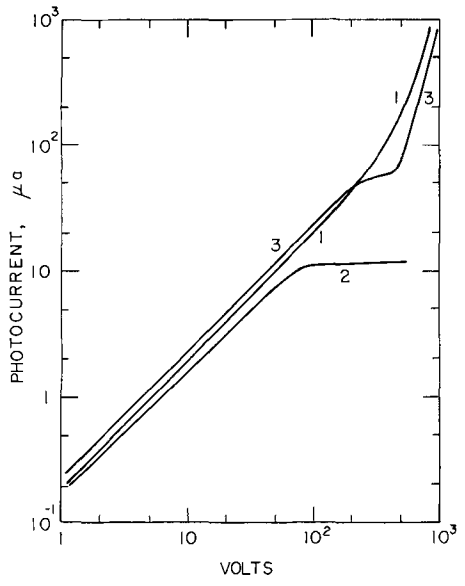

Fig. 9. Photocurrent *vs.* applied voltage for the cell corresponding to curve 2 of Fig. 6 (curve 1), to curve 4 of Fig. 7 (curve 2), and for a standard layer with normal Cu concentration (curve 3). Photoexcitation intensities were chosen to give about the same photocurrent for each cell and correspond respectively to —3.6, —1.8, and —2.9 on the log intensity scale.

dark anneal in He on the layer with 10 times the normal Cu concentration is shown in Fig. 8.

Dependence of photocurrent on applied voltage.—By the previous procedures there were available three quite differently prepared types of cell with similar room temperature dependence of photoconductivity on light intensity. The dependence of the photocurrent in the superlinear range on the applied voltage reveals the difference in these layers. Currents were chosen sufficiently low so that any heating effects in the layers would be eliminated. Results are summarized in Fig. 9, the photoexcitation intensity in each case being adjusted to give about the same photocurrent for each type of cell.

The measured current in the cell with 1/3 the normal Cu concentration, annealed in the light in air to reduce its conductivity (Fig. 5), increases very rapidly with increasing voltage for applied voltages in excess of 100v. In the layer with 3 times the normal Cu concentration, annealed in the dark in He and allowed to stand at room temperature in air (Fig. 7), the current shows a pronounced saturation with voltage for applied voltages in excess of 100v. Finally, in the layer with the normal Cu concentration a region of marked saturation is followed by a rapid increase of current with applied voltage, thus exhibiting both effects seen for the other two types of layers.

Discussion of Results

The significant features of the previous experimental results may be summarized as follows.

1. Annealing in the light in the presence of oxygen causes a decrease in photoconductivity and dark conductivity.

2. Annealing in the dark causes an increase in the photoconductivity and in the dark conductivity, regardless of whether carried out in air or in He, but the effect is more marked if carried out in He.

3. Annealing in the light in He is not substantially different from annealing in the dark in He.

4. All of the above effects are reversible. Annealing in the dark reverses the effect of annealing in light. Annealing in He reverses the effect of annealing in oxygen.

5. Annealing in the light in oxygen has a similar effect to incorporating higher proportions of Cu acceptors in the original layer material.

6. Annealing in the dark has a similar effect to incorporating smaller proportions of Cu acceptors in the original layer material.

7. Although the effects of annealing and varying Cu proportion are superficially interchangeable, the layers exhibit a different dependence of photocurrent on applied voltage depending on the actual proportion of Cu and annealing history.

All of these experimentally demonstrated features can be described by a phenomenological model of the photoconductor layer with the following characteristics. (*A*) Decreases in conductivity are associated with the adsorption of oxygen; increases in conductivity with the desorption of oxygen. (*B*) The effects of adsorbed oxygen are most pronounced at the interparticle links where the development of depletion layers by the adsorption of oxygen can lead to pinch-off of the conductivity.

The process of preparation of the sintered layers makes it a reasonable assumption that the weak links for conductivity are those regions of interparticle contact that had time to sinter in the short time the layer was held above the melting point of $CdCl_2$, the flux for the sintering process. It has been shown that actual interparticle barriers exist in the absence of sintering (3).

The dependence of photoconductivity on light intensity at room temperature shown in Fig. 1 can be described in terms of oxygen sorption effects at the elevated annealing temperature. The rate of oxygen chemisorption on the layer may be attributed to the following mechanisms: (*a*) thermally-activated capture of dark conductivity electrons by oxygen, (*b*) thermally-activated capture of photoexcited electrons by oxygen, and (*c*) thermal release of oxygen from the surface. The possibility of photodesorption of oxygen under suitable circumstances has been mentioned before in connection with Fig. 5, but is probably not a dominant process. A thermal activation step in the capture of free electrons by oxygen must be included to account for the increase in adsorbed oxygen upon annealing at an elevated temperature in light and oxygen. The data indicate that (*b*) is the dominant process below 225°C for annealing in light and oxygen. Above 225°C, process (*b*) is augmented by process (*a*) and the adsorption of oxygen becomes more pronounced. For annealing in the dark and oxygen, (*c*) is the dominant process for temperatures below 175°C, since the dark conductivity is small at lower temperatures. Above 175°C, process (*a*) favoring adsorption reverses the trend established by (*c*) favoring desorption, and the change in photoconductivity with annealing is again negative. Finally, for annealing in helium in either light or dark, process (*c*) is always dominant, and both the photoconductivity and dark conductivity are increased.

Since annealing in the dark in helium for any layer with up to 10 times the normal Cu concentration produces a high-conductivity layer, it may be concluded that the actual proportion of Cu incorporated in the layers is insufficient to give a high-resistivity layer without the contribution of adsorbed oxygen. This is consistent with the observation that the high-conductivity state can be reversibly removed by simply exposing the layer to oxygen, as in Fig. 2. Thus the high-conductivity layer with 1/3 the normal Cu concentration can be transformed to a layer with normal photoconductivity *vs.* light dependence (Fig. 6) by annealing to increase the effect of adsorbed oxygen. Similarly the layer with very low conductivity, prepared with 3 or 10 times the normal Cu concentration, can be transformed to a layer with normal photoconductivity *vs.* light dependence (Fig. 7 and 8) by annealing to decrease the effect of adsorbed oxygen.

The significance of the interparticle conductivity links is brought out in the dependence of photocurrent on applied voltage for the different types of layers. It would be expected that the applied voltage would appear principally across the interparticle links and that

one effect of increasing voltage would be to extract photoexcited holes from these links with a resultant saturation of photocurrent with increasing voltage. This effect is observed both in the layers with normal Cu concentration and in the layers with 3 times the normal concentration (Fig. 9). A second possible effect of increasing applied voltage would be to remove the pinch-off effect of the depletion layer and hence to allow an increased current to flow. This effect is observed both in the layers with 1/3 the normal Cu concentration and in the layers with normal Cu concentration for voltages greater than those involved in the saturation effect.

Acknowledgment

The authors express their appreciation to H. Bratlien who performed some of the measurements.

Photo-Hall Studies of Oxygen Adsorption Effects on Photoconductivity in Sintered Layers

Arthur L. Robinson and Richard H. Bube

Department of Materials Science, Stanford University, Stanford, California

ABSTRACT

The Hall mobility and the free electron density in sintered layers of CdS-CdSe have been measured as a function of photoexcitation intensity, temperature, and ambient atmosphere. Both free carrier density and Hall mobility are reduced by the adsorption of oxygen and increased by the desorption of oxygen. The magnitudes of the effects are such that in all cases the Hall mobility change due to adsorption contributes significantly to the photoconductivity change. Effects associated with photoadsorption of oxygen are reversible by annealing in vacuum. Results can be consistently described in terms of the model for chemisorption of oxygen on sintered layers proposed by Shear, Hilton, and Bube.

The previous paper by Shear, Hilton, and Bube (1) describes the effects of chemisorbed oxygen on the dark conductivity and photoconductivity of sintered layers of CdS-CdSe and CdSe. References to similar phenomena in other materials are also given in the previous paper. Perhaps the most closely related is the investigation of photoinduced chemisorption on insulating CdS single crystals by Mark (2). He found that the free electron lifetime for strongly absorbed light was increased by as much as 35 times by removing the adsorbed oxygen in vacuum.

In order to clarify the mechanism of the processes involved further, photo-Hall measurements were made on sintered layers as a function of photoexcitation intensity, temperature, and ambient atmosphere. By measuring the photo-Hall effect it becomes possible to tell whether a given change in conductivity is due primarily to a change in free carrier density or to a change in free carrier mobility.

Adsorption of oxygen on sintered layers of CdS-CdSe is found to decrease both the free carrier density and the free carrier mobility. Depending on the conditions, the Hall mobility change was comparable to but less than the free carrier change. The observed effects are consistent with a model for the sintered layer in which adsorbed oxygen develops depletion layers because of its acceptor behavior and thereby influences the free carrier density by decreasing the lifetime, and the free carrier mobility by introducing space-charge layer scattering.

Experimental

Apparatus.—Measurements were made in a glass Dewar capable of being evacuated and providing temperature control of a sample between room temperature and 250°C. Atmospheres in the Dewar were either air at atmospheric pressure or a partial vacuum of 10^{-1} Torr obtained with a rotary pump.

A d-c measurement technique for the Hall effect was used, similar to that described by MacDonald and Bube (3). Two Cary vibrating reed electrometers were used, one to measure the potential drop along the sample, and the other to measure the Hall voltage. All normal precautions involving reversal of applied voltage and of magnetic field were taken to insure that the Hall measurements were meaningful. A 6-in. Varian magnet giving a magnetic field of 5000 gauss was used.

Photoexcitation was by an incandescent lamp through a water filter to remove the infrared. Variations in excitation intensity were achieved with calibrated stainless steel, wire-mesh, neutral density filters.

Materials.—Measurements were made on sintered layers of $CdS_{0.45}$-$CdSe_{0.55}$ solid solution with evaporated indium electrodes, prepared by -hp associates-. These layers were prepared on a ceramic substrate with an interelectrode spacing of 6.25 mm, side probe spacing of 1.75 mm, and Hall probe spacing of 1.6 mm. All measurements were made on samples for which ohmic contact behavior had been established. An electric field of 77 v/cm was used for the measurements.

Results

The effects on the free electron density and Hall mobility of successive heating of a sintered layer under photoexcitation in air, and in vacuum, are given in Fig. 1 and 2. Figure 1 shows the variation of free electron density with photoexcitation intensity at room temperature before any annealing experiments, after heating under photoexcitation in air to 250°C, and finally after subsequent heating in vacuum to 250°C. Figure 2 shows the variation of the Hall mobility with photoexcitation intensity at room temperature for the same cycle of experiments. The net effect on the room temperature properties of heating under photoexcitation in air is to decrease the free electron density and the Hall mobility at all photoexcitation intensities. The subsequent vacuum heating restores the Hall mobility to about the same as the initial values, but actually gives a higher free electron density. This higher free electron density under photoexcitation is associated with an appreciably higher free electron density in the dark.

Typical curves showing the variation of free electron density and Hall mobility with temperature for atmospheres of air or vacuum and for extremes of photoexcitation, are given in Fig. 3 and 4. The data are for the same layer as that described in Fig. 1 and 2, the heating in air being followed by the heating in vacuum. The following observations may be

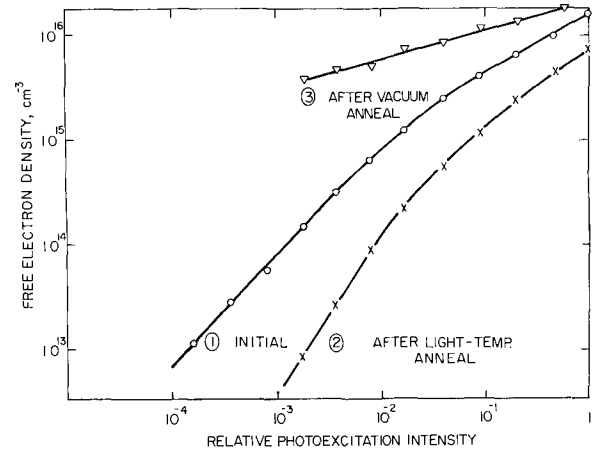

Fig. 1. Free electron density as a function of photoexcitation at room temperature: 1, initial layer; 2, after heating under photoexcitation in air to 250°C; 3, after subsequent heating of same layer in vacuum to 250°C.

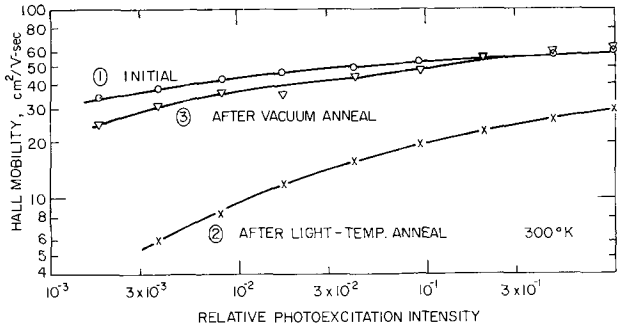

Fig. 2. Hall mobility as a function of photoexcitation intensity at room temperature: 1, initial layer; 2, after heating under photoexcitation in air to 250°C; 3, after subsequent heating of same layer in vacuum to 250°C.

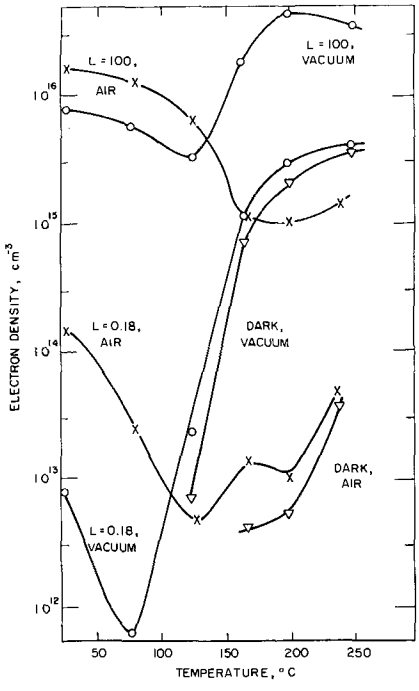

Fig. 3. Free electron density as a function of temperature under excitation conditions corresponding to dark, low intensity (L = 0.18), and high intensity (L = 100), in air and in vacuum. Measurements in vacuum were made on the layer subsequent to the measurements in air.

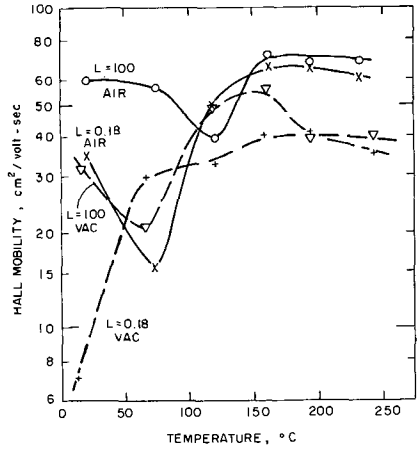

Fig. 4. Hall mobility as a function of temperature under excitation conditions corresponding to low intensity (L = 0.18) and high intensity (L = 100), in air and in vacuum.

Table I. Temperature for beginning of increase of free electron density and Hall mobility

Photoexcitation	Atmosphere	Free electron density, °C	Mobility, °C
Low	Vacuum	75	25
High	Vacuum	125	75
Low	Air	125	75
High	Air	200	125

made from these data, keeping the immediate history of the layer in mind.

1. The free electron density in the dark rises rapidly at a much lower temperature for heating in vacuum than in air.
2. The Hall mobility decreases at first with increasing temperature, but then increases with further temperature increase.
3. The temperature at which the Hall mobility starts to increase is lower the lower the photoexcitation intensity. For heating in air, for example, the Hall mobility for low intensity excitation at 125°C is higher than the Hall mobility for high intensity excitation, quite the reverse of the behavior indicated at room temperature in Fig. 2.
4. The temperature at which the Hall mobility starts to increase is lower for heating in vacuum than in air.

A summary of the temperatures at which increases in free electron density and Hall mobility are found with increasing temperature is given in Table I.

Some of the approximately reversible effects found at constant temperature are illustrated in Fig. 5. A layer held at 195°C experienced varying photoexcitation conditions and atmospheres. Both free electron density and Hall mobility are higher under photoexcitation than in the dark and both are higher in vacuum than in air.

Discussion

The previous paper by Shear, Hilton, and Bube (1) has given evidence for a decrease in photoconductivity upon photoadsorption of oxygen. The results of the photo-Hall studies show that a major part of this decrease in photoconductivity is a decrease in free electron density, through the effect of the adsorbed oxygen on the free electron lifetime as in the work of Mark (2). A significant decrease in free electron mobility also results, however, through the effect of adsorbed oxygen in buiding up a space-charge depletion layer. Space-charge layer scattering is important if the space charge region is of the same thickness as the sample, or is of the same thickness as the excitation absorption depth.

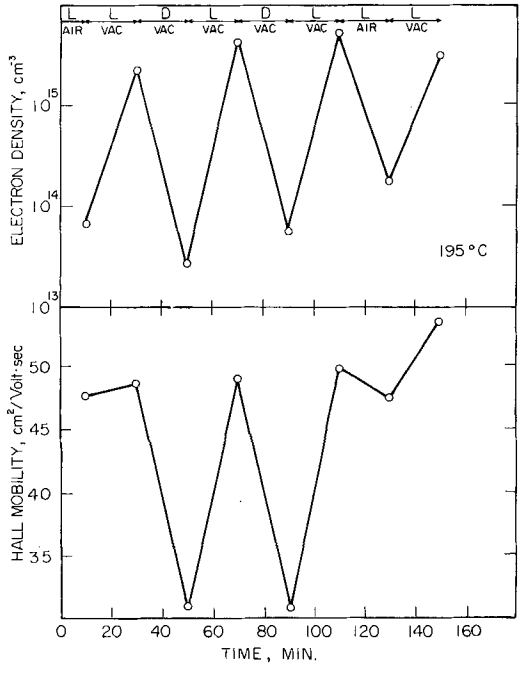

Fig. 5. Variations of free electron density and Hall mobility with photoexcitation and atmosphere changes at 195°C.

The dependence of the free electron density in the dark and under photoexcitation, and of the Hall mobility, on increasing temperature can be understood in terms of the following competing processes. (A) Adsorption of oxygen is increased by increasing temperature in the presence of photoexcitation and air, at least for an intermediate temperature range above room temperature. This effect is consistent with the observation that free electrons thermally excited over the surface barrier could contribute to increased chemisorption. (B) Thermal desorption of oxygen is increased by increasing temperature.

For heating between 25° and 75°C, the free electron density under photoexcitation and the Hall mobility decrease with increasing temperature under all conditions except that for low intensity excitation in vacuum, as shown in Fig. 3 and 4. The exception may not be valid since a very low value of mobility at low intensity excitation exists as the result of the previous heating in air. In this range there is both thermal quenching of photoconductivity in these samples and an increase in photoadsorbed oxygen.

As the temperature is raised still further, a point is reached where the rate of thermal desorption of oxygen exceeds the rate of photoadsorption of oxygen. This temperature is reached first for the measurements in vacuum, next for the measurements with low excitation intensity in air, and last for the measurements with high excitation intensity in air. The Hall mobility in sintered layers at a given temperature normally decreases continuously with decreasing light intensity (4, 5) as indicated in Fig. 2, probably because of photoneutralization of a quasi-continuous distribution of charged scattering centers. At some particular temperature, such as 125°C, for the measurements in air, however, the rate of thermal desorption of oxygen exceeds the rate of photoadsorption of oxygen at low but not at high intensities. The result is the observation of a minimum Hall mobility with decreasing light intensity, followed by an increasing Hall mobility at lower light intensities.

One remaining question is why the mobility starts to increase with increasing temperature consistently about 50° before the free electron density starts to increase. The answer is probably that two factors are decreasing the free electron density with increasing temperature, both thermal quenching of photoconductivity and photoadsorption of oxygen, but only the latter acts to decrease the mobility. As the temperature is reached for which thermal desorption is greater than photoadsorption of oxygen, the Hall mobility increases. However, the effect of thermal desorption of oxygen on the free electron density is only indirectly detectable as a decrease in the rate of thermal quenching. Since thermal quenching of photoconductivity in such materials normally involves a decrease in free electron density by four or more orders of magnitude, it is consistent with the data of Fig. 2 to attribute the much smaller effect of quenching on the compensating effect of oxygen desorption.

The relatively large increase of Hall mobility with photoexcitation in vacuum at 195°C shown in Fig. 5 suggests that photodesorption of oxygen may be a significant process. Photoexcitation in vacuum may be expected to lead to some photodesorption because of the creation of free holes that may be captured by the adsorbed oxygen ions. If this were the case, the observed recovery in the dark must be attributed to readsorption of oxygen in the relatively poor vacuum of 10^{-1} Torr, the dark electron density being high enough at this temperature to provide sufficient free electrons to participate in chemisorption of oxygen.

Acknowledgment

The authors wish to express their appreciation to Dr. P. B. P. Phipps for valuable discussions and assistance during the course of this investigation. This work was sponsored by the Army Research Office (Durham).

Manuscript received April 2, 1965. This investigation constitutes partial fulfillment of the requirements for the degree of M.Sc. in the Department of Materials Science, Stanford University (ALR).

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

New Glass Compositions Possessing Electronic Conductivities

Donald W. Roe

Electronic Components and Devices, Radio Corporation of America, Lancaster, Pennsylvania

ABSTRACT

This paper describes the use of oxides of the transition elements, V, Mo, W, Fe, Mn, and Ti, in various combinations with oxides of the alkali and alkaline earth metals and oxides of silicon, phosphorus, boron, aluminum, and zinc to produce glass compositions in which conductivity results from movement of electrons rather than ions. Conduction mechanisms in these new glasses are discussed, as well as the principles of glass formation involved in the derivation of the glass compositions.

The program described in this paper had as its goal the preparation of new oxide glasses which would have electronic conductivities ranging from 10^{-11} to 10^{-12} mho/cm. Warburg *et al.* (1) have shown that the resistance of glass films in which ions conduct the current increases rapidly with the passage of direct current. Morey (2) summarized similar results for those glasses containing sodium oxide. Tests on thin films of the new glasses with 10^{12} ohm-cm resistivity or less, however, showed essentially no change in resistance with the passage of direct current. Glasses with greater than 10^{12} ohm-cm were not tested for resistance change with passage of direct current.

Past work on oxide glasses reported in the literature shows that electronic conductivity has been achieved through the use of transition element oxides, usually in combination with modifier oxides of the alkali and alkaline earth metals. The works of interest almost all involve glasses containing V_2O_5, MoO_3, Fe_2O_3, or WO_3. Data from several of these papers will be mentioned briefly.

In 1954 Denton *et al.* (3) reported on glasses containing V_2O_5 as a transition element oxide in combination with a single other oxide that was either P_2O_5, GeO_2, TiO_2, As_2O_3, BaO, or PbO. In some applications V_2O_5 was combined with P_2O_5-BaO and P_2O_5-PbO. Conductivities ranged from 10^{-4} to 10^{-7} $(\text{ohm-cm})^{-1}$.

In 1956 Baynton *et al.* (4) reported on glasses based on Mo, W, and U. The MoO_3 glasses, in 20g batches, contained other oxides in combinations as follows: P_2O_5-Na_2O, P_2O_5-BaO-Na_2O, P_2O_5-K_2O, and Na_2O. Glass formation was also observed in the systems Li_2O-MoO_3, Na_2O-MoO_3, and BaO-MoO_3, all containing high percentages of MoO_3. Because they devitrified readily, these glasses were not made in more than 20 mg lots. The WO_3 glasses K_2O-WO_3 and Na_2O-WO_3 were also limited to this amount because they exhibited the same tendency to devitrify. The WO_3 glasses containing P_2O_5-Na_2O, P_2O_5-K_2O-Na_2O, and P_2O_5 did not crystallize; the conductivities of these glasses and the other 20g batches were of the order of 10^{-8} $(\text{ohm-cm})^{-1}$.

In 1957 Baynton *et al.* (5) reported the formation of glasses containing V_2O_5 in combination with BaO-P_2O_5 and Na_2O-BaO-P_2O_5. Conductivities were of the order of 10^{-5} to 10^{-7} $(\text{ohm-cm})^{-1}$. Also in 1957 Mazurin *et al.* (6) reported that glasses containing SiO_2, B_2O_3, Al_2O_3, CaO, and Fe_2O_3 showed electronic conductivities of the order of 10^{-10} $(\text{ohm-cm})^{-1}$ at 150°C. McMillan (7), at the VI International Conference on Glass, discussed his work in the systems MnO-Al_2O_3-SiO_2, FeO-Al_2O_3-SiO_2, CoO-Al_2O_3-SiO_2, and NiO-Al_2O_3-SiO_2; conductivities were of the order of 10^{-11} to 10^{-13} $(\text{ohm-cm})^{-1}$. MacKenzie (8) at the same conference reported on glasses composed of oxides of Fe, V, and Ti in combination with other nontransition-element oxides. Trap and Stevels (9) at the same conference, reported on the electronic conductivity of glasses that contained (*a*) iron oxides; (*b*) iron oxides, manganous oxide, and cobalt oxides; (*c*) iron oxides and manganous oxide; and (*d*) iron oxides and cobalt oxides in various combinations with oxides of silicon, boron, sodium, aluminum, calcium, and strontium.

Conduction Mechanisms

Verwey (10) mixed the oxides of two or more metals and drove one of the metal ions into different oxidation states. For example, ferric oxide mixed with small amounts of titanium dioxide (up to 1%) and fired at 1200°C in air gives a mixture whose conductivity is 0.1 $(\text{ohm-cm})^{-1}$. The conductivity of pure ferric oxide fired at 1200°C in air is 10^{-9} $(\text{ohm-cm})^{-1}$. The introduction of the titanium dioxide caused the formation of an equivalent amount of ferrous ion to give a semiconductor of the general formula

$$(Ti_x^{IV}\, Fe_x^{II}\, Fe_{1-2x}^{III})_2O_3$$

According to Verwey in inorganic oxides of a more or less polar type, a condition for electronic conductivity is that the lattice contains ions derived from the same element but of different valency in the same crystallographic position. McMillan (7) reported that thin films of MnO-Al_2O_3-SiO_2 glasses exhibited higher conductivities after they were heated in air at 400°-650°C for 4 hr. MacKenzie (8) stated that electronic conduction occurs as a result of transfer of electrons between cations of the same element in different oxidation states. Trap and Stevels (9) reported that electronic conductivity can be effected in a system of inorganic oxides by introduction of elements which are present in different valency states. They found that conductivities were extremely sensitive to melting conditions and thermal treatment during preparation.

In the work described in this paper, transition elements were used to effect electronic conduction. The ratios of the oxidation states of the transition elements were determined, it is believed, by the following factors: (i) the presence of other transition elements;

(ii) the atmospheric composition above the melt; and (iii) the basicity of the glass modifiers and glass formers. A second or third transition element was used in an attempt to drive the transition element into two oxidation states. The atmosphere above the melts during melting and homogenizing operations was provided by a hydrogen-oxygen flame slightly rich in oxygen. After the melting and homogenizing operations, the melts were allowed to cool to blowing temperature and thus approach equilibrium with the room atmosphere before resistivity measurements were made. All these glasses exhibited changes of resistivity of less than 10% after being subjected to repeated 3-4 hr cycles of melting and homogenizing. These results indicated that equilibrium with the atmosphere above the melts was closely approached during melting and homogenizing operations. According to Weyl (11), the equilibria between oxidation states of transition elements oxides are shifted toward the higher states as the basicities of the glasses are increased; thus with greater basicity of the modifier-former medium, lower electronic conduction should be observed if only the higher oxidation state is present in the original constituents of the glass.

Principles of Glass Formation

The glass compositions melted in the work described in this paper were derived from considerations of glass-structure theory. Sun's (12) classification of oxides into glass formers and modifiers was followed in the selection of oxides. Most of the glass compositions used have the Y ratio as defined by Stevels (13), in the proper range for glass formation. The Y ratio is defined as the number of bridging oxygen atoms divided by the number of glass-former atoms. For a Y ratio between 4 and 3 the glass is strong; for Y ratios less than 2, the glass is weak. Between Y ratios of 2 and 3, the cohesion of the glass network decreases rapidly. For calculation of this ratio, coordination numbers for Mo and W were assumed to be 4 as in crystals of $CaWO_4$ (14). Vanadium, titanium, boron, silicon, and phosphorus coordination numbers were taken as 4 as in Sun's article. Because the minor constituents such as Fe and Mn were present in relatively small amounts, they were not considered important contributors to the glass formers and therefore were not used in the calculation of the Y ratio.

Experimental

The melts described were prepared in 100g lots, according to standard procedures, in a 100-cm^3 platinum crucible in a hydrogen-oxygen furnace. The carbonates were used as starting materials for most modifier oxides. Foaming due to CO_2 evolution was a general rule; powders in small amounts produced less foaming than pellets. With experience the proper amounts of powders were added to minimize foaming and loss of material. Melting and homogenizing times averaged 3-4 hr each. Resistivities became constant after this time, or showed less than 10% change after 3 to 4 more hours of melting and homogenizing operations. Weight loss was approximately 2% during melting and homogenizing operations as shown by a weight test on one glass composition.

For volume resistivity measurements, "balloons" of glass were blown from the melts at the proper viscosities for gathering sufficient glass with a 1-in. quartz blowpipe. Suitable "eggshells" were cut from these balloons by use of a small hydrogen-air flame. The volume resistivity apparatus consisted of an RCA microammeter, two 45v dry cells, a mercury well, and a sleeve to contain the mercury on top of the eggshell. A grounded silver-paste ring around the periphery of the eggshell excluded surface resistivity measurements. The number of interferometric fringes for the films was measurable, but because of the color of these glasses no reliable measurements of their indices of refraction could be made. Thicknesses of the films, which were measured with a micrometer, ranged from 0.3 to 0.5 mil. Measurements of the thicknesses of the eggshells at the tips of sharp points of the smallest and flatest pieces kept the error in thickness measurements small. The errors in resistivites were caused by inaccuracies in thickness measurements.

Most glasses were melted in only one batch. When additional batches were prepared, however, resistivities were found to be within 10% of those of the previous batch.

Results and Discussion

The glasses prepared can be divided into the following groups according to transition-element oxides and the predominating glass formers: 1, vanadium - boron; 2, vanadium - iron-boron; 3, vanadium - phosphorus; 4, vanadium - iron-phosphorus; 5, vanadium - molybdenum-phosphorus; 6, vanadium - molybdenum-iron-phosphorus; 7, molybdenum - iron-boron; 8, molybdenum - tungsten-iron-phosphorus; 9, titanium - iron-boron; 10, manganese - iron-phosphorus-boron.

The mole fractions reported for these glasses were calculated from the amounts of starting materials. Properties of the glasses, where measurements were made, are discussed in their respective groups. Where the measurements were made, volume resistivities at room temperature are given, changes in resistivities after a vacuum or nitrogen bake at 400°C and after a direct current of the quantity of 10^{-3} coulomb or more per square centimeter was passed through the thin films are also given.

Electronic conductivities were observed for all the glasses of 10^{12} ohm-cm resistivity or less for the passage of direct current of the quantity of 10^{-3} coulomb/cm^2. Less than 25% changes in conductivities were observed for all the glasses of 10^{12} ohm-cm resistivity or less after the passage of direct current of the quantity of 10^{-3} coulomb/cm^2. In Fig. 1 illustrations of the conductivity changes for a glass with ionic conductivity and for a glass with mainly electronic conductivity but with some ionic conductivity can be seen. This figure shows the current (direct) as a function of time at room temperature for a glass with ionic conductivity (composition as given in Table I) and for glass No. 9, Table III, a glass with mainly electronic conductivity. The conductivity of the glass of composition given in Table I increased rapidly with passage of direct current for 65 hr to give a conductivity 5% as large as in the beginning. Glass No. 9, Table III, after 65 hr of direct current passed, had a conductivity 79% as large as in the beginning, indicating a much smaller amount of ionic conductivity than with the Table I composition. The glass whose composition is given in

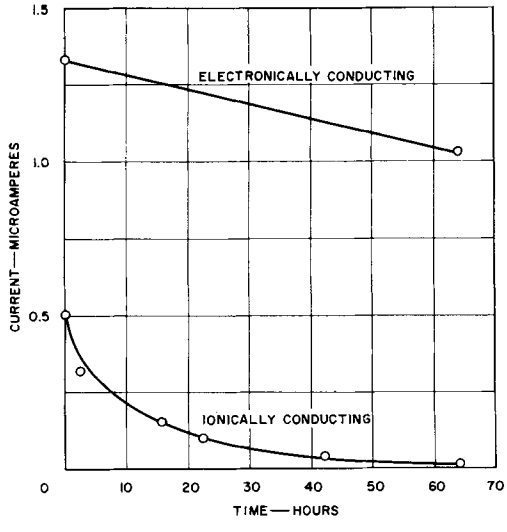

Fig. 1. Comparison of the conductivities of a typical ionically conducting glass (Table I) and an electronically conducting glass (Table III, glass No. 9).

Table I. Composition of a typical ionically conducting glass

Compound	Weight-per cent
Silicon dioxide (SiO_2)	66.59
Iron oxide (Fe_2O_3)	0.045
Aluminum oxide (Al_2O_3)	2.93
Titanium dioxide (TiO_2)	0.017
Calcium oxide (CaO)	7.40
Barium oxide (BaO)	0.08
Magnesium oxide (MgO)	3.83
Sodium oxide (Na_2O)	17.54
Potassium oxide (K_2O)	0.91
Sulfur trioxide (SO_3)	0.04
Arsenic pentoxide (As_2O_5)	0.41
Antimony pentoxide (Sb_2O_5)	0.04
	99.832

Table I has no transition element oxides and has a large mole fraction of Na_2O to give appreciable conductivity by ionic migration of sodium ions. This ionic migration results in a rapid increase of resistance with passage of current.

Conductivities at higher temperatures than room temperature were not measured. Thus activation energies of conduction could not be determined.

No conclusions concerning the effect of a second or a third transition element oxide or the effect of different basicities of the nontransition element oxides could be made from an examination of the tables.

Vanadium-boron glasses.—Twelve melts of vanadium-boron glasses were prepared. Table II shows compositions in mole fractions, melt devitrification results, and resistivities obtained for these glasses.

Devitrification was a problem with five of these glasses. Some relationships between devitrification and the number of constituents of the glasses and the amounts of constituents can be seen from an examination of Table II. Two of the glass compositions that devitrified, No. 9 and 11, had four components, the smallest number in the table. Glass No. 8, another that devitrified, had a small amount of BaO present. A comparison of glass No. 10 with glass No. 5 shows that the latter, which devitrified, had slightly less ZnO. Glass No. 5 and glass No. 4 were similar except that glass No. 5 had no Na_2O and more BaO, ZnO, and CaO than glass No. 4. Glass No. 5 devitrified and glass No. 4 did not.

Resistivities of these glasses can be related to the amount of V_2O_5 present if the compositions are otherwise similar. Glass No. 2, which was very similar in composition to No. 4 except that it had more B_2O_3 and less V_2O_5, had a higher resistivity as expected. The resistivities of glasses No. 7 and 12, a similar pair, are anomalous since glass No. 12 should have a lower resistivity than No. 7, because it had more V_2O_5. Another resistivity anomaly is that glasses No. 7 and No. 12 had a higher resistivities than glass No. 4 even though both glasses No. 7 and No. 12 had more V_2O_5 and less Na_2O than No. 4. The lower Na_2O content in glasses No. 7 and No. 12 should promote more of the lower oxidation state of V_2O_5 in glasses No. 7 and No. 12 than in glass No. 4, and thus give a lower resistivity for No. 7 and for No. 12.

* Melt devitrified.

Devitrification was not a severe problem with these compositions. Only glass No. 12 devitrified. It had the least number of components of any glass in the table.

A test to determine weight loss of a melt was made with these glasses. Glass No. 14 lost only 2% of its total calculated final weight after 72 hr at 800°C.

Several resistivity relationships were observed with these glasses. Glasses No. 3, 5, 7, 8, 9, and 10 had essentially the same mole fractions of modifiers, but differed in amounts of V_2O_5 and B_2O_3. Figure 2 shows that a straight line relationship (except for glass No. 5) exists between the mole fractions ratio B_2O_3/V_2O_5 and the log of the resistivity. This ratio is believed to be significant because B_2O_3 competes with V_2O_5 for the position of glass former. Glasses No. 4, 11, and 13 form a series in which the mole fractions of modifiers are essentially the same and the ratio B_2O_3/V_2O_5 differs. For glasses No. 4, 11, and 13 a plot of the ratio B_2O_3/V_2O_5 (2.48, 2.39, 2.27 for glasses No. 4, 11, and

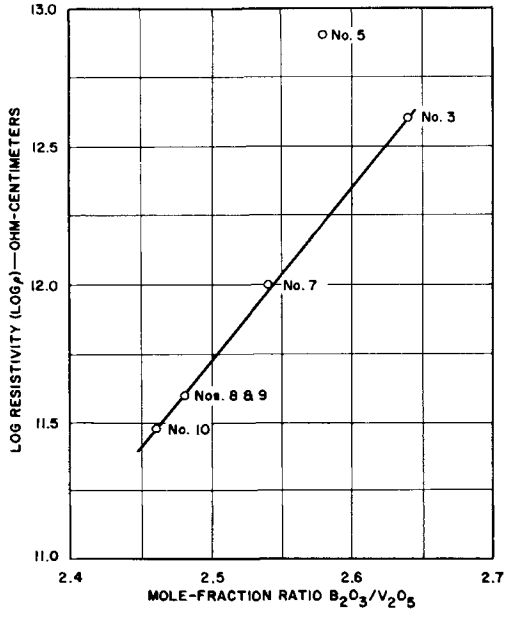

Fig. 2. Resistivity as a function of the mole-fraction ratio B_2O_3/V_2O_5 for the vanadium-iron-boron glasses No. 3, 5, 7, 8, 9, and 10 in Table III.

Table IV. Compositions and resistivities of vanadium-phosphorus glasses

Glass No.	Mole fraction V_2O_5	P_2O_5	CaO	MgO	Volume resistivity (ohm-cm) × 10^{11}
1	0.051	0.618	0.296	0.036	50
2	0.083	0.599	0.301	0.017	5
3	0.110	0.572	0.300	0.018	3
4	0.162	0.518	0.302	0.018	0.06

13, respectively) against log resistivity did not give a straight-line since the resistivity of glass No. 4 was less than that of No. 11 and 13 and not greater as it should have been according to the B_2O_3/V_2O_5 ratio and according to the amount of V_2O_5 present. A comparison of glasses No. 16 and 17 shows that the resistivity decreases slightly with a lower calcium oxide and a higher barium oxide content. The effective higher basicity because of the increased barium oxide should increase the resistivity, however, since more of the higher oxidation state of V_2O_5 is expected.

Vanadium-phosphorus glasses.—Table IV shows the data obtained on 4 vanadium-phosphorus glasses. These glasses were of good quality as thin films and were easy to prepare as melts. Glass No. 4, after being vacuum baked at 400°C for 1 hr, showed a 20% decrease in resistivity. The resistivities of these glasses decrease as the mole fractions of V_2O_5 are increased as shown in Fig. 3. It is remarkable that this straight-line relationship exists for two reasons: (*A*) the compositions differ widely; and (*B*) plot of the mole fraction ratio P_2O_5/V_2O_5 as a function of resistivity is not a straight line.

Vanadium-iron-phosphorus glasses.—Table V presents data on vanadium-iron-phosphorus glasses. Although these glasses were generally of good quality when blown into thin films, they were all on the verge of devitrification in the melt at temperatures at which the viscosity was suitable for blowing bubbles. Without exception the resistivities decreased as the mole fraction of V_2O_5 increased. A plot of mole fraction of V_2O_5 as a function of log resistivity shows essentially a straight-line relationship, as shown in Fig. 4. It is again remarkable that this condition exists, for the same reasons as given for the preceding group of glasses.

Vanadium-molybdenum-phosphorus glasses.—Table VI lists data for two vanadium-molybdenum-phosphorus glasses. These two glasses were of good quality as thin films.

Vanadium-molybdenum-iron-phosphorus glass.—Table VII shows the composition and resistivity of one

vanadium-molybdenum-iron-phosphorus glass. This glass was also of good quality as a thin film.

Molybdenum-iron-boron glasses.—Table VIII lists the compositions of two molybdenum-iron-boron glasses. The resistivities of these glasses could not be measured because the melts crystallized on cooling to temperatures at which the viscosities of the glasses would be suitable for bubble blowing.

Molybdenum-tungsten-iron-phosphorus glasses.—Table IX lists the mole fractions and resistivities of five molybdenum-tungsten-iron-phosphorus glasses. The resistivity of glass No. 3 remained the same after 24 hr at 400°C in a nitrogen atmosphere.

No significant resistivity relationships could be determined, primarily because of the presence of three transition elements and also because of wide differences in the compositions of these glasses. The resistivities of glasses No. 1 and 2 were the same even though the compositions differed appreciably; the CaO content was reduced and the MoO_3, Fe_3O_4, and WO_3 contents were doubled for glass No. 2. Glasses No. 3 and 5 had almost the same composition and resistivity. Glass No. 4 had almost the same resistivity as Nos. 3 and 5; however, it had less CaO, WO_3, and Fe_3O_4, no BaO, and much more MgO. Apparently the lower basicity of No. 4, a result of the increase in MgO, compensated for the lower concentration of WO_3 and Fe_3O_4 to provide almost the same resistivity.

Titanium-iron-boron glasses.—Table X, lists the compositions of two titanium-iron-boron glasses. Because of inhomogeneities, neither of these glasses was satisfactory for bubble formation. A white grainy structure resulted when composition No. 1 was heated in an attempt to dissolve the TiO_2. At this temperature copious evaporation of P_2O_5 also occurred. Neither of these compositions showed glass formation.

Manganese-iron-phosphorus glass.—Table XI shows the composition of the manganese-iron-phosphorus glass. This glass was grain and crystal-free above 1100°C; however, its viscosity was too low for bubble blowing. Below 1100°C crystals formed in the glass melt.

Conclusion

Most of the compositions described in this paper yielded good-quality glasses in the melt. The principles of glass formation discussed appear to be valid for these glass compositions. In those glasses with 10^{12} ohm-cm resistivity or less electronic conductivity was shown to predominate for the quantity of current passed. Ionic migration, although not completely eliminated, did not contribute appreciably to the conduction in the glasses of 10^{12} ohm-cm resistivity or less.

Acknowledgments

The author wishes to express his appreciation to William Kramer for helpful discussions and to Ronald Straley for experimental assistance.

Segregation of Silicon in Gallium Phosphide

M. Rubenstein

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

Gallium phosphide was prepared using a horizontal refining technique. The liquid zone was maintained close to the stoichiometric composition. An ingot, doped with silicon, was zone refined. From electrical, optical transmission, and spectrochemical measurements, it is demonstrated that silicon (at concentrations in the range of 10^{18} at./cc) is a donor impurity with an activation energy of 0.06 ev, that silicon substitutes for gallium, and that the segregation coefficient for silicon in GaP is 0.6.

Gallium phosphide (GaP) has been prepared in a number of laboratories from a stoichiometric or nearly stoichiometric melt (1, 2). In this paper such an ingot was prepared using the horizontal zone melting apparatus sketched in Fig. 1. In this apparatus a molten zone is passed through an ingot. If there is an impurity in the GaP, this impurity will tend to concentrate either at the beginning or end of the ingot, depending on whether the segregation coefficient is greater than or less than unity, respectively (3). Since zone refining has produced no great purification in the case of GaP one is led to believe that most impurities which are ordinarily encountered in the preparation of GaP do not have segregation coefficients much less or much greater than unity. In this paper an ingot of GaP, which will be called R-53, was heavily doped with silicon and then the ingot was zone refined. This ingot was then analyzed so that various conclusions could be drawn concerning silicon in GaP.

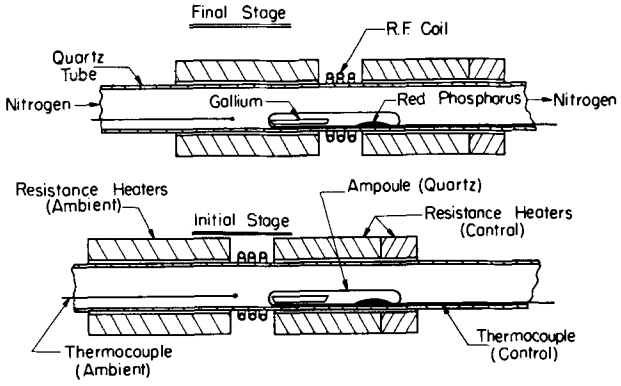

Fig. 1. Schematic view of the furnaces used in the preparation of GaP ingot R-53.

Experimental

Gallium phosphide ingot R-53 was prepared in the following manner. A quartz ampule was sealed at a pressure of 10^{-6}-10^{-5} Torr. Contained in this ampule were weighed amounts of gallium in a boron nitride (BN) boat and phosphorus. The weight of red phosphorus was 10% in excess of the amount necessary to convert all the gallium to GaP plus the amount of phosphorus necessary to maintain the pressure of 16 atm in the ampule.

This ampule was then placed in the furnaces as indicated in Fig. 1 (initial stage). The two resistance heaters determined the phosphorus pressure (the temperature at the right end of the ampule was maintained as the lowest in the ampule). The heating of the gallium and GaP (when it formed) was accomplished with a 10 kw 4 megacycle radio frequency (r-f) generator. The ampule and the boat containing the gallium rested on quartz cradles to prevent the ampule walls from becoming too hot. Nitrogen gas was slowly passed down the outer quartz tube in order to cool the ampule walls. The use of the cradles and the nitrogen was to allow the walls of the ampule to remain cool enough to maintain the pressure of 16 atm while a liquid zone was maintained at about 1500°C.

The phosphorus used in preparing this ingot was purified by aqueous acid treatments, by steam distillations, and by vacuum distillations. The analysis indicating the purity of the phosphorus is shown in Table I.

Table I. Spectrochemical analyses

	Mg	Fe	Al	Cu	Ca	Na	C	B	Si
Phosphorus used in R-53	0.5	ND < 3	ND < 6	ND < 0.5	ND < 0.8	—	98	ND < 14	12
Ga used in R-53									
before degassing	1	ND < 1	ND < 3	ND < 0.3	ND < 2	—	ND < 28	ND < 30	ND < 5
after degassing	2	ND < 1	ND < 3	3	ND < 2	—	ND < 28	ND < 30	ND < 5
GaP section 1	P < 4	P < 9	P < 19(14)	ND < 2	5	—	84	ND < 28	47
section 2	P < 4	P < 9	P < 19(15)	ND < 2	P < 5	ND < 20	76	306	29
section 3	P < 4	ND < 9	ND < 19	ND < 2	P < 5	P < 20	125	52	57
section 4	P < 4	P < 9	P < 19	P < 2	P < 5	P < 20	67	38	129
section 5	P < 4	P < 9	P < 19	2	P < 5	P < 20	285	77	410
section 6	P < 4	P < 9	P < 19	P < 2	P < 5	—	100	92	1,200
section 7	P < 4	P < 5	P < 19	P < 2	6	P < 20	76	120	2,250
section 8*	7	306	ND < 19	46	—	—	—	875	19,200

Detectable limits of other elements checked but not detected:

	Pb	Mn	Sn	Ag	Ba	Se	Na	Li	K	Zn	Cd	Hg	Cr	Sb	Be	Ge
P	1.5	1	1	0.5	2	20	13	9	8	1.5	0.5	15	3	5	—	—
Ga	5	2	1	0.1	1	2	10	20	5	1	0.5	1	1	5	—	—
GaP	5	2	8	2	2	5	20	15	26	5	1	15	10	20	11	15

P indicates that the element was detected but at or just below the limit of detection (beyond the standard curves). Quantities in parentheses are estimations. ND indicates that the element was not detected. All values above are expressed in atomic parts per million.

* Section 8 was a slice taken beyond the slice of section 7. Section 8 was at a distance of 5.7; section 7 was at a distance of 5.2 (see Fig. 6).

Table II. Spectrochemical analysis of boron nitride (expressed in atomic ppm)

	Ca	Si	Al	Fe	Mg
Untreated	6×10^3-6×10^4	2×10^2-2×10^3	60-600	30-300	30-300
Treated	4×10^1-4×10^2	2×10^2-2×10^3	60-600	30-300	3-30

The gallium used was Alcoa 99.9999% material. The analysis for the gallium used is presented in Table I.

In preparing the reactants for this experiment, the gallium was degassed at 800°C for 3 hr at a pumping pressure of about 10^{-5} Torr. The gallium was contained in a quartz boat during this operation. Table I indicates that the silicon concentration in the gallium after degassing was less than 5 ppm (this value was due to improper sampling). The gallium used to prepare the GaP did contain an appreciable amount of silicon (as a two-phase sample). The degassing operation itself incorporated silicon in the gallium by the actual reduction of the quartz (4). However, this silicon was not dispersed throughout the gallium, but was concentrated over a small area on the surface of the gallium. Therefore, using "normal sampling techniques" on the gallium (taking chips from a few sections of the ingot) did not show the large amount of silicon in the gallium ingot. The silicon concentration in the gallium as indicated in Table I is not the real silicon concentration, but the concentration of silicon as indicated using normal sampling techniques.

The boron nitride (BN) boat was machined from a rod and extensively extracted with methanol to remove B_2O_3 and any other impurities which would extract with the methanol treatment. Table II contains an analysis of the BN before and after the treatment with methanol.

Weight losses of 6-7% during the methanol extraction were usual. Almost all of this weight loss was due to the extraction of oxides. B_2O_3 and CaO are both extracted by methanol.

In preparing GaP ingot R-53, a 4 megacycle r-f generator supplied power through a 3 turn work coil. Several mixing zones were passed through the contents of the BN boat at a speed of 1.25 mm/min to react the gallium and phosphorus. Ten refining zones were passed through the GaP at a speed of 0.13 mm/min. The phosphorus pressure during the refining passes was 16 atm. The length of the zone was approximately 2.5 cm. The dimensions of the ingot were $15 \times 1.4 \times 1.2$ cm.

All measurements were made on slices cut perpendicular to the long axis of the ingot. The slices were taken at positions as indicated in Fig. 6.

Spectrochemical analyses.—The impurities in this ingot (see Table I) are primarily silicon, boron, and carbon. One could assume that the iron, magnesium, aluminum, and calcium impurities came from the BN boat (see Table II). The copper impurity could come primarily from the degassed gallium. The sodium impurity could come from any of the sources since sodium determinations were not made on all samples concerned. Since the concentration of silicon is very high in section 8 (see footnote in Table I), it is possible that in this portion of the ingot there are separate silicon and GaP phases. This could account for the unusually high concentrations of magnesium, iron, copper, and boron in slice 8.

Table III. Electrical measurements for R-53

Section	Distance along ingot, x	Temp, °C	Resistivity, ohm-cm	R_H, cm³/coulomb	*Ne*, net electrons/cm³
1	0.8	630	0.383	−8.4	7.45×10^{17}
2	1.2	560	0.524	−14.5	4.3×10^{17}
3	1.8	597	0.292	−5.6	1.1×10^{18}
4	2.6	626	0.084	−2.0	3.1×10^{18}
5	4.0	608	0.030	−0.55	1.1×10^{19}
6	4.8	588	0.035	−0.63	9.9×10^{18}
7	5.2	586	0.037	−0.60	1.04×10^{19}

The carbon contamination certainly has phosphorus as its source, and the boron has the boat as its source. The primary source of the silicon contamination has been discussed above. There is no evidence of segregation caused by zone refining when one considers the concentrations of carbon or boron from section 1 through section 7 (Table I). The concentrations of silicon definitely show a trend of increasing concentration from the beginning to the end of this ingot.

Electrical measurements.—Electrical measurements were made on bridge-cut polycrystalline samples. These measurements were made at temperatures around 600°C because of the nonohmic behavior of polycrystalline GaP at lower temperatures. The samples were approximately 3.5 mm long × 2 mm wide × 0.5 mm thick. Table III contains the compilation of electrical data obtained from the first seven sections of ingot R-53.

A single crystal was cut out of a slice taken from section 3 of ingot R-53. From a bridge-cut sample of this crystal, electrical measurements were made from 700° to −195°C. Figure 2 shows a plot of Hall coefficient as a function of temperature; Fig. 3 contains plots of resistivity and net carrier (electrons) concentrations as functions of temperature. The net carrier concentrations in Table III were calculated $N_e = (e R_H)^{-1}$. As may be seen in Fig. 2, the values of the net electron concentrations given in Table III should be very nearly equal to the exhaustion values. A preliminary analysis of the Hall data indicates that the activation energy of silicon in GaP at these concentrations is about 0.06 ev.

Optical measurements.—Optical transmission measurements were made on polished polycrystalline slices which were about 0.9 mm thick. A Cary Spectrophotometer, model 14 was used to obtain spectra from the band edge of GaP to 2.5μ. Spectra of the first five sections appear in Fig. 4. Sections 6 and 7 did not show any transmission over this wavelength range. The slice from section 2 seems anomalous in that it does not follow the trend set by the series 1, 3, 4, and 5. Although the reason for this is not obvious, the high concentration of boron in this slice (see Table I) may be responsible. The resistivity and Hall coefficient of section 2

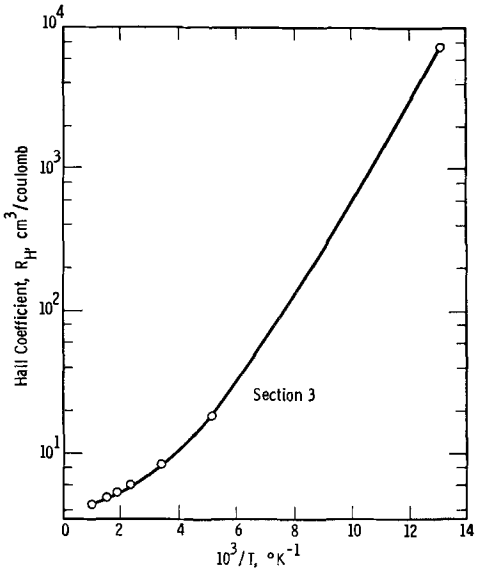

Fig. 2. Hall coefficient plotted as a function of temperature for section 3 of GaP ingot R-53.

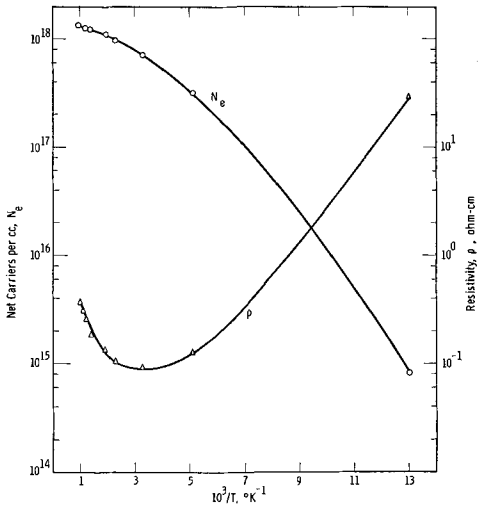

Fig. 3. Net carrier concentration (○) and resistivity (△) plotted as a function of temperature for section 3 of GaP ingot R-53.

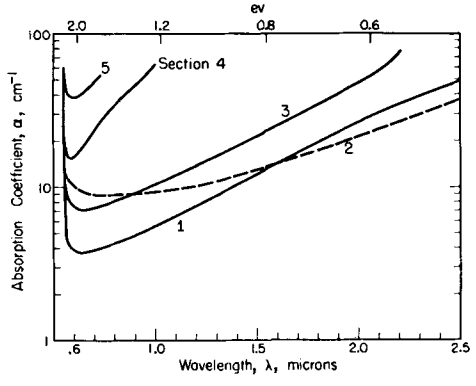

Fig. 4. Optical absorption spectra of polished slices of GaP ingot R-53, sections 1-5 (slice thickness was 0.9 mm).

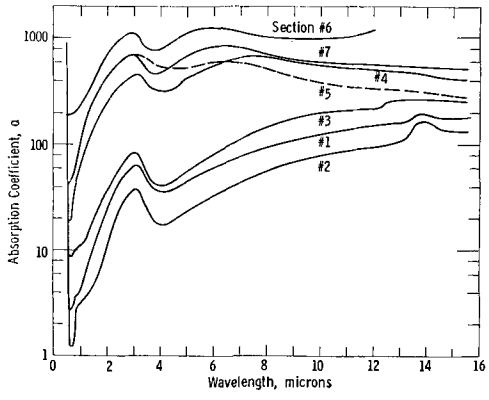

Fig. 5. Optical absorption spectra of polished slices of GaP ingot R-53, sections 1-7 (slice thickness was 0.14 mm).

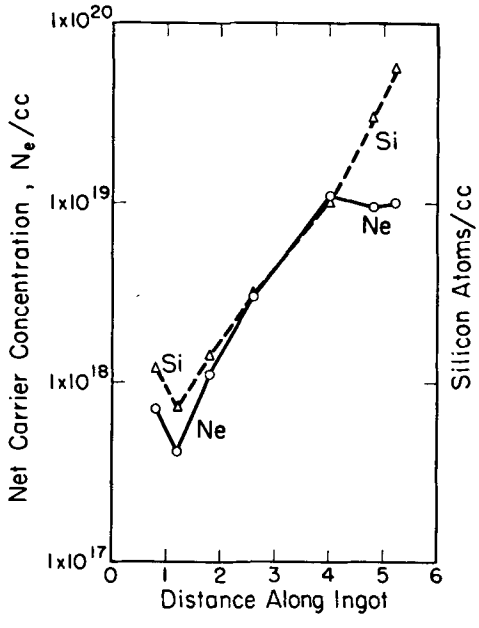

Fig. 6. Net carrier concentration (○) and silicon concentration (△) plotted as a function of distance along GaP ingot R-53.

also does not follow the trend that the other sections do (see Table III).

The slices which were used in Fig. 4 (0.9 mm thick), were lapped and polished to a thickness of about 0.14 mm so that transmission spectra could be obtained for the entire set of 7 sections over a range of wavelengths from the band edge to 15 μ's. A Cary Model 14, and a Perkin-Elmer Model 21 Spectrophotometer were used to obtain the spectra of these slices from the seven sections of this GaP ingot (see Fig. 5). There does not appear to be an inconsistency in section 2. This section has a lower silicon concentration than section 1 according to optical, electrical, and spectrochemical measurements. The spectrum for section 5 seems to be somewhat inconsistent with the other spectra at wavelengths greater than 3μ. This may be due to the nonparallel faces of this slice. On polishing this sample, it was noted that the polished faces were obviously nonparallel.

The absorption band between 1 and 4 μ's was noted by Spitzer *et al.* (5), and the probable interpretation of this band was discussed more recently in ref. (6) and (7). Allen and Hodby suggest that this absorption is due to a transition from a shallow donor impurity to an upper conduction band which has been split off by the lack of a center of symmetry in the crystal (6). The absorption at wavelengths beyond 4 μ's increases with wavelength as λ^n with $n \sim 2$ and is typical of the free carrier absorption found in many semiconductors (6).

Segregation coefficient.—This ingot, which was zone refined with 10 passes, shows the effects of a segregation coefficient less than unity (see Table I, Table III, and Fig. 6). The segregation coefficient can be calculated (3) assuming that the ultimate number of refining passes have been made. In the refining of this ingot, the length of the molten zone is about 2.5 cm, the length of the ingot is 15 cm. Using the equations in ref. (3), one can calculate the segregation coefficient

$$k = \frac{\text{concentration of an impurity in solid GaP}}{\text{concentration of an impurity in molten GaP}} = 0.6$$

Since the ultimate number of zones may not have been passed through this ingot, the true value of k may be somewhat smaller than this value.

Conclusions

Gallium phosphide ingot R-53 has a silicon concentration which varies from about 30 ppm to more than 19,000 ppm from one end to the other end of the ingot. If one were to plot the concentration of silicon as a function of the distance along the ingot and the net carrier concentration as a function of the distance along the ingot, the two curves would seem similar over a range (see Fig. 6). At concentrations greater than 1×10^{19} (400 ppm) the net carrier concentration does not continue to rise as the silicon concentration rises with increasing distance along the ingot. Also the optical absorption curves for sections 5 and 7 are quite similar and the spectrum for section 6, a little greater (see Fig. 5). The trend of increasing optical

absorption for sections 2, 1, 3, 4, and 5 is consistent with the electrical measurements (Table III) and the spectrochemical measurements for silicon (Table I). The beginning of this ingot and also the end of this ingot experienced a different temperature distribution from the main body of the ingot, since the r-f coupling was quite different at these two ends than in the main body. This may be the reason for section 2 having a lower silicon concentration than sections 1 and 3.

The apparent "saturation" of the electrical measurements and to a lesser degree of the optical measurements while the silicon concentration rises (beyond 10^{19} Si at./cc GaP) can be explained if the silicon at these concentrations, as determined by spectrochemical analyses, did not enter the GaP lattice but existed in the slice in grain boundaries or inclusions (as a second phase). The divergence of these two plots (Fig. 6) at silicon concentrations greater than 1×10^{19} could also be explained, if the silicon entered the GaP lattice in gallium and phosphorus sites nonpreferentially. The former explanation seems more reasonable because the absorption for section 6 is greater than the absorption for section 5. The absorption curve for section 7 may be somewhat different than the trend of sections because it is an end section which experiences a different temperature distribution as indicated above. Of course, it is possible that both explanations are partially valid. That is, some of the silicon, at concentrations greater than 10^{19} at./cc, appears as a second phase and some enters the lattice nonpreferentially.

At the lower silicon concentrations, one might expect some difference between the silicon concentrations and the net carrier concentrations because there are other impurities in this material which could be electrically active. If there are about 3×10^{17} acceptors throughout this ingot, a plot of donor (silicon) concentrations measured electrically *vs.* distance along the ingot, and the plot of silicon measured spectrochemically *vs.* distance along the ingot would superimpose for sections 1 through 5.

Since the silicon concentration is the only known parameter that systematically changes in this ingot, since the Hall coefficients indicate that the majority carrier is the electron, and since the silicon concentration changes at the same rate as the net carrier concentration up to 10^{19} carriers per cc, one may conclude that silicon is not only a donor in GaP but that for every silicon atom incorporated into the GaP lattice, one carrier (an electron) is incorporated into the material. Silicon has an activation energy in GaP of 0.06 ev as calculated from the Hall measurements at various temperatures (as plotted in Fig. 2).

Considering only the geometry involved, one might expect the silicon to enter the lattice substitutionally for gallium. The tetrahedral covalent radius of silicon is 7% smaller and 6% larger than that of gallium and phosphorus, respectively. A substitution of silicon for gallium in the GaP lattice, when only considering covalent radii, is consistent with the conclusions derived from the electrical measurements.

Acknowledgment

The author would like to thank Mr. David Dickey who performed the electrical measurements and calculations based on these measurements used in this paper. He would also like to thank Mr. Joseph Rudolph, Mrs. Mary Louise Theodore, and Mr. John Penkrot for the spectrochemical, wet chemical, and carbon analyses, respectively. Discussions with Mr. Dickey and Dr. Hung-Chi Chang were valuable in the writing of this paper.

Manuscript received Nov. 23, 1964; revised manuscript received June 9, 1965. Much of the material in this paper was presented at the Boston Meeting, Sept. 16-20, 1962.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

Structural Evaluation of Silicon Oxide Films

W. A. Pliskin and H. S. Lehman

IBM Systems Development Division, Poughkeepsie, New York

ABSTRACT

Techniques for physical and chemical evaluation of silicon oxide films formed by a wide variety of techniques have been developed. It has been established that by the use of infrared absorption spectroscopy, preferential etching procedures, precise optical measurements of thickness, density, and refractive indices, and carefully chosen environmental tests, differences in the oxide films can be determined. Techniques of oxidation studied were: thermal (oxygen and steam), evaporated, pyrolytic, lead catalyzed, sputtered and anodic. In many cases, improvement of oxide film properties can be achieved by simple thermal treatment of the original films.

Silicon dioxide films are presently used for purposes of surface passivation and diffusion masking during fabrication processes of planar silicon devices. In general, these films are obtained by thermal oxidation in oxygen or steam at elevated temperatures. Techniques other than thermal oxidation are of interest in order to (*i*) minimize problems of junction movement and junction degradation (1), (*ii*) avoid thickness limitations, and (*iii*) to obtain high quality insulating films on nonsilicon surfaces.

The general procedure utilized in this study was to compare the physical and chemical properties of the oxide films prepared by low temperature techniques to those of films grown thermally. Films were evaluated for structural differences, stoichiometry, density, porosity, strain, refractive index, and passivation efficiency. Techniques for evaluating the above-mentioned parameters included the use of infrared absorption spectroscopy, preferential etch procedures (2), precise optical measurements of density, refractive index and thickness (3), and passivation efficiency. By the careful application of these techniques to the oxide films studied, small differences in the films can be easily determined.

The low temperature oxidation techniques which have been examined and evaluated include: evaporation, pyrolytic decomposition (4, 5), lead catalyzed growth (6), anodization (7), and reactive sputtering. Valletta, Perri, and Riseman utilized the methods described herein for the detailed evaluation of silicon oxide films prepared by reactive sputtering (8). Consequently, only brief mention will be given to reactively sputtered films.

Experimental Techniques

Infrared spectroscopy.—There are four ways in which infrared spectroscopy is useful for the evaluation of silicon oxides: (*i*) the half-widths and positions of the Si-O stretching bands near 1090 and 805 cm^{-1} are strongly influenced by the bonding character, stoichiometry, density, and porosity of the films; (*ii*) the intensity of the absorption bands near 3650 cm^{-1} (2.74μ) and 3400 cm^{-1} (2.94μ) due to hydrogen bonded hydroxyl groups and adsorbed water are indicative of the quantity of surface hydroxyl groups and porosity of the oxides; (*iii*) impurities other than hydroxyl groups or water can be detected by their characteristic absorption bands; and (*iv*) approximate film thicknesses can be determined by interference fringes in the spectrum.

All infrared spectra were taken on double beam Perkin Elmer Spectrophotometers; Model 221G was used for the earlier work and Model 521 for the later work. Occasionally, quick references were made using a Model 337. In all cases, a bare silicon wafer of the same thickness and from the same crystal as the sample was placed in the reference beam to eliminate lattice absorption bands.

Selective etch techniques.—A selective etch solution consisting of 15 parts hydrofluoric acid (49%), 10 parts nitric acid (70%), and 300 parts water has been developed which is extremely sensitive to differences in density, stoichiometry, bond strain, and impurities in the silicon dioxide films. This etch has been named "P etch" (2). As examples of the sensitivity of this etch to porosity, the etch rate of pyrolytic films formed at 675°C is 13Å/sec; whereas, the etch rate of thermally (1000°C) grown silicon dioxide is only 2Å/sec at 25°C. Films of electron-gun evaporated silicon dioxide, which are less dense than the pyrolytic films and exhibit more bond straining, etched at rates from 20 to 70Å/sec. Densification of the less dense films lowers the etch rate to that of thermally grown oxide. The etch rate is also sensitive to changes in oxygen content of the film, being slower for oxygen deficient films, as in SiO for which the etch rate is negligible.

Optical techniques.—The refractive indices and film thicknesses were measured by use of Vamfo (3), a specially constructed interference microscope. The refractive index of a film is influenced by its density and its stoichiometry. The greater the density, the greater is the refractive index, but the refractive index is also increased by oxygen deficiency. On the other hand, oxygen deficiency will decrease the etch rate of silicon dioxide films and shift the 9.2μ band to longer wavelengths.

Passivation efficiency.—Passivation efficiency was determined by exposing diodes passivated with oxide layers to high temperature steam and monitoring junction degradation due to moisture penetration.

Thus, by a combination of these techniques, the oxide films can be characterized as to density, composition, porosity, and structure.

Results

Densification of pyrolytic oxides.—Pyrolytic films of pure silicon dioxide can be obtained from the thermal decomposition of tetraethoxysilane at deposition temperatures between 625° and 900°C. These somewhat porous films can be densified by short term exposure to temperatures above 800°C. Densification can be achieved at 800°C in steam ambient with a 15 min heat-treatment. Densification of films in dry gas ambients occurs somewhat more slowly and not quite as effectively as with steam. The densified pyrolytic oxide films were compared to thermally grown oxide films in order to determine the extent of densification.

Infrared (Si-O *stretching band*).—The positions of the Si-O vibrational bands in the infrared spectra of thermally grown (steam followed by dry oxygen at 975°C) silicon dioxide films (~1μ thick) are 1093 cm^{-1} (9.15μ) and 805 cm^{-1} (12.42μ); whereas, nondensified pyrolytic oxide films have bands at about 1080-1085 cm^{-1} and at 813 cm^{-1}. The band positions in the spectra of pyrolytic oxide films are a function of porosity and strain. Films with greater porosity and bond strain show even greater shifts than those previously quoted, as shown by their increased reactivity (9). In comparing an oxide film with thermal oxides, comparable thicknesses were used since both the half-widths and band positions of thermal oxides vary slightly with thickness. The bands in the spectra of the thermally grown silicon dioxide films are sharper than those of the nondensified pyrolytic films. The infrared spectra of pyrolytic oxide films become essentially indistinguishable from those of thermally grown oxide films when properly densified. This is shown in Fig. 1 where Spectrum A is that of a tube furnace (T.F.) pyrolytic SiO_2 film formed at 675°C and Spectrum B is the same film after having been densified in steam at 975°C for 15 min. The densified film is indistinguishable from thermally oxidized films of the same thickness. The spectra show the shifts and sharpening of the absorption bands. The 1082 cm^{-1} band with a half-width of 92 cm^{-1} is shifted to 1093 cm^{-1} and the half-width is decreased to 88 cm^{-1} while the film thickness decreased from 1.13 to 1.09μ.

Infrared spectra of various densified pyrolytic oxides show that steam is more effective than dry ambients in densifying pyrolytic oxide films. The band positions of a pyrolytic oxide, after treatment with helium at 850°C for 5 min, shifted from 1081 and 812 cm^{-1} to 1086 and 810 cm^{-1}; whereas, 5 min of steam

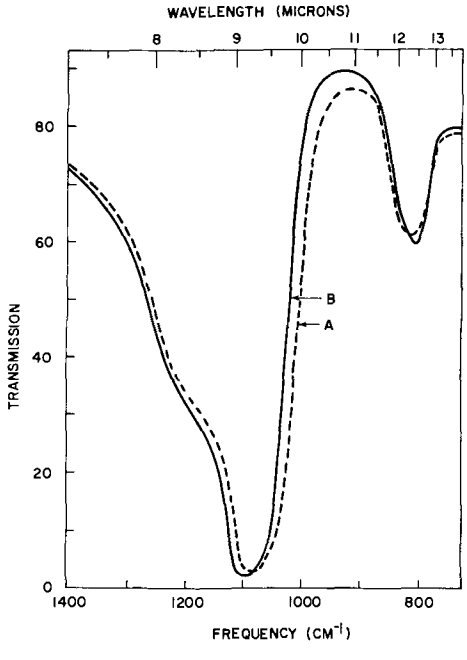

Fig. 1. Steam densification of pyrolytic SiO_2: A, T.F. pyrolytic SiO_2 formed at 675°C, 1.13μ, 1082 cm^{-1}, 92 cm^{-1}; B, densified by exposure to steam for 15 min at 975°C, 1.09μ, 1093 cm^{-1}, 88 cm^{-1}.

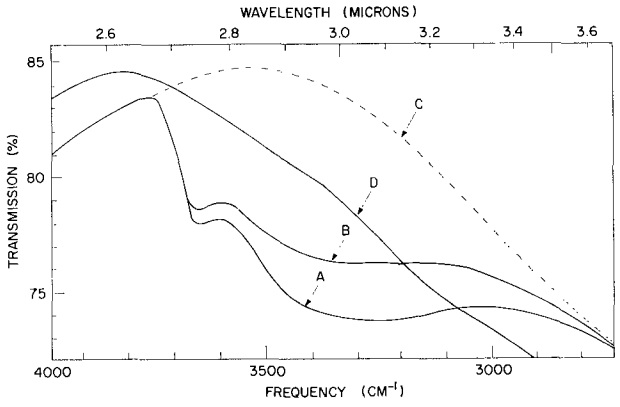

Fig. 2. Spectra showing removal of adsorbed water from a porous pyrolytic oxide: A, spectrum in air (47% R.H.); B, after flushing in N_2 for 20 min; C, estimated background; D, after exposure to argon for 15 min at 800°C (film thickness 1.38μ).

densification at 850°C was sufficient to shift the bands to 1092 and 805 cm^{-1}. In addition, after the steam densification, the vibrational bands were sharper than those after helium densification.

The absorption band at 450-460 cm^{-1} due to the deformation vibration in SiO_2 is not covered in this paper since it behaves in the same manner as the 1080-1090 cm^{-1} band; with increased porosity or strain, the frequency is decreased and the half-width increased.

Infrared (O-H stretching band).—The effect of moisture on the infrared spectrum of a nondensified pyrolytic oxide film is shown in Fig. 2. In Spectrum A, the sample was exposed to air at 47% relative humidity. The amount of water in the sample is indicated by the strength of the broad absorption band in the 3μ region. Some of this water is easily removed as shown by Spectrum B which was obtained by flushing the sample with dry nitrogen in the infrared spectrophotometer for 20 min. By comparison with the background spectrum, it can be seen that this treatment was sufficient to remove about 30% of the adsorbed water. Similar studies on another sample have shown that flushing in dry nitrogen for 4 min removed about 21-22% of the adsorbed water, 10 min flushing removed about 27%, and 160 min removed only 40%. On re-exposure to air, almost all the water was readsorbed within 5 min. After densification by exposure to argon for 15 min at 800°C, Spectrum D was obtained. It shows practically no absorption due to surface hydroxyl groups or adsorbed water. Since similar results were obtained with the other densification procedures, it is concluded that the heat-treatment is sufficient for both removing the surface hydroxyl groups present on the nondensified pyrolytic oxide and densifying the oxide structure such that new moisture is not readsorbed.

Thickness and refractive index.—Figure 2 also shows the effect of shrinkage on the interference pattern of the infrared spectrum by the shift in the maximum from 2.85μ in Spectrum C to 2.61μ in Spectrum D. Considering the variation of refractive index with wavelength and densification, this corresponds to a shrinkage of 9.1%. Before and after densification the thicknesses of many samples were measured with Vamfo, which is a more accurate technique for thickness measurement. The film shrinkage is a measure of the densification. Densifications were also determined based on the refractive index change with the assumption of a linear relationship between density and refractive index. (The relationship is given by $\rho = -4.784 + 4.785\mu$, where ρ is the density in g/cc and μ is the refractive index at 5460Å. It is based on the known densities and refractive indices of various forms of SiO_2.) In some cases where the samples showed appreciable water content, corrections were made for the relative water content. On this basis, good agreement was obtained by the two techniques as shown in Table I from which it is concluded that steam is more effective for densification. This agrees with the infrared results.

Etch rate.—The P-etch rate of nondensified pyrolytic silicon dioxide is much greater than that of thermally grown silicon dioxide or of densified pyrolytic oxides. The etch rate results shown in Table II again show that steam is more effective than dry ambient for densification.

Passivation efficiency.—The passivation characteristics of both densified and nondensified pyrolytic oxide films on silicon devices were determined. Boron

Table I. Densification produced by various treatments

Relative quan. ads. water	Densification treatment			Refrac. index		Density (g/cc)		% Densification	
	Ambient	Temp (°C)	Time (min)	Before dens.	After dens.	Before dens.	After dens.	By R. I.	By film shrinkage
High	Argon	800	15	1.45_0	1.45_5	2.15[b] (1.99)[a]	2.18	1.1[b] (9.2)[a]	9.0
Low	Steam	850	15	1.43_7	1.46_3	2.09	2.22	6.0	6.4
Med.	Nitrogen	975	5	1.44_4	1.45_6	2.12[b] (2.07)[a]	2.18	2.7[b] (5.2)[a]	6.3
Low	Steam	975	15	1.44_4	1.46_5	2.12	2.23	4.7	5.4

[a] Before densification, these samples contained a significant amount of water as shown by their infrared absorption spectra. The relative quantity of adsorbed water was considered in calculating their densities.
[b] The water content was not considered in determining these values.

diffused diodes were used in this experiment. The C_0 of these diodes was 2.5-4.0 x 10^{18} with X_j = 0.11 mils. It had been found that high temperature steam (400°C) exposure at atmospheric pressure causes degradation of the reverse characteristics of thermally oxidized diodes. A 2.3μ, 850°C, high quality, pyrolytic silicon dioxide film was deposited on top of a 0.5μ film of thermally grown silicon dioxide. The wafer was then cut in half with the oxide on one half of the wafer being densified at 975°C for 15 min in steam. Breakdown voltages and reverse currents of the diodes on both halves were measured before and after exposure to steam at 400°C. Results are summarized in Table III. Failures were defined as leakage currents in excess of 1μ amp at 10v reverse bias.

It is readily apparent that there is a great difference between the passivation efficiency of densified and nondensified pyrolytic oxides. Infrared spectroscopy was used to determine the effect of the high temperature (400°C) steam exposure on the oxides. Four oxidized wafers, a thermally grown silicon dioxide, a nondensified pyrolytic oxide, and two steam densified pyrolytic oxides, differing only in densification time, were exposed to steam at 400°C. The pyrolytic oxides were formed at 850°C. The only detectable difference in the oxides on steam exposure was the increase in the absorption of the 2.74μ band due to the formation of hydrogen bonded hydroxyl groups. The results, summarized in Table IV, show that the densified and thermally grown oxide pick up little moisture in comparison with the nondensified oxide. The passivation efficiency of the thermally grown oxide film is reduced by the presence of the nondensified pyrolytic film because it serves as a source of moisture. The moisture is then easily available and diffuses to the junction causing high device leakage currents.

SiO *evaporation.*—Before going into further details of other silicon dioxides, the oxides formed on the evaporation of SiO and SiO_2 will be discussed. The stoichiometry of evaporated silicon oxide films is a strong function of the evaporating parameters and can be followed by observation of the SiO stretching band frequency. The important parameters which determine the type of film formed are the temperature, the rate of evaporation, and the pressure in the evaporating system. Figure 3 shows the spectrum of the film obtained when SiO (Kemet) is evaporated at a fast rate and good vacuum. The rate of evaporation was 375Å/sec and the maximum pressure in the system was less than 1 x 10^{-4} mm of Hg. The transmission spectrum of this film shows one strong absorption band at 10μ

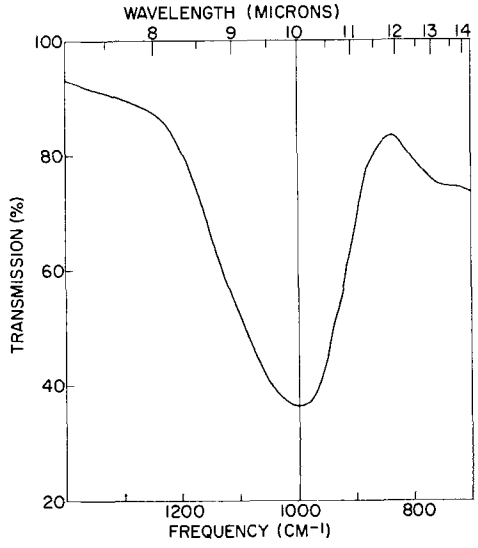

Fig. 3. SiO film formed by evaporation of SiO at a fast rate (375 Å/sec); pressure, <1 x 10^{-4} mm.

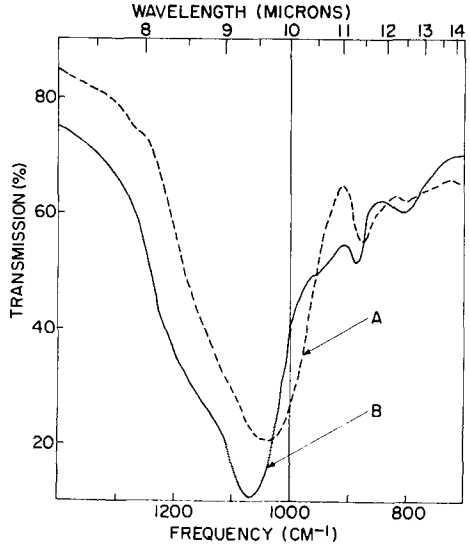

Fig. 4. Films formed by evaporation of SiO at a slow rate (<5 Å/sec) and pressures of: A, <2 x 10^{-4} mm Hg; B, 1 x 10^{-3} mm Hg.

and is the same as the spectrum of the SiO films obtained by Hass and Salzberg (10); whereas, the spectra of SiO_2 show a strong band at 9.2μ, a moderate band at 12.5μ, and a distinct shoulder in the 8-9μ region. At slow evaporating conditions, the spectra shown in Fig. 4 are obtained. With a maximum pressure of 2 x 10^{-4} mm Hg, a film whose spectrum is shown by A in Fig. 4 was obtained. The strongest absorption occurs at an intermediate position between that of SiO and SiO_2. The presence of SiO_2 is indicated by the weak absorption near 12.5μ. In addition, there is a moderate intensity band near 11.5μ which together with part of the strong absorption at 9.6μ is interpreted as being due to Si_2O_3, an oxide intermediate between SiO and SiO_2 (11). Thus, it is felt that this film consists of a mixture of SiO, SiO_2, and Si_2O_3. At slightly higher ambient pressures (1 x 10^{-3} mm Hg of air), a film was produced which is much richer in SiO_2 as shown by Spectrum B. This film consists mainly of SiO_2 with practically no SiO, but some Si_2O_3 is still present as shown by the 11.4μ band. This film was rather porous and in the shorter wavelength region of the infrared some hydrogen bonded Si-OH and adsorbed water was evident. In fact, the weak absorption near 930 cm^{-1} is due to an Si-OH bending vibration.

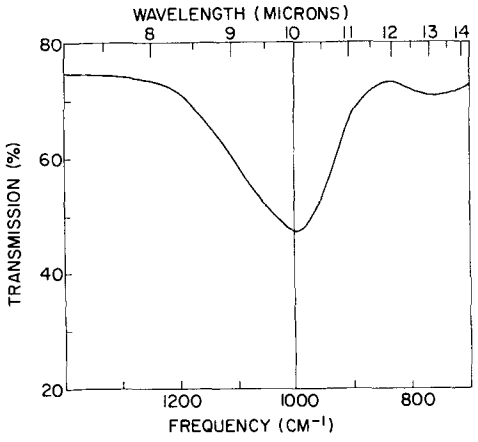

Fig. 5. SiO formed by the evaporation of SiO_2

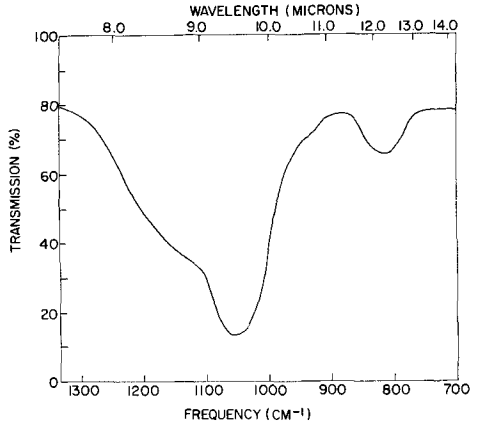

Fig. 6A. Infrared spectrum of electron-gun evaporated SiO_2

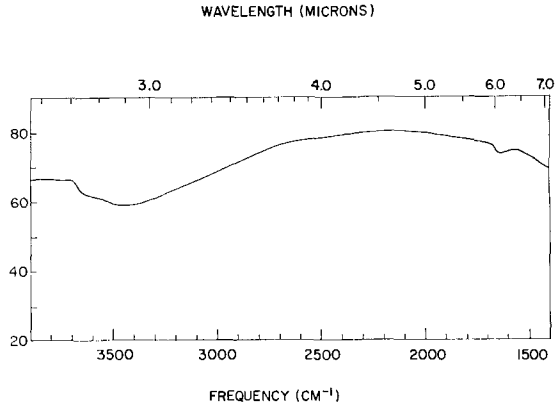

Fig. 6B. Infrared spectrum of electron-gun evaporated SiO_2

All of the previous evaporated films were deposited on unheated substrates. In the case of deposition on heated substrates, decomposition of the SiO to form Si and Si_2O_3 or SiO_2 can occur. The measured refractive index of one such film was found to be 2.02 at 5460Å, but its infrared spectrum indicated the presence of higher forms (intermediate and SiO_2) of oxide. The refractive index of SiO is 1.99_6 and, if the film consisted of pure SiO mixed with higher forms of oxide, the refractive index should be less than 1.99_6. The explanation is that most of the higher oxides in the film were not formed from the oxidation of the SiO with residual O_2 or H_2O in the vacuum system, but were formed by the thermal decomposition of SiO due to the 400°C substrate temperature resulting in a mixture of SiO, Si_2O_3, and Si. With the presence of a significant amount of silicon in the film, the refractive index of the mixed film can be greater than that of pure SiO.

It should be noted that no evidence has been obtained for oxygen deficiency in the pyrolytic SiO_2 films studied. After densification, the refractive indices of the pyrolytic films were comparable to those obtained for thermally grown oxides (1.463 compared to 1.462) and the spectra showed no evidence of Si_2O_3.

Thermal evaporation of SiO_2.—In the straight thermal evaporation of SiO_2 under good vacuum conditions, one obtains films of SiO rather than SiO_2 as shown in Fig. 5. This result is not surprising in view of the fact that the SiO_2-SiO equilibrium highly favors SiO at the elevated temperatures necessary for thermal evaporation of SiO_2 (12).

On the other hand, the films obtained from electron-gun evaporated SiO_2 were more nearly SiO_2 as shown in Fig. 6A. The absorption band position at 9.4μ and the broad half-width are indicative of a porous film. The porosity is also substantiated by the spectrum in the shorter wavelength regions as shown in Fig. 6B where the presence of hydrogen bonded surface silanol groups (Si-OH) is evidenced by the absorption at 3650 cm^{-1} and the presence of water by the absorption at 3400 and 1640 cm^{-1}. The porosity was further substantiated by the very rapid P-etch rate of 30Å/sec.

The shift and half-width of the band at 9μ is not all due to the porosity of the film. A good fraction of it is due to bonding strain in the film. Re-examination of this film after standing for six months at room temperature showed a shift to 1075 cm^{-1} from the initial 1059 cm^{-1} position and significant decrease in half-width. At the same time, the optical density at 3300-3400 cm^{-1} due to adsorbed water increased about 15% showing that there was no significant porosity decrease. But the later spectra showed a moderate intensity band at 930 cm^{-1} due to Si-OH bending which indicated a significant amount of reaction had occurred at room temperature between the oxide and water to form Si-OH. The ease of reaction at room temperature is attributed to the energy stored in the structure due to bond strain. The bond strain and variations in straining can result in broadened spectra. After reaction with the water, the strain is relieved and the bands are shifted to higher frequency and their half-widths decreased. Due to the energy in the strained bonds, strained films would also etch faster than nonstrained films.

The refractive indices (at 5460Å) of electron-gun evaporated SiO_2 samples were higher than that of thermally grown SiO_2 ($\sim$ 1.47 to 1.48 *vs.* 1.462). Normally, a porous SiO_2 film would have a lower refractive index. The explanation is that in addition to being porous and strained, the film is somewhat deficient in oxygen content.

CO_2 *oxidation*.—Another type oxide examined is the CO_2 process silicon dioxide (13). This oxide is generally formed in the epitaxial chamber by the introduction of CO_2 with chlorosilane and hydrogen. Table V shows the etch rates of such samples (14). In columns 1 and 2 are given the deposition times and temperatures. Note that these oxides are formed at much higher temperatures than any of the other type oxides formed other than high temperature thermal oxides. The two films having no post treatment showed etch rates of about 4Å/sec, about twice as fast as that of thermally grown oxides. The refractive index of a thick film of the CO_2 oxide indicated that the oxide was at least as dense as a thermally grown oxide. Its refractive index was 1.465 compared to 1.462 for thermally grown oxide. It was reasoned that this fast etch rate at the surface may be due to the fact that either the oxide near the surface is not as dense as the oxide at greater depths or that the impurity content is greater near the surface. The nonuniformity in the oxide is shown by the results given in Table V. After etching off 1.3μ of oxide from the

Table V. Etch rates of "CO_2 process" silicon dioxide

Deposition Time (min)	Deposition Temp (°C)	Post treatment	Film thickness (μ)	P etch Rate (Å/sec)	P etch Temp (°C)
10	1135	None	0.532	3.90	26.1
36	1135	None	4.33	4.20	26.1
36	1135	Etched off 1.3μ of oxide	2.77	2.42	24.1
4	1125	Additional 5 min at 1125°C	0.784	3.22	22.4
	Thermal oxide		0.581	1.92	24.1
			0.583	2.13	26.1

second sample, the etch rate of the remaining oxide was only 2.4Å/sec. The refractive index was still slightly high but the slower etch rate indicated that the deeper lying portions of the film were either more dense, less strained, or of greater purity. The slightly higher refractive index and faster etch rate can be due to impurities in the oxide such as phosphorus. Part of the slightly faster etch rate may also be due to the high temperature treatment since it has been found that oxides grown in dry oxygen at 1200° or 1000°C thermal oxides which were subsequently treated at 1200°C, etch about 20% faster in P-etch than do 1000°C thermal oxides (15).

A thinner film of the "CO_2 process" oxide was compared with a comparable thickness thermally grown oxide (980°C) using infrared spectroscopy. The results are shown in Fig. 7 and indicate that the oxide is very similar to that of thermally grown oxide. There is only a slight shift of the 9μ band of the "CO_2 process" oxide to longer wavelength. The half-width is also slightly greater than that of the thermally grown oxide.

Reactive sputtering.—Figure 8 shows the infrared spectrum in the 7-14μ region of a reactively sputtered silicon dioxide film. Spectrum A is the spectrum of a reactively sputtered film of 2500Å. Spectrum B is the same film after densification by exposure to nitrogen for 15 min at 980°C. The densified film is nearly the same as that of a thermally grown oxide shown in Spectrum C. The band position of the thermally grown oxide is at slightly higher frequency. From infrared spectra and etch rates, the sputtered oxides when prepared properly, appear to be more dense than T.F. pyrolytic oxides. The etch rate of reactively sputtered

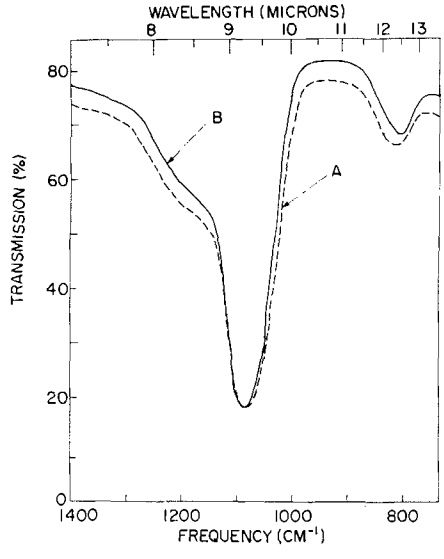

Fig. 7. Band position comparison of: A, "CO_2 process" oxide formed in epitaxial unit; 4600Å, 1083 cm^{-1}, 85 cm^{-1}; B, thermal oxide, 4500Å, 1085 cm^{-1}; 79 cm^{-1}.

oxides which we had examined varied from about 3.8 to 5.2 Å/sec. The refractive index of these reactively sputtered silicon dioxide films was approximately 1.46.

Anodized SiO_2.—The difference between anodized and thermal oxides is especially noticeable with infrared spectroscopy. In Fig. 9, Spectrum A was obtained for a wafer with 1294Å of anodized oxide on one side and 1207Å of oxide on the back side. (Prepared in a solution of 0.05M KNO_3 in N methyl acetamide with no purposely added water. In preparing some of the films 2½% water was added.) The spectrum of the sample, after densification at 993°C for 15 min in nitrogen, is shown as Spectrum B. The densification was sufficient to decrease the film thickness 3%. For comparison, the spectrum of a wafer with 1155Å thermal oxide (dry oxygen at 975°C) on both sides is shown as Spectrum C. It is readily apparent that the band position (1040 cm^{-1}) of the anodized oxide is at much lower frequencies than the band position (1074 cm^{-1}) for the thermally grown oxide or the densified oxide. Furthermore, the band half-width (96 cm^{-1}) of the anodized oxide is much greater than that (73 cm^{-1}) of

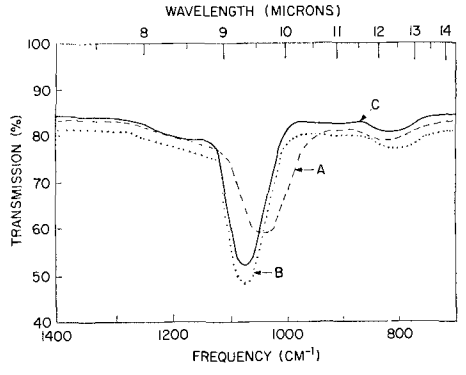

Fig. 9. Spectroscopic comparison: A, anodized with total oxide on both sides of 2501Å (1294 and 1207Å); B, densified by 15 min N_2 at 993°C; C, thermal oxide (dry O_2 at 975°C).

	Total thickness Å	POS cm^{-1}	H.W. cm^{-1}
A	2501	1040	96
B	2426	1074	73
C	2310	1074	73

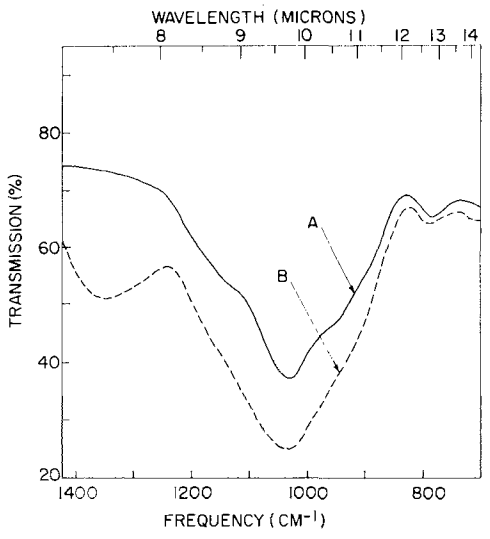

Fig. 10. A, film formed on silicon by 4½ hr in air at 650° above PbO bed; B, 1μ film of a lead borosilicate glass.

the thermally grown or densified oxide. The band position and half-width of this anodized film indicate either a very porous structure or strained bonding or both. The structure is only slightly porous in view of the 3% densification and the relatively small amount of adsorbed water seen in the 3μ region of the infrared spectrum. The refractive index of this anodized film was 1.459 on one side of the wafer and 1.471 on the other (16). Thus, from only the refractive index measurement, one would conclude that the film was similar to thermal SiO_2, but the infrared and the P-etch rate (19Å/sec) show that it is not. Part of the high refractive index and Si-O stretching band shift may be due to a slight oxygen deficiency. A refractive index increase due to oxygen deficiency may be compensated by a refractive index decrease due to the slight porosity such that the over-all refractive index is about the same as thermal SiO_2. It is concluded that the fast etch rate and large band shift were mainly due to bond strain in the oxide. Attempts were made to check for organic impurities by infrared amplification techniques. No organic impurities were visible.

Some of the anodized films which were prepared in glycerin solutions containing more water, were even poorer in quality. They had etch rates as high as 228 Å/sec, low refractive indices (1.30), and showed more water in their spectra, indicating high porosity.

Lead catalyzed oxidation.—We have found that the films formed by catalytic oxidation of silicon using lead oxide (6) are mainly lead silicate as indicated by (*i*) a high refractive index (1.72), (*ii*) extremely fast etch rate in P-etch (600 Å/sec), and (*iii*) by infrared spectroscopy.

A comparison of the infrared spectrum of a lead catalyzed film with that of a lead borosilicate glass film is given in Fig. 10. The latter was formed by fusing a sedimented powder film of known composition (17). Spectrum A is that of an oxide film formed by exposure in air for 4½ hr for 650°C with the wafer just above a lead oxide bed. Except for the B-O stretching vibration near 1360 cm^{-1} in the lead borosilicate glass (Spectrum B), the lead catalyzed film looks more like lead borosilicate than it does SiO_2. It is estimated from the infrared spectra and refractive index that the catalyzed film contains 60 w/o (weight per cent) PbO.

Summary: refractive indices and etch rates.—Table VI summarizes the etch rates of the various silicon dioxides and their refractive indices wherever measured.

Conclusion

On the basis of the described results, the following conclusions can be made:

Table VI. Summary: P etch rates of silicon dioxides

Oxide type and description	Refractive index	P etch rates, Å/sec
T F Pyrolytic	1.44-1.45	6-20
T F Pyrolytic, densified	1.463	2.0
CO_2 process	1.465	2.4-4.2
Reactive sputtering	1.46	3.8-5.2
Anodized	1.30-1.49	18-228
PbO Catalyzed oxidation (lead silicate)	1.72	600
Electron-gun Evaporated SiO_2	1.464-1.487	20-70
Thermal	1.462	2.0

1. Silicon oxide films can be characterized on the basis of refractive index, etch rate, infrared spectra, stoichiometry, passivation efficiency, and thermal densification.
2. Films formed by low temperature techniques have generally inferior properties to those formed by high temperature processes.
3. Porous and strained oxides can be densified to be indistinguishable from thermal oxides.
4. Steam is more effective than a dry atmosphere in causing densification to occur.
5. Surface hydroxyl groups can be removed by densification.
6. For a proper evaluation and differentiation of similar silicon oxide films, all of the described techniques must be accurately utilized.

Epitaxial Growth of Doped and Pure GaAs in an Open Flow System

D. Effer[1]

The Plessey Company Limited, Allen Clark Research Centre, Caswell, Towcester, Northants., England

ABSTRACT

The basic parameters for the transport and epitaxial growth of GaAs in an open flow system have been studied using hydrogen chloride as the transport agent. Selenium- and tin-doped GaAs layers were grown in this system, the maximum doping levels achieved being 3.7 x 10^{18} electrons cm^{-3} and 3.2 x 10^{18} electrons cm^{-3}, respectively. Pure layers of GaAs have been grown by means of the $AsCl_3/Ga/H_2$ reaction. The best layer had a room temperature carrier concentration of 1.75 x 10^{15} electrons cm^{-3} and a mobility of 8800 cm^2/v-sec. At 77°K the mobility value was 38,000 cm^2/v-sec.

Closed tube vapor phase preparations of Group III-V compounds have shown that the basic requirements for their preparation and transport in these systems are: (*a*) a lower valence halide of the Group 3 element, (*b*) arsenic or phosphorus vapor, and (c) a temperature gradient such that the following reversible reaction occurs (1)

$$3MX + 2\,Y \rightleftharpoons MX_3 + 2MY \qquad [1]$$

where M = In or Ga, X = Cl or I, and Y = As or P (of variable atomicity according to the temperature).

In order to extend the applicability of these reactions by using an open tube flow system, the transport of GaAs was studied using H_2/HCl mixtures in an apparatus of the same general form as that illustrated in Fig. 1. Various authors have reported on this method to date (2-7).

Experimental

HCl gas was obtained from a cylinder supplied by B.A.S.F. Germany. The supply lines and needle valve were made of stainless steel. The gas was first dried by means of a trap cooled in solid CO_2/alcohol and then by anhydrous $AlCl_3$. Vessel E, containing concentrated H_2SO_4 served as a constant pressure regulator. During each experiment the gas was slowly bubbled through this vessel and then to waste. The gas was thus passed at constant pressure through the metering capillary, the pressure drop being measured by a gauge containing concentrated H_2SO_4. Oxygen and water vapor were removed from electrolytic purity hydrogen by means of a Deoxo Catalytic Purifier and Linde molecular sieve grade 5A. The flow rate was measured by means of a capillary gauge containing concentrated H_2SO_4.

The GaAs source granules (20-40 mesh) were packed in a demountable quartz tube F which could be weighed.

For most of the work reported here a constant flow rate of 6.9 cc HCl and 45 cc H_2 per minute was used.

Material Balance of the Reaction

In order to study the material balance of the reaction the following quantities have to be known accurately: (*a*) the mass of HCl gas passing through the GaAs source, (*b*) the mass of GaAs reacted, and (c) the mass of either GaAs or $GaCl_3$ formed as products.

To determine the mass of HCl passing per unit time through the metering capillary at a known pressure drop the gas was mixed with hydrogen and absorbed in water. The amount absorbed was determined by titration with standard alkali. The mass of GaAs reacted was determined by weighing the detachable inner source tube F before and after an experiment.

Since it proved difficult to remove the deposited GaAs quantitatively from the walls of the reaction tube, the $GaCl_3$ also formed as a product was dissolved in anhydrous ether and the gallium content determined chemically.

The material balance was studied with the source at various uniform temperatures, the products of the reaction passing down a temperature gradient of approximately 30°/in. In order to account for the reaction occurring during the heating and cooling of the source, for every temperature studied two experiments of different durations were carried out and the net quantities of reactants and products calculated.

The results are shown in Table I.

By the use of the long packed GaAs source and low flow rates of HCl and H_2 the source reaction is assumed to have reached a steady state. At 1000°C the ratio Cl/Ga leaving the source is almost unity. This indicates the formation of GaCl as shown in Eq. [2]. The disproportionation of GaCl in arsenic vapor to form GaAs is shown in Eq. [3]

$$3GaAs + 3HCl \leftrightarrow 3GaCl + 3(As) + 3/2\,H_2 \qquad [2]$$

$$3GaCl + 2(As) \rightarrow 2GaAs + GaCl_3 \qquad [3]$$

Arsenic vapor at these temperatures consists of a mixture of the species As_4, As_2, and As for simplicity (As) is used in equations here and subsequently.

Source temp, °C	Source reaction Atoms Cl in / Atoms Ga out	Wt Ga (g) reacted from source in 16 min	Wt Ga (g) found as $GaCl_3$	% Source Ga reformed as GaAs
1000	1.16	0.256	0.051	80.0
900	1.38	0.215	0.050	76.7
800	2.45	0.120	0.070	41.6
750	2.95	0.100	0.066	34.0

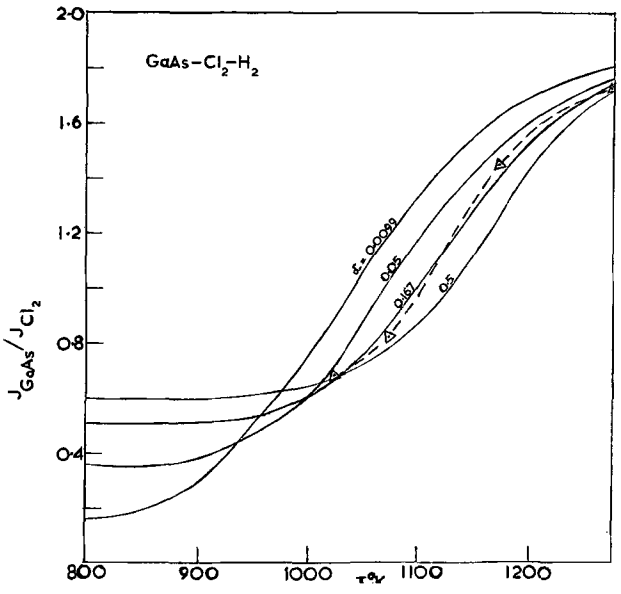

Fig. 2. Theoretical and experimental temperature dependence of GaAs/Cl_2 flux ratios for different chlorine-hydrogen flux ratios.

If the disproportionation reaction were solely responsible for the formation of GaAs the efficiency of conversion would be 66.7%. As an 80% conversion was determined experimentally, Eq. [2] must be reversible to a significant extent. Two reactions are therefore operating at this temperature. From the results it may be calculated that 40% of the GaAs is reformed via the reverse reaction, the balance being formed by the disproportionation reaction. The experimental results shown in Table I may be used to substantiate the theoretical predictions of Fergusson and Gabor (8), on the vapor phase transport of GaAs. In Fig. 2 are plotted the ratio of the flux of Ga to flux of Cl_2 (reciprocal times 2 of source reaction ratio in Table I) against T°K. The conditions of gas flow used in the present system, *viz.*, 6.9 cc/min HCl and 45 cc/min H_2 give a value of

$$\frac{\text{flux } Cl_2}{\text{flux } H_2 + \text{flux } Cl_2} \text{ of } \frac{1}{16}$$

Reasonable agreement is seen between theoretical and practical results.

Effect of Source and Substrate Temperatures on the Rate of Growth

Single crystal substrates of known area cut perpendicular to the {110} direction were chemically polished in a solution of 3 parts H_2SO_4/3 parts 30% H_2O_2/1 part H_2O. They were placed at intervals in a 20 mm diameter reaction tube which was heated by a furnace having a temperature gradient of 30°C/in. The flow rate of gases into the source was 6.9 cc/min HCl and 45 cc/min H_2. The thickness of epitaxial growth was determined by weight measurements. The results are shown in Table II.

The growth rate is reasonably constant at the various source and substrate temperatures except at a source temperature of 750°C when the rate is approximately one half. The results suggest that the reaction leading to the growth of material is limited by the rate of diffusion of reacting species from the vapor phase to the growing layer.

Table II. Rates of growth at various source and substrate temperatures

Source temp, °C	Thickness in microns of layer grown in 20 min at following temperature difference from source					
	25°	50°	75°	100°	125°	150°

800	30	47	43	43	Whiskers	
750	16	27	22	Whiskers		
700	Whiskers					

Table III. Rates of deposition on various substrate orientations

Source temp, °C	Substrate temp, °C	Ratios of growing rates (110)	(100)	(111A)	(111B)
750	700	1.44		1	0.85
750	725	1.06		1	0.75
750	725	1.36	1.14	1	
800	750	1.26	1.08	1	
800	750	1.24		1	0.87

Effect of Substrate Orientation on Growth Rate

The rates of growth on various substrate orientations were studied at the two source temperatures 800° and 750°C. In each experiment three chemically polished substrates of different orientations and of known surface area were maintained at a constant temperature 25°-50°C lower than the source. The flow rate into the reaction system was 6.9 cc/min HCl and 45 cc/min H_2. The thickness of the layer was calculated from the change in weight of the substrates. The results are shown in Table III.

It was very noticeable that growths on the (110) slices were smoother than on the other directions. Typical examples of growths are shown in Fig. 3-6.

Growth and Measurement of Se- *and* Sn-*Doped Layers*

Three methods were considered for the study of the controlled doping of a growing epitaxial layer over a range of composition: (*a*) by means of doped source materials, (*b*) by the use of a separate source of solid impurity present as the element or chloride maintained at a controlled temperature, or (c) by doping the gas stream with gaseous impurities. The first method is limited by the fact that a series of sources of known impurity composition would be required and the third requires complicated metering equipment. For initial research the second method presented a relatively simple and controllable system.

Electrical isolation of the grown layers may be achieved by growing layers on substrates of opposite conductivity type such that electrical isolation would be effected by the p-n junction, or by growing on semi-insulating substrates. The former method was preferred as no information was available about the effect of heat treatments on semi-insulating material at the time this work was performed.

The final method adopted involved growing a layer in the shape of a Hall plate as follows.

Substrates doped with zinc to a level 3×10^{17} holes cm^{-3} were cut perpendicular to the {110} direction and chemically polished by a modification of Sullivan's technique (9). For this a metallurgical polishing machine was adapted to take a flat-bottomed Teflon bowl. The slices were waxed to a Teflon block which was moved inside the bowl by the epicyclic motion imposed by the polishing head of the machine. The polish solution comprised 3 volumes concentrated H_2SO_4/1 volume 30% H_2O_2/1 volume H_2O. The slices were washed by circulated deionized water, rinsed in pure water-free alcohol, and dried in warm air. A 6000Å layer of SiO_2 was deposited by the thermal decomposition of tetraethoxysilane and, by means of photoengraving techniques, a Hall shaped window was etched through. This had three contact areas on one side and one on the other. It was therefore possible to check the uniformity of the final grown layer by measuring the voltage drop between the middle and each of the outside contacts. The surface was briefly etched in the polish solution described above, washed thoroughly in circulated water, and rinsed in water-free alcohol. An epitaxial layer approximately 30μ thick was then grown. The average thickness of the layer was measured by means of a microscope using the silica film as a reference. Tin dot contacts were alloyed to the specimen in a hydrogen atmosphere at

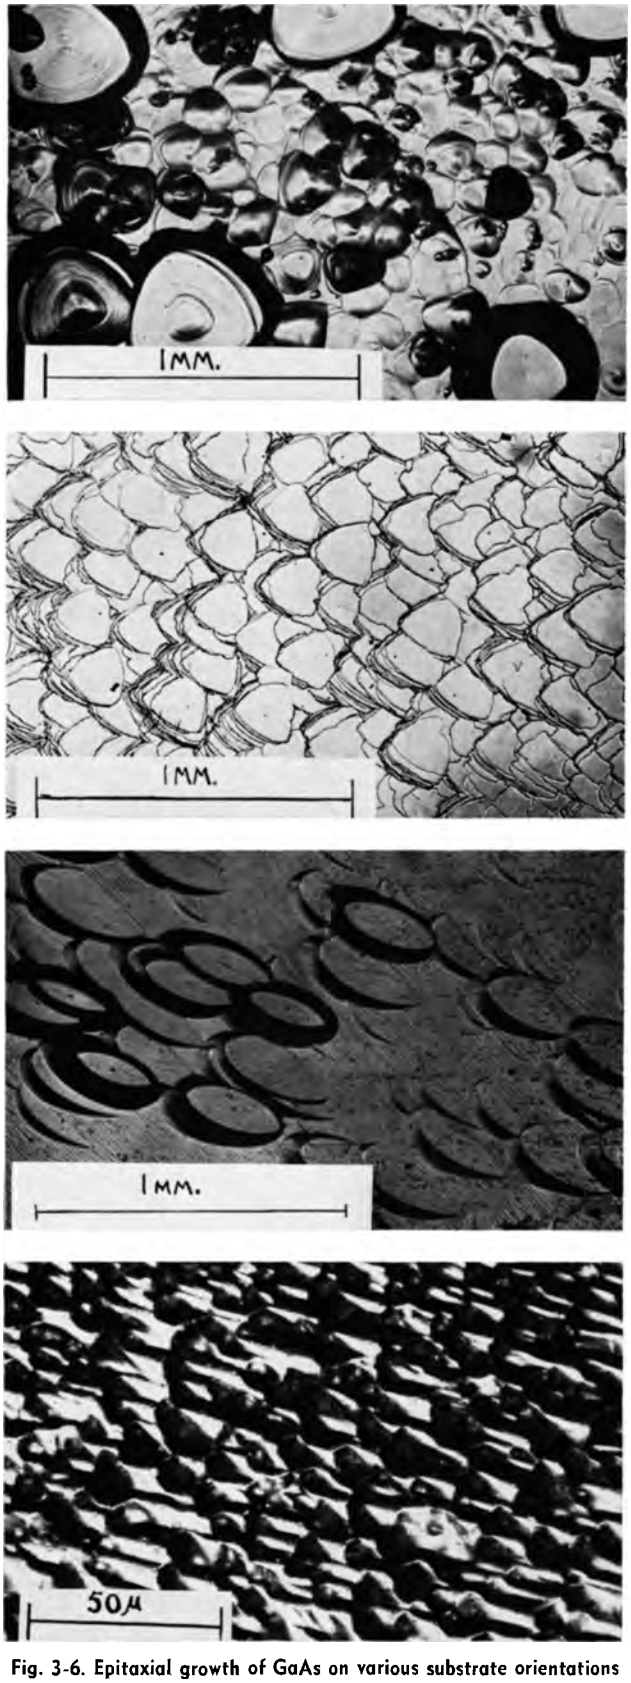

Fig. 3-6. Epitaxial growth of GaAs on various substrate orientations

600°C. The contacts were ohmic to all the layers reported and rectifying to the substrate material. The electrical properties of the layer were then measured at room temperature.

The reproducibility of the electrical properties of epitaxial growths from one identical experiment to another was determined before attempting work on doped layers. Three separate depositions were carried out on to p-type substrates. The results are shown in Table IV. Carrier concentrations were calculated by means of the formula $n = 1/\mathrm{Re}$. These results were taken as a satisfactory basis for future work using this apparatus and technique.

Table IV. Properties of undoped epitaxial layers

Sample	Growth temp, °C	Average thickness of layer after ½ hr growth (μ)	Resistivity (ohm-cm)	Carrier Concentration (cm^{-3})	Mobility $cm^2/v\text{-}sec$

Growth of Selenium-Doped Layers

Several attempts were made to grow selenium-doped layers in an apparatus of a rather simpler design than that shown in Fig. 1. A four zone furnace was used to control the temperature of (*a*) the selenium source, (*b*) an arsenic source if required, (*c*) GaAs source granules, and (*d*) the substrate. The thermal insulation of the furnace winding was kept to a minimum so that long flat uniform temperature zones could be achieved. The temperature of the selenium source and the substrate were monitored by the protected thermocouples as shown. The growth procedure consisted of raising the selenium, GaAs source, and substrate to their operating temperature in a flow of hydrogen and then to commence epitaxial growth by admitting HCl gas to the source. Doped epitaxial layers were successfully grown using relatively low partial pressures of selenium, but at higher pressures a selenium rich layer formed on the substrate which prevented normal growth.

It became obvious that the substrate was reacting with selenium vapor during the heating up cycle and forming GaAs/Ga_2Se_3 compounds. It was necessary therefore to raise the temperature of the selenium and substrate in a reverse flow of hydrogen. The apparatus shown in Fig. 1 has provision for this operation, and selenium doped layers were subsequently grown successfully over a wide range of selenium pressures. Source and substrate temperatures of 800°C and 750°C were used throughout this work. During the warm up period the vapors passed from right to left, the substrate being in a hydrogen atmosphere. When the operating temperature was reached 6.9 cc/min HCl was passed into the GaAs source and sufficient time allowed for steady state conditions to be achieved. The products would again be transported in the opposite direction from the substrate.

Finally the main hydrogen flow was reversed so as to commence epitaxial growth. A hydrogen flow rate of 50 cc/min was passed through both the GaAs source and the side tube. Traps F and G, cooled in solid CO_2/alcohol, served to avoid contamination of the gas metering system. The heating up procedure was tested by placing polished, weighed substrates into the growth position and heating in a reverse flow of hydrogen for 30 min. After this time they were found to have retained their surface polish and had not changed in weight.

A study of the growth of Se-doped epitaxial layers requires a knowledge of the ratio of selenium and gallium atoms present in the gas phase over the growing layer. The number of gallium atoms passing into the vapor phase per unit time may be calculated from the data in Table I. The partial pressure of selenium was determined in the following manner.

A quartz boat was made to fit inside the dopant boat and filled with selenium. At a definite temperature (accurately known by the thermocouple situated under the boat) and in a flow rate of 50 cc/min H_2, the loss in weight of the selenium was noted over a period of 30 min. The weight loss in this time would

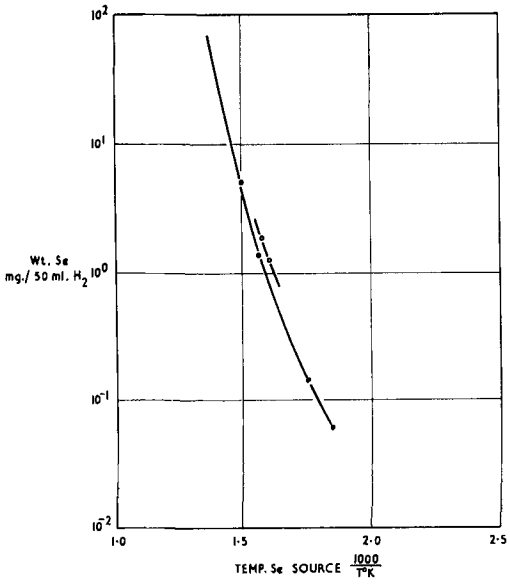

Fig. 7. Partial pressures of selenium vs. temperatures of selenium source.

include that due to the heating up and cooling down of the selenium. A further experiment was conducted at the same temperature over a period of 15 min. The net weight therefore gave the steady weight loss during 15 min at the operating temperature. During this work two different diameter reaction tubes were used. The results are shown in Fig. 7. Several selenium-doped epitaxial layers were grown using the procedure already described. The results are shown in Table V and Fig. 8.

The electrical leakage of the junction between the epitaxial layer and the substrate was determined by etching a channel across the grown Hall plate and through the junction. The two large area diodes so formed were checked for reverse leakage using the tin alloy dot contacts. A typical breakdown voltage of 4-6v was obtained with a reverse leakage of 0.1-0.2 μ-amp.

The behavior of selenium in GaAs has been studied by Vieland and Kudman (10). They find that this element is not fully active electrically in concentrations over 4×10^{17} electrons cm^{-3} and that part enters the lattice as an optically active neutral complex ($VGa Se_3$). The total selenium content in some of their samples was determined chemically and related to the electrically active selenium content. It appeared that the total selenium content of the epitaxial layers could be readily assessed from this data. However, Fuller and Wolfstirn (11) have shown that the electron concentration of selenium is also affected by heat-treatment history of the samples which makes such an assessment untenable.

For one of the Hall shaped layers having a carrier concentration of 3.4×10^{18} electrons cm^{-3} the temperature coefficient of resistivity was determined between room temperature and 280°C. The value —0.08%/°C was obtained.

Table V. Electrical properties of selenium-doped epitaxial layers

Temp Se (°C)	n (cm^{-3})	Mobility (cm^2/v-sec)	Resistivity (ohm-cm)	Diam. reaction tube, mm
285	3.0×10^{17}	2240	9.2×10^{-3}	22

Growth of Sn-*Doped Layers*

Tin-doped layers were grown by the same procedure as described for selenium-doped layers but using anhydrous $SnCl_2$ as the tin source. Several layers were grown using various partial pressures of $SnCl_2$. The effect also of an increased arsenic pressure was studied by incorporating a separate arsenic source. A complete study of tin-doped layers was however not attempted. The results are shown in Table VI.

The junction characteristics of two of these layers were measured by the method described before. A leakage current of 1 μa was measured in the reverse direction at 2.5v.

It is evident from the low mobility values obtained that a large degree of compensation exists in the tin-doped layers. There appears to be a tendency for layers grown in an excess arsenic atmosphere to have a lower mobility and an increased carrier concentration. The latter would seem to indicate that the additional arsenic atmosphere minimizes the formation of arsenic vacancies in the grown layer and increases the net number of tin atoms on Ga sites.

The Growth of Pure Epitaxial Layers of GaAs

Choice of system.—It has been shown that Group III-V compounds may be prepared and transported by vapor phase reactions in a number of ways (1, 12). In the case of GaAs the following systems are equivalent: (*a*) GaAs, HCl; (*b*) $GaCl_3$, Ga, As, H_2; and (*c*) Ga, $AsCl_3$, H_2.

In order to grow the highest purity layers the choice of system will obviously depend on the initial purity of the reacting species. In this respect system (*a*) has obvious disadvantages unless the GaAs is prepared by vapor phase methods initially. The purification of HCl to semiconductor standards however presents a difficult problem. In the remaining two systems the gallium component is common. It can be obtained commercially 99.9999% pure as confirmed by mass spectrographic and arc spectrographic analysis. $GaCl_3$ may be obtained probably to the same level of purity but arsenic purification has always presented difficulties and many samples are found to contain sulfur (13). System (*c*) was chosen for this work because it has the least number of components and also $AsCl_3$ may be obtained 99.999% pure commercially and may probably be further purified by such simple procedures as fractional distillation and zone refining.

Table VI. Electrical properties of tin-doped epitaxial layers

$SnCl_2$ temp	As temp	n (cm^{-3})	Mobility (cm^2/v-sec)	Resistivity (ohm-cm)
420	—	1×10^{18}	600	1.04×10^{-2}
420	440	1.3×10^{18}	540	8.93×10^{-3}
460	—	1.6×10^{18}	810	4.8×10^{-3}
460	440	3.2×10^{18}	650	3.0×10^{-3}

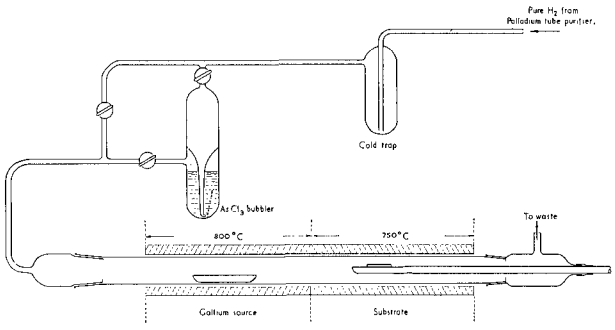

Fig. 9. Apparatus for growth of pure epitaxial layers of GaAS

Reaction mechanism.—An initial study of reaction (c) was carried out in an apparatus similar to that shown in Fig. 9. Initially a furnace was constructed so that the gallium melt, held at 800°C, could be observed. Palladium-diffused hydrogen was bubbled through the $AsCl_3$ at the rate of 50 ml/min. The initial reaction taking place in the furnace was as follows:

$$2AsCl_3 + 3H_2 \rightleftharpoons 6HCl + 2(As) \qquad [4]$$

The arsenic vapor was completely absorbed by the gallium until saturation occurred at a composition 2¼ a/o (atomic per cent) arsenic (14). During this period no free arsenic condensed outside the furnace but gallium was transported as a lower chloride. Disproportionation of this chloride occurred and, outside the furnace, free gallium and $GaCl_3$ condensed. When the melt was saturated with arsenic a skin of GaAs formed over its surface and free arsenic appeared at the furnace outlet.

On cooling the source, GaAs was precipitated from the melt leaving almost pure gallium. The source was again heated to 800°C in a flow of hydrogen. $AsCl_3$ vapors were passed and it was found that an induction period of about 40 min elapsed before free arsenic was seen. Repetitions of this experiment gave the same result. It was initially assumed that the GaAs skin was slowly soluble and that the induction period experienced was the time necessary for the melt to become saturated with arsenic obtained from the GaAs skin. This however was disproved by holding the melt at 800°C for an hour in hydrogen only and then passing $AsCl_3$. An induction period of the same duration was observed. It seems therefore that the GaAs skin is very slowly dissolved by the gallium in this system.

Growth of pure layers.—By the time these experiments were performed semi-insulating GaAs substrate material had been proved to be stable at the temperatures under consideration. All the pure layers were grown on this material, the substrate being cut perpendicular to the {110} direction. The surface preparation techniques used were essentially as described before except that the substrates were given a 10% KCN rinse after the etch polishing operation and before the wash in deionized water. This served to complex any copper ions adsorbed from the acid solution. A final rinse was given in pure, water-free methanol followed by rapid air drying. The substrates were rapidly loaded into the reaction tube through which a rapid stream of pure hydrogen was passed. The furnace was raised to its operating temperature, 800°C for the source and 750°C for the substrate, and the main flow of hydrogen passed through the $AsCl_3$ bubbler at the rate of 50 cc/min. Growth rates of about 1/3 μ/min were observed under these conditions. As the apparatus was extremely simple to operate many successful overnight runs were performed and layers up to 230μ thick were grown. One of these thick layers was checked by x-ray diffraction techniques and the surface shown to be completely epitaxial with the substrate. Normally, layers from 30-60μ were grown and these had a smooth polished appearance with, in many cases, a surface roughness of $\pm 0.2\mu$.

Table VII. Electrical properties of layers grown from the first fraction of $AsCl_3$

Sample	Temperature of measurement	Resistivity (ohm-cm)	n (cm^{-3})	Mobility (cm^2/v-sec)	Duration of growth (hr)
PM127	Room	0.067	3.8×10^{16}	2,460	6½
PM128	Room	0.45	4.0×10^{15}	3,470	5½
	77°K	0.27	2.2×10^{15}	10,500	
PM129	Room	0.43	1.9×10^{16}	7,650	3
	77°K	0.104	1.5×10^{15}	40,100	
	70°K	0.106	1.4×10^{15}	42,100	
	65°K	0.109	1.35×10^{15}	42,500	

The method used for the electrical measurement of the layers consisted of ultrasonically cutting a Hall-shaped sample and alloying tin dot contracts to the relevant positions. The layer thickness was determined on the remainder of the slice by cleaving and then etching the epitaxial junction with 20% cold HNO_3 for 15 min. The first layers measured were found to have a carrier concentration of 1.3×10^{15} to 3×10^{15} donors cm^{-3} with mobilities in the range 5000-6000 cm^2/v-sec.

Two layers grown from the last fraction of $AsCl_3$ were p-type with carrier concentrations of 9×10^{14} cm^{-3} and mobilities of about 500 cm^2/v-sec. The passage of hydrogen through the $AsCl_3$ may be considered as a fractional distillation and it is possible that a higher boiling point p-type impurity chloride is present.

Evidence for the presence of an n-type impurity was obtained by growing layers from a fresh supply of $AsCl_3$. The properties of the first three growths are shown in Table VII.

The following chlorides of n-type impurities have boiling points lower than $AsCl_3$: $SiCl_4$, 58°C; SCl_2, 59°C; $SnCl_4$, 114°C. Se_2Cl_2 boils at the same temperature as $AsCl_3$, 130°C.

These possible impurities may be conveniently minimized therefore by passing hydrogen for several hours into each fresh supply of $AsCl_3$.

Growth on a Vapor Etched Substrate

The effect of cleaning the substrates in situ by vapor etching was studied by reversing the temperature gradient in the reaction tube. The gallium source was kept at a constant temperature of 800°C and the substrates were heated to 900°C. Under the standard flow conditions used an etch rate of approximately 0.5 μ/min was achieved. On cooling the substrates from 900° to 750°C epitaxial deposition took place on to the newly etched surface. The electrical properties of a layer grown in this way are given in Table VIII.

Purification of $AsCl_3$ by Gradient Freezing

A volume of $AsCl_3$ was sealed into an inverted "U" shaped capsule under an atmosphere of argon. The liquid was poured into one of the arms which was then lowered into a freezing mixture at the rate of 1 cm/hr. The last fraction of liquid unfrozen was poured into the empty arm of the capsule. After five such operations the pure liquid was charged into the bubbler and hydrogen passed for several hours. The properties of a layer grown from this material are shown in Table IX.

Growth of Pure Layers in Increased Partial Pressures of Arsenic

An arsenic source was maintained at 425°C in the reaction tube and a layer grown in the normal man-

77°K	0.103	1.6×10^{15}	37,900

ner. The arsenic used was of semiconductor purity (99.999%) but the grown layer was found to contain 3×10^{16} electrons cm^{-3}. The introduction of this relatively impure material had obviously invalidated the purpose of the experiment and so a supply of pure arsenic was prepared in the reaction tube by thermal decomposition of the pure $AsCl_3$ in hydrogen. Using this as a source of arsenic the above experiment was repeated. The slice was back-etched prior to growth as described above. The surface polish of all the back-etched slices have been found to be extremely good, a typical surface roughness of $\pm$ 0.25μ being measured on a Talysurf machine. The electrical properties of layers grown by this method are shown in Table X.

The room temperature mobility of this sample is the highest obtained to date. The carrier density however is not unlike previous samples which does not substantiate a report that epitaxial growth of GaAs in increased arsenic pressures reduces the carrier concentration (7).

The purification of the $AsCl_3$ seems to have reduced the concentration of n-type impurity in the grown layer. It is envisaged that a more careful purification of this component may lead to a still further reduction in carrier concentration.

The regular production of high purity GaAs by epitaxial methods has thus made possible the further exploration of GaAs as a high voltage, high temperature rectifier and field effect device material.

Acknowledgments

The author is indebted to G. Whitsey for performing much of the experimental work, to P. R. Evans for the low temperature measurements, and to J. R. Knight, R. W. Ware, and B. Joyce for helpful discussion and review of the manuscript. Thanks are due to the Ministry of Defence and The Plessey Company for permission to publish.

Manuscript received Aug. 17, 1964; revised manuscript received June 29, 1965.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1966 JOURNAL.

The Hydrogen Evolution Kinetics and Hydrogen Entry into α-Iron

J. O'M. Bockris, J. McBreen,[1] and L. Nanis[2]

Electrochemistry Laboratory, University of Pennsylvania, Philadelphia, Pennsylvania

ABSTRACT

An investigation of the permeation rate of electrolytic hydrogen through Armco iron single crystals and polycrystals by an electrochemical technique is described. The variation of the permeation rate with cathodic overpotential has been determined in alkaline (0.1*N* NaOH), alkaline cyanide, acidic (0.1*N* H_2SO_4), acidic iodide, acidic napthalene, and acidic nitrile (valeronitrile, napthonitrile, benzonitrile) solutions. The potential-permeation behavior as a function of temperature has been investigated in acid (0.1*N* H_2SO_4) solutions. The permeation potential behavior in alkaline solutions indicate a coupled discharge recombination mechanism for hydrogen evolution at low overpotentials while at higher overpotentials the mechanism is slow discharge-fast electrochemical. The effects of CN^-, I^-, and napthalene which increase permeation rate has been interpreted in terms of a lowering of the M-H_{ads} bond energy. Nitriles were found to decrease the permeation rate, and their effect on the permeation rate is interpreted in terms of their vertical adsorption on the electrode hindering the discharge process. The results indicate that hydrogen goes through an adsorbed intermediate state on discharge before entering the metal lattice. Grain boundaries play no part in the hydrogen evolution kinetics or in the entry of hydrogen to the metal.

It has been pointed out (1, 2) that an investigation of the permeation-potential relationships on iron can yield diagnostic criteria, from which decisive information on the mechanism of hydrogen evolution on iron can be obtained.

The effect of anions and neutral organic molecules on hydrogen permeation from aqueous electrolytic solutions has been investigated by many workers (3, 4). However, the mechanism by which these anions and poisons effect the permeation remains a topic of dispute (4, 5).

An investigation of the hydrogen permeation rate through α-iron, from acid and alkaline solutions, un-

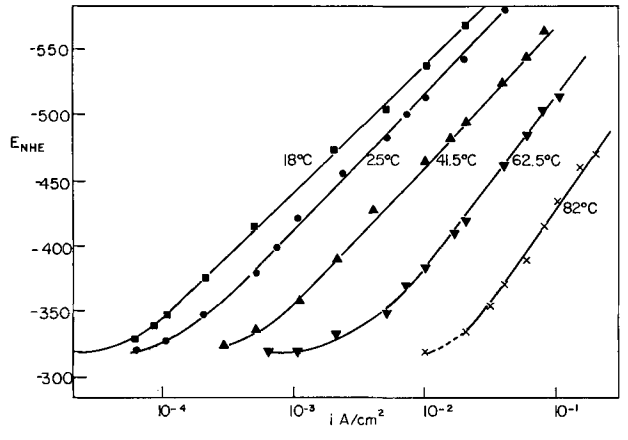

Fig. 1. Current-potential curves for Armco iron in 0.1*N* H_2SO_4 solutions.

der varying conditions of temperature, ambient electrolyte, and cathodic polarization, is presented.

Experimental

Permeation measurements.—Details of the cell and auxiliary apparatus used in this investigation have been described elsewhere (2, 6). Membranes of Armco iron 0.77 mm thick were prepared in a manner described in ref. (7). The Armco iron single crystals used in the investigation were prepared in a similar manner.

Care was taken in acidic solutions to work under conditions of cathodic protection, while doing permeation measurements. In this way, a reproducible electrode surface was always maintained. Temperature control measurements were made in an air thermostat which controlled the temperature to within ±0.5°C. Solutions were prepared from conductivity water and A.R grade reagents. Final purification was made by preelectrolyzing the solutions in an external cell prior to admitting the solution to the cell.

Results

Current-potential behavior in 0.1N H_2SO_4 solutions.—In Fig. 1, current-potential curves for hydrogen evolution on Armco iron in the temperature range 18°-80°C in 0.1*N* H_2SO_4 are given. All curves were obtained galvanostatically. In Table I, the slopes of these curves are tabulated, along with the corresponding transfer coefficient, α. An Arrhenius plot of the current at $V = -0.408$v N.H.E. is given (Fig. 2). This was determined both galvanostatically and potentiostatically. The slopes of the log $i/1/T$ relations obtained by both methods are in agreement and give the heat of activation for hydrogen evolution on iron as 18.1 kcal/mole.

Permeation-potential relationships in acidic solutions.—Permeation-potential plots for Armco iron in 0.1*N* H_2SO_4 solutions, as a function of temperature of 18°-80°C are given in Fig. 3, where J is the steady-state permeation rate; their slopes tabulated in Table I. Because of corrosion on the one hand and

[3] The transmitted hydrogen is measured by the current density as it is anodically oxidized, hence values are reported in microamp/cm².

Table I. Current-potential, permeation-potential parameters and α for Armco iron, 0.1*N* H_2SO_4, at various temperatures

Temperature °C	$(\partial\eta/\partial \log_{10} i)_V$	$(\partial\eta/\partial \log_{10} J_\infty)_V$	α
18	0.097	0.190	0.59
26	0.115	0.240	0.515
41.5	0.125	—	0.498
63	0.135	0.280	0.495
80	0.140	0.280	0.5

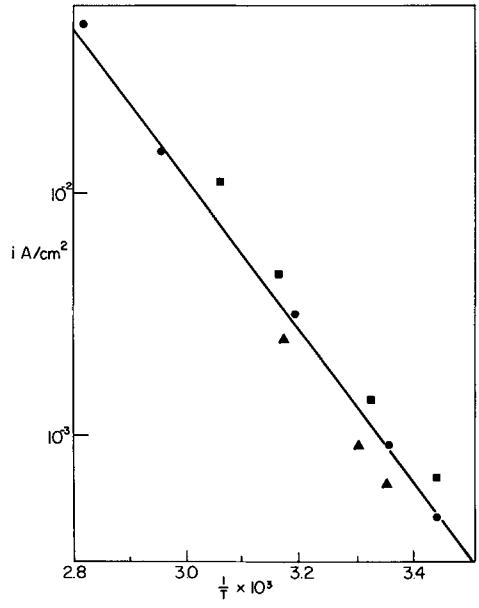

Fig. 2. Arrhenius plot of cathodic current for Armco iron, 0.1*N* H_2SO_4, $E_{NHE} = -0.408$v; ●, galvanostatic measurement; ■, ▲, potentiostatic measurement.

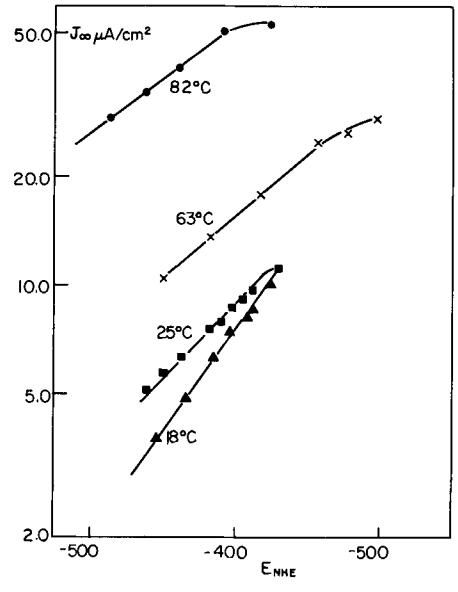

Fig. 3. Permeation-potential curves for Armco iron, L — 0.77 mm, 0.1*N* H_2SO_4.

anomalous permeation effects (which will be described in another publication) on the other, only a limited potential range could be covered.[4] Permeation potential plots are given in Fig. 4 for 0.1*N* H_2SO_4 with additions of potassium iodide. The slope of the curves in each case is —235 mv. Figures 5-7 give permeation potential curves for acidic solutions with additions of valeronitrile, benzonitrile, and naphthonitrile, while Fig. 8 gives the permeation-potential behavior in acidic naphthalene solutions. It may be seen that additions of iodide and naphthalene increase the permeation, while additions of valeronitrile benzonitrile and naphthonitrile decrease it. In all cases these additives increase the hydrogen overpotential, in acid solutions.

Permeation-potential behavior in alkaline solutions.—Permeation potential curves, for pure alkaline (0.1*N* NaOH) and alkaline cyanide (KCN) solutions, are given in Fig. 9. In 0.1*N* NaOH solutions, the Tafel slope

[4] Henceforward, all results are for Armco iron membranes, 0.77 mm thick, at 25°C, unless otherwise stated.

is —122 mv, while the permeation potential curve has a slope of —240 mv below $V = -1.02$v NHE. Above —1.02v NHE the permeation rate increases slowly with potential. Additions of cyanide increase the permeation rate and the hydrogen overvoltage.

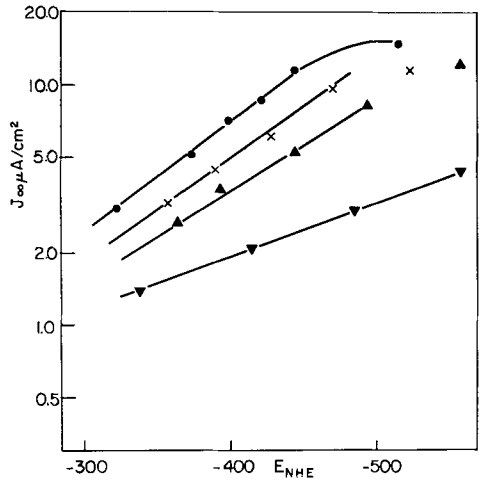

Fig. 7. Permeation-potential curves, Armco iron, $L = 0.77$ mm, $T = 25$°C; 0.1N H_2SO_4 with additions of naphthonitrile: •, none; X, 10^{-6}M; ▲, 10^{-5}M; ▼, 10^{-4}M.

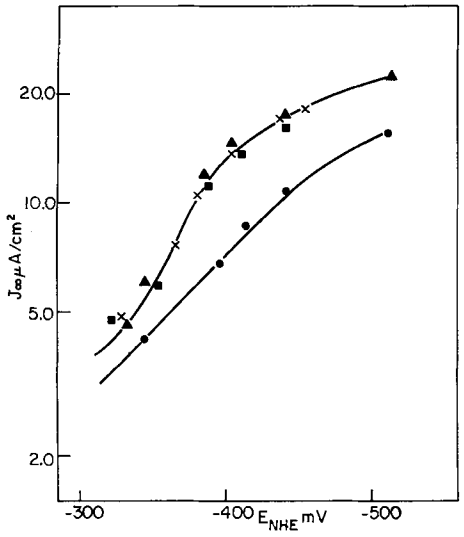

Fig. 8 Permeation-potential curves, Armco iron, $L = 0.77$ mm, $T = 25$°C; 0.1N H_2SO_4 with additions of naphthalene: •, none; ■, 10^{-5}M; ▲, 2 x 10^{-5}M; X, 5 x 10^{-5}M.

Permeation-current relationship.—Figure 10 shows a plot of the permeation rate against the square root of the cathodic current density for acidic (0.1N H_2SO_4) and acidic iodide solutions, while in Fig. 11 a similar curve is shown for 0.1N NaOH. In all cases the curves are linear and the intercept zero.

Single crystals.—The hydrogen concentration directly beneath the cathodic surface of an Armco iron single crystal membrane, at 25°C in 0.1N H_2SO_4, is plotted as a function of potential in Fig. 12, while that for polycrystalline Armco iron is shown for comparison. Both cases yield similar results. The slope of the current potential curve for Armco iron single crystals in acid (0.1N H_2SO_4) solutions is —123 mv while that for the permeation potential curve is —240 mv.

Discussion

Mechanism of the hydrogen evolution reaction in 0.1N H_2SO_4 solutions.—It has been shown elsewhere that, in the case of Armco iron, diffusion through the membrane is rate determining (2). Because of this, the reaction by which hydrogen enters the surface of the metal can be considered to be in equilibrium. If it is assumed that hydrogen, on discharging on the metal, passes through an adsorbed state prior to entering the metal, and that this adsorbed state is the same as that which leads to hydrogen gas evolution, then the permeation rate is directly related to the hydrogen cover-

age on the cathode surface (1, 2). It has been shown elsewhere (8) that

$$\frac{J_\infty}{zF} = \frac{Dc_o}{L} \qquad [1]$$

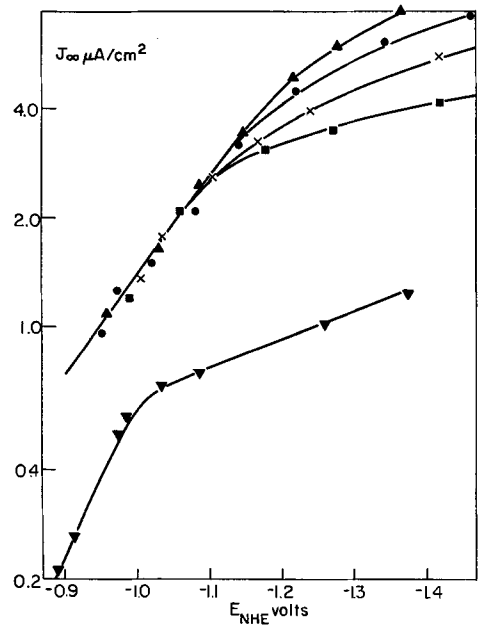

Fig. 9. Permeation-potential curves, Armco iron, L = 0.77 mm, 25°C, 0.1N NaOH, with KCN additions: ▼, none; ■, 1.6 x 10^{-4}M; X, 4 x 10^{-3}M; ●, 0.01M; ▲, 0.1M.

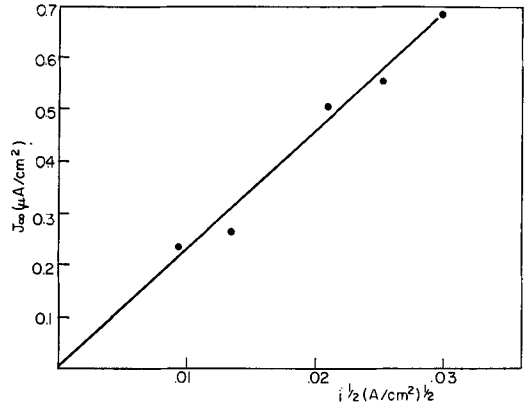

Fig. 11. Permeation-current curves for Armco iron, 0.1N NaOH, L = 0.77 mm, 25°C.

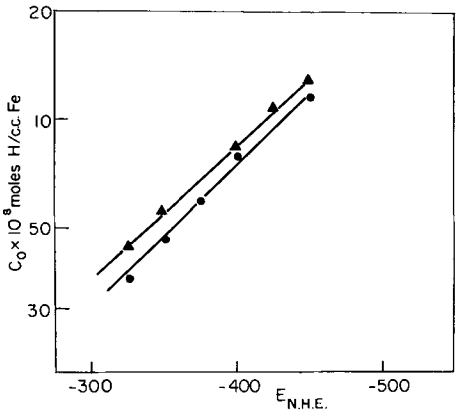

Fig. 12. C_o values for Armco iron polycrystals (▲) and single crystals (●), 0.1N H_2SO_4, 25°C.

where J_∞ is the steady-state permeation rate on amp/cm², D is the diffusion coefficient for hydrogen in the metal, F the Faraday, c_o the hydrogen concentration directly beneath the membrane cathodic surface, and L the membrane thickness. Now for low hydrogen coverages (θ) and dilute solutions of metallic hydrogen (2)

$$k_3\theta = k_{-3}c_o \qquad [2]$$

where k_3 and k_{-3} are the rate constants for the surface to bulk reaction and bulk to surface step respectively. Combining Eq. [1] and [2] gives

$$\frac{J_\infty}{zF} = \frac{D}{L}\left(\frac{k_3}{k_{-3}}\right)\theta \qquad [3]$$

and

$$\frac{\partial\eta}{\partial \ln J_\infty} = \frac{\partial\eta}{\partial \ln\theta} \qquad [4]$$

where η is the hydrogen overpotential. A survey of the data in Table I shows that

$$\frac{\partial\eta}{\partial \ln J_\infty} \simeq -\frac{4RT}{F} \qquad [5]$$

This result is tenable only with a coupled discharge-recombination mechanism for hydrogen evolution at low coverages ($\theta < 0.1$) of hydrogen. The reaction sequence at the cathode surface then is as follows

$$\xrightarrow{+\mathrm{FeH_{ads}}} \quad \xrightarrow{k_2} 2\mathrm{FeH_{ads}} \rightarrow \mathrm{H_2} + 2\mathrm{Fe} \qquad [6]$$

$$\mathrm{H_3O^+} + e + \mathrm{Fe} \xrightarrow[\text{(slow)}]{k_1} \mathrm{FeH_{ads}} \underset{k_{-3}}{\overset{k_3}{\rightleftarrows}} \mathrm{FeH_{abs}} \qquad [7], [8]$$

where FeH_{ads} refers to adsorbed hydrogen on the metal surface, and FeH_{abs} refers to absorbed hydrogen directly beneath the metal surface; k_1, k_2, k_3, and k_{-3} are the rate constants of steps [6], [7], and [8]. The above reaction sequence gives

$$J_\infty = \frac{DzF}{L}\frac{k_3}{k_{-3}}\left(\frac{1}{k_2}\right)^{1/2} i^{1/2} \qquad [9]$$

$$= \frac{DzF}{L} c^{1/2}{}_{H^+}\left(\frac{k_3}{k_{-3}}\right)\left(\frac{k_1}{k_2}\right) e^{-\beta\eta F/RT} \qquad [10]$$

The direct proportionality of the permeation rate to the square root of the current density (*cf.* Fig. 10) is in agreement with Eq. [9], and the slopes of the permeation potential curves in Table I are in agreement with Eq. [10]. From this it may be concluded that in this potential and temperature (18°-80°C) range the mechanism of hydrogen evolution on iron in acidic

(0.1*N* H_2SO_4) solutions is coupled discharge-electrochemical, and that the adsorption of hydrogen on the metal surface is Langmuirean.

Mechanism of hydrogen entry into iron.—Bagotskaya (4) and Frumkin (5) in discussing the effect of poisons in the hydrogen permeation rate have postulated that hydrogen enters the metal in the same elementary act as that in which it is discharged, and that the intermediate state through which hydrogen enters the metal lattice is not identical with the adsorbed intermediate which leads to discharge. They suggest that both reactions (absorption of hydrogen and hydrogen evolution) occur independently. In this case the reaction sequence at the cathode surface is as follows.

$$\begin{array}{ccccc} & & H_{abs} & & \\ & & 4\,\downarrow\uparrow -4 & & \\ & & 1 \quad\quad 2 & & \\ H^+ + e & \rightarrow & H_{ads} & \rightarrow & H_2 \end{array} \qquad [11]$$

Let k_1, k_2, k_4, and k_{-4} be the rate constants for steps 1, 2, 3, 4, and —4, respectively, and β_1 and β_4 the transfer coefficients for steps 1 and 4, respectively. Then the permeation current is as follows

$$J = F\left[k_4 a_{H+} \left(1 - \frac{c_o}{c_s}\right) e^{-\beta_4 \phi F/RT} - k_{-4}\, c_o\, e^{(1-\beta_4)\phi F/RT} \right] \qquad [12]$$

where c_s is the concentration of hydrogen in the lattice at hydrogen saturation, and ϕ is the metal solution potential difference. Substituting for c_o using Eq. [1] gives

$$J = \frac{F k_4 a_{H+}\, e^{-\beta_4 \phi F/RT}}{\left[1 + \frac{L}{D}\left(\frac{k_4 a_{H+}}{c_s} e^{-\beta_4 \phi F/RT} + k_{-4}\, e^{(1-\beta_4)\phi F/RT}\right)\right]} \qquad [13]$$

The only valid limiting case is

$$\frac{L}{D}\left[\frac{k_4 a_{H+}}{c_s} e^{-\beta_4 \phi F/RT} + k_{-4}\, e^{(1-\beta_4)\phi F/RT}\right] >> 1 \qquad [14]$$

since J depends on D and L, *i.e.*,

$$J = \frac{FD}{L\left(\frac{1}{c_s} + \frac{k_{-4}}{k_4 a_{H+}} e^{\phi F/RT}\right)} \qquad [15]$$

Equation [15] in turn yields two limiting solutions

$$J = \frac{FD\, k_4 a_{H+}}{L k_{-4}} e^{-\phi F/RT} \qquad [16]$$

and

$$J = \frac{FDc_s}{L} \qquad [17]$$

the latter (Eq. [17]) being for high negative potentials where the metal approaches hydrogen saturation. Equation [16] gives

$$\frac{\partial \phi}{\partial \ln J} = -\frac{RT}{F} \qquad [18]$$

and

$$J \alpha i^2 \qquad [19]$$

It is thus clear from Eq. [18] and [19] that the model proposed by the Russian workers (4, 5) does not predict the observed result. It may be concluded then that the intermediate through which electrolytic hydrogen passes on entry to the metal substrate is the adsorbed state and is identical to the intermediate which leads to hydrogen evolution. The rate of entry of hydrogen into the metal is determined by the coverage of hydrogen (θ), the energetics of the transfer of hydrogen to the metal bulk, and the energetics of the recombination process which leads to hydrogen evolution.

From the similarity of the experimentally found values of c_o for Armco iron single crystals and Armco iron polycrystals (Fig. 12), it may be concluded that grain boundaries play no part in the hydrogen evolution reaction, or in the absorption of hydrogen on the metal.

Mechanism of hydrogen evolution on iron from 0.1N NaOH solutions.—The Tafel slope, the permeation-potential relationship (Fig. 9), and the permeation-current behavior (Fig. 11) are tenable only with a coupled discharge-recombination mechanism at potentials below —1.02v NHE. Here again, one sees that the hydrogen coverage (θ) is low and that the adsorption of hydrogen is Langmuirean. Since the coverage is low at —1.02v NHE the only explanation for the leveling off of the permeation with potential above —1.02v NHE is a change over to a slow discharge-fast electrochemical mechanism[5] at this potential. These results are in reasonable agreement with Bagotskaya (9) who found, using a qualitative method, that the desorption step changed from recombination to electrochemical at $\eta = -0.34$v in 2*N* NaOH.

In the case of alkaline solutions, it is again clear that hydrogen passes through the intermediate adsorbed state on entry to the metal substrate.

Temperature dependence of the permeation rate and its relationship to the mechanism of hydrogen absorption.—The behavior of the observed slopes of the current potential curve with temperature is in agreement with that predicted from the simple kinetic equations (10), with $\alpha \approx 0.5$ constant with temperature. An analogy may be drawn for the case of nickel (11) where an increase from 9.3 to 16.8 kcal/mole was observed in going from 0.1 to 1*N* HCl. No detailed interpretations of the anomalously high values can be given. However, anion adsorption on Fe and Ni may resemble the adsorption of anions on Pt, which has recently been shown by Balashova to have large regions of potential independence.

Using Eq. [1] and neglecting the membrane thickness change with temperature gives

$$R\left(\frac{\partial \ln J_\infty}{\partial\, 1/T}\right)_L = R\left(\frac{\partial \ln D}{\partial\, 1/T}\right) + R\left(\frac{\partial \ln c_o}{\partial 1/T}\right) \qquad [20]$$

$$= \Delta H_D + R\left(\frac{\partial \ln c_o}{\partial\, 1/T}\right) \qquad [21]$$

where ΔH_D is the heat of activation for diffusion of hydrogen in iron.

From Eq. [9] and [10], one sees that
